	Consider switching to different opioid	Nalbuphine 10–20µg/kg/dose IV q 6 h
	Use antipruritics	Naloxone infusion 0.25–1 µg /kg/h
		Diphenhydramine 0.25–0.5 mg/kg PO/IV q 6h
Sedation	Add non-sedating analgesic (eg, ketorolac) and reduce opioid dose	Methylphenidate 0.05–0.2 mg/kg PO bid (morning and mid-day dosing)
	Consider switching to different opioid	Dextroamphetamine 2.5–10 mg every day
Constipation	Regular use of stimulant and stool softener laxatives	Naloxone infusion 0.25–1 µg/kg/h
		Ducosate
		Child: 10–40 mg PO daily
		Adult: 50–200 mg PO daily
		Dulcolax
		Child: 5 mg PO/PR daily
		Adult: 10 mg PO/PR daily
		Methylnaltrexone, alvimopam dosing is extra from adults

bid, twice a day; PO, orally; PR, rectally; q, every.

hepatic metabolism more slowly in neonates and young infants, and weight-scaled clearances reach mature values generally around 6 months of age [84]. In addition, reduced renal clearance of metabolites (e.g. MEGX, the primary metabolite of lidocaine) can contribute to the risk of seizures in neonates. Although plasma esterases involved in metabolism of amino ester local anesthetics are present in reduced amounts in neonates, chloroprocaine clearance occurs quite rapidly in neonates [85]. Local anesthetics have somewhat larger volumes of distribution and reduced protein binding in neonates [84]. The plasma concentrations that produce cardiotoxicity or risk of seizures in human neonates, infants, and children are extrapolated from case reports, adult case series, and adult preclinical toxicological studies [86]. Infant rats tolerate a higher weight-scaled dose of either bupivacaine or ropivacaine (higher LD50) than adult rats [87].

In our view, it seems prudent to conclude that the maximum systemically safe single dose of bupivacaine, levo-bupivacaine, ropivacaine or lidocaine scales directly with bodyweight, and that the hourly maximum infusion rates in neonates and infants less than 3–5 months of age should be reduced by about 50% relative to the recommended rates for older infants and children.

## **Topical anesthetics**

Topical anesthetics are widely used in children for pain associated with immunizations, venepunctures, accessing indwelling central venous ports, and other types of needle pain [88,89]. The stratum corneum of the epidermis is a relatively impermeable barrier to local anesthetics and a variety of strategies have been developed to permit uptake of local anesthetics across this barrier.

## **EMLA**

Eutectic mixture of local anesthetics (EMLA) (lidocaine and prilocaine) was one of the first topical anesthetics commercially available for use on intact skin and has been extensively used and studied [90,91]. The physicochemical feature of this type of mixture is that it permits a higher aqueous solubility of the uncharged forms. This permits a higher effective concentration at the stratum corneum and increases the rate of uptake. A meta-analysis of controlled trials in children and adults showed that EMLA reduced pain associated with venepunctures in 85% of patients.

Applying a thicker layer and increasing the duration of application to 90–120 min can increase its effectiveness. Applying a thin layer (0.5 mm) compared to a thick layer (2 mm) resulted in significantly less pain relief with venepunctures. Even with longer duration of application, absorption into the epidermis was limited to no more than 6 mm. Application times of less than 45 min result in high failure rates and with short application times, tetracaine gel appears more effective than EMLA [91]. Blanching is commonly seen with EMLA and is due to vasoconstriction of superficial capillaries.

Clinical trials have shown effectiveness of EMLA in reducing the pain or distress of a number of common pediatric procedures, including venous cannulation, venepuncture, circumcision, urethral meatotomy, immunizations, allergy testing, accessing implanted central venous access ports, and laceration repair.

## S-Caine patch

The S-Caine patch (Synera<sup>TM</sup>) is drug delivery device consisting of a eutectic mixture of lidocaine (70 mg) and tetracaine (70mg) integrated with an oxygen-activated heating element. The heating element enhances the delivery of the local anesthetics across the epidermis. When removed from its storage pouch, the heating element becomes activated and the patch begins to heat, warming the skin after application. Controlled trials in children and adults showed that application of the patch for 20 min produced good skin analgesia for venous cannulation [92]. A randomized placebo-controlled trial of the S-Caine patch showed that the majority of patients had good pain relief with vascular access procedures. The most common side-effects were local transient skin reactions, such as localized pruritus and erythema. Unlike EMLA, Synera is associated with mild vasodilation due to the vasodilating properties of lidocaine and mild heating of the skin.

## Jet propulsion injectors

Jet propulsion injectors (J-tip system and Powerject) are needleless syringe devices that utilize compressed gas, typically carbon dioxide, to rapidly propel a predetermined amount of local anesthetic through the stratum corneum. These types of devices are attractive in that the local anesthetic effect occurs within several minutes and it is a needleless system. However, efficacy data are somewhat mixed. A randomized trial in adult patients showed that subcutaneous lidocaine infiltration was significantly more effective at reducing pain from venous cannulation. Other randomized studies in adults have found a failure rate of approximately 10%, and 17% of patients had mild bleeding at the site. A study comparing the J-tip system to EMLA in children found that the J-tip system provided better analgesia than EMLA for IV cannulation [93].

#### Iontophoresis

Iontophoresis employs an electrical field to drive local anesthetics in their charged ionic form across the stratum corneum. Iontophoresis produces cutaneous anesthesia in a much shorter time. The most common anesthetic used by this route is 2% lidocaine with 1:100,000

epinephrine. Skin analgesia occurs within 10-15 min and typically lasts for 15 min. Iontophoresis appears to result in deeper levels of dermal anesthesia and may penetrate deeply enough to numb both skin and veins, allowing for less painful venous cannulation. Randomized prospective studies in children comparing EMLA with iontophoresis of 2% lidocaine and 1:100,000 epinephrine found no significant differences in pain relief with venous cannulation. Superficial and partial-thickness burns have been reported with lidocaine iontophoresis when placed over areas with skin defects or when high currents have been used. A mild tingling sensation often occurs during drug delivery. It is recommended that the system be removed if pain rather than tingling is experienced. Longer application times are needed when lower currents are used, but the tingling sensation can be made almost undetectable.

## **Epidural analgesia**

Epidural analgesia can provide excellent postoperative analgesia for infants and children undergoing a variety of surgical procedures including thoracic, perineal, lower extremity, and abdominal procedures. (Detailed discussion of peripheral nerve blocks can be found in Chapter 18.) Epidural analgesia is also used for certain chronic pain conditions such as complex regional pain syndrome (CRPS) (Fig. 33.6), especially when used as part of a rehabilitation program that emphasizes active mobilization.

An inherent difference between epidural catheter placement in adults and children is that, unlike for adults [94],

Figure 33.6 Complex regional pain syndrome (CRPS) presentation.

most epidural catheters in children are placed while anesthetized. Most pediatric anesthesia providers agree on the safety of placing a lumbar epidural catheter in an anesthetized rather than an awake, moving child. However, there is somewhat more controversy surrounding the safety of direct needle placement in the thoracic region, particularly in infants, due to concerns about neurological complications. Published case series and prospective clinical outcome studies showed generally good safety, though from available data it is difficult to ascribe confidence intervals on the specific risk for anesthetized thoracic needle puncture in different age groups [95,96]. To avoid the potentially increased risk, an alternative method is to advance catheters from the caudal region cephalad to thoracic dermatomes. This may be performed blindly or with additional guidance by fluoroscopy, ultrasound [97], nerve stimulation guidance [98] or by electrocardiography [99]. Several reports in infants show that these techniques can be safe alternatives to direct needle placement, with success rates of roughly 80-98%. Failure rates with blind placement are greater for infants larger than 5kg. Infants clear amide local anesthetics more slowly than older children so that lower infusion rates are necessary and repeated local anesthetic dosing is more likely to produce systemic accumulation of drug and toxicity.

Because of the limitations of using safe local anesthetic infusion rates, it is crucial in infants and young children to place epidural catheter tips in the correct surgical dermatome. When placing epidural catheters directly in a thoracic dermatome or when advancing epidural catheters cephalad to the thoracic region, our practice is to obtain confirmation of proper placement radiographically, through ultrasound or by electrical stimulation. Blind advancement of catheters from lumbar to thoracic levels has a failure rate of approximately 30%. One method of radiographic confirmation of proper epidural catheter tip placement is an epidurogram in which a small amount (0.5-1 mL) of radiocontrast dye is injected through the epidural catheter that can be detected on a plain radiograph (Fig. 33.7). Catheters can also be advanced from lumbar or caudal routes under fluoroscopic guidance, and catheter tip positions can be confirmed by a contrast epidurogram.

In our experience, lumbar-to-thoracic placement of catheters is more successful if placement occurs at L1–2 rather than lower levels, and with the epidural needle angled in a cephalad direction, rather than perpendicular to the spine. It is important to note that the distance from skin to epidural space is much shorter at T12–L1 and L1–2 interspaces than at L3–4 or L4–5 which may predispose to inadvertent dural puncture. In our own practice, we make extensive use of electrical stimulation of epidural catheters [100], for confirming placement in the epidural space, for advancing lumbar and caudal catheters to tho-

**Figure 33.7** Epidurogram following placement of an epidural catheter. Note dye in the thoracic area.

racic dermatomes, and for confirming that the catheter is not wrong-sided (directed contralateral to the side of surgery). In this method, a small amount of electrical current is applied to a saline-filled, wire-wrapped epidural catheter as it is advanced cephalad in the epidural space. Twitches can be observed at the myotomal level of the catheter tip in a current range usually between 2 and 15mA. Characteristic response patterns indicating epidural, vascular, intrathecal or dural placement can be observed as the catheter is advanced. This technique can also provide information on the sidedness of the epidural catheter so that for a unilateral surgical procedure, predominant myotomal twitching on the non-operative side can be detected and the catheter repositioned. Technical success rates of 98% and analgesic success rates of 85% have been described using this method. Even in older adolescents and adults who may undergo regional anesthesia awake or under light sedation, we find that nerve stimulation is tolerated with minimal distress, provided the current is increased gradually.

It is sometimes necessary to confirm proper position of an epidural catheter postoperatively, for example, in the setting of continued pain despite adequate dosing of epidural infusions. Our common practice is to use a chloroprocaine loading dose, particularly for infants and non-verbal children. Chloroprocaine is an ester local anesthetic that is metabolized by plasma cholinesterases. Although infants have reduced levels of plasma cholinesterases, chloroprocaine is nevertheless rapidly metabolized. Because of concerns about toxicity due to accumulation of amide local anesthetics in infants and young children, we prefer to use chloroprocaine in place of lidocaine or other amide local anesthetics to check epidural catheter placement. Since most patients will have received infusions of amide local anesthetics intraoperatively, administering a bolus of chloroprocaine avoids the possibility of reaching toxic plasma levels through additional boluses of amide local anesthetics. We inject a loading dose of 3% chloroprocaine incrementally over roughly 2min through the epidural catheter. For this loading dose, infants receive larger weight-scaled volumes than adolescents. For example, an 8kg infant might receive a total loading volume of 5mL (0.62mL/kg), while a 30 kg 7 year old might receive a total loading volume of 12mL (0.4mL/kg), and patients >50kg get a total loading volume of 15mL. With these loading volumes, there should be clear clinical signs of sensory and motor block if the catheter is correctly positioned within the epidural space. Behavioral measures of pain relief such as relaxed posture and ceasing of crying are helpful in determining whether preverbal patients are experiencing relief, but objective measures should also be present, such as a motor block and a return of vital signs to baseline values.

Selection of drugs for epidural injection should be individualized and will vary with site of surgery, location of epidural catheter tip, and patient-specific risk factors. For most postoperative children, we recommend infusions of local anesthetics in combination with opioids, clonidine or both rather than local anesthetics alone because of the synergistic effect of combining local anesthetics with adjuvants. Bupivacaine is an amide local anesthetic commonly used in epidural local anesthetic infusions because it has a prolonged duration of action and produces more sensory than motor block. As previously discussed, the clearance of bupivacaine and other amide local anesthetics is reduced in neonates and young infants. Pharmacokinetic studies measuring unbound, pharmacologically active bupivacaine in infants receiving continuous epidural bupivacaine infusions showed that plasma bupivacaine levels rise after the first 48h and some infants will have plasma bupivacaine levels nearing or exceeding safe limits. Although most infants had an increase in their serum *α*1-acid glycoprotein concentrations after surgery, the increase did not fully buffer the unbound bupivacaine fraction. Based on these studies, epidural bupivacaine infusion rates in neonates and infants younger than 4 months of age should be limited to 0.2 mg/kg/h. Even at this low infusion rate, accumulation and drug toxicity are possible for infusions lasting more than 72h [101]. Epidural bupivacaine infusion rates of 0.4 mg/kg/h appear to be safe for children over the age of 6 months.

Ropivacaine is an amide local anesthetic that in adult studies was found to be safer and more sensory selective than bupivacaine. Studies of IV ropivacaine in adult volunteers showed less central nervous system and cardiovascular toxicity than bupivacaine. In double-blind comparisons, ropivacaine and levo-bupivacaine both produced similar analgesic effects as racemic bupivacaine but less extensive motor block [102]. Pharmacokinetic data in infants and children show that the clearance of bupivacaine is slightly more than the clearance of ropivacaine in all ages but as with bupivacaine, clearance of ropivacaine is reduced in neonates and young infants compared to older children [103-105]. Our practice is to use ropivacaine infusion rates up to 0.3mg/kg/h in infants younger than 6 months and up to 0.5 mg/kg/h for older children.

Lidocaine is used as an epidural local anesthetic for neonates and infants in some centers [106] because of the relative ease of monitoring lidocaine blood concentrations and because of reduced cardiotoxicity relative to bupivacaine. Note that even with lidocaine concentrations in a safe range, there is the potential for seizures due to accumulation of MEGX [107].

Epidural infusion rates of amide local anesthetics are limited in young infants because of the increased risk of toxicity, as detailed above. Chloroprocaine infusions have been used as an alternative to continuous amide local anesthetic infusions to allow for sufficient epidural infusion rates without the associated toxicity concerns of amide local anesthetics. Studies of continuous epidural infusions of chloroprocaine showed good surgical anesthesia without neurotoxicity [85]. Higher weightscaled infusion rates of chloroprocaine are necessary to achieve a similar extent of sensory block to that seen with bupivacaine and ropivacaine. Our practice is to use 1.5% chloroprocaine at a rate of 0.5 mL/kg/h for mid-thoracic epidural catheters and 0.6-0.7 mL/kg/h for lumbar and low thoracic catheter solutions in neonates and young infants who are monitored in the intensive care unit.

Because of weight-based scaling constraints of local anesthetic infusion rates, one rationale for combining opioids, clonidine or both along with epidural local anesthetic infusions is to provide a stronger analgesic effect while remaining in a safe local anesthetic dosing range. Addition of opioids, either neuraxially or systemically, will intensify the analgesia but increase the frequency of side-effects. Hydromorphone and fentanyl are the most commonly used epidurally administered opioids. In studies in adults, hydromorphone produces analgesia similar to morphine, but with less pruritus. The hydrophilic property of hydromorphone results in more cephalad spread, which can be effective for extensive surgeries that cover multiple dermatomes. However, the cephalad spread of hydromorphone does increase the risk of respiratory depression and we tend to restrict the use of hydromorphone in epidural infusions to infants older than 4 months, infants who are opioid tolerant or those who require ventilatory support for a period of time postoperatively. For older children, we favor hydromorphone over other additives, especially for extensive and painful surgery, for patients who have pre-existing chronic pain and hyperalgesia, and for most cancer surgeries. Fentanyl is used in epidural infusions in infants less than 4 months of age and in children whose surgery does not involve multiple dermatomes or is associated with relatively less pain intensity. In general, slightly lower starting infusion rates should be used when epidural catheter tips are located in the thoracic region or when using hydrophilic opioids.

All neuraxial opioids cause similar opioid side-effects, which are treated in much the same way as side-effects caused by systemically administered opioids. Pruritus is one of the most common side-effects of neuraxial opioids. It is most likely the result of modulation of neurotransmission in the dorsal horn and the trigeminal nucleus caudalis. Low-dose naloxone infusions in doses of  $0.25 \,\mu g/kg/h$  are effective at treating opioid-induced pruritus and nausea without reversing analgesia or precipitating withdrawal symptoms.

Clonidine enhances and prolongs the analgesic effect of local anesthetics without contributing to respiratory depression, nausea, urinary retention, pruritus and other opioid-related side-effects. We tend to employ clonidine most commonly for patients who have persistent epidural opioid side-effects despite standard treatments. Hypotension can occur, particularly in adolescents or in patients with inadequate blood and volume replacement.

Please see Table 33.6 for recommended epidural infusion rates.

## Acute pain services

Over the past 20 years, there has been much focus on the development of acute pain services, in part because of recognition of the undertreatment of postoperative pain, particularly in children. The Joint Commission has mandated specific hospital-wide standards for the treatment of pain and related symptoms in healthcare settings. There is evidence that acute pain services (APS) reduce patient reports of pain intensity and reduce delays in relieving severe pain. However, the effect of APS on other outcomes, such as incidence of side-effects, critical events and length of hospital stay, is equivocal. Other studies did not consistently show similar outcomes.

The specific organization of pain management programs varies depending on numerous factors including

Solution	<1 month	1–4 months	>4 months**
Bupivacaine 0.1% +/– Fentanyl 2 µg/mL +/– Clonidine 0.4 µg/mL	Rarely used	0.2	0.4
Ropivacaine 0.1% +/– Fentanyl 2 µg/mL +/– Clonidine 0.4 µg/mL	Rarely used	0.3	0.4–0.5
Bupivacaine 0.1% + Hydromorphone 10µg/mL	Rarely used	Rarely used	0.3–0.4
Ropivacaine 0.1% + Hydromorphone 10µg/mL	Rarely used	Rarely used	0.3–0.4
Chloroprocaine 1.5% + Fentanyl 0.2 µg/mL +/– Clonidine 0.04 µg/mL	0.5 (mid-thoracic) 0.6–0.7 (lumbar and low thoracic)	0.5 (mid-thoracic) 0.6–0.7 (lumbar and low thoracic)	Rarely used Rarely used

Table 33.6 Recommended epidural infusion rates (mL/kg/h)\*

\* Infusion rates and solutions should be modified according to clinical circumstances. Little information is available on how best to adjust these rates based on degrees of prematurity. Rates shown reflect upper end of usual infusion rates, based largely on both systemic accumulation of local anesthetics and on expected extent of sensory and/or motor blockade. Solutions containing hydrophilic opioids such as hydromorphone may pose a higher risk for delayed respiratory depression, so appropriate frequency of observation and continuous electronic monitoring is recommended. Higher concentrations of opioids may be considered for selected patients who are opioid tolerant.

\*\*Weight-scaled infusion rates should plateau at values recommended for patients weighing around 45 kg, i.e. maximum infusion rates for larger patients should rarely exceed 15 mL/h.

the average number of postoperative patients, the type of surgical procedures performed, and availability of subspecialists. Although the particular model of pain management program is unique to each hospital, there are common features that should be considered in the organization of acute pain services.

- Multidisciplinary group of clinicians dedicated to pain management, including anesthesiologists, nurses, surgeons, pediatricians, and pharmacists.
- Designated personnel to provide 24-h pain management services.
- Hospital-wide protocols or algorithms for pain assessment, analgesic therapy, monitoring of pain and vital signs, treatment of side-effects, and documentation of pain-related information.
- Hospital-wide standards for management of more specialized analgesic treatments such as epidural catheters, PCA, spinal catheters, peripheral nerve catheters, baclofen pumps, and implanted spinal/ epidural ports.
- Education program for clinicians (including pre and post tests).
- Education program for parents and children about risks, benefits, and treatment options.
- Quality assurance program and outcome tracking system.
- Ongoing review of pain management practices.

Formal measures of pain intensity should be assessed at regular intervals and recorded, as is routine for vital signs measurement. Specific pain assessment tools are chosen based on patient's age and cognitive and emotional ability as detailed above in the section on pain assessment in infants and children. In general, a visual analog scale or numerical rating scale is used for children aged 7 years and older. Faces scales, such as the Bieri or Wong–Baker faces, are appropriate for younger children aged 3-7. Ideally, education regarding the use of appropriate pain assessment tools should be reviewed with children and their parents at the preoperative visit. Composite pain scales that include behavioral observations, such as the FLACC Scale, are used for toddlers and non-verbal children. The FLACC and the PIPP are commonly used pain scales for infants and for preterm newborns, respectively.

Protocols for pain and symptom management are the foundation of a comprehensive pain management program. Depending on the type of surgery, patients' medical condition, and the degree of postoperative pain, most postoperative pain is treated by combinations of NSAIDs, opioids, and regional analgesia. For mild postoperative pain, short-acting opioids such as oxycodone alternating with doses of NSAIDs generally provide good pain relief. Oral dosing is preferred when patients are able to tolerate oral intake postoperatively. Parenteral

opioids are used in patients with more severe pain or when patients are restricted in their oral intake. PCA or NCA is widely used for infants and children with acute postoperative pain who require parenteral opioids. Regional analgesia including peripheral nerve catheter infusions and epidural infusions can provide excellent postoperative analgesia with opioid sparing and subsequent decrease in opioid side-effects. Protocols for analgesic administration include standardized PCA, epidural, and peripheral nerve catheter ordersets so that rangedosing of opioids and local anesthetics solutions is standardized and somewhat independent of prescriber. Nevertheless, dosing parameters and choice of specific opioid or combined local anesthetic/opioid solutions should be individualized and based on patients' prior opioid use and side-effect profile, severity of pain, location of surgical pain, medical condition, and psychological state. Inherent in pain management protocols are algorithms and ordersets for treatment of side-effects so that patients do not experience delays in receiving treatment for common side-effects, such as pruritus, nausea, and vomiting.

All patients receiving opioids, either systemically or through regional catheters combined with local anesthetics, should be assessed for signs of respiratory depression. Protocols for monitoring level of consciousness and respiratory depression should involve nursing assessment and documentation of levels of sedation at regular intervals. Our practice is to provide electronic cardiorespiratory monitoring for all patients who have a basal rate added to their PCA, patients with risk factors for respiratory depression with opioids, such as those with certain airway diseases or neurological impairments, and young infants who are at risk for apnea with opioids. There have been reports of hypoventilation and critical events among healthy patients receiving epidural analgesia postoperatively, even when fentanyl was used as the opioid in the epidural infusion. We routinely place all patients receiving epidural infusions on cardiorespiratory monitors. While oximetry may be imperfect in detecting hypoventilation, especially when supplemental oxygen is administered, it probably facilitates rescue before serious harm occurs in many cases [108]. Other routine nursing assessment and documentation should include regular assessment of side-effects, extent of sensory and motor block for patients with regional catheters, and total daily amounts of opioids administered so that day-to-day comparisons can be made.

Hospitals with acute pain services need to have a system of immediate response to critical events. The structure of the immediate response system varies among hospitals but it is essential to have clinicians involved who have expertise in pediatric airway management and who are knowledgeable about the pharmacology of local anesthetics, opioids, and sedatives.

Quality assurance programs should analyze data pertaining to clinical practice, including general outcome measures of PCA, epidural, and other regional techniques. Data concerning adverse events should also be analyzed at regular intervals. Based on analyses of data, quality assurance programs can review institutional policies and practices and make practice guideline recommendations for improvement in safety and patient satisfaction.

## Painful conditions in infants and children

## **Cancer pain**

Children with cancer experience a variety of types of pain related to their disease process and cancer treatments [109]. Studies of cancer pain in children have shown that as successful treatment protocols evolve, pain related to cancer treatments is the more predominant source of pain and suffering, including painful mucositis, postamputation pain, and peripheral neuropathies [110]. Repeated needle procedures, such as bone marrow biopsies, lumbar punctures, and repeated venous access, are particularly distressing for children. Tumor-related pain is often present at the time of the initial diagnosis and also results from disease progression with tumor spread to bone, spinal cord, and nerve plexuses. Children with hematological malignancies often present with bone pain from bone marrow infiltration and abdominal pain from capsular stretch of liver and spleen; those who show a good response to induction chemotherapy generally experience resolution of pain. However, a subgroup of children will continue to experience somatic, visceral and neuropathic pain.

Children undergoing treatment of cancer frequently need diagnostic imaging studies, radiation therapy, and brief needle procedures. Aggressive and proactive management will help decrease pain and anxiety associated with these procedures. Cognitive behavioral therapies, such as guided imagery, are useful for children with procedural pain. Topical analgesics should be routinely used for minor needle procedures such as accessing implanted vascular ports or intravenous line insertions. Depending on age, associated medical problems, and severity of pain and other symptoms, general anesthesia or conscious sedation is generally used for more invasive needle procedures, such as bone marrow biopsies and lumbar punctures. Safe sedation protocols have been established by the American Academy of Pediatrics and serve as guidelines for procedural sedation by oncologists and other

subspecialists. Children with risk factors for conscious sedation or those who fail prior attempts at conscious sedation require consultation by pediatric anesthesiologists. Daily radiation therapy or diagnostic imaging, such as magnetic resonance imaging (MRI), is not typically painful but do require children to be immobile and brief general anesthesia is usually required.

Mucositis is painful inflammation of the mucosa caused by chemotherapy or radiation. It is a common side-effect in children receiving chemotherapy and is especially intense and prolonged with bone marrow transplantation. Topical agents are often used for symptomatic relief in mild mucositis, but there are limited data showing efficacy. Parenteral opioids given through PCA or NCA are generally used for moderate-to-severe pain from mucositis. Oral opioids are not typically used initially since most children experience painful swallowing from mouth and esophageal involvement. Since many children experience significant pain from mucositis for weeks, our practice is to provide approximately 60% of the total daily opioid dose through a basal rate to provide sustained analgesia without requiring the patient to use the PCA button repeatedly throughout the day and night. For patients with mucositis whose pain is poorly controlled with standard PCA or NCA opioids, a recent trial supports addition of low-dose ketamine to the mixture [111].

Nearly all children who have had amputations experience phantom sensations and many experience phantom pain [112]. Postamputation pain occurs more often in children who have had amputations due to cancer rather than trauma, and administration of chemotherapy may be a risk factor in the development of phantom pain. Regional analgesia, including epidural and peripheral nerve catheters, can provide very effective postoperative analgesia after limb amputations. Although severity of early postamputation pain correlates with likelihood of longer-term pain, studies of pre-emptive actions of several regional anesthetic approaches have yielded mixed outcomes. Treatment with antidepressants, anticonvulsants, NMDA-antagonistic drugs, gabapentin, opioids, and clonidine has shown some success but there are limited data from large, controlled clinical trials. Mirror box therapy and other forms of visual feedback therapies have been used with some success in the treatment of postamputation pain [113]. A mirror is positioned so that it reflects movement of the limb as if the amputated limb is intact.

A stepwise program of analgesic therapy proposed by the World Health Organization can provide good treatment of pain in adults with advanced cancer without intolerable side-effects in a large majority of patients. A similar stepwise analgesic approach has been advocated for the treatment of children with cancer pain where NSAIDs, acetaminophen, and low-dose opioids, such as oxycodone, are initially used for the treatment of mild pain. Morphine, hydromorphone and other opioids are titrated to effect as pain escalates. The use of oral opioids is recommended when possible. For patients with persistent pain, an effective opioid regimen includes the use of long-acting opioids, such as methadone or sustainedrelease formulations of morphine or oxycodone. Shortacting morphine, oxycodone, hydromorphone or other opioids are added for breakthrough pain. Oral methadone is useful as a long-acting elixir for children who are unable to swallow pills. Conversion from morphine and other short-acting opioids to methadone requires individualization and close observation because of the incomplete cross-tolerance mentioned above. A rough guide for conversion can be found at www.globalrph.net/ narcoticconverter. Several sustained-release opioid preparations contain microbeads and it is common practice to open the capsule and sprinkle the microbeads into food just prior to use. However, if the microbeads are chewed or left in contact with food for an extended period of time, they release their contents. Not only does this reverse the sustained-release property, it can also increase the risk of overdose. Parenteral opioids are used when pain is rapidly escalating and oral opioids are not effective or when patients are unable to tolerate oral opioids due to nausea, vomiting, gastrointestinal processes or the inability to swallow. In this setting, PCA or NCA is used, generally with a basal rate. Opioid side-effects should be aggressively treated and in cases of intolerable sideeffects, opioid rotation can be helpful.

Although standard dosing of opioids adequately treats cancer pain in most children, a subgroup of children with cancer will have persistent, severe pain despite enormous escalation of opioid dosing (for example 500 mg/kg/h) [114]. Refractory pain despite massive opioid doses is typically seen with tumor metastases to spinal cord and major nerves, causing unrelenting neuropathic pain. Many children with severe cancer pain who are resistant to opioids can be made comfortable through the use of regional anesthetic techniques, such as implanted intrathecal or epidural catheters or ports [115]. The choice of drugs should be individualized and depends on a number of factors, such as location and nature of pain, bowel and bladder function, and level of alertness. In most cases, dilute solutions of local anesthetics and opioids provide good pain relief, although other agents are sometimes added, such as clonidine or ketamine. Our general preference is use intrathecal rather than epidural placement in most cases, because this permits versatile dosing as pain escalates over time, and because over time epidural dosing of local anesthetics is limited by tachyphylaxis and systemic toxicity. We generally prefer placement of ports to facilitate skin care, reduce the risk of infection, and reduce the chance of catheter dislodgment at home. These procedures are performed under general anesthesia and with fluoroscopic guidance. There are a number of technical and management issues involved, and clinicians are encouraged to consult with the authors or with others with experience in this area, since many aspects are not readily extrapolated from either perioperative regional anesthesia or adult chronic pain management.

For a very small percentage of children with advanced disease and refractory pain or terminal dyspnea, there may be a role for administration of sedative infusions. However, in our view, use of sedatives near the end of life should never become routine, and efforts should be made whenever possible to preserve clarity of sensorium and interactiveness [116]. The ethical principle of double effect is commonly invoked to guide prescribing of opioids and sedatives at the end of life. While this principle has become nearly universally accepted, critics have pointed out some difficulties with its justification and application [117].

In addition to pain, children with cancer experience a range of other symptoms, such as fatigue, somnolence, and depressed mood. Some data suggest that the prevalence of symptoms is higher among children who are undergoing chemotherapy, who are hospitalized, and who have solid tumors compared to those with hematological malignancies. A recent study suggested that, as pain is treated more aggressively with opioids, the likelihood of fatigue and somnolence is increased [83]. Studies in adults support the use of stimulants, such as methylphenidate, to counteract somnolence from opioids.

## Sickle cell vaso-occlusive episodes

Painful vaso-occlusive episodes are the most common cause of pain in children with sickle hemoglobinopathies [118]. Other acute processes can also present with pain, such as pneumonia, stroke, priapism, acute cholecystitis, splenic sequestration, and avascular necrosis. Fever can be associated with an uncomplicated pain episode or may be a sign of pneumonia, appendicitis or other infection. The pain from vaso-occlusive crises can be unpredictable in severity, location, and frequency, ranging from occasional, mild episodes to frequent, severe and prolonged episodes requiring repeated hospitalizations. Approximately 5% of children with sickle cell disease account for over 30% of hospitalizations and patients with the highest rate of painful episodes and hospitalizations have higher mortality rates [119]. Painful vaso-occlusive crises can occur in children as young as 6 months of age as the protective effects of fetal hemoglobin decrease. Dactylitis is a painful episode involving the hands and feet and is more common in younger children. Adolescents tend to experience back, limb, and chest pain, although the location can be variable. Priapism is caused by sickling of hemoglobin in the sinusoids of the penis and causes prolonged, painful erection.

Children with occasional mild-to-moderate painful episodes are typically managed at home with NSAIDs and oral opioids. Severe, escalating pain is generally managed in the hospital with NSAIDs and a PCA with basal infusions. Opioids should be titrated to effect with close observation for hypoventilation and signs of excessive sedation. Surveys suggest that even with generous PCA dosing, pain scores remain quite high and a considerable percentage of hospitalized patients with vaso-occlusive episodes experience pain on a regular basis [120]. For some patients with severe chest pain, the high doses of opioids necessary to treat pain can result in somnolence, hypoventilation and inability for effective coughing and incentive spirometry, leading to worsening hypoxemia and further pulmonary decline. In selected cases, continuous epidural analgesia may provide improved analgesia and reduce the need for further systemic opioids and reduce opioid-induced somnolence.

## **Cystic fibrosis**

Patients with cystic fibrosis (CF) experience a spectrum of recurrent or persistent pain, particularly chest pain and headaches in the final year of life [121]. Other common types of pain include recurrent limb pains that are sometimes associated with arthritis, and back pain, which is multifactorial. Chest pain is typically the most commonly reported pain in patients with CF, regardless of severity of lung disease. Coughing and chest wall muscle strain from increased work of breathing lead to chronic musculoskeletal chest pain. Severe coughing can result in rib fractures or periosteal tears that produce pinpoint tenderness on exam and severe pleuritic chest pain.

Headaches may be due to a range of causes, including musculoskeletal strain, chronic sinusitis, migraine, hypoxia, and hypercarbia. Over 50% of patients with CF report chronic headaches. Headaches due to muscular contraction and strain are very common and are worsened by excessive coughing and increased use of accessory muscles of respiration. Sinus disease is found in the majority of patients with CF and can contribute to headache pain. In some cases, surgery can reduce pain from sinus-associated headaches. Migraines can be intractable and particularly difficult to treat in patients with CF; many patients do not experience good relief with typical abortive migraine treatments, such as NSAIDs or 5HT1 receptor-specific agonists. With disease progression and worsening of pulmonary function, hypercarbia and hypoxia play a more predominant causative role.

Patients with CF experience a number of other musculoskeletal chronic pain conditions. Chronic back pain is generally a result of chronic muscle strain from severe coughing; however, thoracic and lumbar compression fractures can occur and are often under-recognized. The incidence of CF-associated episodic arthritis in children seems to be similar to that seen in older patients with CF, while hypertrophic pulmonary osteo-arthropthy is more prevalent in adult patients.

Treatment of children with chronic pain from CF depends in part on location and severity of pain, severity of lung disease, the degree to which pain interferes with good pulmonary toilet and response to opioids. There are no controlled clinical trials of non-pharmacological therapies in children with CF, but many patients find acupuncture, biofeedback and other cognitive behavioral therapies helpful. NSAIDs are often used either alone or combined with opioids without contributing to respiratory depression, somnolence or constipation, and may allow for opioid-sparing effects. There may be a role for COX-2 inhibitors for patients who experience GI side-effects with traditional NSAIDs and may be less likely to contribute to hemoptysis. If patients with CF receive opioids postoperatively, there is a very high incidence of constipation; aggressive and pre-emptive use of stimulant laxatives should be considered.

The indications for chronic opioid therapy for children and adults with CF are a subject of controversy. CF is now associated with a median survival that exceeds 40 years of age in many centers, so chronic opioid administration should be undertaken with consideration of long-term consequences. We commonly employ thoracic epidural analgesia for major thoracic and abdominal surgery in patients with CF, especially those undergoing lung transplantation. Patients with CF may benefit from thoracic epidural analgesia in two additional situations: severe chest pain due to rib fractures or a chest tube, and impending bowel obstruction associated with meconium ileus equivalent. For CF patients with meconium ileus, a thoracic epidural infusion of local anesthetic has several benefits: it relieves pain and reduces the requirement for opioids, which further slow the bowel, and it provides thoracic sympathectomy, which directly accelerates bowel motility. Many patients undergoing lung transplantation have had chronic, severe chest pain prior to transplantation, and we have found that infusing higher concentrations of local anesthetics (e.g. ropivacaine 0.2%) in combination with hydromorphone is sometimes necessary to achieve adequate analgesia.

## **Neuropathic pain**

Neuropathic pain refers to pain associated with injury or altered excitability within the peripheral or central nervous system [122]. Unlike nociceptive pain, neuropathic pain can persist independent of ongoing tissue injury or inflammation. A-δ and C-fibers can become activated through a range of mechanisms, including infection, inflammation, ischemia, and transection. Other causes include tumor involvement of nerves, metabolic disorders and chemotherapeutic drugs such as vincristine. Neuronal reorganization and central sensitization occur through sustained C-fiber discharge and "windup" in the dorsal horn. An array of complex mechanisms induces central neural changes, including ectopic firing of dorsal root ganglion, decreases in magnesium blockade of NMDA receptors, and changes in afferent A-δ fibers that facilitate pain [122]. Pathways containing opioid receptors and endogenous opioids, serotonin, and norepinephrine project to the rostral ventromedial medulla and spinal dorsal horn. Input from the hypothalamus, amygdala, anterior cingulate area, and insular cortex modulates the pathways and can facilitate or inhibit transmission of pain signals.

Many adult neuropathic pain conditions such as diabetic neuropathy, central post-stroke pain, and trigeminal neuralgia are quite rare in children. There may be an age dependence to the nervous system's responses to several types of nerve injury. For example, while traumatic brachial plexus injury commonly produces severe pain in adults, perinatal brachial plexus injury in human neonates rarely appears painful, except for a subset of infants who subsequently undergo nerve grafting procedures [123]. In two models of painful peripheral nerve injury, infant rats show markedly reduced allodynia and other pain behaviors compared to older rats [124]. The age dependence of neuropathic pain may be related in part to the ontogeny of microglial inflammatory responses to nerve injury [125].

The classic description of neuropathic pain in adults of burning, shooting or pins and needles pain is sometimes seen in children but younger children often have difficulty describing their pain. A thorough neurological examination should help detect underlying disease and should assess whether there are dermatomal deficits. Characteristic physical exam findings include allodynia and hyperalgesia. Allodynia refers to previously nonpainful stimuli, such as light touch of the skin, causing pain. The presence of allodynia implies abnormal sensory processing and is an important clinical sign of neuropathic pain. Hyperalgesia refers to normally noxious stimuli, such as light pinprick, producing abnormally exaggerated pain. History and physical examination should guide any additional studies such as testing for thyroid dysfunction, B12 deficiency or heavy metal toxicity. Electromyography can detect signs of denervation in muscles, and nerve conduction studies are useful for objectively assessing function of myelinated large nerve

fibers, but these do not measure function of smaller Cand A-fibers commonly involved in neuropathic pain.

Neuropathic pain may occur in a range of static or progressive neurological disorders in childhood, including mitochondrial disorders. Heterozygous Fabry disease can produce painful small-fiber neuropathies that may begin during late childhood or adolescence [126]. Quantitative sensory testing is a non-invasive method of assessing the function of small as well as large sensory nerve fibers. Unlike nerve conduction studies, quantitative sensory testing is well tolerated by children and does not require sedation.

Adults with neuropathic pain are commonly treated with anticonvulsants and antidepressants. While randomized trials show efficacy for conditions such as postherpetic neuralgia and diabetic neuropathy, it should be noted that effect sizes (based on changes in pain scores) are comparatively small, and benefit is often achieved at doses that would be expected to cause significant somnolence or impaired cognition in many patients [127]. Despite the widespread prescribing of drugs such as gabapentin, pregabalin, and duloxetine, there is very little empirical basis for regarding these drugs as either safer or more effective than older drugs, such as tricyclic antidepressants.

The use of drugs for the treatment of neuropathic pain in children is extrapolated from adult studies since there are very few pediatric prospective trials. For children and adolescents with neuropathic pain, we generally use tricylics and anticonvulsants as first-line drugs. Tricyclics are among the most established analgesics in the treatment of diabetic neuropathy, postherpetic neuralgia, and central post-stroke pain in adult patients. Tricyclics can also be helpful in promoting sleep in patients with sleep disorders due to pain. Nortriptyline and amitriptyline are most commonly used, often in twice-daily dosing with a larger portion of the dose give at bedtime. A baseline electrocardiogram is recommended prior to initiation of these drugs. A typical starting dose for nortriptyline is 0.2 mg/kg with dose titration every 3-5 days. Common side-effects are related to anticholinergic effects, including dry mouth, sedation, tachycardia, constipation, and urinary retention. There is less robust evidence for the use of selective serotonin reuptake inhibitors (SSRIs) in the treatment of neuropathic pain in children, but they are often used as an adjuvant in the treatment of associated mood disorders. Overall, antidepressants, including SSRIs, appear less effective for treatment of major depressive disorders in children compared to adults. In randomized trials, placebo responses are common and substantial; effect sizes relative to placebo are relatively small, and numbers needed to treat (NNTs) average 8 or greater [128]. NNTs are somewhat better (lower) for treatment of anxiety disorders in children [128].

Gabapentin and pregabalin are widely prescribed, in part because of historical concerns about risks of antidepressants exacerbating suicidal ideation or attempts. However, meta-analyses of clinical trials of anticonvulsants suggest that multiple anticonvulsants also may increase these risks, even in patients without epilepsy or known severe mood disorders [129]. Parenthetically, anesthesiologists should note that lipid emulsions, which are used to treat bupivacaine cardiotoxicity, also appear to be effective in reversing cardiotoxic effects of several classes of antidepressants and anticonvulsants [130]. While the overall excess risk of severe mood or behavioral changes from antidepressants or anticonvulsants appears relatively low, in our view, clinicians should titrate these medications gradually, should alert parents to report any concerning changes in behavior or affect, and should employ a system of phone and clinic-based follow-up to detect adverse effects of these medications.

Lidocaine 5% transdermal patches are widely prescribed for neuropathic pain and for other forms of pain. Plasma concentrations of lidocaine are quite low. While these formulations appear quite safe, and there are studies supporting efficacy for several types of neuropathic pain in adults, in our view there is a high likelihood that placebo responses contribute substantially to their reported benefits for many patients.

The use of opioids in the treatment of non-cancer related neuropathic pain remains controversial. Opioid prescribing for chronic pain in adults has increased enormously over the past 20 years, with a concomitant increase in deaths in adults and adolescents due to apparent misuse or diversion of prescribed opioids. Diversion of prescribed opioids has increased rapidly as a problem among adolescents [131]. In adult studies for chronic noncancer pain, evidence for long-term benefit of opioids on pain scores is limited, and most studies show no benefit for measures of functioning or disability. For children and adolescents with non-life limiting chronic pain conditions, there are additional concerns. First, as noted above, opioid tolerance is probably more rapidly achieved in childhood compared to in adults. Second, adolescence appears to be a time of unique vulnerability to addiction to multiple classes of substances. Long-term opioid prescribing for children is relatively infrequent [132]. Due to its NMDA antagonist action, methadone may play a role for select patients with neuropathic pain.

Complex regional pain syndrome type 1 (CRPS1) is characterized by neuropathic limb pain with associated sensory characteristics and neurovascular and sudomotor findings. The term CRPS1 overlaps with what was previously called reflex sympathetic dystrophy or reflex neurovascular dystrophy [133]. Diagnostic criteria for clinical and research purposes have undergone refinement [134]. The classic clinical presentation is burning pain in an arm or leg with allodynia, hyperalgesia, mottling, coolness, swelling and abnormal sweating, although the clinical presentation can vary widely. Various motor findings can also occur such as tremors, fasciculations and dystonia. CRPS 2 refers to this pattern of clinical findings with signs of specific peripheral nerve injury; this is similar to what was traditionally called causalgia. In our view, although there may be important roles for peripheral and autonomic mechanisms, it is useful to view CRPS as being maintained at least in part by abnormal information processing in the brain. These functional brain abnormalities are not purely sensory, but also involve pain modulation [135] and motor representation [136].

Complex regional pain syndrome has unique epidemiological features in children. Multiple case series have found a high female-to-male ratio (approximately 5-8:1) and a preponderance of lower extremity involvement (75–90%) [133,137,138]. The peak age of onset is 10–12 years. It is rarely seen in children less than the age of 6 years. Twenty percent of children have a remote or contralateral limb affected. About 90% of patients recall an inciting trauma but it is usually vague and minor. Some children can present as extremely disabled, have significant school absences and are unable to ambulate independently, but the degree of disability seems to vary widely. Functional MRI (fMRI) has been used to study CNS activation in children with CRPS [139,140]. Some functional and structural changes normalize after the pain from CRPS has resolved, while other changes are persistent [139,140].

Retrospective case series and prospective studies [141] have indicated that the majority of children with CRPS will have improvement in both function and pain through an aggressive rehabilitative approach without the use of nerve blocks or pharmacological agents. The frequency of recurrent episodes may range from 20% to 50% of cases, although most recurrences of symptoms appear to be milder than the initial episode and more readily responsive to reinstitution of aggressive physical therapy, occupational therapy, and cognitive-behavioral therapies. Our practice in treating children with CRPS involves a rehabilitation program with intense physical therapy, occupational therapy, and cognitive-behavioral therapies. A significant aspect of the approach involves patient and parent education about the non-protective nature of neuropathic pain and recognizing factors that reinforce disability and fear of pain. Physical and occupational therapies are directed at active mobilization of the affected limb, resuming independent weight-bearing and aggressive desensitization techniques. For some children, this program can be accomplished as an outpatient but those who fail will need an inpatient or partial hospitalization program. Epidural analgesia or peripheral nerve blocks are used for a comparatively small subgroup of patients who fail to make good progress with good rehabilitation efforts or for those with severe limb swelling or dystonia that persists after an active multidisciplinary treatment program. If the distribution of pain, allodynia and autonomic abnormality is appropriately limited, there are advantages to the use of peripheral or plexus catheters. Our practice is to use an indwelling catheter technique for several days rather than repeated single injections. We tend to place continuous popliteal-sciatic catheters for lower extremity CRPS and either supraclavicular or infraclavicular catheters for upper extremity CRPS. Patients are then hospitalized and receive continuous local anesthetic infusions of ropivacaine, sometime with the addition of clonidine. During their 3-5-day hospital stay, they receive intense rehabilitation with twice-daily physical therapy and cognitive-behavioral therapy. One case series reported excellent outcomes using primarily poplitealsciatic catheters maintained at home in children with "stocking-distribution" CRPS [142].

## **Back pain**

Back pain in adults is a major cause of suffering as well as economic loss due to work-related disability. Nondisabling episodic back pain is relatively common in children and adolescents, but daily persistent back pain is overall much less common than in adults [143]. Since persistent severe back pain is relatively less common in younger children, it is appropriate to evaluate for specific serious causes including infections (osteomyelitis, diskitis, pyelonephritis), tumors, benign abnormalities such as osteoid osteoma, and congenital abnormalities, such as tethered cord and diastematomyelia.

Back pain in our referral practice is more commonly seen in adolescents who are competitive athletes, such as gymnasts, dancers, and cheerleaders. A thorough neurological and musculoskeletal exam is necessary to determine likelihood of conditions such as lumbar disk disease, spondylolysis, spondylolisthesis, sacroiliitis, and muscular strain. Patients with muscular pain without evidence of radiculopathy are treated with an exercise program of core strengthening and reducing repetitive stress and trauma to the spine. With proper patient selection, fluoroscopically guided epidural steroid injections appear to provide intermediate-term benefit in adults with lumbar radiculopathy. Our recent review of experience with fluoroscopically guided epidural steroid injections for children and adolescents with lumbar radiculopathy showed that the majority of patients reported significant reductions in pain with an excellent safety profile. In 2-5year follow-up, fewer than 40% of patients required diskectomy [144].

In adults, extension-related back pain is commonly associated with facet arthropathy. In adolescents, this pattern of pain is commonly seen with spondylolysis and spondylolisthesis. These conditions are commonly treated with a trial of bracing. Adults with cervical or lumbar facet disease commonly receive median branch blocks and, if they provide short-term benefit, radiofrequency denervation procedures [145]. In our practice, we do perform some of these injections using local anesthetic and low doses of steroids. To date, we have been reluctant to perform radiofrequency denervation procedures on patients with a developing spine except in extraordinary circumstances.

Functional abdominal pain (FAP) is a term that has generally been used for recurrent episodic abdominal pain occurring among children and adolescents who are otherwise medically well and who show no evidence for a structural or inflammatory origin of pain [146]. FAP presents in distinct patterns, as codified subsequently by three consensus processes known as the Rome I, II, and III classifications; these have been developed for both adults and children [147]. These conditions account for a high frequency of pediatric office visits, and may account for up to 20% of school days missed due to illness in the US. Most children who present in this manner remain medically well and few eventually are found to have an identifiable structural or inflammatory disorder.

There are common features of functional abdominal pain with respect to clinical characteristics. Most children are between the ages of 4 and 16 years and report episodic, periumbilical pain. Children younger than 4 years should receive further investigation into underlying causes. Children are otherwise generally medically well without systemic signs of disease. Rarely do children report that pain awakens them at night. The diagnostic approach in primary care should be guided by a careful history and physical examination and should avoid unfocused laboratory testing beyond basic studies, such as a complete blood count, urinalysis, and, as appropriate, stool examination. A psychosocial history is important for identifying reinforcing pain behaviors and other behaviors that suggest disability. In general, extensive testing is not helpful and may heighten parental and patient anxiety. Routine radiographic studies without findings on history or physical exam are typically of low yield. For children who have fevers, weight loss, family history of inflammatory bowel disease, and pain that is not periumbilical, these are concerning signs and warrant further evaluation. Abnormalities on physical examination or initial screening tests should also guide additional investigation.

Treatment of functional abdominal pain depends in part on the pattern of clinical presentation and the degree of distress or disability involved. As guided by the history and examination, some clinicians favor empiric trials of treatment of constipation, lactose avoidance or lactose enzyme supplementation, dietary alterations or acid suppression. Education of parents and patients should include discussion about the non-protective character of the pain, and should discourage catastrophizing and overmedicalizing. Cognitive-behavioral interventions are supported by evidence and should be used more widely [148]. In our view, medications form only a part of the management, and should not be used in lieu of lifestyle change, rehabilitative interventions, and cognitivebehavioral interventions. Controlled trials of medications such as amitriptyline have yielded both positive [149] and negative [150] results. Many medications are commonly prescribed based on uncontrolled pediatric case series or extrapolation from adult studies [151].

Episodic headaches are also common in children and adolescents. The frequency of both migraine and tensiontype headaches increases through childhood. Prior to adolescence, boys and girls are similarly affected. With the onset of adolescence, the prevalence increases more in girls than in boys, particularly with migraine. Patients and parents are often worried that headache is associated with serious conditions, such as tumors. As with abdominal pain and chest pain, diagnostic evaluation should emphasize the history, including a psychosocial history, and physical examination, including a systematic neurological examination. Practice parameters on imaging for recurrent headaches in childhood have been published [152]. In the absence of features of the clinical presentation that suggest higher risk, imaging studies are generally of low yield [153] or they identify incidental findings [154] that further increase worry but are of generally limited clinical significance.

While recurrent tension-type headaches or episodic migraine are common, for the majority of children in the general population, they do not dramatically impair daily functioning. The subgroup of children who may be referred to pediatric neurologists or pediatric pain physicians tends to be those with more frequent or more severe headaches, or those who have pathological but not readily "fixable" headaches. Examples of the latter include headaches following head trauma or following multiple ventricular shunt procedures with slit ventricles. The occurrence of more disabling recurrent headaches [155] or chronic daily [156] headaches is more prevalent with certain lifestyles, including obesity, smoking, and lack of physical exercise, with some psychological co-morbidities, including anxiety and depression, and with overuse of analgesic medications.

For children with relatively infrequent migraine episodes, there is evidence to support episodic use of NSAIDs and several triptans for abortive treatment [157]. For children and adolescents with disabling recurrent or chronic daily headaches, in our view, treatment should begin with identification of triggering factors, lifestyle modifications, and avoidance of overly frequent use of acetaminophen and NSAIDs. A number of approaches to cognitive-behavioral therapy show strong evidence of efficacy for both migraine and tension-type headaches, and they should be used widely [148].

The use of prophylactic medications for pediatric migraine is often based on custom and on extrapolation from adult studies. For example, cyproheptadine is widely used, despite absence of controlled trials. While several anticonvulsants are widely used, evidence for efficacy is sparse for most anticonvulsants [158]. There is some support for topiramate in recent placebo-controlled pediatric migraine prophylaxis trials [159]. There are positive trials for amitriptyline, trazodone, and several calcium channel blockers, and trials of propranolol have yielded mixed results [157].

## Conclusion

The management of acute, recurrent, and chronic pain in children has made considerable progress over the past 30 years. While pain assessment is more challenging in infants and preverbal children, pragmatic measures are now available for all age groups. Treatment should be individualized and may involve combinations of pharmacological, regional, rehabilitative and cognitivebehavioral interventions. Multicenter clinical trials will be helpful for conducting adequately powered clinical trials for many forms of acute and chronic pain in pediatrics.

## CASE STUDY

You are working in a pediatric chronic pain clinic when you are paged by one of the emergency room (ER) physicians who asks if you would urgently evaluate a patient who has severe foot pain and is currently being seen in the ER. You agree to see the patient who then shortly arrives in your office. The patient is an 11-year-old competitive gymnast who is accompanied by her mother. The child has an 8-week history of left foot pain, which she attributes to tripping over a gymnastic mat; this event produced a small laceration of her foot and a sprain. An orthopedic surgeon evaluated her after the fall. Her plain radiographs did not show an obvious fracture, but she did wear an aircast boot for 4 weeks without significant improvement. A recent bone scan showed osteopenia of the affected limb. An MRI did not show significant findings. Her pain is significantly worse this morning since falling last night after her left foot "gave out" as she was walking up stairs. She reports that her foot often "gives out" and feels like she has no strength in it. She is otherwise medically well. She describes her pain as a numb, burning sensation over the lateral aspect of her left foot with shooting pains into her calf. She has noticed occasional swelling and redness over the painful area and has also noticed that her foot seems to shake involuntarily. She has difficulty falling asleep due to pain and is unable to have the blankets touch her painful foot.

She and her mother are tearful as she explains how she will miss the state competitions in 1 month if she cannot participate fully. Her mother explains how difficult this has been for the entire family and how she has not been able to work at her job since the onset of her daughter's pain 2 months ago. She does describe how supportive the teachers at her child's school have been by allowing her to attend classes only when she is able to make it.

On examination, she is a small-appearing female who is ambulating with the use of crutches. The lateral aspect of her left foot has a  $3 \times 3$  cm area of slight ecchymosis and edema, which the patient reports comes and goes. Her foot has a mottled appearance. When you lightly touch her foot, she withdraws, begins to cry, and explains that it feels like an intense burning and pins and needles sensation. Her foot and leg feel cool to touch up to the midcalf. She has noticeable atrophy of her gastrocnemius. She refuses to bear weight on her foot during the examination.

You explain to the patient and her mother that her history and physical examination findings are most consistent with a diagnosis of complex regional pain syndrome (CRPS.) Her allodynia and pain in a non-dermatomal distribution are typically seen in CRPS. Neurovascular and motor findings such as edema, intermittent color and temperature changes, and involuntary spasms and tremors are also consistent with CRPS. A bone scan and MRI have ruled out other worrisome conditions such as osteomyelitis or an occult fracture.

Your discussion with the patient and her mother involves extensive education about CRPS and treatment options. CRPS is rare before the age of 8 and peaks around the age of 12–13 years. Girls are six times more likely than boys to have CRPS and the lower extremity is much more commonly involved than an upper extremity by a ratio of 8:1. Twenty percent of children experience spread of their symptoms to a contralateral or remote limb, which is presumably due to central sensitization. The majority of children report an antecedent injury, although in most cases, the injury seems vague and minor, such as the injury that occurred in this patient. Many children with CRPS are involved in highly competitive, individualized sports, such *Continued*  as ballet and gymnastics. Studies have shown that children with CRPS have similar scores on depression and anxiety testing compared to other children with chronic pain conditions. Plain radiograph findings in children with CRPS are variable and can show diffuse osteopenia or appear normal, even with long-standing CRPS. Bone scans also show variable results and have little to no predictive value in CRPS but, as in our patient, can exclude other pathology such as infection.

Although CRPS is a clinical diagnosis, quantitative sensory testing (QST) has been used in children to provide more objective evidence of sensory abnormalities. It is used to assess function of cutaneous somatic small fibers and is particularly applicable to children since it is painless and does not require sedation.

In discussing various treatment options, you explain that studies of children with CRPS show that the majority will show a good improvement of function and of pain scores through a multidisciplinary approach of active physical therapy, occupational therapy, and cognitive-behavioral therapy. You explain that in some cases a nerve block is indicated so that patients are able to participate in physical therapy or if you are concerned about limb perfusion. Although the patient's mother wants a medication such as Percocet that will alleviate her daughter's pain quickly so that she can participate in the state gymnastics competition, you explain that data showing efficacy of medications are lacking and there is no "quick fix." However, since the patient is having difficulty with sleep, you do prescribe 10 mg of nortriptyline at night. You order a baseline ECG to detect any underlying dysrhythmia that would place her at additional risk in taking a tricyclic antidepressant. You explain that in general, you do not prescribe opioids routinely for patients with CRPS. You emphasize to the patient and her mother that cognitive-behavioral techniques such as biofeedback are important to her overall recovery and that therapy will be directed at improving her coping skills, maintaining regular school attendance, and normalizing behavioral responses to pain. She will need to have active participation in physical therapy, particularly in attempting to ambulate without the use of assistive devices and in desensitization techniques. You discuss the non-protective nature of neuropathic pain in that, unlike nociceptive pain, which is protective, neuropathic pain is abnormal processing of nerves and pain does not imply tissue injury. If outpatient therapy is not effective, you discuss the possibility of an inpatient or partial hospitalization program for intense rehabilitation.

The patient and her mother return for a follow-up visit in 3 weeks after an outpatient trial of physical therapy and cognitive-behavioral therapy. She has made very little progress in physical therapy. She is very reluctant to be actively involved in physical therapy because of her severe pain. In fact, she is using a wheelchair almost exclusively now and will not allow anyone or anything to touch her foot, even to examine it. She is tearful throughout the evaluation and keeps her knee flexed to protect her foot. Her foot and calf have a more dusky appearance than before with worsening of muscle atrophy. She reports that she is also experiencing similar pain and color changes in the contralateral foot and ankle. Because of her severe neurovascular findings and her lack of progression in physical therapy due to pain, you offer the patient a nerve block with which the patient and her mother agree. You explain that since her pain is bilateral, you recommend placing an epidural catheter.

Under general anesthesia, she has a lumbar epidural catheter placed guided by fluoroscopy. Using contrast, you are able to visualize the catheter midline in the epidural space with the tip of the epidural at T12-L1. After a negative test dose of lidocaine with epinephrine, you inject 7 mL of 0.25% bupivacaine, which results in bilateral motor and sensory response. She is taken to the recovery room where a continuous epidural infusion of 0.1% bupivacaine with 0.04µg/mL of clonidine is started at 8mL/h, which is 0.2 mL/kg/h. She is admitted for an anticipated 4-5-day hospital stay. During her hospitalization she will receive twice-daily physical therapy and daily cognitive-behavioral therapy. She will have a strict schedule each day consisting of physical therapy, psychology therapy, "home" exercises, and school tutoring. She will have to dress each morning in regular clothes and wear her shoes and socks.

She progresses well during the hospitalization and actively participates in all of her therapies and activities. No new medications are started. During the course of her psychology sessions in the hospital, it becomes apparent that the demands of school and competitive gymnastics have been very stressful for her but she does not want to disappoint her parents by reducing her level of gymnastics. The psychologist feels that pain perhaps served as an excuse for her to reduce some of the stressful demands in her life.

On hospital day 5, the catheter is removed. She continues to experience allodynia and neurovascular symptoms, but feels that overall her symptoms have improved to where she could continue her therapy as an outpatient. She is discharged home with physical therapy and psychology follow-up.

At her 4-week follow-up appointment, she walks into the office without the use of assistive devices. She is also wearing her shoes and socks. She and her mother feel that her symptoms have improved by approximately 50%. She is participating in physical therapy three times per week and is compliant with her daily home exercise program. Through family therapy with the psychologist, it has been decided that she will still participate in gymnastics but not

at a competitive level. Results of neuropsychological testing indicate that she has a mild learning disability and appropriate accommodations have been provided for her in school. Since she is progressing well as an outpatient, you decide not to pursue a hospital rehabilitative program.

In further follow-up at 3 months, her symptoms are almost entirely resolved and she is attending school on a regular basis.

## **Teaching points**

- 1. In evaluating children with painful conditions, it is important to perform a thorough history and physical examination to detect underlying or sometimes overlooked causes of pain. For example, other causes of pain in this patient include an isolated nerve injury resulting from her fall or osteomyelitis, since she had erythema, pain, and swelling associated with an open laceration and a presumed fracture. Most children with allodynia in a non-dermatomal pattern associated with motor and neurovascular changes will have CRPS. However, an underlying malignant tumor causing nerve compression can also cause exquisite neuropathic pain and a careful history and physical examination with attention to neurological signs, lymphadenopathy, and distribution of pain will help to clarify possible etiologies.
- 2. Evidence shows that the majority of children with CRPS will show good response to a conservative approach of intense physical therapy and cognitive-behavioral therapy and many children will never require a nerve block. Nevertheless, treatment must be individualized for each patient. The 11-year-old girl described in this case had a brief trial of outpatient physical therapy and cognitive-behavioral therapy. It was apparent at her follow-up visit that she was unable to actively engage in the physical therapy and cognitive-behavioral therapy and cognitive approach at herapy necessary to recover. It was therefore decided to pursue a nerve block and initiate aggressive physical therapy and cognitive-behavioral therapy in the hospital.
- **3.** There are numerous classes of drugs used in the treatment of chronic pain, including tricyclic antidepressants, anticonvulsants, and serotonin reuptake inhibitors. It is necessary to understand the wide range of sideeffects of these medications and possible interactions as different classes are combined, and medical conditions that may increase risk with a particular drug. Our practice is not to routinely use opioids for chronic, nonmalignant pain but occasionally, short courses of opioids can be helpful, particularly when patients have severe pain and are initiating physical therapy.

## Introduction

One of the most significant changes in medical practice over the past two decades has been the rapid and enormous expansion of outpatient surgery. This growth has been largely fueled by escalating healthcare costs and an imperative need for efficient utilization of shrinking healthcare resources. Recognition of the numerous benefits of outpatient surgery, including less disruption of family schedules, decreased inconvenience to patients, less psychological disturbance, decreased exposure to nosocomial infections and greater patient satisfaction, has further driven the shift toward performing surgery in the ambulatory setting. This change in practice has affected both adults and children. Indeed, in 2006, over 2.3 million ambulatory anesthetic procedures were performed in children under 15 years of age in the United States alone, which translates to 38 procedures per 1000 children and represents an approximately 50% increase over procedures performed in 1996 [1].

Historically, the practice of outpatient surgery was first reported in 1909 [2], and the first outpatient surgical center was established in Sioux City, Iowa, in 1918 [3]. However, it was not until 1984 that outpatient anesthesia became recognized as a specialty and the Society of Ambulatory Anesthesia was formed.

The growth of the specialty of ambulatory anesthesia was accompanied by significant advances in anesthetic techniques, including the availability of better anesthetic agents that enabled patients to recover faster. Improved analgesic agents and the use of regional analgesia techniques allowed patients to be discharged home in reasonable comfort, or with mild-to-moderate pain that could be adequately managed at home. Such advances, coupled with improvements in surgical techniques, including minimally invasive procedures, made it possible to move procedures from the inpatient to the ambulatory setting. These developments have also resulted in patients with more complex co-morbidities being considered for ambulatory surgery. The ongoing challenge is to provide efficient, high-quality, and safe perioperative care to patients with complex medical histories for a large variety of surgical procedures in diverse venues. Continuous scrutiny of existing systems, along with critical ongoing

evaluation of outcomes, is necessary to provide a framework that will guide care that is safe, effective, patient centered, and efficient in the ambulatory surgery setting.

## Design and setting for outpatient surgery

Outpatient surgery may be performed safely and efficiently in the pediatric population in a variety of settings. Such environments include hospital-associated ambulatory care facilities, such as operating room suites within hospitals or satellite surgery centers, unaffiliated freestanding facilities, and individual physicians' offices. One of the most significant reasons for implementing outpatient or day surgery is to maximize efficiencies while decreasing costs. Previous investigators have suggested that the ambulatory surgery center (ASC) model, by virtue of its bias toward high volume, provides more efficient, higher quality care at a lower cost compared to hospital-based facilities [4]. The Institute of Medicine has described high-quality care as care that is safe, effective, patient centered, timely, efficient and equitable [5]. These goals may be achieved by focusing on a select population with as few complicating factors as possible.

To ensure the most efficient operation, facilities and personnel should be dedicated solely to pediatric patients, as well as outpatient or day surgery. Administrative and medical personnel at such a center are able to provide a uniquely effective care plan that is perhaps hindered, disadvantaged or even unobtainable when such children are mixed with adults or a more complicated inpatient pediatric patient population. Resource and space constraints may nevertheless force the co-mingling of various patient groups in a single surgical environment. In such cases, special consideration should be given to the needs of pediatric patients and parents. The separation of inpatient (hospital setting) and outpatient waiting and recovery areas is highly desirable. Likewise, where children and adult patients are mixed, special attention should include the incorporation of child-life experts, playroom facilities, changing stations, feeding considerations, and progressive care into the pre- and postoperative setting.

Generally speaking, outpatient surgery requires the same anesthetic and recovery equipment that would be required for any in-hospital patient. At autonomous surgical sites or physicians' offices, certain other minimum capabilities should be available on site: basic laboratory functions, processing facilities for equipment sterility and maintenance, and an informatics system to accommodate medical record utilization. Standard resuscitation equipment specific to pediatric patients of all ages must be available. A fully stocked difficult airway cart should also be available, and should minimally include some form of video or fiber-optic equipment, as well as materials for an emergency cricothyrotomy. Finally, clearly delineated plans and prearrangements must be conceived and implemented to accommodate any patient who develops complications requiring more extensive care, including emergency transportation and hospital admission [6].

## Appropriate procedures

Outpatient or day surgery should be restricted to procedures that combine expeditious and efficient throughput with patient safety that obviates the need for lengthy observation or involved inpatient care. Such procedures must meet minimal criteria [7–9] that would:

- include a relatively limited duration (usually less than 4h but this may vary from state to state or institution to institution)
- comprise a low hazard of surgical or anesthetic complication
- encompass minimal or easily regulated physiological derangements (including minimal blood loss)
- involve minimal or moderate postoperative pain that is easily treated and managed with oral analgesics (necessitating the ability to resume oral fluids or nutrition in the immediate postoperative period).

By and large, the majority of common pediatric surgeries fit the described ambulatory surgery parameters (Box 34.1). It should be noted that, whereas most adults do not, children do require significant sedation or anesthesia plus comprehensive monitoring for certain brief examinations and minor or rather superficial procedures. As such, myringotomies, circumcisions, cystoscopies, biopsies, and ophthalmological examinations, among others, are often scheduled as outpatient procedures. The fact that the most recent data [1] regarding free-standing ambulatory surgery centers reveal the top three pediatric procedures to be tonsillectomy, adenoidectomy, and myringotomy and tubes only confirms the shift in thought when considering appropriate procedures for the ambulatory setting.

## Ear, nose and throat procedures

Historically, pediatric ear, nose and throat (ENT) surgery (most commonly adenotonsillectomy) required overnight hospital admission due to concerns about the occurrence of hemorrhage and airway compromise. Hence, day surgery was previously practiced on a relatively limited population of older, healthy American Society of Anesthesiologists (ASA) I and II patients without obstructive sleep apnea (OSA). Today, despite the fact that OSA has become a primary indicator for these procedures, the push to attain advantages in efficiency, cost containment, Box 34.1 Commonly performed outpatient surgical procedures

#### Otolaryngology

- Myringotomy and insertion of tubes
- Adenoidectomy
- T&A (unless contraindicated)
- Frenulectomy
- Laryngoscopy
- Closed reduction of nasal fracture
- Foreign body removal
- Brachial cleft cysts
- Endoscopic sinus surgery
- EUA incl. some DL/bronchoscopies

#### Ophthalmology

- EUA
- Eye muscle surgery (strabismus)
- Nasolacrimal duct probing
- Excision of chalazion
- Insertion of lens or prosthesis
- Trabeculectomy

#### Dentistry

- Extraction
- Restoration

#### Orthopedics

- Cast change
- Arthroscopy
- Closed reduction of fracture
- Manipulation
- Hardware removal
- Percutaneous tenotomies
- Arthrograms

#### Urology

- Cystoscopy
- Meatotomy
- Orchiopexy
- Circumcision
- Hydrocelectomy
- Testicular biopsy
- Hypospadias repair

## **General surgery**

- Hernia repair
- Excision of cyst
- Ganglion
- Skin lesion
- Suture of lacerations
- Removal of sutures
- Dressing change
- Muscle biopsy
- Sigmoidoscopy
- Bronchoscopy
- Esophagoscopy
- I&D abscess
- Proctological and vaginal procedures

## **Plastic surgery**

- Otoplasty
- Septorhinoplasty
- Scar revision
- Cleft lip and some cleft palate repairs
- Placement of tissue expanders

DL, direct laryngoscopy; EUA, examination under anesthesia; I&D, incision and drainage; T&A, tonsillectomy and adenoidectomy.

and better resource utilization has made outpatient surgery much more appealing [10,11].

Recent studies have substantiated the general safety of performing adenotonsillar procedures in children 4 years and older as outpatients [11,12]. An analysis of national data for pediatric ambulatory ENT surgery confirms the relative safety of such procedures, with minor complications occurring at rates of approximately 1%; however, complication rates for patients younger than 4 years were significantly higher, with 2.5% of patients (p < 0.001) returning to the surgery center and 9.3% (p < 0.011) having an unplanned hospital admission [13]. Likewise, a systematic literature review noted a statistically significant increase in both complication rates (odds ratio 1.64) and unplanned admissions (odds ratio 1.71) in children younger than 3 years of age [11].

Children with OSA comprise a growing portion of the ENT practice, and these patients have augmented risks

(see subsequent discussion). For predisposed patients, tonsil or adenoid surgery inherently creates the potential for worsened airway obstruction or pulmonary complication in the postoperative period. Data suggest that OSA may markedly accentuate the risk; however, it is difficult to independently separate this effect from the more clearly substantiated age effects. Regardless, the literature supports hospital admission for children 3 years old and younger in whom tonsillectomy and adenoidectomy (T&A) is indicated for OSA [14]. Indeed, outpatient T&A is less cost-effective than planned hospital admission for children in this age range [15].

Presenting indications for scheduled ENT surgery may include pathologies that increase risks. Whether suffering from OSA, obesity, central sleep apnea, facial or oral dysmorphism, or even recurrent or continual upper respiratory infections (URIs), each patient must be evaluated individually when considering their selection for day surgery, especially in a free-standing ASC. Those patients under 4 years old or possessing multiple comorbidities should be seen at a hospital-centered practice to allow for the possibility of lengthier observation or admission.

## **Patient selection**

To accomplish the workflow goals implicit in the outpatient surgery process, patient selection (and preparation) is paramount. Generally healthy ASA class I and II children are excellent surgical candidates who can go home soon after surgery. Initially, ambulatory practices focused on these patients. However, with the evolution of healthcare practice (medications, equipment, interventions), ASA III children with stable systemic disease may also now be cared for in the ambulatory setting. Even more than other patients, these children should be rigorously screened and ought to have prior approval from their surgeon specialist and anesthesiologist to undergo outpatient surgery.

The focal point of the outpatient or ambulatory facility centers on resource allocation. Even a single patient who requires increased attention or unplanned efforts may compromise the overall flow or function of the unit. Such a patient might be a normally healthy child with a history of asthma and a new URI who is more prone to laryngospasm and postoperative bronchospasm, or an otherwise healthy child with micrognathia and previously difficult intubation, or an obese child with known OSA who might need prolonged postoperative monitoring or even positive pressure ventilation. It is not that such patients cannot be safely cared for; it is that their care may be more easily accommodated when their condition is better optimized or at a larger center possessing greater resources and facilities for readily available admission. It is crucial to recognize and triage these patients before they arrive at an ambulatory practice setting.

## Preoperative evaluation/screening

While there are specific conditions or pathologies that would seemingly be in conflict with ambulatory procedures, creating a definitive list is debatable. Much depends on the specific environment in which the procedure is to be done – ASC or physician office versus hospital or tertiary care setting. Likewise, such decisions must take into account the comfort level of the assigned staff or anesthesia provider. The conditions listed in Box 34.2 warrant careful preoperative evaluation and screening to determine appropriateness for ambulatory surgery. They provide a framework from which medical directors may develop guidelines appropriate for their site. **Box 34.2** Patient co-morbidities that require special considerations for ambulatory surgery

- Prematurity/exprematurity
- Obstructive sleep apnea
- Obesity
- Uncorrected or hemodynamically significant congenital heart disease
- Known difficult intubation, airway obstruction
- Myopathy
- Inborn errors of metabolism
- History of malignant hyperthermia
- Down syndrome
- Known coagulation disorders
- Sickle cell disease
- Diabetes mellitus

There are clearly conditions that should generally be avoided in such center, e.g. a patient with a previously difficult airway or one with a coagulopathy that previously required considerable blood products or a patient with unstable congenital heart disease. However, even patients with such conditions may appear on a spectrum. There are two basic areas of concern when evaluating such patients. The first and most important is patient safety. For example, if the ASC or outpatient site does not possess the capability to procure or administer blood products, then the hemophiliac or brittle sickle cell anemia patient should probably not be operated on there.

As noted above, after patient safety, the goal of the ambulatory practice is to optimize throughput and efficiency. Any patient's condition that increases the probable perioperative complexity also increases the potential drain on the ambulatory unit's resources. A severely autistic or developmentally delayed child often requires greater resources or attention in the pre- and postoperative setting and thus impedes unit throughput. The difficulty is deciding at what point the potential for unanticipated problems outweighs the benefit of caring for such a patient in the ambulatory setting.

## Apnea in the infant

Patient age is generally not regarded as the limiting factor for outpatient procedures; however, term neonates in the first 4–6 weeks of life require special consideration due to concerns stemming from the transition from fetal and neonatal physiology to a more mature homeostatic state. Most significantly, those infants whose brainstem regulation of breathing remains immature are at increased risk of apnea after anesthesia.

With improvements in neonatal intensive care, a greater number of premature infants (less than 37 weeks) now survive through the neonatal period, and a proportionally larger number present for surgery in early infancy. Studies clearly demonstrate an increased risk of postanesthetic apnea in ex-premature infants related to postconceptual age (PCA). The most significant analysis combined eight prospective studies and demonstrated that a PCA of 56 weeks was required to reduce the postanesthetic risk of apnea to less than 1% (95% statistical confidence) in infants with a gestational age of 32 weeks. For those with a gestational age of 35 weeks, the required PCA was 54 weeks [16]. Despite the suggestion that regional techniques might reduce or eliminate this risk [17-19], there have been published case reports of apnea after spinal anesthesia [20,21] and, in fact, a Cochrane review of this topic determined that there was no reliable evidence to demonstrate a reduction in postoperative risk of apnea with spinal versus general anesthesia in former premature infants [22]. There are no data that determine the incidence of apnea in infants born at less than 28 weeks' gestation. This accounts for an increasing number of patients who are ex-premature infants.

Even the healthy full-term infant may have periods of apnea [23]; hence, it is prudent to delay outpatient procedures in such patients. Most institutions set a 4-6-week age requirement for term infants. Alternatively, scheduling such patients early in the day allows for an extended observation period if indicated. The recommended cutoff postconceptual age for outpatient surgery in expremature infants varies from 46 to 60 weeks [7,24,25]. Of course, any complicating medical conditions must be considered, and the more premature the infant, the lower the threshold for admission. Likewise, if apnea is documented during the recovery period, the patient should be admitted to hospital for observation. These patients are not candidates for surgery at free-standing centers, due to their need for hospital admission and continuous cardiorespiratory monitoring for apnea.

## Obstructive sleep apnea

Beyond its significance as the primary indication for T&A (see above), OSA and its associated risks must be appreciated and understood in the greater context of all pediatric procedures. Peak prevalence of OSA occurs in 3–6 year olds, but rates are on the rise due to the rapid rise in pediatric obesity. OSA is also more prevalent in children with respiratory disease, prematurity, craniofacial anomalies, hypotonia, myelomeningocele, cerebral palsy and other disorders, such as Down syndrome and Arnold– Chiari malformation. Among its most significant manifestations are neurocognitive and behavioral dysfunction, as well as cardiopulmonary sequelae, including pulmonary hypertension and cor pulmonale [26].

Children with OSA are clearly at increased risk during the perioperative period, and those with severe OSA must be assessed closely before proceeding. American Academy of Pediatrics clinical practice guidelines describe risk factors for respiratory complications in children with OSA undergoing T&A. These include age <3 years, severe OSA on polysomnography, cardiac complications of OSA such as right ventricular hypertrophy, failure to thrive, obesity, prematurity, recent respiratory infection, craniofacial anomalies, and neuromuscular disorders [27]. These guidelines also recommend T&A as the first-line treatment for children with severe OSA, although they do not define the exact polysomnography criteria that are indicative of high risk. Finally, these guidelines recommend that patients deemed as high risk be monitored as inpatients following T&A.

Polysomnography is the recognized gold standard to diagnose and quantify the severity of OSA; however, it cannot predict postoperative clinical outcomes. In one study, its positive predictive value for respiratory complications was only 25% [28]. Postoperative complications in children with OSA include laryngospasm, apnea, pulmonary edema, pulmonary hypertension, and pneumonia [29]. Just the incidence of respiratory complications in such children is significantly higher than the general pediatric population (21% versus 1–2%)[28].

Studies have also shown that children with moderateto-severe OSA (SpO<sub>2</sub> nadir <85%) have increased sensitivity to opioids and are more prone to postoperative apnea [30]. While these patients should be considered on a caseby-case basis, significant or severe OSA should be considered a contraindication to outpatient surgery for all procedures, not just ENT cases.

## Obesity

Sixteen percent of children are obese, and obesity is a significant risk in pediatric ambulatory procedures [31,32]. Compared to non-obese patients, obese children are significantly more predisposed to complicating comorbidities, including asthma, hypertension, gastric reflux, type 2 diabetes, and OSA. More importantly, obesity is associated with an increased incidence of adverse perioperative respiratory events, including difficult mask ventilation, airway obstruction, bronchospasm, significant oxygen desaturation, and overall critical events [33]. Various studies have demonstrated similar perioperative risks, and obesity has been identified as an independent predictor for the likelihood of admission after T&A [34]. Keeping these concerns in mind, the obese patient with any co-morbidity must be evaluated carefully before scheduling for outpatient surgery. Indeed, before being considered for procedures at free-standing ambulatory centers, such patients should be evaluated and approved by the anesthesiologist or the medical director of the center.

## Malignant hyperthermia

Children with suspected or confirmed susceptibility to malignant hyperthermia (MH) present special challenges for outpatient anesthesia. Undoubtedly, these children should receive a trigger-free anesthetic, and their temperature and end-tidal carbon dioxide should be monitored continuously. Arterial blood gas monitoring and dantrolene must be available for management of the rare case of MH. Additionally, children with MH susceptibility may require extended monitoring of temperature and heart rate in the postanesthesia care unit (PACU). In the ambulatory setting, an important question is whether the child with MH susceptibility should be routinely admitted for overnight monitoring following a triggerfree anesthetic. A retrospective study of 285 MHsusceptible children undergoing 406 procedures reported no cases of intraoperative pyrexia [35]. The sample included 25 children with biopsy-proven MH. While none of the children developed pyrexia, six had received routine preoperative dantrolene. Of 10 children who developed postoperative pyrexia, none were believed to be experiencing an MH reaction and none was treated with dantrolene, although four of them had received dantrolene prophylactically.

These data suggest that it may be safe to discharge children with MH susceptibility home following a triggerfree anesthetic. However, the facility must be prepared to monitor them for 4h or more and have the ability to transfer the child to an inpatient setting in the rare but unexpected case of a MH reaction. It remains questionable whether the surgical care of these patients is best handled in a hospital-based facility or a free-standing ASC, given the potential hurdle in the throughput goals at the site.

#### Upper respiratory infection

Among the most difficult scenarios confronting the anesthesia provider in the ambulatory setting is the otherwise healthy child who presents with a new URI. Benign, recurrent viral illnesses may be ubiquitous in the pre- and primary school population and should not necessarily delay surgery. However, more severe symptoms, including fever, lethargy, purulent secretions, a productive cough, or pulmonary involvement, should cause the procedure to be postponed for a minimum of 4 weeks. Likewise, patients with a suspected bacterial infection who are treated with antibiotics should have their condition optimized by their primary care physician before returning for surgery. The difficulty resides in those patients with a URI who fall in between the toxicappearing child and the bright, interactive child.

These infections, whether viral or bacterial, may increase airway inflammation, irritability, and respiratory tract secretions that may persist for up to 6 weeks. This airway hyper-reactivity during anesthesia can lead to adverse respiratory events, a protracted recovery time, or even hospital admission. Indeed, much of the literature on this topic confirms that an active or even recent URI increases the risk of perioperative complications, including atelectasis, hypoxemia, laryngospasm, and bronchospasm in the pediatric population [36–40]. Furthermore, tracheal intubation, a history of prematurity or reactive airway disease, airway surgery, the presence of copious secretions, nasal congestion, and passive smoking may further increase the risk for patients who have an URI [38,39]. Despite such increased risk, there is little evidence of long-term sequelae; the vast majority of adverse events are manageable with the judicious care of experienced practitioners.

Decisions regarding whether to proceed with elective surgery in a child harboring a URI should be based on findings from a detailed history and physical examination. Parents are often clear in differentiating their child's condition from her or his "typical runny nose" or "allergic symptoms." They should be able to provide lucid differentiation between chronic symptoms and an acute illness. Indeed, confirmation of a URI by the parent was a more reliable predictor of laryngospasm than symptom criteria alone [41]. A 3 year old with recurrent ear infections presenting for myringotomy and tube placement may exhibit symptoms such as fever and congestion. Waiting for an asymptomatic window in such a child may be unrealistic, given the waxing/waning course of the patient's pathology (e.g. otitis media) and the fact that most young children have a new URI about six times a year. With a detailed history regarding the frequency of the symptoms and in the absence of findings on auscultation, it may be reasonable to proceed with surgery in this case. If persistent concerns remain, such patients should be referred to a hospital-based center with greater flexibility for observation and admission.

Preoperative evaluations or phone interviews may help identify patients with an URI in whom it is prudent to delay elective surgery. Postponement of such cases before they arrive in the hospital or ASC avoids a wasted trip for the family and prevents interruptions in the surgical schedule at the ambulatory facility. Elective surgery is usually delayed 2-4 weeks for simple nasopharyngitis, 4 weeks for more severe infections, including those treated with antibiotic, and a minimum of 4–6 weeks, including a follow-up with a primary care physician (before rescheduling), for any URI that includes a lower respiratory tract component (bronchitis, pneumonia, asthma exacerbation, etc.). Ultimately, each of these patients must be evaluated on an individual basis, keeping in mind the severity of their symptoms, the urgency of the scheduled procedure, the presence of identifiable risk factors, and finally the comfort level and experience of the anesthesia provider.

For children in whom it is difficult to make a diagnosis due to the ambiguity of their presentation or the existence of multiple risk factors, a more conservative approach should be taken when considering proceeding at a freestanding surgery site or physician's office.

## Asthma

Asthma afflicts approximately 9% of children in the US and is the most common serious childhood illness and the leading cause of school absenteeism. In its severe form, it carries substantial morbidity and mortality. In 2004, it accounted for 3% of all pediatric hospital admissions and emergency department visits [42]. Despite its associated hazards, in the absence of active wheezing and with appropriate patient evaluation, preparation, and perioperative management, children with asthma may be safely anesthetized in an ambulatory setting.

Patient history is crucial when evaluating asthmatic patients. The severity of their condition is based on a spectrum. How frequent and/or severe are their wheezing episodes or exacerbations? How often do they visit the emergency department? Have they ever required admission to the intensive care unit? What is their current medication regimen and has it been stable? Only patients with well-controlled mild-to-moderate reactive airway disease should be considered for outpatient surgery.

Children with mild or intermittent symptoms who do not require continuous medications and who may only require sporadic rescue treatments are usually excellent candidates for surgery. The patient with moderate asthma who requires regular medications to manage their symptoms must continue these medications or treatments through the morning of their procedure. Inhaled steroids and other treatments (e.g. leukotriene inhibitors or cromolyn) necessitate continual use to be effective. A short course of systemic steroids starting the day before the planned procedure may be appropriate for those patients who have required systemic steroids previously. Preoperative prophylactic treatment with a  $\beta$ -agonist may attenuate increases in airway resistance associated with tracheal intubation.

Due to the isolated nature of the free-standing ASC or physician office, a conservative approach is advocated for those patients with asthma who appear well but have evidence of suboptimal disease control: hospitalization for asthma within 3 months of the scheduled procedure; an exacerbation of their asthma within 1 month; wheezing during exercise; more than three wheezing episodes in the past 12 months; the need for systemic steroids within 1 month; a room air  $O_2$  saturation of <96% [7,40]. Caution should be exercised for those patients who are actively wheezing, especially in conjunction with a URI or other respiratory symptoms (e.g. cough or tachypnea). Elective surgery in these patients should be postponed and rescheduled for a time when they are symptom free and their condition is fully optimized. Severe asthmatic patients (baseline wheezing) are at increased risk, despite optimization of their condition by consultants and assertive preoperative treatments, including systemic steroids and increased bronchodilator therapy. Even with aggressive perioperative management, they should only be scheduled at a hospital-based practice in the event that an exacerbation occurs and they require hospital admission.

## Preoperative preparation

The prospect and actual process of any surgical procedure are inherently stressful and anxiety provoking for children and families. Ambulatory surgery may in fact diminish this trauma by minimizing the separation time between parents and children, as well as avoiding a disruptive hospital stay. And yet, the ambulatory model's very emphasis on efficiency and throughput may limit the time and effort allowed for preparation, understanding, and acceptance of the prospective perioperative experience. Fast-tracking patients through outpatient surgical settings restricts the ability to address each patient's psychological needs, needs that may be pronounced in younger children. Ultimately, consideration of these varying child/family requirements (the basis for familycentered care) is integral to the success of the ambulatory model. Ignorance, anxiety, and uncertainty in the preoperative holding area may lead to confusion, patient agitation, delays, and/or staff interventions that strain the surgery center's resources. Moreover, there is evidence that pediatric preoperative patient anxiety is related to emergence delirium (agitation) [43,44] increased pain (hence, opioid requirements with attendant side-effects), and postoperative behavioral problems [45,46]. These outcomes may postpone discharge and further stress the ASC's timetable and resources.

Among the most cited methods for ameliorating surgery's attendant anxieties are the use of sedative premedications, parental presence at induction of anesthesia, and specific presurgery preparation programs for children as well as their parents.

## Premedication

In most circumstances sedative premedication effectively reduces preoperative anxiety, and it may reduce perioperative recall and postoperative agitation or maladaptive behavior. Oral midazolam is the most commonly used agent and benefits from a relatively rapid onset and reliable effect. A dose of 0.25–0.5 mg/kg should be administered 20–30 min prior to taking the child to the operating room (the lower dosing requires a longer interval to be

effective). Establishing protocols and maintaining communication between the preoperative area and the operating room should allow for timely administration of medication and mitigate possible delays in anesthetic induction due to premedication. A particular concern in the ambulatory setting is the possibility of an extended sedative effect delaying patient discharge. There are studies indicating protracted sedation with the higher dosing regimen but most studies have failed to demonstrate an effect that significantly delays patient discharge [47,48]. In any case, most parents and anesthesia providers will accept the infrequent short to moderate psychological trauma.

Alternative agents are available. Oral ketamine (5 mg/ kg) or fentanyl (15–20 $\mu$ g/kg) may be given, although these are sometimes associated with prolonged recovery (ketamine) and nausea, vomiting, and pruritus (fentanyl). For patients unable to co-operate with oral drug administration, midazolam may be given via intranasal or intramuscular (0.2 mg/kg) routes; the onset of action is more rapid (5-10 min). In the exceptionally unco-operative patient, ketamine (3-4mg/kg), often combined with midazolam and glycopyrrolate, may be given by intramuscular injection. The resultant nystagmus caused by ketamine may not be a good option for patients undergoing strabismus surgeries. The intramuscular route, however, should be reserved for situations when all other measures have failed since most children have an inherent phobia for needles. Involvement of a child-life specialist and use of distraction techniques may permit children with a high degree of anxiety to co-operate.

## Parental presence at induction

Much of the parents' and child's anxiety centers on the separation that occurs when the child departs to the operating room. Indeed, sedative premedication is administered in part to facilitate this separation. Intuitively, allowing parents to be present during the induction of anesthesia should help calm the child while simultaneously allaying parental uncertainty and fear. It may also increase co-operation and parental satisfaction with the entire perioperative experience. This approach, while still somewhat controversial, has garnered a great deal of support and has been implemented in many institutions and surgery centers.

Nevertheless, most current evidence does not support parental presence at induction of anesthesia [47,49] because it does not reliably alleviate the anxiety of either the children or parents. In those instances where parental presence did seem to benefit the participants, sedative premedication was shown to be similarly efficacious.

There are clearly cases where parental presence can and is beneficial; however, this depends on an accurate assessment of individual personalities, as well as interpersonal dynamics between patients, parents, and caregivers. Experienced anesthesia providers quickly evaluate and build rapport with patient and parents, but the limited preoperative interaction necessitated by day surgery scheduling certainly militates against clearly or effectively appraising such complex interactions and advocating for or against parental presence. Notwithstanding, children who may benefit are older, less impulsive or active in temperament, and typically have calmer parents who value preparation and coping skills in stressful situations [50].

### **Preoperative preparation programs**

The increased focus on family-centered care often includes preoperative preparation programs that incorporate a variety of techniques and activities designed to allay child anxiety and assuage parental concern. Among those activities for the children are non-medical play, medical play, tours of the operating rooms and PACU, videos or movies relating to the perioperative course, and teaching of relaxation or coping techniques. Parental involvement is encouraged throughout and may additionally involve parental tours, presence at induction of anesthesia, and early admittance to the PACU to be with their child.

Feeling inadequately prepared leads to increased parental anxiety [51], and there appears to be a relationship between parental anxiety and an increased risk for postoperative agitation and maladaptive behavior by the child [45]. Hence, methods of mitigating parental concerns, such as preoperative preparation programs, may expedite and facilitate patient care and the ambulatory process. Furthermore, ancillary benefits may be attained by integrating such programs into an ambulatory process that already requires preoperative evaluation, education, and attaining the records and financial/insurance information prior to the day of surgery.

Due to increased interest in the family-centered care model, many institutions and pediatric-centered facilities have initiated varying forms of these preparation programs. While there are indications that such programs can make a substantial difference in the overall experience of patients and families, and by association ease the workflow and productivity of the ASC, it is still unclear how effective they are at addressing patient anxiety and subsequent sequelae. Study results are mixed when assessing the efficacy of various measures. Yet even when patient anxiety is reduced, there is evidence that preoperative benefits fail to translate to the induction or postoperative recovery period [52]. This may be due to the unstructured and piecemeal implementation of many plans that rely on specific or unco-ordinated measures.

Recent evidence demonstrated that a highly integrated and evolved preoperative program could successfully reduce preoperative anxiety (significantly reduced when compared to control and parental presence cohorts; similar when compared to a premedication cohort), and improve postoperative outcomes (decreased analgesic consumption, decreased emergence delirium, decreased time to discharge) [46]. Such a fully developed program, however, requires significant resources in staffing and expertise and thus would be very expensive to implement and run. Likewise, to be effective it would require parental enrollment and a large commitment of time. These constraints may limit the application of such programs to larger, hospital-centered practices that have more resources and a patient census benefiting from economies of scale.

## Anesthetic agents and techniques

Apart from the economic advantages of ambulatory surgery and anesthesia, there are psychosocial benefits to a child recuperating from surgery at home. Hospital admission is associated with behavioral problems that are possibly due to separation from parents and disruption of family life [53]. To this end, rapid- and short-acting drugs for induction and maintenance of anesthesia have been developed to facilitate early recovery following day case surgery. The ideal anesthetic agent for ambulatory surgery should provide smooth and rapid induction and prompt recovery from general anesthesia, have minimal side-effects, have analgesic properties, and be free of postoperative nausea and vomiting (PONV). Such an agent does not exist. Since induction of anesthesia is a very important component of the overall ambulatory surgery experience, it is important to use the most acceptable and least distressing technique for the child. Induction of anesthesia is most commonly achieved via the inhaled or the intravenous (IV) routes, and maintenance of anesthesia is often exclusively by the inhalational method. In some centers outside the US, rectal administration of drugs is sometimes used to produce sedation or induce anesthesia [54].

## Monitoring

American Society of Anesthesiologists monitoring standards must be applied to all children undergoing an anesthetic regardless of the setting in which the surgery is performed, including office-based settings.

## Induction technique

Inhalational induction of general anesthesia is the most common technique used by pediatric anesthetists in North America. What constitutes the "gentlest" induction method for children remains unclear [55]. Very often, the method of anesthesia induction is guided by the personal preference of anesthesia providers, institutional practice, and cultural factors. For example, because of prevailing needle phobia in many children, anesthesia practitioners in the US often avoid IV induction [56]. However, in many other parts of the world, including Europe, IV induction of anesthesia appears to be more favored [57]. Very few investigators have compared the induction characteristics of IV and inhalational techniques. Some investigators contend that because inhalational induction is not always "smooth," it may be associated with longterm negative memories for children and may be a source of severe stress for parents [55]. Still others claim that IV induction can be a pleasant experience for the child provided topical anesthetic cream is applied to the venepuncture site and the cannulation is performed by a skilled practitioner [53].

## Inhalational agents

The ideal inhalational agent should have many of the following desirable characteristics: it should be pleasant to inhale (permitting a smooth induction and emergence from anesthesia), potent (allowing the concomitant administration of high fractional oxygen concentration), produce rapid induction and emergence from anesthesia (low solubility), and it should be easy to administer and analyze (infra-red). Such an agent should also be stable in storage, should have minimal to no reaction with soda lime and should not be significantly biotransformed in the body. It should have little or no cardiac or respiratory irritant or depressant effects and should possess some analgesic properties. With the almost total withdrawal of halothane from clinical anesthesia in developed countries, sevoflurane has become the prototype inhalational agent.

### Sevoflurane

Sevoflurane, by virtue of its non-pungent smell and relative lack of airway irritant properties, has become the agent of choice for induction of anesthesia via the inhaled route in children. Because of sevoflurane's low blood gas solubility, induction of anesthesia is rapid, as is recovery. This makes it particularly suitable for the ambulatory setting. Other advantages of sevoflurane include its lack of major side-effects, ability to induce and maintain anesthesia with one drug, better conditions for laryngeal mask airway (LMA) insertion, and ability to induce anesthesia without IV access. Notable disadvantages of sevoflurane-based anesthesia, however, include possible pollution of the operating room with anesthetics and excitatory movements during anesthetic induction [58]. A recent meta-analysis comparing the induction characteristics of sevoflurane with propofol concluded that the two drugs had similar efficacy for anesthetic induction, but sevoflurane use was associated with a higher incidence of PONV [58]. Use of sevoflurane for induction and main-
tenance of anesthesia is also associated with excitatory motor movements during induction and emergence [59]. These side-effects may be distressing to parents and may potentially delay discharge from the PACU.

The practice at our institution is to induce anesthesia with sevoflurane and change to isoflurane for the maintenance of anesthesia. In many cases, we begin inhalational induction with a  $N_2O/O_2$  mixture and gradually introduce sevoflurane into the gas mixture. This practice has been shown to dampen the fairly strong odor of sevoflurane and may reduce some of the anxiety and excitement associated with inhalational induction of anesthesia [60].

## Isoflurane

Isoflurane has a pungent odor and causes considerable airway irritation, making it a poor choice for anesthesia induction via the inhaled route. Indeed, previous investigators have reported a higher incidence of coughing, breath holding, excessive salivation, and laryngospasm in children who underwent anesthesia induction with isoflurane compared to those who underwent anesthesia induction with halothane for myringotomy and tube placement [61]. Isoflurane is excreted predominantly in the lungs; there is very little hepatic biotransformation of the drug. It is a popular inhalational agent for anesthesia maintenance due to its lower cost compared to sevoflurane.

### Desflurane

Due to its low blood gas solubility (about 0.42, which is lower than all currently available volatile anesthetics, and slightly lower than nitrous oxide), recovery from desflurane anesthesia is rapid with prompt return of protective airway reflexes [62]. However, the rapid emergence and recovery from general anesthesia with desflurane is associated with a higher incidence of emergence agitation in children [63,64]. In some patients emergence agitation may be severe enough to require the use of supplemental analgesic or sedative medications in the PACU. Use of these medications and the need for additional observation prolong and complicate PACU care and delay discharge home. Some investigators have determined that administration of 2.5µg/kg of fentanyl, given after induction of anesthesia, successfully reduced the incidence of severe agitation associated with desflurane anesthesia in children without delaying emergence from anesthesia [65].

Recent data indicating that desflurane use is associated with faster return of protective airway reflexes in otherwise healthy overweight and obese adults [66] may make desflurane useful in overweight and obese children. Data indicating rapid wash-out of desflurane compared with sevoflurane in morbidly obese patients have also been published [67]. Studies comparing the emergence characteristics of desflurane between obese and normal weight children are warranted.

Due to its pungent odor and associated airway irritability, however, desflurane is unsuitable for inhalational induction of anesthesia. Several pediatric studies [68–70] have demonstrated a high incidence of airway irritation and/or reactivity, including breath holding, coughing, excessive secretions, and laryngospasm.

#### Intravenous agents

Although inhalational induction is more popular with outpatient anesthesia, IV induction and (less commonly) maintenance of anesthesia is sometimes preferred or indicated. There is a smooth, rapid loss of consciousness and emergence is rapid with currently available agents.

#### Propofol

This has rapidly become the most popular IV induction agent because it has many of the properties of an ideal IV agent. Induction of anesthesia is smooth and recovery is rapid, even after prolonged infusion, making it suitable for total intravenous anesthesia (TIVA). Propofol is also becoming the agent of choice for most procedural sedation, especially with recurrent procedures such as radiation therapy or chemotherapy. It is a good antiemetic agent (another desirable characteristic in ambulatory anesthesia) and very often some clinicians may opt for propofol TIVA in patients with a strong history of PONV. It is important to keep in mind that due to their large central volume of distribution and rapid clearance of propofol, children have a higher dose requirement for anesthesia induction with TIVA than adults. The typical induction dose of propofol in children is 2.5–3.5 mg/kg.

Perhaps the biggest drawback to the use of propofol is the fact that up to 70% of patients have pain on injection of the drug [71]. Various techniques have been tried to reduce this rather distressing side-effect. We commonly co-administer lidocaine (1 mg to 1 cc of propofol) and inject the mixture very slowly.

#### Methohexital

This agent is used for rapid induction and rapid emergence from anesthesia. Typically, a dose of 1.5–2 mg/kg is particularly useful for outpatient dental and other minor procedures like punch biopsies, pulse dye laser therapy, etc. A recent large database analysis of oral maxillofacial surgical (OMS) procedures concluded that although its use was safe for ambulatory OMS procedures, methohexital was associated with more frequent complications [72]. The main drawbacks to its use are pain on injection and a high incidence of excitatory phenomena, which may be quite distressing if parents are present when anesthesia is induced. Methohexital is also associated with a high incidence of PONV. Rectal methohexital is sometimes used for brief sedation for computed tomography (CT) scan and other non-invasive procedures. It is administered as a 10% solution at a dose of 20–30 mg/kg. Patients should be closely monitored for the occurrence of respiratory depression [73].

## Pain management

The strategy for postoperative pain management is an integral part of any anesthetic plan. However, pain management becomes particularly important in children undergoing outpatient surgery to ensure that parents are able to manage their child's analgesia effectively at home. The intraoperative analgesic regimen should, under ideal circumstances, allow the child to emerge from anesthesia in reasonable comfort since it is easier to maintain analgesia in a pain-free child than to achieve analgesia in one with severe pain. Effective analgesia is best achieved using multimodal therapies, including non-opioid and opioid analgesics, as well as appropriate regional techniques based on the surgical procedure and the child's co-morbidities. Education of parents and caregivers regarding assessment of their child's pain and analgesic needs following discharge, in addition to detailed instructions regarding the timing and dosage of prescribed analgesics, are important facets of care for children undergoing outpatient surgery.

Non-opioid analgesics may be used alone for the treatment of mild pain or as important adjuncts in combination with opioids or regional techniques for the multimodal treatment of moderate-to-severe pain. Non-opioid analgesics produce dose-dependent responses but are limited by a ceiling effect, i.e. a concentration is reached above which no additional analgesia is achieved. Therefore, moderate-to-severe pain is rarely managed with these drugs alone.

#### Acetaminophen

Acetaminophen is the most common analgesic and antipyretic used in children. The recommended dose for oral administration is 10–15 mg/kg every 4h. An oral loading dose of 30 mg/kg that is followed by a maintenance dose of 10–15 mg/kg may result in an earlier onset of drug action. Rectal administration of acetaminophen results in unpredictable absorption of the drug with variable peak blood concentrations being achieved in 60–180 min [74– 76]. One study reported a greater morphine-sparing effect with a less frequent need for additional rescue analgesics for 24h in children who received 40 mg/kg or 60 mg/kg of rectal acetaminophen, compared to those who received 20 mg/kg or placebo during outpatient surgery [77]. Intravenous formulations of paracetamol (acetaminophen) and its prodrug propacetamol have been available in Europe and Australia for several years. Onset of action following IV administration of paracetamol occurs in 15 min and antipyresis occurs in 30 min [78,79]. One controlled randomized trial reported good analgesia for the first 6h after surgery in children undergoing T&A who received either rectal acetaminophen 40 mg/kg or IV acetaminophen 15 mg/kg after induction of general anesthesia [80]. However, children who received acetaminophen rectally required rescue analgesics later than those who received the drug IV. The IV formulation of acetaminophen was recently approved by the Food and Drug Administration for use in the United States.

The maximum daily dose of acetaminophen via any route should not exceed 75 mg/kg for infants and children; with a maximum dose of 4 g/day for adolescents. Oral acetaminophen is available in a wide variety of overthe-counter and prescription formulations. These include cold remedies and opioid combination products that place children who may inadvertently receive more than one such formulation at risk of an overdose. Careful review of medications and parental education are needed to minimize this risk.

## Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs provide excellent analgesia for mild-to-moderate pain caused by surgery, injury, and disease. Ibuprofen, one of the oldest orally administered NSAIDs, has been used extensively to treat fever and pain derived from a variety of etiologies including surgery, trauma, and arthritis. The recommended dose of ibuprofen is 10-15mg/kg every 6h. Diclofenac 1 mg/kg every 8h per os (PO), per rectum (PR) or IV also provides effective analgesia after minor surgical procedures in children. In the US, it is only available as an oral tablet; rectal and injectable formulations are available in other countries. Previous studies have reported that children who received diclofenac during inguinal hernia repair experienced comparable analgesia to those who received caudal bupivacaine or IV ketorolac [81-83]. Diclofenac yielded better analgesia, less need for supplemental opioids, less nausea and vomiting, and earlier resumption of oral intake compared to acetaminophen in children undergoing tonsillectomy and/or adenoidectomy [84,85]. However, use of diclofenac has been associated with above-average bleeding in children during tonsillectomy [86].

Ketorolac provides postoperative analgesia in children of all ages that is comparable to opioids. Its lack of opioid side-effects, including respiratory depression, sedation, nausea and pruritus, make it a very attractive choice for the treatment of postoperative pain, especially in the ambulatory setting. However, like other NSAIDs, it does carry the risks of platelet dysfunction, gastrointestinal bleeding, and renal dysfunction.

Some studies of ketorolac in children undergoing tonsillectomy reported a 2-5-fold increase in bleeding complications, including measured blood loss, ease of achieving hemostasis, and bleeding episodes in the PACU, that necessitated re-exploration and hospital admission in some cases [87-90]. Two studies were terminated early when preliminary analysis found an unacceptably greater risk of bleeding in children who had received ketorolac [89,90]. A systematic review of the literature included 25 studies related to the use of NSAIDs for T&A and found that compared with opioids, NSAIDs were equi-analgesic, caused significantly less nausea and vomiting, and were associated with more frequent reoperation for bleeding [91]. This study found that the use of NSAIDs would avoid PONV and its attendant complications in 11/100 patients, but 2/100 would be exposed to the risk of postoperative bleeding and reoperation. A Cochrane review involving 13 studies related to the use of NSAIDs and peritonsillectomy bleeding found no statistically significant increase in the risk of bleeding but reported a significant decrease in the incidence of PONV in children who received NSAIDs compared to other analgesics [92]. Taken together, these data suggest that until further data become available, it may be prudent to avoid the use of NSAIDs during or after tonsillectomy and to use alternative analgesics such as acetaminophen and tramadol to reduce opioid requirements.

#### Steroids

The role of dexamethasone as a co-analgesic is becoming increasingly recognized in both adults and children [93]. Dexamethasone provides the added benefit of antiemesis, which is highly desirable in ambulatory surgery. The mechanism of steroid-based analgesia appears to be related to its powerful anti-inflammatory effects and reduction of prostaglandins at sites of tissue injuries [94].

## **Opioid analgesics**

Opioids play a fundamental role in the management of postoperative pain. Unfortunately, their use is associated with a number of side-effects, including nausea, vomiting, pruritus, sedation, and respiratory depression (particularly undesirable in ambulatory surgery). The high incidence of PONV and concern about respiratory depression prompt many clinicians to avoid using opioids or to use them sparingly [95].

Oral opioids are suitable for children experiencing mild-to-moderate pain, those who undergo outpatient surgery or as adjuncts to a regional anesthetic technique. In fact, administering an oral opioid upon awakening in the PACU before a regional block wears off may provide a virtually pain-free recovery period. If dosed appropriately and at regular intervals, reasonably constant blood levels can be achieved with oral opioids. In most cases, oral opioids are better tolerated after resumption of oral intake. Codeine and oxycodone, two of the most commonly prescribed oral opioids, are available in liquid form, making them easy to prescribe for infants and young children. While codeine is the most common opioid prescribed for outpatients, it is a weak analgesic and being a prodrug, it requires conversion to morphine to be effective. Developmental and pharmacogenetic variations in this conversion commonly result in ineffective conversion and occasionally in overdose. At higher doses, side-effects such as nausea, vomiting, constipation, and dysphoria are common. Oxycodone causes significantly less nausea and vomiting and appears to be better tolerated by the postoperative child just resuming oral intake.

Children who wake up in moderate-to-severe pain may require IV opioids such as fentanyl or morphine to achieve rapid and effective pain relief. However, careful titration of dosing and frequent assessment of the child are required to ensure adequate analgesia without excessive opioid side-effects, such as respiratory depression, excessive sedation or PONV, that may prolong the PACU stay and delay discharge. Children with OSA have documented increased sensitivity to opioids and investigators have recommended a 50% reduction in morphine doses for children undergoing T&A who had a pulse oximetry nadir to <85% on preoperative sleep studies [30].

#### **Regional blockade**

Regional blocks with long-acting local anesthetics provide excellent postoperative analgesia, particularly for genitourinary and orthopedic procedures performed in the outpatient setting. Both peripheral nerve blocks and central neuraxial blocks (caudal or lumbar epidural) may be used. The techniques are discussed in detail in Chapter 18. Peripheral nerve and plexus blocks provide relatively long periods of analgesia lasting for 8–12h in most cases and sometimes exceeding 24h. Depending on the nature of the surgery, this may permit the child to transition to non-opioid analgesics at the time the block wears off, thereby eliminating or reducing the use of opioids and their potential untoward effects. However, appropriate analgesic plans must be made for the parents to follow at home to ensure comfort of the child once the block wears off.

The optimal time to place the block remains a subject of debate; however, there are several purported advantages to placing the block before the onset of surgery [96]. In addition to the potential benefit of pre-emptive analgesia, the effectiveness of a block placed after induction of anesthesia can be assessed during the procedure so that the block can be repeated at the end of the procedure if ineffective. An effective block may decrease general anes-

thetic requirements and facilitate faster recovery. On the other hand, placing the block at the end of the procedure requires a deeper level of anesthesia to permit block placement, which would delay awakening. Lastly, a block placed at the end of surgery may require some time to become effective, causing the patient to wake up in pain. A single caudal injection of local anesthetic prior to incision does not shorten the duration of postoperative analgesia after procedures lasting 1h or less. Times from recovery until the first request for analgesics in children undergoing inguinal herniorrhaphy who had caudal blocks placed before incision or after surgery were similar [97]. For prolonged procedures, a second caudal block using half the original volume of local anesthetic may be placed prior to emergence. Central neuraxial blocks can be done in the setting of outpatient surgery with dilute concentrations of local anesthetic (0.1–0.15%), since they provide effective postoperative analgesia while avoiding motor blockade and urinary retention. Additives such as clonidine have also been shown in some studies, but not in others, to prolong the action of "single-shot" central neuraxis and some peripheral blocks.

Ilioinguinal-iliohypogastric nerve blocks provide excellent postoperative analgesia for genitourinary procedures, such as inguinal herniorrhaphy and orchidopexy. They are technically easy to perform (see Chapter 18), and the duration (4h) and efficacy of the block appear similar to caudal blocks when bupivacaine with epinephrine is used. A randomized, blinded study found that an ilioinguinal nerve block was as effective as caudal blockade to the T10 level in children undergoing orchidopexy [98]. However, procedures that involve considerable manipulation and traction on the spermatic cord and testis may be better managed with caudal blockade. While a penile block is effective for both circumcision and distal, simple hypospadias repair, a caudal block provides more effective analgesia for more extensive procedures on the penis, such as repair of penile-scrotal hypospadias [99]. Infiltration of the incision site with local anesthetic provides effective analgesia for 4-6h after surgery and should be used at the end of virtually every operation [100,101].

## Postoperative nausea and vomiting

Postoperative nausea and vomiting (PONV) is a major concern in pediatric outpatient surgery because it may increase patient discomfort, increase the incidence of wound dehiscence, delay patient discharge, and increase the cost of patient care [102]. PONV, the most common cause for delayed discharge from the PACU, is a source of frustration to parents/caregivers and is a frequent cause of unplanned hospital admission or an early postoperative visit to the emergency department secondary to dehydration and electrolyte derangements [103]. Many adult patients rank PONV as the number one complication of surgery they wish to avoid [104].

Young children often have difficulty describing the occurrence or severity of nausea and for this reason, many investigators use vomiting as their endpoint [105]. Older children may be instructed preoperatively to report any nausea experienced in the postoperative period, but it is not clear whether these "suggestions" increase the reported incidence of nausea in children who may simply answer the way the investigators want. Despite these limitations, the incidence of postoperative vomiting (POV) in children is between 8.9% and 42%, approximately twice the incidence for both nausea and vomiting after surgery in adults [106]. PONV rates may be as high as 50–89% following tonsillectomy, possibly due to swallowed blood, pharyngeal stimulation, and the use of opioids [107].

Risk factors for PONV may be broadly grouped thus: patient factors, surgical factors, and anesthetic factors. Patient factors include age greater than 3 years, gender (female > male), previous history of PONV, family history of PONV, and motion sickness [106,107]. Commonly described surgical factors include type of surgery (strabismus surgery, tonsillectomy, laparoscopic surgery and certain urological procedures) and prolonged surgery [108]. Anesthetic factors, though well described, are controversial and include use of nitrous oxide, difficult mask ventilation, use of opioid medications and reversal of neuromuscular blockade [109]. Many investigators agree that a propofol-based anesthetic is associated with the lowest incidence of PONV [58,110]. A simplified risk score for POV in children is presented in Figure 34.1 [111].

Management of PONV is based on primary prevention and pharmacotherapy. Primary prevention includes a careful history to identify risk factors and tailoring the anesthetic technique to patient and surgical risk factors. Ensuring adequate hydration and nasogastric suctioning following tonsillectomy and/or adenoidectomy are other non-pharmacological techniques that have been employed to reduce the incidence of PONV.

## Pharmacotherapy

This may be divided into prophylactic or rescue therapy. It is presently unresolved whether routine prophylaxis is warranted in all patients undergoing general anesthesia or whether prophylaxis should be based on risk stratification. Very often, economic considerations and risk/ benefit analysis determine the choice and use of prophylactic PONV medications [112]. An international panel of experts compiled comprehensive evidence-based guide-lines for the management of PONV under the auspices of the Society for Ambulatory Anesthesia (SAMBA) [111]. These guidelines suggest that the use of prophylactic antiemetics should be based on valid assessment of risk

**Figure 34.1** Risk factors for POV in children. Simplified risk score to predict the risk for POV in children. When 0, 1, 2, 3 or 4 of the depicted independent predictors are present, the corresponding risk for PONV is approximately 10%, 10%, 30%, 55%, and 70%. Reproduced from Gan et al [111] with permission from Lippincott Williams and Wilkins.

factors for POV as detailed in the algorithm in Figure 34.2. These guidelines recommend that children deemed to be at moderate-to-high risk for POV should receive combination therapy with two or three prophylactic drugs from different classes. Additionally, patients who experience POV despite prophylaxis should receive additional antiemetics from a pharmacological class different from the prophylactic drug, since repeating the same drug within 6h of the original dose does not confer any benefit.

Commonly used medications include serotonin (5HT3) receptor antagonists (ondansetron, granisetron, and dolasetron), steroids (dexamethasone), antihistamines (promethazine, benadryl), metoclopramide, and droperidol. A systematic review reported good evidence that dexamethasone and the serotonin receptor antagonists ondansetron, granisetron and tropisetron were clinically effective for PONV prohylaxis in children undergoing tonsillectomy with or without adenoidectomy [113]. Furthermore, this review found that dimenhydrinate, perphenazine, droperidol, gastric aspiration and acupuncture were not efficacious in reducing PONV in this population. The 5HT3 receptor antagonists are rapidly becoming the most frequently prescribed agents for both prophylaxis and treatment of PONV [107]. Recent data indicate that ondansetron (0.1 mg/kg, up to 4 mg) was effective in preventing early and delayed PONV in children undergoing various types of surgeries [114]. Due to its efficacy and safety profile, ondansetron has become the most commonly prescribed antiemetic for prophylaxis and treatment of PONV. Despite its established safety record, it is important to be aware of some of the fortunately rare but serious side-effects of ondansetron, which may cause a lethal outcome. Recent data indicate that it may cause QT prolongation leading to ventricular tachycardia [115]. Rarely, it may be associated with serotonin syndrome [116] and malignant hyperthermia reaction in patients with muscular dystrophies [117,118].

Two novel antiemetic agents are now available that will likely have an increasing role in the treatment of PONV. Palonosetron, a second-generation 5HT3 antagonist, was approved by the FDA in 2003. Due to its unique binding properties and greater binding affinity for the receptor, it has a substantially longer half-life of approximately 40h. A study of adult patients undergoing outpatient laparoscopic surgery with two or more risk factors for PONV found that a single IV dose of 0.075 mg of palonosetron prior to induction of anesthesia significantly increased the complete response rate, i.e. no emetic episodes and no rescue medication compared with placebo [119]. Furthermore, patients who received palonosetron reported less severity of nausea and less interference in their postoperative function due to PONV. Pediatric data with the use of palonosetron are limited to its use for chemotherapy-induced nausea and vomiting. A study that compared children who received ondansetron before the administration of chemotherapy and every 8h through the hospitalization with those who received a single dose of palonosetron prior to chemotherapy reported significantly reduced intensity of nausea and a significant reduction of emetic events for 3 days of treatment, with some benefits for up to 7 days, in the palonosteron group [120]. No data are available that evaluate the use of palonosetron for PONV in children. Its long duration of action makes it an excellent choice for patients undergoing outpatient surgery, and further studies are needed to evaluate its benefits in this setting.

Aprepitant is a neurokinin-1 (NK1) receptor antagonist that crosses the blood–brain barrier and blocks the emetic effects of substance P [121]. Studies in adults have reported that it reduces PONV following joint arthroplasty and

Figure 34.2 Algorithm for management of PONV. Reproduced from Gan et al [111] with permission from Lippincott Williams and Wilkins.

abdominal surgery [122,123]. However, no pediatric data are available for this indication. A single oral dose of 40 mg 1 h prior to surgery is recommended for adults. An IV formulation is now available, but its only indication is for chemotherapy-induced nausea and vomiting.

## **Recovery and discharge**

Recovery from anesthesia is a complex process encompassing several outcomes including normalization of physiological endpoints, return to baseline sensorium and activity, and emotional and psychological recovery. For the patient undergoing ambulatory surgery, assessment of recovery has largely focused on a return of acceptable physiological parameters, ability to ambulate, and recovery of consciousness to allow the patient to be safely discharged home. To that end, a number of simple clinical scoring systems that assess recovery have been developed and tested [124-128]. The most widely used scoring system is the score that Aldrete first described in 1970 [124]. The original Aldrete score was a 0-10-point scale comprising five recovery parameters, each of which was scored 0-2, similar to the Apgar Score. Subsequently a number of modifications of this score were made that incorporate fast-track criteria, oxygen saturation rather than observation of color to identify hypoxemia, and consideration of developmental stages in children [125,127,129]. Table 34.1 describes a modified version of the Aldrete score suitable for use in children.

Another score that is easy to use and is well suited for use in children is the Steward Postanesthetic Recovery Score that incorporates three recovery parameters and is scored 0–2 with a maximum achievable score of 6 (Table 34.2) [126]. In addition to monitoring of physiological variables, such as vital signs, oxygen saturation, and level of consciousness, a standardized recovery score should be calculated for each patient on admission, at appropriate intervals during the PACU stay, and on discharge. Each facility must select the recovery score that works best in their setting, taking into consideration the psychometric as well as pragmatic qualities of the scoring system to facilitate its repeated use.

Recently, the limitations of such scoring systems in evaluating the broader and potentially long-term impact of anesthesia and surgery have been recognized [130,131]. In attempts to assess early and long-term recovery across multiple domains, including cognition, emotional recovery and activities of daily living, studies in adults have evaluated the reliability, validity, precision, and pragmatic qualities of instruments that measure postoperative recovery outcomes at various time periods after surgery [130–133]. Most of these instruments would not be suitable for use in children. The Post-Hospital Behavior Table 34.1 Modified Aldrete score for children

Variable		Score
Airway	Coughing on command or crying	2
	Maintaining good airway	1
	Airway requires maintenance	0
Vital signs	Stable and appropriate for age	2
	Stable but inappropriate for age	1
	Unstable	0
Motor activity	Moving limbs purposefully	2
	Non-purposeful movements	1
	Not moving	0
Consciousness	Awake	2
	Responding to stimuli	1
	Not responding	0

Questionnaire (PHBQ) comprises 27 items across six categories of anxiety, including general anxiety, separation anxiety, sleep anxiety, eating disturbances, aggression against authority, and apathy/withdrawal (Box 34.3) [134]. This instrument was designed specifically to evaluate maladaptive and negative behavioral changes in children and has been widely used to assess postoperative behavior changes in the pediatric surgical population [45,135,136].

#### Discharge criteria

The ASA practice guidelines recommend that each patient care facility should develop suitable recovery and discharge criteria and provide guidance for development of such criteria (Box 34.4) [137]. Box 34.5 summarizes the ASA stance on specific discharge criteria that have been traditionally mandated in some settings, such as requiring that patients void or tolerate oral liquids prior to discharge. These practices prolong recovery stay and evidence to support their benefits in reducing adverse outcomes is insufficient. Indeed, a previous study reported a lower incidence of vomiting and a shorter stay in the day surgery unit in children who were allowed to drink electively compared to those who were required to drink prior to discharge [138]. No child in either group required readmission for vomiting or dehydration. However, the intravenous fluid regimen was liberalized to supply a calculated 8h deficit in addition to maintenance fluids and intraoperative losses. Adequate intravenous hydra-

#### Table 34.3 Criteria for fast-tracking children

	Score
Awake and oriented	2
Arousable with minimal stimulation	1
Responsive only to tactic stimulation	0
Appropriate for age and development	2
Weak for age and development	1
Unable to move extremities	0
BP <15% of baseline MAP	2
BP 15–30% of baseline MAP	1
BP >30% below baseline MAP	0
Coughing, crying, deep breaths	2
Hoarseness with crying or coughing	1
Stridor, dyspnea, wheezing	0
>95% on room air	2
90–95% on room air	1
<90% on room air	0
None/mild discomfort	2
Moderate to severe controlled with IV analgesics	1
Persistent severe pain	0
	Awake and orientedArousable with minimal stimulationResponsive only to tactic stimulationAppropriate for age and developmentWeak for age and developmentUnable to move extremitiesBP <15% of baseline MAP

A minimum score of 10 (with no score <1 in any individual category) is required for fast-tracking children.

BP, blood pressure; IV, intravenous; MAP, mean arterial pressure. Reproduced from Patel et al [129] with permission from Springer. **Box 34.3** Items included in the Post-Hospital Behavior Questionnaire (PHBQ)

I.	Does your child need a pacifier?
	Does your child seem to be afraid of leaving the house with you?
	Is your child uninterested in what goes on around him (or her)?
	Does your child bite his (or her) fingernails?
	Does your child seem to avoid or be afraid of new things?
	Does your child have difficulty making up his (or her) mind?
	Is your child irregular in his (or her) bowel movements?
	Does your child suck his (or her) fingers or thumbs?
II.	Does your child get upset when you leave him (or her) alone for a
	few minutes?
	Does your child seem to get upset when someone mentions doctors
	or hospitals?
	Does your child follow you everywhere around the house?
	Does your child spend time trying to get or hold your attention?
	Does your child have bad dreams at night or wake up and cry?
III.	Does your child make a fuss about going to bed at night?
	Is your child afraid of the dark?
	Does your child have trouble getting to sleep at night?
IV.	Does your child make a fuss about eating?
	Does your child spend time just sitting or lying and doing nothing?
	Does your child have a poor appetite?
V.	Does your child have temper tantrums?
	Does your child tend to disobey you?
VI.	Does your child wet the bed at night?
	Does your child need a lot of help doing things?
	as it difficult to get your child interested in activities (like playing
	games, with toys, and so only?
	Does your child soom to be shy or afraid around strangers?
	Does your child break toys or other objects?
	Does your ching bleak loys of other objects:
Sou	rce: Vernon et al [134].

tion and correction of fluid deficits prior to discharge may be prudent in children who refuse oral fluids in the PACU.

Discharge before voiding has also not been found to result in readmission for urinary retention. In one study, 30/1719 ambulatory patients who were unable to void but met other discharge criteria were discharged home and followed by a home care nurse [139]. Three of these patients required catheterization at home, and all three had undergone rectal or inguinal surgery under spinal anesthesia. Risk factors for postoperative urinary retention in children include a history of urinary retention or urethral surgery. In the absence of these risk factors, children may be discharged before voiding with instructions to the caregivers to call if they have not voided within a given timeframe.

#### Box 34.4 Summary of recovery and discharge criteria

#### **General principles**

- Medical supervision of recovery and discharge is the responsibility of the supervising practitioner.
- The recovery area should be equipped with appropriate personnel and monitoring and resuscitation equipment.
- Patients should be monitored until appropriate discharge criteria are satisfied.
- Level of consciousness, vital signs, and oxygenation should be recorded at regular intervals.
- A nurse or other individual trained to monitor patients and recognize complications should be in attendance until discharge criteria are fulfilled.
- An individual capable of managing complications should be immediately available until discharge criteria are fulfilled.

#### **Guidelines for discharge**

- Patients should be alert and oriented. Patients whose mental status was initially abnormal should have returned to their baseline.
- Vital signs should be stable and within acceptable limits.
- Discharge should occur after patients have met specified criteria
- Use of scoring systems may assist in documentation of fitness for discharge.
- Outpatients should be discharged to a responsible adult who will accompany them home and be able to report any postprocedure complications.
- Outpatients should be provided with written instructions regarding postprocedure diet, medications, activities, and a phone number to be called in case of emergency.

Source: Practice Guidelines for Postanesthetic Care [137].

Sample discharge criteria are presented in Box 34.6. In the US, all patients who are to be discharged from the PACU must be evaluated for discharge readiness by an anesthesiologist in accordance with Centers for Medicare and Medicaid Services (CMS) guidelines [140].

#### **Fast-tracking**

Fast-tracking is the process of bypassing the PACU and transferring the patient who has met specific criteria directly to the step-down or phase II recovery unit. The goal of fast-tracking is to improve efficiency without compromising patient safety or satisfaction. Table 34.3 describes criteria for fast-tracking for children that take into consideration the adequacy of pain relief [129]. A randomized study found a 20min shorter recovery time for children who were fast-tracked when compared to those who were sent to the PACU, even though both groups met fast-track criteria in the operating room [129]. Children in the fast-track group were less likely to be

Box 34.5 Summary of recommendations for discharge

#### Requiring that patients urinate before discharge

 The requirement for urination before discharge should not be part of a routine discharge protocol and may only be necessary for selected patients.

## Requiring that patients drink clear fluids without vomiting before discharge

• The demonstrated ability to drink and retain clear fluids should not be part of a routine discharge protocol but may be appropriate for selected patients. Replacement intravenous hydration is recommended.

## Requiring that patients have a responsible individual accompany them home

 As part of a discharge protocol, patients should routinely be required to have a responsible individual to accompany them home and to monitor for complications.

#### Requiring a minimum mandatory stay in recovery

 A mandatory minimum stay should not be required. Patients should be observed until they are no longer at increased risk for cardiorespiratory depression. Discharge criteria should be designed to minimize the risk of central nervous system or cardiorespiratory depression after discharge.

Source: Practice Guidelines for Postanesthetic Care [137].

given analgesics postoperatively (41% versus 62%) and were more likely to be restless in the phase II recovery unit (31% versus 16%) compared to the children who were sent to the PACU. No child in either group experienced a clinically significant adverse event. A previous study that included patients >12 years of age found that ASA III compared to ASA I, age <60 years and general surgery (compared to orthopedics and ophthalmology) were risk factors for fast-track ineligibility [141]. Consideration of such factors, in addition to standard criteria, may enhance efficient and cost-effective utilization of PACU resources. As stated in the American Society of PeriAnesthesia Nurses standards, "Phase II is a level of care, not a physical place. The decision to fast-track a patient should be based on patient needs, clinical assessments, and desired patient outcomes" [142].

# Complications of outpatient anesthesia

Adverse postoperative outcomes are usually multifactorial in origin and are the result of the patient's underlying

#### Box 34.6 Sample PACU discharge criteria

#### Criteria for discharge to general care inpatient units

- Stable respiratory status (patent airway, adequate respiratory function, adequate oxygen saturation)
- Stable vital signs within an acceptable range for patient's age, condition and preoperative status
- Awake or easily arousable. Level of consciousness appropriate for preoperative developmental age/status
- Operative area without evidence of significant bleeding
- Adequate analgesia so that comfort needs can be easily managed by resources available at the discharge location
- Normothermic or core temperature that is minimally 36°C or temperature within an acceptable range of preoperative status
- Patients who have received spinal or epidural anesthesia must demonstrate maximum sensory block at the T12 dermatome level and be free of orthostatic hypotension.
- Patients who receive racemic epinephrine will be admitted or monitored for at least 8h

#### Criteria for discharge to home

- Tolerate oral fluids with minimal nausea or vomiting or have received adequate intravenous fluid replacement to deter dehydration
- Parents or caregivers have adequate understanding of discharge instructions and are able to provide postoperative care
- Patients who have received spinal or epidural anesthesia must be able to transfer with assistance
- Patients who receive regional anesthesia will be instructed to call the PACU or Surgical Service if they have not voided within 6 h

co-morbidities, anesthetic techniques or the surgical procedure itself. Fortunately, major morbidity and mortality are extremely rare after ambulatory anesthesia. The reported death rate is approximately two per 100,000 procedures [143,144]. However, minor sequelae, such as drowsiness, uncontrolled PONV, unrelieved pain, bleeding, and respiratory complications, may delay discharge and lead to unplanned hospital admission or readmission following discharge.

The most common symptom reported by parents following discharge of their child is unrelieved pain, which was present in 25–91% of patients [145–151]. One study found that tonsillectomy was a predictor for postoperative pain and that the pain lasted for 7 days or longer in 33% of children. Twelve percent of parents believed that postoperative instructions for pain management at home were inadequate [146]. The incidence of PONV following discharge is reportedly 5.9–59% [145–149,152]. Predictors for PONV include emetic symptoms in the hospital, pain at home, age >5 years, and administration of postoperative opioids [146]. Other postdischarge symptoms include drowsiness, headache, dizziness, fever, hoarseness, mild croup, and difficulty voiding. Adequate preparation of the family/caregivers with individualized discharge education regarding the potential occurrence of complications and symptoms may alleviate parental postdischarge anxiety and promote satisfaction.

### Unplanned admission

Unplanned hospital admission for the ambulatory surgery patient increases utilization of resources, is inconvenient for patients and their families, and is a measure of outcome and quality of care. Previous investigators have reported that approximately 2% of children scheduled for outpatient surgery require hospital admission [153-155]. Another study reported that almost 4% of children undergoing ambulatory surgery required a >3h PACU stay and 1.9% required hospital admission [153]. Prolonged PACU stay occurred most frequently due to PONV (19%) or respiratory complications (16%), including bronchospasm, oxygen desaturation, stridor, and apnea. Respiratory complications and surgical problems, including more extensive surgery than was originally planned, were the most common reasons for unplanned hospital admission. Other investigators reported a 1.8% unplanned admission rate that was commonly due to PONV, postoperative bleeding, or unexpected difficulty with the procedure [155]. Another study reported a 2.2% incidence of unplanned hospital admission in children due to uncontrolled pain, surgical complications, need for extensive surgery, and bleeding [154]. In this study, anesthesiarelated causes of unplanned hospital admission included PONV, oxygen desaturation, bronchospasm, and somnolence; social causes including surgery ending late in the day; and medical causes included underlying medical problems or undiagnosed medical disease. Notably, in the latter two studies, orchidopexy was the most common surgical procedure that resulted in unplanned admission. Taken together, these data suggest a need for careful and frequent re-evaluation of selection criteria for outpatient surgery and vigilant monitoring for potential complications in the PACU.

Given the increasing complexity of procedures performed in the ambulatory setting, the diverse settings in which such procedures are performed, and the expanded patient selection criteria, investigators have attempted to identify risk factors for hospital admission following ambulatory surgery. The Outpatient Surgery Admission Index (OSAI) assigns 1 point each for age >65 years, operating time >120 min, cardiac diagnoses, peripheral vascular disease, cerebrovascular disease, malignancy, HIV-positive status, and use of regional anesthesia techniques, and two points are assigned for general anesthesia [156]. The OSAI shows a good correlation between the odds of requiring hospital admission and increasing OSAI score. Most of the conditions used in the OSAI are more prevalent in adults; similar methods for risk assessment in children are needed to enable appropriate allocation of resources and increase the efficiency of ambulatory surgery in this population.

## Conclusion

In this era of healthcare reform, it is inevitable that there will be increasing pressure to provide low-cost, efficient, high-quality surgical care. The practice of ambulatory surgery will likely expand further and at a more rapid pace than it has over the past 20 years. The need for development of innovative delivery systems that capitalize upon low-cost organizational structures and prudent management of resources will require resourcefulness of healthcare professionals and administrators alike. In the ambulatory surgery setting, it will be increasingly necessary to prevent such pressures from constraining clinical judgment regarding the safest and most appropriate patient care.

## CASE STUDY

A 22-month-old male child presented for hypospadias repair as an outpatient.

#### History

He had been healthy since birth and had been followed regularly for his well child visits. His immunizations were up to date, and his growth and development had been normal. The parents reported a history of a "cold" with a runny nose and cough that started 7 days prior to the scheduled surgery. His skin was warm to touch, and he had decreased appetite and activity on the first day of his symptoms. Most of his symptoms had resolved without any treatment, but he continued to have an occasional cough. This was his second upper respiratory infection after beginning daycare 6 months ago.

His review of symptoms was otherwise negative, he was on no medications and he had not undergone surgery previously.

He was born at 41 weeks' gestation by emergency cesarean section for fetal bradycardia. His neonatal course was complicated by hyperbilirubinemia that was treated with phototherapy. This caused him to stay one extra day in the newborn nursery.

His family history was negative for anesthesia-related problems. His mother received an uneventful epidural anesthetic for his birth, and his father underwent an uneventful tonsillectomy (to the best of his knowledge) as a child.

#### Physical examination

The child was active and alert, playing with toys in the surgical waiting room until he was being examined, when he started crying and clinging to his mother. His vital signs were normal for age and his weight was 13.2 kg. He had no dysmorphic features. While it was impossible to perform a detailed airway examination, his neck mobility and anatomy were normal, and his mouth opening was

adequate. His breath sounds were initially coarse but cleared when he was distracted and stopped crying. He had normal heart sounds and no murmurs, extra sounds or clicks.

### Anesthetic management

The child was fearful of strangers and resisted changing into a hospital gown. Because his mother was concerned that he would not co-operate with mask induction of anesthesia, he was premedicated with 7 mg of midazolam orally. He also received 200 mg of acetaminophen suspension orally for pre-emptive analgesia. Within 15 min, the child appeared visibly calmer. However, he resisted being carried by the anesthesia team but did not resist being wheeled into the operating room in a wagon. Anesthesia was induced with sevoflurane, and intravenous access was obtained after induction of anesthesia. Due to the potential for airway hyper-reactivity from his recent URI, an LMA was placed and anesthesia was maintained with oxygen, nitrous oxide, and sevoflurane. After induction of anesthesia, a caudal block was placed using 7 mL of 0.125% bupivacaine with 1:200,000 epinephrine. The surgery was completed uneventfully and the LMA was removed in the operating room prior to transfer to the PACU.

#### **Postoperative management**

The child was asleep but readily arousable on arrival in the PACU. He had stable vital signs and his oxygen saturation was 98% on blow-by oxygen. The oxygen was discontinued and his SaO<sub>2</sub> remained >95% breathing room air. His pain score on awakening was 3/10 by the FLACC Scale. Since 4h had elapsed from his initial dose of acetaminophen, an additional 150 mg of oral acetaminophen was given. He was reunited with his parents in the PACU. After drinking apple juice, the child had two episodes of emesis in the PACU. He was given 2mg of ondansetron and no further emesis occurred. The child refused additional fluids but was able

to void in the PACU. He had complete return of motor function and was able to stand prior to discharge. When he met institutional discharge criteria, he was discharged home with a prescription for oxycodone suspension. Telephone follow-up the next day revealed that the child had an uneventful recovery at home and had required one dose of oxycodone upon awakening the morning after the surgery.

### **Summary**

This case describes the perioperative care of a child undergoing a common urological procedure. It illustrates the effective use of a sedative premedication to facilitate separation from the parent. The use of a regional block allowed the child to awaken with minimal pain and significantly reduced his need for opioids.

## Introduction

Burns and trauma remain a leading cause of hospitalization and need for anesthesia and critical care in the pediatric population. This chapter discusses anesthesia care of burned children by reviewing the epidemiology, pathophysiology, acute resuscitation and management, and anesthetic care of both initial burn procedures and longerterm reconstructive surgery. Next, anesthesia care for children who have suffered other types of trauma will be reviewed and etiology, acute assessment and management during trauma resuscitation, and trauma anesthesia management in the operating room will be discussed.

## Burns

Burns are a significant cause of death and disability in children. In 2007, almost 500 children under the age of 14 died from unintentional fires or burns, making burns the second highest cause of death for children 5–9 years of age, and placing burns in the top six causes of death for

all other age groups [1]. Approximately 15,000 children are hospitalized per year for burn injuries, and 1100 succumb to this injury [2,3]. Table 35.1 illustrates the top three causes of burn injuries for five age groups [4-7]. As illustrated, the majority of pediatric burns are from a thermal source, with scalds predominating until age 5, after which direct contact with fire or flame becomes the leading cause until adulthood. Approximately 30% of burned children suffer inhalation injury with flames, superheated air, toxic gas or smoke [8]. Though children are less likely than adults to suffer from inhalational injury, those with inhalation burns have a significantly higher degree of morbidity and mortality, i.e. 3-10% without inhalational injury and 20–30% with it [9–11]. Burns may also be caused by electricity, chemicals, and radiation. High-voltage electrical burns are particularly problematic, as outward appearance does not accurately portray the extent of damage to tissues and organs.

The fatality rate associated with burns has decreased over time, most likely secondary to the more consistent use of specialized burn centers [12]. In the US, underrepresented minority groups are burned more frequently

*Gregory's Pediatric Anesthesia*, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

 $<sup>\</sup>ensuremath{\mathbb C}$  2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

than the general population and may represent an opportunity for targeted burn prevention education [4].

Burns are classified both by the percent of total body surface area (TBSA) affected and by the depth of the injury. An estimate of the BSA involved is most often made from charts devised by Lund and Browder, which adjust surface area proportions for age (Fig. 35.1).The head is relatively larger and the limbs relatively smaller in children than in teenagers and adults, accounting for the difference in surface area. Burn depth is classified as shown in Table 35.2.

Superficial burns (first degree) involve only the outer epidermal layer. Although the area is erythematous, there

Age group	Etiology – top 3	Cases
Birth – 0.9 years	Scald	2422

	Other, non-burn	668

Table 35.1 National Burn Repository (2010) – burn etiology [4]

is minimal tissue damage and the protective barrier functions of the skin remain intact. Because the nerves are also intact, these burns are often very painful. Partial-thickness (second-degree) burns involve the entire epidermis and variable portions of the dermis. There is blistering, weeping of transudated fluids, and severe pain. A superficial second-degree burn involves only the upper part of the dermis. Burns of this type heal rapidly with minimal scarring; the dermis is repopulated with epithelial cells that reside in hair follicles, sweat glands, and other skin appendages anchored in the deep dermis. A deep seconddegree burn extends further into the dermis; few viable epidermal cells remain. Re-epithelialization is very slow, and scarring occurs if the wound is not grafted. The local response to burn injury involves not only direct coagulation of burned tissue but also microvascular reactions in the surrounding dermis, and progressive vasoconstriction and thrombosis. Survival of the surrounding dermis and epidermal appendages is dependent on the presence of optimal conditions. Residual heat, mechanical trauma,

#### Table 35.2 Depth of burn injury

Classification	Skin and tissue layers involved
First degree (superficial) Second degree (partial thickness)	Epidermis
Superficial second degree	Epidermis and superficial dermis
Deep second degree	Epidermis and deep dermis
Third degree (full thickness)	Epidermis and full-thickness dermis
Fourth degree (full thickness)	Fascia, muscle, and bone

vasoactive mediators, and dehydration may lead to progressive dermal ischemia [13]. Fluid losses and the metabolic effects of deep dermal burns are similar to those of full-thickness burns.

Third-degree burns involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the burned area. The burned skin takes on a dry, leathery, firm consistency with charring or pearly white discoloration [13]. The tissue is avascular and a zone of ischemia exists between the dead tissue above and deeper living tissue below. Survival of this marginally viable tissue is also dependent on there being optimal conditions. Preventing conversion of viable tissue to eschar is a major goal during the resuscitation period. A fourth-degree burn involves all of the skin structures plus the fascia, muscle or bone underneath (Figs 35.2, 35.3).

Major burn injuries warrant special consideration and referral to specialized burn centers that have expertise in caring for pediatric patients. Major burns are defined as third-degree burns of greater than 10% TBSA or a 20–25% second-degree burn (15–20% in infants); burns involving face, hands, feet or perineum; inhalational burn injuries; chemical or electrical burns; burns associated with trauma; circumferential burns, especially of torso; and burns in children with co-existing medical diseases [14]. It must be emphasized that initial classification of burn injury, both in TBSA and depth, is often revised in the first several days following initial surgical excision of burned tissue; therefore it is best to err on the side of caution during initial assessment when deciding whether or not to refer the patient to a burn center (Box 35.1).

Morbidity and mortality from burn injury increase with increasing size and depth of the burn and in younger **Box 35.1** Criteria for definition of major burn injury

- Greater than 10% TBSA third-degree burns
- Greater than 20–25% second-degree burns in children and teenagers
- Greater than 15–20% second-degree burns in neonates and infants
- Burns involving face, hands, feet or perineum
- Chemical or electrical burns
- Burns associated with trauma
- Inhalational burn injuries
- Circumferential burns, especially of the torso
- Burns in children with co-existing medical disease

children. These survival rates have improved in recent years with advances in the care of burned children. These improvements were spurred on by better understanding of resuscitation, support during the hypermetabolic phase, wound coverage, infection control, and treatment of inhalational injury [15-21]. Thirteen-to-eighteen year olds have the highest survival rates. Reports from the 1960s to the 1980s indicated 50% survival with 70% TBSA burns in this age group, and only 20% survival for children below 3 years of age with similar degrees of burn [22]. A report from the 1990s indicates that 84% of 11-18 year olds, 72% of 3-10 year olds, and 43% of children under the age of 2 years survived after >85% TBSA burns. Recent reports from the year 2000 and later indicate that survival of 80% TBSA burns in young children is now >60% [23] and survival of 99% TBSA burns in children over age 14 is 50% [24].

## Pathophysiology of burn injury

The major function of the skin is to provide a barrier to infection and to reduce heat and fluid losses. Major burn

injury disrupts these protective functions. Heat loss ensues when the ability of the peripheral vasculature to vasoconstrict and reduce blood flow is disrupted; this allows heat to be lost from the skin. In addition, disruption of capillaries, arterioles and venules causes significant transudation of massive amounts of fluid and electrolytes. Major burn injury also initiates an enormous inflammatory response to the tissue injury that results in release of both local and systemic inflammatory mediators. Local mediators include leukotrienes, prostaglandins, bradykinin, histamine, nitric oxide, and oxygen free radicals. Systemic inflammatory mediators include interleukins (IL)-1, -6, -8, and -10 and tumor necrosis factor (TNF) [14]. This milieu of proinflammatory cytokines is accompanied by activation of the stress hormone system and release of catecholamines and adrenocortical steroids. This results in a hypermetabolic state which usually occurs 3-5 days after injury, normally lasts until wounds are covered and healing, and slowly subsides over weeks to months. All organs are affected by the inflammatory response and hypermetabolic state. Consequently, anesthesiologists caring for these patients must carefully evaluate them for these changes and be prepared to treat any organ-specific derangements.

During the acute phase these patients may develop decreased tissue perfusion and hypovolemic shock from loss of fluid from both the burn injury site and the inflammation-induced capillary leak. In addition, there may be hemoconcentration and increased blood viscosity, inflammatory mediator-induced myocardial dysfunction, and increased systemic vascular resistance that are the result of increased catecholamine release. Ventricular failure is possible in severe burns [14,25]. Responses to both endogenous and exogenous catecholamines are attenuated in this phase, presumably because myocardial and vascular adrenergic receptors are either maximally stimulated or desensitized by direct effects of the inflammatory mediators. Following the acute effects, which last from a few hours to several days, a hypermetabolic, catecholamine-driven response replaces the cardiovascular depression. Heart rate and cardiac output increase, and often hypertension is present.

The pulmonary system may be affected directly by the burn itself and/or indirectly by the inflammatory response. Inhalation of smoke, flames, toxic gases or carbon monoxide can cause thermal damage and chemical irritation from the products of combustion; these products may cause direct mucosal edema and tissue sloughing, impaired mucociliary clearance, formation of endobronchial casts, inactivation of surfactant, and interstitial edema [14]. Unless superheated gases or particulate matter are involved, only the upper airways are affected by this direct injury. Laryngospasm, bronchospasm, tracheobronchitis and pneumonia, ventilation-perfusion mismatch, and decreased respiratory compliance may develop. Patients with circumferential chest burns often have a restrictive respiratory physiology and decreased total respiratory compliance. Systemic inflammatory response-induced capillary leak may be exacerbated by large volume fluid resuscitation and cause a condition similar to adult respiratory distress syndrome (ARDS). Carbon monoxide (CO) inhalation is more common when fires occur in enclosed spaces. CO inhalation is dangerous because CO binds to hemoglobin with affinity that is >200 times that for oxygen. CO levels that exceed 10–20% are associated with inadequate tissue oxygen delivery. Fires involving nitrogen-containing plastics can cause cyanide toxicity.

A major burn injury is often associated with profound endocrine and metabolic changes that may persist for 9–12 months after the injury and are characterized by release of catecholamines, antidiuretic hormone, renin, angiotensin, aldosterone, cortisol, and glucagon. Basal energy expenditure is increased, core temperature is elevated (38–38.5°C is often the new "normal" temperature), lipolysis, muscle catabolism and glycolysis occur, and insulin resistance develops. The degree of hypermetabolism is proportional to the size of the burn injury. In addition, thyroid (T3 and T4) and parathyroid hormone levels decrease; the latter can depress vitamin D levels.

Renal function may be adversely affected by burn shock and exacerbated by inadequate fluid resuscitation, elevated concentrations of catecholamines resulting in decreased renal blood flow, decreased glomerular filtration rate (GFR), and decreased urine production. Patients with burn-induced electrical injuries, or those with crush injuries, may have extensive muscle damage and myoglobin-induced renal dysfunction or failure. GFR is normal or supernormal during the hypermetabolic phase. Late renal dysfunction or failure can occur from systemic sepsis or from the acute or cumulative effects of nephrotoxic drugs, such as aminoglycoside antibiotics.

Both hypoperfusion and the circulating inflammatory mediators affect the gastrointestinal system early in major burns. Consequently, intestinal ischemia and increased permeability to bacteria and endotoxins may be present. If so, the patient often develops sepsis, ileus, and stress ulceration. A massive capillary leak may lead to ascites and abdominal compartment syndrome. Hepatic dysfunction can occur from liver hypoperfusion, ischemia reperfusion, and circulating inflammatory mediators. Liver injury is diagnosed by the presence of elevated liver enzymes and bilirubin concentrations and by decreased functional liver protein production as evidenced by an elevated prothrombin time. Early enteral feeding with adequate calories is required to meet the needs of the hypermetabolic state and for the rapid growth of young children. Failure to provide these calories affects wound healing.

The hematological system is affected in the acute phase of a major burn. Hemoconcentration from loss of circulating plasma volume is often the first manifestation. Patients are often anemic after the initial resuscitation and treatment phase due to chronic illness and to suppression of erythrocyte production, blood loss associated with frequent debridements, and hemolysis of heat-damaged red blood cells (RBC). The half-life of heat-damaged RBCs is decreased from approximately 21 to 7 days; an ongoing autoimmune hemolytic anemia may also be present. Due to sequestration, the platelet count often decreases to thrombocytopenic levels in the first week following a burn injury. Thereafter, it returns to normal or supernormal levels; in the late phase of the burn injury, thrombocytopenia may be an early indicator of sepsis. Prothrombin (PT) and partial thromboplastin (PTT) times may initially be elevated by liver dysfunction and early derangement of the extrinsic coagulation system, but they return to normal during the ensuing weeks. Fibrin split products are initially elevated, and fibrinogen is decreased for the first several days after a burn, but both return to normal after the initial period; fibrinogen and factor V and VIII levels are then elevated above normal. A hypercoagulable state is often present during the later phases of burn injury. The white blood cell (WBC) count is typically elevated in burn patients, although applying wound dressings that contain silver sulfadiazine may cause leukopenia.

The central nervous system (CNS) of burned patients can be affected by several mechanisms, including hypoxia caused by respiratory injury or CO poisoning. Hypoxia can cause severe CNS injury if it leads to cerebral edema, increased intracranial pressure, coma, and seizures. Burn encephalopathy, which occurs in 14% of burn patients, includes hallucinations, delirium, personality change, seizures, and coma. Hypertensive encephalophathy with seizures occurs in about 7% of hypertensive pediatric burn patients. Electrical burns can directly injure the spinal cord or brain, depending on the entry and exit sites of the current.

Loss of skin, infected burn wounds, tracheal or tracheostomy tubes, and increased gut permeability to bacteria and endotoxins are sources of infection for burned patients. In addition, indwelling foreign devices (central, bladder, and intravenous catheters) are portals for entry of infective organisms. Burn injury depresses immune function, which increases the likelihood of infections. The temperatures and WBC counts of burned patients are persistently elevated and are not reliable indicators of infection in these patients. Feeding intolerance and decreasing platelet count often herald the onset of an infection. Culturing wounds, blood, and the respiratory and urinary tracts and comparing the culture results to earlier cultures is a common means of detecting early infection. Table 35.3 summarizes the changes in organ systems with major burn injury.

# Initial evaluation and resuscitation of the burn-injured child

## Airway and pulmonary management

Anesthesiologists are frequently involved in the initial resuscitation and management of children with major burn injuries in the emergency department or trauma and burn center. Focus on the airway, breathing, and circulation is the first priority. Respiratory or cardiac arrest mandates immediate tracheal intubation. A history of major burn, smoke inhalation, facial burns, stridor, soot in the nares or pharynx, respiratory distress (wheezing, dyspnea, cough, tachypnea, rales, rhonchi), low SpO<sub>2</sub> indicates a high likelihood of respiratory involvement. Strong consideration should be given to early tracheal intubation, even if gas exchange appears to be adequate on initial presentation, because ensuing swelling of the pharynx, tongue, epiglottis, larynx, and trachea often makes conventional tracheal intubation much more difficult or impossible later on. Oral intubation with a cuffed endotracheal tube (ETT) is recommended. A cuffed tube permits ventilation with higher pressures and minimal gas leak if required to treat significant lung injury. Use of a cuffed tube does not result in more subglottic injury than an uncuffed ETT in critically ill children. Also, initial use of a cuffed tube obviates the potential problems associated with changing an uncuffed to a cuffed ETT if the child develops worse respiratory failure [8,26-27] (Figs 35.4, 35.5).

Both the presumed full stomach and the hemodynamic status of the child must be taken into account when choosing an induction regimen for tracheal intubation of acutely burned children. During the initial phases of burn injury, succinylcholine may be used safely. Other neuromuscular blocking agents can also be used, but higher doses of drug may be required. Drugs used for tracheal intubation should have minimal acute hemodynamic effects, especially in the hypovolemic child. Consequently, it may be preferable to avoid using propofol or thiopental, especially in large doses. Ketamine, etomidate, fentanyl, and midazolam are usually excellent choices for securing the airway. In practice, conventional tracheal intubation is not difficult in the very early burn phase because significant airway edema is absent. Hours or days later when significant edema and airway obstruction are present, special intubation techniques, including video laryngoscopy, laryngeal mask airways, fiber-optic bronchoscopy, cricothyrotomy, and the ability to place a surgical airway, will be required. See Chapter 14 for a

Organ system	Early (acute) manifestations first 3–5 days after injury	Late (hypermetabolic) Until major wounds covered, may persist 9–12 months
Cardiovascular	Decreased CO: myocardial dysfunction Hypovolemia Increased SVR	Increased CO Tachycardia Systemic hypertension
Pulmonary	Airway obstruction and edema Carbon monoxide poisoning Laryngospasm and bronchospasm Tracheitis and pneumonia Adult respiratory distress syndrome	Tracheal stenosis Chest wall restriction Infection: pneumonia and tracheitis
Endocrine and metabolic	Increased catecholamines	Increased metabolic rate Increased core temperature (38–38.5°C) Increased protein catabolism Increased lipolysis Increased glucolysis Insulin resistance Decreased thyroid function Decreased parathyroid function
Renal	Decreased GFR Myoglobinuria	Increased GFR Tubular dysfunction from sepsis or nephrotoxins
Gastrointestinal/hepatic	Ischemia from decreased perfusion Stress ulcers, mucosal injury Ileus Endotoxemia Increased liver function tests, decreased prothrombin time	Stress ulcers Ileus
Hematological	Hemoconcentration Hemolysis Thrombocytopenia Elevated PT, PTT, fibrin split products Decreased fibrinogen	Anemia Elevated WBC Hypercoagulable state: elevated factor V,VIII, platelet count, fibrinogen
Central nervous system	Coma Seizures Cerebral edema Increased intracranial pressure	Hallucination Delirium Personality change Seizures Coma
Infection/immunity	Endotoxemia	Chronic immune dysfunction Burn wound infection Respiratory infection Bloodstream infection Urinary tract infection Endotoxemia Antibiotic-associated enterocolitis Infection with antibiotic-resistant organisms

discussion on managing the difficult airway. Special measures for securing the ETT, such as wiring it to the maxilla or securing it with an umbilical tape and tying the tape behind the head, may be required. Some patients with severe airway or facial burns require tracheostomy.

Suspicion of airway burn or smoke inhalation should prompt rapid assessment and securing of the airway. CO poisoning is a potentially treatable problem that is detected by arterial blood co-oximetry or by some new-generation pulse oximeters (Massimo Rainbow SET, Massimo Corp., Irvine, CA, USA) that measure arterial CO levels [28-31]. One hundred percent oxygen should be administered immediately to patients suspected of having CO poisoning, as this significantly reduces CO's half-life in blood. Patients with CO levels of <20% generally present with milder symptoms, such as light-headedness, nausea, and headache. Their true SaO<sub>2</sub> is >80%. Children with CO levels of 20–40% are confused, disoriented and/or lethargic. Those with CO levels above 40% will have coma, seizures, cardiopulmonary arrest, and death if the CO level is not rapidly reduced. When the FIO<sub>2</sub> is 0.21, the half-life of CO exceeds 4h; when the  $FIO_2$  is 1.0, the half-life is 40–80 min. Treatment of severe CO poisoning with hyperbaric oxygen is controversial but may be indicated if this treatment can be initiated quickly. The half-life of CO is only 20 min with an FIO<sub>2</sub> of 1.0 and 2.5–3 atmospheres of pressure [8,32]. Bedside fiber-optic or rigid bronchoscopy may further elucidate the extent of the airway injury. These modalities allow bronchoalveolar lavage and suctioning of the airway to clear them of soot, debris or sloughed mucosa. High-resolution computed tomography (CT) scanning may also be useful for assessing the degree of injury [33]. However, care must be taken to assure adequate ventilation and oxygenation during the procedure.

Pulmonary toilet, consisting of suctioning, saline lavage, and inhaled bronchodilators, should be aggressively pursued in an attempt to limit pulmonary compromise. The principles of mechanical ventilation, as they apply to respiratory failure in general, should be used – see Chapter 37 for an extensive discussion of ventilatory management [34]. Although decreased surfactant production occurs with significant airway injury, surfactant replacement has not been reported to improve the lung function of these patients.

#### Fluid resuscitation

Following recognition that large quantities of salinecontaining fluids are required for resuscitation, major improvements in the outcomes of burn-resuscitated patients occurred [35]. After a major burn, there is a rapid reduction of plasma volume, increased microvascular permeability, impaired cell membrane function, cell swelling, and increased tissue osmotic pressure, all of which cause interstitial fluid accumulation [36,37]. Nonburned tissues also become edematous due to endothelial injury and hypoproteinemia. Loss of plasma volume is greatest during the first 4–6h post injury and decreases substantially by 18–24h if adequate tissue perfusion is maintained. Protein loss is greatest during the first 8 postburn hours. Smaller amounts of protein continue to be lost until the wounds are completely grafted. Adequate initial volume resuscitation is critical for survival of the patient and to prevent conversion of viable ischemic deep thermal burns to non-viable eschar [38].

Controversy still exists as to the appropriate quantity and composition of fluids required in pediatric patients. In children, adult fluid resuscitation formulae do not work well. Overzealous attempts at restoring blood volume may cause excessive burn edema and serious morbidity. Massive burn wound edema may increase the ischemic insult by impairing cell oxygen availability. The goal of fluid resuscitation is to restore and maintain perfusion and tissue oxygen delivery at optimal levels to protect the zone of ischemia in burned tissue [38]. Restoration of plasma volume should be accomplished without overloading the circulation, preferably over a 24-h period. Formulas for fluid replacement, such as the Parkland formula or the modified Brooke formula, use single calculations based on burn size (e.g. 4mL/kg/% TBSA burn) that tend to underhydrate pediatric patients. Better estimates of fluid requirements for children are made by calculating burn-related and maintenance requirements separately.

The Parkland formula can be used for the first 24h by giving lactated Ringer's solution in amounts equal to maintenance requirements PLUS burn requirements of 4mL/kg/% TBSA burn [39]. When using the Brooke formula, it has been recommended to administer maintenance fluids plus an additional 2-3mL/kg/% TBSA burn for children less than 20kg [16]. The Galveston formula is the only one developed specifically for children, which uses BSA for both burn and maintenance fluid calculations [40,41]. The rationale for this approach is that burn-related fluid losses are proportional to burn edema and evaporative fluid losses, both of which are proportional to the surface area burned. This approach avoids underhydration of small children and overhydration of larger children [42]. With the Galveston formula, total fluid requirements for the first day are estimated at 5000 mL/m<sup>2</sup> of burned tissue (burn-related losses) plus 2000 mL/m<sup>2</sup> total BSA (maintenance fluids). Half of the 24-h fluid allowance is administered during the first 8h and the other half is given during the subsequent 16h. An isotonic glucose-containing solution with added albumin is used for the first 24h. This solution consists of 50 mL of 25% human serum albumin added to 950 mL of 5% dextrose in lactated Ringer's solution. For infants less than 1 year of age, the concentration of sodium is lowered and no potassium is added during the first 12-24h after the burn, or before normal renal function has been demonstrated.

Addition of colloid to the initial hydrating solutions is controversial because of concerns that doing so during the first 24h after a burn may increase protein accumulation in the interstitium and accentuate and prolong edema. The transient systemic endothelial injury and capillary leakage after major burns are mediated by proinflammatory cytokines, complement, arachidonic acid metabolites, and oxygen free radicals [43]. Thus, edema occurring in non-burned tissues does not appear to be the result of altered protein permeability but rather the severe hypoproteinemic state of burned patients [44]. After the first several days, fluid losses are primarily due to burn exudates and evaporation from denuded areas. Maximal weight gain and edema occur 2-3 days after the burn. Thereafter a dieresis ensues, and the patients returns to their preburn weight after approximately 14 days [45]. Since the fluid requirements decrease 24 h after a burn, the Galveston program advocates reducing the fluid requirements to 3750 mL/m<sup>2</sup>/TBSA burned plus 1500 mL/m<sup>2</sup>/TBSA per day for maintenance fluids. Table 35.4 summarizes the recommendations for fluid resuscitation.

The response of each patient to the burn injury is unique and so is the amount of fluid required to maintain tissue oxygen delivery. Common clinical methods such as vital signs, examination of the extremities for pulses and perfusion, palpation of the liver edge to judge central venous pressure, and urine output are not reliable in the early phase of burn injury, because the area being evaluated is in burned tissue or is obscured or, as in the case of urine output, is greatly affected by hormonal response to the burn. Arterial blood gases and serum lactate concentration should be measured often; an increasing negative base deficit or high serum lactate concentration is suggestive of hypovolemia. Pulmonary artery catheters, which are helpful for determining thermodilution cardiac output and for measuring mixed venous oxygen saturation, have been used during acute burn resuscitation but are technically difficult to place and may distract from the most important task, which is providing adequate fluid resuscitation. Continuous measurement of central venous oxygen saturation (ScvO<sub>2</sub>) may be useful during resuscitation of these patients, especially since many of them will require central venous access [46,47].

## Early burn wound excision and grafting

Early excision and grafting of burn wounds improve survival of children and shorten their length of hospital stay [48–50]. Consequently, this should be done as soon as the patient's condition is deemed stable. For the first several weeks after a serious burn, it is often difficult to determine when the patient's condition is appropriate to undergo surgery. Massive fluid shifts, critical airways,

	First 24h	Second 24h	Pediatric supplementation for children less than 20kg
Parkland	4mL LR $ imes$ TBSA $ imes$ wt (kg)	Colloid at 20–60% plasma volume	LR at calculated maintenance
Brooke	1.5mL LR + 0.5mL colloid × TBSA × wt (kg)	0.5 mL LR + 0.25 mL colloid × TBSA × wt (kg)	LR at calculated maintenance
Modified Brooke	$2 \mathrm{mL}\mathrm{LR}  imes \mathrm{TBSA}  imes \mathrm{wt}$ (kg)	0.3–0.5 mL colloid $\times$ TBSA $\times$ wt (kg)	LR at 2–3 mL $\times$ TBSA $\times$ wt (kg) + LR at calculated maintenance
Galveston	<ul> <li>5000 mL/m<sup>2</sup> burned (burn-related losses) PLUS</li> <li>2000 mL/m<sup>2</sup> TBSA (maintenance fluids)</li> <li>50 mL of 25% human serum albumin, mixed with 950 mL of 5% dextrose in D5LR (50% of total in first 8h, remainder in last 16h)</li> </ul>	3750 mL/m <sup>2</sup> /TBSA burned (burn-related losses) PLUS 1500 mL/m <sup>2</sup> /TBSA (maintenance fluids)	NA

Table 35.4 Parkland, Brooke, modified Brooke, and Galveston formulas with pediatric supplementation

and concomitant pulmonary injury, as well as other traumatic injuries, must be carefully considered when making the decision. Mixed distributions of burn depth and the indeterminate depth of many burn injuries add to the challenge. Most authorities agree that burn wounds should be excised and covered to reduce the risk of scarring or infection and if it is estimated that the wounds will not heal within 14 days of the injury.

Two types of excisions are possible: tangential and fascial. With tangential excision, the eschar is sequentially shaved in thin slices until a bleeding, viable matrix is reached so a graft can be placed. Tangential excision is associated with significant blood loss and is generally limited to 15% TBSA or less in very young children. Excision to the muscle fascial plane is faster and is associated with significantly less blood loss; however, because fat and lymphatics are removed, the cosmetic results are less favorable. Consequently, fascial excision is usually reserved for patients with burn wound sepsis and for those in whom it is desirable to limit operating time and blood loss (i.e. when the area to be excised is very large, the patient's condition is unstable, or he/she is otherwise at risk for operative complications) [51,52]. For large burns, total fascial excision can be done early or serial tangential excisions can be done every 3-7 days.

The wound is closed with autogenous skin grafts whenever possible. For large burn wounds, where insufficient autologous skin is available to cover the wound, allografts or xenografts can be used to temporarily cover the wounds; these grafts are immunologically rejected within several weeks and are unsuitable for long-term burn coverage. A number of tissue-engineered or cultured epithelial cell products are available. The method used for skin coverage following tissue excision is highly institution dependent [48] (Figs 35.6, 35.7).

## Burn wound dressing changes

Dressing of burn wounds and changing the dressings to assess the wound or to perform further debridement is a daily process in many burned patients. Many dressing materials and regimens are available to promote healing and to prevent infection; the exact protocols used are institution dependent. However, the regularity with which these dressings are changed and the predictable pain and psychological distress this causes pediatric patients are a challenge for the patient and the pediatric anesthesiologist. An interesting recent development has been the application of wound vacuum technology to help close burn wounds. Negative pressure is induced over the wound, which promotes movement of blood, lymph, and interstitial fluid and reduces peripheral edema and bacterial load. Movement of these fluids increases granulation tissue formation and causes epidermal migration [53]. Other dressings and substances that are designed to reduce the frequency of dressing changes, pain, and psychological distress, while producing the same beneficial wound results in children, have recently become available.

#### Long-term burn wound reconstruction

Patients with significant burns anywhere or burns in critical areas, such as the face, neck, hands, feet, or perineum, will of necessity return many times for reconstructive surgery to improve functionality or cosmesis, once the original burn wound has been treated and healed. These patients often require dozens of anesthetics in a relatively

Figure 35.6 Debridement of the burn in Figure 35.3 with hydrosurgery. Reproduced from Fabia and Groner [48] with permission from Elsevier.

Figure 35.7 Coverage of the same burn with split-thickness skin graft. Reproduced from Fabia and Groner [48] with permission from Elsevier.

short period of time. Careful evaluation and anesthetic planning and discussion with the surgeon, particularly when the airway is involved, are essential for these patients.

## Preoperative evaluation of the burn patient

Thorough preoperative evaluation of burn patients is essential when preparing for their anesthetic care. These cases can range from a first-time surgical encounter in a severely burned patient to a patient who is undergoing long-term burn reconstruction and has been anesthetized dozens of times. For the acutely burned patient, attention to the airway and its stability is paramount. If difficult tracheal intubation or reintubation is anticipated, appropriate equipment and surgical back-up must be available. Attention to both the pulmonary and cardiovascular status and oxygen delivery is equally important. Chest radiographs, CT scans, ventilator settings, and blood gases and pH should be reviewed so the extent of the pulmonary injury can be determined. Vascular access is assessed, including the need to insert additional catheters. The most recent laboratory studies, including hematological, coagulation, electrolytes, renal function, hepatic function, and arterial blood gases, should be reviewed. A thorough physical examination is important for understanding the degree of edema, the unburned areas available for monitoring and catheter placement, and the need for ongoing medications and opioids. Review of the past medical, surgical, and anesthetic history is important, as is determining the presence of drug or latex allergies.

A discussion with the burn surgeon is vital to understand the goals of the surgery, the anticipated blood loss, the sites that will be used to obtain skin grafts, and the plan for positioning of the patient. It is important to understand the patient's current nutritional status and method of feeding, i.e. enteral or parenteral (or both), and to minimize interruptions in feeding by timing nil per os (NPO) orders appropriately. Finally, a discussion with the parent and patient (when appropriate) is necessary for understanding past anesthetic issues, for informing them of the anesthetic procedures, for treatment of postoperative pain, and for answering their questions.

Because many of these patients have had multiple anesthetics for dressing changes, tissue excision, and grafting, it is important to involve a child-life or behavioral specialist in the preoperative preparation of these patients. It is good practice to listen to the child and parent and to understand their preferences for issues such as premedication and the induction of anesthesia.

## Intraoperative management of the burn patient

Anxious patients should be given liberal amounts of premedication before transfer from the burn unit or holding area, if possible. Intravenous or oral agents, such as midazolam or ketamine, are effective by either route [54]. Intranasal dexmedetomidine 2µg/kg is effective when given 30-45 min before the procedure. In one study intranasal dexmedetomidine was as efficacious as oral midazolam, 0.5 mg/kg. Both agents produced acceptable separation from parents, induction and emergence conditions, and postoperative pain scores [55]. Parental presence for induction of anesthesia certainly is advocated where available and appropriate. If the patient is receiving continuous infusions of sedatives and/or analgesics, they should be continued during transport of critically ill patients. Careful monitoring of patients receiving these drug infusions is necessary during transport. Strict aseptic technique should be maintained in all aspects of care.

Burned patients may have few areas of non-burned skin for placement of ECG leads, pulse oximeters, and blood pressure cuffs. The anesthesiologist may have to be creative when finding acceptable monitoring sites [14]. Certainly before placing any monitor or catheter in a nonburned area, it is important to ask the surgeon if it is a site he/she plans to use to obtain skin for grafting. For major burn excision and grafting procedures, or for very unstable patients, invasive arterial and central venous monitoring are preferable because they allow beat-to-beat monitoring of blood pressure, blood sampling, measurement of central venous pressure, and reliable vascular access for administration of large amounts of fluids and blood or vasoactive drugs. The femoral area is often unburned and available for central venous or arterial access; however, these areas are often the only ones available for harvesting skin for grafting. Urine output should be measured during major procedures as another means of determining intravascular volume. Given the propensity for hypothermia from large exposed burn surfaces and large fluid volume administration, temperature must also be measured continuously.

The greatest challenges during major excision and grafting procedures are heat conservation and blood loss. Ongoing communication between the surgeon and the anesthesiologist about these issues is essential. Exposure of denuded tissue rapidly leads to hypothermia if no measures are taken to prevent it. Thermoregulation is blocked by general anesthetics and by denervation of burned areas. The slight increase in heat production during the operative period is more than counterbalanced by increased heat loss. Burn patients have a higher than normal core temperature (38-39°C) and are most comfortable in an ambient temperature of 30-31°C [56]. The operating room should be as warm as can be tolerated by surgeons and other personnel and should be draft free. Servo-controlled radiant warmers can be placed above the patient. A warming blanket, forced-air warmer, or a plastic or cloth cover should be placed around nonoperative sites. All fluids that come into contact with the patient, including IV and irrigation fluids and blood products, should be warmed. The inspired gases should be warmed and humidified, or at the very least a condenser humidifier should be used. Operative time should be minimized by a well co-ordinated team effort. For example, one surgical team can excise eschar while another harvests grafts. This allows wounds to be covered as expeditiously as possible and limits most procedures to approximately 1.5h of operating time.

Blood loss is rapid and massive for all but the most limited excisions. It is commonly estimated that 3.5–5% of the blood volume is lost for every 1% of the body surface excised [15]. Excising the scalp is a particularly bloody procedure. For small children, blood replacement with warmed, fresh whole blood should be started as soon as the blood loss begins. Unfortunately, whole blood is increasingly difficult to obtain because of blood bank regulations. Because blood loss is difficult to estimate, arterial and central venous pressure should be measured to help assess intravascular volume. Several measures can be taken to reduce bleeding, including applying dilute epinephrine (1:10,000) soaked sponges, spray-on thrombin, or collagen pads to the wound. Tourniquets can be used in some circumstances. The volume of tissue excised should not exceed 10–15% of TBSA at one procedure.

The complications and consequences of massive transfusion must be anticipated, especially acute citrate intoxication and hyperkalemia. Burned patients are chronically hypocalcemic. Consequently, they commonly develop hypotension with rapid infusion of citratecontaining blood products because the excess citrate reduces the concentration of ionized calcium. Simultaneous administration of CaCl<sub>2</sub> 5-10mg/kg through a central venous catheter reliably blunts this response [57]. Hyperkalemia can occur with rapid transfusion of multiple units of packed RBCs, especially in small children. Thus, frequent measurement of serum potassium concentrations is desirable. Fresh or washed RBCs or measuring the potassium level in each unit before infusion and not infusing units that have K<sup>+</sup> levels >8 mMol/L effectively prevent hyperkalemia. Treatment of hyperkalemia with dextrose, calcium, and insulin, and with alkalization with sodium bicarbonate and hyperventilation plus stopping the surgery may be necessary in extreme cases. Massive transfusion affects coagulation parameters, especially the platelet count. Clotting factors, in the form of fresh frozen plasma, platelets or cryoprecipitate, may also be required. All blood products should be warmed with a properly designed fluid warmer; the ability to rapidly infuse blood products should be available. See Chapter 11 for a more extensive discussion of intraoperative bleeding and administration of blood products. Because bleeding and hypothermia are inter-related, it may be best to abbreviate the procedure if the anesthesiologist is unable to adequately compensate for massive hematological changes. It is preferable to return another day, once resuscitation is complete, rather than risk causing the patient harm.

Because of the hypermetabolic state, there is a need for increased alveolar ventilation. The patient's trachea is usually intubated and ventilation is controlled for all but very short and limited procedures. If the patient has a pulmonary injury and ARDS, a modern anesthesia ventilator is required to deliver adequate inspiratory flows, peak pressures, tidal volumes, and positive end-expiratory pressure. If one is not available, the patient's ICU ventilator should be used [58].

Maintenance fluid requirements are higher than normal in burned patients and these volumes plus additional fluid for intraoperative losses should be administered during the operative period. Surgeons often infiltrate copious amounts of normal saline subcutaneously to facilitate harvesting skin for grafting. This amount of fluid must be compensated for by decreased IV fluid administration. If the patient is receiving parenteral alimentation that contains high concentrations of glucose, similar amounts of glucose (mg/kg/min) should be delivered in the operating room to prevent hypoglycemia. Serum glucose concentrations should be monitored frequently during surgery to detect hyperglycemia and prevent hyperosmolar dehydration.

## Pharmacokinetics of drugs in burned patients

Major burn injuries induce many physiological changes that produce profound alterations in the pharmacokinetics of many drugs [59–61]. In the acute phase, cardiac output and tissue blood flow are diminished. This delays clearance and metabolism of many drugs. Later, during the hypermetabolic phase, the reverse is true. Neural and hormonal mechanisms and other circulating mediators also affect drug deposition and action. The principle of titrating drugs and anesthetics to the patient's needs is never more appropriate than in patients with major burns.

Perhaps the most profound pharmacological changes involve muscle relaxants. Burned patients are supersensitive to succinylcholine after the acute burn phase and insensitive to non-depolarizing muscle relaxants [62]. The use of succinlycholine after the resuscitative phase is contraindicated because it may cause lethal hyperkalemia. The hyperkalemia is related to both the dose and time elapsed from the initial burn injury. The exact time of onset is unknown. The response may last as long as 2 years. Consequently, it has been recommended that the use of succinlycholine be avoided for at least several months after complete wound healing has occurred. Succinlycholine is seldom used today except for airway emergencies. Resistance to non-depolarizing muscle relaxants develops about 1 week after injury and is also related to the magnitude of the burn [63]. If the burn exceeds 20% of the BSA, the dose required to produce an appropriate block is often 2–5-fold greater than normal. This phenomenon also occurs in children, and although the exact duration of this effect is unknown, resistance to non-depolarizing muscle relaxants was documented in a child more than 1 year after complete healing of his burn wounds [64].

The mechanism for these alterations is believed to be a denervation-like phenomenon in which the number of acetycholine receptors is increased and the receptors are located at extrajunctional sites in the muscle membrane. This results in a greatly increased number of binding sites, which increases the dose requirement [62]. Drugs that antagonize muscle relaxants should be used in normal doses.

Cardiovascular responses to adrenergic agents are greatly diminished during the hypermetabolic phase. Topical application of epinephrine during wound excision is well tolerated and causes minimal cardiovascular changes and infrequent arrhythmias [60]. After burn injury, myocardial  $\beta$ -adrenergic receptors have a decreased affinity for ligands, impaired receptor-mediated signal transduction, and decreased adenolate cyclase activity, which results in decreased cAMP production [65,66]. Responses to administered cathecholamines, such as epinephrine and dopamine, are also diminished.

Ketamine and inhaled anesthetic agents have been extensively used in burned patients. Repeated administration of these agents has proven to be safe. Total IV anesthesia with propofol and alfentanil has also been reported [67]. Dose requirements for thiopental are increased to 7–8mg/kg in burned children for at least 1 year after the initial injury [68].

Opioids are the most commonly administered form of analgesia, but the dose requirements for these drugs are high in burned patients [69]. In acutely burned children, the volume of distribution and the elimination half-life of morphine are markedly reduced, and clearance is increased [69]. Many of these children have received long-term infusions or doses of opioids, benzodiazepines or ketamine and have increased requirements for these agents [70]. A recent report indicated that pediatric burn patients who were inadequately sedated with conventional agents were adequately sedated for 11 days with infusions of  $0.5 \mu g/kg/h$  of dexmedetomidine. Tachyphylaxis or respiratory depression did not occur [71].

## Pain in the burn patient

Pain associated with burns is severe, increases with size and depth of the burn, and persists at least until the wounds are well healed [72]. Experimentally induced cutaneous burn injury produced local inflammatory changes that manifest as redness, lowered pain thresholds (allodynia), and enhanced pain response to noxious stimuli (hyperalgesia) [73,74]. Hyperalgesia may be caused by changes in C-polymodal nociceptors that develop a decreased discharge threshold and increased rate of firing [75]. Intense C-fiber stimulation also induces a state of central hypersensitivity in spinal cord dorsal horn neurons [76]. Burn-associated pain can be clinically differentiated into background (constant) and procedural (dressing changes and wound debridement) pain. Successful management of background pain has been reported with acetaminophen and with oral or IV morphine administered every 4h by the clock [72]. Patient-controlled analgesia with morphine is ideal for patients who are able to participate. Opioid tolerance and escalating opioid requirements often develop [77]. See Chapter 33 for a comprehensive discussion of the management of chronic pain and opioid tolerance.

Wound debridement and frequent dressing changes are required for proper wound healing. The procedural pain associated with these activities is often excruciating. Ketamine, opioids, and benzodiazepines are commonly used for sedation and analgesia for these procedures. Light-to-moderate sedation, deep sedation, and general anesthesia may be required. Ketamine is commonly used because it provides intense analgesia with minimal respiratory depression when given IV or orally. A long-acting opioid, such as morphine, may provide adequate analgesia during a dressing change but may cause excessive sedation after the painful stimulus is gone and the patient has returned to the ward. A combination of ketamine and an opioid provides intense analgesia for the surgical event while reducing the opioid dose and its side-effects. Due to its potency and short half-life, fentanyl is a useful drug for burn patients. During the convalescent phase, oral transmucosal fentanyl  $(10\mu g/kg)$  has been used successfully to manage the pain associated with care of smaller burns [72]. Oral or IV midazolam or lorazepam are important adjuncts for allaying anxiety and producing at least partial amnesia for these events.

#### Outcome of major burn injury in children

Over the past several decades more pediatric patients with burns have survived due to remarkable advances in early resuscitative care, later intensive care, and burn wound treatment. Consequently, younger and younger severely burned patients are surviving, including those with burns of greater than 80% of their TBSA. As a result, skin and lung injury may have less influence on survival.

During a 10-year review of 3005 admissions to a specialized pediatric burn unit from 1992 to 2001, there were 72 deaths, 71 of which had a complete autopsy [23]. The characteristics of survivors and non-survivors were compared, and important differences were noted. The overall mortality rate was 2.4%. Those who died had a mean burn TBSA of 66%, versus 26% for those who survived (60% versus 14% for third-degree burns). Also, 60% of patients who died and only 16% of survivors had inhalational burns. The ages and weights of the survivors and non-survivors were similar. Diffuse alveolar

lung damage was the primary cause of death in 25% of patients. Hypovolemia/inadequate resuscitation was the primary cause of death in 16% of patients. Loss of airway/pulmonary aspiration was primary in 15%. Pneumonia and burn wound sepsis each caused 13% of the deaths, and cerebral anoxia caused 10%. The reviewers felt that approximately one-third of all deaths could have been prevented had some deficiency of care not occurred.

The long-term physical, psychological, and quality of life problems of young adults who had burns involving 30% or more of their body were recently determined [24,78]. Eighty to 90% of them had scores within normal limits for most of the domains of physical strength, dexterity, mobility, and activities of daily living. However, more than 50% qualified for a psychiatric diagnosis, especially anxiety disorder. These people rated their quality of life as significantly lower than that of the reference group. The domains of material well-being, physical wellbeing, and extramarital relationships were particularly affected. The psychological and physical effects of a major burn cannot be overstated.

#### Trauma

Trauma is a major cause of hospitalization in pediatric patients, and the leading cause of death in children over the age of 1 year [79]. In the year 2000 approximately \$20 billion dollars were spent treating trauma that occurred in 0–19-year-old pediatric patients . The leading cause of injury-induced death in patients under the age of 1 year is unintentional suffocation due to choking or strangulation; motor vehicle accidents are the leading cause of death for children 1–19 years old. In the 1–11 year age group, drowning is the second leading cause of death; in the 12–19 year olds, homicide is the second leading cause of firearms. The statistics for non-fatal injuries parallel these causes.

This section will review anesthesia care for major trauma in children.

#### Organization of trauma services

In the US, the American College of Surgeons (ACS) designates trauma centers as levels I–III. Pediatric trauma centers are either level I or level II [80]. These designations are determined by ACS site visits and also by state or local governing bodies. Pediatric trauma care may take place in a specialized pediatric hospital or in a larger general hospital with an organized trauma service with pediatric specialists as part of the team. For a level I trauma center designation, a qualified trauma surgeon and anesthesiologist, as well as immediate operating room (OR) availability, must be present in the hospital 24h a day. To be designated a level I trauma center, at least 200 pediatric trauma patients less than 15 years of age must be admitted annually. For a pediatric level II designation, these services must be "promptly available" on a 24-h basis, with at least 100 pediatric patients admitted annually. Other requirements include rapid availability of neurosurgery services, radiology, and blood bank support, as well as a defined program manager, database, and quality and outcomes program.

The exact role of the anesthesiologist varies by institution, but in general he/she is responsible for assessing and managing the airway and for assisting with the resuscitation of severe trauma patients, as well as providing sedation, analgesia, and anesthesia for diagnostic and therapeutic procedures during trauma evaluation and initial therapy. An anesthesia trauma tackle box that contains the necessary drugs and equipment for airway management, including laryngoscopes and blades, oral airways, and a wide range of endotracheal tubes and emergency airway management devices, such as laryngeal mask airways and cricothyrotomy kits, should be readily available and restocked immediately after each use. The anesthesiologist may not be called for all trauma evaluations and initial resuscitations. Most institutions have two or more designations for level of trauma activation that are based on a triage system that takes into account the mechanism of injury and the likelihood of requiring airway intervention. Lower level trauma activation may involve emergency physicians or surgeons only.

#### Initial trauma evaluation

Evaluation of major trauma begins with obtaining a history from the emergency first responders that includes mechanism of injury (motor vehicle accident, fall, drowning), time from injury to treatment, extent of injury, vital signs, and interventions, including vascular access, IV fluids administered, bag and mask ventilation or insertion of a laryngeal or pharyngeal airway or a tracheal tube. Neurological status is assessed and communicated. Time from injury to arrival at the hospital is conveyed, and the trauma system is activated at the level specified by the local institutional policy. Maximal activation usually includes the emergency physician, trauma surgeons, nurses, respiratory therapists, anesthesiologist, and possibly other specialists, such as intensive care medicine specialists. It is important for one physician, usually the trauma surgeon, to lead the evaluation and resuscitation.

Initial evaluation begins with the primary survey of airway, breathing, and circulatory status [81]. Cardiopulmonary resuscitation (CPR) is started or continued in the worst case scenario, with the recognition that the cause of the arrest may be massive hemorrhage from trauma. Chapter 12 presents the principles of CPR in children. The patient's color, respiratory effort and distress, oxygen saturation, pulses, and arterial blood pressure are quickly evaluated, as is the status of vascular access and evidence of ongoing hemorrhage. The neurological system is quickly evaluated using the Glasgow Coma Scale that has been modified for Pediatrics (Box 35.2). After the primary survey and initiation of treatment, the secondary survey is done, which includes a head-to-toe examination that includes the face, head, and neck, focusing on cervical spine injury. Careful removal of a cervical collar is necessary for complete CNS assessment, as is removal of clothing for examination of chest, abdomen, back and spine, extremities, perineum, and rectum. Initial laboratory examination, including complete blood count, arterial or venous blood gases and pH (if indicated), serum electrolytes, blood urea nitrogen, creatinine, glucose, and blood for type and crossmatch, is conducted. Additional vascular access is provided, the bladder is catheterized, and radiographs, including chest, abdomen and extremities, are ordered if indicated. Bedside ultrasound (see below) is a valuable diagnostic tool for initial trauma evaluation. CT scanning is ordered as indicated.

## Airway management in the trauma patient

The anesthesiologist is often the one called upon to evaluate and manage the airway and overall patient status to determine if the trauma patient needs emergency tracheal intubation. Indications for tracheal intubation include significant respiratory distress from airway or thoracic trauma, including rib fractures, pneumothorax, and flail chest. Retractions, grunting, hypoxemia, and unequal breath sounds all indicate that emergency tracheal intubation is required. In addition, tracheal intubation and mechanical ventilation may be required to provide adequate gas exchange and adequate oxygen delivery to the brain of patients with CNS trauma or an altered mental status (Glasgow Coma Score (GCS) ≤8), which may indicate significant brain injury. The laryngeal reflexes of these patients are often absent and they cannot protect their airway from aspiration of gastric contents. CT scanning and transport to the scanner are thought to be safer when the airway is controlled. Significant cardiovascular instability from traumatic hemorrhage is often an indication for controlled ventilation. For lesser levels of respiratory distress and depressed consciousness or cardiovascular compromise, it may be sufficient to provide high-flow 100% oxygen by facemask and continuously monitor the SaO<sub>2</sub> and respiratory status. Because modern CT scanning is so rapid, additional sedation that might mandate tracheal intubation may not be required.

Box 35.2 Glasgow Coma Scale modified for pediatric patients		
	Response	Score
Eye opening	Spontaneous	4
	To speech	3
	To pain	2
	None	1
Verbal	Coos, babbles	5
	Irritable	4
	Cries to pain	3
	Moans to pain	2
	None	1
Motor	Normal spontaneous movements	6
	Withdraws to touch	5
	Withdraws to pain	4
	Abnormal flexion (decorticate)	3
	Abnormal extension (decerebrate)	2
	Flaccid	1

The condition of patients requiring tracheal intubation ranges from full cardiac or respiratory arrest, in which case no additional sedation or muscle relaxation is needed, to combative patients with vigorous cardiac function who require significant doses of induction agents, analgesics, and muscle relaxants. In the absence of suspected CNS trauma, the cardiovascular status and possible intravascular volume deficit are of paramount importance. Patients with hypovolemia are usually given a bolus of isotonic fluid, such as lactated Ringer's solution or Plasmalyte® 10-20 mL/kg, rapidly while the anesthesiologist is preparing for tracheal intubation. The airway is evaluated for potentially difficult facemask ventilation or tracheal intubation; if difficulty is anticipated, back-up methods, such as a video laryngoscope and surgical airway, must be available. The complexity, time, and limited view with blood in the airway often makes flexible fiber-optic endoscopic intubation impractical in emergency trauma situations. Preoxygenation and assisted facemask ventilation, if needed, are provided. Large-bore suction should be readily available.

Intravenous induction drugs that preserve myocardial contractility, blood pressure, and intravascular volume are preferable. Hypovolemic trauma patients often tolerate etomidate 0.2–0.4 mg/kg or ketamine 1–2 mg/kg IV better than thiopental or propofol because these drugs may cause venodilation and hypotension. Muscle relaxation is frequently needed, and emergency trauma intubation is an indication for the use of succinylcholine. If the anesthesiologist is reasonably certain that tracheal intuba-

tion will be straightforward, non-depolarizing muscle relaxants that have few cardiovascular effects are given in sufficient doses to facilitate muscle relaxation. Rocuronium 1.2–2 mg/kg or vecuronium 0.2–0.4 mg/kg is often used.

It should be assumed that the patient has a full stomach, and gentle cricoid pressure should be applied (see Chapter 14). If a cervical collar is present, it should be temporarily removed for airway management. In-line stabilization (not traction) of the cervical spine is provided by an assistant. Because it may take 1-2min for adequate muscle relaxation to occur with non-depolarizing drugs, even when large doses are given, gentle, shallow mask ventilation should be initiated rather than allowing the patient to have a prolonged period of apnea before tracheal intubation. After gentle laryngoscopy and tracheal intubation, careful positive pressure ventilation is commenced while closely monitoring the cardiovascular status, since positive pressure ventilation may compromise venous return and cause hypotension in hypovolemic patients. Use of a styletted, cuffed tracheal tube is preferred to minimize difficulty with intubation and gas leaks. Exhaled CO2 detection is mandatory following tracheal intubation; if no CO<sub>2</sub> is detected, a quick laryngoscopy will determine if the tracheal tube is in the esophagus. If not, it is possible that cardiac output and pulmonary blood flow are so severely compromised that little CO<sub>2</sub> is being presented to the lungs. During or shortly after giving the induction drugs, additional opioids and/or sedative agents are titrated to produce the desired effect.

Tracheal intubation of patients with suspected or actual CNS trauma deserves special attention. Ketamine is contraindicated in this situation because it increases cerebral blood flow and intracranial pressure (ICP). If CNS trauma is isolated and arterial blood pressure and the intravascular volume status are stable, drugs such as thiopental, propofol or etomidate are preferable because they tend to preserve or decrease ICP, cerebral blood flow, and cerebral metabolic rate for oxygen. Adequate depth of anesthesia helps prevent unwanted increases in ICP. Also, it is important to prevent coughing by providing adequate muscle relaxation before attempting laryngoscopy. Pretreatment with IV lidocaine may also mitigate any increases in ICP.

### Airway trauma

Blunt or penetrating trauma to the face and neck should increase suspicion of injury to the pharynx, larynx, trachea, and bronchi. Possible injuries include mucosal edema of the pharynx, glottis, and vocal cords. Laryngeal lacerations, arytenoid cartilage dislocation, cricothyroid disruption, and vocal cord paralysis also occur. Although laryngeal fractures are less common in children than soft tissue injuries, they do occur and may involve any part of the laryngeal skeleton. The degree of injury can range from simple, non-displaced fractures to comminuted fractures with loss of cartilage [82]. Laryngotracheal separation is a particularly serious injury that is more common in younger children because their intercartilaginous membranes are less well developed than those of older children. Trauma of the face or neck that is associated with respiratory distress or subcutaneous emphysema suggests disruption of the aerodigestive system.

Should immediate tracheal intubation be required for airway obstruction or severe distress, it must be determined how successful direct laryngoscopy will be. One should proceed with caution before inducing anesthesia and giving muscle relaxation to avoid the "cannot ventilate-cannot intubate" scenario. Large-bore suction must be available for clearing blood from the airway. Videolaryngoscopy and surgical back-up for cricothyrotomy or emergency tracheostomy must be immediately available. If the patient does not require an emergency airway, CT evaluation or fiber-optic rigid laryngoscopy and bronchoscopy by an otolaryngology or trauma surgeon is indicated. Further surgical management, including repair of the injury via thoracotomy, is done as indicated. It is important for the anesthesiologist to maintain constant vigilance for possible further airway compromise.

### Vascular access

Adequate large-bore peripheral IV access with at least two catheters should be provided as quickly as possible in patients with major trauma. Any peripheral vein can be used. However, if possible, access should be sought in non-traumatized extremities. In addition, it is preferable to obtain upper extremity access in major abdominal trauma or lower extremity access in major thoracic, upper extremity, neck or facial trauma. In the absence of accessible peripheral veins, insertion of an intraosseous needle into the flat surface of the upper tibia will allow essentially any fluid, blood product or medication to be infused [81]. Generally, the time and difficulty of placing central venous catheters preclude their use during initial trauma resuscitation. During this time, the focus should be on obtaining peripheral IV access and on the rapid evaluation and early treatment of trauma injury. Similarly, arterial catheters are not generally inserted during the acute resuscitation but are placed later after initial evaluation and stabilization. See Chapter 17 for a discussion of the details of vascular access.

## Central nervous system trauma

Brain trauma is the leading cause of death among injured children and is responsible for 80% of all trauma deaths.

Each year, almost 30,000 children <19 years of age suffer permanent disability from traumatic brain injury (TBI). Children <13 years of age have 475,000 hospital visits, 37,000 hospitalizations, and nearly 3000 deaths each year related to TBI. Falls account for approximately 40% of pediatric brain injuries, and motor vehicle accidents (MVAs) account for 11%. Pedestrian injuries account for 17% and falls from bicycles 10%. Infants and toddlers are more prone to falls from either a low height or from windows of one or more stories. School-age children are more likely to have sports-related injuries and MVAs. All ages are subject to the sequelae of non-accidental trauma. The teenage population is increasingly affected by penetrating brain trauma from firearms [81].

Head injuries in children range from minor scalp trauma and simple skull fractures to cerebral contusion with cerebral edema. They also include acute subdural, epidural or intracerebral hemorrhage and penetrating brain trauma.

The basic principles of initial evaluation include pupillary examination and determination of the GCS. Signs of serious brain injury and increased intracranial pressure include full fontanelles (when present) and split cranial sutures, depressed level of consciousness, irritability, and "sun-setting sign" (persistent inferior deviation of pupils). Irritability and seizures may also be seen. In older children, headache, neck pain, photophobia, vomiting, decreased levels of consciousness and seizures are also observed. Signs of impending brainstem herniation include Cushing triad (hypertension, bradycardia, irregular respirations) and unequal pupils. Rapid clinical assessment, airway management, immediate CT scanning, and rapid progression to the operating room are the most important principles in managing significant head injury when there is a space-occupying intracranial hematoma.

Maintenance of cerebral blood flow and oxygen delivery to the brain, especially in watershed areas and areas with an intracranial hematoma or edema, is the major goal of managing significant head trauma. The goal is to minimize necrotic death of neurons and astrocytes and to maximize functional outcome. Cerebral perfusion pressure (CPP) (mean arterial pressure minus intracranial pressure) must be maintained at adequate levels, although the normal CPPs of normal children are not known. Because cerebral autoregulation is altered and because every patient is different, and because we do not know the lower limit of cerebral autoregulation, arterial blood pressure should be maintained in the high-normal range for the patient's age. Recent guidelines recommend a CPP of 40mmHg in the youngest children and 65mmHg in teenagers. However, because the ICP of a given patient is not known in the acute setting, it is probably better to maintain a mean arterial pressure (MAP) of 60 in young

children and 85 in teenagers. To do this may require fluid boluses and/or vasopressors [83,84]. The former practice of hyperventilation to reduce cerebral blood flow, intracranial volume, and intracranial pressure has been demonstrated to produce cerebral ischemia in watershed areas. The goal is to maintain appropriate oxygenation and sufficient ventilation to produce a  $PaCO_2$  of 35– 40 mmHg. Only with impending brainstem herniation (unequal or unreactive pupils, decorticate or decerebrate posturing) is hyperventilation indicated, and then only until craniotomy for evacuation of the hematoma can be accomplished.

Other principles of management include providing adequate analgesia, sedation, and muscle relaxation to prevent increases in ICP; often opioids such as fentanyl, benzodiazepines such as midazolam, and nondepolarizing muscle relaxants are used in trauma resuscitation and transport to CT scan and the operating room. Figure 35.8 presents the principles of management of increased ICP in acutely brain-injured patients [85]. These agents are used during the initial craniotomy; isoflurane can be used because it provides a favorable cerebral blood flow: cerebral metabolic rate of O2 ratio. Other principles of management of acute head trauma include using isotonic IV fluids, and not giving excessive amounts because doing so increases cerebral edema. Avoiding hyperglycemia and hyperthermia is also critically important. In the presence of significant cerebral edema or impending herniation, osmotic agents, such as mannitol or hypertonic (3%) saline, can also be given. Surgical management includes craniotomy for evacuation of epidural, subdural or intracerebral hematomas, placement of ICP monitors or ventricular drains or, in severe cases, decompressive craniectomy. See Chapter 23 for a thorough discussion of these procedures and for a more complete discussion of intracranial pathophysiology (Fig. 35.9).

Spinal cord injury is dramatically different in the pediatric population than in adults. Approximately 1100 pediatric patients sustain spinal cord injury each year in the US, which represents less than 10% of all such injuries. Sixty to 80% of the injuries occur in the cervical spine. Spinal cord injury without radiographic abnormality occurs in 30–40% of pediatric patients with spinal cord injuries. Cervical spine injures are rare in patients under 3 years of age, with only 0.66% of blunt trauma patients suffering such injuries in a recent registry report of over 12,000 patients [86].

Patients under 2 years of age are prone to have cord injuries without evidence of bony injury on plain radiographs [81]. Radiographic evaluation includes plain radiographs in the trauma resuscitation room, CT scanning for more accurate diagnosis of bony and soft tissue injuries, and MRI scanning in the subacute setting. Although actual cervical spine injury is relatively uncommon in young pediatric patients, it must always be ruled out when there is evidence of head injury; most patients will have a cervical collar in place upon transfer to the trauma resuscitation area. As noted above, airway management proceeds with caution in known or suspected cervical spine injury. If the cervical collar is removed temporarily for access to the airway, flexion or extension of the spine must be avoided. Following successful tracheal intubation, the cervical collar is immediately replaced and radiographic evaluation proceeds. In the case of quadriplegia or paraplegia from high thoracic spinal cord injury, loss of sympathetic nerve tone in the arterial system may cause spinal shock, which requires treatment with fluid boluses and vasopressors. High-dose methylprednisolone (30 mg/kg plus 5.4 mg/ kg/h for 23h) is used in many centers in the face of significant spinal cord injury, but this is controversial [87,88].

#### Thoracic and cardiac trauma

Approximately 85% of major pediatric trauma is blunt trauma. Rib fractures and pulmonary contusion are seen in about 50% of thoracic trauma patients [81]. Twenty percent of patients have a pneumothorax and 10% have a hemothorax. Evaluation of these injuries is by plain radiography and CT scanning; treatment is by thoracostomy tube. Thoracotomy is rarely indicated in the acute trauma setting. A tension pneumothorax that is accompanied by severe respiratory distress, hypotension, and greatly diminished or absent breath sounds on the affected side is treated acutely by inserting a needle through the second anterior intercostal space. This is followed by insertion of a thoracostomy tube.

Cardiac and great vessel trauma is relatively rare and accounts for less than 5% of thoracic trauma cases. However, the sequelae of these injuries are severe and cannot be overlooked in major blunt trauma or penetrating chest trauma in children. In pediatric patients with cardiac trauma (myocardial contusion, coronary artery injury, aortic dissection), almost 90% have evidence of injury to other organs [89]. Premature ventricular contractions, ECG changes (such as ST segment elevation), and hypotension and shock (due to myocardial dysfunction) may be present. Plain radiography and standard CT scans may not make the diagnosis of cardiac trauma. A diagnosis of cardiac tamponade or myocardial dysfunction can be made quickly at the bedside by echocardiography. Trauma-induced cardiac tamponade is rare in children, but when it is present it is heralded by hypotension and pulsus paradoxus. These patients require emergency pericardiocentesis followed by surgical drainage and repair of the cardiac injury.

**Figure 35.8** Critical pathway for the treatment of intracranial hypertension in children following brain trauma. GCS, Glasgow Coma Scale; ICP, intracranial pressure; CPP, cerebral perfusion pressure; HOB, head of bed; CSF, cerebrospinal fluid; CT computed tomography. Reproduced from Adelson et al [85] with permission from Lippincott Williams and Wilkins.

Myocardial enzymes, such as troponin I and creatine phosphokinase myocardial band, are useful for following the progress of a myocardial injury. Thoracic CT scanning with contrast material is necessary to diagnose aortic injuries, such as dissection. Patients with cardiac trauma who require emergency non-cardiac surgery require extreme vigilance to detect and treat their myocardial dysfunction.

## **Abdominal trauma**

Abdominal injuries occur in 10–15% of major trauma cases in children. Blunt trauma accounts for 85% of abdominal injuries and MVAs account for half of the blunt trauma [81]. The spleen accounts for about 45% of intra-abominal injuries in children [90]. Other injuries include liver contusion or laceration, stomach or intestinal perforation, renal, ureteral or bladder trauma, and

**Figure 35.9** (A) Brain CT scan of acute epidural hematoma in a 3 year old after a fall from a second-story window. Note the signs of cerebral edema with effacement of the lateral ventricles, and lack of gray–white matter distinction. (B) Epidural hematoma after craniotomy and reflection of the dura in the same patient.

retroperitoneal hematoma. Abdominal pain is often diffuse, making localization of the injury difficult in pediatric patients. Plain radiography has limited utility in these patients. Bedside portable ultrasound examination using the FAST protocol (focused abdominal sonography for trauma) allows rapid scanning of all four abdominal quadrants looking for free fluid, which, if found, is evidence of major trauma, i.e. splenic rupture or liver laceration. Unfortunately, this protocol does not have adequate sensitivity and specificity, nor has its use been able to reliably guide surgical decisions in children. CT scanning of the abdomen with IV contrast material is the gold standard for diagnosing intra-abdominal trauma and must be done as rapidly as possible if there is suspicion of significant injury. Oral contrast material is often not used in the acute situation because of delays in administration and movement of the material into the entire gastrointestinal tract.

Non-operative management is the norm for intraabdominal injury in children, including most injuries to the spleen and liver. Ninety to 95% of patients are successfully treated expectantly, and it is rare to require either operative intervention or blood transfusion for isolated grade I or II injuries (a subcapsular hematoma of  $\leq$ 50% of surface area or a capsular tear of  $\leq$ 3 cm that does not involve a major vessel) [91]. Angio-embolization may be attempted in some cases, but it has had limited success in pediatric patients. Laparoscopy is often used instead of a full laparotomy in some abdominal trauma patients [92]. It may be necessary to do an open laparotomy to control major hemorrhage from vascular disruption, or for gastrointestinal perforation or other trauma not amenable to conservative treatment. If this is required, preparations should be made for major blood loss. Surgeons attempt to preserve organ function as much as possible and rarely do a splenectomy, liver resection or nephrectomy.

#### **Extremity trauma**

Trauma to the extremities can involve both bones and soft tissue and is often present in pediatric patients with multiple trauma. Although not the focus of the initial trauma survey and treatment of life-threatening problems, extremity trauma should not be overlooked. Therefore, radiographic evaluation of affected extremities is performed as soon as practical after initial evaluation and stabilization of the patient's condition. Compartment syndrome from crush injuries is a major problem that may require fasciotomies to preserve as much viable tissue as possible. In addition, release of myoglobin from crush injuries may cause renal failure. In larger patients, the possibility of a fat or air embolus should be entertained. Significant blood loss from femoral and pelvic fractures is often concealed, and the anesthesiologist must consider this fact when caring for patients with these injuries, especially if the patient is hypotensive. See Chapter 30 for further discussion of management of orthopedic injuries.

## The multiple trauma patient

Major or multiple trauma is a systemic disease. Consequently, there is a systemic response that is separate from injury to the brain, chest, abdomen or bone. Initially, a neuroendocrine stress response helps preserve blood flow to vital organs, such as heart and brain. This response may last for several days. A more prolonged inflammatory response follows and causes a syndrome that is similar or identical to the systemic inflammatory response syndrome. Manifestations of this syndrome include capillary leak, edema, multiorgan dysfunction, ARDS, disseminated intravascular coagulation, and myocardial dysfunction. When caring for trauma patients, the anesthesiologist must carefully evaluate the patient during and after the initial resuscitation and treatment to determine if these secondary problems exist. Priorities in the initial management of patients with multiple trauma include control of the airway, restoration of intravascular volume and hemoglobin to assure adequate cardiac output and tissue oxygen delivery, and operative management of life-threatening hemorrhage or intracranial pathology. Afterwards, patients can often be stabilized in the ICU, where further diagnostic evaluations are done, and/or they can be returned to the operating room for more definitive treatment [93]. See Chapter 37 for a presentation of the critical care management of multiple organ dysfunction.

## Intraoperative management of the trauma patient

The majority of pediatric patients who suffer major trauma do not require immediate anesthesia and surgery. Rather, the most frequent type of care required of anesthesiologists is airway management during the initial evaluation and treatment in the trauma resuscitation room and transport to the scanner for a 5-10-min CT scan of the brain and abdomen. Then the patient is often transported to the ICU, where further monitoring and evaluation are done and care is planned. The most common reason for immediate operative treatment is evacuation of an epidural or subdural hematoma. The next most common reason is laparotomy for major abdominal trauma. In children, simultaneous laparotomy and craniotomy are rare, as is penetrating trauma to the chest. Patients frequently present to the operating room at a later time for treatment of fractures or soft tissue injury, or for secondary surgery following initial trauma resuscitation.

Major pediatric trauma centers can evaluate, treat, and transport a patient to an operating room for surgery within 30 min of presentation to the center. It is highly desirable for the anesthesiologist to have the help of many people. Consequently, one should not hesitate to enlist surgeons, emergency room or ICU personnel to help in the OR if additional anesthesiologists are not available. The OR must be completely set up at all times with appropriate airway equipment, IV catheters, fluids, and warming devices for a variety of patients from infants to adult-sized teenagers. Pressure infusers that deliver 500 mL per minute must be available. Catheters and transducers for monitoring invasive arterial and central venous pressures must also be available. Proximity to a blood bank that has adequate personnel and can rapidly provide large amounts of packed RBCs, fresh frozen plasma, platelets, and cryoprecipitate is mandatory. If there is insufficient time to fully cross-match blood, typespecific uncross-matched blood is preferable and can be issued within 10-15 min in most centers. In an emergency situation when blood products are required in less time, O negative uncross-matched blood is used. Massive transfusion in a pediatric patient is often defined as transfusion of more than one blood volume over a 24-h period, but a more practical definition in the acute trauma setting is transfusion of 50% of the estimated blood volume in 3h. If massive transfusion with O negative blood is commenced, the anesthesiologist should continue with the O negative blood even after the patient's blood type is known, because there is always a risk that the anti-A and anti-B antibodies found in some O negative blood will cause hemolytic anemia. Some massive transfusion protocols advocate using a 1:1:1 ratio of packed RBCs, fresh frozen plasma and random donor platelets after identifying massive hemorrhage. See Chapter 11 for an extensive discussion of transfusion therapy.

The anesthesiologist's focus when providing care during acute trauma surgery should be to maintain adequate oxygen delivery to the tissues, particularly the vital organs, by maintaining adequate intravascular volume, hemoglobin concentration, cardiac output, oxygenation, and ventilation. An arterial catheter is often helpful in this setting, but precious time should not be taken to insert one of these catheters if doing so delays definitive surgical treatment, e.g. evacuation of an intracranial hematoma. Obtaining adequate large-bore peripheral IV access is a major priority. If an extremity is accessible after draping for surgery, the anesthesiologist may be able to obtain arterial access but this should not distract from the vital monitoring and treatment of hemorrhage and hemodynamic compromise. Central venous access is obtained when there is time to do so, often after the initial care. When possible, frequent point-of-care determinations of blood gases, hemoglobin, coagulation, electrolytes, ionized calcium, and lactate concentration are very valuable in guiding therapy.

A frequent question asked is what anesthetic should be used in what doses for anesthetizing the unstable hypovolemic major trauma patients. An unconscious patient with head trauma is not at risk for intraoperative awareness; resuscitation to restore adequate hemodynamic status should be the main priority. In general, synthetic opioids such as fentanyl are well tolerated by trauma patients. Providing 25–100 $\mu$ g/kg of fentanyl for major trauma is not unusual. If there is brain injury, ketamine should not be used. However, ketamine is quite useful for producing analgesia and amnesia in patients with multiple trauma who have no evidence of CNS injury. Small doses of benzodiazepines, such as midazolam, will often provide amnesia. Nitrous oxide should be avoided in trauma patients because they may have encapsulated air in the chest, abdomen or cranium that might be expanded by N<sub>2</sub>O. Isoflurane, sevoflurane, and desflurane may be used in small doses, while paying careful attention to decreases in systemic vascular resistance. Scopolamine is an amnestic agent often used in critically unstable trauma patients. Muscle relaxation during trauma surgery is essential; non-depolarizing agents that have minimal cardiovascular effects, such as rocuronium, vecuronium or *cis*-atracurium, are preferred.

Exposure, infusion of large volumes of IV fluids, and transport to scanners and performing a scan in cool environments often make trauma patients hypothermic. Consequently, the anesthesiologist must measure core temperature and warm the OR and IV fluids, use forcedair warming, humidify and warm the inspired gases, and use radiant warming devices when needed to maintain normothermia. Coagulopathy, increased systemic vascular resistance, and slow awakening from anesthesia are some of the unwanted effects of hypothermia. Every effort should be made to maintain the patient's core temperature above 35°C. Hyperthermia is also potentially dangerous to these patients because it increases oxygen demand in vital organs, particularly the brain, where it may cause hypoxia and extend the zone of infarction in watershed areas and in areas that surround injured tissue. Box 35.3 reviews the major priorities in anesthetic care of the pediatric major trauma patient.

## Outcomes of trauma care in children

As noted earlier, pediatric trauma is the leading cause of death in 1–19-year-old patients despite major efforts over the past several decades to reduce the incidence of trauma. The key to attaining optimal outcomes of major pediatric trauma is to use the multidisciplinary approach espoused by the American College of Surgeons. Formal data collection, reporting of adverse events and outcomes of trauma patients are an important part of pediatric trauma care. Fostering a culture of patient safety by measuring outcomes, rapidly studying systems and intervening when problems arise, and having regular quality improvement meetings of the entire trauma team are important for optimizing outcomes. See Chapter 45 for a discussion of multidisciplinary communication, safety, and outcomes programs.

## Acknowledgments

Portions of this chapter were previously published as "Anesthesia for plastic surgery," authors Barbara W. Palmisano and Lynn M Rusy, in *Pediatric Anesthesia*, 4<sup>th</sup> edn, edited by George A. Gregory, published by Churchill Livingstone, New York, 2002, pp. 732–41.

#### Box 35.3 Priorities for anesthesia care for major pediatric trauma

#### Airway

- Rapid assessment
- Intubate trachea for GCS ≤8 or respiratory compromise, or need for significant sedation for diagnostic studies
- Rapid or modified rapid sequence with cricoid pressure
- Use small cuffed endotracheal tube
- Remove cervical collar and use in-line stabilization for suspected cervical spine injury
- Use CO₂ detection and auscultation to confirm placement
- Initiate positive pressure ventilation cautiously to minimize compromising venous return
- For trauma: have suction, surgical airway back-up; evaluation with CT or bronchoscopy

#### Central nervous system

- Manage airway pre-emptively to ensure adequate oxygenation and ventilation
- Hyperventilate only for impending herniation
- Maintain CPP (MAP ICP) of 40–65 using volume infusion and pressors if necessary

#### Spinal cord injury

- In-line stabilization (not traction) for airway manipulation
- Anticipate and treat spinal shock: IV volume, pressors
- High-dose methylprednisolone per institutional protocol

#### Thoracic trauma

- Emergency airway intervention for significant distress
- Tube or needle thoracostomy for tension pneumothorax
- Tube thoracostomy for hemothorax
- Cardiac tamponade: pulsus paradoxus, pericardial effusion by echo
   drain emergently
- Cardiac contusion or coronary injury: PVCs, ST elevation, myocardial dysfunction
- Aortic dissection: rapid CT scan with contrast and transport to OR

#### Abdominal trauma

- Evaluation by CT, non-operative management is the norm
- Prepare for massive transfusion if operative treatment necessary

#### **Extremity trauma**

 Compartment syndrome, myoglobinuria and renal failure in crush injury

#### **Multiple trauma**

- Neuroendocrine response
- Systemic inflammatory response syndrome:
- Capillary leak
- ARDS
- Multiorgan dysfunction
- Myocardial dysfunction
- Disseminated intravascular coagulation

ARDS, acute respiratory distress syndrome; CPP, cerebral perfusion pressure; CT, computed tomography; GCS, Glasgow Coma SCale; ICP, intracranial pressure; MAP, mean arterial pressure; OR, operating room; PVC, premature ventricular contractions.

## CASE STUDY

A 3-year-old boy fell from a second-story window and was found by his mother to be moaning weakly and unresponsive. He had obvious trauma to the left side of his head. Paramedics arrived within 5 min and reported regular respirations, a heart rate (HR) of 140 beats per minute (bpm), an arterial blood pressure (BP) of 75/45 mmHg, and a GCS of 6. His SpO<sub>2</sub> was 100%. They obtained 22 G IV access in the saphenous vein, placed the patient on a backboard with a cervical collar, and transported him to the hospital with facemask oxygen. A high-level trauma activation was initiated, and the patient arrived in the trauma resuscitation area of the emergency department within 15 min of injury. The pediatric anesthesia attending and fellow responded and brought with them the trauma tackle box that contained all airway supplies and drugs required.

Upon initial assessment, the GCS remained at 6. The HR was now 160 bpm, BP 65/40 mmHg, respirations irregular, SpO<sub>2</sub> 98% breathing 100% oxygen, and the abdomen was slightly distended. The left pupil was now larger than the right. The trauma surgeon and anesthesiologist agreed that the trachea should be intubated immediately. The neurosurgeon on call arrived shortly thereafter. Quick assessment revealed that the airway would not be difficult to manage. They rapidly administered a bolus of normal saline 150 mL (based on estimated weight of 15 kg) and began preoxygenation with assisted bag and mask respiration. The anesthesiologist gave lidocaine 15 mg, etomidate 3 mg, rocuronium 30 mg, and fentanyl 15 µg IV in rapid succession. The cervical collar was removed and the head and neck stabilized by the neurosurgery resident. Cricoid pressure and gentle rapid mask ventilations were applied. Automated blood pressure measurement was set on the stat mode, and the ECG was continuously monitored. After about 1 min, the pediatric anesthesia fellow quickly intubated the trachea on the first attempt with a styletted, 4.5 mm cuffed endotracheal tube. End-tidal CO<sub>2</sub> was detected, breath sounds were equal, the tube was secured, and the cervical collar was replaced. The blood pressure decreased to 60/30mmHg and an additional 150mL of normal saline plus phenylephrine 10µg were given to increase the blood pressure, which quickly rose to 85/40 mmHg. Positive pressure ventilation was gently instituted. Because of the impending brainstem herniation, hyperventilation was commenced. The primary survey also revealed a contusion on the left flank over the costal margin and no other apparent injury. A second 22 G IV was started in the left hand, and blood was sent for type and cross-match and complete blood count. A Foley catheter was inserted; the urine was clear. Fifteen minutes after arrival, the patient was transported to the CT scanner and

was found to have a large left-sided epidural hematoma with significant midline shift and surrounding cerebral contusion and edema. Because of the abdominal trauma, a rapid CT scan of the abdomen with contrast was done, which revealed a grade II splenic laceration and subcapsular hematoma. Total time in the CT scanner was 10 min.

The patient was then transferred directly to the trauma OR, which was already set up and ready. The OR nursing trauma team was opening equipment for a craniotomy. The patient was turned and positioned, and the neurosurgeon made an incision 35 min after the patient arrived in the emergency department. A 20 G peripheral intravenous catheter was placed in the other saphenous vein during prepping and draping for surgery. Craniotomy commenced and revealed a parietal skull fracture and laceration of the middle meningeal artery. The clot was rapidly evacuated. The estimated blood loss was 500 mL, about half of his blood volume. Cerebral contusion and edema were found in the area adjacent to the epidural hematoma. For this reason, the neurosurgeon had asked that mannitol  $0.5 \,\mathrm{g/kg}$ be given, but this was deferred until the patient's hemodynamic status could be stabilized.

The initial hemoglobin concentration was 10g/dL. The anesthesiologist ordered 4 units of type-specific blood, which arrived in the OR at the same time as the patient. Two units of packed RBCs (PRBCs) were infused rapidly into the 20 G IV via a warmed pressure infuser. Two doses of calcium gluconate, 30 mg/kg, were given during the transfusion. The lowest blood pressure was 55/25 mmHg at the time of maximum hemorrhage; additional 15µg boluses of phenylephrine were given twice during the surgery. Hemorrhage was controlled and an additional unit of PRBCs was given to account for the presumed ongoing splenic bleeding. The blood pressure returned to 90/60 mmHg and the HR was 120 bpm. Despite the team's efforts, the patient became hypothermic (esophageal temperature of 34.2°C). For anesthesia, the patient received fentanyl 35µg/kg, midazolam 0.2mg/kg, and low-dose isoflurane after his hemodynamics were stable. Forced-air warming was used during the entire case.

Because there was significant cerebral contusion and edema, the neurosurgeon placed an intraventricular drain to both measure ICP and to drain cerebrospinal fluid if needed. The patient's pupils were equal at 3 mm and sluggishly reactive at the end of surgery. After hemodynamic stability was established, mannitol was given. The fellow placed a 22 G right radial artery catheter and the attending inserted a 5 Fr triple-lumen femoral central venous catheter at the end of the surgery. The trauma surgery team, which was present in the OR, decided not to operate for the splenic *Continued*  trauma at that time. The initial ICP was 15 mmHg with the patient's head positioned in the midline and elevated 30°. He was then transported to the ICU. Dopamine  $5\mu g/kg/min$  was begun just before leaving the OR.

The patient's ICU course was initially difficult. He had ICPs of 25–30 mmHg despite osmolar therapy, continuous sedation, neuromuscular blockade, moderate hyperventilation, and maintaining MAPs of 80-85mmHg with dopamine. The hemoglobin concentration was stable at 11–13 g/dL. Because the initial platelet count was 85,000 µL and the prothrombin time was 17 sec, two units of platelets and 15 mL/kg of fresh frozen plasma were given. This normalized the clotting parameters. After the neurosurgeon removed CSF to lower ICP, a CT scan revealed no new hemorrhage, but showed significant cerebral contusion plus edema in the left cerebral hemisphere, slit-like ventricles, and a significant midline shift. Because the left pupil began to dilate, the child was returned to the OR 12h after the initial craniotomy for a decompressive craniectomy, duraplasty, and debridement of some non-viable brain tissue. The ICP decreased to 15-18 mmHg. He was returned to the ICU for intensive management of his ICP, which was successful over the ensuing 5 days. However, he developed ARDS and required positive end-expiratory pressure (PEEP) as high as  $8 \text{ cmH}_2\text{O}$ , an FIO<sub>2</sub> as high as 0.70, and ventilator rates as high as 30 breaths per minute to maintain a  $PaCO_2$  of 35–40 mmHg.

Repeat CT scan of the abdomen 3 days after the injury revealed no progression of the laceration or bleeding, and

conservative management was continued. After 7 days, ICP was well controlled and the neuromuscular blockade was discontinued without any change in ICP. The ventriculostomy was removed on day 10. The lungs gradually improved, the patient was weaned from the ventilator; and the trachea was extubated on day 15. He was left with a right hemiparesis. However, he appeared to recognize his mother and reach for familiar objects with his left hand. The patient had no seizures and was transferred to the inpatient rehabilitation unit on day 19.

This case study illustrates the rapid co-ordinated team response at a level I pediatric trauma center, the principles of early airway management, preserving CPP during acute brain injury, rapid diagnosis by CT scanning and transfer to a prepared OR, and prioritizing maintenance of cardiac output and oxygen delivery during significant hemorrhage that occurred in the OR. Further principles of ICP management included dopamine to maintain CPP, mannitol to reduce cerebral edema, ventriculostomy to measure and treat elevated ICP, and early decompressive craniectomy to preserve as much viable brain tissue as possible. The conservative non-operative management of significant splenic trauma is illustrated. After a nearly 3-week ICU stay, the patient had a good neurological outcome given the severity of the injury. With inpatient and outpatient rehabilitation, the prognosis for a good functional neurological outcome is optimistic.

## Introduction

In the past 18 years, as operating room cases have increased by 250% at the Children's Hospital Boston, anesthesia services outside the operating room have increased by almost 350%, to over 7000 cases annually (Table 36.1). Sedation and anesthesia services for children have accompanied technological advances such as surgical procedures guided by intraoperative magnetic resonance imaging (MRI) or computed tomography (CT). Functional MRI studies can now localize specific areas of the brain responsible for particular actions or behaviors. Although the majority of procedures are accomplished in the radiology suite, they are now complemented by anesthesiology support in gastroenterology, pulmonology, radiation therapy and the oncology clinic (Box 36.1). Anesthesiologists have been leaders in establishing guidelines and recommendations for sedation and anesthesia services provided by both anesthesiologists and non-anesthesiologists [1-4]. In this chapter we will explore the special considerations for providing anesthesia and sedation services in various clinical areas outside the operating room and will review common organizational, equipment and personnel considerations and strategies.

## Specific extramural sites

## **Diagnostic radiology** Computed tomography scan

In the late 1970s, computed tomography (CT) was introduced into clinical practice, with the Nobel Prize awarded to its inventors in 1979. CT differentiates between highdensity (calcium, iron, bone, contrast-enhanced vascular and cerebrospinal fluid (CSF) spaces) and low-density (oxygen, nitrogen, carbon in air, fat, CSF, muscle, white matter, gray matter, and water-containing lesions) structures. Because the scan time is quick, CT may be preferable for patients who are medically unstable and in need

**Box 36.1** Multidisciplinary programs involving the Department of Anesthesiology, Children's Hospital Boston

- Advanced Fetal Care Center: Anesthesia, Cardiology, General Surgery, Genetics, Medicine, Neurology, Neurosurgery, Newborn Medicine, Otorhinolaryngology, Plastic Surgery, Radiology, Urology
- Brain Injury Program: Anesthesia, General Surgery, Neurology, Neurosurgery, Orthopedic Surgery, Psychiatry/Psychology, Sports Medicine
- Center for AeroDigestive Disorders (CADD): Anesthesia, Gastroenterology, Otorhinolaryngology Pulmonary Program
- Cleft Lip and Palate Program: Anesthesia, Audiology, Dentistry, General Surgery, Genetics, Nursing, Oral and Maxillofacial Surgery, Otorhinolaryngology, Pathology, Plastic Surgery, Psychiatry/Psychology, Social Work
- Craniofacial Anomalies Program: Anesthesia, Audiology, Dentistry, Genetics, Neurosurery, Nursing, Oral and Maxillofacial Surgery, Otorhinolaryngology, Pathology, Plastic Surgery, Psychiatry/Psychology, Social Work
- Heart Transplant Program: Anesthesia, Cardiac Surgery, Cardiology, Cardiovascular Program, General Surgery, Nutrition, Physical Therapy, Pathology, Radiology
- Intestine and Multivisceral Transplant Program: Anesthesia, Gastroenterology, General Surgery, Nutrition
- Liver Transplantation: General Surgery, Gastroenterology, Nutrition Center, Psychiatry
- Lung Transplant Program: Anesthesia, Cardiac Surgery, Cardiology, General Surgery, Psychiatry/Psychology, Respiratory Diseases
- Pain Treatment Service: Anesthesia, Physical and Occupational Therapy, Psychiatry, Rheumatology
- Trauma Program: Anesthesia, Critical Care Medicine, Emergency Medicine, General Surgery, Neurosurgery, Orthopaedic Surgery, Psychiatry/Psychology, Radiology
- Vascular Anomalies Center: Anesthesia, Cardiology, Cardiovascular Program, Dermatology, Endocrinology, General Surgery, Hematology, Medicine, Neurology, Neurosurgery, Nursing, Oncology, Oral and Maxillofacial Surgery, Otorhinolaryngology, Orthopaedic Surgery, Pathology

of rapid diagnosis, for example, the child being evaluated for abuse, altered mental status, an intracranial hemorrhage or abdominal or thoracic mass. These emergency situations usually necessitate a rapid-sequence induction with tracheal intubation.

Computed tomography scans for visualizing the sinuses, ears, inner auditory canal, and temporomandibular bones (e.g. for choanal atresia or craniofacial abnormalities) may require direct coronal imaging with extreme head extension or absolute immobility for three-dimensional (3-D) reconstruction. The more common studies involving 3-D reconstruction are cardiac, craniofacial and pulmonary (larynx, trachea, bronchi and pulmonary parenchyma) imaging. Paired inspiratory and expiratory multidetector computed tomography (MDCT) performed with general anesthesia is a relatively new technique which enables inspiratory and expiratory breath holding to evaluate tracheobronchomalacia (TBM) [5–7].

The cardiac studies are often done in collaboration with cardiologists and radiologists who are able to make structural and functional assessments of the heart. These scans can also be challenging because adenosine is often requested in order to briefly pause heart function so that image quality is maximized [8,9].

Any patient who is at risk for cervical instability should be properly screened prior to neck extension, such as children with Down syndrome, who are at risk for atlantoaxial instability. The incidence of instability varies from 12% to 32% [10]. Many children with Down syndrome require cervical spine radiographs prior to entering grade school or participating in Special Olympics. Usually, the parents are well aware of the radiological findings. The cervical spine films, however, do not predict the risk of dislocation [11]. Rather, neurological signs or symptoms such as abnormal gait, increased clumsiness, fatigue with ambulation or a new preference for sitting games are predictors of risk. The asymptomatic Down syndrome child with radiological evidence of instability may be approved for procedural sedation but unnecessary neck movement should be avoided. Any child who displays neurological signs or symptoms should not be sedated by either a nurse or an anesthesiologist until neurosurgical or orthopedic consultation is obtained.

Radiologists employ gastrografin (diatrizoate meglumine and diatrizoate sodium) when evaluating abdominal masses. Gastrografin diluted to 1.5% is usually considered a clear liquid but the volume administered orally is not insignificant: newborns less than 1 month of age receive 60–90 mL, infants between 1 month and 1 year of age may receive up to 240 mL and children between the ages of 1 and 5 years receive 240–360 mL. Because sedation or anesthesia should usually be accomplished within a window of 1–2h after ingestion of the contrast, most "elective" nil per os (NPO) guidelines would be violated, yet the scan must be completed while the gastrografin is still in the gastrointestinal tract. There are no published data to guide optimal induction or sedation techniques as they relate to aspiration risk in these circumstances. Fullstrength (3%) gastrografin is hyperosmolar and hypertonic. All gastrografin should be diluted to an isosmolar and isotonic 1.5% concentration of neutral pH. There is one case report of 1.5% gastrografin aspiration in a child [12] with no adverse sequelae; therefore, the risk of using a 1.5% concentration of gastrografin seems low [13].

## Magnetic resonance imaging

The first commercial MRI scanner was introduced in 1990. Over the past two decades MRI has evolved beyond a diagnostic tool for neoplasms, vascular malformations, masses and lesions to encompass a broader role as an aid to diagnosing and evaluating obstructive sleep apnea, developmental delay, behavioral disorders, seizures, failure to thrive, apnea/cyanosis, hypotonia, and mitochondrial/metabolic disorders. Magnetic resonance angiography and venography (MRA and MRV) evaluate vascular flow and can sometimes replace invasive catheterization studies for follow-up or initial evaluations of vascular malformations, interventional treatment or radiotherapy [14].

Functional MRI (fMRI) is an evolving technology which measures the hemodynamic or metabolic response related to neural activity in the brain or spinal cord. fMRI is often able to localize sites of brain activation and is now dominating brain mapping techniques due to its low invasiveness and lack of radiation exposure [15,16]. Some fMRI studies require cognitive facility and are typically interactive with a conscious and responsive patient. fMRI which requires patient responsiveness is generally performed in unsedated children with the aid of distraction techniques and most recently with the use of video goggles (Resonance Technology, Northridge, CA, USA). These goggles are designed specifically for fMRI and are approved for the 1.5 and 3 T environment. They are able to deliver audio and visual stimulation, measure patient response through the use of patient input devices, and track eye movement. fMRI study of sedated children is a relatively new field and those who provide sedation describe propofol and dexmedetomidine infusions as agents which can maintain spontaneous ventilation and immobility while also enabling the child to respond to verbal, tactile or auditory stimulation. fMRI studies on children who require sedation to maintain immobility will be a challenge facing anesthesiologists as we move through this decade.

Three-dimensional studies utilizing MRI have evolved in concert with CT studies. Cardiac studies, vascular imaging and airway examinations have benefited from 3-D technology. The airway studies, in particular, provide a means of diagnosing areas of airway compromise and collapse which were not identified on bronchoscopy and fluoroscopy. These studies have specific anesthetic management implications as they require that the trachea remain un-intubated and the patient breathe spontaneously in order to be able to visualize areas of collapse. The use of intravenous dexmedetomidine, among other techniques, will allow immobility, simulation of natural sleep and maintenance of spontaneous ventilation. As these children present with obstructive sleep apnea, however, the anesthesiologist must anticipate that airway obstruction can occur under sedation as it does during natural sleep [17].

Surgical procedures guided by MRI, commonly referred to as magnetic resonance therapy (MRT), have evolved over the past decade and enable surgeons to benefit from MR imaging intraoperatively. The logistical challenges with creating a surgical suite that is equipped with a MRI scanner are considerable. In addition to the routine precautions that must be taken in a typical diagnostic MRI suite, all surgical supplies and equipment must be MR safe or conditional. In general, access to this surgical suite is restricted to personnel fluent in MR safety procedure and guidelines. MRT is currently being used for neurosurgery to guide the resection of tumors, seizure foci and vascular malformations [18]. Additional applications have extended its use to otolaryngological, general surgery and orthopedic procedures [19].

The MRI environment is unique because of its strong static magnetic field, high-frequency electromagnetic (radiofrequency, RF) waves and a pulsed magnetic field. Magnetic field strengths are measured in units of gauss (G) and tesla (T). One tesla is equal to 10,000 gauss. The main magnetic field of a 1.5 T magnet is about 30,000 times the strength of the earth's magnetic field. The main magnetic field of a 3 T system is 60,000 times the earth's magnet field. To put this into context, the strength of electromagnets used to pick up cars in salvage yards is equivalent to the strength of a 1.5-2.0T magnet. This field strength is able to transform static oxygen cylinders into flying projectiles which can travel at speeds approaching 40 miles per hour. The American College of Radiology established guidelines to minimize the risk of MRI-related mishaps [20] but did not directly address anesthesiologists' unique needs. In 2008 the American Society of Anesthesiologists (ASA) assembled a task force composed of anesthesiologists, a radiologist with MRI expertise, and two methodologists; a Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging followed [21]. This document establishes important recommendations for safe practice as well as consistency of anesthesia care in the MRI environment. In 2008, the Joint Commission recognized the existing and potential hazards of the MRI environment when they published a Sentinel Event Alert [22] specifically identifying eight types of possible injury (Box 36.2).

**Box 36.2** The Joint Commission Sentinel Event Alert. Preventing accidents and injuries in the MRI suite

- "Missile effect" or "projectile" injury in which ferromagnetic objects (those having magnetic properties) such as ink pens, wheelchairs, and oxygen canisters are pulled into the MRI scanner at rapid velocity.
- **2.** Injury related to dislodged ferromagnetic implants such as aneurysm clips, pins in joints, and drug infusion devices.
- 3. Burns from objects that may heat during the MRI process, such as wires (including lead wires for both implants and external devices) and surgical staples, or from the patient's body touching the inside walls (the bore) of the MRI scanner during the scan.
- 4. Injury or complication related to equipment or device malfunction or failure caused by the magnetic field. For example, battery-powered devices (laryngoscopes, microinfusion pumps, monitors, etc.) can suddenly fail to operate; some programmable infusion pumps may perform erratically; and pacemakers and implantable defibrillators may not behave as programmed.
- 5. Injury or complication due to failure to attend to patient support systems during the MRI. This is especially true for patient sedation or anesthesia in MRI arenas. For example, oxygen canisters or infusion pumps run out and staff must either leave the MRI area to retrieve a replacement or move the patient to an area where a replacement can be found.
- Acoustic injury from the loud knocking noise that the MRI scanner makes.
- 7. Adverse events related to the administration of MRI contrast agents.
- **8.** Adverse events related to cryogen handling, storage or inadvertent release in superconducting MRI system sites.

As technology has advanced, 1.5 T magnets have been supplanted by 3 T magnets. The field strength and magnetic force generated by a 3 T MRI scanner are unforgiving to the careless or accidental introduction of a ferrous object into the environment. Placing a magnet outside the MRI scanner is a crude, helpful and sometimes inaccurate way to test objects. If the object is not attracted to the magnet, this is not an absolute indication that there is no ferrous material present. A positive attraction, however, will provide critical information to the anesthesiologist. Some unusual objects which have found their way into the MRI suite in order to become projectiles include a metal fan, pulse oximeter, shrapnel, wheelchair, cigarette lighter, stethoscope, pager, hearing aid, vacuum cleaner, calculator, hair pin, oxygen tank, prosthetic limb, pencil, insulin infusion pump, keys, watches, and steeltipped/heeled shoes [23]. Small objects can usually be easily removed from the magnet; large objects may have so much attractive force with the MRI scanner that they are impossible to remove by manual force. In these circumstances, quenching the magnet may be the only way

#### Box 36.3 MRI safety zones

**Zone I:** This region includes all areas that are freely accessible to the general public. This area is typically outside the MR environment itself and is the area through which patients, healthcare personnel, and other employees of the MR site access the MR environment. *Access*: General public.

**Zone II:** This area is the interface between the publicly accessible uncontrolled zone I and the strictly controlled zone III (see below). Typically, the patients are greeted in zone II and are not free to move throughout zone II at will, but rather are under the supervision of MR personnel. It is in zone II that patient histories, answers to medical insurance questions, and answers to MRI screening questions are typically obtained. Access: Unscreened MRI patients.

**Zone III:** This area is the region in which free access by unscreened non-MR personnel or ferromagnetic objects or equipment can result in serious injury or death as a result of interactions between the individuals or equipment and the MR scanner's particular environment. These interactions include, but are not limited to, those with the MR scanner's static and time-varying magnetic fields. All access to zone III is to be strictly restricted, with access to regions within it (including zone IV; see below) controlled by, and entirely under the supervision of, MR personnel. *Access:* Screened MRI patients and personnel.

**Zone IV:** This area is the MR scanner magnet room. Zone IV, by definition, will always be located within zone III because it is the MR magnet and its associated magnetic field which generate the existence of zone III. *Access:* Screened MRI patients under constant direct supervision of trained MR personnel.

Source: Kanal et al [20].

to release the object. This process is not without substantial risk: as helium gas is vented, condensation and considerable noise fill the suite. All personnel are required to vacate the suite during a quench as there is a risk of hypoxic conditions should the helium accidentally enter the room. The establishment of safety zones in the MRI environment addresses restrictions to access of the MRI environment [20] (Box 36.3). Because the 3 T and 1.5 T scanners have different magnetic field strengths, an object which is safe in a 1.5 T magnet is not necessarily safe in a 3 T magnet. MRI safety labeling is specific for magnetic field strength.

As advances have been made in MRI technology as well as clinical experience, there has been a parallel evolution in labeling practices from the initial standards established by the Food and Drug Administration in 1997 to the current standard for labeling equipment established by the American Society for Testing and Materials (ASTM) International in 2005 [24] (Table 36.2).

Personal risks in the MRI environment apply to anesthesiologists and patients. Anesthesiologists must be aware

Table 36.2	Current	terminology	used to	label	implants	and	devices
------------	---------	-------------	---------	-------	----------	-----	---------

	Old terminology (1997)	New terminology (2005)	Icon label
	Food & Drug Administration	American Society for Testing and Materials (ASTM) International	
MR safe	The device, when used in the MRI environment, has been demonstrated to present no additional risk to the patient or other individual, but may affect the quality of the diagnostic information. The MRI conditions in which the device was tested should be specified in conjunction with the term MR safe since a device which is safe under one set of conditions may not be found to be so under more extreme MRI conditions	An item that poses no known hazards in all MRI environments. Using the new terminology, "MR safe" items include non-conducting, non-metallic, non- magnetic items such as a plastic Petri dish. An item may be determined to be MR safe by providing a scientifically based rationale rather than test data.	'MR' in green in a white square with a green border, or the letters 'MR' in white within a green square.
MR compatible	A device shall be considered "MR compatible" if it is MR safe and the device, when used in the MRI environment, has been demonstrated to neither significantly affect the quality of the diagnostic information nor have its operations affected by the MR system. The MRI conditions in which the device was tested should be specified in conjunction with the term MR safe since a device which is safe under one set of conditions may not be found to be so under more extreme MR conditions. Using this terminology, MRI testing of an implant or object involved assessments of magnetic field interactions, heating, and, in some cases, induced electrical currents while MR compatibility testing required all of these as well as characterization of artifacts	No longer applies	
MR conditional		An item that has been demonstrated to pose no known hazards in a specified MRI environment with specified conditions of use. Field conditions that define the MRI environment include static magnetic field strength, spatial gradient, dB/dt (time-varying magnetic fields), radiofrequency (RF) fields, and specific absorption rate (SAR). Additional conditions, including specific configurations of the item (e.g. the routing of leads used for a neurostimulation system), may be required. In particular, testing for items that may be placed in the MRI environment should address magnetically induced displacement force and torque, and RF heating. Other possible safety issues include, but are not limited to, thermal injury, induced currents/voltages, electromagnetic compatibility, neurostimulation, acoustic noise, interaction among devices, and the safe functioning of the item and the safe operation of the MR system	'MR' in black inside a yellow triangle with a black border. Item labeling must include results of testing sufficient to characterize the behavior of the item in the MRI environment.
MR unsafe		An item that is known to pose hazards in all MRI environments. MR unsafe items include magnetic items such as a pair of ferromagnetic scissors	MR' in black on a white field inside a red circle with a diagonal red band

of many personal items taken for granted - clipboards, pens, watches, scissors, clamps, credit cards, eyeglasses, paper clips, etc. [25-27]. MRI safety issues include implanted objects (i.e. cardiac pacemakers), ferromagnetic attraction creating "missiles," noise, biological effects of the magnetic field, thermal effects, equipment issues, and claustrophobia. Some stainless steel may contain ferritic, austenitic, and martensitic components [28–30]. Martensitic alloys contain fractions of a crystal phase known as martensite, which has a body-centered cubic structure, is prone to stress corrosion failure and is ferromagnetic. Austenite is formed in the hardening process of low carbon and alloyed steels, and has ferromagnetic properties. Iron, nickel, and cobalt are also ferromagnetic. For this reason, the components of any implanted device should be carefully researched prior to entering the magnet. Stainless steel or surgical stainless objects interacting with an external magnetic field may produce translational (attractive) and rotational (torque) forces. Intracranial aneurysm clips, cochlear and stapedial implants, shrapnel, intraorbital metallic bodies, and prosthetic limbs may move and potentially dislodge. Special precautions should be taken with cochlear implants in the 3 T environment as those non-removable magnets may suffer demagnetization in the scanner [31]. Some eye make-up and tattoos may contain metallic dyes and therefore cause ocular, periorbital and skin irritation [32,33]. Some tissue expanders employed in reconstructive surgery have a magnetic port to help identify the location for intermittent injections of saline [34]. Bivona® tracheostomy tubes (Smiths Medical, Kent, United Kingdom) usually contain ferrous material (although not specified in the package insert) and should be replaced with a Shiley® tracheostomy tube (Covidien-Nellcor, Boulder, CO, USA) prior to entering the MRI environment. Recognizing the unique hazard posed by the MRI environment, in 2008 the Joint Commission issued a Sentinel Event Alert [22].

Cardiac pacemakers present a special hazard in and around the MRI scanner, especially in patients who are pacemaker dependent. Most pacemakers have a reed relay switch that can be activated when exposed to a magnet of sufficient strength [35]. This activation could convert the pacemaker to the asynchronous mode. There are at least two known cases of patients with pacemakers who died from cardiac arrest while in an MRI scanner. The autopsy of one patient determined that the death was the result of an interruption of the pacemaker in the magnetic environment [36]. In addition to the risk of pacemaker malfunction, there is also the chance that torque on the pacer or pacing leads may create a disconnect or microshock [37]. Recent studies demonstrate that with careful preparation, select patients with permanent pacemakers and implantable cardioverter-defibrillators may safely undergo imaging in the 1.5 T environment without any inhibition or activation of their device [38]. Patients with implanted cardiac pacemakers or cardioverterdefibrillators should only be scanned in locations staffed with radiologists and cardiologists of appropriate expertise [20]. In general, MRI should not be performed on patients with implanted electronic devices. When MRI is considered essential by the referring physician and consulting radiologist, a plan for managing these patients during the scan should be developed in collaboration with the ordering/referring physician, medical director or on-site radiologist and other appropriate consultants (e.g. the patient's pacemaker specialist or cardiologist, or device manufacturer). For implanted pacemakers and implantable cardioverter-defibrillators, it is anticipated that the cardiologist will be physically available during the scan in case the device malfunctions [21]. Following the MRI, a cardiologist should confirm function of the device and recheck it within 1-6 weeks.

The biological effect of MRI should be considered when offering parent-present induction to a parent who is pregnant. To date, there is no evidence to support the risk of MRI-caused chromosomal aberrations in humans. Studies in amphibians demonstrate that exposure to a 4 T magnetic field does not cause any defects in embryological development [33]. Most institutions do not routinely allow pregnant women to accompany their children into the MRI scanner. MRI scans during pregnancy are discouraged by the American College of Radiology during the first and second trimesters, unless fetal imaging is required or the MRI is necessary for emergency medical care [39].

Some patients experience claustrophobia and have difficulty co-operating during the study. Anxiety reactions [40] are estimated to occur in 4–30% of patients [41]. Patients with extreme skeletal abnormalities such as advanced scoliosis or flexion contractures, although motivated, may be unable to lie motionless or supine on the solid, uncushioned MRI table for the extended duration of a spine MRI. These patients may require general anesthesia for positioning and comfort or may need adjunctive pain medication.

Current advances in physiological monitors and anesthesia machines for the MRI environment have optimized the ability of the anesthesia care provider to provide safe care in the MRI suite. Remote monitor displays make it unnecessary for the anesthesiologist to remain in the scan room during most of the procedure; only during breath-holding procedures or contrast injection is it necessary for the anesthesiologist to enter the scanner room during the imaging procedure. The Dräger Fabius® anesthesia machine (Dräger Medical AG, Lubeck, Germany) was designed for use with MRI and approved by the FDA in 2008 for use within both a 1.5 T and 3 T magnetic field up to field strength of 400 gauss (Fig. 36.1). The Fabius, equipped with two vaporizers, has an electronically controlled ventilator capable of delivering multiple modes of ventilation in the MRI suite.

Advances in physiological monitoring now offer the ability to monitor electrocardiogram and pulse oximetry in a 1.5 T and 3 T MRI scanner via wireless, fiber-optic communication (Invivo Precess®, Invivo, Orlando, FL and Medrad Veris® Monitor, Indianola, PA) (Fig. 36.2). Conventional electrocardiogram (ECG) monitoring is not possible because as the lead wires traverse the magnetic

**Figure 36.1** (A) Modern MRI-compatible anesthesia machine, with two vaporizers and ventilator capable of multiple ventilation modes. This system is certified for function in 1.5 and 3 T MRI systems. The machine must be situated outside the 400 gauss magnetic field radius for proper functioning. fields, image degradation occurs and, most important, the ECG leads will heat and cause patient burns. Fiber-optic ECG monitoring is necessary to minimize the risk of patient burn. Even with fiber-optic cables, it is important to recognize that the connections between the ECG pads and the telemetry box are still hard-wired, and careful attention must be paid to prevent frays, overlap, exposed wires and knots in the cables [42]. It is advisable to provide an interface between the patient's skin and the ECG leads (face cloth). There have been reports of burns from the ECG leads as a result of a current generated between the leads and the patient's sweat. Pulse oximeters are also fiber-optic. Failure to remove the conventional pulse oximeter probe/adhesive has resulted in second- and third-degree burns [42,43]. Respiratory and anesthetic gas monitoring has advanced to the point that complete monitoring, as would occur in the operating room, is now routine with MRI-compatible equipment. For patients with a natural airway, a divided nasal cannula, both to administer supplemental oxygen and to monitor end-tidal CO<sub>2</sub> to detect airway obstruction and to ensure optimal ventilation, is important [44].

Despite the advancing technology in physiological monitors and anesthesia equipment, the MRI environment continues to pose some limitations for anesthesia care. Core temperature monitoring cannot be monitored in the MRI scanner – surface (skin) temperature monitoring cables are available but axillary temperature may not be an adequate substitute for rectal or esophageal temperatures. There are no MRI-conditional nor safe fiberoptic bronchoscopes; difficult airway management must occur outside the MRI scanner room at a safe distance from the magnet.

The advent of special MRI-compatible infusion pumps for agents such as propofol allows the pump to be deployed in the scan room itself, with short tubing lengths to allow accurate delivery of the intended drug or fluid dose. These pumps include the MRIdium® (iRadimed Corp., Winter Park, FL, USA), and Medrad Continuum Infusion System® (Warrendale, PA, USA) (Fig. 36.3). These pumps have remote consoles so that the infusion rates can be changed from the MRI control room via wireless communication algorithms. Although some conventional infusion pumps (Medfusion® 3500 syringe pump, Smiths Medical, Kent, United Kingdom) claim safety in an MRI environment beyond specified distances from the magnet, depending on magnet strength, it is not recommended that these devices be used in the scanner room. Besides the MRI safety aspect, the magnetic and radiofrequency fields can cause pump malfunction in standard systems. An alternative is to utilize standard infusion pumps just outside the door of the scanner room, with multiple lengths of infusion tubing threaded under the door, reaching inside the bore of the scanner to the patient.

**Figure 36.2** Modern MRI-compatible monitor, situated in MRI scanner room. These monitors are capable of monitoring ECG, SpO<sub>2</sub>, oscillometric blood pressure, end-tidal CO<sub>2</sub> via nasal cannula, endotracheal tube, or laryngeal mask airway, anesthetic gases, temperature, and two invasive blood pressures. (B) Remote display in control room. (C) Wireless technology for ECG and SpO<sub>2</sub> which minimizes artifacts and allows accurate signal transmission. (D) Close-up of monitor screen with all parameters displayed. Courtesy Invivo Corp., Orlando, FL, USA.

This is commonly used for patients receiving vasoactive infusions requiring very accurate microinfusion pumps. Problems with this approach include increased resistance through the long tubing causing pump malfunction.

The magnetic field may also affect the ECG. The changes in the T-wave are not due to biological effects of the magnetic field but rather to superimposed induced voltages. This effect of the magnetic field on the T-wave is not related to cardiac depolarization, since no changes to the P, Q, R or S wave have ever been observed in patients exposed to fields up to 2 T. There are no reports of MRI affecting heart rate [45], ECG recording [46], cardiac contractility [47] or blood pressure [48]. One study, however, found that humans exposed to a 2 T magnet for 10 min developed a 17% increase in the cardiac cycle length (CCL, the duration of the R-R interval). The CCL reverted

Figure 36.3 (A) MRI-compatible infusion pump in scan room, with propofol infusing in a 7 kg infant. (B) Remote wireless display and controller.

to pre-exposure length within 10min of removing the patient from the magnetic field [49]. The implications of this finding are unclear. While this change in patients with normal hearts may be of no consequence, the implications of this finding in patients with fragile dysrhythmias or sick sinus syndrome have yet to be determined.

Average noise levels of 95 decibels (dBA) have been measured in a 1.5 T MRI, comparable to noise levels of very heavy traffic (92 dBA) or light road work (90-110 dBA). Exposure to this level of noise has not been considered hazardous if limited to less than 2h per day [50]. There are case reports, however, of both temporary [51] and permanent [52] hearing loss after an MRI scan. 3 T magnets offer the advantage of less image degradation and improved neuro- and musculoskeletal imaging. However, as the field strength increases, so does the noise [53]. In fact, the peak sound pressure level of a 3 T magnet exceeds 99 dBA, the level approved by the International Electrotechnical Commission. Ear protection is required for all patients undergoing MRI studies for research purposes [20]. Earplugs or MRI-compatible headphones are strongly encouraged for all patients and personnel (family members included) who remain in the 3 T magnet during imaging. fMRI provides additional challenges in the 3 T environment: the noise of the 3 T can interfere with the acoustic stimulation generated for purposes of obtaining the fMRI [54,55].

Although studies in mice [56] and dogs [57] suggest that exposure to magnetic fields may increase body temperature, it is unlikely that static magnetic fields up to 1.5 T have any effect on core body temperature in adult humans [58]. This may be of greater concern in infants and small children, for example in cardiac MRI studies which require a long time [59]. The specific absorption rate (SAR) is measured in watts/kg and is used to follow the effects of radiofrequency heating. The FDA allows a SAR of 0.4 W/kg averaged over the whole body [60]. Ex vivo exposure of large metal prostheses to fields over six times that experienced in MRI have not revealed any appreciable heating [61]. So far, there has been no conclusive evidence that RF is a significant clinical issue in magnets up to 3 T. Conversely, the need for a cool room to ensure functioning of the MRI scanner and the lack of MRI-compatible forcedair warming systems, combined with the frequent need for small infants to undergo MRI scanning, frequently results in hypothermia. Often the best prevention is to swaddle the infant in warmed blankets before the procedure to minimize heat loss, and utilize a condenser humidifier if an endotracheal tube or laryngeal mask airway (LMA) is used to manage the airway.

Intravenous gadopentetate dimeglumine (gadolinium) is used to enhance MRI images. With an elimination half-life of 1.3–1.6h, gadolinium is excreted via the kidneys after forming a complex with chelating agents

**Figure 36.4** Macrocystic lymphatic malformation of the neck and right upper extremity, treated with direct injection of ethanol and then four sessions of OK-432 injection. The ethanol injections were ineffective, but the OK-432 resulted in complete regression of the mass. (A) Clinical photograph before OK-432 sclerotherapy shows a large focal right neck mass. (B) Axial CT scan after intravenous contrast medium injection shows macrocysts in the right neck. The thick-walled cyst was previously injected with ethanol. (C) Clinical photograph taken 1 year after four injections of OK-432 shows complete regression of the right neck mass. Reproduced from Burrows and Mason [214] with permission from Lippincott Williams and Wilkins.

[62]. Adults and children have similar elimination halflives with 95% excreted within 72h [63]. Because gadolinium does not contain iodine, it does not produce an osmotic load [64]. Important warnings from the FDA suggest that patients with advanced kidney failure are at risk of developing nephrogenic systemic fibrosis (NSF) or nephrogenic fibrosing dermopathy (NFD) after gadolinium-based MR contrast agents. The FDA first notified healthcare professionals and the public about this risk in June 2006. The American Society of Anesthesiologists MRI Advisory Panel concluded that the anesthesiologist should not administer gadolinium to patients with acute or severe renal insufficiency because of the elevated risk of nephrogenic systemic fibrosis. Rather, the need for and actual administration of gadolinium contrast in this patient group should be the responsibility of the radiologist, nephrologist, and other appropriate consultants [21].

# Interventional radiology and angiography

Interventional techniques include non-vascular and vascular intervention [65]. Embolization and sclerotherapy are utilized for treating vascular malformations, aneurysms, fistulas, and hemorrhage as well as accomplishing renal ablation and presurgical embolization of hypervascular masses. Percutaneous transluminal angioplasty and fibrinolytic therapy are emerging techniques in pediatric institutions. Even in the smallest babies, great success is being reported, and the important contribution that adequate sedation and analgesia can make to ultimate outcome has been recognized [66].

Vascular malformations are congenital aberrant connections between blood vessels and may be composed of lymphatic, arterial, and venous connections (Fig. 36.4). These lesions, present at birth, are often discrete and not clearly visible, although they may expand rapidly, growing with the child. This rapid proliferative phase may occur in response to hormonal changes (pregnancy, puberty), trauma, or other stimuli [67]. Moreover, they may be high-flow or low-flow lesions, depending on which vessels are involved. High-flow lesions include arteriovenous fistulas, some large hemangiomas, and arteriovenous malformations. High-output cardiac failure and congestive heart failure with possible pulmonary edema should be anticipated, especially with high-flow lesions. Low-flow lesions consist of venous, intramuscular venous, and lymphatic malformations.

Because vascular malformations enlarge over time, even asymptomatic lesions may require intervention. Symptomatic patients may suffer from pain, tissue ulceration, disfigurement, airway or cardiovascular compromise, impairment of limb function, coagulopathy, claudication, hemorrhage, and progressive nerve degeneration or palsy. Because large vascular lesions require multiple embolizations, parents and patients are often comforted by seeing familiar faces, another benefit of having a team of anesthesiologists staffing the radiology suites. Vascular embolization can be used as a bridge to surgical resection.

Large hemangiomas may be associated with the coagulopathy of Kasabach–Merritt syndrome. In this condition, the hemangioma traps and destroys platelets and other coagulation factors, resulting in thrombocytopenia and an increased risk of bleeding. As the hemangioma involutes, the coagulation status improves [68]. A condition described as systemic intravascular coagulation (SIC) can occur after the embolization of extensive vascular malformations. This condition is marked by an elevated prothrombin time (PT) with a decrease in coagulation factors and platelets.

When embolizing vascular malformations, radiologists often aim to cut off not only the feeding vessels but also the central confluence (nidus) where much of the arterial shunting occurs. Embolic agents include stainless steel mini-coils, absorbable gelatin pledgets and powder, detachable silicone balloons, polyvinyl alcohol foam, cyanoacrylate glue, and ethanol. The choice of agent depends on the clinical situation and the size of the blood vessel. When permanent occlusion is the goal, polyvinyl alcohol foam and ethanol are often employed. Both occlude at the level of the arterioles and capillaries. Medium to small-sized arteries may be occluded with coils, which are the equivalent of surgical ligation. Particularly in trauma situations, when only temporary (days) occlusion is the goal, absorbable gelatin pledgets or powder are used [69].

Absolute ethanol is injected into vascular malformations to promote sclerosis. Sclerotherapy or embolization with absolute (99.9%) ethanol increases the risk of developing a postprocedure coagulopathy [70] marked by positive d-dimers, elevated PT and decreased platelets. Ethanol causes thrombosis because it injures the vascular endothelium [71]. It also denatures blood proteins. Extensive ethanol injections can cause hematuria and urinary catheters should be inserted to monitor urine output, diuresis, and hematuria. Liberal intravenous fluid replacement will ensure that the hematuria clears prior to discharge. Ethanol can cause neuropathy and tissue necrosis if not injected selectively. Finally, ethanol can also produce significant serum alcohol levels (Fig. 36.5). Up to 1mL/kg of ethanol can be administered; blood ethanol levels have been greater than the intoxication level of 0.008 mg/dL [72]. Patients with high serum ethanol levels are either sedated or extremely agitated, depending on their individual response to intoxication.

Embolization or balloon occlusion of arterial venous malformations (AVM), vascular tumors, intracranial

**Figure 36.5** Graph shows the positive relationship between serum ethanol level and amount of ethanol administered. Solid line indicates the theoretic curve, where x is the amount of ethanol administered, and y is the predicted serum ethanol level. Triangles represent empirical values. Reproduced from Mason et al [72] with permission from the Radiological Society of North America.

aneurysms and fistula carries considerable risk of catastrophic results. Such risks include a sudden intracranial hemorrhage, acute cerebral ischemia, or catheter or balloon migration. If sedated, the patient may require urgent airway management. Very long cases require a urinary catheter, especially if contrast material is utilized. AVMs involving the head and neck frequently require cannulation of the external carotid artery branches and the thyrocervical trunk. All patients scheduled for embolization should be typed and cross-matched for blood. Those patients who undergo embolization of AVMs of the head and neck are at risk for stroke, cranial nerve palsies, skin necrosis, blindness, infection, and pulmonary embolism [73]. It is important to assess and document the full return of baseline neurological status after the patient is extubated.

Recent advances over the past decade have involved the use of provocative testing during cerebral imaging in order to identify and protect targeted areas of the brain prior to embolization. Provocative or superselective Wada testing has become an important part of endovascular management of numerous extracranial and intracranial vascular conditions. It can be used with neurophysiological monitoring in cases in which patient co-operation and steadiness are important [74]. Nevertheless, the value of awake neurological assessment (wake-up test) cannot be overestimated when neurophysiological monitoring responses are equivocal. Barbiturates, etomidate and, most recently, propofol have been described as agents able to maintain sedation while still preserving the patient's ability to respond [75–79].

Cerebral angiography requires motionlessness as well as exquisite control of ventilation. Anesthetic technique, in choice of agent as well as in control of arterial CO<sub>2</sub> tension, may affect cerebral blood flow and volume and hence the quality of the scan. Cerebral angiography in children may be performed for the diagnosis or follow-up of moya moya disease and the anesthetic technique should minimize the risk of transient ischemic attacks (TIA) and stroke during the procedure [80]. Other considerations include controlled ventilation to facilitate access to and visualization of the vasculature for the radiologist. In the event of vasospasm or difficult access, the radiologist's direct administration of nitroglycerin in small doses (25–50µg) may facilitate visualization and access. Occlusion of the venous portion of the AVM without complete occlusion of the arterial inflow vessels could result in acute swelling and bleeding. Vascularity reduction through occlusion of major feeder vessels is the goal of embolizing large AVMs prior to planned surgical excision. This may be accomplished as a staged procedure over several days, involving repeat anesthetics.

Angiographic imaging may be enhanced through the use of glucagon. Glucagon is effective for digital subtraction angiography, visceral angiography and selective arterial injection in the viscera. When needed, glucagon is administered in divided doses of 0.25 mg to a maximum of 1.0 mg intravenously. Risks include glucagon-induced hyperglycemia, vomiting (particularly when given rapidly), gastric hypotonia, and provocation signs of pheochromocytoma [81–83]. Children who receive glucagon should routinely receive prophylactic antiemetics.

#### Ultrasound-directed procedures

Needle biopsies and drainage procedures (kidney, liver, lung, muscle, unknown mass, unknown fluid) are directed with ultrasound guidance. Ultrasound is useful for placement of difficult central catheters (CVL) and peripherally inserted central catheters (PICC lines). The requirement for general anesthesia versus sedation for ultrasoundguided procedures depends in part on the duration of the procedure, the location involved, the risks associated with the procedure and any procedural requirements. The need for controlled ventilation with breath holding may require an endotracheal tube and general anesthesia. Associated secondary effects of the end-organ disease must be kept in mind in the overall anesthetic care plan.

# Nuclear medicine

Nuclear medicine is one of the oldest functional imaging disciplines. These scans are useful for identification of epileptic foci in refractory epilepsy, evaluation of cerebrovascular (moya moya) disease and cognitive and behavior disorders [84]. Anesthesiologists become involved when the child's medical history suggests that procedural sedation would not be appropriate. In order to complete these scans, the child must remain motionless for at least 1 h.

The two most common nuclear medicine studies that require the administration of an anesthetic are single photon emission computed tomography (SPECT) and positron emission tomography (PET) scans. SPECT scans use single photon  $\gamma$ -emitting radio-isotopes and rotating γ-cameras to produce three-dimensional brain images. SPECT scans involve the use of radiolabeled technetium-99 (half-life, 6h), which has a high rate of first-pass extraction as well as intracellular trapping in proportion to regional cerebral blood flow [85]. This scan is ideal when seeking seizure foci, and often precedes surgical resection of the identified focus. The technetium radionuclide is ideal because it remains intracellular and can be visualized on scan hours after a seizure has occurred. Ideally, the child should be scanned within 1-6h of the seizure. The radionuclides are physiologically harmless and nonallergenic. Caretakers should, however, wear gloves to minimize contact with radiation-containing secretions.

Positron emission tomography scans use PET and radionuclide tracers of metabolic activity such as oxygen or glucose metabolism [86,87]. Unlike SPECT scans, PET scans should be performed during the seizure itself. Because of the short half-life of the glucose tracer (110 min), the scan is best completed during the seizure or within 1 h thereafter.

In addition to using PET scans for diagnostic purposes, nuclear imaging is also being used as an intraoperative adjunct to identify neoplasms, in much the same way that MR imaging has been incorporated into the surgical suite. Surgical suites are currently being equipped with PET scanners [88]. The anesthetic implications of the nuclear medicine environment involve largely the safety precautions that must be implemented with respect to the radio-active nuclide. All bodily fluids (includes saliva, sweat, urine) must be handled with radiation safety precautions.

# **Radiation oncology**

Radiation oncologists use ionizing photons to destroy lymphomas, acute leukemias, Wilms tumor, retinoblastomas and tumors of the central nervous system in children. Repeat sessions are typical, requiring reliable motionlessness in order to precisely aim the beam at malignant cells while sparing healthy cells. A planning session in a simulator is often scheduled prior to the initiation of radiation therapy so that fields to be irradiated can be plotted and marked. Radiation therapy is usually very brief and non-painful. The key issue is the anesthesiologist's limited access to the patient. Remote video monitoring as well as ECG and pulse oximeter use are crucial. Two or in some locations three video cameras are used to look at the monitors, the chest, and the face of the patient. Central access in young children helps immensely. It is important to remember that babies undergoing radiation therapy following a prolonged fast are at risk for hypoglycemia; delayed awakening or tremulousness should prompt a glucose determination.

Fractionated radiation therapy divides the total radiation therapy course into discrete daily sessions, allowing normal tissue repair between sessions while the tumor burden is lessened or destroyed. Hyperfractionated or multiple-session daily radiation therapy is a modality reported primarily in adults for head and neck cancer. The rationale for twice-daily fractionation in children is that fractionation to growing bone in rats reduces the growth deficit by 25–30%; the hope is that other normal tissues may be similarly spared during growth [89,90]. While one successful approach has been to give infants an initial formula feed 6h before their first treatment and keep them NPO until recovery from their second anesthetic 6h after the first [91], with the current liberalization of NPO guidelines we prefer to give children clear liquids during their recovery from the first anesthetic and keep them NPO thereafter for 4h prior to the second anesthetic.

Stereotactic radiosurgery ( $\gamma$ -knife) is a major advance in the treatment of selected intracranial AVMs and tumors in children [92]. A focused single large fraction of radiation is used instead of smaller, daily fractions. Stereotactic radiosurgery uses relatively weak intensity  $\gamma$ -rays produced by 201 cobalt-60 (60Co) sources which intersect at a single point where all 201 beams converge to destroy tumors, vascular malformations or abnormal tissue sites within the brain. Normal brain tissue surrounding the abnormality is therefore relatively protected from radiation effects. For optimal results, tumor volume ideally has to be small ( $\leq$ 14 cm<sup>3</sup>) [93].

The stereotactic procedure begins with a CT scan or MRI, followed by computer calculations for dose and the three-dimensional co-ordinates for the beam. The child is placed in a stereotactic head frame which is screwed into the cranium. Most adults are able to tolerate the entire procedure with local anesthesia or sedation. Adults and older children who tolerate this procedure with sedation alone may vomit as a result of the anxiety, the headache or the location of the tumor itself. Once the calculations are complete, the patient is transferred to the radiosurgery suite. Following the irradiation, the patient is allowed to emerge from the anesthetic [92]. The most common perioperative problem is nausea and vomiting, probably due to radiation sensitivity of the chemoreceptor trigger zone. Because the head frame is heavy and cumbersome, it is difficult for the vomiting patient to turn his or her head in order to protect his or her airway. Children (including most adolescents) typically require a general anesthetic. General anesthesia with tracheal intubation is induced prior to placement of the head frame. The key for removal of the head frame is taped to the frame itself. A nasogastric tube is placed for the day's anesthetic.

Stereotactic radiation therapy is more precise localization of the fractionated radiation dose over the same duration of time as conventional radiation therapy, with the adjunctive use of a head frame. Considerations for the head frame include ease of application, reliability, ability to deliver supplemental oxygen and support the airway with a facemask if needed, and rapid removal of the facial restraint should it become necessary.

Total body irradiation (TBI) is generally performed twice a day over a 6-week period, usually in preparation for a bone marrow transplant. As these patients progress with their TBI treatment and become more immunocompromised, there is an increased risk of acquiring an illness during the course of treatment. Vomiting, respiratory illness, poor nutrition or hypovolemia are all possible. Cancellation of a TBI treatment because of an associated illness is discouraged because it disrupts the course of treatment and could compromise the patient's overall prognosis. Ondansetron in combination with dexamethasone or propofol has been found to be beneficial as a prophylactic for nausea and vomiting in children undergoing TBI and should be considered for first-line antiemetic therapy [94]. Although anesthesiologists are wary of the risks of aspiration, both sedation and general endotracheal anesthesia have been found to decrease the incidence of vomiting with TBI [95,96].

# Clinic and office procedures

### Endoscopy

Gastrointestinal endoscopy constitutes the bulk of procedures performed by a pediatric gastroenterologist [97]. Depending upon the patient and the type of procedure contemplated (therapeutic versus diagnostic), children may require no sedation, minimal to moderately deep sedation or general anesthesia. Over the past 15 years, the volume of endoscopic procedures has increased by 2–4fold in the adult community, and has most likely increased at a similar rate in children [98].

Although some recommend that deep sedation be limited to anesthesiologist delivery only [99–105], gastroenterologists have reported that they too are able to safely administer and/or supervise sedation [106]. The American Society of Anesthesiologists' Statement on Safe Use of Propofol makes the point that when it is not possible to have an anesthesiologist involved in the care of every patient then "non-anesthesia personnel who administer propofol should be qualified to rescue patients whose level of sedation becomes deeper than initially intended and who enter, if briefly, a state of general anesthesia" [107]. It is estimated that one-quarter of all adult endoscopies are performed with propofol sedation [98] although there is a wide variation in pediatric practice [108]. Children with more complex medical problems, anticipated airway difficulties, morbid obesity or behavioral problems can undergo their procedure in the operating room. Regardless of the site of the procedure, all patients scheduled for endoscopy should be evaluated beforehand to confirm that they are appropriate candidates. In addition, the anesthetic technique depends on the procedure, the patient and the skill of the endoscopist as well as the limitations and capabilities of the endoscopy suite.

#### Esophagogastroduodenoscopy

Access to the airway is limited once a transoral endoscope is in place. It is important to maintain spontaneous ventilation during deep sedation because any airway intervention needed typically requires the removal of the endoscope. The two most stimulating portions of the esophagogastroduodenoscopy (EGD) are transoral and transpyloric passage of the endoscope. A smooth endoscope insertion can be aided by topical spray of local anesthesia to the oropharynx to help eliminate coughing and gagging.

Most endoscopy-related respiratory complications occur during EGD, especially in infants and younger children, when compared to colonoscopy. A combination of factors may contribute, including the large size of the endoscope, partial airway obstruction, and abdominal distension due to air introduced into the stomach as well as sedation, leading to hypoventilation. This has lead several groups to select 6 months of age as the time prior to which general anesthesia with endotracheal intubation is required for the procedure, due to the higher respiratory complication rate in this age group [103,105]. Targeted controlled intravenous infusions (TCI) of propofol, with or without dexmedetomidine, have been used effectively in children (3-10 years) who underwent EGD with spontaneous ventilation without endotracheal intubation. In the presence of dexmedetomidine, the dose-response curve of propofol appeared unaffected [109].

# Colonoscopy

Access to the airway is unimpeded during a colonoscopy. Deep sedation can be achieved more readily and if respiratory problems occur, airway interventions are straightforward to manage. Patients undergoing colonoscopy will experience increased stimulation during certain parts of the procedure such as traversing the colon to the splenic flexure and the ileocecal valve. At times, abdominal pressure is applied to help advance the colonoscope. The depth of the anesthetic should be adjusted accordingly.

# Endoscopic retrograde cannulation of the pancreas

Many institutions report success of procedural sedation in pediatric patients undergoing endoscopic retrograde cannulation of the pancreas (ERCP) [110,111] but general anesthesia with endotracheal intubation may make the procedure easier to perform, especially if it is of long duration, the patient has significant co-morbid diseases or the procedure is performed with the patient in the prone position.

# **Psychiatric interviews**

Intravenous sodium amobarbital has a long history as an adjunct to psychotherapy, having found its peak use during World War II and immediately thereafter in aiding soldiers to deal with the stresses of combat [112]. This technique has enjoyed a resurgence for diagnostic and therapeutic interventions in adults, although pediatric reports are rare. Weller et al reported success for diagnosis and treatment of prepubertal children and emphasized the "back-up" of an anesthesiologist [113]. The induction of a tranquil state until signs of sedation occur, such as slurred speech, a sense of fatigue, difficulty counting backwards, and "basal" vital signs, is not unlike our daily efforts at anxiolysis during monitored anesthesia care. A bispectral index (BIS®, Aspect Medical Systems, Norwood, MA) monitor may prove to be a useful adjunct as well [114]. The psychiatric interview process under these conditions is fascinating to participate in, if only as an observer. Memory retrieval, for instance the uncovering of relationships between current psychopathology and earlier traumatic life events, or symptom removal via therapeutic suggestions are examples of interventions facilitated by the pharmacologically induced relaxed state made possible by the anesthesiologist during the interview.

# Anesthetic management of extramural procedures

In the several decades since the initial guidelines for pediatric sedation outside the operating room were published [115], not only have numerous organizations taken it upon themselves to fashion standards of practice, they have variously acknowledged and in many cases overtly approved the practice of non-anesthesiologist adminisBox 36.4 Documents from various societies about sedation services

tered sedation and analgesia medications, creating their own standards, guidelines, and policy statements, sometimes reinforced by citing relevant peer-reviewed literature in journals. Furthermore, the regulatory environment is different for every state (Box 36.4). As experts in the continuum of sedation and anesthesiology, we sometimes find ourselves in a cognitively, clinically and diplomatically tense and uncertain situation, which ultimately can only be answered through education, collaboration and consistency of policy, at least at the institutional level. The breadth of these regulations, nevertheless, is staggering.

# Standards

Until the 1990s, sedation in the United States was limited predominantly to delivery by anesthesiologists, radiologists, dental medicine and emergency medicine physicians. It now encompasses other specialties which include gastroenterology, intensive care medicine, hospital medicine, pediatric medicine and nursing [116-118]. Worldwide, however, the majority of pediatric sedation is still administered by anesthesiologists. The challenge facing sedation care providers is the lack of consensus on sedation standards with respect to skills, training, qualifications, sedatives, physiological monitoring, NPO guidelines, routes of delivery, and emergency preparedness. A global look at sedation guidelines reveals that there is lack of consistency not only between the specialties within a single continent, but also between the continents. Different specialty societies as well as institutions in the United States and worldwide have published guidelines, policies and recommendations, many of which do not agree [119]. In the United States, in response to the deaths of dental patients after sedation with midazolam, the National Institutes of Health and the American Academy of Pediatrics published two nearly identical consensus documents on sedation in 1985 [120-123]. Depth of sedation was introduced as a continuum, consisting of three levels: conscious sedation, deep sedation, and general anesthesia. Recently the terminology has evolved to include four depths (minimal, moderate, deep sedation and general anesthesia) and eliminate the term conscious sedation [3,124,125]. This terminology has been adopted by the Joint Commission and specialty societies worldwide. Limitations of the sedation continuum have been recognized, particularly the subjective determinants of using patient response to verbal and tactile stimulation in order to determine the sedation depths. Future efforts should be made to identify objective criteria in order to determine depth of sedation and, more important, the risk of adverse events [126].

### Organization

At a minimum, safe patient care requires appropriate anesthesia equipment and monitors and adequate space and experienced ancillary providers who are knowledgeable and practiced in providing assistance if needed. Each off-site area has its own needs, goals, and guidelines. It is ideal to designate a team of anesthesiologists committed to providing extramural anesthesia care and troubleshooting the logistical challenges in the various locations. Each member should rotate regularly through the different extramural sites in order to maintain familiarity with the procedures, to foster a relationship with the physicians and ancillary personnel and to understand the anesthesia demands unique to each site, including ongoing advances. Technological advances are expanding in the field of radiology, and complicated imaging studies challenge the anesthesiologist to have an understanding of the unique conditions which the study requires.

In the past, extramural locations were not designed with the anesthesiologist in mind. The need for anesthesia had not been anticipated when off-site locations were planned. It is only within the past two decades that the demand for anesthesia services in these sites has substantially expanded. Thus, most off-site locations have not been configured to support an anesthetic. Ideally, anesthesiologists should be involved in the early stages of site design to ensure that minimum standards for anesthesia delivery are met and to troubleshoot engineering issues and advocate for adequate space for anesthetic induction and emergence [114,127]. Physical plant considerations for MRI site planning have been previously described [128]. When anesthesia services are requested, these sites may not meet minimum standards [129] and will require re-engineering to meet minimum requirements of the ASA. The anesthesia machine should be equipped with back-up supplies of E cylinders filled with oxygen and nitrous oxide. If pipeline oxygen is not available, then oxygen should be supplied from H cylinders (6600L) rather than the smaller E tanks (659L). For MRI locations in particular, induction of anesthesia or sedation is often best accomplished in an induction area, immediately outside the scanner room, to allow full access to the patient and use of non-MRI compatible equipment such as laryngoscopes. Issues such as airway obstruction, emergence or need for resuscitation are best addressed in such a location and not in the scanner room.

Scavenging systems should be carefully evaluated in the extramural location. Unlike the OR, passive scavenging systems may not always be possible. A safe means of active scavenging may be provided by the vacuum at the wall or wall suction canisters. A scavenging system should be dedicated solely to waste gases. Many MRI scanners do not have wall suction because MRI-compatible wall suction is not widely available. If the suction is located outside the MRI suite, then a mouse-sized hole may be created in the suite's wall to allow suction tubing to be passed inside [128]. A standard anesthesia cart at each anesthetizing location should be fully stocked with essential medications, necessary additional equipment, a spare self-inflating (Ambu®) bag, endotracheal tubes, LMAs, suction catheters, intravenous supplies, laryngoscope handles and blades, and a variety of oral and nasopharyngeal airways [129].

Electrical circuitry and lighting in extramural locations may not be up to operating room standards even if the outlets are grounded and up to hospital grade. Although some extramural locations carry minimal risk of electrical shock or electrocution, these sites do not have lineisolation monitors (LIM) and will not warn of excess leakage of current. Supplemental lighting for record keeping, label verification, establishment of IV access, and visualization of the patient is critical. Even under the best circumstances, for example, lighting is dim in the MRI scanner and monitoring by simple clinical observation can be limited. Anesthesia personnel may not always remain and video monitoring or hardwiring through reinforced walls can allow remote video display of the patient and physiological monitors within.

A storage area large enough to stock anesthesia equipment and supplies must be easily and quickly accessible. This area should be routinely checked, restocked and kept locked when anesthesia services are not required. The need for redundancy of non-disposable supplies is a matter of philosophy. Are two laryngoscopes enough or should there be a third? Is one ECG monitor enough or should there be a battery-operated monitor for back-up and transport? Drugs should be checked per the usual operating room routine and expired medications replaced. Gas cylinder supplies must be reliable, especially in areas without piped oxygen. A code cart should be conveniently located in an area known to all physicians and ancillary personnel. This cart should be routinely checked and restocked. With larger volumes of patients making these significantly sized critical care areas, strong consideration should be given to having a difficult airway cart available at extramural locations.

Finally, extramural anesthetizing locations are often distant from the operating room. Patients may need to remain anesthetized during transport to or from the extramural location. For these circumstances, assured elevator access with key-controlled emergency over-rides is a must. All anesthesiologists who deliver extramural services should be familiar with their surroundings. Checklists are invaluable to guarantee consistent patient care, anesthesia monitoring, equipment, documentation, and back-up assistance.

### Practitioners

Interdisciplinary skepticism is abundant and the need for leadership remains crucial; a director of anesthesia and sedation at an extramural location can orchestrate, facilitate and co-ordinate these services as well as educate all clinical stakeholders and the public. Specific guidance is provided in several standards (Box 36.5) from the ASA, especially "Statement on Granting Privileges for Administration of Moderate Sedation to Practitioners Who Are Not Anesthesia Professionals" and further in "Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia" (Table **Box 36.5** American Society of Anesthesiologists: relevant guidelines for extramural sedation and anesthesia

36.3). By being available to answer questions, provide on-site consultation, examine patients and provide support or emergency airway expertise, the anesthesiologist can also guide a nurse-administered sedation program. Nurses who provide sedation under the supervision of the ordering physician should be Pediatric Advanced Life Support (PALS) and Basic Life Support (BLS) certified. The Joint Commission requires that individuals who administer sedation are able to rescue patients from whatever level of sedation or anesthesia is achieved, whether intentional or unintentional [22]. This is the context within which the ASA documents were created. Attention to the sedation continuum and a paean for translating subjective assessments to more consistently measureable physiological endpoints has recently been published [126].

As recommended by the Joint Commission, sedationrelated policies and procedures should be part of a quality assurance initiative which should accompany all sedation programs. Ideally, adverse events such as failed or prolonged sedations, paradoxical reactions, hypoxia, emesis, unscheduled admission, cardiac or respiratory events should be identified and entered into a computerized database. In addition, the extramural nurse should call all patients and families within 24h in order to follow up on patient outcome and identify any delayed adverse events.

# Scheduling and preparation of patients

Appropriate planning for an anesthetic begins with familiarity with the procedure. The requesting service (i.e. neurology, surgery) orders the procedure and then leaves the logistics of scheduling to the extramural service (radiology, anesthesiology). Radiologists recognize that the administration of an anesthetic will lengthen their total time commitment to a patient and potentially limit the number of procedures accomplished in a day [130,131]. A well co-ordinated system for screening patients on the day of the procedure is important. Experienced personnel, ideally a certified pediatric nurse practitioner (CPNP), should be designated to take initial vital signs, review recent medical history, begin IVs if necessary and familiarize the family with the upcoming procedure, including anesthesia.

Screening patients for extramural procedures may be challenging and time consuming. Many children are chronically ill, nutritionally impaired, and medically complicated. These issues must be carefully addressed through attention to the patient's history, physical examination, old medical records, outside consultations and close communication with other medical colleagues. Several consultants may need to confer in order to fully understand the patient's current state of health. Not every procedure is elective. Urgent procedures may be required despite an upper respiratory tract infection (URI), ongoing pneumonia, deteriorating physical status, untreated gastroesophageal reflux, sepsis or hemodynamic instability. In these situations, consultation between the anesthesiologist, the requesting physician and the radiologist should confirm urgency. Anesthesia plans should be adjusted to accommodate the requirements of the procedure (e.g. breath holding for chest CT scan) and the patient's medical condition.

It is not always possible for an anesthesiologist to provide sedation and anesthesia for all children when there is a large volume of cases. A structured nursing sedation program can provide safe and effective sedation. In many hospitals the requesting department "outsources" responsibility for sedation to another

	Minimal sedation (anxiolysis)	Moderate sedation/analgesia ("conscious sedation")	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful** response to verbal or tactile stimulation	Purposeful** response following repeated or painful stimulation	Unrouseable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

Table 36.3 Continuum of depth of sedation: definition of general anesthesia and levels of sedation/analgesia\*

**Minimal sedation** (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and physical co-ordination may be impaired, airway reflexes, and ventilatory and cardiovascular functions are unaffected.

**Moderate sedation/analgesia** ("conscious sedation") is a drug-induced depression of consciousness during which patients respond purposefully\*\* to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

**Deep sedation/analgesia** is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully\*\* following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

**General anesthesia** is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired. \* Monitored anesthesia care does not describe the continuum of depth of sedation, rather it describes "a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure."

\*\* Reflex withdrawal from a painful stimulus is NOT considered a purposeful response.

\*\*\* Rescue of a patient from a deeper level of sedation than intended is an intervention by a practitioner proficient in airway management and advanced life support. The qualified practitioner corrects adverse physiologic consequences of the deeper-than-intended level of sedation (such as hypoventilation, hypoxia and hypotension) and returns the patient to the originally intended level of sedation. It is not appropriate to continue the procedure at an unintended level of sedation.

Because sedation is a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to rescue\*\*\* patients whose level of sedation becomes deeper than initially intended. Individuals administering moderate sedation/analgesia ("conscious sedation") should be able to rescue\*\*\* patients who enter a state of deep sedation/analgesia, while those administering deep sedation/analgesia should be able to rescue\*\*\* patients who enter a state of general anesthesia.

department which could include pediatrics, hospital medicine, anesthesiology, intensive care or emergency medicine. After patient screening, an appropriate referral for either general anesthesia or procedural sedation is the usual result. Because MRI is a unique environment, it is more efficient to have the MRI nurses screen the patient prior to and on the day of the procedure. To ensure consistent decision making, the departments of anesthesiology and radiology should develop a set of guidelines and easily identifiable "red flags" (Box 36.6) to help in this triaging process. If there are any questions or need for additional medical history or studies, the nurse and anesthesiologist must confer before making the final decision regarding general anesthesia or procedural sedation. In addition, chronically ill children often have electrolyte disturbances, coagulation and hematological abnormalities and hemodynamic instability. A consent for the administration of general anesthesia or procedural sedation must be obtained, in line with policies established for anesthesia in the operating room.

Because gastroesophageal regurgitation is common in infants, a detailed clinical history should be taken with regard to the incidence and timing of the regurgitation. If the reflux is predictable (i.e. only associated with mealtimes or soon thereafter), children are usually approved for procedural sedation. NPO guidelines are adjusted to minimize the risk of reflux. For example, if the baby refluxes within 2h of solid feeds but never after 3h, then the NPO guidelines for this infant may be extended to 6h for solids.

#### Postanesthesia care

Recovery criteria and the postanesthesia care unit (PACU) environment in an extramural location must be no different from the postanesthesia care delivered to children following an operative procedure. Each site must have sources of supplemental oxygen, the ability to deliver positive pressure ventilation, the availability of suction and monitoring equipment and a nursing staff trained in postanesthesia care. Discharge criteria should be estabBox 36.6 "Red flags" for sedation

- Apnea. If documented by sleep study, strong clinical history or routine use of an apnea monitor, with significant likelihood of respiratory risk; availability of ICU must be considered.
- 2. Unstable cardiac disease. If cyanotic, depressed myocardial function, significant stenotic or regurgitant lesions, will likely require substantial planning, often in co-ordination with a cardiologist or cardiac anesthesiologist, and availability of ICU.
- Respiratory compromise. Recent (<8 weeks) pneumonia, bronchitis, asthma, respiratory infection; if necessary to proceed, may require general endotracheal anesthesia to control coughing, and availability of ICU.
- Craniofacial defect. Potential for airway difficulty; availability of difficult airway equipment or airway procedures (intubation and extubation) in the OR.
- History of a difficult airway. Potential for airway difficulty; availability of difficult airway equipment or airway procedures (intubation and extubation) in the OR.
- Active gastroesophageal reflux or vomiting. If in poor control, with or without medical or surgical treatment, may require general endotracheal anesthesia with a rapid-sequence induction.
- **7. Hypotonia and lack of head control.** If patient is unable to maintain their own airway without assistance, appropriate perioperative planning must include airway support and ICU. Patients with underlying muscular or mitochondrial disorders may have specific anesthetic risks.
- Allergies to barbiturates. Usually the mainstay of a sedation protocol; cross-allergies must be considered.
- Prior failed sedation. Previously unable to be sedated or unsuccessful imaging study because of excessive movement; may require general anesthesia for an optimal study.
- **10. Tremors.** Unlikely to be ablated with sedation; may require general anesthesia for an optimal study.

lished by an anesthesiologist in conjunction with the extramural service and its nursing staff.

Analgesic requirements post procedure are extremely variable. While groin puncture may be only mildly annoying for adults, the inability to move about and the ache of blood dissecting subcutaneously causes considerable discomfort in children. Following angiography, all children require a minimum PACU stay of 4h to ensure that the puncture site does not bleed or develop a hematoma. Ideally, the patient should be pain free and resting supine and motionless in order to minimize the risk of a groin puncture bleed or hematoma. Experienced nursing staff will be able to recognize, manage and call for extra help when they encounter unexpected agitation, delirium or an unanticipated/undesired change in mental status.

Following embolization procedures, patients frequently experience pain or swelling, the severity depending upon the extent of embolization, the agent used for embolization, postembolic swelling and amount of tissue necrosis. A variety of analgesic techniques are available, and the use of steroids perioperatively, while not directly decreasing pain, may be of benefit in reducing edema and postembolic neuritis. Postembolic swelling will influence perioperative airway management for procedures in the head and neck. Pediatric patients may need to remain intubated following such procedures, particularly when edema in the floor of the mouth, tongue, hypo- or oropharynx or anterior neck could compromise the airway.

Nausea or vomiting may increase venous blood pressure because of the Valsalva maneuver, which can aggravate bleeding and swelling in puncture sites or following head and neck procedures. Hypothermia is a risk at some extramural locations because the MRI, CT and interventional radiology equipment require a cool environment. Heating lamps and forced-air heaters may be utilized when safe and appropriate. Finally, with the use of iodinecontaining radiocontrast media, sclerosing and embolizing agents, consideration must be given to adequate volume resuscitation and the risk of a contrast reaction as well as bladder catheterization for detection of oliguria, polyuria or hematuria.

# Resuscitation

Each extramural anesthetizing location is unique with regard to conducting resuscitation. Redundancy of monitoring devices and equipment is important; one should not be limited to a single item that could malfunction at the time of resuscitation. Patients with multiple allergies, shellfish allergies or atopic disease are at increased risk of exhibiting anaphylaxis to iodine-containing contrast. These patients may benefit from pretreatment with steroids and antihistamines. Areas with restricted access, MRI in particular, should have designated adjacent locations to perform full resuscitation. These areas should be equipped with wall oxygen, suction and full monitoring and resuscitation capability. A self-inflating silicone bag (no ferromagnetic working parts) or non-ferrous Jackson Rees circuit should always be kept inside the MRI suite.

The physicians, nurses, anesthesiologists, technologists and support personnel must know the location of a readily accessible code cart. In addition, a hard board to be placed under the patient during resuscitation should be available. Mock codes should be performed regularly to ensure adequate flow, teamwork and delineation of responsibilities in the event of an emergency. The MRI scanner poses a special problem in the event of cardiorespiratory arrest. Currently, there is no defibrillator which has met FDA approval for entering the MRI environment. Rather, the ASA Task Force on Anesthetic Care for MRI Practice advises that resuscitation be initiated in the MRI scanner as the patient is being removed from the MRI environment to an adjacent area equipped with a defibrillator, physiological monitor and code cart [21]. Protracted resuscitation should never be conducted in the scanner because as support personnel rush inside to assist, unremoved ferrous materials will become projectiles and create an even more hazardous situation. Quenching a magnet should not be an alternative, because it requires a minimum of 3 min to eliminate the magnetic field. In addition, inadequate exhaust during a quench has been known to produce hypoxic conditions in the scanner and has resulted in a patient death. A "black quench" (loss of liquid coolant with resulting coil meltdown) could require replacement of the scanner, a costly and time-consuming undertaking.

# Difficult airway management in extramural sites

If a child with a known difficult airway requires endotracheal intubation in order to complete the scheduled procedure, then it is wise to perform the anesthetic induction in the OR, an area where access to difficult airway equipment and extra help is readily available. Regardless of an anesthesiologist's comfort level and familiarity with extramural environments, the same depth of back-up coverage is simply not available.

The unanticipated difficult airway is problematic in a remote location. Therefore it is important to have LMAs stocked in all extramural anesthesia carts. If the trachea cannot be intubated and the lungs cannot be ventilated with a mask, LMAs can provide a successful alternative. Case reports describe the successful use of LMAs in children with difficult craniofacial anomalies, such as Goldenhar syndrome [132,133] and even Pierre Robin sequence [134]. Similarly, a lightwand may facilitate endotracheal intubation in the child with a difficult airway [135]. Recently introduced rigid laryngoscopes with video (e.g. Glidescope®), in infant through pediatric sizes, should be strongly considered for availability in offsite locations.

It is important to recognize that the airway that had not been difficult on induction may become difficult on emergence following sclerotherapy with alcohol and subsequent tissue edema, particularly at the base of the tongue, the neck or the mediastinum [136–138]. These patients will often require several days of airway support and ongoing evaluation in the intensive care unit until tissue swelling and airway compromise are no longer a concern.

# Blood loss management outside the operating room

Transfusion requirements are rare in extramural locations, yet preprocedural anemia, accidental perforation of vascular structures or medical transfusion requirements such as sickle cell disease or prematurity may require transfusion therapy. Equipment familiar to the anesthesiologist and identical to that available in the operating room is a welcome sight in a life-threatening emergency. Calling for additional help, establishing additional vascular access and co-ordinating with the blood bank are crucial. Having a runner available may be critical when there is no equivalent to a circulating nurse. It may become necessary to involve a surgeon urgently and transport the patient to the operating room, in which case another anesthesia team setting up the OR while the patient is being prepared for transport would be optimal.

# Selection of anesthetic technique and agents

The selection of an anesthetic technique, as in any circumstance, depends on the patient's underlying medical condition, age, drug tolerance and anticipated procedure. The assistance of the department of anesthesiology is often sought when prior sedation has failed [139] and therefore the expectation is set that an anesthetic or deep sedation administered by an anesthesiologist will provide ideal conditions and guarantee successful completion of the procedure. The anesthetic care plan will ultimately be a product of institutional expectations, the patient's comorbidities and the anesthesiologist's preference.

Preparation of the stomach and aspiration prophylaxis are of particular concern for urgently scheduled cases (outside NPO guidelines) or when the medical history suggests aspiration risk. If using H2 receptor antagonists, bronchospasm may occur in asthmatic patients because of the relative increased availability of H1 receptors. H2 blockers may also inhibit metabolism of other concurrently administered medications. Metoclopramide accelerates gastric emptying and increases tone in the lower esophageal sphincter, but is associated with a significant incidence of extrapyramidal side-effects in children. Ondansetron works synergistically with other agents through its vagal blocking actions in the gastrointestinal tract as well as through its inhibition of the chemoreceptor trigger zone via serotonin receptor antagonism, particularly for patients undergoing radiation therapy with pulses of chemotherapy [140,141].

The airway management may be influenced by the procedure itself as well as anticipated postprocedure requirements. Access to the patient's airway in locations outside the operating room is often limited – MRI scanners have a long bore with the patient out of the line of sight of the anesthesiologist, radiation therapy accelerators and total body irradiation are sited within a locked room, interventional procedures are often performed so that the patient can be imaged with biplane fluoroscopy and therefore the physical plant is designed to accommodate the imaging equipment and not the needs of the anesthesiologist. Airway obstruction, laryngospasm, and the presence of secretionsmayallbedifficulttodetermine.Hypoventilation and apnea are difficult or impossible to determine by direct observation. As long as an appropriate plan is chosen and appropriate monitoring used, there is no evidence to support a specific standard for airway management.

Barbiturates may be useful as a sole method of providing sedation. Pentobarbital (Nembutal), for example, has the advantage of providing sedation, causing minimal respiratory and circulatory depression and is rarely associated with adverse events [142]. Barbiturates have no analgesic properties and can produce paradoxical reactions, especially in children. Furthermore, no antagonist to barbiturates is available, so dosing should be carefully titrated. Intravenous pentobarbital by titration has been used successfully by radiologists while monitoring oral and nasal air flow, oxygen saturation with a pulse oximeter (SpO<sub>2</sub>), end-tidal carbon dioxide and cardiac rate and rhythm. Transient decreases in SpO<sub>2</sub> in up to 7.5% of patients have been reported; interventions have included stimulation and head repositioning [143,144]. Other studies have described the use of pentobarbital in both the oral and intravenous form [69,145]. For infants less than 1 year of age, oral pentobarbital is more successful and carries a lower rate of adverse events compared to chloral hydrate [145]. The long half-life of pentobarbital (approximately 24h) requires careful and conservative recovery and discharge guidelines. The dosage of pentobarbital is 2-6mg/kg po, up to 9mg/kg in patients who are receiving barbiturate therapy.

Sodium thiopental in a mean induction dose of 6 mg/kgand a mean total dose of  $8.5 \pm 3 \text{ mg/kg}$  has been used successfully as the sole anesthetic for CT/MRI in 200 children from 1 month to 12 years of age [146]. Methohexital has a shorter recovery time than thiopental and is more effective than oral chloral hydrate [147]. Methohexitalinduced seizures in patients with temporal lobe epilepsy have been reported. Thiopental and pentobarbital are alternatives for these patients [148]. For patients taking barbiturate-containing anticonvulsant medications, a higher dose limit is generally more successful. Methohexital has also been used intramuscularly (IM) for radiotherapy, in doses of 8–10 mg/kg. The onset time via this route is often twice or three times longer than rectally administered methohexital [149].

Propofol (2,6-di-isopropylphenol) is an intravenous hypnotic agent which is approved by the FDA in the United States for the induction and maintenance of anesthesia. Its package insert specifies that it "be administered only by persons trained in the administration of general anesthesia" [150]. Although propofol does not have a labeled indication for children less than 3 years of age, it has been used extensively in this age group as a means of providing sedation or anesthesia. Propofol sedation by bolus or continuous infusion for brain MRI can provide successful imaging conditions but with the risk of need for airway intervention and respiratory compromise [151]. A recent comparison of dexmedetomidine with propofol in children with and without obstructive sleep apnea suggests that dexmedetomidine offers the benefit of preserved respiratory drive, less need for artificial airway support and fewer incidences of airway compromise [17,152].

There is a rare, fatal complication known as propofol infusion syndrome (PRIS) with prolonged propofol administration (>48h) at high doses (>4mg/kg/h). PRIS is characterized by metabolic acidosis, rhabdomyolysis of skeletal and cardiac muscle, arrhythmias (bradycardia, atrial fibrillation, ventricular and supraventricular tachycardia, bundle branch block and asystole), myocardial failure, renal failure, hepatomegaly and death [153-158]. Sixty-one patients with PRIS have been recorded in the literature, with deaths in 20 pediatric and 18 adult patients. Seven of these patients (four pediatric and three adult) developed PRIS during anesthesia [159-161]. A fatal case of PRIS at a low infusion rate  $(67 \mu g/kg/h)$  has been reported [161]. In 1992 the deaths of five children who had received long-term, high-dose propofol infusions were reported. These children died from myocardialrelated causes, presumed to be related to propofol, in conjunction with lipemic plasma, a metabolic acidosis and an enlarged or fatty liver [153]. Propofol should be used with caution for sedation in critically ill children and adults, as well as for long-term anesthesia in otherwise healthy patients, and doses exceeding 4-5 mg/kg/h for long periods (>48h) should be avoided [162–164].

Fospropofol (Lusedra®) is a recently introduced, class IV water-soluble phosphorylated prodrug of propofol which is hydrolyzed in vivo to release active propofol, formaldehyde, and phosphate. It is an appealing alternative to propofol because of the lack of pain with injection, a decreased potential for hyperlipidemia with long-term administration and less tendency for bacterial infection. Its use by non-anesthesiologists, however, has generated some concern because its lower (and more slowly achieved) peak levels could prompt repeat dosing in an effort to enhance its onset of effect, in comparison with an equipotent dose of propofol. In addition, its clinical effect is longer in duration. So far, only adult studies have been published. Fospropofol carries the same FDA labeling as propofol insofar as it is only to be administered by a trained anesthesia provider [165].

Opiates reduce anesthetic and pre- and postprocedure analgesic requirements. They are reversible with naloxone. While opioids may be unnecessary for purely non-painful diagnostic procedures, they may be very useful for therapeutic interventions, especially for those patients with postprocedural pain. They are also useful following anthracycline chemotherapy, when patients have documented impaired myocardial function [166]. Because opioids depress the ventilatory response to CO<sub>2</sub>, this respiratory depression may be of particular concern for children with increased intracranial pressure. Opioids may also worsen pre-existing nausea and vomiting, particularly common for children undergoing cancer treatment.

Benzodiazepines have the advantage of anxiolysis with minimal vomiting and cardiorespiratory depression. Diazepam (Valium®) is painful during intravenous injection and may lead to thrombophlebitis; midazolam (Versed®) is water soluble and therefore may be more suitable intravenously or intramuscularly. The elimination half-life of midazolam averages 2.5h, compared to 20–70h for diazepam [167,168]. Young patients or patients with significant liver disease may have prolonged duration and exaggerated effect from benzodiazepines.

Ketamine has enjoyed great popularity during the past 30 years for sedation, analgesia or anesthesia outside the operating room due to its support of the cardiovascular and respiratory systems. Ketamine-induced nightmares, hallucinations, delusions and agitation are rare in children [169,170]. Ketamine sedation programs, administered by registered nurses and supervised by interventional radiologists, have been developed by anesthesiologists for selected patients and procedures [142,171]. This protocol has allowed painful procedures, and even organ biopsies, to be tolerated by patients who previously would have required general anesthesia [142,172].

Dexmedetomidine (Precedex®, Hospira, Lake Forest, IL, USA) is an  $\alpha$ 2-adrenergic agonist that was initially approved by the FDA in 1999 for up to 24h of IV administration to intubated adults. In October 2008, it received additional approval for procedural sedation of adults in areas outside the intensive care unit setting. It is still awaiting approval for clinical usage in most European countries. It is not FDA approved for pediatric use. Despite the lack of labeling, dexmedetomidine administration has been described via a variety of routes for sedation, anxiolysis, analgesia and as an anesthetic adjunct. Dexmedetomidine is unique in that it produces a state which resembles natural sleep. Animal model studies demonstrated that sedation mimics the endogenous sleep pathway, stimulating the locus coeruleus [173]. Studies in children suggest that the endogenous sleep pathway may be similarly stimulated in the pediatric population. The electroencephalograms (EEG) of children sedated with dexmedetomidine have been shown to resemble those of natural non-REM sleep [174]. Particularly for pediatric sedation for radiological imaging studies, dexmedetomidine alone can, in high doses, achieve immobility for MRI and CT examinations [175–177]. While it appears to have minimal effects on respiratory drive and the  $CO_2$  response curve, dexmedetomidine administration may be accompanied by bradycardia, hypotension, and hypertension [175,176,178].

With dexmedetomidine administered at induction doses of 2–3 mg/kg/min over 10 min followed by an infusion of 1.5–2 mg/kg/min, up to a 97.6% success rate for MRI scans has been reported. In this dose range, the incidence of bradycardia was 16%, with a mean arterial pressure within 20% of age-adjusted normal ranges [176]. Although the bradycardia may be disconcerting to pediatric anesthesiologists, there are no reports of cardiac arrest or need for cardiopulmonary resuscitation. Moreover, the use of glycopyrrolate to treat the bradycardia is discouraged, as it may result in extreme hypertension [179].

Some patients will require general anesthesia because of previous sedation failures, the need for a secure airway or procedural logistics. Newer, less soluble anesthetic agents such as sevoflurane and desflurane have pharmacokinetic profiles that compare favorably with propofol in adults [180]; there seems little reason to think that would not be the case with children, although pediatric anesthesiologists often avoid using desflurane because of its pungency and associated airway irritability. Since its introduction to clinical practice in the mid-1990s, sevoflurane has become the volatile anesthetic of choice in children. Its lack of airway irritability and its ability to provide children with stable hemodynamic function coupled with its rapid onset and offset make sevoflurane a useful agent [136].

Volatile agent vaporizer performance in the MRI suite has been studied. The output of a Fortec II® vaporizer (Fraser Harlake, Orchard Park, NY) was variable according to the vaporizer's location and the orientation of the bimetallic strip within the magnetic field [181]. The movements of the bimetallic ferromagnetic temperature compensator within the MRI magnetic field altered vaporizer output by as much as 91% of the dialed output concentration. Several other vaporizers examined (Ohio Forane<sup>®</sup>, Ohio Medical Products, Madison, WI; Ohmeda Isotec IV® vaporizer, Ohmeda, Steeton, England, and the Forane Vapor 19.1<sup>®</sup>, Dragerwerk AG, Lubeck, Germany) were incompatible with the MRI environment because of stronger ferromagnetic internal component content or the location of a ferromagnetic spring within the temperature compensator. Measuring inspired and end-tidal levels of volatile agents when delivering a general anesthetic in the MRI environment, may provide reassurance. Modern MRI-compatible anesthesia systems have magnetic field detector systems that inform the anesthesiologist when the machine is within a magnetic field strong enough to affect vaporizer and machine performance. In general, situating the machine and vaporizers as far from the

magnet as practically possible within the scan room, and following the manufacturer's instructions as to machine operation, will optimize conditions and ensure accurate volatile anesthetic delivery.

Regional anesthesia, rarely administered outside the pediatric operating room, nevertheless remains a valid choice in some circumstances. Intercostal nerve blocks may be very useful for lung or rib biopsies, chest tubes, biliary or subphrenic drainage procedures, and insertion of biliary stents. Nerve block of the brachial plexus by the axillary, interscalene or supraclavicular route has been reported for the brachial approach to catheterization [182,183] and neuraxial block of the lower extremities for femoral catheterizations and percutaneous approaches to the kidney [184]. Spinal anesthesia has been successfully used for repeat painful radiotherapy on lower extremities, in conjunction with regional hyperthermia and limb exsanguination [185].

Indwelling central catheters are implanted in the majority of radiotherapy patients and can be utilized for induction and maintenance of anesthesia, blood draws, intravenous fluid administration and chemotherapy. Dressing changes are often accomplished in conjunction with the sedation or anesthesia. Antiseptic preparation of all injection sites is critical. At the end of the session the catheter should be carefully flushed with heparinized saline. An alternative to central lines is the use of a heparin lock peripheral IV, changed weekly, with careful parental instruction. Smoothness of emergence is particularly important following angiographic procedures because of the risk of dislodging a clot or bleeding at the puncture site. Some of these patients have been heparinized without protamine reversal. Unlike adults, sandbags and weights are not routinely applied to angiographic cannulation sites of children.

Finally, on occasion, the loss of self-control with sedation results in dysphoria, and some patients fare better when completely awake. Minimal medication may be preferable in patients with complicated and unstable medical conditions who may not tolerate the anesthesia or sedation. Some procedures (unilateral carotid barbiturate injection, or Wada test) may require conversation, interaction and responsiveness of the patient. In these situations, no sedation may be the best alternative.

# Safety issues for patients and their anesthesiologists

As anesthesiologists find themselves participating in the care of patients requiring increasingly sophisticated imaging technology, it is appropriate to examine the risks for patients and staff exposed to the types of high energies and contrast agents used.

# **Ionizing radiation**

Radiation exposure is directly proportional to the duration of the procedure and inversely proportional to the square of the distance from the source. Henderson et al monitored the radiation exposure of 16 pediatric anesthesia fellows during a 2-month period [186]. Fellows assigned to the cardiac catheterization lab had fluoroscopy exposure time of 14-85min per case, typically for 2-3 cases per day. For these anesthesiologists, badge readings ranged from 20 to 180 mrem/month. All non-cardiac anesthesia fellows had undetectable (<10 mrem/month) levels. All fellows wore lead aprons, 50% wore a thyroid shield and one stepped at least 10 feet away from the source during every exposure; this latter fellow had a reading of 30 mrem, despite having spent 26h in the cath lab. The annual maximum permissible dose (MPD) for non-radiation workers (including anesthesiologists) is 100 mrem or 1 mSievert (mSv, SI unit). For comparison, the MPD for radiation workers is 50 mSv annually and 10mSv times age cumulatively. MPD during pregnancy for radiation workers (per gestation) is 5mSv. Safety precautions for all anesthesia practitioners include strict requirements to wear lead aprons and thyroid shields in fluoroscopy areas, to wear radiation detection badges and have them measured at regular intervals, step as far away and out of the direct line of radiation as possible, and use mobile transparent, lead-impregnated plastic "walls" as an extra source of protection (Fig. 36.6).

The American College of Radiology has raised public and professional awareness about the risks of ionizing radiation and the importance of tailoring the dosing to the needs of the child. The Society of Pediatric Radiology established the Image Gently campaign to seek alternative methods of lowering radiation exposure to children during imaging studies (www.imagegently.org). This has expanded from radiation during CT imaging to include procedures in interventional radiology [187–189]. Webbased training and education have been developed to offer a quality improvement module for CT safety in children [190].

### High-intensity magnetic fields

Magnetic resonance imaging exposes the patient (and the healthcare workers surrounding the patient) to a static magnetic field, a rapid switched spatial gradient magnetic field and radiofrequency magnetic fields. The static magnetic field, which causes alignment of unpaired tissue protons, may cause movement of ferromagnetic devices such as vascular clips, ventricular shunt connectors, casings for pacemakers, and control devices for pacemakers. Metallic devices in other areas, particularly when invested with fibrous tissue, are less problematic [42,191]. As mentioned previously, tissue expanders may have magnetic ports to facilitate identification of the injection site. Despite their low mass, such ports have a potential for

**Figure 36.6** Anesthesiologist with proper ionized radiation shielding and safety precautions in a cardiac catheterization laboratory. Note full lead apron with thyroid shield, radiation detection badge, lead-impregnated plastic wall. He is also standing at some distance away from the cameras, and not in the direct line of radiation emission.

torque and movement in the presence of a strong magnetic field so the specific type of tissue expander should be identified prior to patient evaluation in an MRI [34]. Assessment of risk in patients with implants or other possibly ferromagnetic devices or objects consists of a careful history including penetrating wounds, physical examination to look for scars and possibly a plain radiograph of the region in question [192]. Other concerns have been increased blood pressure, cardiac arrhythmias, and impaired mental function. While described or theorized on an experimental basis, little clinical documentation is available.

The magnetic field generates an electrical current 2–3 orders of magnitude less than a defibrillator  $(10 \text{ mA/M}^2)$ , compared to  $1000-10,000 \text{ mA/M}^2$ ). This current strength may nevertheless reprogram a programmable pacemaker and interfere with its function [37]. Exposure to a strong external magnetic or electromagnetic field can lead to conversion of a demand pulse generator from synchronous to asynchronous mode, damage to the reed switch (which activates the fixed rate pulse generator), repro-

gramming of pacemaker parameters, induction of currents in the electrode wires, or to displacement of the generator itself. Indeed, it is the sensitivity of some reed switches that has determined the "safety boundary" of magnetic resonance devices as being 5 gauss ( $5 \times 10^4$  T). Patients with implantable defibrillators-cardioverters, implantable infusion (e.g. insulin) pumps, cochlear implants and neurostimulators, are all at risk for having the implant device reprogrammed upon exposure to the magnetic field. Defibrillator failure has been reported in the MRI environment [193].

Radiofrequency (RF) pulses cause heat production in metallic implants and coiled wires such as ECG cables or pulse oximeter cables if looped and lying on the patient's skin. Patients with compromised thermoregulatory abilities, such as those with cardiac problems, fever or taking certain drugs, may be at particular risk. Included in this group are infants, whose SAR is greater than that of adults because of the greater ratio of body surface area to body mass, and whose thermoregulatory abilities may be interfered with during a general anesthetic [58]. SAR refers to the energy absorption (e.g. increasing body temperature) with an increase in the total amount of RF energy absorbed [194].

Increased reports of vertigo, nausea and a metallic taste have been found in a study on human exposure to a 4 T magnetic field (whole-body scanner) [195]. Fertilized frog embryos exposed to a 4 T magnetic field did not demonstrate any adverse effects on early development [33]. An increase in cardiac cycle length of 17% was found in healthy volunteers in a 2 T environment after 10 min of exposure, causing speculation about the effect of the 2 T environment on the sinus node [49]. This may be of particular concern in patients with a pre-existing arrhythmia history. Of more significant concern in pediatric patients is the potential for hypothermia because of the air flow directed through the scanner cavity and the inability to control room temperature or use radiant warmers. The use of warm IV fluid bags, thermal packs, and blankets can decrease heat loss. Excellent reviews of monitoring considerations and equipment choices in the MRI environment as well as patient safety principles are available [26,52,192,194,196,197] and the American College of Radiology (with a representative from the ASA) has published a recent White Paper on magnetic resonance safety [20].

Magnetic resonance imaging and spectroscopy do not employ ionizing radiation. However, secondary harmful effects, such as magnetic objects becoming projectiles within the magnetic field as they approach the bore of the magnet and potentially causing injury, are a consideration [198,199]. Patients (and anesthesiologists) with metallic implants such as vascular clamps, hemostatic clips, dental devices, heart valve prostheses, intravascular coils, filters and stents, ocular implants, orthopedic implants, otological implants, shrapnel, penile implants, and vascular access ports must be individually evaluated for their risk in the MRI environment [200,201].

### Use of intravascular contrast media

In a comprehensive review, Goldberg noted that approximately 5% of radiological exams with radiocontrast media (RCM) are complicated by adverse reactions, with onethird of these being severe and requiring immediate treatment [202]. Anaphylaxis during anesthesia has recently been the subject of several consensus conferences [203-205]. Reactions occur most commonly in patients between 20 and 50 years of age and are relatively rare in children. The male: female ratio is about 1:2.5, not dissimilar to the gender distribution of other allergies such as latex, aspirin and neuromuscular blocking agents. With a history of atopy or allergy, the risk of a reaction is increased from 1.5-10-fold. Reactions vary from mild, subjective sensations of restlessness, nausea and vomiting to a rapidly evolving, angioedema-like picture accompanied by respiratory distress, bronchospasm, arrhythmias and cardiac arrest. Because of the high molar concentration of contrast media (often >1000 mOsm and sometimes >2000 mOsm), caution should be exercised with patients who have a limited cardiovascular reserve such as patients in congestive heart failure or those with cardiomyopathy. In addition, volume-depleted young children (NPO for prolonged intervals, bowel preps) should be prehydrated prior to RCM administration. Because contrast agents are hypertonic, the initial hypertensive response is usually followed by equilibration with the extracellular fluid compartment within 10 min, heralded by the onset of diuresis.

Special attention should be paid when administering iodine RCM to any child with a history of congestive heart failure. Patients with hepatic or renal dysfunction should be observed closely for signs of impaired excretion of the RCM. In sickle cell disease, the increase in blood osmolarity may precipitate shrinkage, clumping, and, ultimately, sickling of erythrocytes and vascular occlusion. Sickled cells are known to align with external magnetic fields to which they are exposed; it is unknown how this theoretical concern compares, for example, with the normal forces of deformation imposed on red cells of patients with sickle cell disease in their normal course through the vascular tree [52]. Those patients dependent on a full intravascular volume status (patients with sickle cell disease, cyanotic congenital heart disease with a restricted pulmonary circuit volume, patients with arteriovenous shunts, etc.) should be monitored carefully for an initial rise in filling pressures and intravascular volume and subsequent diuresis following an osmolar load.

Patients with impaired excretory mechanisms, such as those in renal failure, must be monitored closely following high osmolar loads. Low osmolar RCM are relatively safe with regard to life-threatening reactions, but moderate non-life threatening reactions requiring some treatment occur 0.2–0.4% of the time and a severe life-threatening reaction can occur in 0.04% of patients [206]. The risk of contrast reaction to non-ionic contrast media is rare. A recent review of 12,494 patients reported overall a 0.46% incidence of contrast reaction, all being mild or moderate and none classified as severe [207].

Gadolinium diethylene triamine penta-acetic acid (DTPA) is a low osmolar ionic contrast medium used for MRI, with a slower clearance in neonates and young infants than adults, yielding longer windows for imaging [208]. Free gadolinium has a biological half-life of several weeks with uptake and excretion taking place in the kidneys and liver. Unfortunately, free gadolinium is quite toxic and is therefore chelated to another structure that restricts the ion and decreases its toxicity. The most common adverse reactions are nausea, vomiting, hives, and headache. Local injection site symptoms include irritation, focal burning or a cool sensation. Transient elevations in serum bilirubin (3-4% of patients) have been reported and a transient elevation in iron for Magnevist® and Omniscan® (15-30% of patients) occurs, which tends reverse spontaneously within 24-48h [209]. to Anaphylactoid reactions occur in the order of 1:100,000 to 1:500,000 and are more rare (<1:100,000 doses) in children.

The older literature states that patients who have had anaphylactic reactions to shellfish are at increased risk of anaphylactoid reaction to RCM. The irony of the statement is that it may be correct but for non-obvious reasons. The original rationale was that shellfish contain high quantities of iodine and therefore it was assumed that there would be a risk of cross-reactivity. However, neither shellfish allergy nor RCM reactions are due to iodine. Atopy *per se* is a risk factor; therefore, the association between atopy and anaphylactic reactions to shellfish and a possible predisposition to a RCM reaction may indeed be valid.

The treatment of severe allergic reactions, whether anaphylactoid or anaphylactic, is no different than for any other allergic reaction. Epinephrine, aminophylline, atropine, diphenhydramine, and steroids have all been employed in order to control varying degrees of adverse reactions. A patient who requires RCM administration and who has had a previous reaction to RCM has an increased (35–60%) risk for a reaction on re-exposure. Pretreatment of these high-risk patients with prednisone and diphenhydramine 1h before RCM administration reduces the risk of reactions to 9%; the addition of ephedrine 1h before RCM administration further reduces the rate to 3.1% [210–212].

Allergic reactions rarely occur with oral agents. The incidence of severe anaphylactoid reactions to gastrointestinally administered agents is approximately 0.004:10,000 and the causes remain unknown. Gastrointestinal complications include nausea, vomiting, and diarrhea. One of the factors that may protect against having an allergic reaction is the poor absorption of oral iodinated contrast agents. Indeed, disruption of the gastrointestinal mucosa is recognized as causing an increase in absorption of oral contrast, and the urinary excretion of contrast in a gastrointestinal study is a well-recognized sign. Yet rarely they will be associated with bronchospasm, flushing, periorbital edema, pruritus, rash, rhinitis, and urticaria.

# Conclusion

The demand for anesthesia and sedation services in sites distant from the operating room is continuing to increase. At the Children's Hospital Boston we now have more than 50 multidisciplinary centers focused on specific, complex disorders, often with multiple co-morbidities. Many of these patients require multiple diagnostic and/ or imaging studies for complete evaluation, even if they never are scheduled for surgical repair. Providing patient services in locations remote from the operating room can be challenging and poses risks that may not exist in the operating room. Sedation, monitored anesthesia care, and general anesthesia are all choices which carry risks. Historically, we have considered that avoidance of general anesthesia would minimize the risk of adverse outcome. Closed claims analysis has shown, in adults, that monitored anesthesia care poses risks equal to general anesthesia with respect to severity of injury, death, and permanent brain damage. Furthermore, 24% of all monitored anesthesia care claims involve oversedation and respiratory depression [213]. All stakeholders in the provision of extramural sedation and anesthesia services must recognize that as the demand for these services grows, so also should their ability to understand the specific environment and to perform careful risk analysis when selecting patients and formulating an individual as well as an institutional plan of care.

# CASE STUDY

An 18-month-old, 18 kg boy, is scheduled for an MRI of the brain to evaluate new onset of grand mal seizures, photophobia, and increasing irritability. He has been well previously. He is currently on phenobarbital and phenytoin.

This rather large toddler's preanesthetic evaluation has to consider the efficacy of his anticonvulsant therapy because he is on two medications. Grand mal seizures of the tonic-clonic variety are usually the easiest to control, particularly if they originate from a single seizure focus, but generalized tonic-clonic seizures associated with a progressive metabolic disease, or complex partial seizures, are more difficult to control. Multimodal therapy is often required in these circumstances. The history is important here because seizure thresholds may be affected by the administration of or withdrawal from a general anesthetic, in the first case raising the threshold and in the second case lowering it. Therefore, during emergence, the patient may be at increased risk for a seizure.

Many induction plans are acceptable. Intravenous access may be more diffcult prior to induction due to the size of the patient (18kg at 18 months of age, approximately the size of an average 4 year old), multiple attempts, and the increased stress. Crying and aerophagia would be expected. If a general anesthetic was required we would be inclined to proceed with a parent-present mask induction. If it seemed like deep sedation would be a good strategy and easy intravenous access likely, we would probably plan on using pentobarbital sedation rather than dexmedetomidine, the other alternative we commonly use. The effect of dexmedetomidine on seizure threshold is controversial; some (early) studies indicated that it may lower the seizure threshold, although in these studies enflurane and sevoflurane were used as part of the anesthetic technique. Pentobarbital, on the other hand, would raise the seizure threshold and perhaps provide a greater margin of safety for this poorly controlled toddler.

With this plan, airway management would likely consist of a natural airway with supplemental oxygen, without any adjunctive devices. Use of a divided nasal cannula capable of end-tidal CO<sub>2</sub> monitoring is an important technique in these patients for early detection of airway obstruction, when the anesthesiologist does not have access to the patient's airway. Video camera monitoring of the patient in the bore of the scanner is often useful to detect inadequate sedation or airway obstruction. Minimal obstruction of the natural airway with preservation of pharyngeal muscle tone will allow the procedure to continue with this level of sedation. If significant upper airway obstruction occurs, the rocking motion of the head, neck, and chest may interfere with the quality of the scan, and therefore the anesthetic plan would need to be modified because the study requires a motionless patient. Total intravenous anesthesia might produce this condition with spontaneous breathing, but flexibility needs to be preserved so that the option exists to progress to a general anesthetic with a laryngeal mask or endotracheal tube.

Safety concerns in the environment of the magnet are critical. Ferrous-containing elements of the anesthetic equipment have to be eliminated for the sake of patient safety as well as the test results. Iron-containing materials become missiles in the MRI scanner, depending on iron content and mass, but magnetic attraction obeys the inverse square law such that the closer it gets to the bore of the magnet, the greater the attraction becomes. Oxygen tanks, tables, and anesthesia machines have been "sucked into" the bore of the magnet. For the anesthesiologist and other medical personnel, anything containing iron in pockets can become projectiles as well, such as stethoscopes, scissors, etc. In addition, personal identification cards such as hospital ID cards and credit cards can have their information rendered useless; beepers and telephones will also have their RF chips scrambled to the point of uselessness.

The duration of PACU stay will depend on how many seizures the patient ordinarily has per day, the competence of the parents in dealing with these seizures, and to some extent the risks of driving home (e.g. distance home, distance to closest hospital, etc.). We would probably keep the patient for 4–6 seizure-free hours in the PACU, with the resumption of his previous PO medications, consultation with his neurologist, and postoperative blood levels, which should be easy to obtain. We would restart his anticonvulsants following the scan. The half-lives are drawn out enough and the onset is long enough that his level will neither decline nor be increased drastically if he resumes his usual PO schedule a few hours later. It will probably be unnecessary to give him any intravenous equivalent doses of his phenobarbital or phenytoin.

# How pediatric intensive care units function

Pediatric intensive care units (PICUs) are quintessentially multidisciplinary units that care for patients of other physicians and must integrate all stakeholders, including the families and child, into the care delivery process. It is obvious that they provide life-saving support for children with a broad spectrum of diseases and thus must not only be multidisciplinary across health professions but also among medical specialists. Indeed, the necessity to care for all aspects of a child's critical illness and integrate the knowledge, wisdom, care, and focus of many providers is the key difference between critical care and other specialties. The need to work closely with nurses, respiratory therapists and others at the bedside to "create" critical care necessitates integration of these services and the running of the unit in a fashion unique to critical care medicine. Intensivists must manage the critical care environment, all aspects of it, in a manner often unfamiliar to physicians who admit patients to the hospital inpatient unit. The intensivists must have oversight of unit-specific functioning, from design of the facility to the personnel and systems that are required to optimize its performance. The hallmark of an excellent ICU is that the unit's personnel work at their best at all times, and do not merely coalesce around crises in a reactive fashion. The care children receive should be guided by their medical

*Gregory's Pediatric Anesthesia*, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos. © 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

condition, the needs of the child and family and the knowledge of the intensivists to avoid "surprises." Ideally, no arrest or death should be a surprise in the ICU. A frantic resuscitation occurring in the ICU often indicates poor systems and a failure of recognition and response in a timely fashion [1,2].

The role of the PICU is, put simply, to provide life support. Thus ICUs must provide everything necessary for this function. First, the facility must meet local, state and federal architectural requirements and contain the hardware of life support: ventilators, extracorporeal membrane oxygenation (ECMO) machines, dialysis machines, monitors, picture archiving communication (PACs) systems, computer records, databases, and appropriate beds. The PICU must be staffed appropriately for its function. Clearly, a cardiothoracic ICU will be staffed with nurses and doctors with different expertise from those a medical PICU - but intensivists, nurses, respiratory therapists, social workers, and multiple medical specialists are necessary and should be tailored to meet the needs of the institution. Just as an ICU cannot exist without the proper equipment, it cannot exist merely with the presence of an intensivist and some critical care nurses - intensive care is by necessity a team endeavor. People and place are important but they are suboptimal without process. The protocols and systems around providing every child in every bed at all times with the appropriate and safe care require intentional organization. The existence of multidisciplinary rounds, mortality and morbidity reviews as well as a robust and unitspecific continuous process improvement system is essential to assure outstanding care. An excellent pediatric critical care unit goes further - it inculcates a culture of positive continual change targeted at improving the care it delivers and innovation around that care.

# Relationship between the intensive care unit and the operating room

Intensive care grew from anesthesiology and while there is a lot in common between the two specialties, they have different mindsets. Intensivists manage multiple patients, all aspects of both the patient's care and the care-providing team, and provide care for prolonged periods of time. Very commonly, the continuum of the child's care bridges anesthesiology and the ICU. Communication needs to be excellent between ICU and operating room clinicians, ensuring a seamless transition of care. Our institution has a policy supporting attending handoff between critical care and anesthesia for each case. This communication occurs in both the preanesthetic and postanesthetic setting. Information regarding current ICU management and therapeutic response can simplify a potentially difficult anesthetic. Similarly, information on the operative and anesthetic course will frame and potentially guide the next several days of management. A complete signout regarding an anesthetic includes induction agents, ease of mask ventilation, ease of intubation, decisions regarding extubation, fluid totals, blood and blood products, inotropic agents, medications delivered including timing of antibiotics, complications, laboratory values, most recent blood gas, venous and arterial access, and allergies. Although this information may be available in the anesthetic record, few intensivists are trained to read them, they are frequently not available at transfer, and a short verbal summary by the anesthesiologist provides a greater amount of practical detail.

# Family-centered care in the pediatric intensive care unit

Over time, recognition of the role of the family in the PICU has evolved and the decisions made with regard to how best to serve the family of a critically ill child have changed. The inclusion of the family in the care of their child and the care of the family as a unit have been recognized as an important part of critical care and it is often said that the "family is the patient." These efforts have taken place over the last decade and will continue to grow. Currently, at many children's hospitals, parents are invited to participate in multidisciplinary rounds with the nurses, respiratory therapists and physicians working with their child. Our own experience and the literature suggest that family-centered rounds do not take any more time than that allotted for traditional rounds, and do not compromise teaching [3]. Further, the issues of privacy can be dealt with even in an open bed environment. Satisfaction with this model has been reported by families and care providers in the unit. More ICUs may move to this model over time and in each case there is a short learning curve.

Parents of critically ill children undergo severe emotional distress, no matter how routine the process may seem to caregivers; an ICU is a unique and often terrifying experience for families and children. The need for multiple caregivers, changing shifts, endless physicians (residents, students, fellows, multi-specialists), loss of control, financial worries and many other factors all affect the family's ability to cope. The suffering of other children and families often amplifies anxiety but it may also in a way be able to comfort some families. Helping parents to cope with their child's critical illness and the ICU environment is a central part of intensive care. Parents display many behaviors that help them cope, including excessive clinginess, intellectualizing the process, blaming others (including their spouses), minimizing, and seeking opinions everywhere (the internet, the unit social worker, etc.). To provide optimal care, these mechanisms must be understood. Helping the parents to be parents and educating them about their child's illness are essential. Parental support, support groups, psychological support, child and family therapy, and social workers are all part of the critical care team.

A more difficult question, for some clinicians, will be how to address the issue of parental presence during invasive procedures and cardiopulmonary resuscitation (CPR) efforts. In a recent review of 15 studies addressing the issue of parental presence during procedures or CPR, only two were conducted in the PICU environment [4]. Of the remainder, 10 studies were conducted in the emergency department and there may have been episodes where parents were asked to assist in comforting or restraining their child during placement of peripheral intravenous (IV) lines.

Currently, in some hospitals parents are given the option of staying in the room with their child during complex procedures and even CPR. This is helpful for parents coping with the trauma of a critically ill child. In response to questionnaires, a majority of parents indicated they would stay again in a similar circumstance. These ideas have become more common, leading the American Academy of Pediatrics to issue a policy statement supporting parental presence in the emergency department. There is limited evidence supporting similar policies in the PICU. As each PICU considers its own policy, there are several issues to consider. The concerns of the clinicians will need to be addressed. The limited literature does not indicate that parents are obstructive or interfere with procedures. Additionally, teaching trainees has not been compromised. Nevertheless, this decision cannot be forced on everyone and a means for declining on the part of the clinician as well as the parent must be available. Further, a mechanism to provide an attendant for family members during these events is necessary. This is similar to parental presence during induction of anesthesia. Arrangements need to be made in advance to inform and accompany the family so that clinical care is not interrupted. It has not been an issue for our unit during CPR as the unit social worker or member of the clergy is available to explain to the family what is occurring. Parental presence during procedures may pose a different type of challenge as these events occur more frequently compared to CPR. Yet it would seem logical that in the best interest of the patient and family, someone other than the person performing the procedure should be looking after the family. Given the changes that are occurring in this area, by the next edition of this book it will probably seem that there was never a time when we did not offer parents in the ICU the choice of whether or not to remain during these events.

# **Disclosure of medical errors**

We believe disclosure of medical errors to families is ethically correct. Nevertheless, many continue to resist this due to concerns regarding litigation. Of the 1018 respondents in a recent survey of Illinois residents, 27% indicated they would sue, but 38% stated they would recommend the hospital if appropriate disclosure and remediation occurred. The conclusion drawn by Helmchen et al was: "Patients who are confident in their providers' commitment to disclose medical errors are not more litigious and far more forgiving than patients who have no faith in their providers' commitment to disclose" [5]. In our institution, explanations about medical errors come from the senior member of the team to the family. This is likely the current attending physician, but can be the medical director of the PICU, depending on the complexity of the incident and its outcome. The discussion includes a frank explanation of what happened and why, what the repercussions are, what change of care is planned for their child, and what will be done to prevent a similar error in the future. The ICU social worker is present or immediately available to help validate concerns and provide support. We remain present until all questions are answered or additional time is scheduled if necessary. Errors and outcome are tracked through our quality assurance program and when necessary, a "root cause analysis" is performed. Medical errors can be viewed as an opportunity to improve practice quality and prevent injury to any future patient. We believe families should be informed of errors, and that future research will further support the view that disclosure does not increase the risk of medical liability.

Of course, coping with death and dying is also a necessary function of the critical care environment [6]. Often when nothing medically can be done for the child, the provision of palliative care becomes even more important. Death is not necessarily a failure but should be a well-managed process ensuring minimal pain and suffering for the child and family. Of course, in every society there are multiple ethical issues that arise in providing care for critically ill children. Intensive caregivers must understand the basic principles of ethical care and when to allow families choice and support them over what may be their own beliefs and practices – as long as the goal remains to prevent further pain and suffering [7]. The concept of futility has received much attention in the last few years and is overshadowed by financial, societal, ethical, personal and religious opinions and feelings. It is a difficult concept to define but when the pain and suffering of continuing life are more severe than the inevitability of death, care may become futile. One caution - the term "futile care" should never be ascribed to pain relief, caring support for the child and family, and understanding.

# Continuous quality improvement – how do we measure quality?

How good is an ICU? Does it provide the best quality of care? When there is one ICU in a given institution, to what does it compare itself? Are there objective standards of ICU care and outcomes practices? This is a challenging field, in large part because ICU practices vary widely. For units that have high mortality, high resource utilization and high emotional impact, how can the quality of care be determined? After all, death and poor outcomes can be expected in the face of devastating diseases.

Which ICU is better? One with 1% mortality or one with 5% mortality? Obviously, the answer to this question depends on a number of factors. If the expectation of the first unit is that all children should survive because it cares for children with a low-level severity of illness, then it is underperforming. If the second unit has a very high severity of illness, such that perhaps a 10% mortality might be expected, it is doing very well [8]. There are ways to compare units objectively due to multiple methods of determining severity of illness. Since the pioneering work of Dr Murray Pollock and development of the Pediatric Risk of Mortality Score (PRISM) system of determining severity of illness from physiological and other measures, it has been possible to compare populations of critically ill children for outcomes including mortality and length of stay [9]. Currently, systems including PRISM, the Pediatric Index of Mortality (PIM) and the Pediatric Logistic Organ Dysfunction (PELOD) allow objective ways of determining severity of illness [10,11]. In addition, it is possible to determine the ratio of actual outcomes to expected outcomes and thus have a standardized outcome score. For example, if comparing the two ICUs with 1% and 5% mortalities, we know that the predicted mortality for the first is 0.5% and the predicted mortality for the latter is 15% from their severity of illness scores, so the risk-adjusted mortality (or standardized mortality ratio (SMR)) is 2 for the first unit and 0.3 for the second – a greater than sixfold difference in this performance measure. The higher mortalityrate unit actually does a much better job. This example demonstrates the importance of comparing critical care among ICUs and of using severity of illness-adjusted comparisons.

Aggregating populations of care and comparing them among units permits a continuous degree of comparative effectiveness research among units and populations. Performance of a unit for a given disease, a given population, age group or demographic can be compared and the cause of these differences discovered. The existence of a system to prospectively collect information on all critically ill children admitted to an ICU and adjust the outcomes for severity of illness permits a national infrastructure for continuous quality improvement. Such a system exists in VPS, LLC (https://portal.myvps.org), a national organization of over 100 hospital ICUs with nearly 400,000 patient records. This allows the reporting of comparative quality reports for each member ICU and contributes to improving pediatric critical care nationally and continuously. Membership of such organizations for the purpose of research and quality improvement is a national, US Agency for Healthcare Research and Quality (AHRQ) recognized standard of excellence for critical care. In addition, it allows trending and improving of other quality measures such as failed extubations, unplanned extubations [12], average length of stay, ventilator-associated pneumonias, central line infections, and short-term readmissions. All of these are considered quality measures for pediatric critical care and as for all quality efforts, the first step in improving quality is having a measurable outcome.

This short overview of how PICUs work is far from exhaustive. Familiarity with the processes that run under the surface of an ICU and determine the quality of the care it delivers may help in sharing the care of critically ill children among medical specialists.

The remainder of this chapter will deal with specific disease processes that cause critical illness in children.

# Organ system function and failure

### Circulation

#### Assessment of cardiovascular function

Routine continuous monitoring of physiological variables occurs in the ICU, including heart rate, electrocardiogram, temperature, and end-tidal carbon dioxide (ETCO<sub>2</sub>). Cardiac output should always be assessed by physical examination in addition to monitoring data, and using the invasive and non-invasive methods described below. Poor cardiac output is often heralded by tachycardia, poor heart tones, diminished pulses, cool extremities and, if cardiogenic in nature, presence of third or fourth heart sounds, and evidence of hepatic and pulmonary congestion.

Cardiac output can be measured by multiple methods such as Fick thermodilution or dye dilution, echocardiography, ultrasonic cardiac output monitor (USCOM), and magnetic resonanace imaging (MRI). The first three methods use a change in measured blood concentration of a substance to calculate cardiac output. The principle is that the change in concentration is proportional to the volume of blood that it is being diluted in.

Of the dilutional methods, thermodilution is the most frequently used in PICUs. A special thermistor-tipped catheter is inserted in a central vein and advanced to the pulmonary artery (PA). Cold saline of a known

temperature and volume is injected via a proximal port on the catheter into the right atrium. The saline mixes with the blood as it passes into the ventricle and PA. In this process the blood is cooled a small amount. The thermistor-tipped catheter in the PA measures the temperature of blood as it passes. A computer acquires the temperature profile, integrates the area, and calculates the flow of blood. A very accurate and rapid assessment of cardiac output is obtained, but this technique can be expensive and placement of a pulmonary artery catheter is not without risks. In addition, interpretation of the results can be very difficult in patients with congenital heart disease who have intracardiac shunts. There are risks associated with the insertion, maintenance and removal of the catheter [13] and the risks may be greater in children [14]. The use of pulmonary artery catheters has decreased over time in pediatric critical care.

The Fick method of measuring cardiac output relies on precisely measuring oxygen consumption. The formula is:

$$CO = VO_2 / (C_a - C_v)$$

Where CO is cardiac output,  $VO_2$  is oxygen consumption,  $C_a$  is arterial oxygen content, and  $C_v$  is mixed venous oxygen content. Measurement of oxygen consumption is technical, difficult, and requires a steady physiological state. In addition, the best site to measure venous oxygen content is in the pulmonary artery as measurements from a central venous catheter result in incomplete mixing of blood. The dye technique is not used in pediatrics as it requires injection of indocyanine green dye as the marker to measure change in concentration. See Chapter 17 for a further discussion of monitoring and vascular access.

Echocardiography provides a significant amount of information about cardiac function. M-mode echocardiography provides what looks like an ice pick view through the heart. There is a single line of information at a very high frame rate that can be used to measure fractional shortening of ventricular tissue. Normal left ventricle fractional shortening is 28-44%. However, M-mode echocardiography does not assess regional wall motion abnormalities. Two-dimensional echocardiography provides detailed analysis of the heart structure. The information available is good enough that few children born with congenital heart disease require cardiac catheterization to define the lesion prior to surgical intervention. Tracing the outline of the left ventricle in systole and diastole allows an estimate of ejection fraction to be made. Normal ejection fraction of blood from the left ventricle is 55–65%. Doppler echocardiography allows the velocity of blood moving in the heart to be measured. Using a simplification of the Bernoulli equation, the difference in pressure between two chambers of the heart can be estimated. The formula is  $P_1 - P_2 = 4V^2$  where V is the measured velocity (cm/sec) between two chambers. As an example, right ventricular pressure is estimated by measuring the velocity of a tricuspid regurgitation jet (squared and multiplied by 4) and then subtracting the measured right atrial pressure from a central venous line. In the same manner, pulmonary artery pressure can be measured. Cardiac output (CO) can be measured by echocardiography by taking the area of a valve (A) multiplied by the flow velocity (V) through the valve multiplied by the heart rate (HR) (CO =  $A \times V \times HR$ ). Flow velocity is the integration of the area under the Doppler curve across the valve. Typically, the aortic valve is used.

Echocardiography is limited by available equipment and expertise. Typically, a cardiologist or echocardiography technologist is required to make these measurements. In addition, it is an intermittent event and if the patient has poor echocardiographic windows from a transthoracic approach, transesophageal echocardiography is required. Heavy sedation or anesthesia may be required for transesophageal echocardiography. See Chapter 25 for additional discussion of echocardiography.

An alternative ultrasonic device used to measure cardiac output is the ultrasonic cardiac output monitor (USCOM, Sydney, Australia, www.uscom.com.au), approved for use in the US in 2005. The USCOM is a portable continuouswave Doppler device, which uses an ultrasonic transducer to measure the velocity of blood flow. The transducer is placed in the suprasternal notch and the Doppler signal directed at the pulmonary or aortic valves. Formulas are used to estimate valve area and the velocity is multiplied by the heart rate to provide cardiac output. The system also indirectly calculates stroke volume. The USCOM allows beat-to-beat quantitative evaluation of cardiac hemodynamics and repeated measures can help evaluate the effectiveness of medical therapies. The USCOM has been used in the management of children with septic shock, hypovolemia, and myocardial dysfunction. Studies validating the USCOM are mixed, with some reporting poor association between USCOM and thermodilution [15,16] and others demonstrating agreement with conventional echocardiography [17,18]. The device is much less expensive compared to echocardiography, the required training is limited, and it can be performed as needed in the PICU. Further studies will be needed to determine if this will become a clinically useful tool.

Magnetic resonance imaging provides very detailed pictures of the heart structure. In addition, cardiac output as well as flow velocities can be measured. However, the procedure takes more than an hour, requires sedation or anesthesia, and expert clinicians are needed to interpret the data. This is very rarely used as a technique to gather information on intensive care patients.

### Pharmacology of the cardiovascular system

During periods of physiological stress, the body releases hormones from the adrenal gland, resulting in a rapid increase in the tissue level of cyclic AMP (cAMP). The same support can be provided via exogenous catecholamines. The most common vasoactive medications used in the PICU are those stimulating the  $\beta$  receptor (dopamine, dobutamine, epinephrine, isoproterenol) or inhibiting the breakdown of cAMP by phosphodiesterase (PDE) (milrinone). In rare circumstances medications producing pure vasoconstriction are needed (vasopressin, phenylephrine – an  $\alpha$  agonist).

When the  $\beta$ 1 receptor is stimulated, a series of G-protein mediated changes occur leading to activation of adenylate cyclase. This results in the formation of the adrenergic second messenger cAMP. Cyclic AMP via protein kinase A causes phosphorylation of calcium channel protein. This results in an increased probability of the calcium channel being open with a greater influx of calcium. In the cardiac muscle this influx of calcium results in an increase in the velocity and force of myocardial contraction (positive inotropy). There is also an increased reuptake of calcium into the sarcoplasmic reticulum resulting in increased myocardial relaxation (positive lusitropy). The effect of increased calcium on the sinus node is an increase in rate (chronotropy) [19] and rate of conduction (positive dromotropy). However, a rapid bolus of calcium can cause bradycardia. The reason for this is not definitively known. Some believe it occurs due to a vagal effect [20], others feel it is secondary to the Gibbs-Donnan effect where charged particles near a semi-permeable membrane sometimes fail to distribute evenly across the two sides. The imbalance of calcium causes a transient decrease in automaticity directly on the cardiac cells. See Table 37.1.

# Dopamine

Dopamine is the metabolic precursor of both norepinephrine (NE) and epinephrine. In the heart it releases NE from stores in nerve endings. In the periphery, the activity of the prejunctional dopaminergic DA<sub>2</sub> receptors inhibits NE release, promoting vasodilation. Dopamine activates many receptors at various doses causing  $\beta 1$ ,  $\beta 2$  or  $\alpha$  receptor stimulation. At doses of 5-10µg/kg/min positive chronotropic and inotropic effects are seen through  $\beta$ receptor activation. These doses typically result in an increase in systolic blood pressure with minimal effect on diastolic blood pressure. At doses of 10-20µg/kg/min there is  $\alpha$  receptor stimulation with peripheral vasoconstriction. As the peripheral resistance increases, renal blood flow may fall. At low infusion rates of dopamine, increases in renal blood flow have been demonstrated in healthy volunteers. These low-dose dopamine effects have not been demonstrated in critically ill patients. There are age-dependent responses to dopamine that differ from preterm infant to infant to child [21]. Potentially, in sick preterm infants there can be decreased dopamine clearance and a blood pressure response at a lower value. Titration in preterm and term infants occurs on a case-bycase basis and dose response is more consistent in older children. Dopamine is only given intravenously, as a continuous infusion as it is rapidly metabolized. Dopamine should be given via a central venous line as extravasation into the tissues can cause damage. Emergency circumstances arise where dopamine is given via peripheral IV while a central venous line is being placed. The extremity should be observed closely and the infusion moved to the new central line as soon as possible.

Drug	Dosing	α	β1	β2	Effect
Dopamine	5–10µg/kg/min	0	++	++	More $\beta$ effect at low dose
	10–20µg/kg/min	+++	++	0	More vasoconstrictor effect at higher dose
Dobutamine	5–20 µg/kg/min	+	+++	++	More $\boldsymbol{\beta}$ effect, less vasopressor activity compared to dopamine
Epinephrine	0.05–0.1 µg/kg/min	++	++	++	Has some $\beta 2$ effect at lower doses
	0.1–0.2 µg/kg/min	++++	++++	0	More vasoconstriction and inotropic effects at higher doses
Norepinephrine	0.1–0.5µg/kg/min	++++	++	0	Increases systemic vascular resistance
Isoproterenol	0.05–0.5 µg/kg/min	0	++++	++++	Increases HR and contractility, smooth muscle relaxant
Phenylephrine	0.1–0.5 µg/kg/min	++++	0	0	Produces both venous and arterial vasoconstriction
Milrinone	0.5–1 µg/kg/min				Selective phosphodiesterase III inhibitor
Nesiritide	0.005–0.01 µg/kg/min				Recombinant B-type natriuretic peptide used to increase urine output
Levosimendan	0.1–0.2 µg/kg/min				Calcium-sensitizing agent; increases ejection fraction, reduces catecholamine dose, minimal effect on heart rate and blood pressure

#### Table 37.1 Continuous infusion mediciations for the heart

### Dobutamine

Dobutamine is structurally similar to dopamine and works at  $\beta$  and  $\alpha$  receptors. Its pattern of activity is  $\beta 1 > \beta 2 > \alpha$ . Dobutamine functions primarily as an inotropic agent but it has less vasopressor activity compared to dopamine. Further, for bradycardic patients it is less likely to increase heart rate compared to dopamine. It is used as a continuous infusion of 5–20 µg/kg/min. It can only be given intravenously and is rapidly metabolized. In some studies dobutamine increases myocardial oxygen demand and may be more likely to provoke arrhythmias compared to dopamine.

# Epinephrine

Epinephrine has mixed  $\beta 1$  and  $\beta 2$  receptor activity as well as  $\alpha$  receptor effects at higher doses. Due to vasodilator effects, it is possible to have a decrease in blood pressure at low doses (<0.01 µg/kg/min) but at higher doses blood pressure will increase due to inotropic and vasoconstrictor effects. Epinephrine is useful for the treatment of shock when there is myocardial dysfunction as well as hypotension. It is typically given at a dose of 0.05–0.2µg/ kg/min. Doses up to 1–2µg/kg/min are used but are associated with significant vasoconstriction with decreased perfusion to abdominal organs as blood is shunted to the heart, brain and skeletal muscle; these very high doses should only be used for short periods, i.e. during ECMO cannulation.

Epinephrine is the principal drug used after cardiac arrest; it supports blood pressure during shock. It also has uses in the treatment of bronchospasm and anaphylaxis or hypersensitivity reactions. It is given as a continuous infusion via a central line for its cardiovascular effects and it is rapidly metabolized. It can be given as a subcutaneous medication but vasoconstriction may slow absorption. It can be delivered as an inhaled medication to treat respiratory conditions but the development of tachycardia is possible. Use of epinephrine may cause tachycardia or provoke arrhythmias.

# Norepinephrine

Norepinephrine has strong activity at the  $\alpha 1$  and  $\beta 1$  receptors with little activity at the  $\beta 2$  receptor. It will increase systemic vascular resistance (SVR) and therefore will increase blood pressure. However, there can be vaso-constriction of mesenteric blood vessels with decreased abdominal and liver perfusion. Blood pressure may be increased without improving perfusion in low cardiac output states. Norepinephrine may be the ideal drug for the treatment of vasodilatory or warm septic shock as well as spinal shock. The use of norepinephrine in pediatric ICUs is limited compared to adult ICUs. It is not entirely clear if this is the result of physiological differ-

ences between the age groups or because of personal practitioner choice.

### Isoproterenol

Isoproterenol is a synthetic, potent, non-selective  $\beta$  receptor agonist that has very low affinity for the  $\alpha$ -adrenergic receptors. Isoproterenol increases heart rate and contractility, and lowers systemic vascular resistance by peripheral vasodilation. It can be tried as a pharmacological means of increasing heart rate in cases of complete heart block but in practice the heart rate increases in this scenario are modest and not sufficient to prevent further intervention. Isoproterenol is often used in the immediate postoperative period after cardiac transplantation to maintain acceptable heart rates in the denervated donor heart. Isoproterenol relaxes smooth muscle and is used as a bronchodilator. With its  $\beta$ 2-adrenergic receptor activity, it is also used as a potent pulmonary vasodilator. Isoproterenol can be given intravenously or inhaled.

### Vasopressin

Vasopressin is a pituitary peptide hormone. In the renal tubules vasopressin controls water reabsorption. It also acts on the vasculature, causing vasoconstriction by stimulation of smooth muscle V1 receptors. This results in increased SVR and increased arterial blood pressure. Clinically this drug is used to treat diabetes insipidus, gastric hemorrhage and as a second- or third-line drug to treat hypotension. Vasopressin has been used in adult cardiac arrest with ventricular fibrillation. Pediatric advanced life support (PALS) guidelines do not support the use of vasopressin in pediatric resuscitation. In 2009, Duncan et al [22] published a review of the American HeartAsssociation's National Registry of CPR. Vasopressin was used infrequently in children in only 5% of cases of pulseless cardiac arrest. Children receiving vasopressin had prolonged resuscitation and decreased likelihood of return of spontaneous circulation.

Vasopressin continues to be used with other vasoactive medications in order to support blood pressure during episodes of vasodilatory shock. There is limited pediatric literature [23–25] regarding the use of vasopressin for this indication. The most recent randomized double-blind controlled trial by Choong et al showed no benefit of lowdose vasopressin in conjunction with other inotropic support in the treatment of pediatric septic shock [25]. It is also used to increase SVR after cardiac surgery early in the postoperative period during periods of vasomotor instability.

# Phenylephrine

Phenylephrine is considered a pure  $\alpha$  agonist that increases both venous and arterial constriction in a dose-related manner. It is used extensively in adult anesthesia

to increase blood pressure. Its predominant use in pediatrics is to increase pulmonary blood flow in patients with tetralogy of Fallot during hypoxemic spells [26–29]. All other episodes of hypotension in children are likely best treated by volume expansion, other inotropic agents or decreasing anesthetic depth.

### Milrinone

Milrinone selectively inhibit phosphodiesterase (PDE) III at the cell membrane and decreases the breakdown of cAMP. As cAMP levels increase, protein kinase is activated to promote phosphorylation. This results in increased inotropy as well as vasodilation. PDE inhibitors are remarkable in producing these effects without acting on  $\alpha$  or  $\beta$  receptors. Milrinone is a derivative of the PDE inhibitor amrinone. Amrinone causes thrombocytopenia which limited its use in pediatrics. Milrinone is given as a continuous infusion, usually at a starting dose of 0.5µg/ kg/min and titrated to clinical effect. A loading dose of  $50 \mu g/kg$  is advocated by some but may result in episodes of hypotension. Milrinone has a much more common usage following pediatric heart surgery but has been used in the treatment of vasoconstricted septic shock. In the future there may be a role for milrinone in the treatment of pulmonary hypertension [30-32].

### Calcium

Calcium is essential for myocardial contraction and is commonly used as a functional inotropic agent, especially following surgery for congenital heart disease. It has short-term benefits on blood pressure, but this may be outweighed by long-term detrimental effects [33]. Hypocalcemia may be under-recognized in the ICU. In an adult study, 88% of critically ill patients had reduced serum ionized calcium levels [34]. When appropriate, hypocalcemia should be corrected.

# Nesiritide

Nesiritide is a recombinant form of the human B-type natriuretic peptide. This is the same hormone that is liberated from the ventricles in response to volume overload and increased wall tension. B-type natriuretic peptide acts on guanylate cyclase, resulting in venous and arterial vasodilation. Further effects include myocardial relaxation (positive lusitropy) and increased natriuresis. The recombinant form has been used exogenously in adult critical care for patients with acute decompensated heart failure. The goal for use of nesiritide in adults is decreased right atrial pressure, decreased pulmonary capillary wedge pressure, decreased systemic vascular resistance and then improved cardiac output. Use of nesiritide in pediatrics is limited but the overall goal is an increased urine output and decreased mean central venous pressure. Ryan et al [35] published preliminary experience with nesiritide in children less than 12 months of age and saw a significant increase in urine output even with decreased fluid intake. Usual dosage recommendations for children and adults are an initial  $2\mu g/kg$  bolus followed by a continuous infusion of  $0.005-0.01\,\mu g/kg/min$ . This can be increased to a maximum infusion rate of  $0.03\,\mu g/kg/min$ .

#### Levosimendan

Levosimendan is a novel agent that acts as an inotrope by binding to cardiac myocyte troponin C and increasing the sensitivity of the contractile apparatus to calcium. In the setting of cardiac failure or postcardiac surgery in children, this agent is effective at increasing ejection fraction in many patients, while allowing a reduced catecholamine dose and having minimal effect on blood pressure and heart rate. Central venous pressure is usually unchanged but serum lactate decreases, and central venous oxygen saturation and cerebral oxygen saturation increase. Adverse effects were not found in three recent small pediatric series. A loading dose of  $612\mu g/kg$  followed by an infusion of  $0.1-0.2\mu g/kg/min$  is recommended.

As of this writing, levosimendan is not US Food and Drug Administration approved, but it is available in many other parts of the world and appears to be a promising agent in pediatrics; more study is warranted [36–38].

## **Disorders of cardiac rhythm**

Sinus rhythm originates from the sinus node and has a sinus P-wave morphology. On a 12-lead ECG, the P-waves are upright in leads I, II, AVF, and inverted (negative deflection) in AVR. Sinus tachycardia is not an arrhythmia but patients with this rhythm may be among the most ill in the ICU. Causes include fever, anxiety, pain, hypovolemia, thyrotoxicosis, congestive heart failure and myocardial disease. The goal is to treat the etiology, not the tachycardia. Sinus heart rates up to 180 beats per minute are well tolerated in children without heart disease. The young child's cardiac output is more heart rate than stroke volume dependent. Artificially slowing a compensatory sinus tachycardia can provoke cardiac catastrophe.

Sinus arrhythmia is a phasic irregularity of heart rate seen with respiration. It is a sign of good cardiac reserve and demonstrates greater vagal than sympathetic tone in children. Sinus bradycardia is rarely clinically significant in children; the exception is the neonate, whose cardiac output is more heart rate dependent than the older child because they cannot increase the inotropic state of the heart as readily. Sinus bradycardia may occur in patients who are trained athletes. It is also associated with increased intracranial pressure, hypothermia, hyperkalemia, hypothyroidism, and profound hypoxia. Drugs that may cause it include digoxin or  $\beta$ -blockers. "Sick sinus syndrome" can occur in children following repair of congenital heart disease and may require placement of a pacemaker. When the sinus rate is significantly slowed, escape beats or escape rhythms can occur from the atrium, atrioventricular (AV) node or ventricle. Ventricular escape beats will have a wide complex QRS morphology.

Supraventricular tachycardia (SVT) describes an abnormally elevated heart rate from a variety of causes. This is distinguished from sinus tachycardia. Re-entrant tachycardias include orthodromic reciprocating tachycardia (ORT) and AV node re-entrant tachycardia (AVNRT), both usually thought of as SVT. These tachycardias occur because the electrical conduction is repeated through an apparent accessory pathway (Wolff-Parkinson-White (WPW)) or a concealed pathway (non-WPW ORT) or through AV nodal tissue (AVNRT). Other causes of SVT occur due to abnormal automaticity of cardiac muscle, including ectopic atrial tachycardia, atrial flutter, and atrial fibrillation. In WPW rapid conduction through the accessory pathway during atrial fibrillation can result in ventricular fibrillation and sudden death. This is a rare but fatal complication of WPW.

Unstable re-entrant SVT is heralded by hypotension, poor peripheral perfusion, and altered mental status, and treated with synchronized direct current (DC) cardioversion. If the patient is stable, i.e. blood pressure minimally affected, re-entrant SVT can be acutely treated with vagal maneuvers such as ice applied to the face or a Valsalva maneuver, which slows conduction through the AV node. Adenosine can be used to terminate re-entrant SVT as it blocks the sinus node for a period of time. Adenosine is a short-acting agent, metabolized by red blood cells. The initial dose is 25-50µg/kg given rapidly through the most central venous access possible. Equipment should be immediately available to perform cardioversion if necessary. If the first dose is ineffective,  $100 \mu g/kg$  may be given. If re-entrant SVT recurs other drugs may be necessary. Verapamil blocks the AV node for a longer period of time but the patient must be older than 2-5 years of age to reduce the risk of verapamil inducing other arrhythmias. The dose of verapamil is 0.1 mg/kg over 5 min. Procainamide will block the accessory pathway and it may speed or slow conduction through the AV node. The initial dose is 5-15 mg/kg over 15-45 min. If an infusion is necessary, start the procainamide at  $20 \mu g/$ kg/min. Doses up to 60µg/kg/min may be needed. Amiodarone blocks the accessory pathway and the AV node. The initial dose is 1 mg/kg over 10 min, repeated as needed up to 5 mg/kg. This can be followed with an infusion at 5µg/kg/min. Cardiology consultation should be obtained for SVT evaluation and possible long-term management.

Junctional ectopic tachycardia (JET) is a rapid heart rate for age caused by a focus of abnormal automaticity within or around the atrioventricular junction. The QRS rate is by definition faster than the P-wave discharge rate in JET. This is a very uncommon arrhythmia in the absence of cardiac surgery. It appears occasionally following repair of congenital heart disease, most notably for tetralogy of Fallot. Treatment consists of cooling the patient, reducing exogenous catecholamine infusions as much as possible, and an antiarrhythmic agent, such as procainamide or amiodarone.

Ectopic atrial tachycardia (EAT) is consecutive fast atrial beats without sinus morphology. In multifocal or chaotic atrial tachycardia, different atrial origins may be seen. EAT is usually asymptomatic in the short term, but in the long term can lead to cardiomyopathy. Atrial flutter occurs due to re-entrant circuits around the tricuspid valve. It is very regular with many more atrial than ventricular beats. Atrial flutter is treated with DC cardioversion or pacing. Atrial fibrillation is usually caused by disorganized circuits from near the pulmonary veins. There are irregular difficult-to-see P-waves. Atrial flutter is treated with DC cardioversion.

Premature atrial contractions (PAC) are caused by automaticity of atrial tissue. Even if frequent, PACs are usually benign. Premature ventricular contractions (PVC) are an early occurring, wide complex beat associated with a compensatory pause if the sinus node is not reset. At times, the underlying stimulus for PVCs is the presence of a central venous catheter in the heart. If this catheter can be pulled back from the heart, doing so may reduce PVCs. Unifocal PVCs are usually benign but they can be reduced in frequency by correcting electrolytes including potassium, magnesium, and calcium. In addition, exogenous catecholamines should be decreased if possible. Treating pain or anxiety may reduce endogenous catecholamines, lessening the frequency of PVCs.

All wide complex tachycardias should be treated as ventricular tachycardia until proven otherwise. SVT with aberrant conduction of the QRS can be in the differential diagnosis, but initially the patient should be treated as ventricular tachycardia. If the patient is pulseless, begin CPR and defibrillate followed by medications from Pediatric Advanced Life Support (PALS). If the patient is stable with a pulse, DC cardioversion should be performed or the use of adenosine, amiodarone or procainamide can be considered. Ventricular fibrillation is always treated with CPR and defibrillation, followed by medications following the PALS guidelines. Magnesium should especially be considered if there is any possibility that the arrhythmia is torsade de pointes. See Chapter 12 for further discussion of cardiac arrest and resuscitation.

First-degree heart block is a prolongation of the PR interval. This can be seen in normal children and is almost

always asymptomatic. Second-degree heart block has two forms: Mobitz type I and Mobitz type II. Mobitz type I or Wenckebach phenomenon is a gradual prolongation of the PR interval until there is a dropped QRS. This is because of delay in the AV node and can be benign. Mobitz type II is an all-or-nothing phenomenon, the PR interval remains constant but there are intermittent dropped beats. Every second or third beat is conducted, evidenced by a QRS complex. This is a sign of His-Purkinje disease and is much more common in adults. This can progress to complete heart block (CHB). Thirddegree AV block or CHB is complete dissociation of atrial and ventricular beats. To be diagnosed as CHB, the atrial beats have to be faster than the ventricular beats. This can occur as congenital CHB in infants born to mothers with autoimmune disorders such as lupus. CHB can also be seen after surgery for congenital heart disease. The heart rate may be increased in response to intravenous isoproterenol, but more often requires transthoracic or transvenous pacing.

# Shock

Shock is often described as an inability to provide adequate perfusion of blood and in turn oxygen to tissues that require it. The concept of shock is often explained as a problem of oxygen supply and demand. During periods of normal health, the body supplies excess oxygen to tissues. The amount of oxygen the blood carries to the body is dependent on the amount of oxygen bound to hemoglobin and the amount of oxygen dissolved in blood. The normal oxygen content of the blood is explained by the formula:

 $CaO_2 (mL/dL) = (1.34 g/dL) (SaO_2) (Hb) + (PaO_2) (0.003)$ 

where  $CaO_2$  is the oxygen content,  $SaO_2$  the measured oxygen saturation, Hb the hemoglobin,  $PaO_2$  the arterial oxygen tension, and 0.003 is a factor used to calculate the dissolved oxygen content, in mL per mmHg  $PaO_2$ .

The normal carrying capacity is approximately 20 mL/ dL. The delivery of oxygen (DO<sub>2</sub>) to the tissues is dependent on this carrying capacity and cardiac output (CO): DO<sub>2</sub> (mL/min) = CaO<sub>2</sub> × CO × 0.01. The demand portion of the equation is oxygen consumption. O<sub>2</sub> consumption ( $\dot{V}O_2$ ) is independent of O<sub>2</sub> delivery above a critical point and over a wide range. Below a critical point,  $\dot{V}O_2$  is  $\dot{D}O_2$ dependent. For infants and young children,  $\dot{V}O_2$  is estimated at 175 mL/min/m<sup>2</sup>. Oxygen consumption is equal to oxygen delivery multiplied by oxygen extraction:  $\dot{V}O_2 = \dot{D}O_2 \times O_2 EX$ , where O<sub>2</sub>EX is oxygen extraction and is equal to (CaO<sub>2</sub> – CvO<sub>2</sub>)/CaO<sub>2</sub>. CaO<sub>2</sub> is the oxygen content of arterial blood and CvO<sub>2</sub> the oxygen content of venous blood. The difference between the two is predictably 4–6 mL/100 mL blood. Initially, as oxygen delivery decreases, the oxygen consumption remains constant via increased extraction. Below a critical point in oxygen delivery, oxygen consumption becomes delivery dependent. When oxygen to meet the metabolic needs of the body cannot be delivered, non-essential metabolism is eliminated. Examples are metabolism to maintain growth, thermoregulation, and neurotransmitter synthesis. This allows the remaining oxygen to continue to provide substrate for mitochondria. Certain organs in the body (kidney, skin, skeletal muscle, and intestines) receive a high blood supply relative to their metabolic needs. These organs also have a high proportion of sympathetic nerve innervations, allowing for redistribution of blood flow to organs that do not have adequate  $O_2$  reserves, such as brain and heart.

### **Classification of shock**

Shock can be classified by several schemas. Within different classification schemas, disease states can fall into more than one category and in clinical scenarios several may be working together. One classification includes hypovolemic, cardiogenic, distributive or vasogenic, and extracardiac obstructive shock.

Hypovolemic shock may be due to hemorrhage in cases like trauma or gastrointestinal (GI) losses. Nonhemorrhagic hypovolemic shock includes external losses of fluid from vomiting, diarrhea, polyuria, and poor fluid intake. There can also be a fluid redistribution shock state in cases of burns, trauma, and anaphylaxis.

Cardiogenic shock may be myopathic where the heart muscle itself does not function appropriately. In adults this may be following myocardial infarction. In children myocarditis or cardiomyopathy are more common. As indicated in the extracardiac life support (ECLS) section, in many cases in the PICU this can occur from myocardial stunning (effects of prolonged ischemia during aortic cross-clamping) following bypass for repair of congenital heart lesions. Further subdivisions of cardiogenic shock include mechanical failure such as valvular regurgitation or obstruction. Significant arrhythmias may result in a type of cardiogenic shock as contractions may not be synchronized to the point where there is effective output.

Extracardiac obstructive shock results from a physical impairment preventing adequate forward circulatory flow. This can occur due to inadequate preload secondary to mediastinal masses, increased intrathoracic pressure from tension pneumothorax, constrictive pericarditis, and cardiac tamponade from pericardial effusions. There can also be obstruction to systolic contraction from pulmonary hypertension, pulmonary embolus, and aortic dissection.

Distributive shock is associated with poor peripheral vascular tone and a maldistribution of blood flow to organs within the body. In distributive shock, cardiac
output can be increased but blood pressure may remain low due to a very low systemic vascular resistance. Septic causes of distributive shock can be related to bacterial, fungal, viral or rickettsial infections or toxins produced from these infections. Toxic shock syndrome would be an example of this latter cause. Aspects of anaphylactic or anaphylactoid reactions are a type of distributive shock. Systemic inflammatory response syndrome (SIRS) may present with a picture of distributive shock. Distributive shock can also occur on a neurogenic basis in the case of spinal shock. Adrenal insufficiency with low circulating cortisol results in distributive shock as the vascular bed has difficulty maintaining vascular tone.

## **Diagnosis of shock**

A high index of suspicion is necessary to rapidly identify shock in pediatric patients. The history will provide clues to volume loss or poor oral intake. Fever and malaise may point to infection. However, the history accompanying cardiogenic shock may be vague, with reports of decreased activity and level of alertness. In addition, physical findings may be limited if the patient is currently compensating. A child with shock may present with just tachycardia, cold extremities, and poor capillary refill. In distributive shock, the child may remain warm and have isolated tachycardia. A brief pertinent physical examination should be performed evaluating level of alertness, peripheral perfusion, mucous membranes, pulse rate and quality, respiratory effort, urine output and blood pressure. In children, blood pressure may be maintained until the last possible moment. Hypotension is a sign of late and decompensated shock in children. Initially laboratory values may not show significant metabolic acidosis, depending on how far the illness has progressed.

## **Compensatory mechanisms**

With onset of shock, the body applies compensatory mechanisms to maintain adequate tissue perfusion for as long as possible. Fluid is redistributed from the intracellular and interstitial spaces to the intravascular compartment. There is a decrease in glomerular filtration to decrease renal fluid losses. Aldosterone and vasopressin are released which also decrease renal fluid losses. Increased sympathetic activity and release of epinephrine decrease venous capacitance and attempt to support blood pressure. Heart rate is elevated in an effort to maintain cardiac output. Cardiac contractility is increased through circulating catecholamines and adrenal stimulation. As noted above, sympathetic tone shunts blood away from non-vital organs. At the tissue level, oxygen unloading is optimized by increased red blood cell 2,3-diphosphoglycerate (2,3-DPG), fever, and tissue acidosis.

## Therapy and outcomes of shock

Outcomes associated with aggressive therapy to treat septic shock in pediatric patients have been studied. Septic shock is a good example for discussing therapy for shock in general. The overall goal of treatment of any type of shock is to treat the underlying cause, return the body to a state of adequate oxygen delivery to all the tissues, and remove the metabolic products that developed during anaerobic metabolism. It appears that the faster the body returns to a state of adequate perfusion, the better the overall outcome.

In 1991 Carcillo et al [39] described a population of 34 children who presented to an emergency department with septic shock. Sepsis was defined as positive blood or tissue culture and shock was diagnosed based on hypotension for age, with decreased perfusion, poor peripheral pulses, cool extremities and tachycardia. Within a period of 6h of presentation, all the patients had a functioning pulmonary artery catheter in place. Overall mortality was 47%. However, in the group of patients who received more than 40 mL/kg of fluids in the first hour, there was only one death out of nine patients (11%). The authors go further to point out that this patient did not die during the initial therapy but with a second episode of sepsis 2 weeks later. In this study, rapid fluid administration was not associated with increased cardiogenic pulmonary edema or adult respiratory distress syndrome (ARDS).

In 2001 Rivers et al [40] published a study demonstrating that early, aggressive, goal-directed therapy in the first 6h of care for adults with septic shock improved mortality; 263 adults were enrolled and of these, 133 received standard therapy based on clinician discretion in the emergency department. Those patients randomized to early goal-directed therapy followed protocols to address issues of hypovolemia and support blood pressure with vasoactive agents if necessary. If the patient remained hypotensive, inotropic support was initiated to maintain a mean arterial pressure (MAP) greater than 65 mmHg. If patients were hypertensive, they were given vasodilators and if central venous oxygen saturation was less than 70%, the patients were transfused to a hematocrit of at least 30%. If central venous saturations remained low, dobutamine was started. When necessary, patients for whom hemodynamics could not be optimized were intubated, ventilated, and sedated. There were no significant differences between the groups with regard to baseline characteristics. The in-hospital mortality was 30.5% in the group assigned to early goal-directed therapy compared to 46.5% receiving standard therapy (p < 0.01). Although it was carried out in adults, this work extends and supports the efforts of Carcillo et al from 1991.

The Rivers' publication [40] prompted the formation of a task force from members of the Society of Critical Care Box 37.1 Definitions of shock

- Cold shock: decreased perfusion including decreased mental status, capillary refill >2 sec, diminished peripheral pulses, mottled cool extremities, and decreased urine output <1 mL/kg/h</li>
- Warm shock: decreased perfusion including decreased mental status, flash capillary refill, bounding peripheral pulses, and decreased urine output <1 mL/kg/h</li>
- **3. Fluid-refractory or dopamine-resistant shock:** shock persists despite ≥60 mL/kg fluid resuscitation in the first hour and dopamine infusion to 10 μg/kg/min
- Catecholamine-resistant shock: shock persists despite use of catecholamines, epinephrine or norepinephrine
- Refractory shock: shock persists despite goal-directed use of inotropic agents, vasopressors, vasodilators, and maintenance of metabolic (glucose and calcium) and hormonal (thyroid and hydrocortisone) homeostasis

Source: Carcillo and Fields [41]

Medicine to address shock in children. The result of their work was published in 2002 as "Clinical practice parameters for hemodynamic support of pediatric and neonatal patients in septic shock" [41]. The physiological differences between adults and children make adoption of adult guidelines challenging. The task force reviewed the literature and made recommendations for the diagnosis and treatment of pediatric shock. These guidelines, published by the American College of Critical Care Medicine (ACCM), are incorporated into the American Heart Association's (AHA) Pediatric Advanced Life Support (PALS) Provider Manual. From their work, septic shock can be defined as cold or warm shock. Decreased perfusion is present with decreased level of alertness. The capillary refill will be prolonged in cold shock (>2 sec) and pulses are diminished with cold mottled extremities. In episodes of warm shock, capillary refill is very brisk and pulses may be bounding. See Box 37.1.

The goals of therapy include rapid recognition of shock and early administration of intravenous crystalloid. Fluid should be given as a bolus of 20mL/kg and repeated up to 60 mL/kg in the first 40 min with a goal of reducing heart rate and improving perfusion. When the heart rate does not improve with this volume of fluid, central venous access should be obtained and dopamine infusion initiated. Arrangements should be made to admit the child to a PICU. If shock persists despite fluid and dopamine up to 10µg/kg/min, then epinephrine (cold shock) or norepinephrine (warm shock) is recommended (Fig. 37.1). The areas of the recommendation that have undergone further discussion and debate include the use of pulmonary artery catheters and use of hydrocortisone for concerns of adrenal insufficiency. There has been decreased use of PA catheters in children over time. In the absence of PA catheters, many clinicians are using the central venous pressure, information from echocardiography, and other non-invasive measures of cardiac output such as central venous oxygen saturation (ScvO<sub>2</sub>) or the USCOM to guide decisions. Clinicians currently in training are less likely to place PA catheters and, due to decreased familiarity, may be less able to use all the information provided. Whether PA catheters are of significant benefit seems to depend on the experience and needs of the practitioner.

With regard to adrenal insufficiency during septic shock, there certainly are instances where limited function of the adrenal axis is anticipated. Patients who have recently received glucocorticosteroids, ketoconazole or etomidate may be at increased risk. Disease states such as purpura fulminans or those affecting the hypothalamus, pituitary or adrenal glands will put patients at increased risk. These patients need supplemental corticosteroids to replace what their adrenal glands may not be able to produce. For the remaining children with septic shock, it is not clear whether the risk of relative insufficiency or treatment with systemic steroids alter outcome. Zimmerman presents an excellent review of the history of steroid use as well as the adult and limited pediatric literature for therapeutic use in sepsis [42]. As he indicates, adult studies have shown that high-dose short courses of steroids are associated with decreased survival. In addition, recent data from the CORTICUS trial [43] have shown that low-dose steroids as a physiological replacement during periods of vasopressor-resistant shock resolve shock more quickly but there is no change in mortality. Pediatric studies of low-dose steroids have not been done, but the information generated to date would indicate that steroids in sepsis do more harm than good. There remains institutional and individual bias to throw everything possible at patients to prevent mortality but there is not experimental evidence to indicate that steroids are effective.

The outcome in pediatric shock with adherence to the American Heart Association's guidelines was studied in 2003. Han et al [44] published a retrospective cohort study of children admitted to community hospitals with septic shock who were then transferred to a tertiary children's hospital. The overall mortality for the study was 29%. The study defined reversal of shock as return of normal systolic blood pressure and capillary refill time. For those patients in whom shock reversal was achieved by the time the transport team arrived (median time 75 min), survival was 96%. For each hour that shock persisted, there was a 2.29 times increased odds of mortality. This study indicates that the quicker shock is reversed, the better the outcome.

Further work has been done to evaluate whether the addition of central venous saturations as a goal-directed

endpoint has an impact on mortality in pediatric septic shock. De Oliveira [45] in 2008 published a randomized trial using the ACCM/PALS guidelines for early correction of pediatric septic shock. One group had monitoring of central venous saturations (ScvO<sub>2</sub>) with increased fluid resuscitation, transfusion of packed red blood cells (PRBCs) or inotropic support if ScvO<sub>2</sub> was less than 70%. The group with ScvO<sub>2</sub> goal-directed therapy had a mortality of 12% compared to 39% in the group treated by ACCM/PALS guidelines without this additional ScvO<sub>2</sub> goal. The ScvO<sub>2</sub> group received more crystalloid, transfusions, and inotropic support in the first 6h. The majority of patients with this level of acuity will require a central venous catheter for inotropic support and stable vascular access. This study shows that more information can be gained from central lines than just venous pressure and guiding therapy to improve the balance of oxygen delivery and consumption will save lives. See Box 37.2 for etiologies of circulatory failure.

# Systemic inflammatory response syndrome and multiple organ dysfunction syndrome Systemic inflammatory response syndrome

Sepsis is one possible cause of the systemic inflammatory response syndrome (SIRS). SIRS is a non-specific inflammatory process occurring after trauma, burns,

### Box 37.2 Etiology of circulatory failure in children

#### Hypovolemia: inadequate circulating blood volume

- Volume loss
- Blood loss (trauma, surgical)
- Plasma loss (burns, capillary leak, third-spacing of fluid)
- Water loss (vomiting, diarrhea, decreased oral intake)
- Vasodilation
- Anaphylaxis, drug intoxication
- Sepsis
- Neurogenic: sympathetic blockade, dysautonomia

#### **Diminished cardiac function**

- Myocardial dysfunction
  - Myocarditis, cardiomyopathy
- Hypoxia, acidosis, electrolyte disturbance, toxins
- Postoperative from heart surgery
- Anatomical obstruction to ventricular inflow or outflow
- Physiological obstruction to ventricular outflow
- Increased systemic or pulmonary vascular resistance
- Shunt lesions (e.g. large arteriovenous malformations)
- Dysrhythmias
  - Bradycardia, ectopy, extreme tachycardia

pancreatitis, cardiac bypass, surgery, infection, and other less frequent causes. In 2005 the International Pediatric Sepsis Consensus Conference [46] published their pediatric definitions for SIRS, sepsis and organ dysfunction. SIRS is defined by the presence of two of four criteria, of which one must be abnormal temperature or white blood count. The criteria are:

- 1. *abnormality in core temperature*: the patient can be febrile (>38.5°C) or hypothermic (<36°C)
- abnormality of heart rate: the patient can be tachycardic with a HR >2 standard deviations (SD) for age or in children <1 year of age the patient can be bradycardic <10th percentile for age. The abnormal HR is in the absence of external stimulus such as pain or medications
- **3.** *elevated respiratory rate* >2 SD for age
- **4.** *abnormal white blood count* which is elevated or depressed for age.

See Box 37.3. The consensus definition of sepsis is SIRS in the presence of or as a result of suspected or proven infection. Septic shock is defined as sepsis and cardiovascular organ dysfunction.

Systemic inflammatory response syndrome currently is defined by clinical criteria, but in the future may include laboratory values. In SIRS a specific insult to the body results in an unbalanced inflammatory response that affects coagulation, white blood cell release, cytokine release, chemotaxis, and downstream biochemical proc-

#### Box 37.3 Systemic inflammatory response syndrome definition

- Abnormality in core temperature Can be fever >38.5°C Can be hypothermia <36°C</li>
- Abnormality of heart rate Tachycardia with HR >2 SD for age Children <1 year can be bradycardic with HR <10th% for age</li>
- **3.** Abnormality of respiratory rate Respiratory rate >2 SD for age
- Abnormality of white blood count Elevated or depressed for age

At least two of the four criteria must be present, of which one must be abnormal temperature or white blood count.

esses. Typically infection results in a raised temperature and production of the cytokine tumor necrosis factor (TNF). These events help to fight infections. SIRS may be an excess proinflammatory response by the body or an imbalance of proinflammatory to anti-inflammatory response. Clinically very few children respond to a specific insult with a SIRS response. Most manage their inflammatory insults without significant problem. Early work is demonstrating that there may be a genetic predilection determining which patients develop SIRS. Agbeko et al [47] in a prospective study demonstrated that "polymorphisms in the complement activation cascade modify the risk for early SIRS/sepsis in general pediatric critical care." In the future we might be able to identify which patients are at greater risk.

# Development of multiple organ dysfunction syndrome and outcomes

Organ dysfunction represents a continuum of physiological abnormalities. It is not a simple issue of a normal organ versus a failed organ. Diagnostic criteria have been set forth to define organ failure for the purpose of description and research [48]. In turn, multiple organ failure is two or more organ systems meeting these criteria. Research supports the association between number of organs failing and increasing mortality [48,49].

The pediatric logistic organ dysfunction (PELOD) score was first described by Leteurtre et al in 1999 [50] and validated in 2003 [51]. The PELOD includes assessment of neurological, cardiovascular, renal, respiratory, hematological, and hepatic function (Box 37.4). Other organ dysfunction scoring systems exist incorporating different indicators, but PELOD is the most widely used. An excellent review by Proulx et al [52] in 2009 addressed the issue of multiple organ dysfunction syndrome (MODS) as well as the inflammatory spectrum covering sepsis, SIRS, MODS, and ARDS. A study by Typpo et al [53] using the virtual pediatric intensive care performance system

database analyzed 44,693 PICU admissions with complete data meeting their criteria. Of these, 18.6% (8303 patients) met criteria for MODS on day 1 of hospitalization. Mortality in the group with MODS was 10% compared to 1.2% in the patients not meeting MODS criteria. There was also a longer PICU length of stay and worse functional outcomes. Leteurtre et al [54] recently published results showing increased mortality with an elevated PELOD score on day 1, and a mortality of 50% if a high PELOD day 1 score rose further on day 2. MODS represents another area where consensus definitions and ongoing research studies have provided further information on outcome. Work will proceed using these tools to evaluate the impact of therapy on MODS.

# Respiration

# Assessment of monitoring of respiratory function

The cornerstones of ventilatory assessment remain clinical examination and the chest radiograph. In the nonintubated patient, respiratory rate, subcostal and sternal retractions, nasal flaring, grunting, use of accessory muscles, cyanosis, and  $SaO_2 > 10\%$  below baseline are signs of significant respiratory distress. Diminished breath sounds, rales, rhonchi, and wheezing on auscultation accompany respiratory compromise. Decreased level of consciousness due to hypoxemia or hypercarbia, and respiratory pauses are often harbingers of respiratory arrest. A variety of chest radiograph findings, including lobar or lung consolidation, pleural fluid, pneumothorax or severe hyperinflation due to bronchospasm, are seen in patients with compromised respiratory function. Similar findings may be seen in patients receiving either non-invasive ventilation or full mechanical ventilation, and these findings should be continually re-evaluated, even in the modern era of advanced respiratory monitoring.

The gold standard for measuring oxygenation is an arterial blood gas. Partial pressure of oxygen in arterial blood (PaO<sub>2</sub>) is measured directly from blood. The percent oxyhemoglobin saturation (SaO<sub>2</sub>) is calculated using pH, PaCO<sub>2</sub>, PaO<sub>2</sub>, and temperature but preferably is measured directly by blood oximetry, available on many modern blood gas machines. Capillary and venous blood gases do not measure or predict PaO<sub>2</sub>. Pulse oximetry provides an accurate continuous measure of arterial oxygen saturations (SpO<sub>2</sub>). Pulse oximeters are less accurate for saturations <60%, if there is poor perfusion where the probe is located or if there are other forms of hemoglobin present (methemoglobin, carboxyhemoglobin) interfering with the pulse oximeter. Methemoglobin and carboxyhemoglobin absorb light at the same wavelengths as oxyhemoglobin and deoxyhemoglobin, respectively.

The gold standard for measuring ventilation is the PaCO<sub>2</sub> from an arterial blood gas. As opposed to PaO<sub>2</sub>, a free-flowing capillary blood gas adequately estimates PaCO<sub>2</sub>. In addition, capnography and transcutaneous CO<sub>2</sub> (TCOM) devices are good non-invasive alternatives to monitor ventilation. Capnographs consist of an exhalation chamber, infrared light source, and detector connecting to the adapter end of the endotracheal tube. They produce waveforms of exhaled CO<sub>2</sub> that can either be time based or volumetric. Time-based CO<sub>2</sub> is the most commonly used method and what is normally seen on an anesthesia machine. Information available from capnography includes end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>), respiratory rate and pattern, confirmation of endotracheal tube (ETT) position, dead space calculations, cardiac output and presence of obstructive airways disease. Many PICUs now use continuous capnography as a standard of care in intubated patients in order to rapidly detect changes in ventilation or circuit disconnections.

When viewing the plateau of time-based capnography the level of  $CO_2$  detected approaches  $PaCO_2$  but will never equal it. As such, any elevation in ETCO<sub>2</sub> should be taken seriously and deserves further evaluation. For individuals without pulmonary disease, there is a 2–5 mmHg gradient between ETCO<sub>2</sub> and PaCO<sub>2</sub>. This difference can be even greater in disease states where there is increased dead space, pulmonary vascular abnormalities, decreasing cardiac output, right-to-left intracardiac shunting or pulmonary overdistension. The ratio of relative dead space to tidal volume (V<sub>D</sub>/V<sub>T</sub>) can be calculated

capnography and arterial using blood gas.  $V_D/V_T = [PaCO_2 - \overline{E}CO_2]/PaCO_2$  where  $\overline{E}CO_2 = mean$ expired  $CO_2$ . Graphically  $\overline{E}CO_2$  is the area under the curve of time-based capnography. Time-based capnography also demonstrates obstructive airways disease as an upslope to the plateau phase of the CO<sub>2</sub> curve. The accuracy of capnography improves if there is minimal leak around the ETT and with slower respiratory rates. It is also possible to use capnography to monitor the nonintubated patient, via a divided nasal cannula as is used during monitored anesthesia care.

Volumetric capnography is appearing as an additional feature on modern ventilators. This tracks the  $CO_2$  concentration against exhaled volume. The technique allows a ready determination of dead space calculations and helps to determine optimal positive end expiratory pressure (PEEP) on the ventilator and response to bronchodilator therapy. The PEEP can be titrated to balance optimal oxygenation and lowest dead space fraction.

Transcutaneous  $CO_2$  monitoring (TCOM) heats the skin in a small area underlying the sensor. The warmed capillary bed dilates and there is an increased  $CO_2$  diffusion across the skin. The  $CO_2$  is measured electrochemically. TCOMs require initial calibration compared to a blood gas but this can be a capillary sample. They are useful with high-frequency ventilation or non-intubated patients where capnography cannot be used.

Esophageal pressure monitoring is being incorporated into some ventilators and exists on free-standing devices. A balloon-tipped catheter is placed through the nose and advanced into the distal third of the esophagus. Due to transmitted forces, changes in esophageal pressure reflect changes in pleural or transpulmonary pressure. These changes can be followed while adjusting ventilator settings, providing an assessment of the patient's work of breathing.

Respiratory spirometry includes displaying flowvolume and pressure-volume loops, as well as flow-time, pressure-time, and volume-time graphs. Flow-volume loops measured by the ventilator or by free-standing devices can help diagnose the type of respiratory disease present based on characteristics of curve shapes. For spontaneously breathing patients, the classic presentations of flow-volume loops are inspiration negative and exhalation positive. However, the display on most mechanical ventilators places inspiration positive and exhalation negative (Fig. 37.2). Obstructive airways disease has a classic pattern of a scooped-out appearance on the exhalation portion of the curve (Fig. 37.3). Pressurevolume loops for mechanically ventilated patients help to identify recruitment of the lungs above an area of atelectasis (Fig. 37.4). Graphically, this is seen as a lower inflection point on the inspiratory curve from a flat area to an area of maximal compliance (greatest change in

Figure 37.2 Flow volume loop during mechanical ventilation. Note that exhalation is negative.

Figure 37.3 Flow volume loop with airway obstruction. Note the scooped-out appearance of exhalation.

Figure 37.4 Pressure volume loop during mechanical ventilation.

volume for change in pressure). Pressure–volume loops also contain an upper inflection point or an area above maximal compliance where the lung is overdistended by the current ventilator settings. This area of overdistension looks like a bird's beak and should prompt reductions in set ventilator peak pressure (Fig. 37.5). See Chapter 17 for additional discussion of respiratory monitoring.

## **Respiratory care**

Nasal cannula oxygen can improve a patient's oxygenation by increasing their fraction of inspired oxygen ( $FIO_2$ ). The formula for calculating the anticipated  $PaO_2$  with completely normal lungs is the alveolar gas equation:

 $PAO_2 = (barometric pressure mmHg - water vapor pressure mmHg) \times FIO_2 - (PaCO_2 / respiratory quotient).$ 

For example, with  $FIO_2$  0.40 at sea level, a  $PaCO_2$  40 mmHg, and respiratory quotient (CO<sub>2</sub> production/O<sub>2</sub> consumption, usually estimated to be 0.8), expected  $PaO_2$  would be:

$$[(760 mmHg - 47 mmHg) \times 0.40] - (40 mmHg / 0.8)$$
  
= 235 mmHg

Nasal cannula can increase the  $FIO_2$  up to approximately 40% when it is flowing at 5L/min. Above this, the nasal cannula is uncomfortable after a short period of time, due to the non-humidified gas flow drying and irritating mucus membranes.  $FIO_2$  cannot be increased further as room air is entrained during inspiration. However, of note, the smaller the patient, the lower their inspiratory

Table 37.2 Oxygen delivery by non-invasive means

Device	FIO <sub>2</sub>	Flow (L/min)
Nasal cannula	Up to 40%	<5 L/min
Simple facemask	Up to 60%	6–10 L/min
High-flow humidified nasal cannula	Close to 100%	1–30 L/min
Non-rebreather mask with reservoir	Close to 100%	6–15 L/min
CPAP or BiPAP therapy	100%	As needed to deliver pressure

tidal volume and potentially the greater impact on FIO<sub>2</sub> is made by nasal cannula oxygen.

Using a properly fitted facemask can increase inspired oxygen further. Oxygen delivery with a simple facemask may not be as great as the open holes allow for entrainment of room air. Use of a non-rebreather facemask with an oxygen reservoir and one-way valve for exhalation allows for near 100% oxygen to be delivered. Many children may not tolerate a facemask for a prolonged period of time. Practically, many patients reach this level of support while on a pediatric ward and either show improvement with therapy or progress to requiring PICU admission and intubation. Few patients remain on a non-rebreather mask for long. These systems can be humidified, but do not provide positive pressure. See Table 37.2.

High-flow humidified nasal cannula (HFHNC) oxygen has been used over the past 5-8 years as a means of providing higher FIO<sub>2</sub>. As the oxygen is heated to body temperature and humidified to 100% water vapor, higher flow of gas is much better tolerated than with just nasal cannula. As the flow of oxygen can be delivered at 10L/min or more, close to 100% oxygen can be achieved. There is belief that HFHNC may produce some amount of positive airway pressure, especially in small infants, but this is inadequately studied. The means by which different systems saturate oxygen with water vapor vary and some are proprietary. Many hospitals limit HFHNC use to the ICU. The device provides a significant support of oxygenation while not looking much different from nasal cannula. Some clinicians have significantly underestimated the severity of respiratory failure in patients on HFHNC until they deteriorate further.

Positive airway pressure can be delivered noninvasively. A well-fitting nasal or full-face mask maintains a seal and allows the system to apply positive pressure. Modern ventilators can be set to deliver constant positive airway pressure (CPAP) or bilevel support. More often specific bilevel positive airway pressure (BiPAP) machines are used. Use of non-invasive ventilation requires a patient with ability to protect their airway and a central drive to breathe. With bilevel support a back-up rate can be set. However, if a patient is too dependent on this support, a more definitive airway should be considered. CPAP provides distending pressure and helps to overcome atelectasis, thereby decreasing dead space, improving ventilation/perfusion, and potentially reducing work of breathing. Initial starting pressures of 4-6 cmH<sub>2</sub>O may be used and increased to the level tolerated and clinical improvement. More commonly, BiPAP therapy is used. The expiratory pressure again starts at 4-6 cmH<sub>2</sub>O and can be increased to expand the lungs. The inspiratory pressure is set initially at 5-6 cmH<sub>2</sub>O above expiratory pressure. Both settings as well as inspiratory and expiratory times can be adjusted. An FIO<sub>2</sub> of 1.0 can be delivered. Patients are at risk for aspiration and this is greatly increased with any episode of emesis. BiPAP therapy has been successfully used to treat asthmatics in an emergency department setting and improve aerosolized medication delivery. BiPAP is a common non-invasive therapy for patients with chronic respiratory failure, allowing them to be cared for at home. Pulmonologists often care for patients on night-time BiPAP for chronic respiratory failure or for central hypoventilation syndrome. If these patients are admitted for issues other than worsening respiratory distress, they may be cared for on a pulmonary ward, avoiding an ICU admission.

Short-term use of continuous BiPAP should be the expectation. In the best of circumstances, it is supportive while waiting for therapy to be effective. If used as a bridge to more definitive respiratory care, it should be short. The constant pressure of the mask will lead to tissue breakdown on the face. This is accelerated when the patient's global perfusion or skin integrity is poor. Patients remain nil per os (NPO) while on continuous BiPAP. Tracheal intubation and further respiratory support may allow initiation of enteral feeds. There are benefits to BiPAP therapy as it can be tried without requiring intubation and patients may tolerate BiPAP with little or no sedation.

There are many modes of mechanical ventilation. The preferred mode often depends on the clinical scenario and the intensivist's experience. For *volume-controlled* ventilation, a set tidal volume is chosen. As the ventilator delivers the set volume, changes in respiratory compliance or resistance alter the peak airway pressure to deliver the volume. If the changes to compliance or resistance are significant, as with partial obstruction of airways or endotracheal tube, then very high pressures can be delivered. However, ventilators are set with maximal pressure limits, and with obstruction or deteriorating respiratory compliance the ventilator will alarm and the volume delivered will be limited by peak pressure. For *pressurecontrolled* ventilation, a set pressure is defined. As the ventilator delivers the set pressure, the tidal volume achieved will change depending on respiratory compliance and resistance. If the changes to compliance and resistance are significant, as in airway obstruction or worsening respiratory failure, decreasing tidal volumes may be delivered, resulting in underventilation of the patient. However, practically speaking, the ventilator will alarm for low minute ventilation. For differences between adult and pediatric normal respiratory parameters, see Table 37.3.

One advantage of pressure-controlled ventilation is that most ventilators have a decelerating inspiratory flow

#### Table 37.3 Respiratory mechanics

	Infant	Adult
Respiratory frequency (breaths/min)	30–40	12–16
Inspiratory time (sec)	0.4–0.5	1.2-1.4
I/E ratio	1/1.5–1/2	1/2-1/3
Inspiratory flow (L/min)	2–3	24
Tidal volume mL mL/kg	18–24 6–8	500 6–8
Functional residual capacity (FRC) mL mL/kg	100 30	2200 34
Vital capacity mL mL/kg	120 33–40	3500 52
Total lung capacity mL mL/kg	200 63	6000 86
Total respiratory compliance mL/cmH <sub>2</sub> O mL/cmH <sub>2</sub> O/mL FRC	2.6–4.9 0.04–0.06	100 0.04–0.07
Lung compliance mL/cmH2O mL/cmH2O/mL FRC	4.8–6.2 0.04–0.07	170–200 0.04–0.07
Specific airway conductance mL/sec/cmH <sub>2</sub> O/mL FRC	0.24	0.28
Respiratory insensible water loss mL/24 h	45–55	300

pattern for gas delivery. Inspiratory flow is maximal early in inspiration and then gradually decreases to no flow when peak pressure is reached. For most patients, pressure control results in delivery of a tidal volume for a lower peak pressure relative to the pressure reached to deliver the same tidal volume in volume mode.

Modern ventilators have additional modes including a volume-guaranteed setting where the ventilator adjusts to the lowest pressure needed to deliver a set volume. Commonly, the mode is referred to as pressure regulated volume control (PRVC). After several consistent breaths, the ventilator will reduce the peak pressure over several breaths as long as the set volume is delivered. When it falls below the targeted volume, the pressure is increased until the volume is met. This may be an effective means of reducing pulmonary trauma from high peak pressures in patients with severe restrictive lung disease. However, this mode is most effective when patients are well sedated with or without muscle relaxants. Coughing or competing with the ventilator greatly affects the delivered volume.

The previously mentioned ventilator modes all address the means by which mandatory breaths are delivered. Typically the mandatory delivered breaths are synchronized to the patient's effort to initiate a breath. These triggers to initiate a breath occur by a change in flow or change in pressure in the ventilator circuit. A third triggering strategy has recently been developed by Maquet using the Servo-i<sup>®</sup> ventilator with NAVA® (Neurally Adjusted Ventilatory Assist). A small esophageal probe is placed in the patient, which senses the electrical activity of the diaphragm. The diaphragm activity is used as the trigger to start the ventilator. A possible benefit of NAVA is that patients may be ventilated more comfortably and will require less sedation. Improved synchrony has been shown in an animal study [55]. There is limited work in human infants [56] and further work evaluating the technique is ongoing.

In addition to set ventilator breaths triggered by the patient, further respiratory effort can be supported. When detecting a change in flow or pressure, the ventilator can deliver volume support or pressure support based on the patient's needs. During periods of worsening respiratory illness, the patient can receive additional respiratory support above the set ventilator rate. During periods of improvement some clinicians will use this as a mechanism of weaning from mechanical ventilation. As the patient improves, the set ventilator rate is serially weaned to the point where the patient is mostly or completely breathing with pressure support and PEEP. Pressure support is then gradually decreased to the point where the patient is tolerating just CPAP and then the trachea can be extubated.

High-frequency ventilation describes multiple modes of ventilation where the ventilator's respiratory cycle is far in excess of a normal physiological rate. The earliest published works referring to these systems appeared in the late 1960s with Sanders describing high flow jet ventilation (HFJV) in 1967 [57] and high-frequency positive pressure ventilation (HFPPV) by Oberg and Sjostrand in 1969 [58]. High-frequency oscillatory ventilation (HFOV) was described by Lunkenheimer in 1972 [59] and is the form of high-frequency ventilation most commonly used in pediatric ICUs today. HFOV allows a mean airway pressure to be set. The entire airway and ventilator circuit is pressurized to that value all the way back to a piston on the ventilator. The piston of the ventilator provides small positive and negative ventilatory cycles up to 840 times per minute. The set mean airway pressure maintains airway patency, preventing the cycle of alveolar collapse and overexpansion. A frequency of oscillation is usually chosen between 6 and 14 hertz (1 hertz = 60cycles/sec) and adjustment of this frequency is a component of altering carbon dioxide removal. An amplitude or distance of piston movement is chosen which effectively wiggles the chest. This chest wiggle also contributes to carbon dioxide removal. FIO<sub>2</sub> is adjusted just as in a typical ventilator. The exact mechanism of gas transport with HFOV is not completely understood. Several proposed mechanisms exist, but due to difficulty of study none has been proven.

High-frequency oscillatory ventilation can be used as a rescue therapy for hypoxemia refractory to conventional mechanical ventilation. It is also used as a means of reducing the shear forces which the lung is exposed to with conventional ventilation. This causes HFOV to be used with air leak syndromes from ongoing pneumothorax or bronchopleural fistula. HFOV should not be used if there is obstruction to expiratory flow, as with bronchospasm. In moderate-to-severe obstructive lung disease, HFOV will frequently result in overdistension of the lung and likely pneumothorax. Randomized controlled trials of early use of HFOV in ARDS have been proposed and discussed, but are difficult to enact due to a lack of equipoise.

## Weaning from mechanical ventilation

The pediatric literature is very limited with regard to providing guidance on weaning and extubating from mechanical ventilation. A recent review by Newth et al published in 2009 addresses what is known [60]. Attempts have been made to predict which children can be successfully weaned from mechanical ventilation. Most of the indices are used as research tools. One of the easiest to conceptualize is the Rapid Shallow Breathing Index (RSBI) devised by Yang and Tobin [61]. The RSBI = respiratory rate/tidal volume. When patients are breathing comfortably they have a decreased respiratory rate and are moving larger tidal volumes. Therefore the RSBI decreases.

There are many different techniques for weaning from ventilation. Possibilities include decreasing the set ventilator rate over time, a daily spontaneous breathing trial with pressure- or volume-supported breaths, or increasing cycles of reduced ventilator support until the patient tolerates the decreased support. No clear information exists supporting one means over another. Likely the best current answer is to ask the question on a daily basis whether the patient is able to be extubated. Evidence does show that a significant percentage of patients evaluated for weaning are actually ready for extubation [62,63].

There is an anticipated extubation failure rate; if the intensivist waits until absolutely certain that a patient will not fail, then many patients will be ventilated too long. A review of 16 ICUs for length of ventilation and extubation failure revealed a failure rate of 6.2% (range 1.5-8.8%) for patients intubated longer than 48h [64]. Spontaneous breathing trials are defined periods of decreased support where clinical signs are followed to evaluate respiratory distress. Depending on the institution, this may be pressure support, volume support, CPAP or T-piece ventilation. Some will challenge the patient for 2h and others as little as 15 min. There should be no significant increase in respiratory rate, decrease in saturations, diaphoresis or clinical evidence of increased work of breathing or hemodynamic compromise. Blood gas values should not change significantly during these trials; if they do, it is assumed that the patient is not yet ready for extubation.

A common misconception is that patients with smaller endotracheal tubes are "breathing through a straw" when placed on CPAP or T-piece. This view has been refuted through the work of Manczur et al [65], Willis et al [66] and Hammer et al [67]. The ETT is smaller in diameter compared to an adult, but it is also shorter and the flow rate in infants is low compared to an adult. Flow rates are approximately 0.5 L/kg/min [68]. A 3 kg infant has a flow velocity of 1.5 L/min compared to 30 L/min for a 60 kg adult.

In general, criteria for extubation include intact airway reflexes, hemodynamic stability, manageable secretions, and an appropriate level of alertness. Negative inspiratory force (NIF) may be measured. However, many do not measure it appropriately with a calibrated manometer and inspiration from residual volume. However, a NIF of  $-30 \text{ cmH}_2\text{O}$  or greater is associated with improved success. A leak around the ETT may give additional support that the extubation will be successful. Absence of a leak should not delay extubation if all other conditions are favorable. See Box 37.5 for criteria for extubation. Extubation failure is defined as reintubation within 24h of a scheduled extu-

#### Box 37.5 Criteria for extubation

- Acceptable ABG or saturations on FIO<sub>2</sub> of 0.40 or less with CPAP of 5 cmH<sub>2</sub>O or less and pressure support of 5 cm H<sub>2</sub>O or less
- In the absence of cyanotic heart disease, acceptable  $\text{PaO}_2$  >60 mmHg or saturations >95%
- PaCO<sub>2</sub> not elevated more than 20% of the child's baseline
- Comfortable breathing pattern, without tachypnea, retractions or excessive work of breathing
- · Able to maintain and protect airway
- Appropriate level of alertness
- Able to cough, breathe deeply, and clear secretions
- Hemodynamic stability
- No major instability of other organ systems
- Able to generate an inspiratory force of -20 to -30 cm H<sub>2</sub>O (if measurable)

bation attempt. Upper airway obstruction has been the stated cause in up to 37% of failed extubations [64]. For this reason, many intensivists pretreat the patient who is ready for extubation with a course of dexamethasone starting 6–12h in advance. Further research is needed to define measures which may decrease subglottic edema.

# Specific diseases of the respiratory system Asthma

Estimates from the US Centers for Disease Control indicate the prevalence of childhood asthma is increasing. In 1980 it was estimated at 3.6%, in 2003 it was 5.8% and in 2008 it is estimated the percent of children who currently have asthma is 9.4%. It is fortunate that the majority of children with asthma attacks will never be ill enough to require intensive care. However, for the small percentage of children that do, the morbidity and mortality are much greater. In fact, prior ICU admission and history of intubation for asthma are strong indicators of severe or uncontrolled asthma.

Asthma is a disease of inflammation. The submucosal area of the airways is infiltrated with mast cells, eosinophils, and CD4 lymphocytes. When mast cells are degranulated, leukotrienes and histamine are released, resulting in edema, increased mucus production, and attraction of white blood cells. Asthma attacks and triggering of mast cells can be caused by allergens, infections (viral > bacterial), weather changes, and strong emotions. The inflammatory environment increases airway irritability and hyper-responsiveness. Severe spasm of the bronchial muscles adds to the edema and mucus to reduce the airway lumen. Resistance to laminar airflow is inversely proportional to the fourth power of the radius but with turbulent flow it is to the fifth power. Children experience much greater increases in airway resistance during asthma attacks than adults, due to the smaller caliber of their airways. There is greater resistance to exhalation and the clinical presentation is one of expiratory wheezing. Mucus plugging or complete obstruction of small airways can occur from edema and bronchospasm. The primary initial component is hypoxemia as a result of V/Q mismatch. Air trapping can lead to increased dead space. To compensate, respiratory rate is increased. Typically, the initial PaCO<sub>2</sub> is low. A normal or elevated PaCO<sub>2</sub> may indicate fatigue and impending respiratory failure.

It is important to recognize early that not all wheezing episodes are asthma, and that asthma can occur without wheezing. Wheezing is the sound of obstruction to airflow. In addition to asthma, wheezing can be caused by pneumonia, upper airway obstruction, aspiration of a foreign body, and congestive heart failure. All these conditions merit different therapies. Sudden onset of wheezing in a toddler with no prior history of asthma or atopy should prompt evaluation for foreign body aspiration.

Intermittently, we are surprised when a chest radiograph obtained for wheezing shows cardiomegaly rather than peribronchial cuffing. A chest radiograph is warranted for any first-time wheezing patient and any child admitted to the ICU with wheezing. Airflow is required to detect wheezing by auscultation. Children can present with such significant airflow restrictions that they are unable to wheeze. Such patients presenting with a quiet chest are concerning and require immediate action.

The typical presentation of a child with asthma may be one of a few days of upper respiratory infections (URI) symptoms followed by increased work of breathing. The patient has a decreased SpO<sub>2</sub> in room air and is frequently sitting up. There is accessory muscle use, a prolonged expiratory phase, and possibly pursed-lip breathing (also known as autopositive end expiratory pressure). If a child is able to speak it may only be in one- or two-word bursts. There should be no delay in starting therapy. Supplemental oxygen is given to address hypoxemia. If the child is alert and speaking, with a moderate expiratory wheeze, nasal cannula oxygen may be sufficient. If respiratory distress is more severe, oxygen should be delivered by either simple facemask or non-rebreather facemask. Inhaled  $\beta$  agonists are given to relax bronchial smooth muscles. Typically this is albuterol, but occasionally intravenous terbutaline is needed, as are subcutaneous terbutaline or epinephrine. Steroids should be given early in treatment as they will take time to become effective. If there is not significant improvement with initial therapy, arrangements for ICU admission should be considered. Arterial blood gases are often obtained but usually the clinical picture provides more information to direct care.

# Therapy of asthma Supplemental oxygen

Oxygen can be delivered by a standard nasal cannula, but concentration is limited. High-flow humidified nasal cannula may provide greater  $FIO_2$  and delivery of  $\beta$  agonists with this device is becoming common. Simple facemasks or non-rebreather facemasks are frequently used.

# Inhaled β agonists

Inhaled  $\beta$  agonists relax bronchial smooth muscles. Albuterol is most commonly used and is a racemic mixture of the R- and S-enantiomers. The active R-enantiomer is available (levalbuterol) and may be associated with less tachycardia, but is more expensive. Albuterol is  $\beta 2$  selective, available as metered dose inhaler and solution for nebulization. Initially in the ICU setting, continuous albuterol is preferred and the usual dose is  $0.15-0.5 \,\mathrm{mg/kg/h}$  or  $10-20 \,\mathrm{mg/h}$ . When there is improvement, intermittent doses can be given every 1-2h. Inhaled terbutaline is less  $\beta$ 2 selective compared to albuterol and therefore is used less commonly. Albuterol use is associated with tachycardia. Less often there can be dysrhythmias such as increased premature ventricular contractions. At higher doses diastolic hypotension has been observed. Central nervous system (CNS) stimulation occurs typically with agitation and tremors.  $\beta$  Agonists drive potassium into cells so hypokalemia can be seen on electrolyte panels. Ipratropium bromide is an inhaled anticholinergic that is sometimes paired with intermittent albuterol doses. Ipratropium bromide promotes bronchodilation without decreasing mucociliary clearance.

## Corticosteroids

In an ICU setting intravenous steroids are preferred to oral due to concerns of decreased absorption. Inhaled steroids are of no benefit in the initial ICU setting. Methylprednisolone is commonly used because of its limited mineralocorticoid effects. The first dose is 2 mg/ kg and then 0.5–1 mg/kg every 6h. Some ICUs will prefer dexamethasone or hydrocortisone. Steroids are usually given for the duration of the acute asthma attack. If given for 5 days or less, they typically are not tapered. Hyperglycemia, hypertension and occasionally agitation are seen with systemic steroid use.

## Intravenous fluids

Children admitted with status asthmaticus will likely be dehydrated from poor oral intake during their illness and higher insensible losses from increased respiratory effort. Patients should be rehydrated to a sufficient circulating volume. Excessive fluids should be avoided so as to not contribute to pulmonary edema, which could worsen both oxygenation and airway resistance. For children who require mechanical ventilation, additional fluid may be needed around the time of intubation to prevent hypotension.

## Intravenous and subcutaneous β agonists

Severely reduced air exchange may prompt the use of IV β agonists. If there is limited ventilation albuterol distribution and absorption may be limited. Of the available drugs, terbutaline is often first choice. Terbutaline is relatively  $\beta 2$  selective compared to isoproterenol and epinephrine. For children without IV access it can be given subcutaneously with a dose of 0.01 mg/kg/dose up to a maximum of 0.3 mg. Intravenous terbutaline is given with a loading dose of  $10 \mu g/kg$  over 10-20 min. The continuous infusion is given with a range of  $0.1-10 \mu g/kg/$ min titrated to effect. Intermittently subcutaneous epinephrine is given for severe asthma exacerbation with a dose of 0.01 mg/kg of the 1:1000 solution with a maximum dose of 0.5 mg. Poor perfusion to extremities may limit absorption. Intravenous epinephrine may be an ideal drug for mechanically ventilated patients with hypotension. Isoproterenol is rarely used in status asthmaticus.

### Methylxanthines

The decision as to whether the methylxanthine aminophylline or the  $\beta$  agonist terbutaline is a second-line drug appears to be regional. With the increased use of leukotriene inhibitors for maintenance asthma therapy, fewer children are receiving oral theophylline. Methylxanthines promote relaxation of the bronchial smooth muscle, but the exact mechanism of action is not completely known. IV aminophylline is loaded with a dose of 5-7mg/kg over 30 min followed by a continuous infusion of 0.5-0.9 mg/kg/h. If the patient has received oral theophylline in the prior 24h the loading dose is reduced by 50% or dosing is adjusted based on serum theophylline level. Generally, a loading dose of 1 mg/kg will raise the serum theophylline level by  $2\mu g/mL$ . The goal for theophylline is 10–20µg/mL. Theophylline has a very narrow therapeutic window and levels above 20µg/mL are often associated with nausea, tachycardia, restlessness or irritability. Higher levels have been associated with seizure activity.

## Magnesium

Magnesium sulfate can be given intravenously to relax bronchial muscles. It causes smooth muscle relaxation due to its effect as a calcium channel blocker. Controversy exists as to whether magnesium has a significant clinical benefit and in turn its use is clinician dependent. A magnesium level should be measured with the initial set of electrolytes and hypomagnesemia should be treated. The dose for status asthmaticus or hypomagnesemia is 25– 40 mg/kg given over 30 min. Toxicity of magnesium can include muscle weakness, decreased reflexes, cardiac arrhythmias, and respiratory depression.

# Helium

Helium oxygen mixtures (heliox) are used to improve laminar flow of gas due to the decreased density of helium compared to nitrogen. Helium is about oneseventh as dense as air. Heliox may be potentially beneficial in the treatment of asthma by improving flow in very small airways. However, benefit from helium occurs when it is administered in a high ratio compared to oxygen. The most effective ratios would be 80:20 or 70:30 helium:oxygen. In clinical practice hypoxemia and the need for supplemental oxygen typically limit heliox use.

## Ketamine

Ketamine is a dissociative anesthetic that produces bronchodilation. In usual doses it does not blunt the respiratory drive or cause significant myocardial depression. It does, however, increase oral and airway secretions. Ketamine is a good sedative in conjunction with a benzodiazepine for patients who are intubated and mechanically ventilated. It is still not clear whether ketamine used to treat anxiety is beneficial in preventing intubation in patients during an asthma attack. Ketamine is given as a bolus dose at 1 mg/kg, allowing time for effect before repeating. Ketamine as a continuous infusion is usually given as  $5-30 \mu \text{g/kg/min}$  titrated to effect. As ketamine is a dissociative anesthetic causing dysphoria it is usually given with a benzodiazepine.

# Non-invasive ventilation

There is very limited evidence that non-invasive ventilation (NIV) is effective in children with asthma [69]. Clinically, patients with effective air exchange who fight the mask and positive pressure do not benefit from NIV. Nevertheless, some children with very limited air exchange and fatigue take to NIV easily and appear more comfortable. Non-invasive ventilation may allow time for therapies to become effective (steroids) and may prevent intubation. This should not be used when the level of alertness or ability to protect the airway is diminished.

### Tracheal intubation and mechanical ventilation

Asthmatic patients who require intubation are hypoxemic, acidotic, and greatly fatigued. They have limited reserve and decreased mental status, often from  $CO_2$ narcosis that occurs with acutely elevated  $PaCO_2$  above 80mmHg. In this scenario, it is preferable to have the most experienced practitioner to intubate the patient. Good venous access is necessary and fluid boluses should be ready. Ketamine and a benzodiazepine titrated to effect are a good choice for many practitioners. In our unit a short-acting muscle relaxant such as rocuronium is preferred to allow the patient to breathe spontaneously as soon as possible. A cuffed endotracheal tube should be used as high peak pressures on the ventilator may be necessary. Slow hand ventilation after intubation will prevent alveolar overdistension and the risk of pneumothorax. Acute decompensation following intubation requires prompt evaluation. Causes include displacement or obstruction of the endotracheal tube, pneumothorax or decreased venous return from excessive positive pressure resulting in reduced stroke volume and cardiac output.

## Mechanical ventilation

Controversy remains regarding the best means to mechanically ventilate patients with asthma. During pressurecontrolled ventilation, changes in airway resistance occurring with asthma result in variable tidal volumes. However, volume-controlled ventilation may be suboptimal in that the same tidal volume can be delivered with a lower peak pressure in a pressure-controlled mode. The goal for intubated children with asthma is to achieve spontaneous ventilation as soon as possible. The patient then sets his or her own respiratory rates and inspired tidal volumes, and spontaneous breathing allows active exhalation as early as possible during weaning from mechanical assistance. Pressure support ventilation may be helpful in this scenario [70]. In the short term an increase in PaCO<sub>2</sub> is well tolerated as long as the patient is well oxygenated.

Classically PEEP was limited during treatment of obstructive airways disease such as asthma in view of the perceived risk of hyperinflation [71] and barotrauma. However, since 1988 there have been four studies in adults [72-75] and one [76] in children which suggested that adding extrinsic PEEP during mechanical ventilation is effective. The studies showed that extrinsic PEEP (PEEP added by the ventilator), up to a level matching intrinsic PEEP (residual pressure at the end of the ventilator cycle due to expiratory obstruction), improves effective triggering sensitivity of the ventilator. This in turn diminishes ventilatory work, and reduces mechanical work of breathing (WOB) during assisted and spontaneous breathing. This decrease in WOB reduces stress and improves comfort by reducing need for sedation. Matching PEEP may improve delivery of aerosol therapy via the endotracheal tube, and possibly allow earlier liberation from mechanical ventilation. However, it also carries the negative implication that application of increased levels of PEEP will overdistend the patient's lungs and increase the hazards of hyperinflation such as air leak syndrome [71,77]. According to our studies [66,76], during spontaneous breathing both application of PEEP and breathing with pressure-supported breaths lower WOB. However, the level of extrinsically applied PEEP at which hyperinflation will occur is unknown for any given patient. Theoretically, if the patient is breathing spontaneously, application of extrinsic PEEP to counteract intrinsic PEEP should not cause any increase in end-expiratory lung volume (EELV) until the former supersedes the latter [78]. Further, EELV may even decrease which would decrease dead space and increase compliance. In our current practice intrinsic PEEP is measured by allowing the patient to exhale completely with a ventilator pause and measuring final pressure before the next breath. Extrinsic PEEP is gradually added to the ventilator as respiratory rate and clinical work of breathing are observed. Extrinsic PEEP always kept at a level below intrinsic PEEP. These values are reassessed as the patient responds to therapy. Further research studies are necessary to determine the best means of applying mechanical ventilation to these patients.

### Inhalational anesthetics

Inhaled anesthetics have been used as bronchodilators in critically ill intubated children with asthma. The largest reported case series is six patients [79]. Isoflurane has been used effectively in our ICU with the reduction of bronchospasm and the ability to decrease intravenous sedation, but there are difficulties associated with its use. Most ventilators are not designed to accept a vaporizer. ICU ventilators do not have a circle system so there is a tremendous use of anesthetic vapor. Scavenging is a significant concern to reduce contamination of the patient room. Details of its use and other therapies in the ICU are included in several recent reviews [80-82]. A good choice where available would be to use a modern anesthesia machine with a ventilator capable of performance matching standard ICU ventilators, while having a built-in vaporizer and anesthetic gas scavenging ability.

## **Extracorporeal life support**

Extracorporeal life support (ECLS) has been used as a rescue therapy in near fatal asthma with some positive success. Given the nature of this therapy, the reports are very small in number. As there is usually no other associated disease state, the use of ECLS for asthma may be considered as there are no co-morbidities that would preclude its use. See Box 37.6.

# Acute lung injury and acute respiratory distress syndrome

## **Consensus definitions**

Consensus definitions of disease states from leaders in their fields improve research and clinical care through uniformity. Enrollment criteria and assessments can be standard across hospitals and providers. The American European Consensus Conference on ARDS defined acute

#### Box 37.6 Escalating asthma therapy

#### Supplemental oxygen

- Nasal cannula can deliver  $FIO_2$  up to 40%
- May require facemask oxygen or high-flow humidified oxygen
- Mask BiPAP therapy may decrease work of breathing in co-operative patients

#### Inhaled $\beta$ agonists

- Albuterol is most common, racemic β2-selective agonist
- Continuous albuterol dosing 0.15-0.5 mg/kg/h or 10-20 mg/h
- Xoponex is R-enantiomer of albuterol, expensive but less tachycardia

#### Corticosteroids

- Methylprednisolone used commonly due to limited mineralocorticoid effects
- First dose 2 mg/kg and then 0.5–1 mg/kg every 6 h
- Regional practice may use dexamethasone or hydrocortisone
- If given for less than 5 days, steroid taper usually not indicated

#### Intravenous fluids

- Patients should be rehydrated to a sufficient circulating volume
- Avoid excessive fluids

#### Intravenous or subcutaneous $\boldsymbol{\beta}$ agonist

- Terbutaline can be given subcutaneously if there is no IV access
- Subcutaneous terbutaline 0.01 mg/kg/dose up to max of 0.3 mg
- IV terbutaline load of  $10 \mu g/kg$  over 10-20 min
- IV terbutaline drip 0.1–10µg/kg/min titrated to effect

### Methylxanthines

- Promote relaxation of bronchial smooth muscle
- IV aminophylline load of 5–7 mg/kg over 30 min
- IV aminophylline drip 0.5–0.9 mg/kg/h
- If the patient has been taking oral theophylline, load reduced by 50%
- Target theophylline level is 10–20µg/mL

#### Magnesium

- IV bronchial smooth muscle relaxant
- IV dose for asthma or hypomagnesium is 25–40 mg/kg over 30 min
- Toxicity includes muscle weakness, decreased reflexes, arrhythmias, respiratory depression

### Helium

- Reduces work of breathing due to improved laminar flow
- Helium is 1/7th as dense as nitrogen
- Typically 70% helium required for benefit so hypoxemia usually limits use

#### Ketamine

- Dissociative anesthetic that produces bronchodilation
- Usual doses do not blunt respiratory drive but do increase secretions
- Bolus dose 1 mg/kg, drip 5–30 µg/kg/min titrated to effect
- May cause dysphoria, usually given with a benzodiazepine

#### Non-invasive ventilation

 Mask BiPAP therapy may decrease work of breathing in co-operative patients

### Intubation and mechanical ventilation

- Patients have limited reserve at this point; the most experienced person should intubate
- Ketamine and a benzodiazepine may be good induction agents
- Fluid boluses likely will be required
- Reversing muscle relaxants as early as possible may allow the patient to breath with PS/PEEP

### Inhalational anesthetics

- Isoflurane is a potent bronchodilator
- Technical aspects limit delivery of inhaled anesthetics with modern ventilators

#### **Extracorporeal life support (ECLS)**

- Has been used as a rescue therapy in near fatal asthma
- Very few reported cases

lung injury (ALI) and acute respiratory distress syndrome (ARDS) in 1994 [83]. This acknowledges that respiratory distress can occur in all ages, as the disease had been known at times as adult respiratory distress syndrome [84]. ALI and ARDS are the acute onset of bilateral infiltrates on chest radiograph without evidence of left ventricular dysfunction and a diminished  $PaO_2/FIO_2$  (PF) ratio. The PF ratio for ALI is  $\leq$ 300 and the PF ratio for

ARDS is ≤200. The concern for ventricular function follows from a higher incidence of myocardial infarction in adults leading to decreased cardiac contractility, resulting in pulmonary edema and a lower PF ratio. This would be a separate disease process. Cardiac dysfunction can occur in children, but is less common. Bilateral infiltrates on chest radiograph identify diffuse pulmonary inflammation. See Box 37.7.

**Box 37.7** Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) definitions

- Acute onset of disease
- Bilateral infiltrates on chest radiograph
- No clinical evidence of left atrial hypertension or left ventricular dysfunction
- For ALI  $PaO_2/FIO_2 \leq 300$
- For ARDS PaO₂/FIO₂ ≤200
- In the absence of an arterial line:
  - ALI: pulse oximeter saturation (SaO<sub>2</sub>)/FIO<sub>2</sub>  $\leq$ 260 has been used ARDS: SaO<sub>2</sub>/FIO<sub>2</sub>  $\leq$ 200 has been used

## Morbidity and mortality

Acute lung injury and ARDS are associated with significant morbidity and mortality. Historical estimates had placed mortality at 50% or more. The length of time spent on a ventilator can be weeks or longer. Ventilator free days (VFD) is a term used to compare outcomes with therapy in lung injury. The ventilator free days are the number of days out of 28 that the patient is not mechanically ventilated. Estimates of mortality and decisions about management changed when the ARDS network published a landmark paper in the New England Journal of Medicine in 2000 [85]. For adult patients with ALI and ARDS, ventilation with a lower tidal volume of  $6 \,\mathrm{mL/kg}$ predicted bodyweight resulted in decreased mortality (31%) compared to a tidal volume of 12 mL/kg (39%). The clinical trial was stopped early due to these findings. Additionally, there was also a significant increase in ventilator free days using the lower tidal volume. Concerns were raised following this study that the larger tidal volume control arm did not reflect current care provided in most adult ICUs. Over a period of years clinicians had moved closer to 8-10 mL/kg and if a low tidal volume strategy was used, it was with 5-7mL/kg. The ARDS network trial demonstrated a lower mortality for this disease process (31%), but some portion of this may have been improved overall care. In adult studies the degree of hypoxia at presentation is not associated with increased mortality. The changes to clinical practice following these reports have been significant. The take-home message was: lower peak pressures, smaller tidal volumes and oxygenation supported with increased PEEP. Many intensivists and ICUs have changed their practice.

Flori et al [86] reported a mortality rate for ALI and ARDS in children of 22%. This was significantly lower than adult mortality at the time. These children were enrolled in a time period from 1996 to 2000 at two major pediatric hospitals. In addition, it was demonstrated in children that the initial degree of hypoxemia was associated with mortality. This decreased mortality likely represents the first modern-era publication of pediatric ALI/ ARDS. Albuali et al [87] published outcomes for ALI from a single center in two groups (1988–1992 and 2000–2004). The earlier group was ventilated with significantly higher tidal volumes (10 mL/kg), lower PEEP (6 cmH<sub>2</sub>O), and higher inspiratory pressures (31.5 cmH<sub>2</sub>O) and had a mortality of 35%. The later group used a tidal volume of 8 mL/kg, PEEP of  $7 \text{ cmH}_2\text{O}$ , and inspiratory pressures of 28. The mortality in this group was 21% and there was a significantly increased number of ventilator free days. A higher tidal volume was independently associated with increased mortality. This study also described significant increases in patients receiving adjuvant therapy to treat hypoxemia. There was increased use of inhaled nitric oxide, high-frequency oscillatory ventilation, prone positioning, surfactant administration and extracorporeal life support. Over the long run not all adjuvant therapies have proven efficacious; however, this does demonstrate that other interventions are available.

The similarities between children and adults include the primary causes of ALI/ARDS, which are pneumonia, aspiration and sepsis, and increased mortality for patients with more than one organ system disease. These studies also highlight the differences between adults and children. For pediatric lung injury, the initial degree of hypoxemia relates to mortality, which is not the case for adults. In turn, low tidal volume strategies may be helpful when using PEEP to recruit lungs in pediatric patients. Further, many pediatric studies take into account the amount of ventilator support needed to arrive at a degree of oxygenation. One measure is the oxygenation index (OI):  $OI = (FIO_2 \times mean airway pressure)/PaO_2$ . The mode of ventilation used in respiratory failure also differs between intensivists caring for adults versus children. There are institutional and regional preferences but in general the majority of adults are ventilated with a volume mode and children are ventilated with a pressure mode. Data from our institution [88] assessing outcomes for patients with ALI or ARDS revealed that greater than 90% were ventilated with a pressure control mode.

## **Pediatric research**

Pediatric research for acute lung injury (ALI) is limited by low incidence of disease and relatively low mortality. Recent population studies in Australia, New Zealand, and The Netherlands place the incidence of ALI between 2.2 and 2.9/100,000 for age <16 years [89,90]. Ventilator free days can be used as a surrogate outcome but quality of life indicators as an outcome measure are not common in children. Research groups have been formed to collaborate on research trials in the hope of providing more accurate or rapid answers to these questions. The Pediatric Acute Lung Injury and Sepsis Investigators (PALISI) held their first meeting in 2002 and currently have 78 PICUs participating. Recent studies have evaluated blood transfusion [91] and surfactant therapies with ALI [92]. One potential limitation to study enrollment is the need for an arterial  $PaO_2$  to identify hypoxemia. The routine use of pulse oximetry has meant that many more patients are being managed without an arterial catheter. It has been shown in adults [93] and children [94] that a  $SpO_2/FIO_2$ (SF) ratio provides a useful alternative to PF ratio for enrollment in trials and clinical care. Values to define lung injury using SF ratios are <260 for ALI and <200 for ARDS.

## Therapy

There are a number of therapies providing temporary improvements in oxygenation, but no effect on mortality or ventilator free days. Such therapies include prone positioning and inhaled nitric oxide. Numa et al [95] demonstrated that prone positioning of children did not improve functional residual capacity (FRC) and only improved oxygenation in those with obstructive lung disease. However, prone positioning continued to be used to improve oxygenation in children with ALI or ARDS [96,97]. In 2005 PALISI [97] demonstrated no improvement in ventilator free days for children with ALI treated with prone positioning. Similarly, inhaled nitric oxide use may temporarily improve oxygenation but a review and meta-analysis [98] with mostly adult data showed no reduction in mortality.

Potential rescue therapies for hypoxemia unresponsive to conventional ventilation are high-frequency oscillatory ventilation (HFOV) and extracorporeal life support (ECLS). HFOV maintains a near constant mean airway pressure and oscillation of a piston provides movement of very low tidal volumes. A large randomized cross-over trial showed no improvement in ventilator free days or mortality with HFOV [99]. However, with little else to offer, HFOV remains common in many pediatric centers [100]. A similar effect is seen with ECLS for ARDS. Results of the CESAR trial (described in the ECLS section) for adults with ARDS showed that for patients treated with ECLS, 63% survived to 6 months without disability. This is compared to 47% treated with conventional ventilation. Given the significant resources used by ECLS and its associated risks, decisions regarding its use should take into account other disease states the patient has and their prognosis.

Surfactant use to treat ALI and ARDS has not been promising in adults [101]. A large randomized pediatric trial showed an improvement in mortality and ventilator free days with use of exogenous surfactant [102]. In a small subset of patients from this study who were immunocompromised, surfactant therapy showed potentially an even greater benefit [92]. Patients who develop ALI or ARDS following hematopoietic stem cell transplantation have significant mortality reported as 71% [103]. Clearly any reasonable therapy that could show promise deserves further study.

Transfusion of red blood cells increases oxygen-carrying capacity. Unfortunately, no pediatric data indicate that supranormal values for hemoglobin confer any benefit. In addition, work published by Lacroix et al [91] showed a hemoglobin target of 7.5 g/dL to be as safe as 10 g/dL in stable patients in pediatric ICUs. There are risks to transfusion including fluid overload and transfusion-related acute lung injury. See section on Hematology/ oncology later in this chapter.

There is potential promise from adult studies using glucocorticosteroids in patients with ARDS improving mortality and ventilator free days [104]. However, there are no studies of corticosteroid use in pediatric patients for the treatment of ALI or ARDS.

## Management recommendations

The underlying trigger for ARDS should be identified and eliminated if possible. Sources such as infection, pancreatitis, and tissue necrosis can cause lung injury through inflammation. Antibiotics should be given early for any suspected infection. The overall goal of ventilator management is not to achieve normal blood gases. A degree of hypercarbia and respiratory acidosis may be tolerated in an effort to reduce the lung injury that can occur with overzealous ventilator management. The goal range for pH can be 7.30–7.45. Lower than normal saturations (≥89%) are tolerated, but there are no long-term outcome data on this intervention. To avoid barotrauma and volutrauma, tidal volumes greater than 10 mL/kg and plateau pressures greater than 30 cmH<sub>2</sub>O should be avoided if at all possible. In a pressure control mode of ventilation, adjust the peak pressure to achieve tidal volumes of 6-10mL/kg. After possible fluid resuscitation for shock, overall fluid balance should be restricted if possible.

# Extracorporeal life support

# Background

Cardiopulmonary support in the PICU with extracorporeal life support (ECLS) grew from experience in the operating room. ECLS is also known as extracorporeal membrane oxygenation (ECMO); the latter term is perhaps more descriptive. Work started initially in the neonatal population to support infants with profound hypoxemia due to meconium aspiration, pneumonia, sepsis or persistent fetal circulation with pulmonary hypertension. Over the years, advances in respiratory support such as HFOV, surfactant use and inhaled nitric oxide have decreased ECLS in this population. There remains the need for support of respiratory failure in refractory hypoxemia as well as congenital diaphragmatic hernia and there has been a dramatic increase in ECLS for cardiac support following surgical repair of congenital heart defects.

Similar to cardiopulmonary bypass in the operating room, blood is drained from the body passively by gravity from the largest vein safely accessed in the child. The blood passes through a membrane oxygenator where carbon dioxide is removed and oxygen is added. Blood is warmed and pumped back into the body. Blood returns via the same double-lumen venous cannula in venovenous (VV) ECLS or via an arterial cannula in venoarterial (VA) ECLS. For respiratory support the decision to initially pursue VV or VA ECLS is usually based on the experience of the center. There are associated risks and benefits of each but VV ECLS relies on native cardiac output, whereas VA ECLS can completely support both pulmonary and cardiac function.

Cervical cannulation is preferred in infants and small children. In VV ECLS, a double-lumen catheter is placed in the right internal jugular (IJ) vein. The proximal portion of the catheter drains blood from the right atrium and blood is perfused back via the distal lumen towards the tricuspid valve. VV ECLS relies on the heart to function as the pump returning oxygenated blood to the lungs and body. In VA ECLS a drainage venous catheter is placed via the right IJ into the right atrium and blood is returned via a second arterial catheter placed in the right carotid artery. The return of blood is directed toward the descending portion of the aortic arch and away from the aortic valve. Some institutions will use a second drainage catheter placed retrograde in the internal jugular vein at the level of the jugular venous bulb to improve cerebral venous drainage and monitor jugular venous oxygen saturations.

In adolescents and adults it is possible to provide access for VA and VV ECLS via femoral blood vessels. Following repair of congenital heart defects, if there is respiratory or cardiac failure requiring support, cannulation can occur through the mediastinum. The venous catheter is typically placed via the right atrial appendage and the arterial catheter is placed in the aorta. If there are limitations to outflow via the aortic valve or severe left ventricular dysfunction, a left atrial drain may be placed into the left ventricle to prevent ventricular dilation.

Basic components of the ECLS circuit include a venous reservoir collecting blood draining from the patient, a pump to drive blood flow, and an oxygenator that provides for gas exchange. In the past, the majority of ECLS circuits use a rollerhead pump that produces non-pulsatile blood flow. Centrifugal pumps were used much less commonly and had a higher incidence of hemolysis. Modern pumps, such as the Rotaflow Centrifugal Pump (Maquet Inc., www.maquet.com), use modern designs to minimize blood heating and hemolysis, and are the preferred device in many centers. The other significant difference between these types of pumps is that if there is a downstream obstruction, with a roller pump there is the risk of tubing or circuit rupture. This does not occur with centrifugal pumps, but the flow of blood still decreases. Membrane oxygenators consist of a silicone membrane envelope wound around a central spool. Blood is kept separate from gas and diffusion occurs across the membrane. Hollow fiber oxygenators were used less commonly in the past, but as technology improves they offer some advantages. The Quadrox D and Quadrox iD Pediatric (Maquet Inc., www.maquet.com) offer high gas transfer rates and a low pressure drop across the oxygenator that minimize blood trauma and have become the preferred devices in many centers.

Patients requiring ECLS and those caring for them receive great benefit from the Extracorporeal Life Support Organization (ELSO) and its registry. Since 1989 it has been maintaining a registry on the care and outcomes of patients receiving ECLS at active ELSO centers. There are details on greater than 40,000 national and international patients. The majority of the ECLS literature comes from the ELSO registry and large single-center studies.

### Infant outcomes

Over time a significant improvement in outcomes for ECLS for meconium aspiration has occurred, with survival approximately 95% [105]. This is the best outcome for all ECLS indications and all age groups. With improvement in respiratory support and care, there has been a steady decrease in neonatal ECLS for respiratory failure. At the same time, use of ECLS for cardiac support has increased. In review of the ELSO data from 1996 to 2000 for cardiac ECLS in neonates, there was a 34.2% survival to discharge or transfer [106]. The diagnoses of transposition of the great arteries (TGA) and persistent pulmonary hypertension of the neonate (PPHN), and initiating ECLS at less than 3 days of age were associated with a greater likelihood of survival. Survival was also improved in patients with shorter ECLS runs. Evaluating the entire registry for neonates, survival to discharge was 75% for respiratory failure, 39% for cardiac failure, and 38% if placed on ECLS during cardiopulmonary resuscitation [105]. Due to the need for heparin therapy while on ECLS and its associated risk of intracranial hemorrhage, prematurity is a contraindication to ECLS.

## **Pediatric outcomes**

Pediatric ECLS has been used in many fewer cases compared to neonates and the indications are very different. In children, the causes of respiratory failure are more varied and therefore compared to neonates the outcome in the total registry is worse. For ECLS for respiratory failure, neonatal survival is 75% and for older children 56% [105]. For children, the causes of cardiovascular failure include postoperative, cardiomyopathy or myocarditis. In a population of 1–16 year olds requiring ECLS for cardiac support, the indication was cardiomyopathy in 15.35% of the patients [107]. The overall ELSO registry of survival for pediatric cardiac ECLS is 47% and 39% if initiated during CPR [103]. Results are similar in a large single-center study of cannulation for ECLS during active resuscitation where there was a 33% survival to discharge [108].

# Adult outcomes

The first randomized trial of ECLS in adult ARDS was published in 1979 [109]. Nine ECLS centers participated and the survival was 9.5% with ECLS and 8.3% with conventional therapy. There were significant concerns that inexperience with this new technique contributed to the mortality. In 1994, Morris et al [110] published the results of a randomized trial from one center where extracorporeal carbon dioxide removal was performed with mechanical ventilation versus conventional ventilation for adult ARDS. The 30-day survival was not significantly different between the two groups at 33% versus 42%. However, this was a significant improvement compared to the overall mortality for ARDS. There have been significantly more studies performed over the last several years and many more adults placed on ECLS. The CESAR trial (Conventional Ventilatory Support Versus Extracorporeal Membrane Oxygenation for Sever Adult Respiratory Failure) has recently been published. Of the patients allocated to consideration for ECLS treatment, 63% survived to 6 months without disability compared to 47% allocated to conventional therapy [111]. Potentially due to poor initial outcomes, the overall survival to discharge in adult patients placed on ECLS for respiratory failure is 52% from the ELSO registry [105]. Compared to pediatric patients, many of the adults placed on ECLS for cardiac causes have had cardiogenic shock following myocardial infarction. There is also a population of patients who fail to wean off bypass following cardiac surgery. In turn, the survival for adult cardiac ECLS is 34% and 27% when started during CPR [105].

# **Pediatric indications**

Criteria defining both the use and exclusion of ECLS for children with cardiac, respiratory, or multiorgan failure are less structured compared to those for neonates. In addition, as ECLS programs grow in experience and technology changes, ECLS is initiated in patients who previously would have been excluded for secondary disease. It is clear that hypoxia not responding to conventional ventilation with lung recruitment strategies or to highfrequency ventilation is an indication for ECLS. However, at some point in the disease process the ventilator trauma that has occurred before ECLS may preclude a successful outcome. In a retrospective review by Nance et al [112] of ELSO data for 2550 pediatric patients, survival decreased significantly as ventilator days prior to ECLS increased. For each additional day of pre-ECLS ventilation, the average decrease in survival was 2.9%. Their study also found a decrease in survival with increasing age, on average 2.5% per additional year of age.

Extracorporeal life support has been used as a rescue therapy for additional disease processes. In a singleinstitution study of ECLS used in septic shock, 21/45 patients survived to discharge [113]. ECLS has also been used sporadically to support patients with meticillinresistant *Staphylococcus aureus* sepsis [114] and case reports occur for cardiovascular failure supported with ECLS for specific causes such as ibuprofen overdose [115] or anterior mediastinal mass [116].

Significant complications can occur with ECLS use. Patients will receive blood transfusions as their circulatory volume is now expanded and hemolysis occurs. To prevent thrombosis, the circuit is heparinized which increases the risk of bleeding or heparin-induced thrombocytopenia [117]. Bleeding is the most common complication of ECLS and of greater risk if the patient is status post cardiac surgery. In neonates there remains a risk of intracranial hemorrhage from anticoagulant use, but this is reduced in older populations. There can be significant neurological injury that occurs with ECLS [118] and this risk is greater if ECLS is initiated during CPR [119]. Patients are at risk for the development of systemic infections [120,121], liver and kidney dysfunction. There is an infrequent risk for mechanical components failure of ECLS equipment [122]. As with conventional mechanical ventilation or HFOV, ongoing medications are needed for sedation while on ECLS.

# Cardiac ventricular assist devices as a bridge to recovery or transplant

The decision to use mechanical support for a failing myocardium can be a difficult one, depending on the underlying cause. Myocardial dysfunction can follow cardiopulmonary bypass (CPB) and is separated into those unable to separate from CPB in the operating room and those able to separate from CPB initially. There is a greater chance of a good outcome if there is a period of separation before needing cardiac support. In both cases, however, ECLS may be a reasonable means of support as recovery of myocardial function may occur in a period of several days. When the underlying myocardial dysfunction is secondary to chronic dysrhythmias, dilated cardiomyopathy, viral myocarditis or failed prior surgical palliation for complex congenital heart disease, the need for support may extend beyond a few weeks. Mechanical support may not be a bridge to recovery, but a bridge to transplantation. The possibility of whether the patient can be a candidate for transplantation must be included in the discussion. The need for daily immunosuppressant, medical follow-up, financial and social support for the patient as well as the limitation of donor organs all affect the decision to provide long-term support for a failing heart.

The devices available at each institution are primarily chosen by the cardiothoracic surgical service. Centrifugal ventricular assist devices are commonly chosen for shortterm support. Children more often than adults have right heart failure and may need biventricular support. Equipment may be limited for infants due to their size. Implantable devices are used more commonly in adults but are appearing in pediatrics. Currently the HeartAssist 5<sup>™</sup> is the only FDA-approved device for pediatric use. The Berlin Heart EXCOR VAD has been used extensively on a compassionate use basis by petitioning the FDA, and a multicenter trial of this device is under way.

# **Central nervous system**

## **Baseline neurological examination**

During admission to the pediatric ICU each child receives a neurological examination. Based upon the reason for admission, this may be a limited examination but key elements should always be present. When neurological deterioration is the cause for admission, the level of detail required will be much greater. A detailed exam includes evaluation of level of consciousness (Glasgow Coma Scale) and alertness in context of recent medications for sedation. Additional elements include evaluation of cranial nerve function, respiratory effort and synchrony, motor and sensory function, skin findings, reflexes and tone. Practically speaking, evaluation of alertness recurs each time a clinician is at the bedside. One should note upon entering the room if the patient is awake, alert and appears comfortable or uncomfortable. Can they be easily aroused with gentle stimulation? When they are awoken, are they appropriate? If more stimulation is required, are the responses purposeful? If the child is relatively sedated they should still withdraw from painful stimulation in an extremity. A stereotypical response to painful stimulation such as decorticate or decerebrate posturing indicates significant CNS malfunction and requires further investigation. Decorticate posturing of the upper extremities is flexion at the elbows with the hands clenched. Decerebrate posturing is extension at the elbows with the arms and hands pronated. If the patient does not respond to increasing stimulation, the ability to protect the airway should be assessed. This includes evaluating the presence of a

cough adequate to clear the airway of secretions, gag, and handling of oral secretions. The bedside nurse likely will be able to provide a recent perspective for comparison.

The pupils should be examined for size, equality, and response to light. The pupillary reflex is well preserved and therefore unreactive pupils are an ominous sign. Small reactive pupils may indicate the presence of opioids or barbiturates, but may also be caused by damage to the pons. Large reactive pupils may be caused by atropine, tricyclic antidepressants or pharmacological withdrawal. A fundoscopic examination may show distortion of the optic cup, evidence of increased intracranial pressure. It may also point to signs of non-accidental injury if retinal hemorrhages are present. Due to significant medico-legal implications of diagnosing retinal hemorrhage, an ophthalmologist should confirm this. Additional physical findings can be elicited with further investigation. However, if there is a depressed neurological examination or a significant change, radiological imaging is warranted. A brain computed tomography (CT) scan is often the fastest to obtain but if it does not show any abnormalities and concern persists, it may be necessary to obtain a brain MRI.

# **Glasgow Coma Scale**

The Glasgow Coma Scale (GCS) or Pediatric Glasgow Coma Scale can provide a numeric assessment of activity and function. This can allow care providers to easily discuss the patient's ongoing neurological function. This scale is helpful in studying neurological injury and outcomes. Due to the association between decreased GCS and ability to protect the airway, many clinicians will intubate the trachea electively if the GCS is 8 or less. The pediatric version of this scale has been modified for age-appropriate behaviors in a non-verbal child (Table 37.4).

# Intracranial pressure

Once the cranial sutures have closed, the intracranial pressure (ICP) is determined by the relationship of the volume of the skull and its contents. The typical contents of the cranial vault are brain tissue, cerebral spinal fluid (CSF), and blood. The abnormal contents can include tumor, hemorrhage, and foreign body such as a projectile. Vasogenic or cytotoxic edema can expand brain tissue. The CSF and blood volume can expand if there is obstruction to drainage. The typical curve demonstrating intracranial pressure plotted against change in intracranial volume describes elastance of brain (Fig. 37.6). Elastance is a change in pressure divided by change in volume. As the intracranial volume increases, compensatory mechanisms occur that protect against an initial rise in ICP. Spinal fluid surrounding the brain can be redistributed to the area around the spinal cord or there can be increased absorption through the arachnoid granulations. In

Table 37	7.4 🤆	ilasgow	Coma	Scale
----------	-------	---------	------	-------

Activity	Adult/child response	Infant response	Score
Eye opening (E)	Spontaneous	Spontaneous	4
	To verbal stimuli	To verbal stimuli	3
	To pain	To pain	2
	None	None	1
Best verbal response (V)	Oriented, appropriate	Coos and babbles	5
	Confused conversation	Irritable cries	4
	Inappropriate words	Cries to pain	3
	Incomprehensible sounds	Moans to pain	2
	No response	None	1
Best motor response (M)	Obeys verbal command	Normal spontaneous movement	6
	Localizes stimulus	Withdraws to touch	5
	Withdraws from noxious stimulus	Withdraws to pain	4
	Decorticate flexion	Decorticate flexion	3
	Decerebrate extension	Decerebrate extension	2
	No response (flaccid)	No response (flaccid)	1

Total score is sum of E + V + M.

Minimum score is 1E + 1V + 1M = 3.

Maximum score is 4E + 5V + 6M = 15.

**Figure 37.6** Intracranial pressure–volume relationship. Under normal circumstances, small increases in the volume of the intracranial contents (points A and B) cause only minimal increases in ICP. In pathological conditions that increase the volume of intracranial contents, a small further increase in volume (points C and D) causes a marked increase in ICP.

addition, the cerebral blood volume and CSF can be displaced extracranially. Blood and CSF together normally make up approximately 10% of the volume. When these mechanisms are exhausted, ICP increases. When this rise occurs slowly, the patient's level of alertness will be preserved longer than if it occurs suddenly. Initial presenting symptoms for a slow increase in ICP include nausea, vomiting, headache, decreased appetite, and malaise.

As pressure increases there may be focal neurological symptoms and a decreased level of alertness. Late findings include hypertension (attempt to maintain cerebral perfusion pressure) and then reflex bradycardia caused by the hypertension. If the expansion of brain tissue is asymmetrical there can be stereotypical neurological findings of impending brain herniation as different portions of the brain are compressed against ossified structures.

In the ICU measures can be used to lower ICP, but only to a certain extent. Basic management includes maintaining the head in a midline position and elevated to at least 30° to improve drainage of blood. The patient should be kept well sedated to decrease agitation and spikes in ICP. Some ICUs will premedicate the patient with bolus doses of sedatives or intravenous lidocaine prior to endotracheal suctioning as this may prevent spikes in ICP. This degree of ICP management typically implies that the patient is intubated and has their airway protected. In turn, some have used ventilation strategies to manipulate the ICP. Hyperventilation will effectively decrease cerebral blood flow through vasoconstriction. However, these effects are temporary, and cerebral blood flow regulation will reset to this lower value of PaCO<sub>2</sub> in a matter of hours. Current recommendations advocate adjusting ventilation to keep PaCO<sub>2</sub> at the lower range of normal, i.e. 34–36 mmHg. Hypoxia should be prevented as well as hypotension.

The cerebral perfusion pressure (CPP) is the mean arterial pressure minus the ICP or the central venous pressure (CVP), whichever is greater. An elevated CVP may be an issue with infants who have undergone palliative surgery for congenital heart disease. A value for minimum or ideal CPP can be described for adult patients, but this is a more difficult issue for pediatrics where the population can span preterm infants to teenagers and weights from less than 1 to over 100 kilograms. When necessary, the mean arterial pressure can be increased with inotropic support or judicious intravascular volume expansion.

The core body temperature should be monitored and fever treated aggressively. For each 1°C increase in temperature, the cerebral metabolism increases approximately 6%. However, data are not as clear regarding the benefits of active cooling. Some studies have demonstrated worse long-term outcome using cooling as a therapy following cardiac arrest. Further studies in pediatric patients are ongoing.

Intravenous fluids are typically decreased to two-thirds maintenance levels, but additional fluid boluses may be necessary. IV fluids should be isotonic and the patient's serum sodium should be followed and maintained at the high end of normal. Hypertonic or 3% normal saline can be used to raise serum sodium if necessary. Hypertonic saline is also used as a means to address elevations in ICP. Hyperglycemia should be avoided as this may result in further neuronal cell death. Diuretics may be used, both osmotic and loop, in an effort to reduce brain water and improve blood rheology.

Additional medications that may be helpful include muscle relaxants when necessary to prevent the patient from coughing or straining against the ventilator. Barbiturates may be necessary to induce EEG burst suppression and coma.

# Invasive pressure monitoring of intracranial pressure

Many patients leaving the operating room following craniotomy will have an extraventricular drain in place. This allows ICU monitoring of ICP and CSF drainage as needed to lower ICP. When the lateral ventricles are very small in size, further drainage of CSF is ineffective. When necessary, ventriculostomy can be performed as a bedside procedure by a neurosurgeon in the ICU providing the same benefits. Following placement of a burrhole in the skull, a catheter is advanced into a lateral ventricle with return of CSF. Another type of pressure monitoring device consists of a fiber-optic catheter placed through the burrhole, but outside the dura under the skull. Changes in pressure are transmitted along this catheter to a measurement device. ICP is measured, but CSF cannot be drained. The ventricular catheter has a higher risk of infection, but allows drainage whereas the fiber-optic catheter has a lower risk of infection but the pressure measured can be subject to drift over several days. Some fiber-optic models cannot be recalibrated to 0mmHg once inserted.

## Non-invasive measures

Non-invasive measures of brain perfusion are available. Transcranial Doppler (TCD) ultrasonography measures the blood flow velocity in the basal cerebral arteries, most typically the middle cerebral artery. TCD can help diagnose emboli, stenosis or vasospasm with subarachnoid hemorrhage. Placement of the device and interpretation of TCD readings require specialized training. Near infrared cerebral oximetry is a readily available alternative. These devices consist of a light source of known intensity and wavelength and a detector to measure the light exiting the tissues. The light or laser emitting diode and the detector are built into a sensor, which is placed on the forehead below the hairline. The device has an integrated computer converting changes in light intensity to clinical information such as regional tissue oxygen saturation. These are useful to follow as a trend monitor and provide information in addition to the clinical picture. These sensors are also being used to measure regional blood flow in somatic areas by placing them over the flank to assess renal perfusion. Studies correlating use of these devices and outcomes are ongoing.

## **Postoperative management**

The management of children following neurosurgery depends on the type of procedure performed. Common surgeries in children involve shunting of CSF, craniofacial remodeling, repair of Chiari malformations, and treatment of CNS tumors. For every postoperative neurosurgery patient, ventilation should be monitored closely. Impaired ventilation will raise PaCO<sub>2</sub>, increasing cerebral blood flow, which will impair ventilation further. Because of concern for respiratory depression, adequate pain control may be difficult to achieve. Many neurosurgeons forego continuous infusions of opioid medications and limit PRN doses significantly. Frequent neurological checks and titration of medications to effect may allow for improved pain relief.

Hydrocephalus is enlargement of brain ventricles not secondary to volume loss of brain tissue. Obstructive hydrocephalus results from obstructed drainage of CSF, and communicating hydrocephalus is the result of decreased reabsorption of CSF. In addition, there can be arachnoid cysts or collections of CSF which may cause mass effect. Hydrocephalus presents in infants with an enlarging head, full fontanelle, loss of appetite, vomiting and irritability. In children, the presentation is headaches, irritability, loss of appetite, and vomiting. Obstruction can be alleviated with either shunting or fenestration. In the immediate postoperative period these patients need to be followed closely with frequent neurological checks and vital signs as it is possible for acute obstruction to occur secondary to hemorrhage. If there is an acute change in condition neurosurgery consultation and an emergency head CT should be considered.

Postoperative ICU management of craniofacial remodeling is generally concerned with blood loss and

hypovolemia. In shorter cases for just calvarial remodeling, there may not have been enough time to adequately resuscitate the patient intraoperatively. Frequent hematocrit measurements should be obtained and the patient transfused as necessary. Swelling will occur, but this rarely causes airway compromise. More complex surgeries involve correction of abnormalities of the calvarium, skull base or facial bones. These longer surgeries typically have greater blood loss and many patients will require further transfusion in the ICU. In addition, swelling is usually more severe and patients may remain intubated at the completion of the case to prevent airway compromise. It may be necessary for the patient to remain intubated for several days for swelling of the face to resolve prior to extubation. Because of difficulties with suctioning through a preformed curved endotracheal tube, many ICUs will have policies regarding the smallest preformed tube allowed. Acute obstruction of the ETT and the inability to suction will cause life-threatening consequences. In addition, these patients require ongoing sedation and pain relief during this time period. If it is anticipated that the patient will remain intubated for more than a day, it may be advisable to place a percutaneous central venous line.

Chiari malformations are disorders in which the posterior fossa structures are restricted in their space and are herniating caudally through the foramen magnum and rostrally through the incisura. Following surgery to correct these defects, ICU management involves maintaining airway patency and adequate ventilation. Following arterial blood gases may identify hypoventilation before it is detected clinically. The swallowing reflex and vocal cord control may be diminished from the disease process and surgery. These patients will need good pulmonary toilet. Vital signs are closely observed as a hematoma in the posterior fossa may result in airway compromise or apnea before a change in level of alertness becomes obvious.

Approximately 70% of the tumors in children present in the posterior fossa and the most common tumor type is astrocytoma. The ICU management after tumor resection, as noted above for other surgeries, focuses on frequent neurological assessment, vital signs, and attention to adequate ventilation. A change in condition is an indication for an immediate brain CT scan. Hemorrhage into the posterior fossa may cause respiratory compromise. If there is an extraventricular drain in place, ICP can be followed directly. Additional complications that occur include seizures, the syndrome of inappropriate antidiuretic hormone secretion (SIADH), cerebral salt wasting, and diabetes insipidus. Seizures should be treated promptly but taking care that boluses of drugs that may depress blood pressure or respiration, i.e. benzodiazepines, are not given too rapidly. If necessary, the airway may need to be secured. SIADH may occur 24– 48h following surgery. The retention of free water will result in a decreased serum osmolality, which may worsen cerebral edema. Electrolytes should be monitored as well as hematocrit in patients after craniotomy for this reason. Fluid restriction may be sufficient until this resolves but some may require therapy with 3% hypertonic saline.

Cerebral salt wasting occurs in some patients following neurological injury or insult. The urine output is greater than seen with SIADH but remains concentrated. There are significant urinary losses of sodium and 3% hypertonic saline may be required. Frequent monitoring of electrolytes and intake/output is required. Diabetes insipidus may follow removal of suprasellar tumors. This may occur 12-24h after surgery when antidiuretic hormone stores are exhausted. The clinical picture is a sudden increase in urine output with a low urine specific gravity (<1.005). Initial therapy is volume replacement with isotonic fluids. A vasopressin infusion may be required with frequent monitoring of electrolytes, hourly intake and output, and urine specific gravity. If diabetes insipidus persists, endocrinology consultation is important to assist with anticipated long-term management. See Chapter 23 for a further discussion of neurosurgical procedures.

## **Status epilepticus**

Status epilepticus (SE) is defined as seizures lasting longer than 30 min or recurring so frequently that there is no return of consciousness between episodes. However, the 30-min cut-off is relatively arbitrary and is not supported by clinical data. More importantly, seizure activity increases CNS energy demand and with loss of control of the airway there may be hypoxia limiting energy production. Data in children have shown that new-onset seizures cluster by duration. The majority of seizures last less than 5 min. In one study by Shinnar et al [123], 76% were less than 5 min. Seizures lasting longer than 5 min should be treated more aggressively as they can become status epilepticus or refractory status epilepticus. In addition, delay in treatment may make resolution of seizure activity more difficult.

Initial supportive care includes monitoring vital signs including saturations, providing oxygen and supporting the airway as necessary. Many patients arrive in the ICU after paramedic transport having received rectal diazepam as first-line therapy. When IV access is established lorazepam 0.1 mg/kg is usually regarded as the first step. Electrolyte levels including glucose, calcium and magnesium should be measured. Hypoglycemia is treated with IV glucose 0.5 g/kg followed by maintenance glucose-containing fluids. Hypocalcemia is treated with either calcium chloride 10–20 mg/kg or calcium gluconate 30–60 mg/kg. Calcium gluconate is the safer of the two as CaCl<sub>2</sub> may cause sclerosis of veins and tissue necrosis if

the intravenous line is infiltrated. Calcium gluconate requires conversion by the liver into the active form. As medications to stop the seizure activity are given, it is common that the airway and ventilation will need to be supported. If the patient is to be intubated, either a shortacting muscle relaxant should be used or if possible none at all. Seizure activity may continue after intubation and in the presence of neuromuscular blockade the clinical exam is limited.

If seizure activity persists the patient can be given additional lorazepam 0.1 mg/kg and then loaded with either fosphenytoin or phenobarbital. Fosphenytoin is a watersoluble phenytoin prodrug and is used in preference to phenytoin, which can cause hypotension, arrhythmias, injection pain, and thrombophlebitis if given too quickly. Fosphenytoin is dosed in phenytoin sodium equivalent units (PE) and the loading dose is 10–20 mg PE/kg. If phenobarbital is used, the loading dose is 10–20 mg/kg. The majority of seizures likely will stop with the use of a benzodiazepine and phenobarbital or fosphenytoin.

Additional treatment of status epilepticus that is refractory to this therapy may include high-dose barbiturates, high-dose benzodiazepines, propofol, valproic acid, and inhalational agents and is beyond the scope of this chapter. These efforts should be performed in consultation with a pediatric neurologist.

## **Central nervous system infections**

Infants and young children who develop acute central nervous systems infections present with acute onset of fever and altered level of consciousness. They may have headache, stiff neck, bulging fontanelle, photophobia, vomiting, decreased oral intake, and seizures. Patients may also present with signs of shock. The younger the child, the less reliable the secondary symptoms and a high index of suspicion is warranted.

The typical causes of bacterial meningitis in a neonatal population include group B streptococci, gram-negative bacilli, and *Listeria monocytogenes*. In infants greater than one-month old, this changes to *Streptococcus pneumoniae*, *Neisseria meningitides*, and *Haemophilus influenzae*. Since the introduction of the *Haemophilus influenzae* B vaccine the incidence of meningitis caused by this organism has dramatically decreased. Results from a lumbar puncture make the definitive diagnosis but at times the patient is too unstable to perform this or there is concern about a focal CNS mass lesion that would elevate the ICP. Antibiotics should not be delayed when the lumbar puncture cannot be performed rapidly. Antibiotics may alter some of the CSF findings but should not completely obscure the final diagnosis.

Over time penicillin-resistant strains of *Strep. pneumoniae* have emerged in some geographic regions. Empirical antibiotic coverage has changed to reflect this resistance. Vancomycin and a cephalosporin dosed for meningitis is an appropriate initial therapy until bacterial identification and antibiotic sensitivities are known. Routine administration of dexamethasone to reduce inflammation in bacterial meningitis remains controversial. Current recommendations support the use of dexamethasone for bacterial meningitis with *H. influenzae* type B.

# Nephrology

The kidney, in a resting state, receives 20–25% of the cardiac output. Autoregulation by the kidney maintains near constant renal blood flow and glomerular filtration rate. Creatinine is an end-product of skeletal muscle catabolism and is excreted solely by the kidneys. Blood urea nitrogen (BUN) is a by-product of protein metabolism. Values for BUN can increase independent of renal function as a result of dehydration, high protein intake, and degradation of blood from the GI tract.

Maintaining an appropriate fluid balance is very important in critical care. Even in patients who have normal renal function, diuretics are often used to limit lung water and help with cardiorespiratory dysfunction. After medications for sedation, the ascending loop diuretic furosemide is likely one of the most widely used drugs in pediatric intensive care. Furosemide is secreted into the tubular lumen by the proximal tubular cells and reaches the ascending loop of Henle by way of the tubular fluid. A prescribed starting dose of furosemide is typically 1 mg/ kg up to approximately 10 mg total dose for patients who are naïve to diuretic therapy. The lowest dose necessary to increase urine output should be used. As renal dysfunction develops, potentially larger doses are needed to maintain the same diuretic effect. Furosemide can be used as a continuous infusion and some practitioners believe there are fewer electrolyte disturbances with this method of delivery.

As with all other patients in the ICU, strict intake and output measurements are necessary. In addition, frequent electrolytes need to be followed as diuretic therapy will cause hypokalemia and hypochloremia as well as other electrolyte wasting. In low albumin states, the delivery of furosemide to renal secretory sites is decreased. Diuresis may be improved by administering 25% albumin just before or with the diuretic. The typical dose is 0.5–1 g albumin/kg. When the patient fails to respond to furosemide or the urine output cannot keep up with the intake, larger doses of this loop diuretic can be given. Additional diuretics acting at other locations such as hydrochlorothiazide (distal tubule) can be added. The drug spironolactone, which blocks the hormone aldosterone, is a weak diuretic but may prevent potassium losses. Failure of increasing doses of diuretics to be effective

likely represents worsening renal perfusion and/or renal failure.

Acute renal failure (ARF) is the abrupt onset of renal dysfunction where there is insufficient removal of nitrogenous wastes and problems with fluid and electrolyte balance. Toxins, drugs, inflammation, and autoimmune disorders can cause ARF. Commonly in the ICU, however, it is the result of insufficient renal blood flow or systemic hypoperfusion. This can result in peritubular edema mediated by prostaglandins or the renin-angiotensin system. Poor urine output can also result in intraluminal debris that takes time to clear after return of renal perfusion. The structural and functional changes to the kidney that occur with ARF are usually reversible but this may take days to weeks.

Acute renal failure is described by the area of obstruction and whether urine is still being made. The obstruction can be prerenal, in the kidney parenchyma, or postrenal. Decreased renal blood flow and perfusion result in prerenal azotemia. Azotemia is the term for the accumulation of nitrogenous by-products of protein metabolism. Intravascular fluids in the case of dehydration or fluids and inotropic support may be needed to reverse prerenal failure. True parenchymal renal disease may be due to toxicity caused by the renal excretion of drugs, toxins, or autoimmune processes. It may also be the result of hypoperfusion to the kidney over a longstanding duration. Postrenal obstruction is an obstruction to urine flow distal to the kidney. Posterior urethral valves or an obstructed Foley catheter can cause this. The urine collecting system is typically dilated on ultrasound examination. In non-oliguric renal failure, urine continues to be produced but is typically of poor quality, i.e. solutes are not being cleared well. Oliguric or anuric ARF is associated with no urine output and may be more concerning. Evaluation of urine sodium, specific gravity, and osmolality can help determine whether the cause of renal failure is prerenal or renal (Table 37.5).

In the circumstance of rising BUN, creatinine and decreased urine output, it is reasonable to try to support the patient to prevent impending renal failure. If possible, the circulating blood volume and renal perfusion should be improved. In many circumstances in the ICU, there may be a total body fluid overload and a decreased intravascular volume secondary to hypoproteinemia and capillary leak syndrome. Some practitioners will give moderate- to high-dose diuretics with some additional fluid in an effort to prevent oliguric renal failure. Whether this is effective is not well proven.

# Hyperkalemia

As the patient develops renal failure, management needs to be directed at maintaining optimal fluid and electrolyte balance. Decreased renal function will cause decreased Table 37.5 Laboratory differentiation of oliguria

Test	Prerenal oliguria	Intrinsic renal failure
Urine		
Sodium	Low (<20 mEq/L)	High (>40 mEq/L)
Specific gravity	High (>1.020)	Low (<1.010)
Osmolality	High (>500 mOsm/L)	Low (<350 mOsm/L)
Urine/plasma ratios		
Osmolality	>1.3:1	<1.3:1
Urea nitrogen	>20:1	<10:1
Creatinine	>40:1	<20:1
Urine sediment	Normal	Proteinuria; hematuria; casts
Fractional excretion of sodium (FE-NA)	<1%	>2%

excretion of potassium. Hyperkalemia may provoke cardiac arrhythmias leading to death and therefore requires immediate treatment. The potassium should be removed from any IV fluids immediately. Clinically there is a peak in the T wave at moderately elevated potassium levels; as the potassium level increases there may be ST segment depression and widening of the QRS complex. As the potassium rises further, there may be conduction abnormalities, bradycardia, ventricular fibrillation or asystole. Calcium in the form of calcium chloride 10-20 mg/kg or calcium gluconate 30-60 mg/kg should be given IV to stabilize the cardiac cell membrane. Sodium bicarbonate 1–2mEq/kg IV will make the blood pH more basic, driving potassium into cells. Glucose and insulin also drive potassium into cells. Glucose is given as 1-2g/kg IV with insulin 1 unit per 4g of glucose IV. If the patient is intubated, increasing minute ventilation increases blood pH, driving potassium into the cells. None of these treatments actually reduces total body potassium. The ion exchange resin Kayexalate is sodium polystyrene sulfate which can bind potassium. It is given orally or rectally in suspension but does require excretion from the body. The dose is 1g/kg orally and it can be given every 6h; rectally, it can be given every 2-6h. The enema route is less effective than oral administration. If severe hyperkalemia persists after all the above maneuvers, emergency dialysis (see below) is required.

## Abnormalities of sodium

Severe hyponatremia and hypernatremia is another electrolyte disturbance that can be seen in the ICU. Hyponatremia may present with seizure activity when the level is less than 120 mEq/L. Initial treatment would be to raise the serum sodium above 124 mEq/L with 3% hypertonic saline. However, in the absence of seizures, if a patient reached this low value slowly, it can be corrected slowly. The same condition applies to hypernatremia. Rapid correction of elevated serum sodium is likely more harmful than the value itself.

# **Oliguric renal failure**

When oliguric renal failure is present the fluid intake should be reduced. At times, just meeting insensible fluid losses is appropriate. However, in many circumstances the ongoing need for blood products or fluid boluses to support blood pressure causes much more fluid than insensible losses to be given. In addition, achieving adequate nutrition may be difficult. In the face of ongoing fluid shifts and significant electrolyte disturbance, renal replacement therapy may be necessary. See Box 37.8 for indications for dialysis. The modality will depend on the experience and resources of the institution. If the decision has been made to begin renal replacement therapy, its initiation should not be delayed. There is evidence supporting improved outcomes when there is a shorter time from an ischemic insult to starting dialysis.

# **Peritoneal dialysis**

Peritoneal dialysis (PD) has the benefits of being relatively low cost, causing less hemodynamic compromise compared with venovenous filtration, requires no central venous line and is technically simpler. Essentially the peritoneum is used as the dialysis filter. If long-term therapy is anticipated, a tunneled catheter may be placed by the pediatric or urology surgeons. For temporary therapy, pediatric surgeons may place a PD catheter at the bedside or nephrologists may place a percutaneous catheter. PD works well in infants and smaller children. The volume of fluid removal is a result of the volume of dia-

#### Box 37.8 Indications for dialysis

- Severe hyperkalemia
- Metabolic acidosis unresponsive to therapy
- Fluid overload with or without severe hypertension
- Fluid overload with or without congestive heart failure
- Uremia causing encephalopathy, pericarditis or bleeding
- Non-obstructive anuria
- Inborn errors of metabolism
- Certain drug overdoses
- Significantly elevated (>100) BUN may be a relative indication
- Some clinicians feel dialysis may reduce inflammation with sepsis or systemic inflammatory response syndrome

lysate infused, dialysate glucose percentage, the length of time it remains in the abdomen and frequency of exchange. As this therapy is relatively inefficient it is not the ideal choice for severe life-threatening pulmonary edema and hyperkalemia. Strict intake and outputs and frequent electrolytes will guide therapy.

# Hemodialysis and continuous renal replacement therapy

Hemodialysis (HD) may be the therapy of choice for patients who are already on chronic dialysis and have vascular access. Portable dialysis machines are available in many hospitals. In other ICU settings, patients on chronic HD will be placed on continuous venovenous hemofiltration rather than transporting them to the dialysis center in the hospital. There appears to be better hemodynamic stability with continuous fluid removal rather than intermittent HD. The patient's overall condition and ability to be transported will best dictate the location of care.

Improvement in technology has allowed the use of continuous renal replacement therapy in smaller infants. Continuous venovenous hemofiltration (CVVHF) is likely the most common type of continuous renal replacement therapy (CRRT). This provides isotonic fluid removal but minimal solute clearance. These circuits can be easily converted to perform dialysis (CVVHD) providing more solute clearance. Arteriovenous filtration (CAVH) is possible but occurs less commonly. Accurate flow rates are important in circumstances where more than 15% of the patient's circulating blood volume can be sequestered in the CVVH tubing. The further limitation in small infants requiring dialysis is venous access. Modern CRRT devices machines can operate with two separate 5 Fr single-lumen catheters, but typically a dual-lumen 7 Fr catheter at a minimum is required. This size catheter can be difficult to place in an edematous infant, and thrombosis is a significant risk. Anticoagulation for CVVH can be provided either with heparin or with regional citrate administration. Citrate can be administered just proximal to the CRRT machine, which creates a regional area of hypocalcemia in the circuit, preventing activation of the coagulation cascade. Intravenous calcium is administered to the patient via a central line. Protocols are available which dictate the amount of citrate and calcium to be infused based on ionized calcium levels for the circuit and the patient. The use of regional anticoagulation with citrate avoids the concerns of systemic anticoagulation, which can be an issue in multiple organ failure.

In an effort to advance the field of pediatric CRRT, a prospective registry was developed in 2001 (ppCRRT) [124]. The registry was closed in 2005 with complete data on 344 patients [125]. Data from the ppCRRT cohort demonstrated a 58% survival. Current work is being directed

at introducing CRRT early in the patient's illness. It has been demonstrated that the degree of fluid overload at initiation of CRRT is associated with patient mortality [126]. This has been found to be independent of patient severity of illness scoring.

# Hematology/oncology

# Oncology in the pediatric intensive care unit

There has been significant improvement in survival rates for pediatric cancer over the past several decades. There has also been an expansion of number and types of diseases treated with bone marrow transplantation, and more centers now perform hematopoietic stem cell transplants. As a result, there has been a concomitant increase in the population of oncology patients in the pediatric ICU. Some of the critical care these patients receive will be on specialized oncology wards or bone marrow transplant units. The environmental isolation procedures employed in these specialized units are difficult to replicate in other areas. Depending on the institution, some oncology wards will allow the use of low doses of inotropic support, for example dopamine of up to 5µg/kg/ min. More ill patients require ICU admission for sepsis and shock not responding to fluid resuscitation and lowdose inotropic support, respiratory failure, and renal failure requiring CVVH. There is some evidence supporting improved outcomes for pediatric oncology patients requiring ICU care in recent years [127,128]. However, there remains an increased mortality in patients following hematopoietic stem cell transplantation.

During the course of their illness, there are times when patients with malignancy are left profoundly immunocompromised from disease and therapy. With a decreased ability to fight infection, they are at risk for sepsis. The first indication of sepsis may be fever while neutropenic and studies have looked at predicting which patients will go on to be bacteremic [129]. A recent study by Pound et al showed that ICU mortality for sepsis was not significantly different between oncology patients (15.9%) versus matched controls (11.6%) [130]. There was not a significant difference in survival between groups until 6 months post PICU discharge. This was similar to the overall ICU mortality in pediatric oncology patients published by Fiser et al in 2005 [131] for patients admitted to St Jude Children's Research Hospital. Information from this group also supports the clinically identified findings that patients after bone marrow transplantation fared worse (30% mortality) and patients requiring both mechanical ventilation and inotropic support had a high mortality (64%). Thankfully, it appears that the survival in oncology patients is improving over time. Again, data from St Jude Children's Research Hospital published in 2008 by Tamburro et al [132] demonstrated improved survival for oncology patients requiring mechanical ventilation in later eras. In the time period 1996–1998 survival was 31%, in 1999-2001 46%, and in 2002-2004 61%. It is not possible to say how much of this improved survival is a result of improvements in technical and clinical care or a change in attitude resulting in patients being transferred to the PICU earlier. From a culture standpoint the shift to earlier admission to the ICU has occurred in many hospitals. From review of the literature, those patients admitted to the ICU after hematopoietic stem cell transplant have worse outcomes and the development of respiratory or multiple organ failure decreases survival. It is unlikely that this information would prevent resources being offered to an individual patient, but potentially it can guide discussions with the family and the primary service.

# **Transfusion therapy**

Many patients in the PICU will require transfusions of blood components during their stay (Table 37.6). Anemia can be secondary to blood losses or bone marrow suppression. Thrombocytopenia may be secondary to platelet losses, poor production or sequestration in the spleen. Decreased coagulation factors may be secondary to underlying liver failure. All of these conditions result in the requirement for transfusion and its associated risks. Transfusion reactions can be classified into immune and non-immune mediated problems. The non-immune complications include viral or bacterial infections transmitted

#### Table 37.6 Blood component therapy

Product	Dose	Comments
Packed RBCs	10 mL/kg	Raises hemoglobin 2–3 g/dL; now tolerating hemoglobin 7–10 g/dL in absence of ongoing bleeding
Random donor platelets	1 unit/10kg or 5–10mL/kg	These are pooled units from multiple donors
Apheresis platelets	10 mL/kg	Donation from a single individual
Fresh frozen plasma	10–15 mL/kg	Will provide 20–30% of coagulation factors often resulting in normal clotting
Cryoprecipitate	1 unit/10kg	Contains a significant amount of fibrinogen (60–80 mg/dL)

through blood components, volume overload, hypothermia, coagulopathy and electrolyte changes. Prolonged storage of packed red blood cells does result in erythrocyte hemolysis. This can lead to elevated potassium in the transfused unit. Rapid transfusion of red blood cells in trauma or acute blood loss during surgery can lead to hyperkalemia. If a unit of PRBCs is transfused over 2–4h, this is typically not a problem in the ICU as long as there is not renal failure. The immune-mediated reactions include those causing intravascular and extravascular hemolysis. These reactions are often regarded as the most severe and life threatening. These risks are reduced with blood cross-matching and careful patient and blood unit identification. Immune-mediated non-hemolytic reactions include febrile reactions, mild allergic, anaphylactic reactions, and transfusion-related acute lung injury (TRALI).

## Transfusion-related acute lung injury

Transfusion-related acute lung injury is likely an underreported complication of transfusion. There are an increasing number of studies in the adult ICU literature regarding this complication but studies in pediatric ICU patients are limited [133-136]. The diagnosis relies on excluding other causes of pulmonary edema such as volume overload, sepsis, and cardiogenic pulmonary edema. There is a two-hit model of TRALI indicating that predisposing inflammation plays a role in the development of lung injury following transfusion. The first injury or hit is due to an inflammatory condition present in the lungs and the second hit is transfusion of a blood product. It is still unclear whether it is the presence of neutrophils, human lymphocyte antigen (HLA) antibodies or biologically active lipids present in older blood units that causes the damage. In a study published by Church et al [137], there was an association with increased mortality in pediatric patients with ALI who received transfusion of fresh frozen plasma. This effect was independent of the severity of hypoxemia, the presence of disseminated intravascular coagulation (DIC), or multiple organ dysfunction syndrome. Clearly, transfusion of any blood product has risk and the risk/benefit ratio should be carefully considered in each clinical situation. Lacroix et al [91] demonstrated reduced transfusion of PRBCs to patients in a PICU by adopting a restrictive transfusion strategy. They targeted a hemoglobin threshold of 7 g/dLin one group versus 10g/dL in another and showed a 44% reduction in transfusion without an increase in adverse outcomes. These were patients with a blood pressure not less than 2 standard deviations below an age-appropriate mean and not on increasing doses of inotropic medication.

# Coagulopathy

Sepsis, trauma, malignancy, pancreatitis, and liver failure are among conditions leading to coagulation problems for PICU patients (Table 37.7). The underlying inflammatory state resulting from infection can cause activation of coagulation and inhibit the natural anticoagulation mechanisms. Liver failure results in diminished production of clotting factors. In 2001 the International Society of Thrombosis and Hemostasis published a scoring system for DIC using platelet count, fibrin-related markers, prothrombin time, and fibrinogen [138]. Their definition separated the condition into non-overt DIC and overt DIC. In non-overt DIC the hemostatic system is stressed by inflammation or non-inflammatory disorders of the microvasculature but compensation is maintained. In overt DIC the hemostatic system is decompensated. A scoring system such as this allows research on DIC to be performed and provides the clinician a measure of response to therapy. In 132 PICU patients with sepsis or shock, Khemani et al [139] demonstrated an association with elevated DIC score and mortality. The DIC scale has a maximum of 8 total points. Points are given for lower platelet counts and fibrinogen, for prolongation of the prothrombin time, and for evidence of fibrin degradation. Patients with overt DIC (DIC score  $\geq$ 5) had 50% mortality. Mortality was 20% for patients with a DIC score <5. The association for elevated DIC score and mortality remained

### Table 37.7 Tests of clotting function

Test	Normal range	Interpretation
Platelet Count	100,000 to 400,00/μL	<50,000 may require transfusion to reduce surgical bleeding
Prothrombin time (PT)	10 to 12.5 seconds	Tests extrinsic and common pathways; prolonged in liver failure, vitamin K deficiency, DIC
Activated partial thromboplastin time (aPTT)	25 to 36 seconds	Tests intrinsic and common pathways; prolonged in liver failure, hemophilia A, Von Willebrand Disease, DIC
Fibrinogen	200 to 400 mg/dL	Depleted in liver failure, DIC
Fibrin Split Product	Positive test: >40 mcg/mL or titer 1:50	Elevated in DIC or other fibrinolytic process
D-dimer	Positive test: <1 mg/mL	Indicates simultaneous activity of thrombin and plasmin; positive in DIC

Table 37.8	; (	Components	of	the	DIC	score
------------	-----	------------	----	-----	-----	-------

	0	1	2	3	Max points possible
Platelet count (/mm³)	>100,000	51–100,000	≤50,000	-	2
Fibrinogen (mg/dL)	≥100	<100	-	-	1
FDP titer (mg/mL)	≤ 5	-	6–40	>40	3
Prolonged PT (sec)	<3	3–6	>6	-	2
Total score					8

All individual components are summed for a total of 8 possible points. If d-dimer is used instead of FDP titer, then cut-off values for the DIC score are (0:  $\leq 2 \text{ mg/L}$ , 2: 2.1–8 mg/L, 3: >8 mg/L) Source: Khemani et al [139].

Source. Knemani et al [159].

even after controlling for severity of illness or use of inotropic support (Table 37.8).

Treatment of DIC is aimed at resolving the underlying condition, which caused imbalance of the coagulation system. Given the findings of Church et al [137] with regard to increased mortality associated with fresh frozen plasma transfusion, it will be important to study outcomes with correction of DIC. The DIC score gives both the researcher and clinician a means of doing this.

# Sickle cell disease

The most common of the hemoglobinopathies is hemoglobin S or sickle cell trait. Depending on the location of the PICU, a number of patients with various thalassemias may be admitted. Of the hemoglobinopathies, complications from sickle cell disease will cause the most frequent admission to the PICU. Hemoglobin S results from a point mutation in the  $\beta$ -chain at codon position 6 resulting in valine substitution instead of the normal glutamine. The abnormal  $\beta$ -chains produced from the mutation combine with normal  $\alpha$ -chains to form abnormal hemoglobin S. When two copies of the gene are present, hemoglobin SS is produced. Deoxygenation of SS erythrocytes leads to intracellular hemoglobin polymerization, loss of deformability, and changes in cell morphology. In a deoxygenated state, the abnormal erythrocytes form the classic sickle cell. Patients with hemoglobin SS disease have chronic severe hemolytic anemia.

# Sickle cell crisis

There are three types of crisis that occur in patients with sickle cell disease: hemolytic, aplastic, and vaso-occlusive. Hemolytic crises are characterized by increased hemolysis resulting in an acute decrease in hemoglobin. This is accompanied by a significant reticulocytosis in an effort to increase red cell production. Aplastic crises are characterized by acute decrease in hematocrit and hemoglobin, but are accompanied by a fall in reticulocytes. Bone marrow production of red cell precursors has slowed or stopped. Aplastic crises are most often associated with infections and greater than 90% are due to parvovirus B19. The vascular occlusive crisis is what is thought of as the classic sickle cell crisis. These crises may be precipitated by infection, acidosis, dehydration or hypoxia. Sickled RBCs block small vessels causing infarction, splenic sequestration, and priapism. Infarcts may occur in any organ but are most notable in bones, lungs, kidney, skin, spleen, eye and CNS.

## Acute chest syndrome

Acute chest syndrome (ACS) is a vaso-occlusive crisis resulting from sickling of RBCs in the lungs. This is the second most common complication and leading cause of death in sickle cell disease. Acute chest syndrome is defined as a new pulmonary infiltrate on chest radiograph in combination with fever, chest pain, or respiratory symptoms. The clinical course for the patients can be quite variable. In a 30-center study performed by the National Acute Chest Syndrome Study Group, almost half of the patients who were later diagnosed with acute chest syndrome presented initially for another cause, mostly pain [140]. Pulmonary fat embolism to the lungs is reported frequently and is associated with a particularly severe course. It is believed the embolism most likely results from bone marrow necrosis with intravascular release of necrotic bone marrow fat. Infection is also a common etiology of ACS, with Chlamydia pneumoniae and mycoplasma being the most commonly identified pathogens.

Early recognition of ACS is imperative. Children may present with few symptoms, therefore a chest radiograph should be obtained in all febrile children with sickle cell disease. Therapy should start immediately after diagnosis. Antibiotic treatment should be cefuroxime or cefotaxime with a macrolide as well. Adequate hydration is necessary allowing for diuretic therapy if the patient becomes fluid overloaded. They should be supported with oxygen, incentive spirometry if able, and potentially bronchodilators. Pain needs to be adequately controlled. If the patient is anemic a simple red cell transfusion may be helpful but more likely an exchange transfusion will be needed. As hemoglobin rises, blood viscosity increases. Sickle cell blood has a much greater viscosity in the deoxygenated state. Red cell exchange can reduce overall viscosity of blood and improve oxygenation [141]. Improvements in microvascular perfusion may be more likely from reduced viscosity caused by exchange transfusion than from reduction of inflammatory mediators. Red cell exchange has been shown to reduce white blood count, platelet count, and soluble vascular cell adhesion molecule-1 in patients with sickle cell disease [142]. However, this effect was short-lived and there was no effect on interleukin-1 $\alpha$ , interleukin-1 $\beta$ , interleukin-8, or tumor necrosis factor- $\alpha$ . Of the patients in the National Acute Chest Syndrome Study Group [140], 13% required mechanical ventilation and the mortality in the intubated group was 19%.

# Neurological complications of sickle cell disease

Another area in which exchange transfusion is vital is in the treatment of neurological complications from sickle cell disease. The incidence of stroke in a population of patients with sickle cell disease under 20 years of age has been reported to be 0.44 per 100 patient-years [143]. Given the catastrophic nature of this type of brain injury, studies have been undertaken to identify patients at increased risk and to intervene before the development of stroke. The Stroke Prevention Trial in Sickle Cell Anemia (STOP) was undertaken to evaluate whether initial stroke could be prevented in children with sickle cell disease through chronic transfusion therapy. Patients were identified as at increased risk for stroke if they had an elevated velocity on transcranial Doppler. The study group was assigned to a transfusion regimen that maintained a hemoglobin S concentration of <30% [144]. Chronic transfusions reduced the risk for stroke development by more than 90% compared with the patients receiving standard of care. These results caused the trial to be stopped 16 months early. The long-term side-effects of this treatment include iron overload and alloimmunization [145].

While the management strategy for children with sickle cell in an outpatient setting may require further study, it appears clear that any child with an acute neurological change should receive exchange transfusion. In our institution this is often undertaken in the ICU.

From a practical standpoint, exchange transfusion is not without risk. Central venous access needs to be obtained in most cases. There is the risk of volume overload or hypovolemia, requiring great attention to volume withdrawn and replaced. There are all the associated risks of receiving blood products. There is the chance of hypothermia in small patients. Each center's method for handling these procedures will be based on the resources available with their hematology department and blood bank.

# Endocrine disease in the pediatric intensive care unit

# Hyperglycemia and diabetes mellitus

Hyperglycemia in the pediatric ICU has two major categories with distinct concerns and outcomes. The first is the population of patients with type 1 diabetes mellitus admitted to the ICU with their initial presentation of the disease, or those patients with known diabetes with recurrent problems of insulin balance, or non-compliance with insulin regimens. The second population with hyperglycemia is those children with critical illness who develop elevated glucose during treatment for their underlying disease process.

The management of type 1 diabetes has changed dramatically over the years with increased frequency of blood sugar monitoring, changes in insulin preparations, and the use of insulin infusion pumps. Fewer children who have previously been diagnosed are being admitted to the ICU with recurrent episodes of diabetic ketoacidosis (DKA). In addition, with the development of protocols to treat DKA, in some hospitals these patients may be cared for on the pediatric ward. At our institution, the criteria that prompt ICU admission include severe dehydration, significant hypo- or hypernatremia, blood pH <7.2, serum blood glucose >800, severe headache, altered level of consciousness, age <5 years, and uncertain treatment prior to arrival. These criteria help identify those patients at greatest risk for increased morbidity or mortality from diabetic ketoacidosis.

In insulin-deficient states, glucose will not enter cells, and fat or protein is metabolized for energy. Ketones and organic acids are the by-products of this metabolism and they accumulate in serum. Dehydration occurs from the osmotic diuretic effects of glucosuria and may be worsened by decreased oral intake and emesis. There are significant losses of water, sodium and potassium and this may result in decreased intravascular volume severe enough to result in poor tissue perfusion. Patients may often be 10-15% dehydrated. Metabolic acidosis is identified on admission by a low serum bicarbonate; compensation develops through the blood buffering system. The respiratory centers respond with hyperventilation in the face of low pH and this is seen as tachypnea or, when more severe, as Kussmaul respirations. As dehydration is a significant element of the disease, the initial history should include details of oral intake, and recent vomiting or diarrhea. New-onset DKA may be provoked by infection and this should be considered in the history and physical examination. Most importantly, due to the risk of cerebral edema, a neurological examination should be performed and the family should be questioned for any change from normal level of consciousness. Baseline labs include complete blood count, electrolytes, venous pH,

glucose, BUN, and hemoglobin A1C level. If the patient has new-onset disease, a panel of insulin autoantibodies is often measured.

The goal of therapy is to provide insulin to allow glucose to enter the cells and intravenous fluids to correct the dehydration. It will take some time to resolve the metabolic acidosis and electrolyte disturbances. Therapy is tailored to prevent significant fluid or osmolar shifts. This relates to the most significant morbidity or cause of mortality in DKA, cerebral edema.

The cause of cerebral edema in DKA has not been completely elucidated. It occurs in approximately 1% of patients with DKA. The development of cerebral edema in this disease process is associated with significant mortality (reported as 21-25% in population-based studies) and residual neurological morbidity in survivors (reported as 15-35%) [146-148]. This complication remains difficult to study due to its low incidence, and most reports in the literature are case series or non-controlled studies. In addition, studying the in vivo metabolism of glucose and fluid shifts in the brain remains difficult. The use of MRI may be a good surrogate. Studies evaluating brain MRIs of patients undergoing treatment for DKA revealed narrowing of the lateral ventricles in 54%[149] and increases in whole-brain blood-brain barrier permeability in 77% [150]. In a large prospective case-control study, 43 cases of cerebral edema among 2940 episodes of DKA were identified over a 3-year period [151]. Cerebral edema was present in five of 43 cases at the time of admission and the median time to development in the remaining 38 patients was 7h after admission.

Predictors of the development of cerebral edema included degree of baseline acidosis as well as abnormalities of sodium, potassium, and BUN. In addition, early administration of insulin and large volumes of fluid resuscitation were associated with cerebral edema. The authors of this study point out that these types of studies cannot identify safe doses of fluid and insulin but only guiding principles. Consensus statements have been published [151-154] which address issues of monitoring, insulin delivery, and fluid/electrolyte replacement. Still, the majority of clinicians feel too rapid a correction of glucose may produce a rapid change in osmolarity, which could potentially initiate or aggravate cerebral edema. After a reasonable circulating intravascular volume is reestablished, a majority of clinicians advocate a very slow correction of the patient's fluid deficit. Finally, fluid resuscitation should supply sufficient sodium so as not to cause a rapid change in osmolarity for the same reasons as above. The oversimplification of this therapeutic approach is: "Keep them dry, keep them sweet, and keep them salty."

With these goals stated, the DKA treatment protocol at our institution will limit patients to one bolus of 10 mL/

kg of 0.9% normal saline over 30–60 min unless there is significant hypotension. Once urine output has been documented, maintenance fluids include potassium chloride at 40 mEq/L with the possibility for potassium phosphate to help correct losses. Insulin is started as a continuous infusion at 0.1 units/kg/h but even smaller doses have been advocated in the literature [155]. Bicarbonate is rarely needed. Electrolytes are repeated every 4h and bedside blood glucose every hour. When the blood glucose approaches 250 mg/dL, the maintenance fluids are changed to include 10% dextrose. Intravenous dextrose is added sooner if the blood glucose is falling too rapidly.

If there is any change in the neurological examination or a severe headache, a CT scan or MRI of the brain may be obtained.

It is very important to follow electrolytes closely. The potassium level may be normal initially but it will fall quickly once insulin is provided. If there is any evidence of infection from the history and physical examination and initial white blood count, cultures should be obtained and appropriate antibiotics for sepsis should be started.

# Stress hyperglycemia

Hyperglycemia is common in critical illness. Stress hyperglycemia is often the cause of elevated blood glucose values in the ICU. The elevated glucose results from insulin resistance during illness, increased endogenous production of glucose or excessive administration with intravenous fluids. How best to manage hyperglycemia has been a significant issue over most of the past decade. The final answer with regard to whether tight glucose control is harmful or beneficial remains elusive. Significant changes in management in adult ICUs followed a landmark paper by van den Berghe et al [156]. In this study of 1548 patients, intensive insulin therapy (IIT) reduced mortality from 8% to 4.6% compared to conventional treatment. This article has been cited thousands of times in the literature and multiple studies have been undertaken to replicate this in other populations. In a large international adult medical population, the NICE-SUGAR trial [157], IIT to maintain serum glucose 81-108 mg/dL (4.5-6.0 mmol/L) was associated with increased mortality.

It is clear from most of these studies that attempts to regulate glucose very tightly result in an increased frequency of hypoglycemia. A review of the literature by Lipshutz and Gropper [158] summarizes the adult situation well: "We conclude that while avoidance of hyperglycemia is clearly beneficial, the appropriate glucose target and specific subpopulations who might benefit from IIT have yet to be identified." The situation remains as difficult in children. Studies have demonstrated that elevated serum glucose is associated with increased mortality in PICU patients [159–162]. Increased glucose variability results in higher mortality as well [161,162], potentially indicating loss of allostasis with disease progression. Whether control of glucose variability will improve outcome remains to be seen. In the United Kingdom a large randomized trial of glucose control is being undertaken: the Control of Hyperglycaemia in Paediatric Intensive Care (CHiP) study. Results of this study are likely several years away. In the meantime it seems prudent to avoid extremes of hyperglycemia and hypoglycemia; some PICUs are targeting serum glucose of 80–180 mg/dL as reasonable.

# Adrenal dysfunction in the pediatric intensive care unit

The diagnosis of adrenal insufficiency in the PICU suffers from the lack of a consensus statement. Critical illness is associated with an increase in baseline serum cortisol level. In addition, there are ICU patients with normal serum cortisol levels who cannot increase their cortisol production in response to further stress or exogenous stimuli. Testing for adrenal dysfunction entails obtaining a baseline level and then providing adrenocorticotropin hormone (ACTH) and repeating the cortisol level at 30 min or 60 min or both. The standard dose of ACTH for this test is 250µg, although an alternative test regimen of 1µg has been proposed. Currently, there is no consensus on how much the cortisol level needs to rise to declare the function appropriate. Pizarro et al [163] published a study of 57 children with septic shock some of whom had adrenal insufficiency. Their study defined adrenal insufficiency as a change in serum cortisol <9µg/ dL following a 250µg ACTH stimulation. Absolute adrenal insufficiency was defined as a baseline cortisol  $<20 \ \mu g/dL$  and relative adrenal insufficiency as  $>20 \ \mu g/dL$ dL. In their sample of 57 patients with septic shock, 18% had absolute adrenal insufficiency and 26% had relative adrenal insufficiency. They compared the incidence of adrenal insufficiency in their study to other criteria previously published and found it would vary between 9% and 44%.

To effectively study this disease process further, a consensus definition is needed. Until there is a single definition providing an understanding of the clinical picture, the criteria set by Pizarro et al seem like a reasonable starting point for the clinician. When the diagnosis of adrenal insufficiency is made, hydrocortisone should be given. The initial dose is 50 mg for small children and 100–150 mg for larger children and adults. Following the initial dose, hydrocortisone is added to the intravenous fluids at 100 mg/m<sup>2</sup>/day. Endocrinology consultation is advised for assistance and follow-up.

# Gastroenterology and nutrition issues in the pediatric intensive care unit

# Enteral feeding and parenteral nutrition

Nutrition and feeding in the pediatric ICU often occur as an afterthought. Unfortunately, there are many obstacles to appropriate nutrition in critically ill patients; lack of consideration of this need should not be one. Feeding should be approached in a similar manner as weaning and extubation from mechanical ventilation, and should be addressed proactively on a daily basis. If it is possible that a patient will be able to be fed enterally, this should be attempted. There is evidence that an ICU-based adoption of a feeding protocol allows patients to reach goal enteral nutrition more rapidly [164]. However, for other issues with nutrition in the ICU there is less clear-cut evidence. It should be reasonable to assume that early initiation of nutrition and enteral feeds should be associated with improved outcome but in fact this is very difficult to prove. In a prospective adult ICU study, Barr et al [165] demonstrated that patients enrolled in a nutritional management protocol reached goal enteral feeds earlier. However, by day 4 of the study the caloric intake was not different between the groups. They did show a significant reduction in mortality in patients who received enteral nutrition, but the reduction occurred in both groups. Regression analysis was used to control for confounders to demonstrate a reduction in length of mechanical ventilation with early enteral nutrition.

In a study using historic controls in a PICU, Gurgueira et al [166] demonstrated an increase in enteral nutrition after implementation of a nutritional support team. During the 11-year period of the study, there was a significant reduction in mortality for infants who received early enteral nutrition. There was no change in mortality for postoperative surgical patients after implementation of a nutritional support team. This highlights the very important aspect that patients with limited reserves such as infants are at greater risk for "starvation in the ICU." Given the 11-year period this study reviewed, it would be impossible to identify the change in nutritional support (which occurred recently) as the cause of decreased mortality. Certainly during the same time overall reduction in infant mortality would be anticipated.

A Cochrane database review was published by Joffe et al [167] in 2009 to address the "impact of enteral and total parenteral nutrition (PN) on clinically important outcomes for critically ill children." The authors were only able to identify one randomized clinical trial in pediatrics. The study by Gottschlich et al [168] from 2002 enrolled children with >25% body surface burns who were randomized to early versus late enteral nutrition. There were no clinically significant differences between groups based on early initiation of enteral feeds. The conclusion of Joffe et al [167] was that "there is little evidence to support or refute the need to provide nutrition to critically ill children in a pediatric intensive care unit during the first week of their critical illness." Certainly further research will be needed to correlate nutrition with outcome. Until that time reasonable decisions must be relied upon.

In supplying the basics to our patients, we must first assure their fluid balance is appropriate. Fever, tachypnea, diarrhea, diuretics, and the presence of nasogastric suctioning all increase fluid losses. Only some of these may be accounted for in strict intake and output measurements. Daily weights and BUN/creatinine ratios may help identify patients who are volume depleted or overloaded. Further basic provisions would be enough food. This includes enough calories to meet resting energy expenditure, enough protein to prevent proteolysis, and enough trace elements and vitamins to prevent further disease. The last basic tenet is providing enteral intake whenever possible to decrease complications. Possible complications include the metabolic, mechanical and infectious issues that are associated with parenteral nutrition. Enteral nutrition also helps prevent atrophy of the intestinal lining and may reduce translocation of bacteria out of the intestines into the bloodstream. Also, enteral feeds with fiber help avoid constipation, which can be a big problem in the ICU.

Estimating resting energy expenditure (REE) can be very difficult in ICU patients. Published values for REE in pediatric ICU patients are between 37 and 62 kcal/kg/ day [169-171]. Values for individual patients may be widely different. Intubated and sedated patients and those with multiorgan system failure may have a lower REE. Further, sepsis or systemic inflammatory response syndrome may produce a hypermetabolic state with activation of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis. A decreased uptake of glucose leads to hyperglycemia and there is decreased lipid uptake as well. There is increased breakdown of protein. Unfortunately, simply supplying glucose during the stress response does not prevent this protein breakdown and nitrogen loss. To treat each patient's metabolic needs individually, the goal would be to measure their own caloric expenditure. This is very difficult in critically ill children. Indirect calorimetry may be the gold standard but requires accurately measuring oxygen consumption and carbon dioxide production. Difficulties include the need for a metabolic cart or mass spectrometer as well as a steady clinical condition. It is possible to calculate energy expenditure by giving oral water that has been labeled with <sup>2</sup>H<sub>2</sub>O and H<sub>2</sub><sup>18</sup>O and measuring isotope output. This doubly labeled water method is also difficult. Finally, even initiating enteral feeds does not mean they can continue. Feeding interruptions are frequently necessary in the ICU to perform procedures requiring sedation or anesthesia that mandate a period of nil per os to minimize aspiration risk.

Studies estimate that 25% of patients admitted to the PICU are malnourished [172]. Infants have limited reserves as well. These groups should be targeted to initiate enteral feeds early. If procedures interrupt feeding, efforts should be made to pass the feeding tube beyond the pylorus so the limitations for procedures will be for a shorter duration. Concerns about reflux are another reason to attempt to feed into the small intestine. Nutrition consultation and obtaining a daily weight that is readily visible to the care team are important principles in these patients. If this group does not tolerate enteral feeds, parenteral nutrition will need to be considered sooner. Peripheral parenteral nutrition may be a temporary solution but the higher the dextrose or amino acid concentration, the greater the risk for phlebitis or infiltration of a peripheral intravenous line. There are risks to placing a central venous line for parenteral nutrition such as vessel injury, bleeding, malposition, and infection. There are additional risks to PN such as hepatic stenosis, cholestasis, elevated triglycerides, and electrolyte disturbances. Weighing the balance of risk benefit for PN in malnourished patients likely falls on the side of PN. For wellnourished children who are likely to return to feeding in 4-5 days, the benefit from PN is not so great as to outweigh its risks.

# **Immunity and infection**

# Infection control

#### Empiric antibiotic coverage

Recommendations for empiric antibiotic coverage are difficult in the current practice of pediatric critical care. Use of very broad-spectrum antibiotics in an indiscriminate manner may result in further antibiotic resistance. In addition, bacterial susceptibilities vary significantly based upon region, hospital, and patient population. Due to the incidence of meticillin-resistant Staphylococcus aureus, the first choice for antibiotics for a patient presenting with sepsis in our hospital is vancomycin and a third-generation cephalosporin. As culture results begin to return, antibiotic choices can be more selective, with final changes often waiting for culture sensitivities. For newly admitted patients with serious or unusual infections, infectious disease consultation is important to guide decisions about empiric antibiotic coverage based upon current culture isolates and antibiotic resistance.

## Prevention of nosocomial infection

Hand washing with antiseptic soap or alcohol-based gels before and after contact with any patient, or any other surface or equipment that may be contaminated, is an important priority in the care of critically ill patients. Lab coats and stethoscopes are frequently contaminated and often overlooked as potential sources of infection. Nosocomial or hospital-acquired infections are estimated to occur in 5–10% of all hospitalized patients. These infections are a significant cause of morbidity and mortality that can be avoided by adherence to guidelines for hand hygiene (HH). In studies physicians are less likely to adhere to HH compared to nurses. Interventions targeting improvement also have not shown sustained results. However, the impact of any individual on hand hygiene and preventing infection should not be underestimated.

In a unique study by Schneider et al [173], junior trainees (critical care fellows and nurse orientees) were paired with senior supervisors who were unaware they were being observed for HH adherence. With the clinicians unaware of their observation, HH adherence was 22% among trainees and 20% among senior supervisors. Still unaware of observation, the trainees were paired with senior clinicians who had been notified of the study. At this point the senior supervisors had 94% adherence to hand hygiene and the trainee percentage adherence rose to 54% (Table 37.9). This supports findings of other studies that HH compliance is greater when people know they are observed. Importantly, it is novel in demonstrating that role modeling positive behavior can have an impact on hand hygiene. Parents in our unit are instructed and reminded to ask clinicians to wash their hands if they have not seen them do this. We should not be afraid to remind our peers to wash their hands to protect our patients.

# Ventilator-associated pneumonia

Patients benefit from ventilator support during episodes of respiratory failure. However, loss of airway protective mechanisms by the placement of an endotracheal tube through the vocal cords increases the risk of development of pneumonia. Patients previously uninfected are at risk for nosocomial infection and patients intubated for pneumonia are at risk for secondary infection. There is associated increased length of mechanical ventilation, mortality, and cost. In a study by Srinivasan et al [174], patients with

Control period	20%	22%
Study period	94%	54%

Source: Schneider et al [173].

ventilator-associated pneumonia (VAP) had longer ventilation, longer ICU stay, and an increase in absolute hospital mortality. Mortality was 10.5% in the group who developed VAP and 2.4% in the group who did not. The median difference in hospital cost incurred by the extended stay was greater than \$50,000. This is consistent with the additional cost of \$40,000 associated with adult VAP [175].

Ventilator-associated pneumonia is defined as a new onset of lower respiratory tract infection in patients ventilated for ≥48h. Diagnostic criteria include fever or temperature instability, low or elevated white blood count, new infiltrate on chest x-ray, and positive respiratory culture. The incidence of VAP in intubated PICU patients was reported in 2002 as 5.1% [176] or 11.6/1000 ventilator days. The date is of note as potentially the incidence of VAP will decline in the coming years. The Institute for Healthcare Improvement (IHI) initiated a campaign to save 100,000 lives over the period of 2 years by starting evidence-based interventions in six specific clinical areas. Three of these areas deal with the prevention of infection: VAP, central line infection, and surgical site infection. It has been demonstrated that the use of bundles of interventions or information can reduce infections in these areas. These bundles have been tailored for use in pediatric patients [177] and the reduction in VAP has been significant. Bigham et al [178] observed a reduction in VAP rate from 5.6 to 0.3 infections per 1000 ventilator days following the introduction of a ventilator bundle. There was also a significant reduction in length of stay, mechanical ventilator days, and mortality rates. One of the interesting findings after institution of bundles is that the cumulative impact of the combined interventions is greater than the sum of individual parts.

The elements of a pediatric VAP bundle include those things which reduce bacterial colonization of the mouth, sinuses, and stomach as well as those preventing aspiration of contaminated secretions. Mouth care is performed every 2–4h with chlorhexidine rinse. The oropharynx is suctioned prior to endotracheal tube suctioning or deflating its cuff. The condensation is drained out of the ventilator tubing every 2–4h without disconnecting the circuit. The ventilator tubing is drained prior to repositioning or moving the patient. In-line suction catheters are used to reduce the number of airway circuit disconnections. The head of the bed is elevated to between 30° and 45° unless there is a specific contraindication. Our experience with bundles is they are relatively easy to perform and have a significant impact on the development of VAP.

# **Central line infections**

Reliable venous access is necessary in critically ill patients and even more so when dependent on vasoactive

infusion or other drugs which cause peripheral vein injury. The adage remains true, however, that if you do not place a central line you cannot get a central line infection. Catheter-associated bloodstream infections (CA-BSI) like VAP result in increased hospital stays, costs, morbidity, and mortality. Pediatric cardiac intensive care units may provide the best information regarding the impact of CA-BSI on mortality. The overall risk of sepsis and a bloodstream infection (BSI) in general is likely lower in a cardiac ICU compared to a medical ICU. In a prospective study, Abou et al [179] demonstrated an 11% mortality rate in patients with a BSI compared to 2% in non-BSI patients. It has been demonstrated that additional care during insertion and with daily catheter care will reduce the risk of CA-BSI. In a quality improvement study [180] initiated in 29 PICUs across the country, CA-BSI rates were reduced by 43% with the use of central line insertion and maintenance bundles. Bundle items were adapted using expert opinion from adult standards, in addition to information from the US Centers for Disease Control. Insertion bundles focused on use of chlorhexidine prep for patients  $\geq$ 2 months and maintaining complete sterile barriers. This means mask, gown, glove, and full sterile drape of the patient bed. Maintenance bundles include daily assessment of a need for a central venous line as well as strict catheter site, hub, and tubing care guidelines. Dressing changes are performed with a 30-sec chlorhexidine scrub followed by 30-sec air dry. Our institution participated in this study and at one point had no CA-BSI for up to 500 days. As noted in the VAP section, it is strict attention to all the details that reduces the overall risk. The same care procedures are also used whenever a central venous catheter is accessed throughout our hospital in an effort to reduce nosocomial infections overall.

## Urinary tract infection

The greatest risk factor for the development of a urinary tract infection (UTI) while in the ICU is the present of a bladder catheter. Removing these when not necessary reduces the chance of developing a UTI. Because of sedation, age, or developmental delay, many patients cannot indicate the symptoms of a developing UTI. Evaluation of fever or change in white blood cell count should include examination of the urine for microscopic analysis and culture. If removal of the catheter is not possible a bladder care bundle is necessary. In our unit periurethral cleaning with a chlorhexidine cloth occurs at least once a shift. The urine collection bag is always below the level of the bladder and is drained completely before moving the patient. Prior to this bundle it was possible to see urine reflux from the collecting tubing back into the patient's bladder as they were moved from transport gurney to ICU bed. This no longer occurs and catheterassociated UTIs have been significantly reduced.

# Transport of the critically ill pediatric patient

There are two types of transport that concern the pediatric ICU physician. The first is the intrahospital transport of critically ill patients to other areas including the operating room or for radiological procedures. The second is interhospital transport of patients from referring hospitals. For transports within the hospital, the first issue to address is the risk/benefit of moving a critically ill patient. Is there enough information to be gained from a CT scan or MRI, which will help determine a course of therapy, which makes the transport necessary? The more the patient is dependent on technology, the more difficult or hazardous it will be to move them. Simply, intubated patients with central venous and arterial lines requiring inotropic infusions are at greater risk. The team providing care may include the bedside nurse, respiratory therapist, and ICU physician. All necessary medicines and equipment to resuscitate the patient should be brought on transport. One cannot rely on equipment being available and working in other areas of the hospital. Transport monitors have the ability to monitor heart rate, saturations, and non-invasive blood pressure. Some can measure arterial blood pressure, intracranial pressure, or end-tidal carbon dioxide. End-tidal CO2 should be monitored if available to prevent hypocarbia from overaggressive hand ventilation.

The systems in place to address the needs of interhospital transport will depend on the goals and resources of the tertiary hospital receiving the patient. Information supports the use of ground transports as well as rotor or fixed wing flight. The location of the receiving and referring hospitals will affect the means of transport more than any study indicating that one is better than the other. By the same token, it is more important that the transport team is well organized and trained in pediatric care than whether it is nurse or physician led. There can be further discussion on both sides as to whether the tertiary hospital should send a team of experts or whether resources in the community are sufficient for a one-way transport. Distance from a tertiary center and the clinical scenario must be taken into account. Experience and culture of the particular unit likely will play a role in determining transport method. Details regarding the equipment necessary and development of a transport team are beyond the scope of this chapter and excellent textbooks have been written on this topic such as Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients [181], most recently updated in 2006 and available through the American Academy of Pediatrics

The majority of care provided by emergency medical services is for adult patients. Children make up approximately 10% of paramedic calls. The number of times that each individual team member provides bag-valve mask ventilation to a child is limited. Their experience may be even more limited for intubation or other advance practice procedures. In addition, small community hospitals may have limited equipment or expertise to care for critically ill children. Arrangements should be made as soon as possible to transport these children to a pediatric facility. However, the concept of the "golden hour" was not to support the notion of scooping up the patient and running back to the tertiary care facility. Regardless of the resources, the referring hospital should resuscitate the child to the best of their ability prior to transport. It is likely that a call for transport will be made shortly after arrival of a child *in extremis*. Transport teams have been known to arrive while CPR is still ongoing. By common sense as well as policy, transport teams do not retrieve children from other hospitals while performing CPR. The ambulance or helicopter is a hostile environment. Intubation or placement of venous access should best occur before leaving the referring hospital. Medications can be given, inotropic support can be started, the ventilator can be changed while en route but it is best if this does not have to occur.

The control physician receiving the referring call should obtain information on the history and current physical examination of the child with complete vital signs. Ongoing efforts to resuscitate the patient should be noted. A decision is made regarding make-up of the transport team based on the information received. Telemedicine may provide a different picture of the patient's clinical status but we are more often relying on the impression of the physician caring for the child. Given their experience of caring for children, some have been known to overestimate the severity of illness. After accepting the patient, there should be contact with the referring hospital until the transport team arrives. Appropriate guidance should be given and clinical updates obtained.

Transport by helicopter requires a consideration of altitude physiology. The alveolar gas equation provides the relationship between barometric pressure, FIO<sub>2</sub>, pressure of water vapor, PaCO<sub>2</sub>, and respiratory quotient. PAO<sub>2</sub> = ( $P_B - P_{H2O}$ )(FIO<sub>2</sub>) – (PaCO<sub>2</sub>/R). At sea level  $P_B$  is 760 mmHg, but at an altitude of 8000 feet it is 565 mmHg. To maintain reasonable saturations, supplemental oxygen may be needed and with significant lung disease hypoxemia may remain despite an FIO<sub>2</sub> of 1.0. Further, at these altitudes there can be expansion of gas already contained in the body. This may mean the potential increase of a pneumothorax or, more commonly, endotracheal tube cuff pressure.

As a final word on transport, many tertiary pediatric hospitals view it as their responsibility to the community to help train and educate emergency medical practitioners. While working in the operating room, pediatric anesthesiologists are often asked to allow a paramedic or transport nurse to work with them to learn to manage the pediatric airway. As the true experts in this field, pediatric anesthesiologists can teach the skills that improve the care these first-line providers give to children.

# CASE STUDY

The patient was a 3-year-old 20kg girl who presented to the emergency department with a 3-day history of fever and rash. The patient was seen by her regular pediatrician one day after developing a fever to 38.5°C and she was noted to have a slight maculopapular rash. A blood culture, throat culture, and complete blood count were obtained and the patient was started on oral azithromycin. Two days later, as the symptoms persisted and the patient now complained of abdominal pain, the family returned to the pediatrician who referred them to the emergency department.

Initial vital signs in the emergency department were a temperature of 38°C, heart rate 150 beats/min, respiratory rate 24/min, and blood pressure 81/63 mmHg. She was described as being somnolent but appropriate when stimulated. Her skin exam was remarkable for a diffuse blanching maculopapular rash throughout her body and a newly developed petechial rash covering her wrists and ankles. In addition to the fever and rash, the patient complained

of abdominal pain. Peripheral venous access was obtained and a bolus of 40 mL/kg of normal saline was given. There was a slight improvement in her systolic blood pressure with the initial fluid bolus but no improvement in her heart rate. Initial blood work obtained was significant for a white blood count of 2000 per µL, with an absolute neutrophils count of 1260/µL. Her hemoglobin was 10.6 g/dL, hematocrit 32.2%, and platelet count of 69,000 per µL. Her coagulation studies were mildly abnormal with a prothrombin time of 15.8 sec and partial thromboplastin time of 31 sec. Fibrinogen level was normal at 364 mg/dL but the D-dimer was elevated at greater than  $8 \,\mu g/mL$ . With her laboratory values, a blood culture was obtained and intravenous cefotaxime and vancomycin were administered. The infectious disease consultation was obtained, and they agreed with the possibility of meningococcemia versus streptococcus or staphylococcus infection.

Shortly after receiving antibiotics, the patient's blood pressure decreased and she was given three 20mL/kg

normal saline fluid boluses. She temporarily required nasal cannula oxygen for an episode of desaturation. Arrangements were made to admit the patient to the intensive care unit. Upon arrival in the ICU, her vital signs were temperature of 40°C, heart rate 165 beats/min, respiratory rate 32/min, blood pressure 91/48 mmHg, and SpO<sub>2</sub> 99%. She was described as crying, uncomfortable, edematous, and with a diffuse rash over her body. Her neck exam had full range of motion without signs of meningismus. Cardiac examination was unremarkable other than tachycardia. She had 2+ distal pulses with a capillary refill less than 3 sec. Her hands and feet were cold. Her abdominal examination was without organomegaly or masses. She was diffusely tender to palpation but there was no guarding or rebound.

The patient continued to be tachycardic with cold extremities and at this point she had received 100 mL/kg of normal saline. Dopamine was started at  $5\mu g/kg/min$  through a peripheral vein while arrangements were made to obtain central venous access. Cefotaxime and vancomycin were continued at meningitic doses. Given the thrombocytopenia, lumbar puncture to rule out meningitis was delayed. After several hours in the ICU, her blood pressure improved and she was able to be weaned off dopamine.

The patient remained off inotropic support through the night but required further additional fluid boluses. In the morning her heart rate had returned to normal and she was awake and alert. From a respiratory standpoint, she was requiring 1L/min of nasal cannula oxygen to maintain saturations. On her lung examination there were crackles at the lung bases. Radiological studies showed small bilateral pleural effusions at both lung bases. Morning laboratory examination revealed persistent thrombocytopenia, anemia, leukopenia, and neutropenia. There was a predominance of eosinophils on her peripheral blood smear. The C-reactive protein was elevated at 13. There were no positive cultures either from her regular pediatrician's office or from those obtained in the emergency department.

Viral studies including Epstein–Barr virus and cytomegalovirus were pending at this time.

The patient continued to convalesce in the ICU over the next few days. There was a gradual improvement in her fever curve and rash. Her neurological examination remained at an appropriate baseline. She had been 2.3L fluid positive over the few days in the ICU and her urine output was increased. Her pleural effusions remained present on chest radiograph but she did not require increased FIO<sub>2</sub>. The summary from the services involved described her as having systemic inflammatory response syndrome (SIRS) with some degree of bone marrow suppression. The etiology of her SIRS could have been from culture-negative sepsis. Bacterial cultures were all negative to date but the patient had received a few days of oral antibiotics prior to admission. There were no positive viral studies. Lumbar puncture was performed after her platelet counts began to increase and this showed a white blood count of  $39/\mu$ L and red blood count of  $7/\mu$ L. The Infectious Diseases Service recommended an empirical 10-day course of antibiotics at meningitic doses given the antibiotic pretreatment prior to cultures. A peripherally inserted central catheter was placed by interventional radiology for ongoing venous access. She was transferred to the pediatric ward service and was discharged home after completion of intravenous antibiotics.

This case demonstrates the presentation of an acuteonset systemic inflammatory response syndrome of infectious etiology, and rapid response to diagnostic studies, without delaying necessary hemodynamic management and monitoring with intravascular fluid resuscitation and intropic support. Importantly, broad-spectrum antibiotic therapy against the likely infecting organisms was administered without delay. Fortunately for this patient, she did not have full-blown multiorgan failure resulting in ARDS, renal, liver, and cardiac failure, as is often seen in this syndrome; she thus did not require mechanical ventilation, high-dose inotropic support (or even ECLS for sepsis), or renal replacement therapy.

# General approach to the patient with a genetic syndrome

A syndrome is the occurrence of more than one recognizable phenotypical trait that occurs together in a specific association, with a cause that is thought to be a specific genetic defect. A geneticist or dysmorphologist is usually able to determine a diagnosis from the phenotype of the patient, but as the science of molecular genetics advances, more of these syndromes have a known genetic cause and inheritance. It is presumed that many of those without a known cause will have their genetic bases determined in the near future. Definitive diagnosis of the more common genetic disorders is most often made from conventional karyotyping, chromosomal microarray (CMA) or fluorescence in situ hybridization (FISH), from peripheral blood lymphocytes. An association is a constellation of several recognizable phenotypical traits, either without a known genetic cause or with a variety of genetic causes. The distinction between a syndrome and an association is often not clear, and this chapter will use these terms interchangeably. The term "sequence" is also often used, as in "Pierre Robin sequence," but in modern terminology this term is also normally replaced with "syndrome."

Because many of these children will require anesthesia or sedation for diagnostic or therapeutic procedures, the pediatric anesthesiologist will encounter patients with syndromes frequently, often almost on a daily basis. This chapter will first review the general approach to the patient with a genetic syndrome, and then review in more detail a few of the most common syndromes associated with challenges in anesthetic care. Finally, a listing of 103 syndromes associated with anesthetic management issues will be presented alphabetically.

#### **Airway considerations**

Management of the airway is always a central consideration for the pediatric anesthesiologist, and many patients with genetic syndromes have abnormal airways. Among the most common are syndromes with mandibular hypoplasia, including Pierre Robin sequence, Treacher Collins syndrome, and Goldenhar syndrome (hemifacial microsomia). Other conditions include cleft lip and palate, high arched palate with small mouth opening, cervical vertebral fusion limiting neck movement, and soft tissue obstruction from macroglossia or other causes. It is important to obtain a thorough preoperative history of airway problems, including snoring, airway obstruction during sleep, and acute life-threatening events. History of previous anesthetics and tracheal intubations is crucial and whenever possible, examination of previous anesthetic records or speaking to the patient's previous

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

anesthesiologist, otolaryngologist or craniofacial surgeon is very important. Examination of the airway for mouth opening, and visualization of the pharynx and soft palate, as well as neck range of motion, should be done carefully. Finally, any imaging studies such as chest, neck, and facial radiographs, computed tomography (CT) or magnetic resonance imaging (MRI) scans should be reviewed.

A management plan for the difficult airway should be developed. Details of difficult airway management are presented in Chapter 14. Details of anesthetic management for craniofacial surgery are presented in Chapter 32. Table 38.1 includes airway considerations for each of the 103 syndromes listed.

### **Cardiac manifestations**

A number of genetic syndromes have a cardiac component, and the importance of a thorough cardiac history and physical examination cannot be overemphasized. In the presence of an abnormal cardiac examination consisting most often of systolic and/or diastolic murmurs, the cardiac anatomy and pathophysiology must be understood, and any recent diagnostic studies such as echocardiography must be reviewed. In neonates without a cardiac diagnosis presenting for some types of surgery, i.e. a patient with VACTERL association (see below) presenting for tracheo-esophageal fistula (TEF) repair, cardiac consultation and echocardiography should be obtained if possible because of the high incidence, 30-40%, of cardiac abnormalities [1]. Other common syndromes with frequent cardiac involvement in patients presenting for noncardiac surgery include CHARGE and velocardiofacial syndromes (see below). A discussion with the patient's cardiologist is indicated for severely affected patients. Details of cardiac development are reviewed in Chapter 5 and anesthetic management and pathophysiology in cardiac disease are discussed in Chapter 25.

### Neurodevelopmental abnormalities

Many patients with genetic syndromes have malformations of the central or peripheral nervous systems, and for many without obvious malformations, there is associated neurodevelopmental delay. This may manifest as general intelligence lag, gross or fine motor problems, speech and language delay, and behavioral problems. It is important to understand neurodevelopmental status in any patient with a genetic syndrome; the chronological age may be very different from the developmental age and the approach to preoperative preparation, communication, premedication, and parental presence may need to be altered accordingly. Many of these patients have undergone multiple medical encounters and interventions, and may be very anxious in the preanesthetic period.

### **Vascular** access

Patients with genetic syndromes may have limb abnormalities that preclude conventional intravenous access, and alternative sites may need to be planned. This may include external or internal jugular vein access if the limbs are not available. In addition, patients with genetic syndromes often have had multiple hospitalizations and procedures, and peripheral venous access may be very difficult, and central veins may also be thrombosed from previous catheters. Absence of typical superficial veins and presence of cutaneous collateral vessels should increase suspicion for difficult access. If indicated, additional studies, i.e. ultrasound, MRI or CT scanning, may be necessary to plan for vascular access.

### **Orthopedic considerations**

Scoliosis, hip dysplasia, and limb contractures are common in patients with genetic syndromes. Severe scoliosis should prompt an evaluation of the respiratory and cardiac status of the patient and may alter plans for postoperative ventilation and intensive care. Positioning of anesthetized patients with these problems must be done very carefully so as not to injure affected areas.

### **Other considerations**

Particularly with rare disorders or disorders that the anesthesiologist is not familiar with, it is important to consult a reference source whenever possible to become familiar with the basic problems of the particular syndrome and devise a rational anesthetic plan. Table 38.1 lists 103 syndromes, ranging from the most common (fetal alcohol syndrome, Down syndrome, autism spectrum disorder) to the most rare. Another excellent general source is the US National Institutes of Health website: health.nih.gov/category/GeneticsBirthDefects [2]. The US NIH online Mendelian Inheritance in Man database (www.ncbi.nlm.nih.gov/omim), and US Institutes of Health Genetic and Rare Diseases Information Center (http://rarediseases.info.nih.gov/GARD) also have excellent information including the gene map locus, if known. Many other published and electronic resources are available, including general review articles [3] and textbooks [4]. It behooves the pediatric anesthesiologist to have these resources at hand because of the frequent presentation of these patients on the day of surgery, when the luxury of time for a thorough search for information is not available. In addition, the parents and other caregivers are usually extremely knowledgeable about the patient, and often the condition itself, and can offer valuable information about how the patient has responded to particular interventions in the past. It is important to listen to the parents' and patient's requests and concerns when approaching the patient with a genetic syndrome.

## Management of common important syndromes

### Down syndrome

Down syndrome (DS), or trisomy 21, is the most commonly identified genetic form of mental retardation, and the leading genetic cause of specific birth defects and medical conditions [5]. Approximately 95% of children with DS have an extra chromosome 21 due to abnormal segregation of chromosomes during gamete formation – about 4% due to chromosome 21 translocations and 1% due to chromosome 21 somatic mosaicism [5]. The estimated maternal age-adjusted prevalence of DS in the United States is 14 per 10,000 livebirths, or one in 732, suggesting that approximately 5400 infants are born annually with DS. Advanced maternal age is by far the most significant risk factor for DS.

Down syndrome patients experience a number of problems that result in them presenting to the anesthesiologist for diagnostic and therapeutic reasons, and have common features which present a challenge to the anesthesiologist. All DS patients by definition have the characteristic facial features of upslanting palpebral fissures, flat facial profile, and relatively large tongue; they also have mental retardation and hypotonia (Fig. 38.1). About 50% of DS patients have congenital heart disease (CHD), consisting of complete atrioventricular canal in the majority of patients, but ventricular septal defect, tetralogy of Fallot, and other lesions are also seen. Neonates with DS should be screened for congenital heart disease, and parents questioned

about cardiac history before any anesthetic. Of particular note is that for reasons incompletely understood, DS patients develop pulmonary hypertension much earlier, and to a more severe degree, than patients without DS with the same cardiac lesion. Especially in unrepaired CHD in DS, an assessment of pulmonary artery pressures should be considered; echocardiography is often sufficient for this purpose. Chapter 25 discusses anesthetic management in CHD.

Airway obstruction is common in children with DS, caused by the relative midface flattening with constricted oropharyngeal space, small nasal passages, relatively large tongue, tonsils, and adenoids [6]. This may lead to obstructive sleep apnea, which may further exacerbate any pulmonary hypertension. DS children present frequently for tonsillectomy and adenoidectomy, and may require special diagnostic testing, and postoperative admission and monitoring. Despite this propensity for upper airway obstruction, the vast majority of DS patients have a straightforward mask airway and tracheal intubation.

Atlanto-occipital instability occurs in up to 15% of DS patients, defined by excessive movement on cervical flexion-extension radiographs [6]. However, the vast majority of these patients are asymptomatic, and many infants with DS who present for an anesthetic have incompletely ossified cervical spine vertebrae and radiographs are not reliable. Therefore, cervical spine radiographs are not indicated in the asymptomatic DS patient before anesthesia. A careful history of neck pain or neurological symptoms, and previous anesthetics or tracheal intubations is important for every DS patient. If such a history is positive, elective anesthetics should be postponed until a thorough evaluation, often involving cervical spine radiography, CT scan or MRI, is done. Very careful handling of the cervical spine during airway management and surgical positioning is indicated. This includes avoiding extremes of flexion, extension, and rotation, and holding the cervical spine in neutral position whenever possible. The majority of DS patients' tracheas can be intubated easily by direct laryngoscopy with these precautions.

Gastrointestinal problems occur in about 10% of patients with DS, with duodenal atresia and annular pancreas accounting for the majority of these findings [5]. Esophageal atresia/tracheo-esophageal fistula may also be present in patients with DS. These conditions often result in a neonate with DS presenting for urgent surgery for bowel obstruction; a careful search for associated conditions, especially CHD, is important in such patients.

Down syndrome patients frequently have abnormal thyroid function, with about 2% having congenital hypothyroidism and up to 25% of patients from birth to 10 years having compensated hypothyroidism, with elevated thyroid-stimulating hormone (TSH) levels and low-normal T4 levels [7]. These patients often go undetected due to the other characteristics of DS, i.e. developmental delays, hypotonia, and obesity. Hypothyroidism is especially important in cardiac or other major surgery, where a subclinical state may be unmasked by the major stress in the perioperative period, which can affect myocardial function by desensitizing the heart to endogenous and exogenous catecholamines. Therefore, it is recommended that DS patients have screening thyroid function testing before major surgery.

Down syndrome children are at increased risk for acute leukemias, both myeloid (AML) and lymphocytic (ALL) [8]. DS children differ in their outcomes and response to treatments, as well as treatment toxicity and side-effects, compared to non-DS children. Survival and outcome are improved in DS patients with AML, but equivalent to non-DS patients in ALL. Side-effects, particularly mucositis and severe infections, are more frequent in DS patients undergoing intensive chemotherapy induction regimens. The anesthesiologist must evaluate the DS patient with leukemia for all of the other manifestations of DS noted above.

Finally, vascular access may be challenging in patients with DS, with peripheral venous access difficult because of increased adipose tissue, internal jugular access made difficult by a short webbed neck and increased adipose tissue, and radial arterial access difficult because of the small size of this artery [9].

In a recent study from a major US children's hospital, 9% of 479 anesthetics in children with complex special healthcare needs were for children with DS, representing 1.25% of all anesthetic cases [10]. This series indicates the frequency with which the pediatric anesthesiologist will encounter patients with DS, and a thorough understanding of the above noted disorders with DS is important in order to deliver appropriate anesthetic care to these patients.

### **VACTERL** association

The VACTERL association was first proposed in 1972. The acronym comprises V for vertebral defects, A for anal or other intestinal atresia, C for cardiac defects, TE for tracheo-esophageal fistula, R for renal malformations, and L for limb defects. It was first proposed as the VATER association and this is occasionally still used; the frequent inclusion of cardiac and limb defects necessitated the change [11].

The genetics of this disorder are complex, but candidate genes in patients and animal models include defects or deletions in the sonic hedgehog gene on chromosome 7, *FOX* transcription gene cluster on chromosome 16, and *Gli2* gene on chromosome 2 [12,13]. Not all patients have all features of this association, but the TE fistula is often accepted as essential for the diagnosis, along with at least one other major defect in one of the five additional categories. In the other categories, cardiac lesions are the most prevalent, seen in 30-50% of patients [13]. Ventricular septal defect and tetralogy of Fallot are common, and most CHD is acyanotic at presentation. In the case of the VACTERL association with complex CHD with patent ductus arteriosus-dependent systemic or pulmonary circulation, mortality after TEF repair exceeds 50% [14]. Vertebral anomalies are seen in about 25% of patients, including hemivertebrae, fused or butterfly vertebrae or extra vertebrae. Renal system anomalies are found in approximately 20% of patients and include horseshoe kidney, renal agenesis, vesicoureteral reflux, hypospadias, dysplastic kidney, and cryptorchidism. Atresias of the gastrointestinal tract are seen in approximately 15% of patients, with the significant majority of these being anal atresias. Limb anomalies are observed in about 10% of patients, with digital anomalies and absent radius the predominant defects.

The frequent and significant defects in the VACTERL association mean that these children are often presenting for repeated anesthetics for both diagnosis and treatment, necessitating a thorough preoperative evaluation encompassing an assessment of the lesions in all categories, and also of the developmental and emotional state of the child who has often endured multiple medical interventions. These children are most often developmentally normal.

#### **CHARGE** syndrome

The CHARGE syndrome was first described in 1979 and the acronym is C for coloboma, H for heart defect, A for atresia choanae, R for retarded growth and development, G for genital hypoplasia, and E for ear anomalies/ deafness [15]. Further refinement of diagnostic criteria in 1998 designated major features seen in most all CHARGE patients, but rare in other patients, as the 4Cs: coloboma of iris or retina, microphthalmia (80% of patients); choanal atresia/stenosis either unilateral or bilateral or membranous or bony; cranial nerve anomalies - olfactory tract, facial paralysis, sensorineural deafness, and incoordination of swallowing; and characteristic ear anomalies - cup-shaped ear (80-100% of patients). The minor criteria, seen less frequently in CHARGE syndrome and less specific, include the cardiac malformations (75-80% of patients), most often conotruncal defects including tetralogy of Fallot, aortic arch anomalies, and also atrioventricular canal; genital hypoplasia including micropenis and cryptorchidism; cleft lip and palate; TE fisula; distinctive CHARGE facies and features - sloping forehead and flattened tip of nose; growth deficiency; and developmental delay [15].

The incidence of CHARGE syndrome is estimated to be approximately 1 per 10,000 livebirths [15]. A leading can-

didate gene, discovered recently, is the chromodomain helicase DNA binding protein 7 (*CHD7*) gene on the long arm of chromosome 8 which results in the expression of a protein that participates in chromatin remodeling during early development and allows a level of epigenetic control over target genes expressed in mesenchymal cells derived from the cephalic neural crest [16]. Mutations of this gene are found in 60–65% of individuals with CHARGE syndrome, and over 150 mutations have been discovered which encode for short, non-functional CHD7 protein.

A thorough evaluation of all organ systems is required before anesthetizing a patient with CHARGE syndrome. Neonatal choanal atresia or stenosis may be particularly challenging, requiring repeated anesthetics for imaging, the repair itself, and re-evaluation and follow-up procedures. The cardiac procedures are particularly common. With the advent and more widespread use of the cochlear implant, many CHARGE patients will also undergo this procedure. Although mental retardation and other developmental delays are common, these features are variable and some patients may have normal intelligence. Autism spectrum disorder behavioral syndromes are increasingly recognized in these patients [15].

### Micrognathia syndromes: Pierre Robin sequence, Treacher Collins syndrome, Goldenhar syndrome

Among the most common causes for difficult airway management and tracheal intubation in pediatric patients is micrognathia, and an evaluation for this problem is done in every patient. There are a number of craniofacial syndromes leading to micrognathia, including the Pierre Robin sequence, Treacher Collins syndrome, and hemifacial microsomia (Goldenhar syndrome). Pierre Robin sequence (PRS) is defined as micro- or retrognathia, glossoptosis, and cleft soft palate. Isolated PRS does not have a known genetic cause and is not associated with other syndromes; the isolated form is seen in approximately half of the patients but the published series vary from 11% to 81%. Incidence is approximately 1 per 8500 livebirths, with mortality during childhood 2.2-26% [17]. PRS associated with genetic syndromes is most often seen with Stickler syndrome and velocardiofacial syndrome (see below and Table 38.1). Mildly affected patients may need minimal medical intervention, while severely affected patients manifest airway symptoms in the neonatal period. The constellation of upper airway anomalies frequently leads to obstructive apnea, and the intensity of medical intervention is proportional to the degree of upper airway obstruction. In significantly affected neonates, airway interventions such as prone positioning, nasal continuous positive airway pressure, endotracheal intubation or tracheostomy may be required. Feeding difficulties are common and feeding gastrostomy may be required. Airway surgery including cleft palate repair, veloplasty, and mandibular operations may be necessary. Details of difficult airway management are presented in Chapter 14.

Treacher Collins syndrome (TCS) is an autosomal dominant disorder of bilateral facial development, which affects approximately 1 in 50,000 livebirths; however, up to 60% of cases appear to be a *de novo* genetic mutation. TCS is a genetic developmental disorder of the first and second branchial arches, resulting in extensive neural crest cell abnormal development. The TCS phenotype includes hypoplasia of the maxilla, zygoma, and mandible, lateral downward sloping of the palpebral fissures, coloboma of the lower eyelids, defects of the external and middle ears, and sensorineural deafness (Fig. 38.2). The protein coded by this gene is called Treacle, and the hypothesis is that it assists in ribosomal DNA transcription during particular stages in embryonic development, particularly that of the structures of the head and face [18,19]. These patients may require extensive bony and soft tissue facial reconstruction over multiple procedures, including orbital and zygomatic reconstruction before age 10, external ear reconstruction, and mandibular advancement as teenagers when bony growth is complete. Difficulties in airway management for the anesthesiologist arise from the mandibular hypoplasia and high arched palate frequently encountered in TCS patients.

Goldenhar syndrome, also known as oculo-auriculovertebral syndrome or hemifacial microsomia, is a developmental disorder of the first and second branchial arches that affects approximately 1 in 5600 livebirths, is most frequently unilateral, and is characterized by malformations/hypoplasia of the external and middle ear often with sensorineural hearing loss, mandibular hypoplasia, eye abnormalities such as microphthalmos and epibulbar dermoids, and vertebral anomalies including cervical spine malformations and scoliosis (Fig. 38.3). Most cases of Goldenhar syndrome are sporadic, and heterogenous manifestations of the phenotype are common, ranging from very mild hemifacial asymmetry, preauricular ear tags or pits, to severe deformity and mandibular hypoplasia. Congenital heart disease is present in approximately one-third of patients, most commonly septal and conotruncal defects [20]. Developmental delay and autism spectrum disorder are seen in some patients [21]. Difficulties with airway management and tracheal intubation are common in this syndrome due to the mandibular hypoplasia and lack of space for direct laryngoscopy. These patients frequently present for anesthesia and sedation for diagnostic and therapeutic procedures for ear, facial, and cardiac anomalies. Techniques such as fiberoptic or video-assisted laryngoscopy are frequently required for airway management [22,23].

### Cardiac syndromes: Williams syndrome, Noonan syndrome, velocardiofacial syndrome (22.Q11.2 deletion)

Williams syndrome (WS) is a genetic syndrome whose phenotype involves supravalvular aortic stenosis and characteristic facial features including periorbital puffiness, flat nasal bridge, long philtrum, full cheeks, and full lower lip (Fig. 38.4). Other features include developmental delay, friendly or outgoing personality, hypercalcemia, hypotonia, joint laxity, and hypertension. WS affects approximately 1 in 10,000 livebirths and has been localized to a 1.5 Mb base pair deletion on one copy of chromosome 7, involving 26–28 genes, including the elastin gene, at 7q11.23 [24]. This deletion can arise from a spontaneous mutation or can be inherited as an autosomal dominant familial form. Fifty to 75% of WS patients have cardiac disease, most frequently supravalvar aortic stenosis, and peripheral pulmonary artery stenosis. These changes are

**Figure 38.4** Williams syndrome facies in a young child. Note the periorbital puffiness, flat nasal bridge, long philtrum, wide smile, full cheeks and full lower lip. Reproduced from Waxler et al [24] with permission from Slack Incorporated.

characterized as an elastin arteriopathy, and the usual large quantity of elastin present in the medial layer of large arteries is absent, resulting in limited distensibility and stenosis of the artery. In addition, adhesion of the aortic valve leaflet edges to the narrowed sinotubular junction can result in obstruction of the coronary artery ostia, leading to impaired coronary blood flow [25]. It is this feature which leads to sudden death in WS patients, both spontaneously and during diagnostic and therapeutic procedures requiring anesthesia and sedation [26]. Careful anesthetic management to balance myocardial oxygen supply and demand, including avoidance of excessive tachycardia, hypotension, and hypovolemia, is an important principle. The peripheral pulmonic stenosis is often present during infancy but improves over time. Details of anesthetic management for left heart obstructive lesions are presented in Chapter 25.

Noonan syndrome is characterized by cardiac disease and distinctive facial features including hypertelorism with downslanting palpebral fissures, ptosis, and low-set, posteriorly rotated ears. The cardiovascular manifestations are most commonly valvar pulmonary stenosis in about 60%, hypertrophic cardiomyopathy in 20%, atrial septal defects and ventricular septal defects in approximately 10% and 5%, respectively, and patent ductus arteriosus in 3% [27]. Other defects include webbed neck, shield chest, and abnormal lymphatic drainage resulting in lymphedema. The syndrome occurs in approximately 1 in 1000–2500 livebirths and may occur sporadically, or with an autosomal dominant inheritance, predominantly by maternal transmission. Approximately 50% of cases have a missense mutation in the PTPN11 gene on chromosome 12, which encodes for a protein, tyrosine phosphatase SHP-2. This enzyme is involved in a variety of signal cascades for receptors for hormones, cytokines,

**Figure 38.5** Facial features of velocardiofacial syndrome. Note small low-set posteriorly rotated ears and slight retrognathia; the patient also has a high arched palate with submucous cleft. Reproduced from Shprintzen [28] with permission from Wiley-Blackwell.

and growth factors and in a number of developmental processes [27]. Intervention requiring anesthesia is most commonly balloon valvuloplasty or surgery for pulmonary valve stenosis.

Velocardiofacial syndrome (VCFS) is also known as DiGeorge syndrome or sequence, 22Q11 deletion syndrome, CATCH 22, and conotruncal anomalies face syndrome. This disorder has a wide spectrum of phenotypical findings with more than 180 clinical features. It is one of the most common multiple anomaly syndromes, with incidence estimates of approximately 1:2000 livebirths. VCFS is inherited as an autosomal dominant disorder and is caused by a microdeletion at chromosome 22q11.2 [28]. The phenotype is extremely variable and there is no single clinical feature present in 100% of cases, and so the diagnosis is defined by the chromosome defect itself. Congenital heart disease is present in 70% of cases, and constitutes a high percentage of all conotruncal cardiac anomalies, including more than 50% of cases of interrupted aortic arch, over 15% of patients with tetralogy of Fallot, about 50% of truncus arteriosus cases, and about one-third of posteriorly malaligned ventricular septal defects. Hemizygosity of the gene TBX1 is responsible for the cardiac defects. Other defects commonly encountered are cleft palate, most commonly submucous clefts, facial anomalies, including high arched palate, low-set ears, and occasionally varying degrees of micrognathia (Fig. 38.5). Other important features present in a variable percentage of patients are partial hypoparathyroidism resulting in neonatal hypocalcemia and relative immunodeficiency from abnormal lymphocyte function. Developmental delay is common in VCFS, although in some patients intelligence may be normal.

Patients with the cardiac diseases noted above should be tested for the 22q11.2 deletion using FISH, and the other defects, especially hypocalcemia and immune dysfunction leading to increased infection risk, should be sought as well, as these may affect anesthetic management. In patients with simpler forms of CHD and VCFS, i.e. tetralogy of Fallot, VSD, and simple truncus arteriosus, surgical outcomes are not worse than in patients without a chromosome defect. However, in interrupted aortic arch, surgical outcomes are worse with the 22q11.2 deletion. Finally, the later neurodevelopmental outcomes at 1 year or more after cardiac surgery are definitely worse overall with 22q11.2 deletion [29]. In spite of the known mild craniofacial anomalies in this syndrome, airway management and tracheal intubation are most often straightforward.

### Autism spectrum disorder

Autism spectrum disorder (ASD) is an increasingly recognized neurodevelopmental disorder of empathy that encompasses autism, Asperger syndrome, atypical autism, and pervasive developmental disorder not otherwise specified. ASD is characterized by impairments in social communication and social interaction of varying degrees, and also includes restricted and repetitive behaviors and impairments of imaginary thought [30]. The prevalence is now thought to be approximately 1:150 children, with boys affected four times more frequently than girls [31]. There is increasing evidence that ASD has a genetic basis, including data indicating that the relative risk to siblings is 25 times higher than the general population, and twin studies showing higher rates in concordant twins. Genome association studies have identified several candidate genes on different chromosome regions, including 2q, 7q, 15q, 15p14.1 and X. In addition, syndromes such as fragile X, Down syndrome, velocardiofacial syndrome, and others account for 1–2% of ASD patients [30].

Anesthetic management of patients with ASD, especially preoperative preparation, premedication, and induction of anesthesia, presents problems unique to this population [32]. When possible, parents of patients with ASD should be contacted in advance of the anesthetic to gain some understanding of the degree of the patient's ASD, their particular behaviors, and interventions to avoid. Outpatient surgery whenever possible, and returning the patient to their home environment and routines as soon as possible, are important for the ASD patient. Parental presence and/or premedication with oral midazolam or ketamine, or in some cases intramuscular ketamine, are reported to be effective in this population.

The most common procedures in the ASD population include dental restorations, otorhinolaryngological procedures, and brain MRI scans [32]. Scheduling these patients first in the day, admitting them a short time before induction of anesthesia, admitting them to a quiet secluded recovery area, removing intravenous catheters whenever possible, parental presence in the recovery room, and discharging home as soon as possible all are reported to help in minimizing behavioral disruptions in the ASD population.

#### **Epidermolysis bullosa**

Epidermolysis bullosa (EB) is a group of hereditary bullous skin disorders distinguished by blister formation as a result of mechanical trauma. Although there are over 20 subtypes of EB, it can be divided into three major types: EB simplex (mutations in keratin 5 and 14 genes), where the epidermis only is affected; junctional EB (mutations in laminin 5 or type XVII collagen genes), where the basement membrane is involved; and dystrophic EB (mutations in type VII collagen genes) in which the dermis is primarily involved. Mutations in 10 additional genes encoding protein components of the basement membrane have also been implicated in various subtypes of EB [33].

Clinical manifestations vary from mild to severe, with dystrophic EB (DEB) the most severe and the form most frequently requiring surgical and anesthetic intervention (Fig. 38.6). The majority of patients with DEB have blisters and wounds that are present at birth or shortly after,

**Figure 38.6** Dystrophic epidermolysis bullosa. Note severe blistering with hypertrophic scarring and contractures in axillae and antecubital foaase. Note also pseudosyndactyly from severe chronic contractures. Reproduced from DERMIS Dermatology Information System [37] with permission.

with a variety of blister sizes that heal with atrophic scars and development of contractions [34]. These occur commonly on the dorsum of the hands, feet, elbows, and knees. Friction caused by scratching or other mechanical forces is very damaging in EB. Oral, pharyngeal, and esophageal blistering is common in EB, leading to contractures of the mouth and tongue. The pain associated with these blisters leads to decreased oral intake and poor nutrition. Esophageal strictures, dental caries, and gum disease are also common in DEB. Contractures on the extremities can cause severe scarring to the point that a pseudosyndactyly is created. Corneal scarring can also occur.

General management of EB involves teaching the family to avoid friction and shearing forces, special clothing and feeding techniques, draining of blisters and treatment with silver sulfadiazine for large infected blisters, special dressings with hydrofiber foam with silicone coating, and topical corticosteroids. Feeding open gastrostomy, dental treatment, and analgesia as well as a multidisciplinary approach are crucial to optimize outcomes for this complicated patient population.

All of these problems lead to the need for anesthesia and sedation for diagnostic and therapeutic procedures, which can be very challenging and are best carried out in a specialized center that cares for large numbers of these patients. However, these patients may present in a number of settings, and may require emergency interventions and so the pediatric anesthesiologist must be familiar with their care. Common surgical procedures in EB include dressing changes, casting, repair of contractures and pseudosyndactyly, dental restoration, esophagoscopy and esophageal dilation, open gastrostomy, longterm indwelling central venous access, skin biopsy, and eye surgery [34].

The most important principle of anesthetic care of children with EB is that friction and shearing forces, and not direct pressure, are responsible for new bullae formation. Airway management problems are frequent, secondary to neck contractures and pharyngeal bullae. After thorough evaluation of preoperative condition, an oral premedication can be given if needed. Veins are often easily visualized and cannulated in these patients and are often an option for premedication and anesthetic induction. The number of transfers of the patients should be minimized, as sliding causing shearing forces between stretcher and operating room bed, for example, may contribute to bullae formation. For the attachment of monitors, IV cannulae or airway devices, adhesives should be assiduously avoided. It is often preferable to secure a peripheral IV cannula with a single suture. A clip-on pulse oximetry probe is used and ECG electrodes can be used by cutting away the adhesive portion and laying only the gel part on the skin, or covering the skin with paraffin gauze or a gelpad. Noninvasive blood pressure monitoring is used, but the skin is first padded with Webril® soft gauze. Nasopharyngeal and rectal temperature probes are avoided.

Inhalation induction can be used, but the facemask must be thoroughly lubricated with petrolatum jelly or protected with paraffin gauze, and great care should be taken to avoid shearing forces on the skin of the face and neck. In general, tracheal intubation has been the preferred airway management method, with a tube half size smaller than normal; with gentle laryngoscopy the incidence of new laryngeal or pharyngeal bullae is low [34]. Anticipated difficult airway management because of contractures or severe intraoral bullae must be accompanied by a careful plan, including the availability of videolaryngoscopy, fiber-optic bronchoscopy, and laryngeal mask airways (LMA). The LMA can also be used for airway maintenance successfully with little risk of new severe intraoral bullae, but maintenance of the airway with a facemask for long periods of time should be avoided. Non-depolarizing muscle relaxants can be used, but succinylcholine should be avoided. Standard intravenous induction agents, maintenance agents, and opioid and regional anesthesia may be used safely in these patients. Emergence from anesthesia and tracheal extubation must be done carefully, again avoiding shearing forces on the face; intraoral suctioning must be done gently. Avoidance of use of conventional facemasks for oxygen administration in postanesthesia recovery is important; increasing oxygen concentration by blowing humidified oxygen over the face from a 22 mm corrugated oxygen tubing is an effective method. Evaluation for new bullae and communication with the patient's dermatologist about any changes in treatment plan after an anesthetic are very important.

## Listing of 103 syndromes encountered by the pediatric anesthesiologist

Table 38.1 lists, in alphabetical order, 103 syndromes encountered by the pediatric anesthesiologist, with considerations for anesthesia noted by organ system, emphasizing airway, cardiac, pulmonary, and neurological disease associations.

## CASE STUDY

A 6-month-old girl presented for an MRI of the brain, spine, and heart. She was born at 39 weeks' gestation weighing 3.4kg with polyhydramnios and multiple congenital anomalies. Because an orogastric tube could not be passed, yet there was abdominal gas present on radiograph, a diagnosis of type C esophageal atresia with distal tracheoesophageal fistula (TEF) was made. She did not have respiratory distress, and room air oxygen saturation was 92%. Other findings included a systolic II/VI cardiac murmur, and echocardiogram revealed a double outlet right ventricle, with large subaortic ventricular septal defect and large patent ductus arteriosus, as well as a hypoplastic aortic arch. Additional findings on renal ultrasound were bilateral hydronephrosis with a multicystic and dysplastic right kidney and an enlarged and abnormally positioned left kidney. She also had imperforate anus and ambiguous genitalia. On chest and abdominal radiograph it was evident that she had vertebral anomalies, including partial fusion of C5 and C6 vertabrae, complete fusion of L3-L4 vetrbrae, and sacral agenesis beginning at the S4 level. Finally, she exhibited rocker bottom feet.

A diagnosis of VACTERL association was made. PGE1 infusion was begun in the neonatal period, and repair of the TEF was done as the first priority on the first day of life, via a right thoracotomy. No ventilation difficulties were encountered and a small TEF was ligated and divided, and the esophageal atresia was repaired primarily without problems. Then, a colostomy and a feeding gastrostomy were performed, again without incident. The patient's trachea was left intubated, and 5 days later she was taken to the cardiac operating room for an aortic arch repair, and pulmonary artery banding via median sternotomy on cardiopulmonary bypass, and again did well with postoperative oxygen saturations of 80-85% on room air, and an appropriate mean echocardiographic gradient of 3.5 m/sec across the pulmonary artery band. Ten days postoperatively from the cardiac repair, she underwent placement of a percutaneous left nephrostomy tube because of progressive hydronephrosis, to preserve renal function until more definitive surgery could be done. After a 4-week hospitalization she was discharged home.

On the day of the MRI the patient's only medication was trimethoprim/sulfamethoxazole for urinary tract infection prophylaxis. She had undergone three additional anesthetics to replace the nephrostomy tube, all without incident. The MRI was scheduled to image her spine defects in detail and rule out any brain anomalies. She was alert, afebrile and responsive, room air saturation was 76%, heart rate 135, respiratory rate 24. Weight was 6.5 kg (10th percentile). Examination of the airway revealed no abnormalities; mandible was normal size. Neck appeared slightly short but had full range of motion. Lungs were clear to auscultation bilaterally, and she had no signs of respiratory distress. There was a long harsh IV/VI systolic murmur at the right sternal border. There were well-healed right thoracotomy and median sternotomy scars, as well as a colostomy and gastrostomy button, and a percutaneous nephrostomy tube. She had significant kyphoscoliosis. Echocardiogram done at cardiology clinic visit the week before revealed good biventricular function, large subaortic VSD measuring 12mm, and a 4.8m/sec pulmonary artery band gradient. Plans had been made for a complete biventricular repair versus bidirectional cavopulmonary connection when she was 8-9 months of age. Laboratory studies at that time included a hemoglobin concentration of 17g/dL, normal electrolyes, BUN of 11 mg/dL and creatinine 0.3 mg/dL. Cardiac MRI was requested to further define the size of the left ventricle, and the anatomical relationship of the VSD to the great vessels, to assist in determining whether a full biventricular repair was possible.

Because of the approximately 3h planned scan time, the patient's age and cardiac lesion with requested apnea for the cardiac imaging, general endotracheal anesthesia was chosen. Emergency drugs were available, including epinephrine, phenylephrine, and atropine, as well as isotonic crystalloid solutions and 5% albumin for intravascular volume expansion. After application of standard monitors, inhalation induction was initiated with sevoflurane in the MRI suite outside the scanner room. The pediatric anesthesia fellow managed the airway while the faculty anesthesiologist attempted peripheral intravenous access.

Inhalation induction proceeded slowly with FIO<sub>2</sub> 1.0 and increasing inspired sevoflurane concentrations up to 5%. After three attempts a 22 G peripheral IV was started in the left foot. During induction systolic blood pressures were 60-80 mmHg, heart rate 120-150 with sinus rhythm. SpO<sub>2</sub> began at 65% with crying, but quickly improved to 80-85%. Rocuronium 1 mg/kg was administered and the trachea intubated with a 3.5 mm cuffed endotracheal tube. After a period of 5 min observation and ongoing stability, she was moved into the MRI scanner with MRI-compatible monitoring. The brain and spine scans were completed first, with 90 min scan time. Brain MRI was normal, and the vertebral anomalies were confirmed and tethered spinal cord noted. Anesthesia was maintained with 1.5-2% endtidal sevoflurane and FIO2 at 0.5. Two periods of mild hypotension and arterial desaturation to SpO<sub>2</sub> 70-75% were treated by decreasing the inspired anesthetic, and intravenous boluses of 10 mL/kg lactated Ringer's solution. Intravenous contrast was not used during this phase because of the concern over her renal function. During the cardiac MRI the patient was stable with SpO<sub>2</sub> 80–85%. Two 30-sec periods of apnea were requested, and were accomplished with preoxygenation with FIO<sub>2</sub> 1.0 and manual hyperventilation. A reduced dose of gadolinium MRI contrast was administered, and excellent cardiac images were obtained with the patient stable throughout. After a 3h, 10 min anesthetic, the patient's trachea was extubated with the patient awake after reversal of neuromuscular blockade with neostigmine 70  $\mu$ g/kg and glycopyrrolate 14 $\mu$ g/kg. The patient spent 3h in the recovery area, returned to baseline room air saturations of 75–80%, and was alert, responsive, in no distress, and had resumed gastrostomy and nipple feeds.

### After the cardiac surgery, additional procedures planned were colostomy take-down and repair of imperforate anus, and repair of hydroureter. No interventions for the spine or feet were planned at this time.

This patient, with all the manifestations of VACTERL association, illustrates the complex multisystem nature of the disorders of some patients with syndromes, along with the need for multiple anesthetics for therapeutic and diagnostic procedures. A thorough evaluation of all systems, including access to all previous medical records, is important in planning care of these patients.

<b>Table 38.1</b> Genetic syndromes encountered by the pediatric anesthes
---

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
1	Achondroplasia (autosomal dominant, mutation chromosome 4p16.3, 1:25,000, fibroblast growth factor receptor 3 (FGFR3))	Upper airway stenosis, retruded chin, increased mandibular plane angle	Possible spinal cord compression from small foramen magnum/ intervertebral foramina	NA
2	Adrenoleukodystrophy (Siemerling-Creutzfeldt disease, Schilder disease, X-linked recessive, 1:42,000 males, mutation chromosome Xq218, ABCD1 transporter protein)	NA	Two types: (adult) non- inflammatory adrenomyeloneuropathy & (children) inflammatory cerebral myelinopathy	Adrenocortical insufficiency
			Seizure disorder	
			Hypotonia	
			Altered somatosensory evoked potentials: central pathways in women/ peripheral & central pathways in men	
3	Alagille syndrome (autosomal dominant, 1:100,000, chromosome 20p12 microdeletion, JAG 1 signaling pore)	NA	Intracranial hemorrhage/ stroke; developmental delay	90% with cardiovascular anomalies; most commonly branch pulmonary artery stenosis
				Other cardiac lesions: tetralogy of Fallot, tricuspid atesia, patent ductus arteriosus, ventricular septal defect

Pulmonary Other		Additional anesthetic considerations	References
Smaller than predicted lungs/ airways, reduced vital capacity but normal function; respiratory abnormalities from small thoracic cage, airway obstruction, or cervicomedullary compression	Obesity; joint laxity with bow-legs; transient thoracolumbar kyphosis usually resolves with independent gait	Few reports of difficult mask ventilation/ laryngoscopy/intubation; assess cervical spine for foramen magnum stenosis/ upper cervical canal narrowing; post-op respiratory complications reported: atelectasis, respiratory distress, pulmonary edema; reports of successful neuraxial analgesia/anesthesia; evaluate with rapid-ACTH test and/or stress dose steroid administration; altered response to non-depolarizing neuromuscular blocking drugs with upper motor neuron disease; possible hyperkalemia with hypotonia – avoid succinylcholine; altered drug metabolism with anti-seizure therapy	38-48
NA	NA	NA	
NA	Spontaneous bleeding of unknown etiology	Airway assessment: unusual facies, possible cervical spine abnormalities with no reports of difficult intubation	49
	Biliary excretion abnormalities more than synthetic/ metabolic hepatic abnormalities	Abdominal distension may predispose to gastroesophageal reflux	50
	Butterfly vertebrae; possible shortened interpedicular distance	Neurological assessment: avoid succinylcholine with myopathies	51
	Exocrine pancreatic insufficiency	Cardiac work-up	52
	Renal disease	Assess coagulation profile – caution with neuraxial analgesia/anesthesia	
	Vitamin K malabsorption – coagulopathies	Caution with positioning – rickets/hepatic osteodystrophy	(Continued)
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Alagille syndrome (continued)			
4	Angelman syndrome (maternally inherited chromosome 15 deletion, chromosome 15q11-13 deletion, 1:10–20,000, UBE3A ubiquitin pathway)	Progressive microcephaly; brachycephaly after age 2 years	Developmental delay; happy disposition with bursts of laughter	Vagal hypertonia
		Macrostomia & mandibular prognathism worsening with age	Puppet-like movement: ataxia, hypotonia, hyper-reflexia	
		Protruding tongue improving with age	Seizure disorder	
			γ-Aminobutyric acid system disordered function; varies from hyper- to hypofunction	
5	Antley-Bixler syndrome (trapezoidocephaly-synostosis syndrome, autosomal recessive, very rare disorder, chromosome 10q26, fibroblast growth factor receptor 2 (FGFR2))	Midface hypoplasia +/– choanal stenosis/ atresia	Craniosynostosis	Reports of cardiac defects; atrial septal defect
			Brachycephaly; trapezoidal when viewed from above	
			Large anterior fontanelle	
			Ocular proptosis	
6	Apert syndrome (acrocephalosyndactyly, 1:160–200,000, sporadic autosomal dominant, chromosome 10q26, fibroblast growth factor receptor 2 (FGFR2))	Flat elongated forehead; obtuse nasofrontal angle; maxillary retrusion/mandibular prominence	Achrocephalia due to synostosis of coronal suture	NA

Pulmonary	Other	Additional anesthetic considerations	References
	Vitamin D malabsorption – rickets/pathological fractures		
	Vitamin E malabsorption – peripheral myopathy/ neuropathy		
NA	NA	Caution using benzodiazapines/ halogenated anesthetic agents	53
		Altered drug metabolism with anti-seizure therapy	54
		Hypervagal tone predisposes to bradycardia	55
		Muscular atrophy – titrate neuromuscular blocking drugs to effect with monitoring	56
45–50% mortality from respiratory complications: choanal stenosis/atresia, or midface hypoplasia	Femoral bowing, radiohumeral synostosis	Definitive airway (tracheostomy) may be required for choanal atresia	57
	Urogenital abnormalities: ureteral obstruction/ hydronephrosis, hypoplastic/fused labia	Mask ventilation/endotracheal tube placement may be challenging with midface hypoplasia – no reported difficult airway cases	58
		Meticulous eye protection for proptosis	59
		Vascular/arterial access may be challanging with limb deformities	
		Normal intellegence with cranial vault remodeling	
Cleft soft palate; reports of closure causing frank airway obstruction	Symmetrical syndactyly involving 4 extremities	Possible increased intracranial pressure	60

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Apert syndrome (continued)	Upper/lower airway compromise, obstructive sleep apnea: lack of tracheal distensibility	Non-progressive ventriculomegaly, corpus callosum agenesis, others	
		Laryngotracheal anomalies: laryngomalacia, cartilaginous tracheal sleeve, bronchomalacia	>60% Cervical spine fusion; C5-6 most commonly	
		Tracheal intubation is more difficult following midface distraction surgery	Early craniosynostosis surgery correlates with improved mental function	
		Airway compromise may worsen with growth		
7	Arnold-Chiari malformation (1:1–5000, association with connective tissue disorders)	Vocal cord paralysis	Herniation of cerebellum portions through foramen magnum, medulla oblongata kinking – hydrocephalus	Heart rate dysregulation
		Laryngeal obstruction: vocal cord paralysis, paradoxical vocal cord motion, laryngomalacia	Chiari Type II associated with meningomyelocele	Arterial pressure dysregulation
			Brainstem dysfunction – velopharyngeal incompetence, gastroesophageal reflux, vagal hypertonia	
			Obstructive & central apnea	

Pulmonary	Other	Additional anesthetic considerations	References
Obstructive sleep apnea is common		Obstructive sleep apnea may complicate mask ventilation	61
Increased incidence of perioperative wheezing		Airway: possible direct laryngoscopy but caution with cervical spine instability	62
		Bronchoscopy may be necessary to diagnose cause of upper/lower airway compromise	63
		Radiographic studies to rule out craniovertebral abnormalities/instability	64
		Recommended fiber-optic intubation following midface distraction surgery	65
		Laryngeal mask airway may rescue airway and facilitate endotracheal tube placement	66
			67
			68
			69
			70
			71
NA	NA	Brainstem dysfunction may require surgical airway	72
		Dysphagia and vocal cord paralysis predispose to aspiration	73
		Neck flexion/extension may exacerbate brainstem compression	74
		Posterior fossa surgery in prone position predisposes to venous air embolism	75
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Arnold-Chiari malformation (continued)		Hypoxic/hypercapneic arousal response deficits	
8	Arthrogryposis multiplex congenita (1:3000, multiple causes)	Laryngotracheal anomalies: vocal cord paralysis	Possible aqueductal stenosis with internal hydrocephalus	Congenital heart defects reported: patent ductus arteriosus, aortic stenosis or coarctation
		Cleft lip/palate, short neck, trismus	Possible myelomeningocele	
		Micrognathia	Vertebral anomalies: spina bifida, sacral agenesis, scoliosis, kyphosis	
		Mandibulofacial dysostosis, macrostomia, decreased supraglottic tone	Muscle atrophy	
9	Autism spectrum disorder (Asperger syndrome, atypical autism, pervasive developmental disorder, 1/150, candidate genes chromosome 2q, 7q, 15q, 15q14.1 and X)	NA	Autism: profound impairment in language, social- emotional functioning, restricted repetitive behaviors	NA
			Asperger: hyperfunctioning language & motor control problems	
10	Becker muscular dystophy (benign pseudohypertrophic muscular dystrophy, X-linked recessive, 1:20,000 males, mutation dystrophin gene, Xp21.2)	NA	May have neurocognitive dysfunction	ECG changes, hypertrophic cardiomyopathy, dilative cardiomyopathy +/– preserved systolic function

Pulmonary	Other	Additional anesthetic considerations	References
		Acute sinus arrhythmias reported during surgery in 4th ventricle	76
		Autonomic dysfunction should resolve following decompression	77
		Ventilatory support may be necessary postoperatively for apnea	78
Thoracic deformities: hypoventilation, hypoplastic lungs, restrictive lung disease	Distal joint contractures; medially overlapping fingers, ulnar deviation, camptodactyly, foot deformities	Possible difficult intubation – micrognathia and trismus; usually easy bag-mask ventilation	
	Esophageal dysfunction and gastroesophageal reflux	Consider/evaluate cervical spine involvement	79
	Genitourinary abnormalities: renal fusion/absence, hypospadias, inguinal hernia	Possible difficult IV access	80
		Reports of hypermetabolism/hyperthermia distinct from malignant hyperthermia	81
		Avoid succinylcholine – myopathies; sensitive to non-depolarizing neuromuscular blocking drugs	
		Caution with positioning – contractures	
		Possible post-op respiratory complications – restrictive lung disease, poor cough/ gag	
NA	Criteria: impaired social interaction, impaired verbal/non-verbal communication, restricted interest range, resistance to change	Behavioral problems may be challenging during induction/emergence from anesthesia	82
		Consider family participation, oral midazolam/ketamine for preoperative sedation	83
Respiratory muscle weakness may predispose to pulmonary infections	Dystrophinopathy – altered size or abundance of dystrophin protein – characterized by muscle weakness	Dysphagia may predispose to aspiration	84
	Predisposed to rhabdomyolysis and hyperkalemic cardiac arrest with "triggering" agent	Cardiac work-up for cardiomyopathy	85 (Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Becker muscular dystophy (continued)			
11	Beckwith-Wiedemann syndrome (sporadic, 1:13,700, chromosome 11p15.5 mutations, multiple variants, insulin-like growth factor 2 (IGF2) likely involved)	Macroglossia	NA	Chronic airway obstruction may predispose to cor pulmonale
		Upper airway obstruction: macroglossia, prognathism, adenotonsilar hypertrophy		
12	Carpenter syndrome (acrocephalopolysyndactyly type II, autosomal recessive, 1:1 million, chromosome 6p11, RAB 23 gene, RAB guanosine triphosphatase family of vesicle transport proteins)	Cleft lip/palate	Craniosynostosis: midline sutures fuse before coronal sutures	Congenital heart: ventricular/atrial septal defects, patent ductus arteriosus, pulmonic stenosis, tetralogy of Fallot most common
		Hypoplastic mandible/ maxilla Short, thick neck	Variable intelligence	

Pulmonary	Other	Additional anesthetic considerations	References
		Concern for hyperkalemic cardiac arrest with triggering agents	86
		No apparent relation with malignant hyperthermia	87
			88
NA	Abdominal wall defect: omphalocele	Smaller than expected endotracheal tube size – cuffed may be preferred	89
	Visceromegaly: nephromegaly, hepatomegaly,	Glossomegaly – predisposes to upper	90
	splenomegaly, pancreatomegaly	airway obstruction on induction/ emergence from anesthesia	
	Increased incidence of intra-abdominal tumors	Glossomegaly – relatively improves with growth	91
	Hypoglycemia likely from hyperinsulinemia	Hypoglycemia from increased insulin secretion	92
		Videolaryngoscope and laryngeal mask airway described for difficult airway control	
NA	Syndactyly upper/lower limbs	Small mandible, short obese neck may cause challenging intubation	93
	Obesity: proximal limbs, face, neck and trunk	Evaluate for congenital heart disease	94
		Report of abnormal anatomical features leading to unexpected/severe blood loss	95
			96
			97
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
13	<b>Cat eye syndrome</b> (trisomy 22, Schmid-Fracarro syndrome, chromosome 22 partial tetrasomy, sporadic- spontaneous 3 or 4 copies of short arm and section of long arm, 1:50,000 and 1:150,000, cat eye syndrome critical region gene-7 (CECR7) protein)	Micrognathia, microcephaly	Ocular coloboma and motility defect	Congenital heart defects: ventricular/atrial septal defect, total anomalous pulmonary venous return, tetralogy of Fallot, patent ductus arteriosus
		Cleft palate or absent uvula	Muscular tonus dysregulation, visual and hearing impairments	
14	Catel-Manzke syndrome (Pierre Robin syndrome with hyperphalangy and clinodactyly, X-linked recessive, 26 cases reported, gene defect not known)	Pierre Robin anomaly: micrognathia, glossoptosis, cleft palate	NA	Severe congenital heart disease: septal defects, aortic defects, dextrocardia
15	<b>Central core disease</b> (central core myopathy, autosomal dominant, chromosome 19q13.1, mutations in the ryanodine receptor-1 gene)	NA	NA	Structural abnormalities are rare
16	<b>Cerebrocostomandibular</b> <b>syndrome</b> (rib gap defects with micrognathia, sporadic inheritance, 65 cases reported, gene defect not known)	Pierre Robin: small mandible (micrognathia), cleft palate, glossoptosis	Mental retardation – likely from upper airway obstruction leading to neonatal hypoxia	Ventricular septal defect has been reported

Pulmonary	Other	Additional anesthetic considerations	References
Scoliosis or chest deformity	Preauricular skin tags/pits	Micrognathia may predispose to difficult intubation – reports of awake nasal fiber-optic and through laryngeal mask airway	98
Rib or sternal anomaly	Anal atresia with rectal fistulas	Cardiac work-up for congenital heart defects	99
	Urogenital malformations: external genitalia malformation, renal agenesis, hydronephrosis, VUR	Abnormal renal/hepatic function may alter anesthetic drug pharmacokinetics	100
	Limb deformity	Limb abnormalities may result in challenging arterial access	
	Vertebral anomaly		
	Intra/extrahepatic biliary atresia		
Pectus carinatum/excavatum	Bilateral hyperphalangy and clinodactyly of the index finger	Pierre Robin: difficult or impossible endotracheal intubation	101
	Vertebral/rib anomalies	Cardiac work-up for congenital heart defects	102
			103
Respiratory involvement is exceptional but severe	Myopathy: proximal (hip girdle) muscle weakness, but also axial muscles	RYR1 gene mutation – high malignant hyperthermia risk	104
	Ortho complications: hip dislocation, scoliosis, foot deformities, ligamentous laxity, rarely contractures	Closely linked to malignant hyperthermia susceptibility	105
	Elevated serum creatine kinase, selective muscle involvement pattern on MRI	Avoid triggering anesthetic agents/drugs	106
Scoliosis	Kidney abnormalities: cysts, persistent urinary tract infection, reflux and ectopia	Pierre Robin: difficult or impossible endotracheal intubation	107

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Cerebrocostomandibular syndrome (continued)	Possible tracheal ring anomalies	Absent olfactory bulb	
17	Charcot-Marie-Tooth syndrome (hereditary sensorimotor neuropathy, peroneal muscular atrophy, multiple modes of inheritance, 1:3000, duplication chromosome 17p12 (75%), PMP22, 38 other gene mutations in neuronal proteins: myelins or axons)	NA	Peripheral motor and sensory neuropathy – demyelinating	NA
			Primarily peroneal muscle atrophy with foot drop	
			Progressive muscle weakness beginning in legs	
			Autonomic dysfunction possible with postganglionic sympathetic involvement	
18	CHARGE association (parental gonadal mosaicism in some cases, spontaneous mutation, 1:10,000, mutation chromosome 7q21.11, chromodomain helicse DNA binding protein 7 (CHD7) gene–neural crest epigenetic chromatin remodeling)	Swallowing/sucking difficulties	Colobomata: typical iris coloboma to anophthalmos	Right-sided congenital heart disease: tetralogy of Fallot, pulmonic stenosis, double outlet right ventricle
		Cleft palate associated with congenital heart disease, mostly tetralogy of Fallot	Cranial nerve dysfunction: CNI – anosmia, CNVII – facial palsy, CNVIII – hearing loss, CNIX/CNX – velopharyngeal inco-ordination	Atrioventricular septal congenital heart disease: ventricular/atrial septal defect associated with tetralogy of Fallot

Pulmonary	Other	Additional anesthetic considerations	References
Thoracic insufficiency syndrome from "implosion" of the thorax from congenital posterior rib pseudoarthrosis		Thoracic insufficiency syndrome from rib pseudoarthrosis may necessitate mechanical ventilation	108
			109
			110
Respiratory insufficiency possible with severe disease	NA	Questionable response to neuromuscular blocking drugs – reports of successful use of non-depolarizing drugs	111
		Hyperkalemic arrest possible with succinylcholine – successful use	112
		reported	
		sweating with autonomic dysfunction	113
		Nitrous oxide does not worsen neuropathy	114
		Total intravenous anesthesia without muscle relaxants/triggering agents reported	115
Atresia choanae	Hypogenitalism	Possible difficult/impossible endotracheal intubation with micrognathia	116
Tracheoesophageal fistula associated with congenital heart disease, mostly tetralogy of Fallot	Renal anomalies (malrotation, hydronephrosis, reflux) associated with congenital heart disease, mostly atrioventricular septal defect	May require continuous positive airway pressure to maintain airway patency with laryngomalacia/velopalatal insufficiency	117
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	CHARGE association (continued)	Hypoplastic mandible (micrognathia) associated with congenital heart disease, mostly tetralogy of Fallot Three major issues: micrognathia, laryngomalacia, subglottic stenosis	Delayed motor development, may involve truncal hypotonia	Aberrant subclavian artery and/or right aortic arch
19	<b>Cockayne syndrome</b> (Weber-Cockayne syndrome, Neill-Dingwall syndrome, autosomal recessive, 1:250,000, mutation chromosome 5q12, 10q11, ERCC6 or ERCC8 gene: proteins repairing damaged DNA transcription-coupled repair mechanism)	Microcephaly, micrognathia, dental overcrowding	Progressive neurological degeneration with spastic quadriparesis	Individual reports of aortic dilation and dilated cardiomyopathy
		Postcricoid narrowing (subglottic stenosis)	Developmental regression	Progressive arteriosclerosis with hypertension
		Bird-like face, beak-like nose, inappropriately large teeth	Photosensitivity	Hypertension with renal disease
				Reports of myocardial ischemia from hypertension
20	<b>Cornelia de Lange syndrome</b> (sporadic mutation, 1:30,000, mutation chromosome 5p13.1, NIPBL gene affecting cohesin complex)	Micrognathia, macroglossia, microbrachycephaly	Motor/mental retardation	Congenital heart disease: ventricular septal defect most common

Pulmonary	Other	Additional anesthetic considerations	References
	Vertebral anomalies (hemivertebrae, scoliosis) associated with congenital heart disease	May require smaller than expected endotracheal tube for subglottic stenosis	118
		Aspiration risk with swallowing dysfunction	119
		Cardiac work-up for congenital heart defects	120
		Thyroid/parathyroid functional studies for similarities between CHARGE and DiGeorge syndromes	121
		High incidence of post-operative airway events	
		Successful airway management with laryngeal mask airway has been reported	
NA	NA	Difficult intubation reports with successful use of laryngeal mask airway	122
		Aspiration risk, but mental retardation makes awake fiber-optic intubation challenging	123
		Reported cerebral ischemia with nifedipine	124
		Difficult intravenous access with contractures	125
			126
			127
Frequent pulmonary aspiration from severe gastroesophageal reflux	Micromelia +/– oligodactyły	Possible difficult intubation with aspiration risk	128

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Cornelia de Lange syndrome (continued)	Frequently narrow, arched palate or complete cleft	Strabismus	
		Short neck and cylindrical trunk	Neonatal hypertonia	
			Self-injurious behavior	
21	<b>Costello syndrome</b> (faciocutaneoskeletal syndrome, spontaneous mutation, 300 reported cases, mutation chromosome 11p15.5, mutation HRAS gene: proteins controlling cell growth and division)	Mucopolysaccharidosis- like: macrocephaly, bulbous nose, big mouth, large tongue	Possible seizure disorder	Cardiavascular malformation – pulmonic stenosis
		Possible choanal stenosis or congenital laryngeal web		Hypertrophic cardiomyopathy
		50% with perioral/ perinasal papillomas manifesting in childhood		Rhythm disturbances – supraventricular tachycardia
		Short neck		
		Abundant tracheobronchial secretions		
		Hypertrophied adenoids/ base of tongue		
22	Cri du chat syndrome (chromosome 5p deletion syndrome, 5p minus syndrome, Lejeune syndrome, sporadic deletion, 1:20–50,000, deletion chromosome 5p15.2)	Microcephaly, micrognathia	Hypotonia replaced by hypertonia with age	20–30% with congenital heart disease: ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot
		Typical cry: small, narrow, diamond- shaped larynx; small hypotonic epiglottis	Psychomotor and mental retardation	

Pulmonary	Other	Additional anesthetic considerations	References
	Dystrophic dwarfism	Unco-operative patient making induction challenging	129
	Forearm and hand deformities	Reduced anesthetic requirements	130
			131
			132
			133
Connective tissue disorder-like: limb disorders with possible kyphosis and/or scoliosis	Hypoglycemia possible from growth hormone/ cortisol deficiency &/or hyperinsulinemia	Airway management with macroglossia, short neck, hypertrophied supraglottic tissue	134
		Possible change in drug metabolism from anti-seizure therapy	135
		Cardiac work-up for structure, function, & rhythm	136
		Reports of pulmonary hypertension, elevated catechols, hypertrophic cardiomyopathy, obstructive sleep apnea, pulmonary infiltrates, severe scoliosis	137
		Possible central temperature regulation defect	138
			139
Laryngotracheal anomalies: vocal cord paralysis	Metabolic anomalies: purine synthesis defect	Consider pre-op CT evaluation of airway	141
	Progressive scoliosis	Possible difficult intubation – successful laryngeal mask airway use reported	142
			(Contin I)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Cri du chat syndrome (continued)	Laryngeal abnormalities: hypoplastic larynx, narrow laryngomalacia, diamond-shaped larynx		
		Epiglottal abnormalities: long, curved, floppy, hypoplastic & hypotonic epiglottis		
23	Crouzon syndrome (craniofacial dysostosis, autosomal dominant, 1:60,000, mutation chromosome 10q26, fibroblast growth factor receptor 2 (FGFR2))	Maxillary hypoplasia, midface complex underdevelopment	Craniosynostosis, ocular proptosis and shallow orbits	NA
		Severe airway obstruction: midface hypoplasia, adenotonsillar hypertrophy, laryngotracheomalacia		
		Cervical "butterfly" vertebrae & some cervical fusion		
24	<b>Cystic fibrosis</b> (mucoviscidosis, autosomal recessive, 1:4000, chromosome 7q31.2 mutation, cystic fibrosis transmembrane conductance regulator (CFTR): chloride transporter channel protein)	NA	NA	Possible right ventricular enlargement from bronchiectatic lung disease via hypoxic pulmonary vasoconstriction and pulmonary vascular remodeling

Pulmonary	Other	Additional anesthetic considerations	References
		Pharyngeal muscle hypotonia may cause soft tissue airway obstruction	143
		Cardiac work-up for congenital heart disease	144
			145
			146
Laryngotracheal anomalies: cartilaginous tracheal sleeve	NA	Possible difficult intubation: abnormal facies & possible fused cervical vertebrae	147
		Possible increased intracranial pressure with craniosynostosis	148
		Possible obstructive airway with craniosynostosis	149
			150
Exocrine gland mucosal obstruction – small airway plug, poor ciliary clearance, chronic colonization/infection	Exocrine gland mucosal obstruction – pancreatic insufficiency, biliary obstruction, male infertility	Pulmonary bacterial colonization, apical blebs, and prone to pneumothoraces	151
Obstructive airway disease on PFTs: decreased FEV1, decreased peak exp flow, increased residual vol	Protein/fat malabsorption – fat-soluble vitamin deficiency with vitamin K-deficient coagulopathy	Assess pulmonary function/reactivity – airway patency may depend on muscle tone in older patients	152
Nasal polyps, chronic sinusitis	Diabetes mellitus and insulin resistance	Cardiac work-up to assess right ventricular function	153
	Neonatal meconium ileus from abnormally thick meconium	Glucose control	
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Cystic fibrosis (continued)			
25	Diastrophic dysplasia (autosomal recessive, 1:100,000, chromosome 5q32-q33.1, SLC26A2 gene: protein for normal cartilage formation)	50% with cleft palate	Normal intelligence	NA
		Dysmorphic facial features: retrognathic mandible	Cervicothoracic spina bifida occulta	
		Cervical kyphosis with substantial C1-C2 instability	Possible spinal cord compression from kyphoscoliosis	
		Laryngomalacia, laryngotracheal stenosis		
26	<b>DiGeorge (22q11-) syndrome</b> (velocardiofacial syndrome, CATCH-22, conotruncal anomalies face syndrome, sporadic or autosomal dominant, 1:2000, microdeletion chromosome 22q11.1, TXB1 deletion causes most cardiac defects)	Craniofacial anomalies: cleft palate, micrognathia, small mouth	Learning difficulties, other pyschiatric disorders	Cardiac defects: tetralogy of Fallot, interrupted aortic arch, ventricular septal defect, pulmonic stenosis, tricuspid atresia
		Small thyroid cartiledge with increased anterior angle		
		Short trachea with reduced number of cartilage rings		
		Laryngobronchomalacia		
		Tracheal bronchi		

Pulmonary	Other	Additional anesthetic considerations	References
	Distal intestinal obstruction syndrome with abdominal distension, nausea/vomiting	Coagulopathy/altered drug metabolism with hepatobiliary involvement	
	Fatty liver with 10% complicated by cirrhosis & portal HTN	Decreased bone density – positioning (fracture risk), kyphoscoliosis	
	Low bone mineral density	Consider alternatives to narcotic analgesia to avoid respiratory suppression	
Thoracolumbar kyphoscoliosis – may interfere with pulmonary function	Reduced height, hand/feet deformities, joint contractures	Smaller than expected blood pressure cuff	154
	One-third with scoliosis	CT evaluation of cervical spine	155
		Possible difficult intubation with micrognathia and cervical spine kyphosis	156
			157
			158
NA	Hypo- or aplasia of parathyroid gland resulting in hypocalcemia	Reports of vasomotor instability	159
	Hypo- or aplasia of thymus gland resulting in immune deficiencies	Cardiac work-up for congenital heart disease	160
	Renal & skeletal anomalies	Possible difficult airway with dysmorphic facies	161
	DiGeorge anomaly is likely a feature of velocardiofacial syndrome	Possible difficult extubation with velopharyngeal insufficiency	162
		Recurrent infection risk with thymic dysfunction	163
		Persistant hypocalcemia with parathyroid dysfunction leading to seizures	164
		Report of tachycardia from epinephrine injected with local anesthetics	165
			(Continued)

### 1026 Part 3 Practice of Pediatric Anesthesia

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
27	<b>Down syndrome</b> (trisomy 21, meotic non-dysjunction event, maternal origin, 1/732)	High arched narrow palate, macroglossia, subglottic stenosis	Mental retardation	Congenital heart disease: endocardial cushion defects, ventricular septal defect, patent ductus arteriosus,tetralogy of Fallot
		Atlantoaxial subluxation	Possible altered response to opioids	Predisposed to pulmonary hypertension
		Smaller tracheal lumen diameter		Predisposed to bradycardia with inhaled induction; halothane, sevoflurane
				Possible difficult arterial/venous access
28	Duchenne muscular dystrophy (pseudohypertrophic progressive muscular dystrophy, recessive X-linked, 1:3500, mutation chromosome Xp21, absent dystrophin)	33% with macroglossia	Intellectual impairment	Cardiomegaly leading to dilated cardiomyopathy
				ECG changes: short PR interval, right ventricular hypertrophy, Q waves in leads II, III, aVF, V5, V6

Pulmonary	Other	Additional anesthetic considerations	References	
Upper airway obstruction/sleep apnea	Dental abnormalities	Radiologic cervical spine abnormalities do not correlate to neurological symptoms	166	
	Duodenal atresia, Hirschsprung disease with gastroesophageal reflux	Atlantoaxial instabilitity may increase with loss of muscle tone under anesthesia	167	
	Immunosuppression and hypothyroidism	Smaller enotracheal tube (0.5–1 mm) to avert tracheal trauma	168	
	Hypotonia, hyperextensibility, dysplastic pelvis	Possible difficult vascular access	169	
		Possible bradycardic response to high concentration volatile anesthetic agents		
Restrictive defect from diaphragm, intercostal, & accessory respiratory muscle weakness	Abnormal gait to difficulty climbing stairs to Gower sequence to wheelchair bound with muscle atrophy	Cardiac work-up for cardiomyopathy	170	
Glottic dysfunction with inadequate intrathoracic pressure needed for adequate cough	Elevated serum creatine kinase from extensive skeletal muscle wasting	Avoid succinylcholine – hyperkalemic cardiac arrest	171	
	Progressive scoliosis	Avoid volatiles – rhabdomyolysis & cardiac arrest	172	
	Progressive dysphagia	No apparent relation with malignant hyperthermia	173	
		Pulmonary insufficiency may complicate extubation	174	
		Gastric dysmotility may predispose to aspiration		
		Non-depolarizing neurmuscular blocking drugs may have longer duration of action		
		Corticosteroids improve muscle function, cause obesity, hypertension, glucose intolerance, osteoporosis		
			(Continued)	
No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
-----	---	--	---	--
29	Dutch-Kentucky syndrome (Hecht-Beals syndrome, congenital contractural arachnodactyly, distal arthrogryposis type 9, sporadic inheritance, very rare syndrome, mutation chromosome 5q23-q31, fibrilin-2 gene: connective tissue protein)	Limited mouth opening	NA	NA
		Reports of mandibular prognathism & micrognathia		
30	Ehlers-Danlos syndrome (EDS)	Dysphonia – hemi- laryngeal weakness	Mild/mod weakness, myalgia, and easy fatiguability in majority of patients	Bleeding symptoms for all EDS types
	EDS – classic type (autosomal dominant disorder type V collagen; 1:20–50,000)			Mitral valve prolapse, aortic root/sinus of Valsalva dilation, septal defects
	EDS – hypermobility type (autosomal dominant or recessive mutation in tanascin X gene)		Decreased/absent analgesic effect from lidocaine given subcutaneously, or local anesthetic cream	Mitral valve prolapse, aortic root/sinus of Valsalva dilation, septal defects
	EDS – vascular type (autosmal dominant mutation in type III collagen gene: 1:100– 250,000)			Medium and large-size vessel fragility leading to rupture
	EDS – kyphoscoliosis type (autosomal recessive mutation in gene for lysyl hydroxylase: fewer than 60 cases)	Atlantoaxial subluxation may occur in type IV		
	EDS – arthrochalasia type (mutation in type I collagen gene; fewer than 30 cases)			

Pulmonary	Other	Additional anesthetic considerations	References
NA	Hand and feet deformities	Difficult intubation – trismus is unrelieved by general anesthesia, muscle relaxants, physical force	175
		Reports of retrograde guidewire-assisted FO intubation	176
		Reports of nasal (blind & FO) intubations	177
			178
			179
NA	NA	Bleeding symptoms are responsive to desmopressin	180
			181
	Classic: I and II – skin hyperextensibility, widened atrophic scars, joint hypermobility	Report of scoliosis correction using spinal fusion complicated by bleeding & wound dehiscence	182
			183
	Hypermobility: III – hyperextensibility +/– smooth, velvety skin, generalized joint hypermobility		184
			185
	Vascular: IV – translucent skin, arterial/intestinal/ uterine fragility, extensive bruising, characteristic facies:	Premature death from organ rupture (arterial, bowel, uterus)	186
		Report of success using recombinant factor VIIa	187
	Kyphoscoliosis: VI – joint laxity, muscle hypotonia, progressive scoliosis, scleral fragility	Report of scoliosis correction using spinal fusion complicated by arterial avulsion/ rupture	188
			189
	Arthrochalasia: VIIA/B – joint laxity with recurrent subluxations, congenital B/L hip dislocation		190
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Ehlers-Danlos syndrome (EDS) (continued)			
	EDS – dermatosparaxis type (10 cases reported)			
31	Epidermolysis bullosa (EB)	Oral: cyclic blistering leads to milia, ankyloglossia, microstomia	EB simplex with plectin deficiency is associated with slowly progressive muscular dystrophy	Dilated cardiomyopathy associated with low plasma carnitine
	EB simplex (mutations keratin 5 and 14 genes)	Larynx: trauma leads to supraglottic bullae/ cysts, glottic VC cysts/ webs, subglottic stenosis		
		Pharyngoesophageal: blisters lead to odynophagia, esophageal scar/web/ stenosis to dysphagia		
	EB junctional (mutations laminin 5 or collagen XVII genes)			
	EB dystrophic (mutation type VII collagen, 1:50,000 overall incidence )			

Pulmonary	Other	Additional anesthetic considerations	References
			191
	Dermatosparaxis: VIIC – severe skin fragility, sagging, redundant skin	Gentle intubation with minimal inspiratory pressures to avoid airway hematomas	192
		Consider possible cervical instability	
		Cardiac work-up to assess valves and great vessels	
		Avoid central vascular access or place under U/S visualization	
		Prepare for significant blood loss	
		Caution with neuraxial anesthesia/ analgesia	
Respiratory tract lesions from mouth to bronchi with plectin deficiency	Poor nutrition and gastroesophageal reflux are common	Anemia likely but blood draws may be done post induction	193
	Cutaneous scarring causes joint contractions of fingers/toes	Gastroesophageal reflux may necesitate oral antacids	194
	Conjunctival bullae in cornea may compromise vision	"No touch" principle to minimize friction	195
	Anemia, glomerulonephritis, nephrotic syndrome are common	Avoid "sticky" items, lubricate eyes, diligent pressure point padding	196
	Epitheliomas (squamous cellular carcinomas) in 3rd/4th decade	Consider pulse-ox to monitor oxygen saturation and heart rate without ECG or use needle ECG probes	197
	Acute/chronic pain from wounds	Pad beneath blood pressure cuff; avoid intra-arterial monitoring to prevent wrist scarring	198
	Unrelated to porphyria – thiopental is no longer contraindicated	Microstomia may lead to difficult intubation	199
		Avoid oropharyngeal/laryngotracheal trauma from intubation – use uncuffed ETT, lubricate everything	
		Cardiac work-up for DCM may be indicated Utilise regional analgesia whenever possible	
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
32	Fabry disease (Anderson- Fabry disease, angiokeratoma corporis diffusum, alpha- galactosidase A deficiency, X-linked recessive, 1:55,000 males, mutation chromosome Xq22, alpha-galactosidase A)	Possible angiokeratomas (raised, red, non-blanching telangiectases) in oral mucosa	Cerebrovascular complications: stroke, hemiplegia, hemianesthesia, transient ischemic attacks	Progressive hypertrophic infiltrative cardiomyopathy
			Acroparesthesia (as well as gastrointestinal and joint pain) responsive to enzyme replacement therapy	Valvular abnormalities
			Corneal verticillata (whorls) leading to "haze," retina vascular abnormalities	Arrhythmias and conduction abnormalities
				Atherosclerotic lesions and hypertension
				RV commonly involved – progress to severe diastolic/systolic RV dysfunction
33	Familial dysautonomia (Riley-Day syndrome) (hereditary sensory and autonomic neuropathy, type III, autosomal recessive, 1:3700 Ashkenazi Jewish ancestry, mutation chromosome 9q31-33, IKBKAP (inhibitor of kappa light polypeptide gene enhancer in B-cells); regulates transcription)	NA	Emotional lability – anxiety, depression	Baroreflex abnormal: efferent sensitivity to resistance vessels, efferent to heart
			Alacrima – absence of overflow tearing	Orthostatic hypotension without compensatory tachycardia
			Peripheral sensory deficits: abnormal pain/ temperature, decreased deep tendon reflexes	Decreased heart rate variability
			Central sensory deficits: decreased cranial nerve V pain perception, diminished corneal reflexes	Supine hypertension

Pulmonary	Other	Additional anesthetic considerations	References
Dyspnea, cough/wheezing, hemoptysis, obstructive airway disease responsive to enzyme replacement therapy	Hypohydriasis	Caution anticholinergics with hypohydriasis	200
	Gastrointestinal disturbances: diarrhea, pain, nausea/vomiting	Avoid trauma to oral mucosa with angiokeratomas	201
	Nephropathy is dominant feature: from chronic to endstage renal disease	Cardiac work-up for ischemia, valvular dysfunction, arrhythmias	202
		Renal work-up for insufficiency, failure, end-stage renal disease	203
		Caution with positioning due to peripheral neuropathy	204
		Caution using neuraxial anesthesia/ analgesia due to peripheral neuropathy	205
			206
Insensitivity to hypoxia & hypercarbia	Oropharyngeal inco-ordination leading to dysphasia & aspiration	Aspiration risk with intubation	207
Cardiorespiratory dysregulation both awake/asleep likely representing alveolar hypoventilation	Incompetent lower esophageal sphincter leading to gastroesophageal reflux	Reports of general anesthesia with significant hemodynamic instability	208
Bronchial/interstitial inflammation consistent with chronic gastric aspiration	Esophageal dilation with fluid overload leading to aspiration	Reports of regional anesthesia minimizing hemodynamic instability	209
	Gastroesophageal reflux is independent of sensory dysfunction severity	Assess intravascular volume status	210

# 1034 Part 3 Practice of Pediatric Anesthesia

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Familial dysautonomia (continued)			"Sympathetic storm" – hypertension, tachycardia, diaphoresis, functional ileus Higher normalized QT variance – risk for ventricular arrhythmias
34	Familial periodic paralysis (FPP) (autosomal dominant myopathy; variable penetrance)	NA	NA	Dyskalemias leading to arrhythmias
	FPP: hypokalemic (mutation chromosome 1q32, HOKPP gene)		Flaccid weakness associated with decreased serum potassium	
	FPP: hyperkalemic (mutation sodium channel gene SCN4A on chromosome 17)		Flaccid weakness associated with increased serum potassium	
	FPP: Anderson syndrome (Anderson-Twail syndrome)	Dysmorphic features: micrognathia, cleft palate, macrocephaly	Periodic paralysis may be hyper-, normo- or hypokalemic	Long QT syndrome is primary cardiac manifestation, independent of periodic paralysis
				"triggered activity" by delayed afterdepolarizations
	Long QT syndrome 7			Reports of bicuspic aortic valve, coarctation, pulmonic stenosis
	Anderson cardiodysrhythmic periodic paralysis (mutation chromosome 17q23.1-q24.2)			

Pulmonary	Other	Additional anesthetic considerations	References
	Chronic kidney disease with significant orthostatic hypotension	High risk for postoperative pulmonary complications, including abnl response to hypoxia/hypercapnia	211
	Spine deformities: scoliosis/kyphosis	High risk for postoperative nausea/ vomiting with no reports of response to potent 5-HT3 antagonists	212
	Poor bone quality: osteopenia/osteoporosis		213
			214
Respiratory insufficiency during an attack	Progressive myopathy affecting pelvic girdle and proximal/distal lower extremity with fatty replacement		215
			216
		Theoretical risk of malignant hyperthermia without case reports	217
		Avoid exogenous insulin/glucose, alkalosis	218
		Reports of successful use of atracurium	219
		Reports of successful spinal anesthesia	220
		Avoid epidural mepivicaine as it lowers serum potassium	221
			222
		Avoid exogenous potassium, acidosis, succinylcholine	223
		Reports of successful use of propofol & propofol/remifentanil	224
	Proximal muscle atrophy without mytonic disorders	Possible difficult intubation with micrognathia	
	Bone deformities: wormian bones, scoliosis	Mandatory cardiac evaluation	
	Reports of unilateral renal dysplasia		

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
35	Fibrodysplasia (myositis) ossificans progressiva syndrome (autosomal dominant, 1:1.5 million, mutation chromosome 2q23- q24, ACVR1 gene)	Progressive muscle ossification: neck/ paraspinal rigidity to shoulder/spine to hips/knees to jaw	NA	Cardiac muscle is spared from ossification
		Variable cervical spine vertebral fusion +/– adjacent muscular ossification		ECG changes: right bundle branch block, T wave inversion, ST change
36	Fetal alcohol syndrome (teratogenic syndrome, 1/100)	Facial anomalies: short palpebral fissures, thin upper lip, smooth philtrum	Microcephaly and structural brain anomalies	Cardiac defects: atrial/ventricular septal defect common
		Possible flat midface	Cognitive deficits: attention deficit hyperactivity disorder	
			Delayed motor development and impaired fine/gross motor skills	
			Maladaptive behaviors: poor judgment, distractibility, poor social cue perception	

Pulmonary	Other	Additional anesthetic considerations	References
Severely restrictive chest wall disease suggesting diaphragmatic breathing dependence	Short laterally deviated great toes from birth	Trauma (surgery, biopsy, tourniquet) may initiate ossification	225
Diaphragm is spared from ossification	Heterotopic ossification: neck/spine/shoulder girdle proceeding axial to appendicular, cranial to caudal, proximal to distal	Chest wall restriction leads to respiratory failure, atelectasis, inadequate cough	226
		Awake FO intubation – DL avoided to prevent TMJ ankylosis	227
		Avoid tracheostomy – ossification at incision site may cause airway obstruction	228
		Avoid IM injection – ossification at injection site	229
		Avoid neuraxial techniques	230
		Successful U/S-guided peripheral nerve block has been reported	231
			232
			233
			234
			235
	Clinodactyly of 5th finger, camptodactyly, "hockey stick" palmar crease	Induction may be challenging with cognitive deficits	236
		No known association with upper airway abnormalities	237
		Single case report of difficult intubation	238
		Cardiac work-up as indicated	239
			240 (Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
37	<b>Fragile X syndrome</b> (X-linked dominant, 1:3600 males, 1:4–6000 females, mutation chromosome Xq27.3, FMR1 gene, involved in translation)	Increased risk for obstructive sleep apnea: adenotonsillar hypertrophy, narrow oropharyngeal cavity, hypoplastic midface	Most common form of inherited mental retardation	Mitral valve prolapse and/or aortic root dilation may occur in adolescence
		High arched palate	Behavior traits: tactile defensiveness, hand flapping/biting, perseverative speech	Fragile X tremor/ataxia syndrome: autonomic dysfunction
			Fragile X tremor/ataxia syndrome: normal intellect, progressive cerebellar ataxia, parkinsonism, dementia	
38	Fraser syndrome (autosomal recessive, 1:230,000, FRAS1 or FREM 2 genes, mutation chromosome 13q13.3 or 4q21)	Laryngotracheal anomalies: laryngeal atresia/stenosis	Ocular abnormalities: cryptophthalmos +/– microphthalmos, anophthalmos, corneal opacification	Reported: left ventricular hypertrophy, Ebstein anomaly, coarctation, atrial/ ventricular septal defect, tricuspid atresia, dextrocardia, transposition
		Glottic web or subglottic stenosis	Reports of hydrocephalus & structural abnormalities	
		Cleft lip/palate	Reports of developmental delay and hypotonia	
39	Friedreich ataxia (autosomal recessive, 1:50,000, mutation chromosome 9q13- q21, frataxin gene: protein involved in mitochondrial iron metabolism)	NA	Progressive ataxia, dysarthria, loss of joint position/ vibration, absent tendon reflexes, hypotonia	Possible cardiomyopathy
				Transition from hypertrophic to hypokinetic dilated cardiomyopathy occurs

40 Glycogen storage diseases (GSD)

Pulmonary	Other	Additional anesthetic considerations	References
Possible pectus excavatum deformity	Male macro-orchidism	Cognitive deficits make induction challenging	241
	Hyperextensible metacarpophalangeal joints, plamar/hallucal crease, pale blue irises	Cardiac work-up as indicated: MVP, autonomic dysfunction	242
			243
			244
			245
Choanal stenosis or atresia	Syndactyly	Difficult/impossible intubation – consider microlaryngoscopic evaluation preoperatively	246
Pulmonary hyperplasia likely from fetal lung fluid retention with tracheal stenosis	Genitourinary malformations: imperforate anus, renal agenesis	Consider increased ICP	247
		Cardiac work-up and renal function	248
			249
NA	Possible scoliosis	Cardiac work-up	250
		Avoid neuromuscular blockade whenever possible	251
		Reports of successful use with monitoring	252
		Central neuraxial blockade is relatively contraindicated	253
		Reports of successful spinal anesthesia	254
	GSD-0: glycogen synthase deficiency, 2 subtypes – muscle, liver		255
			(Continued)

### 1040 Part 3 Practice of Pediatric Anesthesia

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Glycogen storage diseases (continued)			
	GSD Type 0: glycogen synthase deficiency		Subject to hypoglycemic seizures with GYS2 (liver) GSD Cognitively and developmentally normal	Report of sudden cardiac death- mitochondrial compensatory phenomenon
	GSD Type I: von Gierke disease (glucose-6-phosphate deficiency, 1:50–100,000)		Subject to hypoglycemic seizures	Possible cardiomyopathy
	GSD Type II: Pompe disease (acid maltase deficiency, 1:60–140,000)	Infantile onset: macroglossia	Infantile onset: rapidly progressive muscle weakness – axial hypotonia, areflexia	Infantile onset: cardiomegaly/cardiomyopathy leading to cardiac failure

Pulmonary	Other	Additional anesthetic considerations	References
	GSD-I: Glucose-6-Phosphatase System Deficiency, 4 subtypes		
	GSD-II: defective lysosomal alpha-glucosidase, 4 onset forms		
	GSD-III: Amylo-1,6-Glucosidase Deficiency, 6 forms		
	GSD-IV: glycogen branching enzyme deficiency, numerous forms		
	GSD-V: Muscle Phosphorylase Deficiency, 2 forms		
	GSD-VI: liver phosphorylase deficiency		
	GSD-VII: phosphofructokinase deficiency, 2 forms		
	GSD-VIII (VIIa, IX, X): tissue-specific phosphorylase kinase deficiency		
	No apparent relation with MH		
	Wide fluctuation in glucose ,hypo- to hyperglycemia, in GSY2 (liver) GSD	Test exists to differentiate between GYS1 (muscle) and true mitochondrial disease	256
	Fasting ketotic hypoglycemia without muscle symptoms or hepatomegaly	Monitor blood glucose and limit NPO preoperatively	257
			258
	Hypoglycemia without dietary carbohydrate intake	Monitor blood glucose & limit NPO preoperatively	259
	Hepatomegaly, anemia, osteopenia, hyperuricemia, proteinuria	Maintain euglycemia and normal pH intraoperatively	260
	Gout, renal stones, nephropathy leading to proteinuria, hypertension, and renal dysfunction	Bispectral index score may not reflect anesthetic depth with hypoglycemia	261
	Acquired (reversible) platelet dysfunction (prolonged BT; abn aggregation, less adhesiveness) with hypoglycemia	Propofol infusion may exacerbate hyperuricemia	262
		Reports of propofol-induced pancreatitis	263
		Caution with regional anesthesia with possible platelet dysfunction	264
		Caution with positioning – osteopenia	265
Infantile onset: respiratory insufficiency with frequent infections	Infantile onset: hepatomegly , elevated creatine kinase	Respiratory insufficiency & hypertrophic cardiomyopathy pose significant anesthetic risk	266
		Maintain intravascular volume and diastolic blood pressure for coronary perfusion	267
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Glycogen storage diseases (continued)			
		Late onset: macroglossia is infrequent	Late onset: progressive proximal muscle weakness – lower>upper extremity, Gower sign, decreased deep tendon reflexes	Late onset: cardiomegaly/cardiomyopathy is uncommon
	GSD Type III: Debrancher deficiency (Cori or Forbes disease) (glycogen	Frequent midface hypoplasia		
	debrancher deficiency, 1:100,000)			
		Possible macroglossia	Distal myopathy: mild sensory deficits and fasciculations	Distal myopathy: absence of severe cardiomyopathy
				Up to 50% with cardiomyopathy resembling

idiopathic hypertrophic cardiomyopathy

Pulmonary	Other	Additional anesthetic considerations	References
		Reports of arrhythmias due to decreased coronary perfusion with propofol	268
		Reports of successful regional anesthetic techniques	269
Late onset: respiratory insufficiency/failure with infections, dyspnea on exertion, obstructive sleep apnea, orthopnea	Late onset: moderate hepatomegaly, scoliosis/ kyphosis/lordosis	Respiratory insufficiency poses anesthetic risk	
		Hypotonia/wheelchair bound – avoid neuromuscular blocking drugs and succinylcholine for prolonged weakness and hyperkalemia	
		Reports of prolonged respiratory depression with volatile agents	
		Midface hypoplasia/macroglossia may contribute to difficult airway	270
			271
	Distal myopathy: adult onset, slowly progressive, involves calves/peroneal muscles with rare hepatic involvement	Assess sensory deficiets preoperatively	272
Respiratory muscle myopathy: myogenic respiratory failure	Respiratory muscle myopathy: adult onset, selective respiratory muscle involvement without limb muscle involvement	Report of respiratory myopathy reversal with high protein diet	273
		Assess respiratory function	274
	Severe generalized myopathy (juvenile onset): complete recovery at puberty		275
Severe generalized myopathy (adult onset): respiratory failure	Severe generalized myopathy (adult onset): progressive to wheelchair bound, hepatic involvement, neuropathy	Assess respiratory function	
		Assess hepatic function & monitor glucose intraoperatively	
		Avoid NMBD (hypotonia) & succinylcholine (hyperkalemia)	
		Assess neuropathy preoperatively, positioning consideration	
	Minimal variant myopathy: predominantly hepatic involvement, cardiomyopathy	Assess hepatic function & monitor glucose intraoperatively	
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Glycogen storage diseases (continued)			GSD cardiomyopathy has relative normal exercise stress/ECG results
	GSD Type IV: brancher deficiency (Andersen disease) (glycogen branching enzyme deficiency, very rare)			Possible cardiomyopathy
	GSD Type V: McArdle syndrome (muscle glycogen phosphorylase deficiency, 1:100,000)			
	GSD Type VI: Hers disease (liver glycogen phosphorylase deficiency, 1:65–85,000)			
	GSD Type VII: phosphofructokinase deficiency (Tarui disease) (muscle phosphofructokinase deficiency, very rare)		Progressive partial complex seizure, diplopia, decreased deep tendon reflexes, facial palsy, bradydiadochokinesia, distal UE weakness Increased calcium permeability in red blood cells possibly explaining diminished deformability leading to hemolysis	Progressive: low voltage ECG to supraventricular tachycardia, thick mitral valve to mitral valve insufficiency, left atrial enlargement/left ventricular hypertrophy to diastolic dysfunction

Pulmonary	Other	Additional anesthetic considerations	References
		Cardiomyopathy resembles idiopathic hypertrophy but with normal stress/ exercise tolerance	
	Classic Anderson: hepatosplenomegaly, progressive liver cirrhosis (with portal hypertension) leading to death	Cardiac work-up for cardiomyopathy	276
	Phenotypic variant: with peripheral myopathy +/– cardiomyopathy, neuropathy, or cirrhosis	Coagulation profile as assessment for degree of liver failure	277
	Cardioskeletal variant with normal glycogen brancher enzyme activity leading to death from cardiac failure		
	Cardiomyopathy with deficienct glycogen brancher enzyme activity leading to death from cardiac failure		
	Exercise-induced muscle cramps, injury, and myoglobiniuria relieved by extramuscular glucose delivery	Caffeine halothane contracture test positive report; but no case reports of malignant hyperthermia – minimal risk	278
	Exercise induced creatine kinase elevation, hyperkalemia, and acute renal failure	Preoperative creatine kinase, lactate dehydrogenase, creatinine; avoid tourniquet/shivering	279
		Avoid malignant hyperthermia-triggers: succinylcholine, volatile agents	280
		Avoid sympathetic stim, increased temp, neuroleptics	
	Hepatosplenomegaly, hypotonia at young age; but minimal hypoglycemia	Limit NPO/monitor glucose	281
	Muscle cramps, exercise intolerance, rhabdomyolysis/myoglobinuria +/– hemolytic anemia/hyperuricemia	Cardiac work-up	282
		Reports of rhabdomyolysis leading to acute renal failure	283
		Glucose infusion is ineffective	284
			285
			286 (Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Glycogen storage diseases (continued) GSD Type VIII (IX) (phosphorylase kinase deficiency, very rare)		Delayed motor development	Hypercholesterolemia/hypertriglyceridaemia
41	Goldenhar syndrome (hemifacial microsomia, oculo-auriculo-vertebral syndrome, sporadic mutation, 1:5600, genetics imcompletely analyzed, possible TCOF1 gene at 5q32)	Unilateral facial hypoplasia: prominent forehead, zygomatic hypoplasia, maxillar/ mandibular hypoplasia	Epibulbar dermoid/ lipodermoid, eye anomalies; microphthalmia, anophthalmia, etc.	30–60% CHD: 40% conotruncal, 30% septal, 15% targeted growth, 7% situs/ looping, 4% left-sided obstruction
		Unilateral macrostomia — lateral facial cleft	Preauricular skin tag/blind fistulas, microtia or other external ear malformations	
		Vertebral anomalies: atlas occipitalization, synostosis	Vertebral anomalies; bifid spine	
		Laryngotracheal anomalies: cartilaginous tracheal sleeve	Often with occipital encephalocele	
		Significant incidence of C1-C2 instability	Oftern with complex retardation of development	
		Often with cleft lip/ palate/tongue, unilateral tongue hypoplasia, parotid gland aplasia		
		Often with tracheoesophageal fistula/esophageal atresia		
42	Hajdu-Cheney syndrome (arthrodento-osteodysplasia, autosomal dominant, 50 cases reported, genetics not fully analyzed)	Micrognathia, progressive midface flattening to apparent prognathia	Wormian bones, open sutures, basilar invagination, bathrocephaly, platybasia, hydrocephalus	Possible congenital heart disease; patent ductus arteriosus, ventricular septal defect, valvular disorder
		High arched palate or cleft palate	Platybasia may cause: stretched cranial nerves, increased intracranial pressure, foramen magnum compression; syringomyelia may develop	Hypertension with renal cystic disease

Pulmonary	Other	Additional anesthetic considerations	References
	Hepatomegaly	Limit NPO/monitor glucose	287
	Fasting hyperketosis/hypoglycaemia		
NA	Vertebral anomalies: hemivertebrae, fused vertebrae, scoliosis	Difficult airway – reports of failed intubation	288
	Often with rib/extremity anomalies	Reports of successful intubation with multiple techniques	
	Genitourinary anomalies: ectopic kidney, renal agenesis, vesicoureteral reflux, ureteropelvic junction obstruction	Evaluate cervical spine for instability	289
		Cardiac work-up	291
			290
			291
NA	Acro-osteolysis, vertebral compression, scoliosis/ kyphosis	Assess renal function and neurological deficits	292
	10% renal abnormalities: cystic disease, hypoplasia, vesicoureteral reflux, glomerulonephritis, hypertension, chronic renal failure	Possible difficult airway – micrognathia, C-spine instability, dental abnormalities	293
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Hajdu-Cheney syndrome (continued)	Abnormal dentition	Progressive paresthesia with acroosteolysis	
		Short neck	Occasionally associated with facial spasm & rarely trigeminal neuralgia	
43	Hallermann-Streiff syndrome (Francois dyscephalic syndrome, autosomal recessive, 200 reported cases, mutation chromosome 6q21-q23.2 in some patients, GJA1 gene)	Small face, brachycephaly with frontal/parietal bossing	Possible developmental delay, seizure disorder	5% congenital heart disease: pulmonic stenosis, atrial/ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot
		Hypoplastic mandible, anteriorly displaced TMJ, high/narrow palate, dental anomalies	Ocular findings: microphthalmia, cataracts, nystagmus, strabismus	Reported biventricular failure from tracheomalacia causing respiratory insufficiency
		Laryngotracheal anomalies: tracheomalacia		
		Upper airway obstruction from micrognathia with glossoptosis may cause cor pulmonale		
44	Hemophilia	NA	Intracranial haemorrhage is significant cause of mortality	NA

Pulmonary	Other	Additional anesthetic considerations	References
		Reports of cervical instability	294
		Possible airway obstruction postoperatively	295
		Reports of upper airway obstruction	296
		Reports of vocal cord paralysis	297
		Prone to fractures (long bones and spine) – care with positioning	298
Narrow upper airway predisposing to infections & OSA	Possible skeletal deformities, hematopoietic (immunodeficient) defects	Difficult airway: mandibular hypoplasia/ microstomia, displaced TMJ, abnormal teeth	299
		Tracheostomy may be required but difficult with cricoid cartilage at/near suprasternal notch	
		Reports of successful intubation with multiple techniques	300
		Cardiac work-up	301
			302
			303
NA	Classification: both VIIIc or Ixc	Assess factor concentrations – treat as indicated	304
	Severe if <1% of normal activity – spontaneous joint/muscle bleeding, bleeding after injury	Arrange for specific factor therapy as indicated	305
	Moderate if 1–5% of normal activity – minor injury-induced joint/muscle bleeding, excessive bleeding post surgery/dental procedure	Oral intubation preferred to avoid nasal bleeding	306
	Mild if 5–40% of normal activity – no spontaneous bleeding, bleeding post surgery/dental procedures	Reports of successful use of multiple anesthetic techniques	
	p. 0000000		(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Hemophilia (continued)			
	Hemophilia A (X-linked recessive, 1:5000 males, mutation chromosome Xq28, factor VIII gene)			
	Hemophilia B (Christmas disease, X-linked recessive, 1:50,000 males, mutation chromosome Xq27.1-q27.2, factor IX gene)			
45	Hereditary angio-edema (C1 esterase inhibitor deficiency) (hereditary angioneurotic edema, autosomal dominant, 1:10–50,000, mutation chromosome 11q11-q13.1, deficiency C1 esterase inhibitor gene)	Poor dentition	NA	NA
		Acute laryngeal edema is significant cause of mortality		

Pulmonary	Other	Additional anesthetic considerations	References
	X-linked trait: affects males but female carriers have 1/2 normal concentrations – may predispose to excessive bleeding	Neuraxial techniques relatively contraindicated; no "safe" factor level defined	
	Risk of human immunodeficiency virus/hepatitis infection from blood product replacement therapy prior to recombinant factor development		
	DDAVP raises VIIIc concentration effectively in mild hemophilia A	Report of non-operative splenic laceration therapy with recombinant factor VIII in Jehovah's Witness	307
	Recombinant factor VIIIc therapy for mod/sev hemophilia A	Reports of hyponatremia & seizures in young patients given DDAVP	308
	Inhibitors (antibodies to RF-VIIIc) develop in 30–50% hemophilia A patients	Report of recombinant factor VII use to achieve hemostasis with factor VIII inhibitor	309
		Report of successful peripheral nerve block in hemophilia A patient	310
	Recombinant factor lxc therapy for hemophilia B	Significant risk of anaphylaxis in hemophilia B patients with inhibitors	311
	Inhibitors (antibodies to recombinant F-Ixc) develop in 1–3% hemophilia B patients	Report of acute hepatitis in hemophilia B patient after isoflurane anesthesia	312
NA	C1 esterase inhibitor inhibits many mediator cascades which result in plasma leakage	Prepare for upper airway obstruction due to oropharyngeal/laryngeal edema	313
	Postcapillary plasma leakage into dermis resulting in non-pitting edema of hands/feet, genitalia, face/tongue, larynx, bowel	Elective surgery: reports of successful monitored/regional/general anesthesia	314
	Bowel wall swelling leads to spasmodic abdominal pain with vomiting	Avoid airway manipulation, prophylaxis when airway manipulation is indicated	315
	Prophylaxis treatments: Danazol, epsilon aminocaproic acid		
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Hereditary angio-edema (continued)			
46	Holt-Oram syndrome (heart-hand syndrome, atriodigital dysplasia, autosomal dominant, 1:100,000, mutation chromosome 12q24.1, TBX5 gene mutation: promotes cardiomyocyte differentiation)	NA	NA	Congenital heart disease: septal defects
				Frequent cardiac conduction disease: bradycardia, atrioventricular block, atrial fibrillation
				Atrial sepal defect most common, but reports of endocardiac cushion defect with left ventricular hypoplasia
				Vascular abnormalities: persistant left superior vena cava, renal arterial malformations, absent radial artery
47	Homocystinuria (cystathionine beta-synthase deficiency, autosomal recessive, 1:344,000, mutation chromosome 21q22.3)	High arched palate, dental crowding with incisor protrusion	Eye: ectopia lentis leading to myopia, retinal detachment & glaucoma	Arterial/venous thrombosis, cutaneous flushing
			Frequent mental retardation, not seen in Marfan	Medium sized artery (coronary, renal subclavian, iliac, carotid) medial changes: dilation & thrombosis
48	Hunter syndrome (mucopolysaccharidosis type II, X-linked recessive, 1:110–320,000 males, mutation chromosome Zq28, deficient enzyme, iduronate- 2-sulfatase)	Dural hyperplasia/ thickening ligamentum flavum lead to cervical myelopathy with UMN signs	Normal intelligence with progressive neurodegeneration leading to vegetative state as teenagers	Cardiac disease: cardiomyopathy, asymmetrical ventricle septal thickening, mitral/aortic valve thickening

Pulmonary Other		Additional anesthetic considerations	References
	Acute treatments: C1 INH concentrate, fresh frozen plasma, epinephrine, diphenhydramine		
NA	Skeletal deformities: thenar/carpal bones, occasionally hypoplastic clavicles/shortened radii	Cardiac work-up: structure/function, internal cardiac defibrillator assessment	316
		Vascular access may be difficult	317
		Upper limb peripheral nerve blocks may be challenging	318
		Report of successful neuraxial anesthesia/ analgesia	
Thorax: pectus excavatum, scoliosis	Marfanoid habitus – dolichostenomelia, "long, thin extremities"	Caution: arterial/venous puncture may initiate thrombosis	319
Rarely spontaneous pneumothorax	Generalized osteoporosis (not seen in Marfan) leading to codfish vertebrae and vertebral collapse	Avoid prolonged nitrous oxide – inhibits methionine synthase conversion homocysteine to methionine	320
		Measure to decrease thrombosis/ embolization – hydration, hemodynamic stability	321
		Minimize time without anticoagulation therapy	
		Consider neuraxial analgesia/anesthesia if coagulation status is appropriate	
NA	Gastrointestinal dysfunction: idiopathic diarrhea, spontaneous gastric perforation, bowel pseduo-obstruction	Difficult airway: short neck, high larynx, large tongue, cervical instability	322

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Hunter syndrome (continued)	Coarse facies:	Narrowing of the bony neural canal predisposing to cervical cord compression	Sudden death – likely arrhythmia from coronary insufficiency
		Temperomandibular joint stiffness and short stiff neck	Compressive myelopathy from meningeal thickening causing communicating hydrocephalus	
		Adenotonsillar hypertrophy contributing to obstructive sleep apnea, progressive upper airway obstruction, infections		
		Glycosaminoglycan deposition in pharynx/ larynx wall – laryngeal inlet prolapse/stridor/ airway compromise		
		Progressive tracheal deformation; cricoid to lower bronchi		
		Trauma (airway instrumentation) may induce mucopolysaccharide deposition		
		C1 & C2 subluxation with odontoid dysplasia		
49	Hurler syndrome (mucopolysaccharidosis type I, autosomal recessive, 1:100,000, mutation chromosome 4p16.3, iduronidase deficiency)	Facial dysmorphism, obstructive sleep apnea is nearly universal	Normal intelligence	Cardiac disease: cardiomyopathy, asymmetrical ventricle septal thickening, mitral/aortic valve thickening
		Coarse facies:/gum hypertrophy, macroglossia	Possible hydrocephalus	Sudden death – likely arrhythmia from coronary insufficiency
		TMJ stiffness & short stiff neck	Ocular findings: corneal clouding, glaucoma	Mitral/aortic valve dysplasia, left ventricular hypertrophy, normal function – same or better following bone marrow transplant

Pulmonary	Other	Additional anesthetic considerations	References
		Reports of postobstructive pulmonary edema at induction/extubation	323
		Reports of successful intubation using multiple techniques: blind nasal, fiber-optic, LMA	324
		Reports of intubation failure using laryngeal mask airway	325
		Report of delayed awakening following single dose of opioid	326
			327
			328
			329
NA	Progressive joint stiffnes with decreased mobility, severe back pain, lumbar spondylolisthesis with cord compression	Difficult airway: short neck, high larynx, large tongue, cervical instability	330
	Poor hand function likely from carpal tunnel syndrome	Epiglottis tip behind soft palate – oral airway exacerbates rather than relieves obstruction	
	Hepatosplenomegaly – likely leading to high incidence of umbilical hernia	Reports of postobstructive pulmonary edema at induction/extubation	
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Hurler syndrome (continued)	Adenotonsillar hypertrophy contributing to obstructive sleep apnea, progressive upper airway obstruction, infections		
		Glycosaminoglycan deposition in pharynx/ larynx wall – laryngeal inlet prolapse/stridor/ airway compromise		
50	Jeune syndrome (asphyxiating thoracic dystrophy, thoracic-pelvic-phalangeal dystrophy, autosomal recessive, very rare, mutation chromosome 15q13, gene product not yet known)	NA	Ocular abnormalities: retinitis pigmentosa	Absent
51	Kearns-Sayre syndrome (mitochondrial disease, ophthalmoplegia-plus, oculocraniosomatic disease, oculocraniosomatic neuromuscular disease with raggel red fibers, spontaneous inheritance, 1:125,000, various mitochondrial DNA deletions transmitted from mother)	Possible weak pharyngeal muscles: increased risk for aspiration	Progressive external ophthalmoplegia	Atrioventricular conduction defects:
			Pigmented retinal degeneration: visual loss	Heart block (second- or third-degree atrioventricular block): may need pacemaker
			Sensorineural hearing loss	Congestive cardiomyopathy

Pulmonary	Other	Additional anesthetic considerations	References
		Reports of successful intubation using multiple techniques	
		Report of failed epidural anesthesia – likely from mucopolysaccharide deposits on meninges	
			331
Respiratory distress: bell- shaped/long narrow small thorax with handlebar clavicles	Renal tubular-concentrating defect and proteinuria and diffuse interstitial fibrosis/glomerular sclerosis	Severe respiratory insufficiency – desaturate with agitation from asynchronous rib/abdominal motion	332
	Hepatic disease to portal hypertension to transplantation	Minimize airway pressures to avoid barotrauma	333
	Cystic pancreatic disease	Assess renal function to guide fluid management	334
	Short long bones, postaxial polydactyly, trident acetabulum	Assess hepatic function – abnormal drug metabolism	335
Decreased respiratory drive	Mitochondrial myopathy		336

Pes	cavus
-----	-------

Lactic acidosis, worse with fasting: avoid 337 excessive preoperative fasting and lactated Ringer's, include glucose with intravenous fluids Possibly more sensitive to rocuronium, 338 atracurium, succinylcholine, and mivacurium

(Continued)

## 1058 Part 3 Practice of Pediatric Anesthesia

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Kearns-Sayre syndrome (continued)		Ataxia	
			Cranial nerve dysfunction	
			Bulbar and limb girdle muscle weakness	
			Myopathy with proximal limb weakness	
			Seizures	
			Dementia	
52	King-Denborough syndrome (malignant hyperthermia susceptibility-1, King syndrome, autosomal dominant, 1:5–15,000 children, mutation chromosome 19q13.1, RYR1: ryanadine receptor mutation)	Micrognathia, webbed neck, & dental crowding/ malocclusion	Normal intelligence with delayed motor development	NA
			Myopathy: elevated resting creatine kinase, muscle weakness, decreased deep tendon reflexes	
53	Klippel-Feil syndrome (autosomal dominant and recessive forms, 1:1500– 5000, mutation chromosome 8q22.1 (dominant) or 5q11.2 (recessive), GDF6 gene (dominant) or unknown gene (recessive)	Laryngotracheal anomalies: laryngeal stenosis, vocal cord stenosis	Vertebral fusion, spina bifida, some myeloencephalococele, syringohydromyelia, Chiari malformation	Congenital heart disease (14%): ventricular septal defect

Pulmonary	Other	Additional anesthetic considerations	References
		Consider avoiding succinylcholine in myopathic patient due to risk of exaggerated hyperkalemia	
		Possible impaired respiratory control: consider titration of narcotics and other respiratory depressants	
		Unclear, but unlikely, association between mitochondrial disorders and malignant hyperthemia. Only one reported case in literature links malignant hyperthermia and mitochondrial disorders	
		At risk for developing metabolic acidosis and myocardial failure after propofol infusion	
	Orthopedic abnormalities:		
	Short stature		
	Kyphoscoliosis		
	Hirsutism		
	Fatal hyperosmolar coma and hyperglycemia after steroid therapy		
	Exercise intolerance		
Pectus carinatum/excavatum, scoliosis or kyphoscoliosis, lumbar hyperlordosis	Closely linked to malignant hyperthermia susceptibility	Multiple reports of KDS diagnosis following malignant hyperthermia event – use non-triggering anesthetic	339
		Succinylcholine is contraindicated due to hyperkalemic response in myopathies	106
		Report of successful epidural anesthesia	340
Scoliosis	Genitourinary anomalies (30%): renal agenesis, renal/pelvic/ureteral duplication	Difficult airway: cervical spine instability/ fusion, microtia, short/webbed neck, micrognathia	62

(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Klippel-Feil syndrome (continued)	Malformation of laryngeal cartilages with voice impairment	Extraocular muscle palsies, lower extremity paresthesias, respiratory apnea, mental retardation, spasticity	
		Micrognathia, cleft palate, microtia, bifid uvula, facial asymmetry		
		cervical spine (C2-C3) vertebral fusion, short webbed neck, torticollis, cervical ribs		
54	Klippel-Trenaunay-Weber syndrome (angio- osteohypertrophy syndrome, sporadic inheritance, <i>de</i> <i>novo</i> translocation t(8:14) (q22.3;q13), rare, several hundred cases reported, AGGF1: angiogenic factor 1 gene may be involved)	NA	Glaucoma	Capillary malformations: port-wine stains
			Spinal cord arteriovenous malformations	Venous malformations: varicose veins +/– persistent lateral embryological veins
				Frequently: venous incompetence & lymphatic malformations
				Hemangiomas with thrombotic events, high output cardiac failure, and bleeding
55	<b>LEOPARD syndrome</b> (multiple lentigenes syndrome, autosomal dominant, very rare, approx. 100 reported cases, mutation chromosome 12q24, protein-tyrosine phosphatase, non-receptor type II (PTPNII): regulates intercellular signaling)	Prognathism	Sensorineural deafness	Electrocardiographic conduction abnormalities: consider preoperative ECG

Pulmonary	Other	Additional anesthetic considerations	References
Central respiratory apnea	Restricted extremity movement	Cervical spine evaluation	341
		Cardiac work-up	342
		Risk for postoperative apnea/obstruction: central respiratory apnea, micrognathia/ cleft palate	343
		Reports multiple airway management techniques: fiber-optic, laryngeal mask airway, videolaryngoscopy	
NA	Unilateral soft tissue or bony hypertrophy	Avoid hypertension to prevent spontaneous bleed – blunt sympathetic response to direct laryngoscopy and endotracheal tube	344
	Occasional hip dysplasia or syndactyly	Avoid hypovolemia to prevent expanding hemangiomas with thrombocytopenia/ DIC	345
	Scoliosis	Avoid hypervolemia to prevent increased perfusion to non-autoregulated vessels	346
	Chronic disseminated intravascular coagulation	Avoid scopolamine (interferes with aqueous humor drainage) with glaucoma	347
		Cardiac work-up for high-output failure as needed	
		Regional analgesia/anesthesia may be relatively contraindicated	
		Multiple successful neuraxial anesthetics reported with spinal imaging & coagulation status verified	
Pectus excavatum or carinatum	Multiple lentigenes (large freckles) on the skin	NA	348

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	LEOPARD syndrome (continued)	Micrognathia	Possible mental retardation	Hypertrophic obstructive cardiomyopathy: consider preoperative screening echocardiography
		Flat nasal bridge	Learning difficulties	Pulmonic stenosis
		Cleft palate		Subaortic stenosis, mitral valve disease
		Dental abnormalities		Left atrial myxoma
56	Long QT (prolonged QT syndrome including Jervell-Lange-Nielson, Romano-Ward, and Andersen syndromes, autosomal dominant or recessive, approx. 1:10,000, at least 12 different mutations mostly of sodium and potassium channel protein genes)	Possible difficult intubation with Andersen syndrome: micrognathia, cleft palate, low-set ears, hypertelorism	Syncope during exertion, seizures	Prolonged QTc:
			Jervell-Lange-Nielson syndrome:	Sudden death due to ventricular tachyarrhythmia, classically torsade de pointes
			Congenital nerve deafness	
			Andersen syndrome:	
			Potassium-sensitive periodic paralysis: avoid succinylcholine due to risk of hyperkalemia	
				Andersen syndrome patients have concenital

cardiac defects and a high incidence of sudden death

Pulmonary	Other	Additional anesthetic considerations	References
Restrictive lung disease with possible pulmonary hypertension	Characteristic facies:		349
	Ocular hypertelorism, low-set ears		350
	Flat nasal bridge		
	Orthopedic abnormalities:		
	Retardation of growth (growth deficiency)		
	Winged scapulae		
	Possible kyphoscoliosis		
	Genitourinary abnormalities:		
	Abnormal genitalia, cryptorchidism, hypospadias		
	Renal agenesis or hypoplasia		
NA	Andersen syndrome		351

Orthopedic abnormalities: syndactyly, short stature, scoliosis, clinodactyly	Avoid drugs that increase QT interval: droperidol, ondansetron	352
	Avoid hypocalcemia, hypomagnesemia, hypokalemia	353
	Avoid adrenergic stimulation including loud environment	354
	Avoid hypothermia	
	Avoid light (or insufficient) anesthesia, hypertension, brady- or tachycardia, hypoxemia, hypo- or hypercapnia	
	Avoid reversal of neuromuscular blockade with anticholinergic and anticholinesterase medications	

(Continued)
No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
57	Marfan syndrome (variable inheritance, often autosomal dominant, 1:3–10,000, mutation chromosome 15q21.1, mutation fibrilin-1 gene)	High arched palate	Widened lumbosacral canal may lead to increased cerebrospinal fluid volume: may need larger than normal doses of spinal or epidural anesthetics	Aortic dissection: avoid hypertension
		Crowded teeth	Spinal arachnoid cysts	Mitral valve prolapse
				Aortic or pulmonary artery dilation: consider preoperative echocardiography to confirm absence
				Aortic insufficiency
				Possible progressive narrowing of coronary arteries
58	Maroteaux-Lamy syndrome (mucopolysaccharidosis VI, arylsulfatase B deficiency, autosomal recessive, 1:238–433,000, mutation chromosome 5q11-q13, deficient arylsulfatase B)	Possible difficult to impossible direct laryngoscopy and intubation	Normal intelligence	Heart failure is most common cause of death
	Mucopolysaccharidosis VI	Frontal bossing	Spinal compression from dural thickening, usually cervical: avoid neck extension	Aortic valve calcifications
		Depressed nasal bridge	Communicating hydrocephalus from lumbar stenosis	Possible mitral valve involvement
		Enlarged tongue, gingival hypertrophy	Hearing loss: conductive and sensorineural	Hypertension
		Thick mucous secretions	Atlantoaxial instability from odontoid dysplasia	

Pulmonary Other Additional anesthetic considerations	References
Pectus excavatum Characteristic facies: Widened lumbosacral canal may lead to increased cerebrospinal fluid volume: may need larger than normal doses of spinal or epidural anesthetics	355
Pulmonary blebs with Dolichocephaly, long and narrow facies: Avoid hypertension spontaneous pneumothoraces	356
Obstructive sleep apnea Lens dislocation, elongated globe, myopia	357
Possible tracheomalacia Increased risk of glaucoma, retinal detachment   Possible emphysema and bronchogenic cysts Orthopedic abnormalities:	358
Tall with arm span greater than height	
Winged scapula	
Joint laxity leading to recurrent dislocations	
Ulnar deviation, arachnodactyly	
Scoliosis, kyphosis	
Congenital contractures, flat feet	
Gastrointestinal/genitourinary abnormalities:	
Inguinal, umbilical, and femoral hernias	
At risk for airway obstruction: Characteristic facies: NA	359
Pectus carinatum Coarse face, "tight" skin	360
Recurrent upper respiratory Hirsutism infections	361
Sleep apnea Corneal clouding	362
Restrictive lung disease Orthopedic abnormalities:	Continued

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Maroteaux-Lamy syndrome (continued)	Short, stiff neck		
		Possible atlantoaxial instability		
		Intubation difficulty worsens with age		
		At risk for airway obstruction due to mucopolysaccharide deposits in the lips, tongue, epiglottis, tonsils, adenoids, lower airway		
59	MELAS syndrome (mitochondrial myopathy– encephalopathy–lactic acidosis–stroke syndrome, spontaneous inheritance, rare, various mitochondrial DNA deletions transmitted from mother)	NA	Encephalopathy	Cardiomyopathy
			Stroke-like episodes with sudden onset of hemiparesis, hemianopsia, cortical blindness	Possible Wolff-Parkinson-White syndrome: consider preoperative ECG
			Encephalomalacia and degeneration with focal infarcts, cortical or cerebellar atrophy, or basal ganglia calcifications	
			Seizures	
			Recurrent headaches	

Pulmonary	Other	Additional anesthetic considerations	References
	Normal growth for first few years, then stops		
	Hypoplasia of hip acetabulae with small, flared iliac wings		
	Hypoplasia of L1–2 vertebrae with lumbar kyphosis		
	Proximal femoral dysplasia		
	Contractures of joints due to deposits of polysaccharide in ligaments		
	Restricted mobility of hips, knees, elbows		
	Carpal tunnel syndrome, claw hand		
	Hepatosplenomegaly with hypersplenism: results in anemia, thrombocytopenia, genitourinary abnormalities: umbilical and inguinal hernias		
Respiratory failure	Mitochondrial myopathy	Lactic acidosis, worse with fasting: avoid excessive preoperative fasting and lactated Ringer's, include glucose with intravenous fluids	363
	Exercise intolerance	Possibly more sensitive to rocuronium, atracurium, succinylcholine, and mivacurium	364
	Onset: childhood	Consider avoiding succinylcholine in myopathic patient due to risk of exaggerated hyperkalemia	365
	Orthopedic abnormality: short stature	Possible impaired respiratory control: consider titration of narcotics and other respiratory depressants	366
	Gastrointestinal abnormality: recurrent vomiting	Unclear, but unlikely, association between mitochondrial disorders and malignant hyperthemia. Only one reported case in literature links malignant hyperthermia and mitochondrial disorders	
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular

			(continucu)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
64	Morquio syndrome	Possible difficult mask ventilation, direct laryngoscopy, and intubation	Cervical spine instability, odontoid hypoplasia with atlantoaxial subluxation: evaluate cervical spine preoperatively	Mitral and aortic valve disease, especially aortic insufficiency late in the disease
	Mucopolysaccharidosis IV	Short neck with limited movement	Sensorineural or mixed hearing loss	Possible pulmonary hypertension, cor pulmonale due to lung disease
	Mucopolysaccharidosis IVA (galactosamine-6-sulfatase deficiency, autosomal recessive, 1:216–640,000 (A and B), mutation chromosome 16q24.3)	Neck flexion may occlude the airway	Normal intelligence	
		Cervical spine instability		
		Possible limited mouth openining		
		Prominent mandible or maxilla		
		Redundant pharyngeal mucosa		
		Macroglossia		
		Tonsillar and adenoid hypertrophy		
	Mucopolysaccharidosis IVB (autosomal recessive, 1:216–640,000 (A and B), mutation chromosome 3p21.33, deficiency in beta-galactosidase)	Widely spaced maxillary anterior teeth		
		May require smaller than predicted endotracheal tube		
		Enamel hypoplasia with pitting (type A)		
		Possible copious tracheobronchial secretions: consider antisialagogue		

Pulmonary	Other	Additional anesthetic considerations	References
Restrictive lung disease from kyphoscoliosis	Type A: severe form	NA	382
Pectus carinatum, rib flaring	Type B: milder form		383
Obstructive or central sleep apnea	Characteristic facies:		384
Recurrent lower airway infections	Dense calvarium		
Susceptible to pulmonary hemorrhage after bone marrow transplant	Coarse facial features		
	Short, anteverted nose		
	Short neck with limited movement		
	Broad mouth with redundant pharyngeal mucosa		
	Macroglossia		
	Widely spaced maxillary anterior teeth		
	Corneal clouding, glaucoma		
	Orthopedic abnormalities:		
	Short stature due to shortened trunk and neck		
	Shortanad long bones short bonds		
	Odontoid hypoplasia with atlantoaxial subluxation		
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Morquio syndrome (continued)			
65	Myotonic dystrophy, type I (Steinert disease, congenital myotonic dystrophy, autosomal dominant, variable penetrance, all forms 1:8000, congenital variety is a small proportion, mutation chromosome 19q13.2-q13.3, DMPK gene: myotonic dystrophy protein kinase)	ΝΑ	Facial, neck, distal musculature myotonia, with preservation of limb girdle strength until later in the disease	Greater than 90% of patients have conduction abnormalities, especially first-degree heart block and intraventricular conduction delays: recommend preoperative ECG
			Myotonia worsens after exercise	Sudden death with third-degree heart block and ventricular tachyarrhythmia
			Muscle wasting	Cardiac enlargement, interstitial fatty infiltration and fibrosis
			Generalized myotonia: can be induced by anesthetic or surgical manipulation, cold or shivering – keep normothermic	Left axis deviation and ST-T wave changes on ECG
			Myotonia is not prevented or reversed with muscle relaxants or regional anesthesia	Impaired ventricular function late in the disease
			Can infiltrate muscle with local anesthetic to attenuate contraction	Mitral valve prolapse
			Succinylcholine can induce sustained contraction of chest wall muscles, making positive pressure ventilation difficult even in intubated patients: avoid succinylcholine for this reason and for the risk of exaggerated hyperkalemia	

Pulmonary	Other	Additional anesthetic considerations	References
	Flattened vertebral bodies (platyspondyly)		
	Kyphoscoliosis, lumbar lordosis		
	Joint laxity and instability: needs careful intraoperative positioning		
	Genu valgum		
	Gastrointestinal abnormality: hepatosplenomegaly		
Recurrent aspiration pneumonia due to bulbar weakness	Most common myotonic syndrome	More likely to have apnea after intravenous anesthetics including propofol, benzodiazepines, opioids, barbiturates: needs postoperative monitoring for possible respiratory depression	385
Poor cough and alveolar hypoventilation due to weak diaphragm and intercostal muscles	Not associated with malignant hyperthermia		386
Central or obstructive sleep apnea	Characteristic facies:		387
	Premature frontal baldness		388
	Muscle wasting with hollowed cheeks and temporal fossa		
	Facial weakness, "expressionless" face		
	Extraocular muscle involvement, cataracts		

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Myotonic dystrophy, type I (continued)		Variable sensitivity to non-depolarizing muscle relaxants Avoid anticholinesterase drugs for reversal of non-depolarizing muscle relaxants as they can precipitate myotonia: use shorter acting muscle relaxants that do not need reversal Mild mental retardation	
66	Nager syndrome (mandibulofacial dysostosis with proximal limb anomalies, autosomal dominant and recessive, very rare disorder, approx. 100 reported cases, mutation chromosome 9q32 reported, ZFP37 candidate gene: protein for cartilage development)	Possible difficult direct laryngoscopy and intubation	Conductive hearing loss: atretic external auditory canals	Associated with congenital heart defects
		Absent zygomatic arches	Possible hydrocephalus	
		Malar hypoplasia	Possible agenesis of corpus callosum	
		Small mouth		
		Severe micrognathia with mandibular hypoplasia		
		Laryngeal or epiglottic hypoplasia		

Pulmonary	Other	Additional anesthetic considerations	References
	Neonates with congential myotonic dystrophy can have facial weakness with tent-shaped mouth		
	Orthopedic abnormality: clubfoot deformity		
	Gastrointestinal abnormalities:		
	Dysphagia, reduced peristalsis: at risk for perioperative aspiration		
	Intestinal pseudo-obstruction, pneumoperitoneum		
	Genitourinary abnormality: gonadal atrophy or ovarian failure		
	Endocrine abnormalities:		
	Possible insulin resistance		
	Possible increased incidence of colloid goiters		
	Obstetric abnormalities:		
	Associated with premature labor, uterine atony, and postpartum hemorrhage

	Nager syndrome (continued)			
		Choanal atresia: cannot place nasal airway, perform nasal intubation, or place nasogastric tube		
		Cleft palate, soft palate agenesis, velopharyngeal insufficiency		
67	Neurofibromatosis	Possible difficult mask ventilation and intubation		Renovascular hypertension from arterial vasculopathy of the abdominal aorta
		Cervical spine stiffness	Peripheral nerve involvement may preclude regional anesthesia	Hypertension secondary to pheochromocytoma
	Neurofibromatosis type 1 (von Recklinghausen disease, autosomal dominant; 50% arise as new mutations, 1:3500, mutation chromosome 17q11.2, neurofibromin gene 1: GTPase activating enzyme)	Macroglossia	NF1: peripheral and central nervous system neurofibromas	Aneurysm rupture
		Tumors of tongue or larynx	NF2 "central neurofibromatosis": bilateral schwannomas of CNVIII, brain meningiomas, schwannomas of dorsal roots of spinal cord	Pregnancy can worsen hypertension
		Dysplasia of sphenoid wing	Pregnancy can initiate or exacerbate growth of neurofibromas	Arterial vasculopathy
		Mediastinal extratracheal tumors	Spinal cord neurofibromas may erode spine and compress cord	
		Macrocephaly	Possible pituitary or hypothalamic dysfunction	

Pulmonary	Other	Additional anesthetic considerations	References
	Possible cervical vertebral anomalies		
	Possible scoliosis		
	Low-set ears		
	Down-slanting palpebral fissures		
	Absent eyelashes in medial third of lower lids		
Restrictive lung disease from kyphoscoliosis	NF1: 85% of patients – cutaneous café au lait spots, osseous abnormalities, possible pheochromocytomas, higher incidence of malignant disease	High incidence of spinal cord involvement – verify no cord lesions with imaging prior to spinal or epidural techniques	
Pulmonary fibrosis with pulmonary hypertension in adulthood	NF2: no cutaneous manifestations		392
Pectus excavatum	Other tumors: neurofibrosarcoma, parathyroid adenoma, rhabdomyosarcoma, duodenal carcinoid, somatostatinoma, pheochromocytoma		393
	Possible endocrinopathies: central precocious puberty, growth hormone deficiency		394
	Newer reports show normal response to succinylcholine and non-depolarizing muscle relaxants, not increased sensitivity		395

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
73	<b>Pentalogy of Cantrell</b> (thoracoabdominal syndrome; Cantrell pentalogy, sporadic, very rare, mutation chromosome Xq25-q26.1 in some patients)	Cleft lip or palate	Hydrocephaly or anencephaly	Ectopia cordis (heart protrudes through open sternum)
		Cystic hygroma		Congenital heart defects:
				Ventricular septal defect, atrial septal defect, tetralogy of Fallot, left ventricular diverticulum
				Absent pericardium
74	Pfeiffer syndrome (acrocephalosyndactyly type V, autosomal dominant, 1:100,000, mutation chromosome 8p11.2-p11.1 in some patients, FGFR1 gene: fibroblast growth factor receptor 1, mutation chromosome 10q26 in some patients, FGFR2 gene)	Possible difficult intubation	Craniosynostosis	Congenital heart defects
		Craniosynostosis with maxillary hypoplasia	Conductive hearing loss due to atresia of external auditory canal	
		Fused vertebrae (usually upper cervical spine) limits mobility	Possible seizures, hydrocephalus, Arnold- Chiari malformation	
		Possible laryngomalacia, tracheomalacia, calcified trachea, tracheal stenosis		
		Rare choanal atresia: cannot place nasal airway, perform nasal intubation, or place nasogastric tube		

Pulmonary	Other	Additional anesthetic considerations	References
Failure of sternal fusion	Defects in midline fusion	NA	449
Dianhragmatic hernia	Gastrointestinal abnormalities: midline		450
Diaphragmatic nerma	supraumbilical abdominal wall defect		450
Hypoplastic lungs	Omphalocele		451
Possible pulmonary hypertension	Diaphragmatic hernia		452
	Genitourinary/renal abnormalities:		453
	Renal agenesis		454
	Hypospadias		455
Obstructive sleep apnea related to midface hypoplasia and nasal obstruction – needs postoperative observation	Orthopedic abnormalities:	NA	456
	Craniosynostosis		457
	Mild syndactyly, polysyndactyly, radiohumeral synostosis of elbow		458
	Broad thumbs and great toes		
	Characteristic facies:		
	Kleeblattschaedel anomaly (cloverleaf skull)		
	,		(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Pfeiffer syndrome (continued)			
75	PHACE association (posterior fossa malformations– hemangiomas–arterial anomalies–cardiac defects– eye abnormalities–sternal cleft and supraumbilical raphe syndrome, very rare, gene defect not known)	Facial hemangiomas, including subglottic – may bleed with airway instrumentation	Posterior fossa brain malformations including Dandy-Walker malformation	Arterial anomalies – atresia, aneursyms, stenosis, aberrant arterial origins
		Possible micrognathia	Internal carotid artery aneurysm and anomalous branches	Cardiac anomalies including coarctation of the aorta
			Ischemic strokes	
			Agenesis of corpus callosum, cerebrum	
			Developmental delay	
			Seizures	
			Contralateral hemiparesis	
			Absent pitutitary or partially empty sella turcica	
			Spinal dysraphism	
76	Pierre-Robin syndrome (Robin sequence, sporadic if non-syndromic, familial if syndromic, 1:8500, mutation chromosome 17q24.3-q25.1 in some patients, candidate genes: SOX9, KCNJ2, KCNJ16, MAP2K6)	Possible difficult mask ventilation and intubation	Possible brainstem dysfunction with central apnea	Cor pulmonale from severe chronic airway obstruction
		Micrognathia		Possible vagal hyperactivity
		Glossoptosis		
		Cleft soft palate		

Pulmonary	Other	Additional anesthetic considerations	References
	Small nose with flat nasal bridge		
	Gastrointestinal abnormalities:		
	Prune belly syndrome, malrotation, duplication		
Possible sternal clefting, possible complete or partial agenesis of sternum	Hemangiomas of face	ΝΑ	459
	Eye abnormalities:		460
	Congenital cataracts, glaucoma		461
	Choroidal hemangiomas		462
	Cryptophthalmos, exophthalmos, microphthalmos		
	Colobomas		
	Esotropia		
	Optic atrophy, optic nerve hypoplasia		
	Possible supraumbilical raphe		
	Endocrine abnormalities:		
	Congenital hypothyroidism		
	Possible pituitary insufficiency		
	Marked female predominance		
Obstructive apnea leading to hypoxia	Characteristic facies:	NA	463
	Severe micrognathia		
	Glossontosis		464
	Gestrointestinal abnormalities		465
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	<b>Pierre-Robin syndrome</b> (continued)	Obstructive apnea (airway obstruction usually improves with age)		
		Neonates may require prone positioning, nasal airway, surgical fixation of tongue to lip or mandible		
77	Prader-Willi syndrome (sporadic, 1:10–25,000, absence of paternal genes from the 15q11-q13 segment, SNRPN, P, UBE3A and necdin gene involvement)	Possible difficult direct laryngoscopy and intubation	Abnormal hypothalamic function:	Pulmonary hypertension due to chronic hypoventilation
		Morbid obesity	Hyperphagia	Hypertension
		Viscous saliva	Temperature instability – hyper- or hypothermia	Possible arrhythmias, especially premature ventricular contractions
		High risk of gastric aspiration	Hypogonadotropic hypogonadism	NA
		Dental enamel hypoplasia	Short stature	
			Neurosecretory growth hormone deficiency	
			Labile temperament with outbursts of rage	
			Hypotonia, especially in neonatal period, but improves with age	
			Psychomotor retardation	
			Relatively insensitive to pain	

Other	Additional anesthetic considerations	References
Feeding difficulties due to anatomical abnormalities		
Possible swallowing difficulties due to brainstem dysfunction		
Orthopedic abnormalities:	NA	466
Short stature		467

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
78	<b>Progeria</b> (Hutchinson-Gilford syndrome, sporadic, 1:8 million, mutation chromosome 1q21.2, lamin A gene: component of nuclear envelope)	Possible difficult direct laryngoscopy and intubation	Childhood cerebrovascular disease	Early and progressive coronary artery disease leading to death in mid-teens from ischemic heart disease
		Micrognathia	Normal intelligence	Hypertension
		Decreased temporomandibular joint mobility	Possible conductive hearing loss	
		Limited mouth opening		
		May require smaller than expected endotracheal tube		
		Abnormal teeth – more susceptible to loss		
		Maxillar and mandibular hypoplasia with beak-like nose		
		Decreased subcutaneous fat: mask ventilation may be difficult		
79	Proteus syndrome (sporadic, very rare, about 200 reported case, mutation chromosome 10q23.31, PTEN gene: antagonizes PI3K and MAPK signaling)	Possible difficult direct laryngoscopy and intubation	Vertebral anomalies can cause spinal stenosis	Hypertrophic cardiomyopathy
		Macrocephaly, cranial hyperostosis	Seizures	Cardiac conduction defects
		Cervical spine abnormalities	Retinal or optic nerve abnormalities	Capillary, venous vascular malformations
		Thickened epiglottis	Meningiomas	Venous thrombosis
		Fixed torticollis		Lymphatic malformations
		Anomalous teeth		

Pulmonary	Other	Additional anesthetic considerations	References	
Thin ribs	Accelerated aging	NA	470	
Small thoracic cage	Progressive alopecia		471	
	Decreased subcutaneous fat: monitor for hypothermia		472	
	Fragile skin with sclerodermatous changes		473	
	Orthopedic abnormalities:			
	Short stature			
	Arthritic, stiff joints			
	Skeletal degeneration			
	Osteoporosis and pathological fractures: must carefully position patients			
	High-pitched voice			
	Orthopedic abnormalities:	Cystic lung disease: avoid nitrous oxide, monitor peak airway pressures	474	
Pectus excavatum	Partial gigantism, hemihypertrophy		475	
Increased incidence of pulmonary embolism from venous thrombosis	Hyperostoses, often near epiphyses causes impaired mobility		476	
	Macrodactyly, syndactyly		477	
	Soft tissue hypertrophy of hands and feet		478	
	Neck elongation from vertebal enlargement			
	Hemivertebrae, dysplastic vertebrae, dystrophic disks, spondylomegaly

-----	---	---	------------------------	--
	Proteus syndrome (continued)			
80	Prune belly syndrome (Eagle-Barrett syndrome, triad syndrome, sporadic, 1:40,000, some cases associated with trisomy 18 or 21)	Micrognathia In utero compression from oligohydramnios can lead to Potter facies: (hypertelorism, epicanthal folds, low-set ears, flattened beaked nose)	NA	Congenital heart defects including patent ductus arteriosus, atrial septal defect, ventricular septal defect, and tetralogy of Fallot

Pulmonary	Other	Additional anesthetic considerations	References
	Scoliosis, kyphosis		
	Subcutaneous hamartomas		
	Thickened skin on palms and soles		
	Lipomas, lymphangiomas		
	Possible hypogammaglobulinemia		
	Possible renal abnormalities		
	Ovarian cystadenoma, testicular tumors		
Pulmonary hypoplasia due to distal urinary tract obstruction and oligohydramnios	Gastrointestinal abnormalities:	NA	479
Weak cough due to deficient abdominal musculature: at risk for postop atelectasis, respiratory failure	Absent abdominal wall musculature		480
Chronic bronchitis	Redundant folds of skin		481
Flat diaphragm, accessory muscles more important	Chronic constipation		482
Possible pectus excavatum	Possible imperforate anus		
	Possible malrotation of the gut		
	Genitourinary abnormalities:		
	Severe bladder and ureteral dilation		
	Cryptorchidism		
	Hydronephrosis with small dysplastic kidneys		
	Recurrent UTIs		
	Possible renal failure		
	Urethral atresia in females		
	Orthopedic abnormalities:		
	Congenital dislocation of the hips		
	Clubfoot deformity		
	Possible polydactyly, syndactyly		
	Scoliosis, torticollis		
	Possible lower limb defects due to compression of iliac vessels by the dilated urinary tract		(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Prune belly syndrome (continued)			
81	Rett syndrome (X-linked dominant, 1:15–20,000 females: surviving males have Klinefelter (XXY), mutation chromosome Xq28, MECP2 gene: lower epinephrine levels)	Progressive microcephaly (normal head circumference at birth)	Developmentally normal until age 6 to 18 months, then regression to dementia and autism	Prolonged QT interval: avoid drugs that prolong QT
		Upper airway obstruction		Possible increased risk of sudden death
				Tachybradyarrhythmias
			Daharian na blana	Vasomotor changes in lower extremities
			Choreo-athetosis, dystonia, ataxia, myoclonic jerks, stereotypical automatism	
			Hand wringing	
			Seizures	
82	Rubinstein-Taybi syndrome (broad thumb-hallux syndrome, broad thumbs and great toes, characteristic facies:, mental retardation, autosomal dominant, 1:10,000, mutation chromosome 16p13.3, CREB binding protein: a nuclear protein participating as a co-activator in cAMP- regulated gene expression)	Possible difficult direct laryngoscopy and intubation	Mental retardation	Congenital heart defects in one-third
		Microcephaly	Motor retardation	
		Hypoplastic maxilla	Hypotonia with stiff and unsteady gait	
		Prominent forehead	Seizures	
		Broad nasal bridge with beaked nose and deviated nasal septum	Hyper-reflexia	

Pulmonary	Other	Additional anesthetic considerations	References
	Male predominance 20:1		
While awake, abnormal respiration with intermittent hyperventilation and occasional apnea; this improves while asleep. Possible postoperative respiratory complications	Orthopedic abnormalities:	Very sensitive to sedative drugs and volatile anesthetics – patients have a faster onset and a prolonged emergence	483
Kyphoscoliosis can lead to restrictive lung disease	Short stature	High pain threshold: titrate analgesics	484
	Kyphoscoliosis	Hypotonia and limb spasticity: susceptible to perioperative aspiration with advanced disease	485
	Hip dislocation		486
	Osteopenia, pathological fractures		
	Small hands and feet		
	Thin body habitus: avoid hypothermia, needs careful positioning		
Obstructive sleep apnea	Characteristic facies:	NA	487
Sternal abnormalities, including pectus excavatum	Prominent forehead with large anterior fontanelle		488
Possible postoperative respiratory failure	Hypertelorism		489
Aspiration risk	Thick, arched eyebrows		
	Nasolacrimal duct stenosis		
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Rubinstein-Taybi syndrome (continued)	Possible choanal atresia: cannot place nasal airway, perform nasal intubation, or place nasogastric tube	Agenesis of corpus callosum	
		Short upper lip with pouting lower lip	Large foramen magnum	
		Microstomia	Possible spina bifida occulta	
		High-arched palate		
		Micrognathia with overcrowding of teeth		
		Easily collapsible larynx		
		Aspiration risk		
83	Russell-Silver syndrome (Russell-Silver dwarf, Silver-Russell dwarfism, sporadic or uniparental disomy (10%), 1:30– 100,000, mutation chromosome 11p15.5, parental disomy 7p11.2, gene: methylation defects)	Possible difficult intubation and mask fit	Normal intelligence	NA
		Micrognathia	Weakness during infancy	
		Triangular facies: with large head in relation to the face (pseudohydrocephalus because head circumference is actually normal) Facial asymmetry		

Pulmonary	Other	Additional anesthetic considerations	References
	Downward-slanting palpebral fissures, ptosis, glaucoma, strabismus, iris coloboma		
	Orthopedic abnormalities:		
	Short stature		
	Broad thumbs and first toes		
	Clinodactyly of fifth finger		
	Slipped capital femoral epiphyses		
	Flat feet		
	Scoliosis, cervical kyphosis		
	Genitourinary abnormalities:		
	Cryptorchidism, shawl scrotum, hypospadias		
	Occasional renal anomaly		
	Gastroesophageal reflux		
NA	Orthopedic abnormalities:	Possible fasting hypoglycemia from 10 months to 2 to 3 years old: avoid extended perioperative fasting, monitor glucose, use glucose-containing fluids	490
	Short stature, small for gestational age	Consider use of non-triggering anesthetics as malignant hyperthermia has been reported in these patients, although unknown if true malignant hyperthermia or abnormal thermoregulation	491
	Possible scoliosis	-	
	Skeletal asymmetry, limb length discrepancy		

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Russell-Silver syndrome (continued)	Use smaller than predicted endotracheal tube secondary to patient's small size		
		Inverted V-shaped mouth		
84	Schwartz-Jampel syndrome (chondrodystrophica myotonia, myotonic myopathy, dwarfism, chondrodystrophy, ocular and facial anomalies, autocomal recession your	Possible difficult direct laryngoscopy and intubation		NA
	rare, mutation chromosome 1p34-p36, HSPG2 gene which codes for perlecan, a heparin sulfate proteoglycan)			
	Chondrodystrophica myotonia	Micrognathia		
		Small mouth with pursed lips		

Pulmonary	Other	Additional anesthetic considerations	References
	Hemihypertrophy		
	camptodacytly, clinodactyly of fifth finger		
	Possible congenital hip dysplasia		
	Gastrointestinal abnormalities:		
	Feeding problems		
	Gastroesophageal reflux: at risk for aspiration		
	Esophagitis		
	Genitourinary abnormalities:		
	Cryptorchidism		
	Hypospadias, posterior urethral valves		
	Renal anomalies		
	Possible inguinal hernia		
	Associated with testicular seminoma, hepatocellular carcinoma, Wilms tumor, craniopharyngioma		
	Café au lait spots		
	Possible growth hormone deficiency		
	Excess sweating during infancy		
	Possible bluish sclearae during infancy		
	Prone to hypothermia		
Pectus carinatum			492
Kyphoscoliosis can lead to restrictive lung disease	Characteristic facies:	Generalized myotonia: can be induced by anesthetic or surgical manipulation, cold or shivering – keep normothermic	493
Possible aspiration pneumonia	Fixed, mask-like facies	Myotonia is not prevented or reversed with muscle relaxants or regional anesthesia	494

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Schwartz-Jampel syndrome (continued)	Short neck with decreased range of motion Small larynx, high- pitched voice Jaw muscle rigidity		
			Muscle hypertrophy or atrophy Mental retardation	
85	Sickle cell disease (autosomal recessive, 1:5000 overall, 1:500 African Americans, mutation chromosome 11p15.5, beta globin)	Prominent maxilla from increased marrow space	Transient ischemic attacks	Congestive heart failure
			Strokes	Myocardial fibrosis
			Peripheral neuropathy	Hemolytic anemia
			Chronic pain syndrome	Increased risk of pre-eclampsia during pregnancy

Pulmonary	Other	Additional anesthetic considerations	References
Possible respiratory distress, postoperative complications	Narrow palpebral fissures, blepharophimosis, myopia	Can infiltrate muscle with local anesthetic to attenuate contraction	495
	Orthopedic abnormalities:	Avoid succinylcholine due to risk of hyperkalemia	496
	Short stature	Avoid anticholinesterase drugs for reversal of non-depolarizing muscle relaxants as they can precipitate myotonia: use shorter acting muscle relaxants that do not need reversal	
	Progressive joint contractures with joint limitation: need careful positioning	Possible resistance to rocuronium has been reported	
	Carpal tunnel syndrome		
	Bowing of long bones, ankle valgus, pes planus		
	Kyphoscoliosis, lumbar lordosis		
	"Marionette-like" gait		
	Gastrointestinal/genitourinary abnormalities:		
	Umbilical and inguinal hernias		
	Small testes		
Acute chest syndrome leads to pulmonary infarctions	Orthopedic abnormalities:	Perioperative recommendations:	497
Intrapulmonary right-to-left shunting from bronchopulmonary anastomoses	Aseptic necrosis of hip	Avoid cold, stasis, exertion, infection, dehydration, acidosis, and hypoxemia	498
Airway hyperreactivity	Skeletal deformities from marrow hyperplasia and pain crisis, including dactylitis	Treat hypotension with fluids rather than vasopressors	499
Pulmonary hypertension	Bone infarcts with arthropathies	Possible tolerance to narcotics from treatment of pain from vaso-occlusive crises, may require larger doses	500
Restrictive lung disease	Thoracic kyphosis, lumbar lordosis	Perioperative Transfusion in Sickle Cell Disease Study Group compared aggressive transfusion to hemoglobin S <30% to conservative regimen of preoperative transfusion to hemoglobin 10 g/dL with no specific hemoglobin S level. Conservative regimen was as effective in preventing perioperative complications as the aggressive regimen and was associated with fewer transfusion-related adverse events	501 (Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Sickle cell disease (continued)			
86	Smith-Lemli-Opitz syndrome (Rutledge lethal multiple congenital anomaly syndrome, polydactyly, sex reversal, renal hypoplasia, unilobar lung, lethal acrodysgenital syndrome, autosomal recessive, 1:20–40,000, mutation chromosome 11q12-q13, DHCR7 gene: reduces or eliminates the activity of 7-dehydrocholesterol reductase, preventing cells from producing enough cholesterol)	Possible difficult direct laryngoscopy and intubation	Hypotonia in young children, hypertonia in older children	Congenital heart disease, especially tetralogy of Fallot and ventricular septal defect
		Microcephaly	Demyelination of brain and peripheral nerves	
		Micrognathia	Hypoplasia and abnormal morphogenesis of brain structures	
		Cleft palate, small and hard tongue	Seizures	
		Short nose with anteverted nostrils	Mental retardation	

Pulmonary	Other	Additional anesthetic considerations	References
Obstructive sleep apnea due to adenotonsillar hypertrophy	Growth failure	Minor or low-risk surgeries may not require preoperative transfusion	502
	Gastrointestinal abnormalities:		503
	Splenic sequestration of red cells and platelets		
	Autoinfarction of spleen leading to immune incompetence against encapulated bacteria, including pneumococci and <i>Haemophilus</i>		
	Gallstones		
	Intrahepatic sickling can be painful		
	Genitourinary abnormalities:		
	Polyuria, proteinuria, inabilitiy to concentrate urine (avoid hypovolemia)		
	Chronic renal insufficiency		
	Pyelonephritis, glomerulonephritis		
	Renal papillary necrosis		
	Painful priapism		
	Increased risk of pre-eclampsia, placental abruption, placental previa, and intrauterine growth retardation during pregnancy		
Pulmonary hypoplasia, single-lobed lungs	Caused by an inborn error in cholesterol biosynthesis	NA	504
Recurrent aspiration leading to pneumonia	Charcteristic facies:		505
	Microcephaly		506
	High, square forehead		507
	Ptosis, epicanthal folds, strabismus, cataracts		
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Smith-Lemli-Opitz syndrome (continued)	Short neck	Behavior problems	
		Prominent incisors		
87	Spinal muscular atrophy (SMA) types I and II (Werdnig-Hoffmann disease) (autosomal recessive, all types: 1:10,000 total incidence)	Type I:	Type I:	NA
		Difficulty handling secretions due to swallowing problems	Hypotonia, weakness, no deep tendon reflexes	
		Tongue atrophy and fasciculations	Normal intelligence	
	SMA I – acute Werdnig- Hoffmann disease, acute infantile SMA (autosomal recessive, 1:25,000, mutation chromosome 5q12.2-q13.3, SMN1 gene: regulates telomeres)	Type II:	Type II:	

Pulmonary	Other	Additional anesthetic considerations	References
	Low-set ears		
	Short nose with anteverted nostrils		
	Orthopedic abnormalities:		
	Syndactyly of second and third toes		
	Postaxial polysyndactyly		
	Simian crease, flexed fingers		
	Dislocated hips		
	Gastrointestinal abnormalities:		
	Feeding problems, failure to thrive		
	Gastroesophageal reflux, vomiting		
	Hepatic dysfunction		
	Hirschsprung disease, rectal atresia, pyloric stenosis		
	Genitourinary abnormalities:		
	Hypospadias, cryptorchidism		
	Ambiguity of external male genitalia with micropenis		
	bifid or hypoplastic scrotum		
	Male pseudohermaphroditism		
	Renal hypoplasia, renal duplication		
	Ureteropelvic junction obstruction		
	Hydronephrosis, renal cysts		
	Possible adrenal insufficiency		
Type I:	Type I:		508
Respiratory distress	Usually diagnosed age <6 mo		509
Shallow respirations	Death from respiratory failure by age 2 yr without mechanical ventilation		
Paradoxical respiratory pattern with diaphragmatic breathing	Type II:		

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Spinal muscular atrophy (SMA) types I and II (continued)	Tongue atrophy and fasciculations in half of patients	Fine tremor of hands	
			Decreased to absent deep tendon reflexes	
			Normal intelligence	
	SMA II – chronic Werdnig- Hoffmann disease, intermediate SMA (mutation chromosome 5q12.2-q13.3, SMN1 gene: regulates telomeres)			
88	Spinal muscular atrophy type III (Kugelberg- Welander disease) (juvenile spinal muscular atrophy, mild SMA, autosomal recessive, mutation chromosome 5q12.2-q13.3, SMN1 gene: regulates telomeres)	NA	Muscle atrophy and weakness initially affects the proximal limb muscles then progresses distally	NA
			Possible calf pseudohypertrophy	
89	Stickler syndrome (arthro- ophthalmopathy, hereditary progressive, autosomal dominant, 1:7500–9000, mutation chromosome 12q13.11-q13.2, genes: COL2A1, COL11A1, COL11A2, COL9A1, abnormal collagen type II and XI)	Possible difficult direct laryngoscopy and intubation	Sensorineural or conductive hearing loss	Mitral valve prolapse
		Micrognathia		

Other	Additional anesthetic considerations	References
Intermediate severity		
Diagnosed from age 7 to 18 months		
Cannot walk independently but can sit unaided		
Orthopedic abnormalities:	May require postoperative ventilation	
Type II – kyphoscoliosis, possible calf hypertrophy	Avoid succinylcholine due to risk of exaggerated hyperkalemia	
	Variable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring	
Usually diagnosed in early toddler years to as late as adolescence	Avoid succinylcholine due to risk of exaggerated hyperkalemia	508
Normal life expectancy	Variable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring	509
Males more severely affected		510
Orthopedic abnormalities:		
Kyphoscoliosis and contractures		
Connective tissue disorder	NA	511
	Other   Intermediate severity   Diagnosed from age 7 to 18 months   Cannot walk independently but can sit unaided   Orthopedic abnormalities:   Type II – kyphoscoliosis, possible calf hypertrophy   Usually diagnosed in early toddler years to as late as adolescence   Normal life expectancy   Males more severely affected   Orthopedic abnormalities:   Kyphoscoliosis and contractures   Connective tissue disorder	Other Additional anesthetic considerations   Intermediate severity Intermediate severity   Diagnosed from age 7 to 18 months Intermediate severity   Cannot walk independently but can sit unaided Intermediate postoperative ventilation   Orthopedic abnormalities: May require postoperative ventilation   Type II - kyphoscoliosis, possible calf hypertrophy Avoid succinylcholine due to risk of exaggerated hyperkalemia   Valiable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring Valriable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring   Normal life expectancy Valriable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring   Normal life expectancy Valriable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring   Nales more severely affected Intervention   Orthopedic abnormalities: Yariable sensitivity of non-depolarizing muscle relaxants: recommend avoidance or monitoring   Yaphoscoliosis and contractures Intervention   Connective tissue disorder NA

Characteristic facies:

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Stickler syndrome (continued)	Midface hypoplasia with flat nasal bridge, anteverted nares		
		Cleft palate, tooth abnormalities		
		May have associated Pierre Robin syndrome		
90	Sturge-Weber syndrome (encephalotrigeminal angiomatosis, sporadic, unclear inheritance, 1:50,000, no chromosome abnormality identified)	Possible difficult mask ventilation and intubation	Capillary or cavernous hemangiomas (port wine stains, nevus flammeus) in the cutaneous distribution of the first or second division of the trigeminal nerve	High output heart failure due to shunting
		Angiomas of tongue or larynx can interfere and rupture	Leptomeningeal angiomatosis usually ipsilateral to the facial cutaneous vascular malformation	Possible congenital heart defects
		Angiomas of the mucous membranes	Spinal cord hemangiomas: verify absence prior to neuraxial anesthesia	
		Possible hypertrophy of bones and soft tissues in regions adjacent to areas of facial angioma	Seizures	
			Mental retardation	
			Linear intracranial calcifications	
			Hemiatrophy of brain	

Pulmonary	Other	Additional anesthetic considerations	References
	Flat facies: with flat nasal bridge, anteverted nares		513
	Epicanthal folds		
	Orthopedic abnormalities:		
	Hyperextensible joints, joint pains		
	Marfanoid habitus, arachnodactyly		
	Short stature, narrow long bones		
	Scoliosis, kyphosis, lumbar lordosis		
	Herniation of thoracic disks, flat vertebrae		
	Hip subluxation, clubfoot deformity		
	Early-onset osteo-arthritis		
	Ocular abnormalities:		
	Myopia, dislocated lens, glaucoma, chorioretinal degeneration		
	Retinal detachment, cataracts		
	Vision loss		
Vascular abnormalities in the lung	Characteristic facies:	NA	514
	Facial port-wine stain, or angioma, in distribution of trigeminal nerve		515

	Optic atrophy		
	Gastrointestinal abnormalities:		
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	<b>Sturge-Weber syndrome</b> (continued)		Hemiplegia: avoid succinylcholine Behavior problems Headaches	
91	Thrombocytopenia-absent radii (TAR) syndrome (inheritance unclear, 1:250,000, chromosome deletion at 1q21.1, 11 candidate genes)	Possible micrognathia	Possible intracranial hemorrhage	Congenital heart defects:
		Avoid nasal intubation or nasal gastric tubes due to risk of epistaxis		Tetralogy of Fallot
				Coarctation of the aorta
				Atrial septal defect
92	Treacher Collins syndrome	Possible difficult to	Normal intelligence	Concenital heart defects possible
92	Treacher Collins syndrome (mandibulofacial dysostosis; Franceschetti-Klein syndrome, autosomal dominant, 50% <i>de novo</i> mutations, 1:50,000, mutation chromosome 5q32- q33.1, TCOF1 gene (treacle: ribosomal DNA transcription)	Possible difficult to impossible direct laryngoscopy and intubation	Normal intelligence	Congenital heart defects possible

Pulmonary	Other	Additional anesthetic considerations	References
	Colonic ischemia		
	Hematemesis from gastric bleeding		
	May be associated with Klippel-Trenaunay-Weber syndrome		
NA		Thrombocytopenia (congenital or develops in infancy); episodes decrease with age: need preoperative platelet count, hematocrit	518
	Characteristic facies:		519
	Port-wine stain on forehead		
	Ptosis strahismus		
	Small unturned nose		
	Orthonedic abnormalities:		
	Bilateral absence of radii with the presence of both thumbs		
	Hypoplastic or absent (unilateral or bilateral) ulnae		
	Abnormal humerus or shoulder		
	Dislocated hips, knee subluxation, coxa valga		
	Dislocated patella, femoral and tibial torsion		
	Small feet, abnormal toe placement, foot edema		
	Small stature		
	Arthritis of ankle and knees		
	Gastrointestinal abnormalities:		
	Pancreatic cysts, Meckel diverticulum, hepatosplenomegaly		
	Cow's milk intolerance		
	Various renal anomalies		
Sleep apnea	Characteristic facies:	NA	520

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Treacher Collins syndrome (continued)	Malar hypoplasia with possible cleft zygoma		
		Mandibular and pharyngeal hypoplasia: leads to narrow airway		
		Small mouth		
		High arched palate, cleft palate or cleft lip		
		Teeth malocclusion		
		Patient may need to be placed in prone position to assist in spontaneous ventilation as tongue may fall back into pharynx		
93	Trisomy 13 (Patau syndrome, sporadic, meotic non- dysjunction, 1:10,000, chromosome 13 trisomy)	Possible difficult direct laryngoscopy and intubation	Hypotonia	Congenital heart defects:
		Microcephaly: may require smaller than predicted endotracheal tube size	Myelomeningocele	Ventricular septal defect, tetralogy of Fallot
		Wide sagittal suture and fontanelles		Double-outlet right ventricle
		May require smaller than predicted endotracheal tube size	Developmental delay	
		Cleft lip or cleft palate	Febrile seizures	
		Short neck	Holoprosencephaly with agenesis of corpus callosum	
		Micrognathia	Cerebellar hypoplasia

	Low-set ears with external canal atresia: conductive deafness		
	Absent parotid gland		
	Genitourinary abnormality:		
	Possible cryptorchidism		
Possible apnea: monitor postoperatively	Characteristic facies:	Spinal dysraphism: confirm absence prior to neuraxial technique	525
Pectus carınatum	Microcephaly with occipital scalp defect		526
Kypnoscollosis	Low-set ears, adhormal helices		
	Broad, flat nose		
	Microphthalmia anophthalmia cataracts		
	Optic nerve hypoplasia, limited vision		
	Short neck		
	Capillary hemangioma on forehead		
	Gastrointestinal abnormalities:		(Continued)
			(Continued)

No.	Syndrome: name, eponyms, inheritance, incidence, gene locus, gene product	Airway	Central nervous system	Cardiovascular
	Trisomy 13 (continued)			
94	Trisomy 18 (Edwards syndrome, sporadic, meotic non-dysjunction, 1:6–8000, chromosome 18 trisomy)	Possible difficult direct laryngoscopy and intubation	Sensorineural hearing loss	Greater than 95% incidence of cardiac defects:
		Microcephaly, prominent occiput, narrow bifrontal diameter	Severe mental retardation	Ventricular septal defect, atrial septal defect, patent ductus arteriosus, bicuspid aortic valve
		Micrognathia	Hypotonia in neonatal period	Pulmonic stenosis, coarctation of the aorta
		Cleft lip or cleft palate	Hypertonia after neonatal period	Aberrant subclavian artery: confirm absence prior to placement of subclavian central venous line
			Possible holoprosencephaly	

Pulmonary	Other	Additional anesthetic considerations	References
	Microscopic pancreatic dysplasia		
	Malrotation, omphalocele, Meckel diverticulum		
	Genitourinary abnormalities:		
	Unilateral renal agenesis, renal and urogenital		
	duplication		
	Hydronephrosis, polycystic kidneys		
	Renal insufficiency		
	Cryptorchidism, hypospadias		
	Hypoplastic ovaries, abnormal insertion of fallopian tubes		
	Orthopedic abnormalities:		
	Polydactyly of hands, possibly feet		
	Flexion deformities of hands, simian crease		
	Radial aplasia		
	Prominent heel, rockerbottom feet, clubfoot deformity		
	Joint subluxation		
Short sternum	Characteristic facies:	NA	527
Possible diaphragmatic muscle hypoplasia	Microcephaly, prominent occiput		528
Absent or malformed right lung	Short palpebral fissures		
Recurrent apnea in neonatal period	Epicanthal folds, ptosis, corneal opacity		
	Low-set, malformed ears		
	Gastrointestinal abnormalities:		
	Omphalocele, Meckel diverticulum, malrotation		
	Anal anomalies, ectopic pancreatic or splenic tissue		
	Failure to thrive		
	Genitourinary abnormalities:		
	Cryptorchidism		
	Ectopic kidneys, horseshoe kidney, polycystic kidney		
	Hydronephrosis, duplication of collecting system		
			(Continued)

	Contractures, especially knees and fingers: needs careful intraoperative positioning		
	Gastrointestinal abnormalities:		
	Hepatomegaly, chronic liver disease, jaundice, cirrhosis, albuminuria: confirm absence of coagulopathy prior to neuraxial technique		
	Genitourinary abnormalities:		
	Impaired adrenal cortical function or atrophy: may need stress dose steroids		
	Renal cortical cysts		
	Cryptorchidism		
	Less severe forms include neonatal adrenoleukodystrophy and infantile Refsum disease		

## CHAPTER 39 Pediatric Anesthesia in Developing Countries

### Adrian T. Bosenberg

Department of Anesthesia, Seattle Children's Hospital, Seattle, WA, USA

Organization, 1140	Types of surgery, 1147	Conclusion, 1149
Equipment procurement and maintenance,	Anesthesia monitoring and drugs, 1147	Case study, 1150
1143	Postoperative pain relief, 1148	Annotated references, 1151
Evaluation of patients, 1145	Follow-up care, 1149	

### Organization

Children constitute more than half the population in many developing countries [1–3]. Many of these children are victims of circumstance, orphaned by HIV [3,4], natural disasters, war, social unrest, economic crises, and famine (Figs 39.1, 39.2). Providing anesthesia for children in the developing world can be very challenging [5–9] because for the most part anesthetic practice has not kept pace with the advances made in the developed countries [7]. Our understanding of anesthesia in the developing world is based on personal experience or anecdotal reports provided by local healthcare workers or visitors on medical missions. This reflects the low incentive to publish in the face of a heavy clinical workload and staff shortages.

Many developing countries have a colonial history and were exploited for their raw materials. The infrastructure was developed for the benefit of the colonial power and not the country or region [2,3]. As a result, many of these countries are today characterized by poverty, poor housing and educational standards, limited health resources and social services [1,5,7–13]. Of the world's poorest countries, 70% are in sub-Saharan Africa [11–13], an area ravaged by HIV, malaria, and tuberculosis [4].

Access to safe anesthesia and pain relief following surgery is considered a basic human right in the 21st century. International standards for the safe practice of anesthesia, adopted by the World Federation of Societies of Anaesthesiologists (WFSA) in 1992, are seldom met in developing countries [5]. Provision of safe anesthesia requires trained anesthetists, essential equipment, consumables, and drugs [14–19]. All these essentials are seldom found in the operating rooms of the developing world [17–19]. The anesthetic issues published in previous decades persist and, in many instances, are remarkably similar to those seen today [2,13,20–23]. Improving the safety of surgery and anesthesia worldwide, but particularly in the developing world, has finally become the focus of the World Health Organization (WHO) and WFSA [17–21].

Different countries have different problems demanding different solutions. Conditions may even vary significantly within the same country [2,5]. The essential differences include the medical personnel and their level of training, the spectrum and nature of disease, the facilities, including access to electricity and running water, the equipment available, and access to cheap, generic and perhaps outmoded drugs [8,22–24] (Fig. 39.3). The ratio of anesthetists to population varies greatly (Table 39.1, Fig. 39.4). It is not surprising that perioperative mortality and morbidity are high by developed world standards and, not surprisingly, inversely related to the anesthetic manpower [25]. The expectations of the local population are often commensurate with the facilities and quality of the available care.

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

Anesthesia does not enjoy a high profile and lacks the voice to demand access to resources in developing countries. Anesthesia is not perceived to be an attractive career for many undergraduates [26–28] who receive little, if any, exposure to the specialty [29–31]. Indeed, very few developing countries can afford specialist anesthesiolo-

**Figure 39.1** Victims of war. Mutilating injuries acquired almost two decades ago during the Rwandan genocide received basic treatment only. Child survivors face an intense struggle for survival as a consequence of displacement, separation from or loss of parents, poverty, hunger and disease in countries that are subject to total collapse of economic, health, social and educational infrastructures.

gists, except perhaps in the principal hospitals. The "pediatric anesthesiologist" is invariably someone who may have a special interest or affinity for children or has simply been allocated to pediatric anesthesia for the day because there is no one else. Pediatric anesthesiologists *per se* are a luxury.

Table 39.1	Anesthetic	mortality	per	100,000	and	the	year	reported

Year	Country	Anesthetic death rate	Hospital setting	Reference
1987	Zambia	1:1925	University/ teaching	21
2000	Malawi	1:504	Central	21
1994– 2001	Zimbabwe	1:482	District	21
2006	Nigeria	1:387	Teaching	21
2005	Тодо	1:133	Teaching	21
2007	Pakistan	1: 5556	University	21
2002	Ghana	1:1250		96
2007	Benin	1:103	University	106
1996– 2004	Brazil	1:1020	Tertiary / teaching	107
1992– 2006	Pakistan	1:2888	University/ teaching	108
1987	United Kingdom	1:185,000		21

Data from Walker and Wilson [21] and others [106-110].

**Figure 39.2** Traditional healers and tribal customs. Traditional healers play a significant role in healthcare. (A) A potion had been placed over this baby's fontanelle to close it. (B) Keloid. Extensive keloid formation after injury or tribal scarification is a common complication in Africa. Tribal ear piercing as a child led to this disfiguring keloid formation. Access to specialist treatment is limited. (C) Uvulectomy. This child had a uvulectomy performed to ward off "evil spirits" and treat a sore throat.

**Figure 39.3** Anesthesia equipment. (A) Boyles machine. Considered obsolete in many developed countries, this machine was used to provide anesthesia for a newborn. The 2L bag on the T piece was patched with zinc oxide tape and was used by the author to successfully resuscitate a newborn delivered by emergency caesarean section. (B) Drug cupboard. Anesthetic supplies are basic, similar colored glass ampoules are poorly labeled and almost illegible. The risks of administering the wrong drug, as a result, are high. (C) Diathermy. A steel plate with poor connections places the child at risk of an electrical burn.

**Figure 39.4** Anesthesia providers per 100,000 people. DRC, Democratic Republic of the Congo; UK, United Kingdom; US, United States. Data from Dubowitz et al [25] and Bridenbaugh [109].

In 1996 the Education Committee of the WFSA set out to establish pediatric anesthesia fellowship training programs. The aim was to train individuals from a medically disadvantaged country in a more medically advanced country, ideally in their own language [17]. Whether this training should take place on site within a given country or off site in an established program has been a topic of debate recently [31–39].

Through a WFSA-driven sponsorship program, a cohort of pediatric anesthesiologists is being trained in Chile [36], Tunisia, South Africa, and soon Kenya [17,32,35]. The advantage of this training is that the trainees are exposed to similar problems to those they would encounter in their own country. On completion of their training, they must return to their country of origin and champion the development of pediatric anesthesia as a speciality [2,17,32]. In those countries where a training program has been developed,

the value of a pediatric anesthesiologist is enormous [17,35].

The vast majority of anesthetics are delivered by nonphysicians [2,5,13,40], a reality that has remained constant over many decades. Supervision of "non-physician anesthetists" or "anesthetic officers" is invariably inadequate [31,32,41,42] and access to textbooks, journals or other medical literature is limited [2,5,13]. Internet access and communication, considered the norm in the developed world, are limited given that functional computers are scarce and electrical supplies and telecommunication networks are unreliable.

Some countries, such as Nigeria, Kenya and India, have trained significant numbers of physician anesthetists, but these physicians tend to practice in large hospitals in urban areas [2,6]. The majority of anesthetics in rural communities are still provided by nurses or unqualified personnel, with little medical background, who are "trained on the job" [2,5,13,40]. In many African [43] and Asian countries [44], the doctor/patient ratio is so low that the ideal of employing a physician specifically to provide routine anesthesia is out of the question [2,25,27]. Salaries are insufficient to attract suitably trained and qualified practitioners for more than short periods. Emigration of scarce trained personnel to developed countries in search of better salaries and an improved lifestyle exacerbates these shortages [2,26,27,45].

### Equipment procurement and maintenance

Essential equipment to provide safe anesthesia for children, particularly neonates, is often lacking [2,12-14,16,40,46] (Fig. 39.3). Neonatal or pediatric ventilators are virtually non-existent outside the main centers [12]. Syringe pumps and other control devices are impractical in environments that have an erratic electricity supply. Laryngoscopes, both metal and plastic, are usually available but generally not well maintained. Even batteries may be in short supply and light bulbs unreliable. Endotracheal tubes in the full pediatric range are rarely found; disposable endotracheal tubes are consequently recycled [14] as there is little or no alternative. Laryngeal mask airways (LMA) in pediatric sizes are considered a luxury. Intravenous fluids are very expensive if not manufactured locally, and many developing countries do not have any local production facilities [6]. The choice of intravenous fluid is therefore limited and in relative short supply.

Unreliable electrical supplies add to the challenges in the developing world. In many hospitals, particularly in rural areas, neither mains electricity nor reliable and functional back-up generators are available [2,5,47]. General facilities for infection control, such as running water, disinfectants or gloves (sterile or non-sterile), are not constantly available even though the reuse of disposable equipment is "normal" practice in many countries [5,13,14,48].

Anesthetic machines fall into two categories: modern sophisticated machines or simple low-maintenance equipment [47]. Modern electronic machines, provided by well-meaning international donors, have a poor track record in austere environments [1,2,12–14]. Sophisticated equipment needs to be understood but operating manuals provided in a foreign language are of no benefit. Sophisticated machines require maintenance and technicians trained to repair them. Service contracts are not considered viable. Unfortunately, these machines are consequently discarded when the first fault occurs. Guarantees are unlikely to be honored and faults are considered too expensive to repair. Poorly maintained equipment becomes hazardous and even life threatening in untrained hands [47].

Simplicity and safety have long been the key to anesthetic equipment in developing countries [6,13,14,49–51]. Ideally the anesthetic machine should be inexpensive, versatile, robust and able to withstand extreme climatic conditions (temperature (hot or cold), humidity, dust and altitude), able to function even if the supply of cylinders or electricity is interrupted, easy to understand and operate by those with limited training, economical to use, and easily maintained by locally available skills [51-53]. The cheapest, most practical, and most widely used anesthetic is inhalational anesthesia administered through an EMO (Epstein Macintosh Oxford) or OMV (Oxford miniature vaporizer) draw-over vaporizer [14]. Oxygen concentrators supplement oxygen delivery and eliminate the need for expensive oxygen cylinders whose reducing valves are often faulty or destroyed in austere environments. The most appropriate ventilator is the Manley multivent ventilator, which essentially functions like a mechanical version of the OIB (Oxford inflating bellows) and can be used with a draw-over system [53].

A general scheme for inhalation anesthesia in developing countries is shown in Figure 39.5 [54], first proposed by Ezi Ashi et al [55]. Four different modes can used and can be modified according to the available supplies and services. The basic mode A is for use when there is no electricity and no supply of compressed gases. The apparatus consists of a low-resistance vaporizer, linked by valves to the patient to act as a draw-over system with room air as the carrier gas. The self-inflating bag or hand bellows makes it possible to provide artificial ventilation while the vaporizer remains as a draw-over. The addition of low-flow oxygen to the inspired gas (mode B) is dependent on the availability of an oxygen cylinder. The addition of a length of reservoir tubing to the circuit

anesthesia with air, spontaneous ventilation or self-inflating bags. Draw-over vaporizers are required. Mode B provides oxygen enrichment but requires the availability of oxygen cylinders. Plenum vaporizers can be used. Mode C requires electricity to power the oxygen concentrator, air compressor, and/or ventilator. A mechanical ventilator, e.g. Manley, does not require electrical power. Mode D requires a Boyles machine and nitrous oxide cylinders. 1. T piece with reservoir tube and facemask; 2. Ambu Paedi valve; 3. self-inflating bag (Ambu); 4. Oxford inflating bellows (OIB); 5. Oxford miniature vaporizer (OMV) with halothane; 6. OMV with trichloroethylene; 7. EMO vaporizer with ether. These circuits and manual ventilators are interchangeable and ether, halothane, and trichloroethylene can be used on their own or in series. 8. Farman's entrainer with an oxygen cylinder (9) can be used to supplement oxygen or an electrical power source (10) is available with an oxygen concentrator (11), air compressor (12) or Manley ventilator (13). Nitrous oxide (14) and Boyles apparatus (15) allow anesthesia practice equivalent to that of developed countries.

enables oxygen to be stored on expiration, to be used on the next inspiration, making it substantially more economical [56].

When electricity is available (mode C) the operation of the anesthetic apparatus can be extended by permitting (a) the use of an air compressor to provide continuous gas flow (which in turn will allow the use of a Boyles apparatus and plenum vaporizer); (b) oxygen concentrator; and (c) ventilators. When nitrous oxide is available (mode D) all types of inhalation anesthesia currently available in developed countries can be practiced. In situations where services and supplies are interrupted even acutely, it is possible to change from one mode to another without requiring other anesthetic apparatus. Draw-over anesthesia enables inhalation anesthesia to be administered using atmospheric air as the carrier gas [14]. The essential features of this system consist of a calibrated vaporizer with sufficiently low resistance (EMO and OMV) to allow the negative pressure created by the patient's inspiratory effort to draw room air through the vaporizer during spontaneous ventilation. Positive pressure ventilation can be provided by means of a selfinflating bag or bellows (OIB), with a valve to prevent the gas mixture re-entering the vaporizer, as well as a unidirectional valve at the patient's airway to direct expired gases to the atmosphere, preventing rebreathing (mode A, Fig. 39.5). In this way an anesthetic can be administered in the absence of compressed gases. The vaporizer has an inlet for supplementary oxygen that can be attached to the oxygen output tube of an oxygen concentrator, or oxygen cylinder if available (modes B and C, Fig. 39.5).

The EMO (Penlon Ltd) and the OMV (Penlon Ltd) are the more commonly used low-resistance vaporizers [14]. The EMO is only calibrated for ether but its performance is linear for other agents. The OMV is calibrated for a variety of agents [51,53]; despite the lack of temperature compensation, its performance is stable under most conditions. Both these vaporizers have been used successfully in pediatric anesthetic practice [23] but it is recommended that they be converted to form a T-piece for greater safety.

The OMV has been evaluated as a simple draw-over system for pediatric anesthesia. Wilson et al [46] showed that when a self-inflation bag is used in a draw-over mode, more efficient vaporization occurs despite vaporizer cooling. However, the respiratory efforts of neonates or weak infants are insufficient to operate the valve mechanisms of the self-inflating bag, e.g. Ambu bag, necessitating continuous assisted ventilation even in the presence of ether, which stimulates ventilation.

Oxygen concentrators can improve oxygen availability, independent of compressed gas and electrical power supply, by linking oxygen concentrators to a draw-over anesthetic apparatus as first described by Fenton [14,57]. Maintenance requirements are low and servicing is recommended only after approximately 10,000 hours of usage. The benefits are enormous but a reliable electricity supply is critical.

The concentrator functions by using a compressor to pump ambient air alternately through one of two canisters containing a molecular sieve of zeolite granules that reversibly absorbs nitrogen from compressed air [53,58]. The controls are simple and comprise an on/off switch for the compressor and a flow-control knob to deliver 0–5L/min. Flow of oxygen continues uninterrupted as the canisters are alternated automatically so that oxygen from one canister is available while the other regenerates. A warning light on a built-in oxygen analyzer illuminates if the oxygen concentration is <85% and the concentrator switches off automatically when the oxygen concentration is <70%. This is heralded by visual and audible alarms. Air is then delivered as the effluent gas. Modern machines are relatively silent.

The oxygen output of the concentrator depends on the size of the unit, the inflow of oxygen, the minute volume, and pattern of ventilation. The addition of dead space (or oxygen economizer tube) at the outlet improves the performance, and predictable concentrations >90% oxygen can be obtained with flows between 1 and 5L/min independent of the pattern of ventilation. Much lower concentrations and less predictability were noted when the dead space tubing was omitted [56].

The possible hazards of oxygen concentrators are few, provided they are positioned in the operating room so that the in-draw area is free from pollutants. Failure of power supply or failure of the zeolite canisters will result in the delivery of ambient air. A bacterial filter at the outlet combined with the use of dust-free zeolite should prevent contamination of the delivered gas. Dirty internal air filters may produce lower oxygen concentrations and must be checked. An oxygen storage tank and booster pumps afford protection against the vagaries in electrical supply.

Intravenous fluid administration must also be given careful consideration [2]. Small intravenous cannulas are a precious commodity and butterfly needles are still used (and in some cases reused!) [59]. Syringe pumps and other control devices are impractical in environments that have an erratic electricity supply [2]. Unmonitored IVs can have disastrous consequences including volume overload, sepsis, tissue loss, compartment syndrome or even loss of limb [2]. The choice of intravenous fluid is often limited and in short supply [2,53,60].

### **Evaluation of patients**

The burden of disease in the poorest countries is formidable. Children of the developing world are victims of circumstance, natural disasters, war, social unrest, and economic crises [8,12,61–65]. An estimated 10 million children die annually before their 5th birthday [5,64,66]; that is one of every six children born in Africa, and one of every 12 children born in South Asia [5]. Approximately 50% of these deaths occur in the neonatal period [5] and birth asphyxia, prematurity, sepsis, and tetanus are the major causes. In the older child diarrhea, pneumonia, malaria, HIV/AIDS, measles, and trauma are major causes [5,64,67].

For many in rural areas, timely access to medical care is a remote possibility (Figs 39.1, 39.6) [59,60]. Fear, poor understanding, and lack of education often result in delayed presentation to medical facilities [13,68-70]. Illiterate people in rural areas may simply not be aware that surgical treatment is possible [14]. Superstition may also play a role in compounding the anesthetic risk. Frequently, well-meaning traditional healers have had prior involvement, exposing the child to additional risk (see Fig. 39.2) [2,15,71] caused by potions that may be hepatic-renal toxins or enemas that may perforate the bowel [72-74]. Further delays are engendered when patients have to undertake long journeys to hospital. As a result, dehydration, infection, sepsis, and complications compound the surgical problem and the anesthetic risk. Tertiary referral is often only made when complications arise [8,12,13,40,47,73-75].

**Figure 39.6** Cleft lip and palate. In many developing countries worldwide the failure to provide surgical services may lead to lifelong disability, social exclusion or even premature death. This family all had an isolated cleft lip that had remained unrepaired until they were successfully treated during a volunteer mission with Operation Smile.

Perinatal mortality in some parts of the developing world is 10 times greater than that in developed countries [5,66]. The common denominators include early child-bearing, poor maternal health and, above all, the lack of appropriate and quality medical services. Onethird of pregnant women still have no access to medical services during pregnancy, and almost 50% do not have access to medical services for childbirth [12,61,65]. The majority of parturients deliver at home or in rural health centres [61] where basic neonatal resuscitation equipment is often deficient or non-existent [12]. Those who require surgery may need to be transferred, but specialized transport teams rarely exist.

The safe administration of anesthesia should take into account the pre-existing condition of the child. Preoperative investigations are generally limited, perhaps stretching to hemoglobin and screening for malarial parasites. There are few functional laboratories in the rural areas and trained technicians are virtually nonexistent. Similarly, radiographic studies are often rudimentary and of poor quality [2,9,14]. Even an experienced anesthesiologist with minimal access to laboratory or radiographic investigations and limited in the choice of resuscitation fluid would be challenged to manage these children.

Co-morbidities need to be excluded or treated prior to elective surgery. Tuberculosis (TB) remains an important cause of morbidity and mortality [40,76]. The epidemiology of pediatric tuberculosis is shaped by risk factors such as age, race, immigration, poverty, overcrowding, and HIV/AIDS [48,76–79]. The emergence of drugresistant tuberculosis adds to the burden and is a constant danger to healthcare workers in general and anesthesiologists in particular. Primary TB infection usually does not produce clinical illness in well-nourished immunized children, whereas reactivated pulmonary tuberculosis is a chronic or subacute disease, which may present a variety of challenges for the anesthesiologist. These range from a need to prevent transmission by contamination of the anesthetic circuits to the risks associated with pleural effusions, pulmonary cavitation, and bronchiectasis. Mediastinal and hilar lymphadenopathy may severely compromise the airway.

Primary TB and its complications are more common in children than in adults. Once infected, young children are at risk of progression to extrapulmonary disease [76,77]. *Mycobacterium tuberculosis* can cause symptomatic disease in any organ, and is usually a reactivation of a latent site of infection. The most common sites of reactivation are lymph nodes, bones, joints, and the genitourinary tract. Less frequently, the disease may involve the gastrointestinal tract, peritoneum, pericardium or skin. TB meningitis and miliary TB, both more common in children, carry a high mortality [76]. In view of the high prevalence of HIV infection in tuberculous children, HIV testing should be performed on all children with TB; conversely TB should be sought in all HIV-positive children [78].

Rheumatic heart disease is more common than congenital heart disease in many developing countries, reflecting the socio-economic problems of poverty, overcrowding, malnutrition, and lack of antibiotics. Children often present late with life-threatening symptoms secondary to repeated infections and superimposed endocarditis. The acute deterioration precipitated by endocarditis may be the factor that prompts the search for medical attention. Valve replacement can be life saving but longterm follow-up of anticoagulant therapy is not feasible without laboratory facilities nearby.

Malaria is caused by one of four species of malaria parasites: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Effective and safe prophylaxis against malaria has become increasingly difficult because the species that causes the most severe illness, *P. falciparum*, has become widely resistant to chloroquine and in some areas to other antimalarial drugs as well [80]. Severe malaria even when optimally treated carries a mortality of 10–25% [80]. Prompt diagnosis and early treatment are important determinants of outcome.

Uncomplicated malaria usually presents with flu-like symptoms (fever, headache, dizziness and arthralgia). Gastrointestinal symptoms may predominate and include anorexia, nausea, vomiting and abdominal discomfort or pain that may mimic appendicitis. Malaria in children can present with an acute life-threatening disease or run a chronic course with acute exacerbations. The acute manifestations include three overlapping syndromes: respiratory distress secondary to a severe underlying metabolic acidosis (pH <7.3), usually a lactic acidemia, severe

anemia (Hb <5) that can develop hypovolemia very rapidly even within hours [81], and neurological impairment as a manifestation of cerebral malaria. Seizures are an important presenting feature in 60–80% of cases. Prolonged seizures that are refractory to treatment and those that occur on antimalarial treatment are ominous signs and are usually associated with neurological sequelae or death [81].

Children with chronic malaria adjust physiologically to low hemoglobin levels but may decompensate rapidly when challenged with a febrile illness or surgery. The characteristic physical findings in children with severe anemia are respiratory distress and a hyperdynamic circulation. Blood transfusion may be administered rapidly in these children with metabolic acidosis since most have a depleted intravascular volume. Although controversial, exchange transfusion has been advocated for severe malaria. Unfortunately, many malaria endemic areas also have a high prevalence of HIV, adding significantly to the risk of blood transfusions.

Chronic recurrent malarial infections may manifest with splenic enlargement. This may cause delayed gastric emptying and pose an aspiration risk on induction of anesthesia. The spleen may also enlarge acutely or rupture spontaneously during coughing, vomiting or defecation. Rupture during external cardiac massage has also been described. Malaria may cause bloody diarrhea with massive loss of fluid resembling dysentery in children. Development of renal failure with severe malaria is not uncommon. Malaria may present preoperatively or may complicate the postoperative course. Children in endemic areas who develop postoperative fever must be investigated for malaria. This is especially true if they have had a blood transfusion.

### **Types of surgery**

It is estimated that 85% of children in developing countries will require surgery of some sort before their 15th birthday [4]. Congenital anomalies, trauma (road traffic accidents, assaults, falls, burns, bites, fractures), and infections (abscess, osteomyelitis) make up the bulk of the surgical workload [11–13,68,71]. Burns, particularly in young children, affect resources in many developing countries [60] but especially in sub-Saharan Africa [59].

While the burden of disease is dominated by infections and malnutrition [48], pediatric trauma has low advocacy and as such is given scant attention [5,12,40,68]. Socioeconomic advances in some countries have introduced a new danger in the form of faster, more powerful vehicles without the necessary maintenance culture or road discipline. Trauma prevention strategies are given low priority despite the acknowledged impact it has on the economy of any country. Road traffic accidents are thus inevitable. Additionally, many developing countries are at war and this has led to massive trauma and injuries to children who are both participants in the fighting and innocent bystanders. Effective systems to handle the polytrauma victims that result are hard to find [40]. Even simple bone fractures may have disastrous outcomes. Inappropriate management by traditional bonesetters can result in compartment syndromes or even gangrene [71].

Many pathological conditions, seldom seen in industrialized countries, are more prevalent in developing countries because of poor health education, malnutrition, the close proximity of livestock to humans, earth-floored homes, poor sanitation, and contaminated water supplies.

In some hospitals, neonates are not considered candidates for surgery because "they always die" [56] whereas in others, they undergo surgery without anesthesia [82] because "it's safer" and some still believe that neonates do not feel pain. When surgery is performed on neonates, there are additional challenges, particularly in emergency situations [61]. Not only is there a lack of appropriately sized equipment [40] but it may be extremely difficult to maintain normothermia even in relatively warm climates, let alone provide ventilatory support.

Regrettably, even neonates who have skilful anesthesia and surgery may die because of inadequate postoperative care [13,83]. Overwhelming infection, sepsis, respiratory insufficiency, and surgical complications are the main causes of morbidity and mortality [12,61]. The development of highly specialized neonatal anesthetic and surgical services [51,82,83], essential for a good outcome after neonatal surgery [12,40,61], is a low priority.

### Anesthesia monitoring and drugs

In a recent survey, only 13% of anesthesiologists were able to provide safe anesthesia for children [2]. In this survey the minimal requirements for anesthesia were an oxygen supply, suction apparatus, a pulse oximeter, a tilting table, a pediatric breathing circuit, a laryngoscope, facemasks, endotracheal tubes, oropharyngeal airways, and intravenous cannulas suitable for use in children [2]. Implausible as these findings may seem to those who have not experienced the austere conditions in some parts of the developing world, many anecdotal reports, both recent and in the past, bear witness to this stark reality.

Monitoring is therefore very basic – a precordial stethoscope or a finger on the pulse [6]. Electrocardiogram (ECG) monitoring is used when available but is also dependent on a constant supply of electricity, ECG pads, and proper maintenance. Appropriately sized blood pressure cuffs are scarce, non-invasive blood pressure monitors even more so. Even though pulse oximetry has been shown to be the most useful monitor, and should be available in all centers where pediatric surgery is performed [6,12], this ideal is far from reality. Recently global pulse oximetry has become the aim of a recent WHO initiative (Millennium Goal 4) [5,20]. The current standard of monitoring expected in the developed world is unrealistic.

The supply of anesthetic gases and drugs, particularly to rural medical facilities, is erratic and unreliable [5,14]. Furthermore, the cost of many drugs, particularly the modern agents, has risen beyond the reach of most health budgets. Anesthesiologists in developing countries therefore have to resign themselves to using cheaper agents or generics.

Ether and halothane remain the mainstay of anesthesia in many countries [2,9,13,23,58]. Unfortunately, ether, and more recently halothane, has virtually disappeared from operating rooms in the developed world. As a result, the demand for these cheaper agents has fallen and lack of profitability claimed by some manufacturers has threatened the withdrawal of halothane [1,14]. While this may make commercial business sense, these agents sustain the anesthesia services for millions of patients in the developing world and their loss would have a huge impact [1,14].

In many remote rural areas anesthesia for children remains largely ketamine based [5,13,14,82,84], even when halothane or ether is available. Lack of airway equipment such as tracheal tubes, facemasks or breathing circuits and the perception that intravenous access is not necessary are further reasons for its popularity in this setting [5,69,85]. Ketamine is simple to use, relatively inexpensive, provides anesthesia, analgesia, and cardiovascular stability and some preservation of the airway reflexes [2,6,69]. Ideally ketamine should be used with midazolam to reduce the hallucinatory side-effects. Benzodiazepines, however, are not commonly available.

For developing countries, the cost of nitrous oxide is prohibitive in terms of storage, erratic delivery, and budgetary constraints [55,57]. Closed or semi-closed anesthetic systems are considered dangerous in an environment where the oxygen supply is erratic [45] and agent monitors are not available [14,47]. The erratic supply of soda lime and compressed gas cylinders further limits it use. Consequently, the potential benefits and cost savings of low-flow anesthesia are lost [55]. Scavenging is almost non-existent.

The choice of muscle relaxants is also limited [13]. Suxamethonium, gallamine, curare, alcuronium, or pancuronium are the usual options, and the choice is dictated by their availability or the availability of reversal agents. For this reason, muscle relaxants are not commonly used. Other drugs considered basic to anesthesia are seldom available in the developing world [2,5,13,23]. These include induction agents (propofol), analgesics (morphine, pethidine), reversal agents (naloxone), and longacting local anesthetics (bupivacaine, ropivacaine). Opioid analgesia may not be permitted in some cultures. The ability to deal with complications, such as malignant hyperthermia, is virtually non-existent. Dantrolene is simply too expensive and the shelf-life too short to be cost-effective.

Regional anesthesia has many benefits, in terms of safety, cost savings, and immediate postoperative analgesia [6,12,40,41,61,83,86-89]. Generally, children in developing countries are very accepting of this form of analgesia. However, there seems to be a general reluctance to perform regional anesthesia in children [13,40,90] even in some institutions in the developed world. Possible reasons include lack of training or expertise, fear of failure, and the unavailability of drugs, disposables, and other ancillary equipment (nerve stimulators, portable ultrasound) [41]. Improvisation may be the key. Access to the epidural space can be obtained if the appropriate equipment is not available by using a technique first described before the introduction of pediatric epidural needles into clinical practice. A catheter can be threaded well into the epidural space through an intravenous cannula inserted into the caudal space via the sacral hiatus in neonates and small infants [91]. Furthermore, cheap non-insulated needles can be used, with a nerve stimulator, for peripheral nerve blocks when more expensive insulated needles are not available [92].

### **Postoperative pain relief**

Pain management in children is another factor that divides the developed world from the developing world. Providing pain relief in the face of limited resources, a limited spectrum of analgesics, if available, and inadequately trained staff is a challenge [2,13,14]. Attempting to apply similar standards to those used in sophisticated units is fraught with difficulty. Illiteracy, malnutrition, poor cognitive development, differing coping strategies, pharmacogenetic, cultural, and language differences all add to the complexity of the problem [93,94].

Children of the developing world learn to cope with vastly different problems. Their attitude towards pain, and tolerance thereof, is different. Children from an impoverished background seem more stoical and indifferent to even severe pain. Following cardiac surgery, for example, some appear to need very little pain relief and are easily soothed by lollipops or play therapy [62].

Pain assessment of children from an impoverished background is difficult and may be inaccurate [93,94,95]. Many children in acute pain do not show facial expression. Is this stoicism or simply a reflection of malnutrition, lack of social stimulation, severity of illness or even cultural attitude? Language difficulties, cultural barriers, willingness to share information, emotional expressiveness, and outdated attitudes of the caregiver may sanction this quandary [93,94]. Some societies convey pain readily, while others teach that expression of pain is inappropriate. In many parts of Africa boys are not supposed to express pain. Reporting the pain of testicular torsion, for example, may be delayed and would be considered taboo if the boy lives with his mother only.

Although there are many pain assessment instruments available, few have been validated in children from the developing world [93,94]. There is an urgent need not only to make analgesics universally available but also to develop strategies that can be safely applied to the children of the developing world. Local conditions will dictate their use and applicability. Simple pain management strategies may produce the most benefit with the least risk whereas more complex techniques, that offer the most benefit, require a minimum standard of monitoring and regular reassessment to allow individualized titration of analgesia. These are seldom available. The final choice of analgesia, unfortunately, is dictated by economic pressures or by the facilities available rather than what would be considered in the best interest of the child. Nonetheless, it is morally, ethically and physiologically beneficial to provide children with effective analgesia despite the immense inequalities that exist in our world [93].

### Follow-up care

Perioperative morbidity and mortality are understandably high by developed world standards [5,13,47,49,84]. Facilities considered mandatory for the surgical care of children, such as the provision of adequate analgesia, a recovery area for immediate postoperative observation, ventilatory support or high care following surgery [9,12– 14], are inadequate or non-existent in many parts of the developing world. In some countries pediatric surgery is even considered too expensive to justify these additional needs [12,13].

There is precious little information on the anesthesia morbidity or mortality in developing countries [13,49,50,95]. Fisher et al reported on the incidence of anesthesia-related problems seen by volunteer services working over 18 months [49], which reflects the quality assurance data of trained anesthesia providers working in the developing countries. This is vastly different to the reality where the risks associated with surgery and anesthesia vary widely [22,25] (see Table 39.1). For example, in Ghana a 0.08% mortality for elective surgery was recently reported [96] while there was a 20% mortality for intestinal obstruction of the newborn in a Nigerian teaching hospital [97].

We have little idea of the incidence of problems associated with anesthesia provided by non-physicians,

nurses or unqualified personnel "trained on the job" [13,22,98,99]. In some areas, even today, neonatal surgery may be performed without anesthesia [83] or simply under local infiltration only [84,97,100,101] in an attempt to improve outcome. Understandably, late presentation, respiratory failure, infection or anesthetic complications [83,100,101] are still the major contributors to a poor outcome.

Follow-up care is generally poor. The follow-up visit is generally not considered worth the added financial burden. Long distances, lack of transport, and poor telecommunications prevent patients from returning. Even patients who live nearby are lost to follow-up and seldom return unless there are complications.

### Conclusion

The practice of anesthesia in a developing country will always be challenging, particularly for those who provide anesthesia for children. The challenges vary and it is wise to expect the unexpected and have the flexibility to improvise in the face of an ever-changing world racked by famine, war, violence, natural disasters, and political unrest. The nuances of practice in different communities will inevitably vary and may even challenge some fondly held beliefs in pediatric anesthesia.

Different standards may emerge from different parts of the world. Such standards need not necessarily be considered inferior but may well open the way for the assimilation of new ideas [103]. A safe anesthetic is not necessary the most expensive one. After all, it is generally not the agents that we use but the skill with which we use them that determines outcome. It should never be necessary to depart from the dictum *primum non nocere*. Simplicity may be the key, but there is no place for double standards. Guidelines evolved over time in the UK, USA, and Australia [103,104] may be untenable in many parts of the world, but every attempt should be made to exercise the same standard of care as expected in the developed countries. Our children deserve no less!

What can be done to improve the lot of children who undergo anesthesia in the developing world? Audits of morbidity and mortality are the first steps towards improvement provided action is taken to address the problems uncovered. Publications reflecting outcomes in developing countries have increased over the past decade [105–108] (see Table 39.1). Sending money is another suggestion [105] but unfortunately, with all the goodwill in the world, there is no guarantee that money will ever reach the right people and be put to the best use. Purchasing equipment without subsequent maintenance is wasteful. Disposables are short-lived even if they are recycled. Human resources are needed!

**Figure 39.7** Gastroschisis is a major problem in the developing world. The outcome is poor because of a paucity of facilities for neonates. This baby with significant intrauterine growth retardation was not diagnosed antenatally and presented late for closure. The risk of

sepsis is high. The bowel content (kidney dish) was emptied as far as possible to facilitate closure. Postoperative ventilatory support was not available.

Attracting trained anesthesiologists to work in the developing world is the challenge [1,108–110]. Temporary sojourns with volunteer medical groups are for the most part stimulating but few, if any, of these volunteers are likely to return for longer periods, let alone permanently. Is it the environment? Is it the lack of home comforts? Is it the family that finds it difficult? How much influence does political uncertainty have? Unfortunately, until these questions and many others can be addressed, anesthesia in the developing world, particularly for children, is unlikely to advance [1].

The WHO has also recognized that surgery is a public health issue and has launched the 'Safe Surgery Saves Lives' program. The WHO has also emphasized that safe surgery does not exist without safe anesthesia [2,19–21]. Training anesthesiologists in the skills required for pediatric anesthesia is a slow process. It is hoped that the WFSA program [105] will soon snowball so that children undergoing surgery in developing countries will reap the benefit.

### CASE STUDY

A 1.8kg newborn male with gastroschisis presented to the emergency room of the regional hospital. The baby had been delivered in a remote hut in a village some 5h away. His mother, an 18-year-old primigravida, had not attended antenatal clinic because she lived at least a 1h walk away from the nearest clinic. Her HIV status was unknown. The baby, whose gestational age was unknown, was delivered by a "traditional midwife" who after resuscitation had wrapped the baby in towels and sent the mother to the nearest clinic for further management. On arrival at the clinic after an hour's walk, the baby was clearly hypothermic, had a weak cry and the bowel, that had extruded further, was covered with a green film suggesting meconium staining.

At this point the baby's lower body was placed in a plastic bag and the local ambulance driver was notified that the baby needed to be transported to the regional hospital. The ambulance was undergoing repairs but would only be ready in an hour. There were no IV fluids or antibiotics available at the clinic. There were no laboratory facilities to check the blood glucose, hematocrit, electrolytes or acid– base status; the bottle of "Dextrostix" had expired. The initial examination had been conducted in semi-darkness because of another temporary power outage.

The ambulance finally arrived 2h later and needed to refuel *en route*. On arrival at the regional hospital, the baby's temperature was 34.1°C. The blood glucose measured 25 mg/dL, the urea was elevated and the hematocrit was 54%. No incubator was available, but the child was warmed with an overhead radiant heater. The gastroschisis

was wrapped in cling film, and the child was prepared for surgery. The surgeon was not immediately available because he was busy with an ectopic pregnancy.

A peripheral IV line was started and a bolus of 10 mL/ kg Ringer's lactate was given for resuscitation. Glucose was added after the initial resuscitation. Antibiotics in the form of ampicillin and gentamicin were given intravenously. The general surgeon, who had been working all night, became available after completion of the ectopic pregnancy. The baby was taken to the operating room, anesthesia was induced with halothane, and the trachea was intubated after suxamethonium administration. No other muscle relaxants were available. The lungs were hand-ventilated with a modified Ayre's T piece by the anesthetist who had recently completed his 6 months of "training on the job." There was no scavenging system or suitable ventilator for postoperative ventilatory support. The surgeon aimed to achieve primary closure to improve the chances of survival. A caudal block using 2.5 mL/kg 0.25% bupivacaine with epinephrine 1:400,000 was placed by the visiting anesthesiologist using a 22 G scalp vein needle. The surgeon, in an attempt to reduce the bowel volume, managed to "milk" approximately 30 mL of meconium from the bowel using normal saline irrigation through a Jacques red rubber catheter (Fig. 39.7). The bladder was also emptied (3mL) using Crede's method since there were no urinary catheters available. If primary closure was not possible the surgeon aimed to fashion a "silastic" bag from an intravenous bag. Fortunately this was not needed.

Primary closure was achieved with difficulty. The abdomen was tense but the dorsalis pedis pulse was palpable and there was good capillary refill of both feet. The baby was able to breathe spontaneously but there was no way to measure the increase in airway pressure, blood gases or capnography to evaluate respiratory function. The residual effects of the caudal provided analgesia and some degree of motor block without respiratory depression. Ideally, a caudal catheter could provide continuous or intermittent blockade, but neither a caudal catheter nor a functional infusion pump was available.

The closure was completed within 9 hof delivery. Although closure was achieved as soon as possible, the delay was expected to have a negative influence on the outcome because of the high risk of sepsis [83,102]. The mother's positive HIV status became apparent and both mother and child were started on antiretroviral therapy. The HIV status was not expected to affect the baby's outcome [79]. Early initiation of total parenteral nutrition (TPN) would have been ideal but was not possible because of the budgetary limitations in the regional hospital. Furthermore, neither central venous access nor peripherally inserted central catheters (PICC) were available nor could they be performed at this hospital. Ten percent glucose in quarter normal saline was the only IV fluid available to provide some calories, but its use placed the infant at significant risk of hyponatremia-induced convulsions.

The postoperative course was stormy, punctuated by episodes of sepsis related to infiltrated peripheral IVs, wound sepsis, and minor dehiscence. Enteral nutrition was tolerated by 28 days of age and the baby was discharged after 40 days in hospital and referred for follow-up at the surgery and the HIV clinics.

### Introduction

Complications in the perioperative care of children range from very minor to devastating. This chapter describes some of the most common and severe complications that may be encountered in the day-to-day care of children in the perioperative environment. Limited space prohibits an exhaustive review of all the existing data pertaining to the topic, and for many complications, data, especially pediatric-specific data, are either lacking or insufficient to provide the reader with thoughtful guidance. Nonetheless, for many commonly encountered situations and most serious problems, data are available for clinicians to develop strategies and to stratify risk in a way that allows them to provide the best care possible to the children under their care. Covered in this chapter are cardiac arrest, malignant hyperthermia, toxicity to local anesthetics, propofol infusion syndrome, positioning injuries, latex allergy, and anaphylaxis.

# Cardiac arrest in the pediatric perioperative period

It is widely recognized and a credit to the field that the risk of major morbidity or mortality experienced by both adults and children undergoing a procedure requiring anesthesia has declined dramatically over a generation. Mortality, the most robust measure of outcome in pediatric anesthesia, has declined along with a similar decline in adult perioperative mortality. Figure 40.1 shows the decline in mortality observed among children over the past 50 years [1–14]. Pediatric mortality rates have in the past been assumed to be greater than those for adults; however, recent data suggest that except for infants, rates for children and younger adults are similar. The mortality rates among children undergoing non-cardiac surgery range from 0.4 to 1.6 per 10,000 anesthetics [13,15]. However, among infants and especially those undergoing cardiac surgery, mortality rates are much higher [13,16].

Great care must be used when comparing rates of cardiac arrest (CA) or mortality because patient type, setting, procedure, and age distribution have a profound impact on the frequency and outcome of CA among pediatric patients. Also important are factors such as the span of time over which cases are ascertained and whether the cases are gathered from one or many institutions because practice varies over time and from one institution to another. Finally, of obvious importance is the accuracy of denominators because incidence can be determined only if total case volume is available. Recent studies have defined the incidence of CA in the pediatric population. Flick et al [13] at the Mayo Clinic reported the incidence of CA among more than 92,000 children undergoing anesthesia between 1988 and 2005. They found an overall rate of CA of 8.6 per 10,000 anesthetics, with those undergoing cardiac surgery having a dramatically higher incidence than that observed among those undergoing non-cardiac procedures (127 per 10,000 versus 2.9 per 10,000). These findings were similar to those of Odegard et al at Boston Children's [16], Tay et al in Singapore [17], and Braz et al in Brazil [18]. Each of these studies was derived from a single institution and therefore provides accurate estimates of incidence but they are less well suited to providing insight into cause and consequence of the events.

The most important contribution to the existing knowledge related to pediatric CA in the operative setting comes from the Pediatric Perioperative Cardiac Arrest (POCA) Registry. The POCA Registry was created at the University of Washington in 1994 as an extension of the American Society of Anesthesiologists (ASA) Closed Claims Project and was supported by the American Academy of Pediatrics Section on Anesthesiology and Pain Medicine. In 1985, the ASA Committee on Professional Liability, with the cooperation of 28 insurance providers, began collecting data obtained from closed malpractice cases in the United States. In 1993, Morray and colleagues [19] reported a comparison of pediatric and adult closed claims and found that claims in children disproportionately involved infants, healthy children (ASA Physical Status (PS) I), death or permanent injury, and deficiencies in anesthesia care. Claims paid for malpractice involving pediatric care tended to be higher than those paid for adults.

To further study complications arising during the anesthetic care of children, the POCA Registry has subsequently provided valuable insights into the risk factors and outcomes associated with pediatric perioperative CA [12]. The registry, now closed, collected data from pediatric anesthesia practices throughout the United States and Canada and then reported their findings. The initial report was made in 2000 and provided data gathered from 63 institutions that had submitted a total of 289 cases of CA in children [12]. A subsequent report was published in 2007 [20].

The POCA Registry compiled CA data from as many as 79 primarily academic institutions and in its most recent report provided information on 397 cases covering a 7-year period. Reports from the POCA Registry grouped events as either related or unrelated to anesthesia and focused the analysis primarily on those judged to be anesthesia related. When comparing data from the first report (289 cases, 1994-1997) to the second report (397 cases, 1998-2004; 193 anesthesia related), the distribution of cases judged to be anesthesia related was similar at 52% and 49%, respectively. These rates are higher than those observed by Flick et al [13] (18%) when the POCA definition of anesthesia related was applied to the Mayo data. Likewise, in a series of 41 arrests among children undergoing cardiac procedures, Odegard et al [16] found that 26.8% were anesthesia related, and Braz et al [18] found that 20% were anesthesia related [21]. The designation of anesthesia related is obviously subjective but allows for the elimination of cases from review that might obscure important patterns, risk factors, or causes.

The children at greatest risk have been identified by Morray et al [12] and others [13,17,20] and include higher ASA PS rating, young age (neonates and infants), presence of congenital heart disease, and the need for emergency procedures. In the initial report from the POCA Registry, 32% of anesthesia-related CA occurred in children who were ASA PS classes 1 and 2, whereas in the subsequent report, the frequency of CA in PS 1 and 2 children had fallen to 25%. Over a similar time period, Braz et al [18] found in all CA that only four of 35 arrests (11%) occurred among the healthiest children. Flick et al [13] found that, among those undergoing non-cardiac surgery, half the 26 CAs occurred in children who were ASA PS 3 or less. Clearly, the higher the ASA PS is, the greater the risk of complications of all types, including CA [10]. It would appear that fewer healthy children are experiencing CA than in the past. This has been attributed by some to the shift from the use of halothane to sevoflurane as the primary inhalational anesthetic used in children [14,22].

Co-existing disease, as reflected by the ASA PS, is without question the strongest predictor of risk for CA and death as an outcome, particularly for those children with congenital heart disease undergoing both cardiac and non-cardiac procedures. In a cohort of more than 92,000 patients at the Mayo Clinic, Flick and colleagues [13] described 26 CAs among patients undergoing noncardiac procedures and 54 events during cardiac procedures. However, a total of 61 patients (87.5%) were known to have congenital heart disease, suggesting that for all procedures, the presence of congenital heart disease is a strong predictor of CA. Interestingly, the frequency of CA among children undergoing cardiac surgical procedures declined in the cohort over the study period of more than 15 years. This was attributed to the more aggressive use of extracorporeal membrane oxygenation (ECMO) for failure to wean from cardiopulmonary bypass (CPB) [23]. Patients who previously would have experienced CA during a cardiac procedure are now placed on ECMO and are no longer captured in analysis of perioperative CA. Morray et al [12] in the POCA Registry and Odegard et al [16] in a study of CA among patients undergoing cardiac surgical procedures at Children's Hospital Boston excluded most or all of those patients from their analysis. At the Children's Hospital Boston [16], the overall rate of CA during cardiac surgery was found to be 79 per 10,000 anesthetics, whereas at the Mayo Clinic, the rate was 127 per 10,000, probably reflecting the inclusion of those patients failing to wean from CPB in the Mayo series [13]. Regardless of the analysis, the presence of cardiac disease is a powerful predictor of not only CA but also mortality.

Unquestionably, neonates and infants are at greater risk. In the study by Olsson and Hallen [24], the risk of CA among infants was found to be 17 per 10,000 anesthetics, more than three times the risk for older children and almost six times that of adults less than 60 years old. More recent studies have found somewhat lower rates, ranging from 9 to 15 per 10,000 anesthetics [13,18]. Among neonates, CA rates are dramatically magnified to as high as 200 per 10,000 anesthetics [18]. Beyond 12 months, rates appear to decline rapidly to levels similar to those found in young adults.

Emergency procedures have been found by some to be associated with greater risk of CA and other major complications [13,17,24]. Additionally, Morray et al [12] found in the initial report of the POCA Registry that the odds of mortality from CA increased almost fourfold among those experiencing CA during an emergency procedure. Similarly, time of day appears in some studies to affect risk such that those children undergoing procedures during off hours (typically after 5 p.m.) and on weekends are at increased risk for CA [25]. The cause of this elevated risk is unclear; however, one can speculate that the acuity of illness and the lack of availability of resources such as experienced personnel and equipment may affect procedures taking place during those times [13].

Of great interest to the pediatric anesthesia community is the question of provider and risk for CA. The benefit of specialty-trained pediatric anesthesiologists has been examined as has the presence of trainees. The data are not sufficient, however, to draw clear conclusions. Sprung et al [26] found in a study of adults and children that the provider at the time of the arrest was not predictive of ultimate survival after intraoperative CA. Alternatively, Olsson and Hallen [24] suggested that the incidence of CA was inversely proportional to the availability of specialist anesthetists. In a pediatric study, Keenan et al [27] examined the effect of subspecialty pediatric anesthesia care on the occurrence of CA among infants cared for at a major academic center. They found that of the four CAs observed in the cohort, all occurred in the non-pediatric anesthesiologist group (incidence 19.7 per 10,000 anesthetics; p = 0.048). A follow-up study [28] found a similar relationship when the frequency of bradycardia was compared between pediatric and non-pediatric anesthesiologists, and a large study by Mamie et al [29] demonstrated a reduction in critical events among children cared for by specialist pediatric anesthesiologists, especially during ear, nose, and throat surgery.

Analysis of correctable causes of CA may lead to improvements in anesthetic care. In the 1950s, deaths related to administration of curare were reported and led to changes in practice [1]. Later in the 1960s and 1970s, airway obstruction and aspiration were common antecedents to CA [3,4]. Over subsequent decades, improvements in care resulted in a reduction in the incidence of CA and also a predominance of inadequate ventilation and anesthetic overdose as frequent causes [8,24]. Data from the Closed Claims Project in the 1990s [19] suggested a decline in respiratory causes of CA; this decline was confirmed by subsequent analysis of POCA and other data [12,14,15,20]. The change may be attributable to the introduction of pulse oximetry and, later, capnography. Medication-related CA declined after the late 1990s and was reflected in the second report of the POCA Registry [14], suggesting that the conversion from halothane to sevoflurane may have been responsible.

The decline in respiratory- and medication-related CA was accompanied by a concomitant rise in the proportion of events related to cardiovascular causes in the data reported by Bhananker et al [20] from the POCA Registry. These were primarily related to blood loss and its replacement (hyperkalemia secondary to massive transfusion). Similar findings were observed in the Mayo Clinic series [13]. The findings reinforced the need for adequate hemodynamic and electrolyte monitoring as well as avoidance of the use of whole, irradiated, or old blood whenever possible (Fig. 40.2, Table 40.1).

Respiratory events, although proportionately less common, continue to be an important source of CA in children. Laryngospasm was the most frequent antecedent event identified in the POCA data. This is supported by other large series that examine adverse events such as those by Mamie et al [29], Tay et al [17], and Murat et al [15]. These arrests may be attributed to the failure to rapidly recognize and effectively treat laryngospasm before the onset of bradycardia that may be accentuated by the use of intramuscular or intravenous succinylcholine.

Outcomes of CAs among children in the perioperative setting are, not surprisingly, dependent on the cause. Overall survival ranges from 21% according to Flick et al [13] to 28% [20], 37% [18], 57% [17], and 92% [16]. The higher survival reported by Odegard et al [16] was among cardiac surgical cases and did not include those who failed to wean from CPB or were placed directly onto ECMO support. In general, the outcome of in-hospital CA among children is better than that of adults, and CA occurring in the operative setting has better outcome than CA occurring elsewhere in the hospital [30]. Cardiac arrest in children outside the hospital has a poor outcome, with only a 12% survival to discharge; this survival

rate is based on a meta-analysis by Donoghue et al in 2005 [31].

As more robust methods of capturing clinical events become more widely available and organizations such as the Society for Pediatric Anesthesia and others develop and support methods of capturing these data across multiple institutions, the ability to quantify and study these rare events will improve and so will the care of children. See Chapter 43 for further discussion of databases and outcomes research. For treatment of cardiac arrest, see Chapter 12.

### **Control of temperature**

### Physiology of temperature control

The management of temperature is critical in the care of pediatric patients. Much more so than adults, children are susceptible to changes in environmental temperature and the effects of anesthetics on thermoregulatory responses. As mammals, humans are homeothermic and therefore maintain their body temperature within a narrow range. Core temperatures in humans are in general maintained at within 0.2°C around the thermal set point of 37°C. To achieve this precise temperature control, a complex array of thermoregulatory processes that are not completely understood are required.

From the earliest experiences in the use of general anesthetics, it has been recognized that these agents impair normal thermoregulatory mechanisms and without intervention will inevitably result in hypothermia in patients of all ages and sizes. Pickering [32], in a 1958 lecture to the Royal College of Physicians, discussed (among other things) the potential benefits of hypothermia and stated, "The practical difficulty in cooling men is to break through the defences of the body; the most effective means is to give an anaesthetic, which (as we have seen) has been shown to interrupt at some point or points the reflex arcs which protect against cooling, particularly shivering." Although perioperative hypothermia may have a benefit in selected patients and clinical settings, the effects of cold may have profound negative effects, including increased bleeding, infection, renal dysfunction, and alterations in the pharmacology of anesthetic agents and other medications [33-36]. Although relatively rare, severe hyperthermia is much less well tolerated than hypothermia and will, in settings such as malignant hyperthermia (MH), result in death unless effectively treated. In this section, the physiology of thermoregulation is discussed along with temperature measurement and disturbances encountered in the perioperative setting as well as strategies to prevent or manage these alterations.

Temperature regulation in homeotherms is highly complex and not completely understood. Clearly, temperature regulation is among the most closely guarded of all physiological processes and involves interplay among peripheral and central receptors and controllers distributed widely throughout virtually the entire organism. Temperature control is not symmetrical; that is, much greater control is exerted over increases in central temperature as opposed to central hypothermia. Temperatures higher than 44°C constitute the upper limit of survival in humans, whereas temperatures as low as 30°C are experienced in the operative setting without profound effect [37]. This asymmetry is, in all likelihood, related to the effect of high temperatures on the tertiary structure of proteins (Fig. 40.3).

The dominant control of temperature can be localized in the preoptic anterior hypothalamus (POAH) although the dorsomedial nucleus, periaquaductal gray matter of the midbrain, and the nucleus raphe pallidus in the medulla also play an important role [38]. In the most commonly described model, the POAH is at the center of a negative feedback loop that involves afferent input from superficial and deep temperature receptors and efferent output to effectors in the sweat glands, blood vessels (dilation-constriction), muscles (shivering), brown fat deposits (non-shivering thermogenesis), and respiratory centers (hyperpnea). The thalamus functions much like a thermostat to closely maintain core temperature by reducing heat loss and activating heat production in response to cold afferent input and dissipating heat and decreasing thermogenesis in response to warm afferent input [39]. The interthreshold range, i.e. the range over which the thalamus senses temperature as normal, is between 36.8°C and 37.2°C although there are diurnal variations and differences between men and women associated with menstruation. Temperatures within the thalamus outside the normal range will initiate an effector response to return the central temperature to the normal set point.

The POAH contains warm-sensitive, cold-sensitive, and temperature-insensitive receptors. However, warm sensors vastly outnumber cold and insensitive receptors, emphasizing the survival importance associated with guarding against hyperthermia. Warm sensors exert primary control over temperature by integrating thermal inputs from the periphery and by directly sensing thalamic temperature [40]. The dendrites of these warm sensor neurons lie adjacent to the third ventricle and therefore directly sense cerebrospinal fluid temperatures [41]. As temperature rises, these sensors increase firing rates and initiate autonomic responses to reduce core temperature as well as providing tonic inhibition of cold sensors. Likewise, reduced input to warm sensors is the primary mechanism of initiating sympathetic responses to thermogenesis and thermal preservation. Coldsensitive neurons are relatively few in number and are much less important in temperature control within the POAH. Temperature-insensitive sensors function to provide inhibition to warm sensors in response to afferent input from the periphery as well as to activate cold sensor neurons. The integration of input to warm sensors, cold sensors, and insensitive neurons within the POAH establishes separate but highly integrated mechanisms for the response to cold and warm core temperatures. The response to cold relies predominantly on afferent input mostly from skin to inhibit warm sensor activity rather than a reduction in firing of central cold sensors. At temperatures 0.5°C lower than normal, warm sensor neurons essentially cease firing [42]. In contrast, a response to increasing core temperature relies primarily on the

increased firing of warm sensor neurons and does not depend on peripheral input.

Afferent input into the central thermoregulatory controllers is derived from receptors distributed throughout the body, primarily in the skin and oral and urogenital mucosa. In contrast to the central sensors, peripheral receptors are predominantly cold sensors (a ratio of about 10:1) [42]. Traditionally, these sensors have been thought to provide input only to central sensors where these inputs are integrated and result in an effector response. More recently, however, this theory of negative feedback has been challenged to the extent that an alternative model has been proposed suggesting that skin receptors may directly activate effectors in a feedforward rather than feedback loop [43]. Direct activation allows for preemptive control of temperature, primarily enabling defense against cold. This model of control suggests that the sensation of cold is a byproduct of control rather than an effector. Activation of cold sensors produces the sensation of cold and an effector response as a parallel process rather than a sequential one.

Regardless of the mechanism, input from peripheral sensors (primarily cold) located in the skin are sent to the brain via thin myelinated A  $\delta$  fibers through the spinor-

eticulothalamic tract to the thalamus and other brain regions involved in thermal control. These sensors' peak firing rate occurs at temperatures between 25°C and 30°C. Peripheral sensors in the skin are exquisitely sensitive and respond to temperature changes as small as 0.0003°C. They are most sensitive to rapid rather than gradual change in temperature and are the major source of peripheral thermal input [44].

Sensors (predominantly warm) are found in deep tissues of the core and send afferent signals via unmyelinated C fibers with peak firing rates at temperatures between 40°C and 50°C [45]. These sensors also respond primarily to change in temperature rather than to absolute temperature. Firing rates increase with increasing or decreasing temperature and subsequently accommodate to a new stable temperature [37]. This phenomenon explains both adaptation to temperature change and also the observation that responses to temperature change are most vigorous when change occurs rapidly.

Efferent output to temperature effectors occurs via autonomic and behavioral mechanisms. In humans, behavioral mechanisms predominate either directly or, in the case of a young child, indirectly through the actions of a caregiver. Behavioral control of temperatures allows humans to survive temperatures lower than -100°C and higher than 2000°C (temperature on the surface of the moon and surrounding the shuttle during re-entry) [37]. Behavioral control allows for the use of deep hypothermic circulatory arrest and survival from MH. In day-to-day care of children in the perioperative setting, the pediatric anesthesiologist must provide indirect control of body temperature to avoid the negative consequences associated with both hypothermia and hyperthermia.

Autonomic control of temperature is achieved through thermoeffectors, including piloerection, sweating, cutaneous vasoconstriction or vasodilation, shivering, brown fat metabolism (non-shivering thermogenesis), and, to at least a minimal extent, hyperpnea. These effectors function to either conserve or dissipate heat, depending on the specific need. Outputs to the effectors are integrated within the POAH as well as at the level of the spinal cord and potentially through even more direct mechanisms. Clearly, the most effective non-behavioral means of both heat conservation and dissipation is vasodilation or vasoconstriction of cutaneous blood vessels. In adult humans, skin blood flow can be increased in response to hyperthermia to as high as 6-8L/min and, when combined with sweating, is the most effective means of heat dissipation [39].

Given the large surface area-to-weight ratio of infants, heat loss and gain are much more rapid. The normal newborn has a surface area-to-volume ratio of approximately 1, whereas in the adult, the ratio is closer to 0.4. In the adult in a thermally neutral environment, cutaneous blood flow is approximately 250 mL/min, dissipating approximately 90 kcal/h. When core temperature rises, a gradient is created between the central and skin temperatures, resulting in a reduction in peripheral cold sensor activity and subsequent cutaneous vasodilation with a severalfold increase in blood flow. Heat is then effectively transferred from the core to the periphery, and the thermal set point is re-established. In cold environments, blood flow is shunted away from cutaneous vessels by closing arteriovenous shunts that are maximally open in a thermally neutral environment. Reducing blood flow up to tenfold may result in as much as a 50% reduction in heat loss [46].

Shivering increases heat production in adults by a factor of five for brief periods or by a smaller factor for sustained periods. It is involuntary muscular activity that is central in origin and can be reliably reproduced by cooling of the hypothalamus (POAH). In neonates and young infants, shivering is often believed not to occur although it is difficult to find a reference to that effect or to define the age at which shivering can be expected to occur. Darnall [47] has suggested that neonates can indeed shiver although shivering is a secondary mechanism of heat production much less efficient than non-shivering thermogenesis and therefore rarely observed. When  $\beta$ blocking agents that inhibit non-shivering thermogenesis are given to guinea pigs, they demonstrate shivering at temperatures higher than normally observed [48]. Regardless, shivering, if it occurs in infancy, plays a relatively minor role in heat generation. Instead, neonates and infants are, to a large extent, dependent on nonshivering thermogenesis.

Non-shivering thermogenesis, resulting primarily from the metabolism of brown fat, is the most important means of thermal response to cold in hibernating animals as well as in neonates and infants. Once thought to occur only in infants, brown fat has been identified in adults and may be important in future research on weight management [49]. Brown fat is adipose tissue that is rich in mitochondria that have a unique capacity to uncouple oxidative phosphorylation, thereby generating large amounts of heat rather than adenosine triphosphate (ATP). The uncoupling of oxidative phosphorylation is dependent on uncoupling protein (UCP1), a 33 kD protein found on the inner membrane of the mitochondria in brown fat [50]. This tissue comprises approximately 2–6% of bodyweight in a newborn and is found in the mediastinum, between the scapulae, around the adrenals, and in the axillae. Non-shivering thermogenesis is mediated by sympathetic stimulation in response to cold stress and, as previously stated, can be inhibited by  $\beta$ -blocking agents. In addition to norepinephrine and epinephrine, thyroxin and glucocorticoids may also stimulate lipolysis of brown fat. Lipolysis of brown fat, compared with that of white

adipose tissue, results in oxidation of approximately three times the amount of fatty acid (30% versus 10%) within the lipocyte [51]. A considerable proportion of free fatty acids is released into the bloodstream to be oxidized elsewhere in the body. Ultimately, the metabolic result of maximum oxidation of brown fat is a near doubling of heat production, with an increase in oxygen consumption from 5.4 mL/kg/min to 9.3 mL/kg/min [52]. The capacity for substantial heat production through non-shivering thermogenesis is present at birth and persists through the second year of life.

In animals, hyperpnea makes a major contribution to thermoregulation, especially of the brain. In humans, the role of panting is less pronounced but it is nonetheless important. There are two phases of the panting response. The first phase, thermal tachypnea, is characterized by increased respiratory frequency with reduced tidal volume, resulting in heat loss but no change in carbon dioxide tension [53]. This pattern produces preferential ventilation of anatomical dead space, including the nasopharynx, selectively cooling the brain. The second phase, thermal hyperpnea, produces a reduced respiratory rate coupled with an increased tidal volume, resulting in alveolar hyperventilation hypocapnia and alkalosis. In humans, thermal hyperpnea predominates and can at times account for 46% of cephalic heat loss [54]. Given the relative size of the infant cranium, it could be assumed that this figure may be larger, although no data support this assumption.

An interesting theory is related to the role of yawning in thermoregulation, especially with regard to selective brain cooling [55]. In a study group of college students, contagious yawning was eliminated by selective cooling of the forehead [56]. In preterm and near-term infants, yawning begins at approximately 20 weeks and decreases in frequency between 31 and 40 weeks, coincident with development of homeostatic control [57]. Also interesting is the role of opioids in yawning behavior. Opioids are known, through  $\kappa$  receptor activity, to produce hypothermia in animals and also to inhibit yawning. Additionally, the administration of naloxone increases yawning in opiate-dependent humans [58]. Ultimately, the importance of yawning is uncertain in humans and especially in neonates and infants.

### Mechanisms of heat loss

Unintentional hypothermia is the major concern that motivates inclusion of a discussion of thermoregulation in this and every text of pediatric anesthesia. Although heat is lost and gained from the body in similar ways, heat gain is a relatively rare concern, whereas avoiding heat loss is part of the anesthetic management of every child. A basic understanding of the mechanisms of heat loss is central to the prevention of unintentional hypothermia. Hypothermia has beneficial effects in a few select clinical situations such as hypoxic ischemic brain injury, head trauma, CPB, and deep hypothermic circulatory arrest, but it has clear negative effects in most dayto-day perioperative situations. Hypothermia inhibits immune responses and is a source of renal dysfunction and coagulation abnormalities. It affects the action of various medications, including muscle relaxants, that are components of many anesthetics provided to adults and children.

Heat loss in the operating room environment occurs through radiation, convection, evaporation, and conduction, in order of importance. Radiant heat loss is the heat loss that occurs between two objects in the environment. All objects in the operating room, whether animate or inanimate, gain or transfer heat to one another in a process that would, in the absence of intervention, lead to equilibrium. The heat of the sun and the heat generated by an infrared warming light are typical examples of radiant heat sources. Radiant heat loss is somewhat less easy to imagine but much more important in the operating environment. Radiant heat is transferred as electromagnetic waves in the infrared spectrum and is unaffected by air currents, air temperature, or distance between the radiating surfaces. Radiant heat loss becomes an increasingly important source of heat loss as the temperature of surrounding objects and surfaces decreases. In a neutral thermal environment, radiant heat loss accounts for about 39% of total heat loss, whereas at 22°C, radiant losses increase to nearly 80% of the total [59].

Radiant heat loss can be calculated using a simplified formula that accounts for radiant properties of the two surfaces, surface area, and temperature difference between the objects. The radiant heat loss can be estimated for a typical young child on the basis of the following assumptions: if human skin has an emissivity coefficient of close to 1.0, a body surface area of 0.5 m<sup>2</sup> at a temperature of 22°C and skin temperature of 36°C would continuously radiate approximately 40W. This energy loss can be greatly reduced by use of simple coverings such as clothing, sheets, or blankets. Even light clothing can dramatically reduce radiant heat losses. It may at times not be possible to cover the child. In this circumstance, the most effective means of maintaining temperature is increasing the temperature of objects within the environment (heating the operating room) or, alternatively, providing a source of radiant heat energy such as an infrared heat lamp or other radiant heater. In this example, increasing the ambient temperature to 30°C would reduce radiant heat loss by almost 50%, keeping in mind that in order to achieve this, the environment must be at equilibrium. Simply raising the air temperature briefly has little effect until all objects in the environment have had sufficient time to equilibrate.

Convective heat loss is second to radiation as a source of energy loss in the operating room environment. It accounts for approximately 34% of heat loss in a neutral thermal environment. Convection is the loss in heat that occurs as a result of mass motion of a fluid, typically either air or water. The amount of heat loss depends on the velocity of air (water) movement and the difference between the temperature of the object (person) and the surrounding fluid. For those living in northern latitudes, the concept of wind chill is a familiar example of the effects of convection on cooling or heat loss from one object to the surrounding air (termed forced convection). Although air currents in the indoor environment are minimal, it is important to keep in mind that a warm object heats the surrounding air (termed natural convection). The warmer air is less dense and rises away from the warm object, thus creating an air current that promotes convective heat loss. The addition of even light covering inhibits this air current and reduces convective heat loss. The rate of convective heat transfer ( $\dot{Q}$ ) is determined by the following formula:  $\dot{Q} = hA(T_s - T_b)$ , where *h* is the constant heat transfer coefficient of the fluid, in this case air, A is the surface area in meters squared,  $T_s$  is the surface temperature, and  $T_b$  is the temperature of the fluid (air). The transfer coefficient is situationally dependent and must be determined for each setting, making use of this formula problematic in the clinical setting.

Heat loss through conduction occurs whenever the body comes in direct contact with a cooler object that is not in motion (air or water are objects in motion) such as the operating table or other solid. Similar to convection, the transfer of heat is dependent on the temperature difference between the two objects, the densities of the objects, and the area of contact. The greater the area of contact and the greater the density of the cooler object, the more heat is transferred. A soft mattress transfers less heat than a solid surface such as an x-ray table. The mathematical expression of this relationship is identical to that for convection:  $\dot{Q} = hA(T_s - T_b)$ . However, in this case, heat transfer is related to *h*, the conductivity or thermal properties of the solid, A, the area in contact, and the temperature difference between the body  $(T_s)$  and object  $(T_b)$  in contact. Heat loss via conduction is typically small and accounts for about 3% of heat loss in a neutral thermal environment.

Evaporative heat losses are encountered whenever a fluid evaporates from the surface of an object such as a patient whose abdomen has been prepared with a solution such as povidone-iodine. Evaporation is an important means of cooling the body when the body temperature exceeds 37°C. Heat loss through sweating, evaporation of another liquid from the skin (skin preparation solutions), or insensible losses from an open abdominal wound or via the respiratory tract depend on the vapor pressure gradient between the skin and surrounding air and the velocity of air movement. The formula is familiar from the previous discussion; however, in the case of evaporation, the difference is not in temperature but rather vapor pressure between skin and surrounding air:  $\dot{Q} = hA(P_s - P_a)$ , where  $\dot{Q}$  is heat transfer in watts, h is the coefficient of evaporation and accounts for the latent heat of vaporization of the liquid as well as the air flow velocity, A is the area covered by the liquid in meters squared, and  $P_s$  and  $P_a$  are the vapor pressures of the liquid at the skin surface and the surrounding air.

Evaporative heat loss accounts for approximately 25% of total heat loss, of which roughly half can be attributed to respiratory losses. In the infant, respiratory losses can be assumed to be greater given the increased minute ventilation per kilogram of bodyweight. The use of warm, humidified inspired gases eliminates this source of heat and free water loss. Table 40.2 summarizes the mechanisms of heat loss, and prevention and treatment in anesthetized children.

### Anesthetics and thermoregulation

Anesthetic agents produce consistent effects on thermoregulation in infants, children, and adults. All agents act to increase the interthreshold range by both increasing the upper threshold and decreasing the lower threshold such that the range of temperatures within which thermoregulatory mechanisms are not initiated becomes much wider. Under normal circumstances, the poikilothermic range is limited to 0.2°C. Under anesthesia, that range increases to between 2°C and 4°C, depending on the agent. The interthreshold range is determined on the lower end by measuring the temperatures at which vasoconstriction and shivering are initiated and on the higher end by the initiation of sweating. Vasoconstriction and shivering track consistently at approximately 1°C difference, regardless of the effects of anesthesia, such that vasoconstriction is initiated at a 1°C higher temperature than shivering.

The effects of anesthetics on the interthreshold range are not symmetrical. The upper boundary of the range is increased only by 1–1.5°C, whereas the lower threshold is decreased by approximately 2.5°C. The effect is that hypothermia is much more likely to occur than hyperthermia, especially given the typical ambient temperature of most operating rooms. At this point, it is also important to recognize that the most effective responses to both hyperthermia and hypothermia are behavioral, and these responses are obviously absent under general anesthesia. Although the range over which no response to temperature change occurs increases under anesthesia, the intensity of response does not. Cutaneous vasoconstriction under isoflurane anesthesia in healthy volunteers occurred at 34.6°C and was similar in intensity to that

Mechanism	Relative % of heat loss	Causes	Prevention/treatments
Radiation	39% in NTE (80% at 22°C)	Cold room temperature	Warm room as high as 26°C; heating lamp; cover with clothing, sheets, blankets, caps, wrap extremities – plastic, cotton wadding
Convection	34% in NTE	Motion of air/fluid	Cover with clothing, sheets, blankets, caps, wrap extremities – plastic, cotton wadding; forced-air warming; warmed IV fluids
Evaporation	25% in NTE	Respiratory losses; drying of skin, preparation fluids and other fluids on skin	Condenser humidifier or active warming/ humidification of gases; warm skin prep solutions
Conduction	3% in NTE	Direct contact with cooler object not in motion, e.g. OR table	Circulating water blankets; forced-air warming

Table 40.2 Mechanisms of heat loss in anesthetized infants and chil	dren
---	------

NTE, neutral thermal environment. See text for detailed explanation.

achieved in awake volunteers. Shivering can also be observed in anesthetized patients, although it is much less common because it occurs at a temperature 1°C lower than vasoconstriction. Like vasoconstriction, the intensity of shivering observed is unchanged.

Non-shivering thermogenesis is the predominant means of heat generation in neonates and infants. It too is inhibited in the setting of general anesthesia. Halothane 1.5% inhibits non-shivering thermogenesis by 70% in rodents [60]. Human infants under propofol and fentanyl anesthesia fail to increase metabolic rate despite core temperatures 2°C below the vasoconstrictive threshold, suggesting that non-shivering thermogenesis is absent in this setting [61], although Ohlson et al [62] failed to demonstrate an inhibitory effect on non-shivering thermogenesis by propofol in hamsters.

Inhalational anesthetics affect the thermoregulatory threshold of infants and children in a manner similar to that observed in adults. Bissonnette and Sessler [63] showed that halothane and nitrous oxide reduce the thermoregulatory threshold in children to 35.7°C, whereas in a previous study [64], they found that under isoflurane, the threshold was further reduced to levels similar to those observed in adults (34.4-35.3°C). In both studies children were stratified by weight, and in neither study did threshold response vary significantly with weight. Sevoflurane and desflurane have been found to produce similar changes in thermoregulatory responses although desflurane is unique in that it reduces the magnitude or gain of the vasoconstrictive response to hypothermia [65-67]. Xenon has been shown to have a greater inhibitory effect on thermoregulation than isoflurane, whereas nitrous oxide is less inhibitory [68]. In general, the thermoregulatory response to inhalational anesthetic agents appears to be similar in adults and children and is not determined by weight or age. Inhalational anesthetics, with the exception of nitrous oxide, appear to inhibit non-shivering thermogenesis [62].

The effects of intravenous anesthetics on thermoregulation vary. Propofol produces a linear decrease in the threshold temperature for vasoconstriction and shivering, while only slightly increasing the threshold for sweating in humans, as demonstrated by Matsukawa, Kurz, and colleagues [69,70]. Unlike volatile anesthetics, propofol does not appear to inhibit non-shivering thermogenesis. Ohlson et al [62] compared the effects of various anesthetic agents on brown fat metabolism and found that propofol and ketamine did not inhibit nonshivering thermogenesis in hamsters. Midazolam appears to impair thermoregulatory control only minimally compared to the effects of propofol and narcotics [71].

The individual thermoregulatory effects of opioids have not been widely studied. Spencer et al [72] showed that, in rats, different opioid agonists had differing effects on thermoregulation depending on the type of receptor stimulated ( $\mu$ ,  $\kappa$ ,  $\delta$ ) with the  $\mu$  agonist increasing the set point and  $\kappa$  and  $\delta$  agonists reducing it. Kurz et al [73] examined the thermoregulatory effects of alfentanil in human volunteers and found a minimal increase in set point for sweating and a linear, serum concentrationdependent decrease in set point for vasoconstriction and shivering similar to those observed for other general anesthetics. Meperidine similarly reduces set point and also appears to diminish the threshold for nonshivering thermogenesis by its effects on the  $\alpha$ 2-adrenergic receptor [74–76]. Clonidine and dexmedetomidine also act as  $\alpha$ 2-agonists and reduce the threshold for vasoconstriction and shivering but have little or no effect on sweating [77].

Postoperative shivering is a problem that primarily affects older children and adults and occurs in two patterns termed thermoregulatory and non-thermoregulatory. Thermoregulatory shivering is related to hypothermia and appears similar to shivering that occurs in other settings. Non-thermoregulatory shivering seems to have an etiology separate from thermoregulation because it occurs in normothermic patients in the postoperative period and is also seen in patients such as laboring women who have not been exposed to an anesthetic and are not hypothermic. The exact mechanism of this type of shivering is not entirely clear; however, its appearance is distinct in that it is predominantly clonic, resembling the clonus seen in spinal cord-injured patients [78]. Postanesthetic shivering occurs in approximately 50% of patients allowed to become hypothermic and in 27% of non-hypothermic patients, 15% of whom display a primarily clonic pattern of shivering [79]. Pain appears to be a factor also; patients with lower pain scores are less likely to shiver postoperatively [80].

Shivering in children is not well studied; however, a few studies have been published that describe the problem. Akin et al [81] prospectively followed more than 1500 children in the postanesthetic care unit and found the incidence of shivering to be 3.5%. Older children, those undergoing long procedures, and those in whom anesthesia was induced with an intravenous agent appeared to be at greater risk, whereas those whose anesthetic was supplemented with a caudal block appeared to be a lower risk. Lyons et al [82] found a rate of almost 15% in a smaller study and found that anticholinergic use was also a risk factor.

The consequences of shivering are primarily confined to patients who do not have the cardiovascular reserve to tolerate as much as a 380% increase in oxygen consumption that may be associated with shivering [83]. Shivering may also increase intraocular and intracranial pressure and should certainly be treated in those settings. The majority of episodes in children, however, are brief and do not necessarily require treatment other than external warming. When pharmacological treatment is desired for comfort or safety, meperidine appears to be the most efficacious agent. Its usefulness may be the result of its activity as an  $\alpha$ 2-adrenergic receptor agonist based on its opioid activity. In keeping with this, other  $\alpha$ 2agonists have been used successfully to treat shivering. Dexmedetomidine and clonidine have been used successfully, although clonidine appears to be most useful in preventing rather than treating this problem. Other narcotics have been used but with mixed results and none with the efficacy of meperidine.

### Thermoregulation and regional anesthesia

In children, regional anesthesia is nearly always combined with a general anesthetic, which is not usual in adults. The thermoregulatory effects of regional anesthesia are confined primarily to neuraxial techniques as the effects of extremity and other blocks tend not to involve a large enough area to greatly affect core temperature. The effects of neuraxial anesthesia on thermoregulation have been extensively studied by Sessler and others, mostly in adults [84-94]. Bissonnette and Sessler, in two studies [63,64], examined the effect of general anesthesia with regional block in children, a situation that has clear relevance to clinical pediatric practice. In the first study [64], in which isoflurane was used in combination with caudal blockade, the authors found that thermal responses in children were similar to those in adults and were independent of bodyweight and age. The use of combined neuraxial and general anesthesia was thought not to be an important factor in determining responses. In the second study [63], halothane was used in combination with either penile or caudal block. Thermal responses were not different between the two groups and were similar to those in adults and children under general anesthesia without regional anesthesia. It appears from these studies that the combination of regional anesthesia with general anesthesia has little impact on thermoregulation in children.

### **Temperature monitoring**

The ASA requires that temperature monitoring be available for all patients under anesthesia. Accurate measurement of temperature in the operative period is primarily directed at the detection of hypothermia. Less common but no less important are instances of notable fever, especially those related to MH. Temperature is measured using various technologies at multiple sites with accuracy that varies widely. The appropriate unit of measure is degrees Celsius as the Fahrenheit scale is cumbersome and outmoded, and, like most aspects of the US customary system ("English units"), should be abandoned in clinical practice.

The measurement of temperature has a rich and fascinating history that cannot be covered in this text. One of the first thermometers, invented by Rhomer at the turn of the 18th century, used red wine as an indicator. Fahrenheit invented the mercury thermometer in 1714 and later the Fahrenheit scale, which unfortunately remains in use in the United States and a few other countries. The Celsius scale originally designated 0° as the boiling point and 100° as the freezing point of water. Linnaeus inverted the scale to its present format in the middle of the 18th century, and the scale became widely popular as the centigrade scale, later designated the Celsius scale in 1948. The official metric unit of temperature is the Kelvin named after its inventor Lord Kelvin in 1848. The Kelvin scale is based on absolute zero and uses the triple point of water (273.16°K) as a reference. The triple point of a substance is the temperature at which all three phases co-exist in equilibrium.

Monitoring temperature requires that an accurate instrument be used at an appropriate site that reflects the temperature of interest. Modern thermometers use thermistors, thermocouples, infrared, and liquid crystal technologies. All are sufficiently accurate for most applications although thermistors are probably the most accurate and liquid crystal thermometers the least accurate.

Typically in the operative setting the temperature of interest is an estimation of core temperature, although the ability to measure core temperature is often limited by the availability of appropriate sites and instruments. Core temperature is undefined but represents the major input into thermoregulation and therefore is of the greatest importance in terms of measurement. Sites such as the tympanic membrane, bladder, esophagus, nasopharynx, and rectum are typically considered to represent core temperature; each has limitations, however. It has been suggested that the core temperature is the temperature of the thalamus; however, the core temperature can more appropriately be described as the temperature at which the thalamus responds rather than its own intrinsic temperature. Since the thalamus receives input from throughout the body, core and thalamic temperatures may differ.

Peripheral temperature varies widely over time and by location and therefore is much more limited as a measure of thermoregulatory input or status. Skin temperature, including axillary measurement, is often the simplest and most accessible site for monitoring. When the sensor has been placed properly, axillary temperature correlates well with measures of core temperature in infants, making it useful for brief procedures during which marked temperature change is not anticipated [95]. Placement of skin temperature probes elsewhere on the skin surface is much less likely to reflect core temperature and should be used with that caveat in mind. Figure 40.4 shows the correlation of various temperature measurement sites as measured in children weighing between 5 and 30kg. Esophageal, rectal, and axillary temperatures are similar, but forearm and fingertip temperatures are much lower and clearly do not reflect core temperature [95].

## Hypothermia, hyperthermia, and internal heat transfer

Heat loss or gain in the operative setting results in the transfer of heat either to or from the core. Redistribution hypothermia results from the transfer of heat from the core to the periphery caused by vasodilation usually induced by anesthetic agents. This heat transfer is responsible for the initial drop in temperature of  $1-1.5^{\circ}$ C

**Figure 40.4** The average difference between temperatures at five different measurement sites and tympanic membrane temperature in 20 children weighing between 5 and 30 kg. The central sites (esophagus  $\diamond$ , rectum  $\blacksquare$ , and axilla  $\blacksquare$ ) did not differ significantly, whereas the temperatures of the peripheral skin surface (forearm  $\blacktriangle$  and fingertip  $\bullet$ ) were significantly lower than the central temperatures. Vertical bars illustrate the standard deviation. Standard deviations of the rectal temperatures (omitted for clarity) were similar to those of the esophageal and axillary temperatures. Standard deviations of fingertip temperatures were similar to those of the forearm temperatures. Adapted from Bissonnette et al [95] with permission from Lippincott Williams and Wilkins.

typically observed in the first hour under anesthesia. Once initiated, the process is difficult to reverse; it can be prevented, however, through the use of prewarming and active warming immediately after the induction of anesthesia [96]. Active warming through the use of heated gases, heated forced air, heat lamps, heating pads, or heated intravenous fluids can be effective to slow or eliminate heat loss during the intraoperative period, but the most effective means of limiting heat loss is increasing the ambient temperature of the operating room.

Warming intravenous fluids is a relatively ineffective means of treating or preventing hypothermia except in situations such as rapid blood loss or CPB in which large volumes of blood are transferred to the patient in a very short time. The ineffectiveness of warming fluids is otherwise true for several reasons. Intravenous fluids can be warmed safely to temperatures only slightly above core temperature to prevent hemolysis, typical procedures require relatively small amounts of fluids, and finally, fluids warmed in an intravenous bag are often significantly cooler by the time they reach the patient. This is particularly true in small children, infants, and neonates with low intravenous flow rates and when warmed fluids are likely to cool prior to reaching the child. Whereas warm fluids are not an effective means of restoring normothermia, cold fluids are a much more effective means of cooling, primarily because cold or cool fluids have a much larger temperature gradient (15°C below core temperature for room temperature fluids) than warmed fluids (1–2°C above core temperature). Therefore, it is important to warm fluids when severe hypothermia can be anticipated, but warmed fluids are not an effective means of treating even mild hypothermia.

The use of a heated and humidified breathing circuit is also only modestly effective in either preventing or treating intraoperative hypothermia because heat loss through the respiratory tract accounts for only about 10% of total heat loss. Of that 10%, roughly two-thirds is accounted for in the process of humidifying inspired gases, suggesting that the use of a passive heat and moisture exchanger (artificial nose) is probably sufficient for most situations. In children, especially infants, the role of respiratory heat loss may be greater, given that minute ventilation is much higher than in adults. In a study in infants that compared active heating and humidification with either no intervention or passive humidification, Bissonnette and Sessler [97] found a marked difference in rectal temperature 2h after induction. This difference suggests that, at least in infants and neonates, active heating and humidification may be useful, at least for longer or more extensive procedures. For shorter procedures that do not involve major body cavities, the use of an artificial nose (condenser humidifier) maintains sufficient airway humidity above the 50% needed for mucociliary function.

Surface warming using warm fluid-filled mattresses effectively reduces conductive heat losses, but these losses are a minor contributor to overall heat loss. As with heated airway gases and intravenous fluids, a major limitation of surface warming is the small increment between the temperature of the warming device and that of the patient. The use of high temperatures to warm externally creates an unacceptable risk of thermal injury. Therefore, the use of traditional hot water blankets has limited value in the management of hypothermia in the pediatric operative suite. Newer circulating-water devices have been developed that are more effective than either older systems or current forced-air systems [98]. This is due to the increased capacity of fluids to transfer heat and the increased surface area in contact with the skin.

The most widely used and effective means of external warming is forced-air (convective) warming devices. They have been in use for more than a decade and have an excellent safety record, despite reports of burns in children [99]. When a sufficient area of the body surface is covered, these systems can eliminate heat losses from the skin.

Despite the development of new technologies, the most effective means of preventing intraoperative hypothermia remains the maintenance of high ambient temperatures and the use of simple insulators such as plastic sheeting or cloth coverings. Few data suggest that one type of covering is superior, but all are highly effective means of reducing surface heat loss and are of minimal cost. Ultimately, however, to maintain normothermia in infants, an ambient temperature of 26°C is required, which is uncomfortable, especially for the surgical team [100]. For longer or more invasive procedures in which major body cavities are exposed, active warming may be necessary and can be most comfortably and effectively achieved with the use of forced-air convective systems.

Hyperthermia in the operative setting is relatively rare compared with hypothermia. Temperatures exceeding 38°C may result from intrinsic processes such as infection, drug fever, transfusion reaction, or MH or may be the result of excessive warming. Children – especially infants and neonates – are most susceptible to hyperthermia induced by overly aggressive warming. It is important to investigate and eliminate the cause of the hyperthermia rather than to simply treat with antipyretics. Clearly, the most concerning cause of hyperthermia in the operative setting is MH.

### Malignant hyperthermia

### History of malignant hyperthermia

Malignant hyperthermia is a pharmacogenetic syndrome characterized by a hypermetabolic state of skeletal muscle, typically induced by exposure to specific anesthetic agents, including all the halogenated volatile agents as well as succinylcholine. The syndrome typically presents with fever, profound acidosis, rhabdomyolysis, and, if untreated, death in the majority of cases.

Malignant hyperthermia was first described in 1960 in a letter to the editor of The Lancet [101] and subsequently in an article in the British Journal of Anaesthesia entitled "Anaesthetic Deaths in a Family," reported by Denborough et al [102]. In that paper, the authors described the MH symptoms in a young man and several of his family members who had previously experienced unexplained anesthetic deaths. The young man survived a halothane anesthetic but displayed what are now known to be classic signs and symptoms of what later became known as MH. The term malignant hyperthermia was first used in a 1966 paper by Wilson et al [103] describing phosphorylation defects as a possible mechanism for MH. A subsequent 1972 report identified a characteristic phenotype for some affected individuals [104]. This entity was termed King–Denborough syndrome, and Britt et al [105] confirmed the heritability of the syndrome in a 1969 paper. Key to the understanding of MH was the early recognition of the pale soft exudative pork or porcine

stress syndrome as an animal model for the human disorder.

### **Genetics and pathophysiology**

Both contraction and relaxation of skeletal muscle are energy-requiring processes that depend on the coupling of excitation to contraction through acetylcholinemediated depolarization of the muscle membrane and sarcoplasmic reticulum. Depolarization results in the release of calcium stored within the sarcoplasmic reticulum. The released calcium binds to actin thin filament proteins, allowing activation of myosin thick filaments and ultimately initiating muscle contraction. The sequestration of Ca<sup>2+</sup> is active and required for relaxation of the motor unit. In MH, high levels of intracellular calcium persist, resulting in sustained contraction and continued consumption of ATP in a cellular attempt to restore Ca<sup>2+</sup> homeostasis. This consumption of ATP leads to the production of heat and ultimately muscle breakdown that is characteristic of MH. Therapy with dantrolene is directed at reducing intracellular calcium, thereby allowing for muscle relaxation and elimination of uncontrolled ATP metabolism.

Over the generation since its original description, MH has been determined to be a pharmacogenetic syndrome related to abnormalities in the gene coding for the skeletal muscle ryanodine receptor (RyR1) and in a few cases in the CACNA1S gene. Both gene products control intracellular calcium metabolism. The CACNA1S gene codes for a voltage-gated skeletal muscle Ca<sup>2+</sup> channel and accounts for less than 1% of cases [106]. The RyR1 receptor functions in skeletal muscle as a Ca<sup>2+</sup> channel that regulates intracellular calcium in a bidirectional manner. The mechanism by which abnormal RyR1 channels fail is unclear but may be related to abnormalities in receptor sensitivity to normal or abnormal ligands. The channel may become hypersensitive to activators such as Ca<sup>2+</sup>, is less sensitive to inhibitors including both Ca<sup>2+</sup> and Mg<sup>2+</sup>, or responds to a pharmacological agent (dantrolene, halothane) to alter calcium efflux or influx (Fig. 40.5).

The pattern of inheritance in MH is autosomal dominant although a considerable proportion of affected individuals appear to follow a recessive pattern or no identifiable inheritance pattern. This is likely the result of variable expression or reduced penetrance within or among affected families. Genetic diagnosis is increasingly available but cannot identify a large portion of susceptible individuals [106–108]. Therefore, accurate diagnosis continues to rely on the use of the caffeine-halothane contracture test (CHCT) first developed more than 30 years ago [109,110]. The test is called the *in vitro* contraction test in Europe and requires a muscle biopsy to obtain fresh muscle that can be exposed under controlled conditions to halothane and caffeine. Strict criteria are used to define positive, negative, or equivocal tests [111–114]. Regardless, the false-positive rate is approximately 6% using European guidelines and 9% using those from North America [114,115]. Testing is increasingly restricted to a few centers and can only be accurately performed using fresh muscle from adults and children older than about age 6 years [116]. Genetic testing may be performed on relatives of a known case (with positive or equivocal CHCT result) with a positive genetic test [117]. Although a negative genetic test among relatives does not preclude the remote possibility of another MH mutation not included in the test battery within the same family, it nonetheless provides a high degree of reassurance [113].

### Epidemiology

Malignant hyperthermia is a rare disorder affecting fewer than 1:50,000 adults and as many as 1:3000 children [118], representing approximately 13 cases per million hospital discharges in the United States [119] or 1 per 100,000 in New York State in 2005 [120]. Although large epidemiological studies have not been performed recently, it appears that the frequency of MH has declined with increased awareness and a greater degree of certainty as to the agents that are and are not associated with the syndrome. MH may occur at any age although it is most common in children and young adults. It has been reported rarely in infants and among the elderly [121,122]. Concentrations of cases can be found among large extended families or among members of closed or relatively closed communities. In a recent review of data compiled by the Malignant Hyperthermia Association of the United States, Larach and colleagues [123] found that of 286 cases reported between 1987 and 2006, 75% were male, most were young (median age 22 years), a disproportionately large number were muscular (29%), and most were white (70%).

### Acute presentation

In the past, agents known to trigger MH included ether, halothane, and enflurane. Currently, sevoflurane, isoflurane, desflurane, and succinylcholine are known to trigger an episode of MH. Desflurane and sevoflurane are weak triggers for MH and therefore may be associated with episodes that are less fulminant than those seen in association with older agents and succinylcholine [124-127]. The rate of triggering may also be slowed or even eliminated by other factors, including the use of non-depolarizing muscle relaxants, barbiturates, and hypothermia [128]. Nevertheless, specific pharmacological triggering agents are not necessary to initiate a reaction among susceptible individuals. Carr et al [129], in a series of more than 2000 biopsy-proven MH patients, observed a rate of triggering of 0.46% despite the use of a non-triggering anesthetic.

**Figure 40.5** A schematic representation of the key structures involved in excitation-contraction coupling, including the ryanodine receptor (RYR) located on the sarcoplasmic reticulum (SR) membrane. DHPR indicates dyhydropyridine receptor. Adapted from Hopkins [205] with permission from Oxford University Press.

The clinical presentation of MH is highly variable and may at times be confused with other conditions such as rhabdomyolysis. The classic features of the disorder are non-specific and can be found in association with many other conditions. The combination of a highly variable presentation with non-specific signs and symptoms in a rare disorder explains the continued association of MH with poor outcomes, including death. This also explains the frequency with which MH is confused with other conditions. To assist in the clinical diagnosis of MH, Larach and colleagues [130] developed a clinical grading scale.

The presentation of MH relates to the underlying hypermetabolic state after exposure to a triggering agent such as a volatile anesthetic or succinylcholine. Hypermetabolism of skeletal muscle produces tachycardia, tachypnea, fever, muscle rigidity, acidosis (both respiratory and metabolic), hyperkalemia secondary to rhabdomyolysis with associated dysrhythmia, and ultimately cardiovascular collapse and death. Each of the symptoms can be traced to the calcium-induced hypermetabolic state within the skeletal muscle. Rigidity, occurring in approximately 40% of patients in the series described by Larach et al [123], is a function of sustained contraction that may lead to muscle breakdown and release of large amounts of potassium. The release of potassium in the setting of profound acidosis is often the proximate cause of ventricular dysrhythmia, CA, and ultimately death unless resuscitation efforts are successful. It must be kept in mind that acute hyperkalemia, fever, acidosis, and other manifestations of MH are associated with other conditions and may be confused with MH, although regardless of the etiology, treatment may be the same. Table 40.3 lists the order of appearance of clinical signs of MH in a series of 255 patients reported by Larach et al [123].

Laboratory evidence of MH reflects the underlying pathology. Thus, along with the aforementioned hyperkalemia and metabolic and respiratory acidosis, a rapid rise in creatine kinase (CK) and myoglobinuria reflect muscle destruction. Coagulopathy is common as are pulmonary edema and cardiac and hepatic dysfunction. Survivors of the acute phase will have evolving evidence of acute renal failure, with increasing serum creatinine and oliguria or anuria [123].

The onset of symptoms of MH is variable and may occur within minutes or may at times be delayed for hours [131-133]. Many patients with MH have had uneventful anesthetics in the past, with 30% having had as many as three previous exposures without triggering. Tachycardia and, in the spontaneously breathing patient, tachypnea are usually the first signs and are virtually always present, and the absence of tachycardia should cast doubt on the diagnosis of MH. In general, the more rapid the onset, the more severe the presentation; however, fulminant cases of MH have been described in patients whose first symptoms did not appear until after admission to the postanesthesia care unit or even many hours later [132,133]. Clearly, accurate and timely recognition requires a high degree of clinical suspicion and vigilance. As many as 20% of patients experience a recrudescence of symptoms an average of 13h after the initial reaction. Those at greatest risk for recrudescence are those with delayed onset and muscular build [134].

### Patients at risk

Recognition of MH must begin with an appreciation of the patient populations at greatest risk. Susceptibility to MH has been a subject of controversy since its original description. In a 1985 paper, Britt [135] described a series of features that suggest the potential for MH: "While some are perfectly healthy, others complain of: ptosis and strabismus in childhood; kyphoscoliosis or lumbar lordosis; club foot, various kinds of hernias . . . joint hypermobility . . . undescended testicle; calcium stones . . . poor dental enamel ... " [135]. The author's extensive list reflected the lack of knowledge regarding the disorder available at that time. Currently, it is believed that MH is associated with only a few conditions, including central core disease, Evans myopathy, and King-Denborough syndrome [136-138]. The presence of strabismus, scoliosis, or other non-specific findings cannot be considered helpful in identification of those at risk.

Clearly succinylcholine-induced masseter spasm and susceptibility to MH are associated. The combination of halothane and succinylcholine produces masseter spasm in approximately 1% of children anesthetized for otolaryngological procedures [139]. Among those exhibiting masseter spasm, the association with MH depends to a large extent on the presentation. Those with mild jaw stiffness

Clinical sign	Medial (first, third quartile) appearance number <sup>c</sup>	Range of appearance number <sup>c</sup>	No. (%) of patients with sign
Masseter spasm	1.00 (1.00, 1.00)	1.00–4.00	68 (26.7)
Hypercarbia	2.00 (1.00, 2.00)	1.00-8.00	235 (92.2)
Sinus tachycardia	2.00 (1.00, 2.00)	1.00–7.00	186 (72.9)
Generalized muscular rigidity	2.00 (1.00, 3.50)	1.00–6.00	104 (40.8)
Tachypnea	2.00 (1.00, 3.00)	1.00–6.00	69 (27.1)
Other	2.00 (1.00, 4.00)	1.00–7.00	43 (16.9)
Cyanosis	2.00 (2.00, 4.00)	1.00–7.00	24 (9.4)
Skin mottling	2.00 (1.00, 3.50)	1.00–7.00	16 (6.3)
Rapidly increasing temperature	3.00 (3.00, 4.00)	1.00–7.00	165 (64.7)
Elevated temperature <sup>d</sup>	3.00 (2.00, 4.00)	1.00-8.00	133 (52.2)
Sweating	4.00 (3.00, 5.00)	1.00–8.00	45 (17.6)
Ventricular tachycardia <sup>d</sup>	4.00 (2.00, 5.00)	1.00–7.00	9 (3.5)
Cola-colored urine	5.00 (3.00, 5.00)	2.00–9.00	35 (13.7)
Ventricular fibrillation <sup>d</sup>	5.50 (4.00, 8.00)	1.00–8.00	6 (2.4)
Excessive bleeding	6.00 (5.00, 6.00)	4.00-8.00	7 (2.7)

Table 40.3 Order of appearance of clinical signs<sup>a</sup> during 255<sup>b</sup> malignant hyperthermia events

<sup>a</sup>Table lists the abnormal clinical sign and appearance order (judged to be inappropriate by the attending anesthesiologist or other physician) during malignant hyperthermia (MH) events. Clinical signs are listed in order of occurrence with the earliest signs listed first and the latest signs listed last. (No points on the clinical grading score are accumulated for the presence of the following adverse signs: cyanosis, skin mottling, sweating, excessive bleeding, and other.)

<sup>b</sup>For 31 cases, clinical sign appearance order was not known. (Appearance order is not required to calculate clinical grading scale score, and no additional points accrue for early appearance.)

<sup>c</sup>Appearance number is the numerical order in which a clinical sign appeared, e.g. the first clinical sign that appeared during an MH event would be assigned the appearance number of 1, the second clinical sign that appeared during an MH event would be assigned the appearance number of 2, and so on.

<sup>d</sup>An early version of the AMRA (adverse *m*etabolic/*m*usculoskeletal *r*eaction to anesthesia) report form did not request these signs in one fatal case in which the maximum temperature was 41°C, but these findings were noted elsewhere in the AMRA report and have been counted in this table. Adapted from Larach et al [123] with permission from Lippincott Williams and Wilkins.

appear to have only a slight increase in susceptibility to MH, whereas those exhibiting what has been termed "jaws of steel" are thought to have as high as an 80% concordance with MH. Patients with masseter spasm and an associated elevation of CK to more than 20,000 units/L have been demonstrated to have a 100% concordance with MH susceptibility [140]. As the use of succinylcholine has declined, especially in children, so has the frequency of masseter spasm. Larach et al [123] noted that, among subjects with probable or certain MH in their database, 20% had masseter spasm as a finding during their MH event.

For the clinician, a decision must be made about whether to continue with a procedure after a patient experiences masseter spasm. Some advocate canceling the planned procedure [140] and others recommend conversion to a non-triggering anesthetic and proceeding, provided no further evidence of MH is seen [140,141]. Although clear guidance cannot be given, the decision should probably be based on the severity of the masseter spasm, the urgency of the procedure, the environment (children's hospital versus free-standing surgical center), and the resources available to provide care should the event progress to fulminant MH despite a change to a non-triggering anesthetic. A child experiencing masseter spasm should almost certainly be admitted for observation and a serum CK level determined, preferably before any surgical incision to assist in determining risk for MH in the future. Weglinski and colleagues [142] demonstrated that among children with idiopathic elevations of CK and no history of masseter spasm, 49% were found to be susceptible after biopsy and CHCT. As noted previously, the combination of masseter spasm and CK higher than 20,000 units/L is virtually diagnostic. Follow-up of the child who has experienced masseter spasm should probably include counseling with regard to the risk of MH, need for biopsy now or in the future, avoidance of triggering agents in the future for the child and firstdegree relatives, and referral to pediatric neurology to evaluate for other potential causes of masseter spasm (e.g. congenital myotonia).

The association between various myopathies and MH remains an area of controversy. Specifically, are children with undiagnosed myopathies at increased risk? And are

those patients with Duchenne-type muscular dystrophy also at increased risk? As previously stated, only three myopathic conditions can be clearly associated with MH: central core disease, Evans myopathy, and King– Denborough syndrome. Other myopathies have been associated with MH in the past but have not been clearly demonstrated to be linked and are no longer considered to require MH precautions. Osteogenesis imperfecta, Schwartz–Jampel syndrome, myotonia, and other myopathies have been at one time or another associated with MH, and previous editions of this and other texts have recommended the use of non-triggering anesthetics for children with a myopathy.

The relationship between MH and dystrophies, including Duchenne and Becker, however, remains uncertain. Reports in the past have described sudden CA and death in children known to have a muscular dystrophy and attributed those events to fulminant MH. It has become clear, though, that these events are more likely to be the result of rhabdomyolysis and subsequent hyperkalemic CA rather than true MH. The question remains as to whether volatile anesthetics are the cause of the rhabdomyolysis and consequently should be avoided in these patients. Clearly, succinylcholine is associated with this phenomenon and should never be used in a patient with a known or suspected dystrophy (or myopathy). In the young boy with Duchenne-type muscular dystrophy, the decision to avoid both succinylcholine and a volatile agent is relatively straightforward, as there are obvious alternatives. However, it is less clear how to approach the child with an undiagnosed myopathy, because the alternative, typically propofol, may be contraindicated in children with mitochondrial disorders [137,138].

#### Acute management

Successful management of an acute MH episode depends on early recognition and swift application of a treatment protocol that has been well thought out in advance of the need. Figure 40.6 is a poster from the Malignant Hyperthermia Association of the United States that describes the management of fulminant MH.

Specific management includes discontinuation of triggering agents and institution of therapy with dantrolene. Non-specific therapy is aimed at the effects of acidosis, fever, rhabdomyolysis, and consequent hyperkalemia, including correction of acidosis with hyperventilation and sodium bicarbonate; active cooling using cooling blankets, iced saline lavage, cooled fluids, etc.; maintenance of urine output with mannitol and furosemide; and management of hyperkalemia with bicarbonate, glucose, and insulin. Additional therapies directed against dysrhythmia such as procainamide and amiodarone may be useful; however, rhythm disturbance is almost certainly secondary to hyperkalemia, and therapy should be primarily directed at reducing serum potassium.

First available in the late 1960s as an oral muscle relaxant for use in patients with spasticity, dantrolene was recognized as an effective therapy for MH in pigs by Harrison in 1975 [143] and 2 years later in humans by Austin and Denborough [144]. The drug was of limited value for acute management, given the need to deliver it orally. It was extremely useful, however, for prophylaxis, and when solubility problems were resolved, it became available for intravenous use in 1979.

Dantrolene acts to inhibit excitation contraction coupling in skeletal muscle by inhibiting calcium release at the level of the sarcoplasmic reticulum. It depresses twitch height by more than 70% in humans when given intravenously in a dose of 2.5 mg/kg. Bio-availability of the oral form, once an issue of concern, is very similar to that of the intravenous form [145]. Elimination is by hepatic conversion to an active 5-hydroxy metabolite that is excreted in the urine, with a half-life of approximately 9h for the parent and 15h for the metabolite [146].

Dantrolene is used for either prophylaxis or acute management and is indicated as prophylaxis in adults and children with biopsy-proven MH. The drug is highly effective and, when used in sufficient doses early in the course of acute MH, is virtually 100% effective in preventing mortality. The trend in mortality associated with acute MH up to 1993 was described by Strazis and Fox [147]. Mortality declined dramatically in the years immediately after the introduction of dantrolene, from more than 60% to less than 10%. Currently, mortality has further declined to less than 5%.

## Preparation and care of the susceptible patient

Identification of the patient at risk and the provision of a safe, non-triggering anesthetic environment are the primary goals for those providing care to those at risk for MH. Patients at risk have been discussed previously and include those with a previous history of MH or masseter spasm and a CK higher than 20,000 units/L within 24*h*; those with one of the previously mentioned myopathies (central core, Evans, King–Denborough); those with an idiopathic elevation of CK; and first-degree relatives of a person with known or suspected MH. These patients should be managed as if they are known to have MH, regardless of whether they have been tested.

Testing consists of either the CHCT (in Europe, *in vitro* muscle contracture testing), considered to be the gold standard, or newer genetic testing to identify individuals who carry one of more than 29 different *RYR1* mutations. The CHCT is essentially 100% sensitive and approximately 80% specific but requires a surgical procedure, can only be done in a few centers around the world, is

### Effective May 2008 EMERGENCY THERAPY FOR MALIGNANT HYPERTHERMIA

### **DIAGNOSIS vs. ASSOCIATED PROBLEMS**

### Signs of MH:

- Increasing ETCO2
- Trunk or total body rigidity
- Masseter spasm or trismus
- Tachycardia/tachypnea
- Mixed Respiratory and
- Metabolic Acidosis Increased temperature (may be late sign)
- Myoglobinuria

### Sudden/Unexpected Cardiac

### Arrest in Young Patients:

- Presume hyperkalemia and initiate treatment (see #6)
- Measure CK, myoglobin, ABGs, until normalized
- Consider dantrolene
- Usually secondary to occult myopathy (e.g.,
- muscular dystrophy)
- Resuscitation may be difficult and prolonged
- ACUTE PHASE TREATMENT
- GET HELP. GET DANTROLENE Notify Surgeon
- Discontinue volatile agents and succinylcholine. Hyperventilate with 100% oxygen at flows of 10
- L/min. or more.
- Halt the procedure as soon as possible; if emergent, continue with non-triggering anesthetic technique.
- Don't waste time changing the circle system and CO2 absorbant.

### Dantrolene 2.5 mg/kg rapidly IV through large-bore IV, if possible

- To convert kg to lbs for amount of dantrolene, give patients 1 mg/lb (2.5 mg/kg approximates 1 mg/lb).
- Dissolve the 20 mg in each yial with at least 60 ml sterile, preservative-free water for injection. Prewarming (not to exceed 39° C.) the sterile water may expidite solublization of dantrolene. However, to date, there is no evidence that such warming improves clinical outcome
- Repeat until signs of MH are reversed.

Pr

() Observe the patient in an ICU for at least 24

hours, due to the risk of recordescence. Dantroice 1 mg/lug q 4-6 hours or 0.25

+ CK every 8-12 hours; less often as the values

infusion with careful attention to both urine and serum pH values).

and her/his physician. Refer patient to the nearest Biopsy Center for follow-up.

subsequent development of Acute Renal Failure. CK levels above 10,000 IU/L is a presumptive sign of rhabdomy olysis and myoglobinuria. Follow standard intensive care therapy for acute rhabdomyolysis and myoglobinuria

This protocol may not apply to all patients; alter for specific needs.

- Trismus or Masseter Spasm with Succinylcholine Early sign of MH in many patients
- If limb muscle rigidity, begin treatment with dantrolene
- For emergent procedures, continue with non-triggering agents. evaluate and monitor the patient, and consider dantrolene
- · Follow CK and urine myoglobin for 36 hours.
- Check CK immediately and at 6 hour intervals until returning to normal. Observe for dark or cola colored urine. If present, liberalize fluid intake and test for myoglobin
- Observe in PACU or ICU for at least 12 hours
  - 6 Hyperkalemia Treat with hyperventilation, bicarbonate, glucose/insulin, calcium.
  - Bicarbonate 1-2 mEq/kg IV.
  - For pediatric, 0.1 units insulin/kg and 1 ml/kg 50% glucose or for adult, 10 units regular insulin IV and 50 ml 50% glucose.
  - Calcium chloride 10 mg/kg or calcium gluconate 10-50 mg/kg for life-threatening hyperkalemia.
  - · Check glucose levels hourly.
  - Follow ETCO2, electrolytes, blood gases, CK, core temperature, urine output and color, coagulation studies. If CK and/or K+ rise more than transiently or urine output falls to less than 0.5 ml/kg/hr, induce diuresis to >1 ml/kg/hr and give bicarbonate to alkalanize urine to prevent myoglobinuria-induced renal failure. (See D below)
  - Venous blood gas (e.g., femoral vein) values may document hypermetabolism better than arterial values.
  - Central venous or PA monitoring as needed and record minute ventilation.
  - Place Foley catheter and monitor urine output.

#### Non-Emergency Information

Figure 40.6 Poster prepared by the Malignant Hyperthermia Association of the United States (MHAUS) to provide the clinician with essential information for the care of the malignant hyperthermia patient. Reproduced with permission from reference [206] with permission from the Malignant Hyperthermia Association of the United States.

expensive, and cannot be done accurately on children under the age of 6 years (age criteria vary for each testing site). Genetic testing will not identify all those who are susceptible and therefore must be used in combination with muscle biopsy testing in those with a negative genetic test result. The test is especially useful to evaluate family members of a patient known to have MH; however, a negative test result does not rule out MH because not all the genetic mutations responsible for MH have been identified. Genetic testing is, however, much less expensive and does not require travel or a surgical procedure.

For the patient determined to be at risk, a non-triggering anesthetic should be provided, avoiding the use of volatile anesthetic agents and succinylcholine. The use of regional anesthesia is an excellent option because amidetype local anesthetics have not been found to carry risk either in animal models or in clinical practice. The anesthesia machine should be flushed of residual anesthetic, absorbant changed, agent and vaporizers either removed or otherwise rendered inoperable. Various protocols have been recommended for specific anesthesia machines. The Draeger Fabius machine (Draeger Medical Systems Inc, Telford, Pennsylvania) requires more than six times as long to adequately flush as the older Draeger Narkomed [148]. This is similar to the time required to flush the Draeger Primus compared to the Ohmeda Excel (GE Healthcare, Piscataway, New Jersey) [149]. Both new machines required more than 1h to reduce the anesthetic agent concentration to less than 5 parts per million. This protracted preparation time may require that a clean machine be kept available or that MH-susceptible cases be cared for as the first case on the surgery schedule to avoid delays.

### Summary

In summary, MH is a rare pharmacogenetic disorder that is likely to become increasingly rare, given its increased recognition, more frequent use of weak triggering agents, and less frequent use of succinylcholine. Prompt recognition and early treatment with dantrolene should make severe morbidity or mortality extremely rare. As genetic diagnosis becomes increasingly available and sensitive, this disorder will be more easily identified and managed in the future.

### **Propofol infusion syndrome**

Propofol is an intravenous anesthetic agent used for the induction of general anesthesia in children and adults. Because of its rapid onset and offset of action, it is an ideal agent for sedation of mechanically ventilated patients. Developed in 1980, it had been used for a number of years

in both adults and children without report of severe adverse events.

In 1992, Parke et al [150] reported on the deaths of five children in whom metabolic acidosis and myocardial failure developed after propofol infusion. All these children had upper respiratory tract infections, ranged in age from 4 weeks to 6 years, and were sedated with propofol at a rate ranging between 66 and  $178\mu g/kg/min$  (4–10.7 mg/kg/h) for between 66 and 115h. The constellation of metabolic acidosis, bradyarrhythmia, and heart failure was typical for these patients. The dose range was within that recommended by the British Medical Association at that time, 150–2500 µg/kg/min (9–150 mg/kg/h). Parke was the first to suggest that propofol infusion, although safe in adults, perhaps should not be used for sedation for children.

In 1998, Bray [151] further characterized this constellation of symptoms as propofol infusion syndrome (PRIS) by review of information collected from the literature on 18 children who received propofol and had similar adverse effects. The majority of affected patients had respiratory tract infections, although other associations have been reported subsequently by other providers [5]. These other situations were found to occur in young, healthy patients who had sustained head trauma and had received intravenous steroids, as well as vasopressors. In Bray's series, the terminal event was myocardial failure, ventricular dysrhythmia, or, in some instances, a resistant and progressive bradycardia, which has further been identified as the Brugada syndrome [152].

Postmortem examination commonly reveals a fatty liver and myocardial fiber necrosis, metabolic acidosis is common, and plasma is lipemic. According to Bray [151], there appeared to be a definite association between PRIS and propofol infusions higher than a mean dose of  $67 \mu g/kg/min$  (4 mg/kg.h) and lasting 48 h or longer.

Although the dose limits suggested by Bray [151] provide guidance, the rapid development of tolerance requires an increased rate of propofol infusion to maintain adequate sedation, and the relatively low dose suggested by Bray is often quickly exceeded. The catecholamine surge, present in acute neurological conditions or produced in various other stress models, may result in sympathetic overactivity with secondary endogenous catecholamine toxicity that may be responsible for decreasing the anesthetic effect of propofol as well as contributing to the direct myocytolytic effects of catecholamines [153].

The mechanism of the myocytotoxic effect of propofol given in prolonged doses has not yet been entirely elucidated. It is known that propofol uncouples oxidative phosphorylation and energy production in the mitochondria, impairs oxygen utilization, and inhibits electron flow along the mitochondrial electron transport chain. These cellular effects result in a clinically apparent decrease in ventricular performance. Additionally, in this setting propofol may directly antagonize  $\beta$ -adrenoceptor binding and act directly on calcium channel proteins, resulting in diminished cardiac contractility [153].

Cardiac and peripheral muscle necrosis is often evident on postmortem examination. This may be the result of an imbalance of energy demand and supply [153]. Free fatty acids, derived from lipolysis of adipose tissues, are, under fasting conditions, the most important fuel for both the myocardium and skeletal muscle [153]. Oxidation within the mitochondria is the key process generating electrons, which are subsequently transferred to the respiratory chain. As propofol can impair the movement of electrons through this chain, the subsequent accumulation of free fatty acids can eventually lead to various grades of myocytolysis. Furthermore, the accumulation of unused free fatty acids has proarrhythmogenic properties that contribute to the overall clinical picture of dysrhythmia and myocardial failure observed in PRIS (Fig. 40.7) [153].

Although PRIS is most commonly observed after a prolonged propofol infusion, there have been some reports of development of this syndrome after just a few hours of continued propofol infusion in pediatric patients. Koch et al, in 2004 [154], reported the first case of suspected PRIS after short-term infusion of propofol in a child. The patient was a 5-year-old girl admitted to the hospital after endovascular coil embolization of a high-output arteriovenous malformation. Propofol infusion was started at  $250 \mu g/kg/min (15 mg/kg/h)$ . A progressive elevation in serum lactate developed within 6h of admission, and a diagnosis of PRIS was considered. The lactic acidosis rapidly resolved after propofol infusion was tapered and discontinued, and the child subsequently recovered (Table 40.4).

There is some thought that, in patients receiving propofol infusion, frequent monitoring of acid-base status and lactate level may alert the clinician to early development of PRIS [155]. Veldhoen and colleagues [155] described a 17-year-old boy who sustained multiple skull fractures in a motor vehicle accident. A propofol infusion was initiated to allow continued endotracheal intubation, and over the ensuing hours, escalating doses were required to maintain adequate depth of sedation. A maximum of 8mg/kg/h was administered for 14h early in the hospital course. On the fourth day, propofol was discontinued as a progressive lactic acidosis was noted. Despite serial measurement of acid-base status and lactate and eventual discontinuation of propofol after lactate was noted to increase, albeit modestly, the child subsequently had CA and eventually died as a result of profound myocardial failure. This was the first report of mortality due to PRIS despite careful monitoring of metabolic parameters and prompt discontinuation of propofol with increased lactate. It should be noted, however, that the child received a continuous infusion of propofol at a dose exceeding that recommended  $(67 \mu g/kg/min \text{ or } 4 mg/kg/h \text{ for a limited duration of no longer than } 48h)$  [155]. Figure 40.8 details this patient's hospital course.

Some predictors have been identified for mortality in patients with suspected PRIS [156]. Patients with suspected PRIS who died were more likely to be younger than 18 years old, be male, have received propofol for more than 48 h, and have been concomitantly treated with catecholamine therapy. The presence of cardiac symptoms, hypotension, rhabdomyolysis, renal involvement, metabolic acidosis, or dyslipidemia also heralded increased mortality in these patients.

Because of the association with propofol and derangement of the flow of electrons through the respiratory chain in the mitochondria, it is also thought there may be a genetic susceptibility to PRIS manifested as a mitochondrial fatty acid oxidation abnormality.

Current recommendations for propofol administration are as follows: pediatric patients should not receive infusions of propofol that exceed  $67 \mu g/kg/min (4 mg/kg/h)$ for more than 48h. For those individuals with mitochondrial myopathies or known mitochondrial defects, it is probably prudent to avoid propofol infusions altogether unless there is no viable alternative or to use adjunctive medications to facilitate sedation and allow a lower dose of propofol as infusion. Regardless, it would certainly be recommended to monitor acid–base status as well as lactate level on a regular basis (every 6h) to minimize the chance for development of PRIS. The development of a metabolic acidosis or rise in lactate without further cause would warrant discontinuation of propofol infusion and administration of an alternative sedating medication.

### Local anesthetic toxicity and intralipid administration

Thousands of doses of local anesthetic medications are administered to pediatric patients every day in hospitals and outpatient surgical centers throughout the world. Local anesthetic medications may act not only as the sole agent for analgesia; more often, they serve as an important component of an anesthetic technique that uses a combination of both regional and general anesthesia.

Cocaine was the first local anesthetic, isolated from coca leaves in the 1860s by Albert Niemann, a German chemist. Cocaine was initially used by Sigmund Freud in 1884 to assist a patient in weaning from morphine. The first clinical use of cocaine for nerve block occurred in 1884 by Dr William Stewart Halsted to create surgical anesthesia. The first modern local anesthetic developed was lidocaine in the 1940s [157].

Figure 40.7 Propofol infusion syndrome is a critical illness; cardiac failure and rhabdomyolysis are associated with high-dose propofol, catecholamines, or steroids. CNS, central nervous system; FFA, free fatty acid. Adapted from Vasile et al [153] with permission from Springer.

Dose and status	Admission	Time after admission, h						
		2	4	6	8	10	18	24
Propofol, mg/kg per h	15	15	15	15	6	6	0	0
рН	7.45	7.38	7.31	7.34	7.33	7.36	7.39	7.37

Local anesthetics prevent neural transmission through inhibition of fast sodium channels as well as via inhibition of  $\gamma$ -aminobutyric acid in pathways located in the cerebral cortex [158]. Local anesthetics are of either the amide or the ester type and are metabolized via differing mechanisms. Local ester anesthetics are metabolized via plasma pseudocholinesterase; local amide anesthetics are metabolized via the liver. It is important to understand that the toxicities of local anesthetics are additive. Therefore, when two local anesthetics are combined, the maximum dose of the local anesthetics must be carefully determined, keeping in mind the overall ratio of each of these medications.

Ever since the first use of cocaine for medical purposes, there have been reports of its adverse reactions on the nervous, respiratory, and cardiac systems. In 1885, four publications dealt with serious adverse events, including death. A report by Mayer [159] in 1924 raised medical awareness of the toxic reactions to these medications with a report of 40 fatalities related to local anesthesia. In pediatric patients, local anesthetic toxicity is relatively rare. Among the largest series that have reviewed complications of regional anesthetics in the pediatric population, Giaufre et al [160] reported a complication rate of four per 10,000 systemic toxic reactions after the performance of epidural injection of local anesthetic. In this series, no systemic toxicity was associated with peripheral nerve blocks.

When neurotoxicity occurs, it typically precedes the more severe cardiotoxicity. In awake patients, tinnitus, a metallic taste in the mouth, and circumoral tingling are frequent initial symptoms. As the blood level of local anesthetics increases, there is progression to motor twitching followed in some by grand mal seizures. In those who progress to cardiotoxicity, the manifestations include cardiac arrhythmia and hypotension, with eventual cardiovascular collapse [161]. McClenahan [162] reported the first pediatric death in 1955 after local anesthetic toxicity after the child consumed a dibucaine troche. He described a wide-complex bradycardia unresponsive to conventional treatment with sodium bicarbonate and other medications.

In 2006, Rosenblatt et al [163] reported the first successful use of a 20% lipid emulsion in a human patient during resuscitation after a presumed bupivacaine-related CA. The rationale for use of lipid emulsion had been introduced by Weinberg et al in 1998 [164] with initial studies in rats and subsequently dogs, demonstrating that lipid infusions both raise the threshold for cardiotoxicity and increase the likehood of survival in rodents receiving a large single intravenous dose of bupivacaine [164]. Ludot et al [165] presented the first case report of successful resuscitation after presumed local anesthetic toxicity in a child. A 13-year-old child received a lumbar plexus block under general anesthetic and subsequently experienced ventricular tachycardia 15 min after injection of lidocaine and ropivacaine with epinephrine. Plasma levels of local anesthetics were obtained during early resuscitation and indicated local anesthetic toxicity.

Within 2min of intralipid administration, normal sinus rhythm was achieved [165].

Experience in animals and humans suggests that intravenous lipid emulsion increases the lethal threshold and decreases mortality after systemic overdose of local anesthetics and animals [166]. This finding represents an important advance in the care of both adults and children, given that cardiopulmonary bypass has traditionally been the therapy of last resort in adults and children with CA secondary to local anesthetic overdose [167].

#### Mechanism of action of lipid emulsion

The "lipid sink" theory described by Weinberg suggests that local anesthetic is sequestered in the plasma lipid fraction, thereby isolating tissue from the toxic effect [167]. Lipid may also have a direct inotropic effect on the heart and that effect may contribute positively to its ability to reverse bupivacaine-induced cardiac depression (Fig. 40.9) [167].

Clearly, evidence supports the early use of lipid emulsion in the treatment of local anesthetic toxicity. Rather than waiting for progression to a non-productive or unstable rhythm, treatment with lipid emulsion should be initiated as soon as possible. Weinberg [167] suggested that lipid emulsion should be used at the earliest signs of local anesthetic toxicity, for example, when the neurological signs and symptoms appear and before the onset of more serious cardiac manifestations. Subsequently, Shah et al [168] reported the successful use of a lipid emulsion

**Figure 40.9** Hemodynamic response to lipid infusion. The arterial pressure trace of a rat is shown over approximately 12 min. The arrow at B indicates intravenous injection of bupivacaine, 20 mg/kg, over 20 sec. The arrows at R indicate resuscitation by closed chest compression. The L1 arrow indicates infusion of 30% soybean oil emulsion, 5 mL/kg, over 10 sec. Recovery of hemodynamic profile occurs after the second lipid bolus, L2 (*arrow*). Adapted from Weinberg [167] with permission from Lippincott Williams and Wilkins.

in a 40-day-old infant with presumed local anesthetic toxicity after caudal injection.

According to Weinberg's recommendations [167], the dose of 1mL/kg of lipid emulsion 20% over 1min could be repeated every 3–5 min for a maximum dose of 3 mL/ kg. At the point of conversion to sinus rhythm, infusion of lipid emulsion 20%, at a rate of 0.25 mL/kg/min should be continued until hemodynamic recovery. Initiation of intralipid infusion is often needed because the sequelae of local anesthetic systemic toxicity can potentially persist or recur even hours after the initial exposure. Given this potential, monitoring of patients should continue for at least 12h, particularly if there has been evidence of severe cardiovascular compromise. A number of lipid emulsions are available and have been used during resuscitation of local anesthetic systemic toxicity, including Intralipid (Baxter Healthcare Corporation, Deerfield Illinois), Liposyn (Hospira Inc, Lake Forest, Illinois), and Medialipid (Braun Medical, Boulogne, France) [169]. None has been demonstrated to be superior, and all are based on proprietary intravenous lipid formulations used for total parenteral nutrition. Medialipid was the formulation used by Ludot et al [165] in their 2008 report.

The role of more conventional medications used during resuscitation from local anesthetic overdose has been investigated. There is evidence for impairment of lipidbased resuscitation with a single dose of epinephrine of  $10 \mu g/kg$  or greater. Dose-response trials suggest that small epinephrine doses (1-2.5µg/kg) may be advantageous in terms of rapid recovery; however, higher doses of epinephrine appear to adversely affect both metabolic and hemodynamic recovery profiles. Although experimental animals treated with high-dose epinephrine had earlier return of circulation than the saline-treated or lipid-treated controls, this earlier return of circulation did not translate to sustained hemodynamic stability and, in fact, contributed to their mortality [170]. Likewise, studies in swine that included the use of vasopressin and epinephrine along with lipid administration demonstrated that survival was not improved with this practice [171]. Despite the fact that propofol is formulated in a 10% lipid emulsion, it should not be used as a substitute for lipid administration, because a fatal dose of propofol would have to be administered to achieve a therapeutic level of lipid. Propofol also may cause dose-related bradycardia and hypotension and can potentially further impair myocardial contractility in the setting of local anesthetic toxicity [158].

#### Summary

Local anesthetic systemic toxicity, although a rare event, can have devastating consequences. It has been suggested that every facility that administers local anesthetics to patients should assure the rapid availability of lipid

emulsion for the treatment of toxicity [163]. Lipid emulsion should be used early in treatment, even before the devastating effects of cardiotoxicity have occurred. As previously described, the initial dose of lipid emulsion 20% is 1 mL/kg over 1 min. This dose could be repeated every 3-5min for a maximum dose of 3mL/kg. At the point of return of hemodynamic stability, consideration should be given to initiation of an infusion at the rate of 0.25 mL/kg/min. Because local anesthetic toxicity may recur even after hemodynamic stability, patients should be monitored for at least 12h if there has been evidence of cardiovascular compromise. In addition, during resuscitative efforts, attention must be paid to the ABCs of standard cardiopulmonary resuscitation. The use of epinephrine in doses higher than  $10\mu g/kg$ , administered along with lipid emulsion therapy, may not translate to improved survival and may even contribute to higher mortality. Smaller doses of epinephrine limited to  $1-2.5\mu g/kg$  may be tolerated well during resuscitation. Similarly, the addition of vasopressin to this regimen may not be beneficial, although additional research may be necessary to fully elucidate the effects of more traditional therapy when combined with lipid emulsion therapy.

# Nerve and positioning injuries

The anesthesiologist is primarily responsible for safe and comfortable positioning of the surgical patient during the operative period. Despite great care and attention, nerve injuries do occur and can lead to temporary or, rarely, permanent disability. Not surprisingly, few data directly address positioning injuries in children. Clinical practice is therefore primarily dependent on data extrapolated from adult studies to the pediatric population.

The incidence of peripheral nerve injuries in pediatric patients appears to be much lower than that among adults although data are limited to a handful of case reports. Morray et al [19], using the ASA Closed Claims database, found that the rate of peripheral nerve injuries in children was only 1% of claims, whereas in adults, the figure was 16%. Given that pediatrics represents about 10% of all anesthetics performed, these data tend to confirm the sense that positioning injury is recognized less frequently in children than in adults.

In an adult population, Welch et al [172] evaluated a total of 380,680 anesthetics administered over a 10-year period; only 112 were associated with a nerve injury (0.03%). In that study, nerve injury was defined as a new sensory and/or motor deficit. Nerve injuries from the surgical procedure itself were excluded. This series represents the largest number of consecutive patients ever reviewed for all types of perioperative peripheral nerve injuries. In the Welch et al study [172], as in others, it was difficult to define nerve injury related to positioning

because existing deficits, injuries occurring in the postoperative period, and predisposing conditions make case finding challenging. In that study, by far the most common of the positioning-related injuries was that affecting the ulnar nerve [172]. Box 40.1 is a simplified guide to the recognition of various nerve injuries [173].

The practice advisory for the prevention of perioperative peripheral neuropathies published by the ASA in 2002 provides guidance that, although directed primarily at adult patients, can be useful for children as well [174]. Even when the ASA guidelines are followed, however, injury cannot be prevented in all patients, most likely secondary to predisposing conditions. Welch et al [172] demonstrated that certain populations may be more likely to have perioperative positioning injuries due to co-morbid conditions. This study reported associations with the following surgical specialties: neurosurgery, cardiac surgery, general surgery, and orthopedic surgery. Medical co-morbid conditions such as hypertension, tobacco use, and diabetes mellitus were also associated with peripheral nerve injuries in the perioperative setting. It is interesting to note that the Welch et al study did not demonstrate an increased frequency in peripheral nerve injuries in patients maintained in a prolonged lithotomy position, although it has been shown in previous studies [175] that the lithotomy position for more than 2h has been a major risk factor for injury. Upper extremity nerve injuries were more common than lower extremity injuries. During this study, three different databases were examined. Sensory deficits were slightly more frequent in one database, whereas motor deficits were more frequent in another, and, not surprisingly, patients with a motor component to their injury are more likely to pursue legal measures.

Ischemia and infarct are mechanisms of localized injury to the peripheral nerves of an anesthetized patient. Winfree and Kline [176] indicated that disruption of blood supply to the nerves is integral to the mechanism of injury. Thus, it is reasonable to consider that patients with disease states that affect changes in blood flow might have a higher frequency of positioning injuries. Pediatric patients, who are less likely to have some of the above co-morbid conditions, may have a lower frequency of peripheral nerve injuries due to positioning.

In addition to peripheral neuropathy and subsequent neurological deficits, the occurrence of postoperative vision loss (POVL) is of particular concern during the performance of particular procedures. The causes of POVL are threefold: ischemic optic neuropathy (including anterior and posterior types), central retinal occlusion, and cortical blindness [177]. A number of factors, which may be under the control of the anesthesiologist, have been identified as being associated with POVL, including patient positioning, intraoperative hypotension, and blood loss. Patients who had ischemic optic

Box 40.1 Simplified clinical identif	ication of major peripheral nerve injuries
Arm	
Median nerve	Numbness over the index finger; weakness of abduction of the thumb
• Ulnar nerve	Numbness over the little finger; weakness of abduction and/or adduction of the fingers; weakness of flexion at the distal interphalangeal joints of the little and ring fingers if the lesion is at the elbow
Radial nerve	Weakness of extension at the distal interplanalgeal joint of the thumb and of the wrist and finger extensors
Musculocutaneous nerve	Weakness of flexion of the elbow
Circumflex nerve	Weakness of abduction of the shoulder
Brachial plexus	Various combinations of lesions within the median, ulnar, radial, musculocutaneous, and circumflex nerve territories
Leg	
Femoral nerve	Weakness of flexion of the hip; numbness over the thigh
Obturator nerve	Weakness of adduction of the hip
Sciatic nerve	Weakness of ankle dorsiflexion and plantarflexion; weakness of knee flexion, if the lesion is proximal; numbness below the knee
Common peroneal nerve	Weakness of dorsiflexion of the ankle and toes
Tibial nerve	Weakness of plantarflexion of the ankle and toes
Adapted from Sawyor et al [173] w	ith permission from Elsevier

neuropathy had longer periods in the prone position with a larger estimated blood loss compared with those patients with central retinal artery occlusion. The majority of patients with ischemic optic neuropathy had both eyes affected, whereas recovery was very unlikely in the group of patients who had central retinal artery occlusion. Recovery of vision is more likely in ischemic optic neuropathy, with 44% of patients recovering their vision compared with 0% recovery in the central retinal artery occlusion group [178].

Etiology of ischemic optic neuropathy is unknown and possibly multifactorial; it is more commonly associated with large blood loss, hypotension, anemia, the prone position, and/or vaso-occlusive disease, although specific etiologies for anterior and posterior ischemic optic neuropathy may differ [179,180]. Conversely, the etiology of central retinal artery occlusion is thought to be caused by direct pressure on the globe from facemasks or cushions when the patient is in the prone position, by emboli or by low perfusion pressure in the retina [179].

Postoperative vision loss is often thought of as being associated with spinal surgery; however, other surgical procedures may be complicated by problems similar to those encountered during prolonged spinal procedures and might also be associated with this complication. Indeed, Lee et al [181] reported on the first case of POVL caused by anterior ischemic optic neuropathy in a pediatric patient who underwent cranial vault reconstruction. Because cranial vault reconstruction is often associated with the possibility of a large volume of blood loss, prolonged surgery, often in the prone position, and occasionally the need for controlled hypotension, these conditions do increase the chance for ischemic optic neuropathy. The child described by Lee et al [181] had an uneventful anesthetic and immediate postsurgical recovery but was readmitted on postoperative day 6 with bilateral blindness.

Although rare, the potential for nerve injury in children should not be ignored. Careful positioning, special attention to those at greatest risk, and awareness of nerve injury as a cause of postoperative pain, limited mobility or visual loss, even in the non-verbal or preverbal child, should be maintained.

# Anaphylaxis and its treatment

Anaphylaxis is a progressive, potentially fatal, IgEmediated reaction associated with histamine release into the systemic circulation. Upon histamine release, hypotension, edema, and hypoxia, even circulatory arrest and death may occur. To improve survival and outcome, rapid diagnosis and treatment are important. Multiple factors may lead to anaphylaxis (e.g. food allergies, insect stings, and drugs). Interestingly, 20% of patients treated for anaphylaxis had no identifiable cause [182]. This section focuses on drug-induced anaphylaxis in the perioperative period.

# Definition

In 2006, the Second Symposium on the Definition and Management of Anaphylaxis recommended the following definition: "Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death" [183]. Due to the powerful sequelae of histamine release into the systemic circulation, immediate diagnosis and treatment are of utmost importance. Anaphylaxis is due to an IgEmediated immediate hypersensitivity reaction, resulting in immediate release of potent chemical mediators from mast cells and basophils. Histamine is the predominant mediator being released, followed by prostaglandin D2, leukotrienes, platelet-activating factor, tryptase, and eosinophil and neutrophil chemotactic factors. In contrast, anaphylactoid reactions are not IgE mediated but cannot be distinguished clinically from anaphylaxis. The most important organ systems affected by anaphylactic reactions are cutaneous, respiratory, cardiovascular, and gastrointestinal [184].

#### Epidemiology

The incidence of anaphylactic reactions in the perioperative period ranges from 1 in 10,000 cases to 1 in 20,000 cases [185]. Unfortunately, incidence data are often underestimated because of under-reporting. Interestingly, 90% of anaphylactic reactions appear at anesthesia induction. Mortality rates are reported to be between 3% and 9%. Most of the deaths related to anaphylaxis are drug induced, followed by food- and insect sting-related causes. Data regarding pediatric anaphylaxis in the United States vary because of insufficient reporting in the pediatric population and discrepancies in the definition of anaphylaxis. Data from 2004 estimated the incidence of anaphylaxis among children and adolescents to be 10.5 episodes per 100,000 person-years [186], lower than the incidence in the general population.

The population of the United States seems to have a higher incidence of anaphylaxis compared with that in other countries. Factors such as expansion of diet and increasing use of peanut products in foods have been attributed to this finding. Children and adolescents with atopy, asthma, eczema, and a history of allergies are at an increased risk of anaphylaxis. Although male sex may be a predisposing factor for development of anaphylaxis, genetic factors and racial differences do not seem to play a role. However, any patient who has had an anaphylactic reaction is at increased risk of recurrence. The severity of the previous anaphylactic reaction does not predict the severity of the recurring reaction [184].

In regard to anaphylactic reactions within the perioperative period, non-depolarizing neuromuscular blocking agents (NMBAs), latex, and antibiotics are at the top of the list of offending agents. Death from anaphylaxis is rare. However, lack of reporting and difficulty diagnosing anaphylaxis posthumously with any specific test contribute to inaccurate numbers related to morbidity and mortality.

# Etiology

Although this section is focused on drug-induced anaphylaxis in the perioperative period, there is some relationship between food allergies and drug-induced anaphylaxis. Food is actually the most common cause of anaphylaxis in children, followed by medications, insect stings, blood products, latex, vaccines, and contrast dye [186,187]. While children can outgrow many food allergies, e.g. milk, eggs, and soybeans, certain food allergies persist. Foods causing persistent sensitivity include peanuts, tree nuts, and shellfish. These foods are responsible for more severe and near-fatal and fatal anaphylactic reactions [188].

Among drug-induced anaphylactic reactions, allergy to penicillin is the most common [186]. Among individuals with penicillin allergy, 4–10% have cross-reactivity to other penicillin-related drugs [187]. Some medications contain food-related substances to which food-allergic individuals may react. Propofol, marketed as Diprivan (AstraZeneca, Wilmington, Delaware), is used for sedation and general anesthesia in children. It contains egg and soybean products that increase the risk of anaphylaxis in individuals with these specific food allergies.

#### Pathophysiology

The IgE-mediated hypersensitivity reaction has been classically used to describe anaphylaxis. The body is introduced to different allergens via different routes including ingestion, skin contact, or intravenous injections or infusions. Interestingly, a small amount of allergen is sufficient for cells to react. On initial exposure to an allergen, IgE isotype antibodies are produced and bind to highaffinity FceRI receptors located in the plasma membrane of tissue mast cells and blood basophils. Lymphocytes, eosinophils, and platelets bind IgE antibodies via lowaffinity FccRII receptors. This initial antigen sensitization is clinically silent. On re-exposure, epithelial and endothelial barriers break down. This allows the antigen to come into contact with its specific IgE antibodies. The multimeric allergen cross-links two specific IgE receptors, thereby creating a bridge between two IgEs. The two IgE receptors aggregate and induce a signal transduction cascade, releasing systemically preformed biochemical mediators. Histamine is being released predominantly from intracellular granules in cells within tissues and blood, followed by neutral proteases (tryptase, chymase), and proteoglycans (heparin). Proinflammatory phospholipid-derived mediators, including prostaglandin D2, leukotrienes, thromboxane A2, and plateletactivating factor, are released soon after. Thereafter, mast cells release numerous chemokines and cytokines that initiate recruitment and activation of additional inflammatory cells.

The release of these mediators mediates the symptoms of anaphylaxis, i.e. increased vascular permeability with erythema, edema, and pruritus, vasodilation, bronchospasm, and increased smooth muscle tone.

Mast cell and basophil activation with subsequent chemical mediator release can also be triggered via activation of the complement system and direct actions on mast cells and basophils. However, the symptoms are indistinguishable from those triggered via IgE.

# **Timing of reactions**

While most anaphylactic reactions occur within minutes of exposure to the offending agent, an additional delayed response is also possible. Delayed reactions may occur up to 72h after the initial reaction. In addition, inadequate treatment of the initial reaction may predispose individuals to delayed reactions [189]. Route, quantity, and type of antigen do not seem to play a role in delayed reactions. Severity of the initial reaction does not predict the occurrence of a delayed reaction. Corticosteroid treatment specifically in delayed anaphylactic reactions has not been effective [190].

# Causes of anaphylaxis in the perioperative period

The most common cause of anaphylaxis in the perioperative period is neuromuscular blocking agents (NMBAs), with an incidence ranging from 50% to 70% [182–191], followed by latex and antibiotics [192]. Usually, anaphylactic reactions occur shortly after induction, which is especially true for NMBAs and antibiotics, but may occur at any time with all potentially allergenic agents [192]. Latex allergy, which contributes to a high number of anaphylactic reactions in the perioperative period, is discussed separately in this chapter.

In NMBAs, the quarternary ammonium groups (NH<sup>4</sup><sub>4</sub>) on the NMBAs are responsible for the anaphylactic reactions. Quarternary ammonium groups also exist in foods, cosmetics, and drugs. Prior contact with quarternary ammonium groups contained in foods, cosmetics, and drugs may lead to anaphylaxis on subsequent exposure to NMBAs. In addition, NMBAs may trigger mast cell degranulation through activation of nicotinic acetylcholine receptors on cell surfaces [182]. Cross-reactivity between NMBAs occurs in approximately 60–70% of those tested [192].

Antibiotics are also known to cause anaphylaxis, especially in the perioperative period. Specifically  $\beta$ -lactam antibiotics (e.g. penicillins and cephalosporins) and vancomycin seem to trigger anaphylaxis [193]. In regard to vancomycin, direct mast cell activation seems to be the cause. The specificity of skin testing with  $\beta$ -lactams is between 97% and 99%, whereas the sensitivity is about 50% [185].

Anaphylaxis in response to thiopental or propofol is reported infrequently, whereas anaphylaxis to etomidate and ketamine is extremely rare [191,192]. Anaphylaxis to opioids is very rare as well [191,192].

Anaphylaxis to local anesthetics is uncommon and has decreased in frequency as a result of the reduced use of the ester group of local anesthetics. Most allergic reactions are attributable to the common metabolic product of the ester local anesthetic, para-amino benzoic acid [191,192], which also leads to cross-reactivity among all local anesthetics belonging to the ester group. Allergic reactions to amide local anesthetics remain anecdotal. Ingredients included in local anesthetic solutions such as antioxidants or preservatives, including metabisulfite or parabens, may also elicit allergic or adverse reactions [193]. Cross-reactivity among esters is common, whereas it is rarely seen in the amide group and is absent between esters and amides.

#### Diagnosis

Because anaphylaxis may progress within minutes to a life-threatening condition, its immediate diagnosis is essential. The first line of evidence for the diagnosis of anaphylaxis includes the features and severity of clinical signs as well as the timing between the introduction of a suspected allergen and the onset of symptoms. The amount of resuscitative agents required to treat the occurrence gives insight into the severity of the reaction [192].

Dewachter et al [194] adapted a clinical severity scale from Ring and Messmer [195] to describe perioperative immediate hypersensitivity reactions. Although this scale does not take into account the pathophysiological mechanisms, it is appropriate for grading the clinical severity and guiding the clinical care of immediate reactions [192]. Grades I and II describe cutaneous and cutaneous-mucous signs. Although cutaneous symptoms such as flushing, pruritus, or urticaria may be the first indication of an anaphylactic reaction, these are often missed in the operating room where patients are covered with drapes and blankets. In addition, anesthetized patients cannot verbalize complaints regarding pruritus or nausea. Bronchospasm has been reported to be the first sign of anaphylaxis in the operating room followed by hypotension, hypoxemia, and angio-edema, which relates to a grade III reaction [182], followed by CA, which is grade IV. Grades I and II are usually not life-threatening conditions, whereas grades III and IV are emergency situations necessitating prompt resuscitation.

In cases of suspected anaphylaxis, the time of occurrence is important. Appearance of symptoms within minutes of anesthetic induction implicates an intravenous agent. Reactions 15 min or more after induction suggest skin or mucous membrane contact of the offending compounds. Biphasic reactions, with an initial event followed by a second delayed reaction, have been described to occur in 6–23% of patients with anaphylaxis [184]. Delayed reactions can occur up to 72 h after the initial reaction. Insufficient treatment with epinephrine during the initial reaction increases the risk of a delayed reaction.

Box 40.2 shows the clinical criteria for diagnosing anaphylaxis. This was developed by the participants of the Second Symposium on the Definition and Management of Anaphylaxis, which was thought to capture at least 95% of the cases of anaphylaxis [183]. It is important to notice that the criteria listed refer to patients not undergoing anesthesia at the same time as there is suspicion for an anaphylactic reaction.

#### Laboratory tests

During acute management of anaphylaxis, no test is needed to confirm the diagnosis. However, if the diagnosis is uncertain, elevated levels of histamine, serum tryptase, or both may be helpful [184]. Histamine and tryptase are the major components being released during mast cell degranulation. While histamine is the major compound being released during anaphylaxis, its detection is difficult because of its short plasma half-life of 15–20 min. After a grade I or II reaction, blood samples for histamine measurement should be drawn within 30 min. After severe reactions (grades III and IV), histamine may still be increased 2h after the reaction. Saturation of the enzymatic metabolism of histamine is the suggested mechanism that allows detection of increased histamine levels for this prolonged period after the reaction [196].

Tryptase is a mast cell neutral serine protease and a preformed enzyme. Two major forms –  $\alpha$ -tryptase and  $\beta$ -tryptase – have been identified [191]. While  $\alpha$ -tryptase is increased in mastocytosis, pro-β-tryptase serves as a measure of mast cell mass. Mature β-tryptase is preferentially stored in mast cell granules and, when systemically released, reflects mast cell activation with mediator release. Serum tryptase concentrations reach a peak between 15 and 60 min, with a half-life of approximately 2h [191,192]. In grade I or II reactions, blood samples may be drawn within 15 and 60 min and within 30 min and 2h in grade III or IV reactions [192]. An increase of total tryptase concentrations (i.e. the sum of  $\alpha$ -tryptase and β-tryptase) is highly suggestive of mast cell activation as seen in anaphylaxis, but its absence does not preclude the diagnosis. Some studies have demonstrated low sensitivity of tryptase levels in the diagnosis of anaphylaxis [191].

As a result of an immediate non-allergic reaction (e.g. histamine release), histamine may be increased, whereas tryptase remains normal. Because histamine and tryptase concentrations correlate with the severity of the allergic reaction, combined histamine and tryptase measurements have been recommended for the diagnosis of immediate reactions, whereas others recommend only tryptase [191,192].

More specific testing should be done in patients who have more than just cutaneous symptoms. Specific IgE testing can be done 2–3 weeks after an anaphylactic reaction. Skin testing is more sensitive than measuring IgEspecific antibodies and remains the gold standard for the

Box 40.2 Clinical criteria for diagnosing anaphylaxis

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g. generalized hives, pruritus or flushing, swollen lips-tongue-uvula)

AND AT LEAST ONE OF THE FOLLOWING:

(a) Respiratory compromise (e.g. dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)

(b) Reduced BP or associated symptoms of end-organ dysfunction (e.g. hypotonia (collapse), syncope, incontinence)

- 2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
  - (a) Involvement of the skin-mucosal tissue (e.g. generalized hives, itch-flush, swollen lips-tongue-uvula)
  - (b) Respiratory compromise (e.g. dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
  - (c) Reduced BP or associated symptoms (e.g. hypotonia (collapse), syncope, incontinence)

(d) Persistent gastrointestinal tract symptoms (e.g. crampy abdominal pain, vomiting)

3. Reduced BP after exposure to known allergen for that patient (minutes to several hours):

(a) Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP<sup>a</sup>

(b) Adults: systolic BP of less than 90 mmHg or greater than 30% decrease from that person's baseline.

BP, blood pressure; PEF, peak expiratory flow.

<sup>a</sup>Low systolic BP for children is defined as less than 70mmHg from 1 month to 1 year, less than (70mmHg + [2 × age]) from 1 to 10 years, and less than 90mmHg from 11 to 17 years.

Adapted from Sampson et al [183] with permission from Elsevier.

detection of IgE-mediated reactions by exposing the mast cells of the skin to the suspected allergen in patients who have had anaphylaxis [185].

Premedication with H1 or H2 receptor antagonists, with corticosteroids, or with a combination of these agents has not been proven to prevent anaphylaxis [192]. Therefore, skin tests allow identification of the offending agent and demonstrate the pathophysiological mechanism of the reaction (allergic versus non-allergic). A 4–6-week delay after the reaction is required to avoid a false-negative test result because of mast cell depletion [192]. After the final test results, patients should be given a detailed report to provide to caregivers prior to future anesthetic exposures.

#### Management and treatment

Management of patients in whom anaphylaxis develops in the perioperative period is challenging. Most of them will have received multiple medications and present with more advanced symptoms, and their condition progresses faster than in other settings. Anaphylaxis during anesthesia is especially challenging since most of the time the initial symptoms of urticaria or erythema are not observed because the patients are covered by drapes. It is important for all people involved in the care of these patients to help identify the cause so that future exposures can be avoided [182].

Due to its severity, the diagnosis and treatment of anaphylaxis must occur simultaneously. Treatment is directed toward managing the most severe symptoms, including cardiovascular collapse, bronchospasm, and airway edema. Initiation of intravenous epinephrine and other therapies and expeditious interruption of suspected causative agents must go hand in hand. In addition to ventilation with 100% oxygen, volume support and definitive airway managment are required [182]. Patients should be placed supine in the Trendelenburg position, and the surgical procedure abbreviated if possible when anaphylaxis occurs intraoperatively.

Administration of intravenous epinephrine and expansion of intravascular volume are essential to the perioperative management of anaphylaxis [191,192]. Epinephrine's  $\alpha$ -agonistic effects reverse vasodilation, while its  $\beta$ -agonist effects treat bronchospasm and release of inflammatory mediators. Because epinephrine has a short half-life, repeated doses or a continuous infusion may be necessary. There is no absolute contraindication during anaphylaxis for the use of epinephrine, and early administration should be the rule [191,192].

Due to the increased vascular permeability, fluid therapy with crystalloid or colloid solutions should be initiated immediately. Bronchospasm is treated with an inhaled  $\beta 2$  agonist (salbutamol or albuterol) [191,192]. Given that cardiovascular collapse and bronchospasm occur together, epinephrine remains the first-line therapy as it corrects both cardiovascular disturbances as well as bronchoconstriction through its  $\beta$ 2-adrenergic effects. Intravenous corticosteroids early in the course of therapy are recommended because of their anti-inflammatory effects although the beneficial effects are delayed at least 4–6h [192]. Corticosteroids, H1 receptor antagonists, or both are often recommended, with varying success, in the management of anaphylaxis [191,192].

Affected patients are sometimes unresponsive to catecholamines, possibly because of desensitization of adrenergic receptors. The use of arginine vasopressin may be an alternative as its vasoconstrictive effects are mediated by non-adrenergic vascular arginine vasopressin V1 receptors [197].

#### Summary

Perioperative anaphylaxis is a severe and rapid clinical condition that can lead to mortality even in previously healthy patients. Because of its infrequent presentation and variable clinical presentation, perioperative anaphylaxis may not be diagnosed immediately. The severity of symptoms as well as the rapidity of symptom progression demand prompt and aggressive treatment. The combination of clinical, biochemical, and skin test evidence will identify the responsible agent and allow the patient to avoid it in the future.

# Latex allergy

Natural rubber latex (NRL) is derived from the rubber tree, Hevea brasiliensis, one of over 200 lactifer-type plants belonging to the family Euphorbiaceae [198]. Among numerous compounds released by NRL, the heatstable proteins retained in NRL are responsible for the adverse events. Although the risks of hypersensitivity as well as anaphylactic reactions to latex are well recognized, the frequency of events is increasing [199]. In addition to healthcare workers, children with atopy and spina bifida and those undergoing frequent procedures requiring surgical instrumentation are at increased risk. Among all the products containing NRL in the healthcare environment, surgical gloves made from NRL have the highest prevalence for latex sensitization. Overall, the continued use of latex and the resulting sequelae of allergic reactions impose a high cost in terms of patient risk as well as provider risk and a financial burden to the healthcare system [199].

#### History

Use of latex items can be tracked back to 1600 BCE in ancient Mesoamerica. However, surgical gloves came into common use in the early 20th century. Descriptions of allergic reactions to NRL appeared in the medical literature by 1927, but the description of an immediate allergic reaction to NRL was not published until 1979. Since 1980, the allergic potential of NRL has been more widely recognized, and different approaches have been taken to study latex sensitivity [200].

#### Epidemiology

Due to differences in populations studied and methods used to verify sensitization, the reported prevalence of latex allergy in the general population varies widely, ranging from less than 1% to 6.7% [199]. A French survey obtained between 1989 and 2001 reported that latex was the second highest cause of perioperative accidents, at a rate of 27%. The healthcare environment has the highest incidence of latex sensitivity, ranging form 3% to 17% [201]. Anesthesiologists themselves have a high prevalence of latex sensitization [202]. As mentioned above, gloves made from NRL have been associated with the greatest prevalence of sensitization in the hospital setting.

#### **Mechanism of sensitization**

Frequent exposure remains the main cause of sensitization. This finding resulted in the recommendation that children undergoing frequent surgical procedures, for example, children with spina bifida, should be handled latex free from the very beginning of their management. As a result of this initiative, these children are automatically listed as being latex sensitive. In addition, children with atopy are at increased risk, especially children with food allergies to tropical fruits such as avocado, kiwi, and banana who have been shown to be at increased risk. Some evidence suggests that genetic profiles may potentiate latex reactions to hevein (HLA-DR phenotypes) [199]. The route of exposure may also play a role. In the case of NRL, skin exposure and inhalation exposure are more common. Skin exposure is of particular importance because it may result in airway hyper-reactivity leading to allergen-induced asthma [203]. Independent of the exposure, patients with latex sensitivity develop increased levels of IgE-specific latex protein. Increased IgE levels are responsible for the symptoms, and IgE levels may increase with increased exposure frequency.

#### Identification of patients at risk

Identification of patients at risk relies primarily on the history but may be aided by the use of questionnaires developed specifically to identify these patients.

Although some patients initially present with only cutaneous symptoms, cardiovascular symptoms as well as bronchospasm are common clinical features. Cutaneous manifestations are often inapparent as patients in the operating room are typically covered by drapes. As a consequence, the initial manifestation may be increased airway resistance manifested by high airway pressures and wheezing, rapidly followed by cardiovascular collapse. Typically, these events occur within 30–60 min after induction [191].

Although some high-risk groups of patients are widely recognized to be at increased risk (e.g. those with myelomeningocele), others have been identified such as those with spina bifida, multiple surgical procedures during childhood, cerebral palsy, mental retardation, quadriplegia, and atopy, including allergies to avocado, banana, chestnut, kiwi, papaya, peach, and nectarine.

#### **Diagnostic methods**

Obtaining a thorough patient history may suggest the diagnosis of latex allergy; specific laboratory tests are needed to confirm the diagnosis. Currently two tests are available: skin prick test and detection of IgE specific to latex protein (radio-allergosorbent test). Skin prick tests are inexpensive, sensitive, and specific. However, they must be performed in the physician's office with appropriate precautions because of the real risk of anaphylaxis.

The sensitivity of the measurement of latex-specific IgE is lower than that for the skin prick test, being positive in only 60–90% of sensitized patients [199]. With first exposure, patients produce latex-specific IgE, and the levels increase with each subsequent exposure. Sensitivity of the measurement of latex-specific IgE depends on the number of prior exposures.

#### **Prevention in patients at risk**

The first line of prevention is identification of children at risk. Creation of a latex-free or latex-sensitive environment within the perioperative area is desirable and encouraged. Complete avoidance of latex products prevents severe anaphylactic reactions. Indeed, De Queiroz et al [199] reported that since creation of a latex-free environment in all operating rooms and perioperative areas in 2002, no latex anaphylactic reactions have occurred after more than 25,000 procedures over a period of 5 years.

A latex-free protocol should include a checklist on how to manage children with latex allergy in every department involved in the care of children. Arrangements for a latex-free environment need to be made not only for the operating room but also for the recovery room and postoperative period. Communication between the different care teams (anesthesiologist, surgeon, nurses) is crucial. In the operating room, there should be a cart with latexfree equipment readily available to be used in these patients. Box 40.3 summarizes the recommendations for prevention of latex allergy [199].

Aerosolized latex allergen from previous cases requires at least 90 min to clear. The recommendation is to schedule elective procedures as first cases since levels of aerosolized latex allergens are at their lowest. Otherwise, a **Box 40.3** Recommendations for primary prevention of latex allergy (reducing exposure to latex protein to prevent sensitization for latex)

- Bring a latex-free cart into the room
- Use a latex-free reservoir bag, airways, and endotracheal tubes, and laryngeal mask airways
- Use a non-latex breathing circuit with plastic mask and bag
- Ventilator must have non-latex bellows
- Use IV tubing without latex ports; utilize stopcocks if available
- Cover all rubber injection ports on intravenous bags with tape and label in the following way:
- Do not inject or withdraw fluid through the latex port. Note: pulmonary artery catheters (especially the balloon), central venous catheters, and arterial lines may all contain latex components
- Use non-latex gloves
- Use non-latex tourniquets, electrodes, and examination gloves
   Draw medication directly from opened multidose vials (remove
- stoppers) if medications are not available in ampoules
- Utilize latex-free syringes, bladder catheter, and nasogastric tubes
- Use stopcocks to inject drugs rather than latex ports
- Minimize mixing/agitating lyophilized drugs in multidose vials with rubber stoppers

time gap of 90 min should be allowed to lower latex allergen levels between patients [199].

Pre-emptive use of medication to reduce allergic reactions is controversial. Although there have been recommendations to use medications such as diphenhydramine, cimetidine, and prednisone prophylactically, the current opinion is not to do so. In addition, premedication is not necessarily successful in preventing latex anaphylaxis and might even mask the initial immune response [199].

In children in whom latex exposure cannot be completely avoided, desensitization may be an option. Sublingual, subcutaneous, or percutaneous desensitization may improve cutaneous reactions as well as rhinitis and asthma.

#### Prevention: complete avoidance

Complete avoidance of latex in the perioperative care areas is the most effective way to prevent sensitization to latex. The American College of Allergy, Asthma, and Immunology released recommendations to avoid latex material in healthcare institutions [204]. Indeed, since children at risk are better identified, the incidence of latex allergy has markedly decreased. There are numerous reports of reduction of latex sensitization with the implementation of a latex-free perioperative environment. In addition, avoidance of latex can reduce latex-specific IgE in these patients and progression of symptoms. Although latex is ubiquitous in medical equipment and devices, manufacturing of single-use latex-free items has improved tremendously. In addition, there is more emphasis by manufacturers on labeling items to identify potential latex content. To maintain a latex-free perioperative environment requires continuous meticulous effort by all healthcare workers involved as well as continuous education among healthcare staff. After all, anaphylactic reactions to latex are most commonly encountered in the perioperative period.

# Introduction

The ability to pharmacologically render patients insensible to noxious stimulation using general anesthetics and sedatives represents one of the greatest discoveries in medicine. Undoubtedly, life-threatening conditions have been mitigated by surgical interventions that could only be performed with advanced physiological monitoring and meticulous administration of anesthetic drugs. While the exact molecular mechanisms by which these medications provide immobility, analgesia, and amnesia remain under investigation, most are thought to provide their physiological effects either by potentiating neuronal activity involving  $\gamma$ -aminobutyrate (GABA) receptors, by inhibiting N-methyl-D-aspartate (NMDA) glutamate receptors, or by a combination of the two.

Worldwide, every year millions of children are exposed to GABA<sub>A</sub>-agonists or NMDA-antagonists to ablate the stress response to noxious stimulation and to mitigate potential, stress-related morbidity during painful procedures and imaging studies. However, recent findings in laboratory animals have demonstrated a widespread increase in apoptotic brain cell death, an inborn cell suicide program, immediately following exposure to these drugs early in life. Moreover, several animal studies have also observed subsequent neurocognitive impairment. These findings in newborn animals have led to significant concerns among pediatric anesthesiologists.

Given the potentially serious consequences of longterm neurological sequelae following uneventful pediatric anesthesia, this chapter presents the pediatric anesthesia provider with an overview of this rapidly emerging field of research by summarizing the currently available data from animal models and human clinical studies. These findings will be moderated by a review of the neuroprotective effects of anesthetic drugs. Moreover, the impact of other perioperative events, such as pain, stress, inflammation, hypoxia-ischemia, co-morbidities, and genetic predisposition, on long-term neurological function will be discussed. Finally, the reader will be introduced to the phenomenon's putative mechanisms and to the currently proposed ameliorating strategies.

# **Historical perspective**

General anesthetics have been widely used for more than 160 years and are administered to millions of children every year [1]. Prior to the 1980s, general anesthetics were routinely withheld from hemodynamically unstable

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

premature and term neonates. The rationale for this practice was to avoid further hemodynamic deterioration in surgical neonates who were perceived to be unable to tolerate the myocardial depressant effects of anesthetic drugs. However, the denial of adequate doses of anesthetics or analgesics in these patients ignored the fact that the neonatal central nervous system is capable of sensing pain and mounting a stress response following a surgical stimulus, even in premature infants [2]. Subsequent studies by Robinson and Anand demonstrated that the administration of opioids blunted physiological responses to surgical stress without compromising hemodynamic stability and minimized postoperative morbidity in critically ill neonates [3-5]. These developments, along with more technological advances in hemodynamic monitoring and mechanical ventilation, have resulted in the current humane practice of administering anesthetics and analgesics even to the most critically ill neonates during and after surgery.

# Nociception and stress in the neonate

Neonatal animal models testing the effects of stressful conditions and exposure to recurrent painful stimulation have demonstrated widespread neuronal cell death and adverse neurological outcome as a result from these deleterious conditions [6]. Both somatic as well as visceral noxious stimulation in the neonate appear to alter processing of nociceptive inputs in adulthood. Thus, neonatal injury can subsequently be associated with either hyperalgesia or hypoalgesia, depending upon the type and severity of injury and the sensory modality tested [7]. In addition to altered pain processing, repetitive or persistent pain in the neonatal period may lead to changes in brain development, widespread alterations in animal behavior, cognitive function, and increased vulnerability to stress and anxiety disorders or chronic pain syndromes [6,8,9]. Specifically, inflammatory pain associated with repeated injection of complete Freund's adjuvant (CFA) in rat pups resulted in hyperalgesia and lasting changes in nociceptive circuitry of the adult dorsal horn [10]. Rat pups receiving repeated formalin injections into the paw developed subsequent generalized thermal hypoalgesia [7]. Moreover, early adverse emotional experiences can induce long-lasting age-, brain region-, and neuronal subgroup-specific imbalances of the inhibitory nervous system [11], disturb development of the nociceptive system and cause long-term behavioral changes [12], as well as leading to persistent learning impairment [13]. Repetitive painful stimulation in neonatal animals has been shown to lead to decreased pain thresholds and increased anxiety later in life [8,14,15]. In addition to alterations of the central nervous system, repetitive painful skin lacerations have also been found to lead to long-term, local sensory hyperinnervation [16]. Therefore, fetuses and neonates subjected to pain and stresses associated with painful procedures may be at risk for longterm adverse outcomes.

The pre-emptive administration of analgesics and sedatives, such as morphine or ketamine, in this context, has been found to ameliorate the deleterious effects of neonatal pain [6,13,15]. Importantly, painful stimulation in turn obviated adult behavioral impairment due to neonatally administered morphine [13].

Similar to these animal studies, clinical reports have demonstrated that neonates and infants can mount a metabolic and endocrine response to perioperative stress and painful stimulation [17,18] which includes increases in catecholamines, cortisol, β-endorphins, insulin, glucagon, and growth hormone [17,19,20]. Some of these markers, such as cortisol, can remain elevated for more than a year, potentially due to cumulative stress related to multiple painful procedures early in life [21]. Administration of potent anesthetics, opioid analgesics, and regional anesthesia has been shown to inhibit intraoperative stress and improve postoperative outcome [4,19,22], reduce the incidence of sepsis and disseminated intravascular coagulation, as well as decreasing mortality [5]. Even less invasive procedures, such as circumcisions, when performed without analgesia, can exaggerate pain responses later in life [23]. In contrast, topical or regional anesthesia for circumcision will blunt the immediate humoral stress response [24] and obviate long-term hyperalgesia [23].

In premature neonates, an association has been observed between painful stimulations early in life and subsequent diminished cognition and motor function [25]. At more than 1 year of age, children who were born at less than 32 weeks' gestational age without significant neonatal brain injury or major sensorineural impairment were compared with full-term controls regarding cognitive and motor development. Results demonstrated that the number of skin-breaking procedures from birth to term (including heel sticks, intramuscular injections, chest tube placements, and central line insertions) predicted lower subsequent cognitive and motor development as assessed using the Bayley Scales of Infant Development-II. Importantly, after controlling for severity of illness and days on intravenous morphine or dexamethasone, gestational age at birth was not significantly associated with cognitive or motor outcome. These findings suggest that repetitive pain-related stressful experiences and not prematurity per se were responsible for poor neurodevelopmental outcome [25].

While this study did not examine the effects of anesthetic or analgesic administration during painful stimulation on subsequent outcome, a small, retrospective study suggested improved outcome following anesthetic exposure during painful stimulation. In that study, painful stimulation during reduction of herniated bowel without anesthesia in infants suffering from gastroschisis tended to more frequently lead to serious adverse events, such as bowel ischemia, need for total parenteral nutrition, and unplanned reoperation than in infants undergoing the same procedure with general anesthesia [26]. However, despite the fact that large numbers of painful and stressful procedures are being performed in vulnerable neonates, recent data indicate that the majority of these are still not accompanied by analgesia [27].

Taken together, the data from animal and human studies suggest that pain-related stress experienced early in life is deleterious to the developing nervous system, that sedatives and analgesics may alleviate many of the degenerative effects, and that pain in children still remains undertreated.

# Developmental anesthetic-induced neurotoxicity

Concerns regarding potentially deleterious effects of general anesthetics on neurological function were first raised after more than a century of their routine clinical use. Personality changes observed in young children following administration of vinyl ether, cyclopropane, or ethylchloride for otolaryngological surgery were interpreted as long-term neurological sequelae caused by the anesthetic agents [28]. While these findings were not immediately acted upon, approximately two decades later the focus of research into potentially deleterious effects of anesthetics shifted to occupational exposure of the unborn fetus during pregnancy [29-32]. Chronic exposure of pregnant rats to subanesthetic doses of halothane during their entire pregnancy led to delayed synaptogenesis and behavioral abnormalities in their offspring. However, it took almost another two decades until initial studies were carried out examining anesthetic exposure early in postnatal life, more closely representing pediatric anesthesia practice. In these ground-breaking studies, widespread neuronal degeneration was observed following prolonged ketamine exposure in neonatal rat pups [33]. The researchers likened this phenomenon to abnormalities observed in children suffering from fetal alcohol syndrome caused by the combined GABA<sub>A</sub>agonist/NMDA-antagonist ethanol [34-36]. Accordingly, these findings were followed up by using a combination of the GABA<sub>A</sub>-agonist midazolam, the combined GABA<sub>A</sub>agonist and NMDA-antagonist isoflurane, and the NMDA-antagonist nitrous oxide, demonstrating immediate brain structural abnormalities as well as long-term decreases in neuronal density and impaired neurocognitive function following a 6h exposure to the anesthetic

combination [37,38]. Acute neuronal degeneration immediately following exposure to all routinely used anesthetics and sedatives has now been confirmed by numerous laboratories in several immature animal models [39,40]. However, the link between neurodegeneration and longterm neurocognitive impairment remains controversial, because several studies have demonstrated extensive initial neurodegeneration without long-term functional impairment [41–44].

Given the serious implications of potential long-term cognitive impairment following exposure to sedatives or anesthetic early in life, the direct clinical applicability of these laboratory findings continues to be intensely debated [45,46]. These concerns led to a risk assessment by the United States Food and Drug Administration's Life-Support Advisory Committee in March of 2007, stating that the "existing and well-understood risks of anesthesia (hemodynamic and respiratory) continue to be the overwhelming considerations in designing an anesthetic, and the understood risks of delaying surgery are the primary reasons to determine the timing" (transcript available at www.fda.gov/ohrms/dockets/ ac/07/transcripts/2007-4285t1.pdf.)

# Experimental evidence for anesthetic neurotoxicity

To date, more than 100 articles and numerous abstracts have described brain structural abnormalities and/or functional impairment following exposure to the vast majority of clinically utilized sedatives and anesthetics in immature animal models, including chicks, mice, rats, guinea pigs, swine, sheep, and rhesus monkeys. While the exact molecular mechanisms by which anesthetics provide their therapeutic effects remain uncertain, two main putative targets are the NMDA and GABA receptors.

#### N-methyl-D-aspartate-antagonists

Glutamate represents the most ubiquitous excitatory neurotransmitter in the mammalian central nervous system. Drugs routinely used in clinical anesthesia and sedation practice that provide their hypnotic effects predominantly by inhibition of the NMDA-type glutamate receptor include ketamine and nitrous oxide [47], as well as the less frequently, clinically utilized noble gas xenon [48]. Pioneering animal studies carried out in the 1990s demonstrated widespread degeneration of brain cells in newborn rat pups following the repeated administration of ketamine [33]. These findings have subsequently been replicated and expanded upon by several other laboratories [39,49]. Most of these studies demonstrated deleterious effects on the developing brain structure following the administration of multiple doses of up to 75mg/kg of ketamine (Table 41.1). Conversely, a single dose of up

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Buprenorphine	1.5 mg/kg/d to dam	Rat, E7–21	Decrease in striatal nerve growth factor	Wu et al [91]
Chloral hydrate	50–300 mg/kg × 1	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium	Cattano et al [92]

Clonazepam	0.5-4 mg/kg $ imes$ 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al [35]
Desflurane	7% for 30–120 min	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al [74]
Desflurane	7.4% for 6h	Mouse, P7–8	Increased neuroapoptosis compared with no anesthesia, but similar to equi-anesthetic doses of isoflurane or sevoflurane	lstaphanous et al [75]
Dexmedetomidine	$1-75\mu\text{g/kg} imes 3$	Rat, P7	No increase in neuroapoptosis	Sanders et al [64]
Diazepam	10-30mg/kg  imes 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al [35]
Diazepam	5-30 mg/kg $ imes$ 1	Rat, P7	Increased neurodegeneration above 10 mg/kg	Bittigau et al [93]
Diazepam	5 mg/kg × 1	Mouse, P10	No increased neurodegeneration in cortex, but increased in thalamus, no subsequent behavioral or learning deficits	Fredriksson et al [59]
Diazepam	20 mg/kg on P6 and on P8	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al [94]
Enflurane	2–4% for 0.5h	Mouse, prenatal E6–17	Learning impairment in adulthood	Chalon et al [95]
Fentanyl	$50 \mu g/kg/h$ for $72 h$	Rat, P14	Diminished morphine antinociceptive sensitivity in juvenile and adult animals	Thornton et al [85]
Halothane	10ppm for 40h/ week	Rat, conception to P60	Learning deficits and decrease in synaptic density	Quimby et al [29]
Halothane	10 ppm for 40 h/ week	Rat, conception to P60	Defects in visual and spatial learning tasks	Quimby et al [30]
Halothane	50–200 ppm continuously	Rat, conception to P28	Dose-dependent decrease in cerebral synapse density	Uemura et al [31]
Halothane	25–100 ppm continuously	Rat, conception to P60	Decrease in apical and basal dendritic length and numbers	Uemura et al [96]
Halothane	25–100 ppm continuously	Rat, conception to P60	Decrease in synaptic density, no learning impairment	Uemura et al [32]
Halothane	1–2% for 0.5h	Mouse, prenatal E6–17	Learning impairment in adulthood	Chalon et al [95]
Heroin	10 mg/kg/d to dam	Mouse, E8–18	Hyperactivity and spatial learning deficits in adulthood	Yanai et al [97]
Heroin	10 mg/kg/d to dam	Mouse, E9–18	Increased neuronal apoptosis and impaired spatial learning and memory in juvenile animals	Wang et al [98]
Heroin	500 µg/mL	Rat, E16–17 cortical neuronal cultures	Decrease in neuronal viability, increase in apoptosis and DNA fragmentation	Cunha-Oliveira et al [99]

# Table 41.1 Preclinical studies into structural and neurocognitive effects of anesthetic exposure in neonatal animals

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
lsoflurane	0.2–0.3 mM	Mouse, P14 and P60 hippocampal slices	Block of synaptic transmission more pronounced in P14 slices, compared with older animals	Simon et al [100]
lsoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 6h	Rat, P7	Increased neuroapoptosis and neurodegeneration, adult learning impairment	Jevtovic-Todorovic et al [37]
Isoflurane	0.75–1.5% for 6h	Rat, P7	Increased neurodegeneration	Jevtovic-Todorovic et al [37]
lsoflurane+ midazolam+ thiopental	1.5% for 4h + 1 mg/kg + 7 mg/kg to ewe	Sheep, prenatal E120	No increase in neuroapoptosis, as assessed 6 d postanesthesia	McClaine et al [101]
Isoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 2–6h	Rat, P1–14	Increased neuroapoptosis following exposure on P7, not P1–3 or P10–14	Yon et al [66]
Isoflurane+ nitrous oxide +midazolam	0.55% + 75% + 1 mg/kg for 4h	Swine, P5	Increased neurodegeneration in neocortex	Rizzi et al [102]
Isoflurane	1.5% for 1–5h	Rat, organotypic slice culture	Increased neurodegeneration only after 5h of exposure	Wise-Faberowski et al [103]
Isoflurane	2.4% for 24h	Rat, primary cortical neuron culture	Increased apoptosis	Wei et al [104]
Isoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 2–6h	Rat, P7	Increased neuroapoptosis	Lu et al [67]
lsoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 6h	Rat, P7	Increased neuroapoptosis, ameliorated by melatonin	Yon et al [68]
Isoflurane	0.75% for 4h	Mouse, P5	Increased neuroapoptosis, ameliorated by pilocarpine	Olney et al [105]
lsoflurane	0.75% for 6h	Rat, P7 and mouse organotypic hippocampal slices	Increased neuroapoptosis, exacerbated by nitrous oxide and ameliorated by xenon	Ma et al [62]
lsoflurane	0.75% for 6h	Rat, P7 and mouse, P8 organotypic hippocampal slices	Increased neuroapoptosis, ameliorated by dexmedetomidine, not reversed by gabazine	[106]
Isoflurane	2.4% for 24h	Rat, primary cortical neuron culture	Increased cellular degeneration, blocked by isoflurane or halothane preconditioning	Wei et al [107]
Isoflurane	1.3% for 6h	Rat, prenatal E21	Decrease in neuroapoptosis, no impaired learning, improved memory retention in juvenile animals	Li et al [108]
Isoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 6h	Rat, P7	Decreased neuronal density in multiple brain areas in adulthood	Nikizad et al [38]

(Continued)

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
lsoflurane+ nitrous oxide +midazolam	0.55% + 75% + 1 mg/kg for 4 h	Guinea pig, prenatal E20–50	Increased neuroapoptosis between E35–40 and decreased adult neuronal density, not after E50 or in fentanyl control group	Rizzi et al [109]
Isoflurane	0.75% for 4h, 1.5% for 2h, or 2% for 1h	Mouse, P5–7	Increased neuroapoptosis	Johnson et al [110]
Isoflurane+ nitrous oxide	0.75% + 75% for 6h	Rat, P7	Increased neuroapoptosis in spinal cord	Sanders et al [111]
Isoflurane		Mouse, P4	Increased neuroapoptosis, ameliorated by hypothermia	Olney et al [112]
Isoflurane	1.4%	Rat, cortical and hippocampal neuron culture, harvest P1, DIC 5	Increased neuroapoptosis, reduction in dendritic spines and number of synapses, ameliorated by administration of tPA or inhibition of p75 <sup>NTR</sup>	Head et al [113]
lsoflurane+ nitrous oxide	0.55% + 75% or individually for 2–8h	Rat, P7	Increased neuroapoptosis and neurodegeneration after exposure of 6 hours or longer, ameliorated by L-carnitine, no increase by either agent administered individually	Zou et al [114]
lsoflurane	1–2% for 10min	Mouse, PO	Neonatal and adolescent impairment in tests of body co-ordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al [115]
Isoflurane	1.2% for 12h	Rat, primary cortical neuron culture	Increased cytotoxicity, ameliorated by xestospongin C	Wang et al [116]
Isoflurane	0.75% for 6h	Rat, P7	Increased neuroapoptosis, ameliorated by dexmedetomidine	Sanders et al [64]
Isoflurane	1.5% for 6h	Mouse, P7	Increased neurodegeneration early after exposure, no adult learning impairment, no decreased adult neuronal density	Loepke et al [41]
lsoflurane	1 MAC for 1–4h	Rat, P7	Widespread brain cell death following exposure for >2 h, not 1 h; adult neurocognitive deficits only after 4 h exposure	Stratmann et al [117]
Isoflurane	1 MAC for 4h	Rat, P7	Decreased progenitor proliferation, deficits in fear conditioning and memory impairment in adulthood	Stratmann et al [43]
Isoflurane	3.4% for 4h	Rat, neuronal progenitor culture, harvest P2, 2–12 weeks in culture	No neurodegeneration or activation of caspases 3 or 7, decrease in caspase 9, inhibition of proliferation, preferential differentiation to neurons	Sall et al [118]
Isoflurane+ nitrous oxide +midazolam	0.75% + 75% + 9mg/kg for 6h	Rat, P7	Decreased synaptic density in subiculum 2 weeks after treatment	Lunardi et al [119]
Isoflurane	1.6% for 5h	Rhesus monkey, P5	Increase in neocortical apoptotic cell death	Brambrink et al [70]

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Isoflurane	1.6% for 5h	Rhesus monkey, P5	Increase in apoptotic cell death of neurons in neocortex and immature oligodendrocytes in white matter	Olney et al [120]
Isoflurane	1.3% or 3% for 1h to dam	Rat, E21	No increase in neuroapoptosis or S100β blood levels following lower dose, but both increased following higher dose	Wang et al [121]
Isoflurane	1.7% for 35 min × 4 d	Rat, P14Mouse, P14	No increased immediate hippocampal neuronal cell death, no difference in adult learning of easy task, impairment in adult learning of difficult learning and recognition tasks	Zhu et al [122]
Isoflurane	1.5% for 30– 120 min	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al [74]
Isoflurane	0.75% for 6h	Mouse, P7	Increased neuroapoptosis and serum levels of $$100\beta$ immediately following exposure, no long-term impairment in learning and memory tests	Liang et al [44]
lsoflurane	2% for 2h and/or caffeine 80mg/kg	Mice, P4	Increased neuroapoptosis following caffeine, worse than following isoflurane exposure, demonstrating potentiation following combination exposure	Yuede et al [123]
Isoflurane	1.5% for 6h	Mouse, P7–8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of desflurane or sevoflurane	Istaphanous et al [75]
Ketamine	20 mg/kg × 7	Rat, P7	Increased neurodegeneration	Ikonomidou et al [33]
Ketamine	25–75 mg/kg × 1–7	Rat, P7	Increased neurodegeneration only after 7 repeated doses of 25 mg/kg	Hayashi et al [50]
Ketamine	50 mg/kg × 1	Mouse, P10	Cortical neurodegeneration; hypo- and hyperactivity, abnormal habituation in adulthood	Fredriksson et al [124]
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration, worsened by co- administration of diazepam	Fredriksson et al [59]
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration and impairment in memory tasks in adulthood	Fredriksson et al [57]
Ketamine	10–25 mg/kg × 1–7	Rat, P7	Neurodegeneration observed after 7 repeated doses of 25 mg/kg, plasma levels 7 times higher than during human anesthesia	Scallet et al [125]
Ketamine	1.25–40 mg/kg × 1	Mouse, P7	Neurodegeneration after doses of 5 mg/kg or higher, no gross neurobehavioral abnormalities 7 days after treatment	Rudin et al [60]
Ketamine	0.1–10µM for 6–48 h	Rat forebrain neuron culture	Increased DNA fragmentation after higher doses for longer periods of time	Wang et al [53]
Ketamine	10–40 mg/kg × 1	Mouse, P7	Increased neurodegeneration following doses of 20 mg/kg or higher, worsened by midazolam co-administration	Young et al [58]
				(Continued)

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Ketamine	1–20µM for 2–24h	Rhesus monkey forebrain neuron culture	Increased DNA fragmentation and decreased mitochondrial function after higher doses for longer periods of time	Wang et al [55]
Ketamine	0.01–40µg/mL for 1–48h	Rat GABAergic neuron culture	Neuronal cell loss and decrease in dendritic length and branching with higher concentrations for longer exposure times	Vutskits et al [54]
Ketamine	100µM for 48h	Rat, cortical neuron culture	Increased apoptosis, ameliorated by NMDA, IGF-1, alsteropaullone, or iodoindirubin	Takadera et al [126]
Ketamine	0.1–30µM for 24h	Rat, cortical neuron culture	Decreased cell viability and increased DNA fragmentation, ameliorated by erythropoietin	Shang et al [127]
Ketamine	20–50 mg/ kg/h × 24 h	Rhesus monkey, E122, P5 or P35	Increased neurodegeneration in two younger age groups, ketamine plasma levels higher than in humans	Slikker et al [51]
Ketamine	1–100µg/mL for 1–24h	Rat GABAergic neuron culture	Neuronal cell loss with higher concentrations or longer exposure times	Vutskits et al [56]
Ketamine	2.5 mg/kg × 2 for 4 d	Rat, P1–4	Minimal neurodegeneration, but ameliorated pain-induced neurodegeneration and subsequent learning abnormalities	Anand et al [6]
Ketamine or S-ketamine	1–8 mM or 0.6–4 mM for 24 h	Neuroblastoma cells	Increased apoptosis, but up to 80% less cell death following S-ketamine	Braun et al [128]
Ketamine	25 mg/kg × 1	Mouse, P10	No increase in neurodegeneration, but subsequent learning impairment, worsened by co-administration of thiopental or propofol	Fredriksson et al [61]
Ketamine	1–20µM for 24h	Rat forebrain neuron culture	Increased DNA fragmentation after higher doses, blocked by nitroindazole	Wang et al [129]
Ketamine	5–25 mg/kg × 1	Mouse, P10	Dose-dependent alterations in levels of developmentally expressed proteins and adult behavioral abnormalities	Viberg et al [130]
Ketamine	2.5 mg/kg × 2 for 4 d	Rat, P1–4	No increase in neuronal cell death, no change in adult learning and exploratory behavior and ameliorated pain-induced neurodegeneration and behavioral abnormalities	Rovnaghi et al [131]
Ketamine	20 mg/kg × 6	Rat, P7	Decreased body weight 1–3 days after exposure, no abnormal spontaneous behavior observed during first 4 days	Boctor et al [132]
Ketamine	30 mg/kg + 15 mg/ kg every 90 min × 2	Mouse, P15–90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al [133]
Ketamine	40 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium co-administration	Straiko et al [72]
Ketamine	5–20 mg/kg × 1–6	Rat, P7	Increased apoptosis and neurodegeneration only observed following 6 repeated doses of 20 mg/kg	Zou et al [134]

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Ketamine	20 mg/kg × 7	Rat, P7	Increased apoptosis and neurodegeneration, decreased weight gain, increase in BDNF and TrkB cDNA	lbla et al [135]
Ketamine	20–50 mg/kg/h for 3–25 h	Rhesus monkey, P5 or 6	Neuronal degeneration only in neocortex following 9h exposure or longer, no degeneration in deeper brain areas	Zou et al [52]
Ketamine	30 mg/kg + 15 mg/ kg every 90 min × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al [73]
Ketamine	5–20 mg/kg × 5	Rat, P7	Increased neuroapoptosis in neocortex and thalamus, increase in cell cycle proteins	Soriano et al [136]
Ketamine	0.1–1000µM × 6– 48 h	Rat, cortical neuron culture	Increase in expression of caspase 3 and cell cycle proteins	Soriano et al [136]
Methadone	10 mg/kg/d to dam	Rat, E5–21	Decreased brain monoamines in juveniles and hyper-responsive in adulthood	Rech et al [137]
Methadone	10–15 mg/kg/d to dam	Rat, E8–21	Increased excitability tested in juvenile animals using the acoustic startle reflex	Hutchings et al [138]
Methadone	9 mg/kg/d to dam	Rat, E7–21	Increased noradrenergic activity in hippocampus of male juveniles	Robinson et al [83]
Methadone	9 mg/kg/d to dam	Rat, P1–10	Reduced activity of dopaminergic neurons in frontal cortex of juvenile males	Robinson et al [83]
Methadone	9 mg/kg/d to dam	Rat, E7–21	Reduction in nerve growth factor, disruption of cholinergic neuronal activity	Robinson et al [84]
Midazolam	9 mg/kg × 1	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al [37]
Midazolam	$9 \mathrm{mg/kg}  imes 1$	Mouse, P7	Increased neuroapoptosis	Young et al [58]
Midazolam	$9  \text{mg/kg} \times 1$	Mouse, P5	Increased neuroapoptosis	Olney et al [105]
Midazolam	3–9 mg/kg × 1	Rat, P1–14	No increase in neuroapoptosis	Yon et al [66]
Midazolam	0.25–25µg/mL	Rat GABAergic neuron culture	No effect on neuronal survival	Vutskits et al [139]
Midazolam	25 mg/kg + 15 mg/ kg every 90 min × 2	Mouse, P15–90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al [133]
Midazolam	25 mg/kg + 15 mg/ kg every 90 min × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al [73]
Midazolam	50 mg/kg	Mouse, P10	No impairment of learning and memory in adulthood	Xu et al [42]
Morphine	10 mg/kg/d to dam	Rat, E12–21	Gender- and region-specific changes in $\boldsymbol{\mu}$ receptor density in neonatal rats	Hammer et al [81]
Morphine	5 mg/kg/d	Rat, P1–4	Decreased µ-opioid receptor density in striatum following exposure	Tempel el al. [80]

(Continued)

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Morphine	20 mg/kg/d to dam, except for E11; 10 mg/kg/d	Rat, E11–18	Decreased μ-opioid receptor density in adulthood	Rimanoczy et al [82]
Morphine	1μM for 1–2 d	Mouse, P5–6 cerebellar neuronal precursor culture	Marked decrease in DNA synthesis, without effect on cell survival	Hauser et al [140]
Morphine	5 mg/kg × 3 doses, then 10 mg/kg twice a day to dam	Rat, E11–18	Impairment in spatial learning in adulthood	Slamberova et al [86]
Morphine	1–100 µM for 5 d	Human, GW16–22 fetal microglial, astrocyte, and neuronal cultures	Progressive increase in apoptosis in neurons after 2-d exposure, or microglia after 3 d but not in astrocytes	Hu et al [141]
Morphine	2 mg/kg/d to dam, progressively increased by 2 mg/kg/d	Rat, EO–P21	Impairment in spatial learning in young adulthood	Yang et al [87]
Morphine	20 mg/kg/d	Chick, E12–16	Impairment in long-term memory formation	Che et al [142]
Morphine	2 mg/kg/d	Rat, P3–7	Impairment in adult cognitive function	McPherson et al [88]
Morphine	15μM for 7d	Mouse, E16 hippocampal neuronal culture	Increased apoptosis, decreased neuronal density	Svensson et al [143]
Morphine	4 mg/kg/d	Mouse, P5–9	Impairment in reward-mediated learning in adulthood	Boasen et al [13]
Morphine	5 mg/kg × 3 doses, then 10 mg/kg twice a day to dam	Rat, E11–18	Decreased synaptic plasticity and impaired learning in juveniles	Niu et al [90]
Morphine	2 mg/kg/d to dam, progressively increased by 2 mg/kg/d, max. 14 mg/kg/d	Rat, EO-P21	Decreased performance in learning tasks in adulthood	Lin et al [89]
Nitrous oxide	50–150% for 2–6h	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al [37]
Nitrous oxide	50–150% for 2–6h	Rat, P1–14	No increase in neuroapoptosis	Yon et al [66]
Nitrous oxide	75% for 6h	Rat, P7 and mouse organotypic hippocampal slices	No increase in neuroapoptosis in rats, increased neuroapoptosis in mice	Ma et al [62]
Pentobarbital	$5-10 \text{ mg/kg} \times 1$	Rat, P7	Increased neurodegeneration	Bittigau et al [93]
Phenobarbital	40–100 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by $\beta\text{-estradiol}$	Bittigau et al [93]
Phenobarbital	50 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by β-estradiol	Asimiadou et al [144]

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Phenobarbital	30 mg/kg × 2	Mice, P6	Long-term alterations in brain protein expression	Kaindl et al [145]
Phenobarbital	75 mg/kg	Rats, P7–8	Increased neuroapoptosis, enhanced by lamotrigine administration	Katz et al [146]
Phenobarbital	25 mg/kg	Mice, PO	Neonatal and adolescent impairment in tests of body co-ordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al [115]
Phenobarbital	50 mg/kg (P6), 40 mg/kg (P8)	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al [94]
Propofol	0.5–10µg/mL for 8h	Rat GABAergic neuron culture	Dose-dependent decrease in GABAergic enzyme GAD after higher doses	Honegger et al [147]
Propofol	10–100μg/mL for 2 h–10 d	Rat dissociated neuronal culture P1 or P7	Increased cell death in P1 neurons following higher doses, no evidence for neurotoxic effects in organotypic hippocampal culture on P7	Spahr-Schopfer et al [148]
Propofol	1–50 µg/mL	Rat GABAergic neuron culture	Increased neuronal cell death following highest dose, altered dendritic development following lowest dose	Vutskits et al [139]
Propofol	5–500μM for 2–24h	Chick neuron explant culture	Dose-dependent neurite growth cone collapse	Al-Jahdari et al [149]
Propofol	10–60 mg/kg × 1	Mouse, P10	Increased neurodegeneration following highest dose	Fredriksson et al [61]
Propofol	25–300 mg/kg × 1	Mouse, P5–7	Increased neuroapoptosis following doses higher than 50 mg/kg	Cattano et al [71]
Propofol	6mg/kg/h for 24h	Swine, PO	No increased neurodegeneration	Gressens et al [150]
Propofol	5μM for 5h	Rat hippocampal neuron culture	Increased neuroapoptosis	Kahraman et al [151]
Propofol	50 mg/kg + 25 mg/ kg every 90 min × 2	Mouse, P15–90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al [133]
Propofol	25 mg/kg	Rat, P7	Increased neuroapoptosis, decrease in nerve growth factor,	Pesic et al [152]
Propofol	50–100 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium co-administration	Straiko et al [72]
Propofol	0.01–1 mg/mL for 3–48 h	Rat, primary cortical neuron culture, harvested E18	Highest concentration improved cell viability after up to 6 h of exposure, but reduced cell viability after more than 12 h	Berns et al [153]
Propofol	30 mg/kg every 90 min × 3	Rat, P6	No increase in neurodegeneration in most brain areas, except for defined areas, subtle neurological impairment in adult animals	Bercker et al [154]
Propofol	50 mg/kg + 25 mg/ kg every 90 min × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al [73]
				(Continued)

Anesthetic agent	Dose and duration	Species, age	Pathology	Reference
Sevoflurane	4% for 24h	Rat, primary cortical neuron culture	No increase in apoptosis	Wei et al [104]
Sevoflurane	2% for 12h	Rat, primary cortical neuron culture	No increase in cytotoxicity	Wang et al [116]
Sevoflurane	1.7% for 2h	Mouse, P7	Increased neuroapoptosis	Zhang et al [155]
Sevoflurane	3% for 6h	Mouse, P6	Increased neuroapoptosis, impairments in fear conditioning and social interaction in adulthood	Satomoto et al [69]
Sevoflurane	4% or 8% for 12 or 6h, respectively	Rat, primary cortical neuron culture, E18	No difference in cell viability compared with untreated controls	Berns et al [156]
Sevoflurane	3–5% for 6h	Rat, P6	No increase in neurodegeneration immediately after exposure, no long-term neurological impairment	Bercker et al [154]
Sevoflurane	2.1% for 0.5–6h	Rat, P4–8	Seizure activity during exosure and neuroapoptosis partially blocked by administration of bumetanide	Edwards et al [157]
Sevoflurane	2.5% for 30– 120 min	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al [74]
Sevoflurane	1.1% for 6h	Mouse, P7	Increased neuroapoptosis immediately following exposure, no long-term impairment in learning and memory tests	Liang et al [44]
Sevoflurane	2.1% or 3% for 2h or 6h	Mice, P6	Increased neuroaoptosis following the longer, but not the shorter exposure time. Transgenic Alzheimer disease mice more susceptible.	Lu et al [158]
Sevoflurane	2.9% for 6h	Mouse, P7–8	Increased neuroapoptosis compared with no anesthesia, but similar to equi-anesthetic doses of desflurane or isoflurane	Istaphanous et al [75]
Thiopental	$5-25 \text{ mg/kg} \times 1$	Mouse, P10	No increase in neurodegeneration	Fredriksson et al [61]
Xenon	75% for 6h	Rat, P7 and mouse organotypic hippocampal slices	No increase in neuroapoptosis	Ma et al [62]
Xenon	70% for 4h	Mouse, P7	Increase in neuroapoptosis, decreased isoflurane-induced neuroapoptosis	Cattano et al [63]

DIC, days in culture; P, postnatal day; E, embryological day.

to 75 mg/kg of ketamine did not seem to lead to widespread cytotoxic effects [50]. Whole brain slices from neonatal rats receiving ketamine for at least 6h demonstrate increased cleaved caspase-3 expression, which leads to apoptotic cell death (Fig. 41.1) Moreover, a dosedependent increase in ketamine-induced neuronal cell death has recently also been observed in non-human primates [51,52]. In these studies, a 24-h infusion of ketamine (20–50 mg/kg/h) significantly increased neuronal cell death in prenatal (gestational age 122 days) or neonatal (5-day-old) rhesus monkeys. However, a ketamine infusion for 3h did not lead to any increased neurodegeneration in these monkeys and even a 24-h infusion failed to cause neuronal degeneration in older, 35-day-old animals. Ketamine neurotoxicity has also been studied using *in vitro* preparations from neonatal rats and rhesus monkeys [53–55]. Primary cortical cells cultured in ketamine for 6h or longer led to an increase in neurodegeneration in both species, whereas shorter exposure times did not. However, lower concentrations of ketamine have been shown to decrease dendritic arborization in differentiated neurons in culture [56]. Microscopic images of primary neurons exposed to ketamine demonstrate a reduction in neurite length and the number of branching points (Fig. 41.2).

It currently remains unknown whether the seemingly large doses of injectable anesthetics used in animal neurotoxicity studies can be directly compared with the relatively smaller doses used in clinical practice (further discussed below). However, it should be noted that in neonatal mice, lower concentrations than those found deleterious in rats and also single doses of ketamine and propofol have been found to induce neuroapoptosis, which may indicate differential susceptibilities among species [57,58].

Long-term neurological function following neonatal ketamine exposure has so far only been examined in a few studies. A single ketamine exposure of 50 mg/kg in newborn mice led to subsequent abnormal behavior as well as impaired learning and memory acquisition in adolescent animals [59]; however, in another study, albeit without formal tests of learning, no gross neurobehavioral abnormalities were observed 7 days after neonatal administration of up to 40 mg/kg [60]. Moreover, adult rats that were injected as neonates with four daily, relatively small doses of ketamine (5 mg/kg) performed as well as their unexposed peers in subsequent learning and

memory tasks [6]. Concomitant administration of GABAmimetic drugs, such as midazolam, thiopental or propofol, a common practice during clinical anesthesia and sedation, significantly exacerbated the deleterious effects of ketamine [58,61].

Less information is available regarding the effects of the NMDA-antagonists nitrous oxide or xenon on brain development. Whereas nitrous oxide by itself, even under hyperbaric conditions, did not seem to increase neuronal cell death [37,62], xenon showed differential effects, being deleterious in one study [63] and not in another [62]. The two compounds, however, differed in their effects when co-administered with isoflurane; nitrous oxide exacerbated isoflurane-induced neurotoxicity [37,38,62,64] whereas xenon alleviated some of isoflurane's cytotoxic effects [62,63].

#### γ-Aminobutyrate<sub>A</sub>-agonists

γ-Aminobutyrate represents the main inhibitory neurotransmitter in the adult central nervous system, while it has excitatory properties in the developing brain [65]. To date, the impact of this developmental switch on anesthesia-induced neurotoxicity remains unresolved. Regardless of these uncertainties, numerous GABAAagonists are commonly used as anesthetics or sedatives in young children and animal studies have demonstrated the harmful impact of exposure to these compounds during early development on brain cell structure and later neurological function. Several animal studies have been carried out in immature animal species examining the effects of isoflurane, sevoflurane, halothane, thiopental, pentobarbital, enflurane, clonazepam, diazepam, midazolam, chloral hydrate, or propofol (see Table 41.1).

Many of these studies have been carried out by the Jevtovic-Todorovic laboratory, which examines the combined administration of the GABA<sub>A</sub>-agonist midazolam, the mixed GABA<sub>A</sub>-agonist and NMDA-antagonist isoflurane, and the NMDA-antagonist nitrous oxide. This combination caused a widespread, dramatic increase in the rate of brain cell degeneration in newborn animals shortly after cessation of a 6h exposure [37,66-68]. In addition to the immediate deleterious effects on brain structure, longterm abnormalities in spatial learning tasks and decreased neuronal cell density were observed in adult rats exposed to the anesthetic combination as neonates [37,38]. Sevoflurane has been also shown to induce neuroapoptosis in neonatal mice and lead to learning deficits and abnormal social behaviors [69] while a recent report suggested that it may cause less immediate neuroapoptosis compared with isoflurane [44]. Neurostructural abnormalities have also been reported in neonatal rhesus monkeys following exposure to clinically relevant doses (0.75–1.5%) isoflurane for 5 h [70]. Subanesthetic doses of the GABA<sub>A</sub>-agonist propofol have also been shown to induce neuroapoptosis in postnatal day 5 mice [71,72].

Collectively, these reports demonstrate that the neuroapoptotic effect of anesthetic drugs peaks during the neonatal period in rodents. Older rats seem to be much less susceptible to the neuroapoptotic process, while still subject to anesthesia-induced disruption in dendritic spine architecture, as demonstrated in 15-day-old mice [73,74]. These findings suggest that juvenile rodents may experience anesthetic-induced alterations in synaptogenesis and neuronal cross-talk.

However, long-term correlates of neonatal brain cell death and dendritic alterations on subsequent neurological function remain unresolved. Our group has previously demonstrated that isoflurane as a single agent, while causing widespread neuronal degeneration in neonatal mice immediately following the exposure (Fig. 41.3), did not lead to long-term impairment in spatial learning and memory tasks or to alterations in neuronal density in adult animals [41]. Similar results have recently been observed following the single administration of midazolam [42], isoflurane [44] or sevoflurane [44], suggesting that under certain circumstances, the developing brain may either be able to recover from the neonatal neuronal degeneration or that neonatal brain cell loss may not be causatively linked to adult learning impairment. Studies by Stratmann and co-workers have indicated that hypercarbia during anesthetic exposure might contribute to the immediate neurodegenerative effects, while not necessarily being causatively linked to longterm neurocognitive impairment [43]. Recent work performed by the Loepke laboratory has demonstrated that neurodegeneration, observed immediately following a prolonged anesthetic exposure to desflurane, isoflurane or sevoflurane, is comparable among the three anesthetics (Figs 41.4, 41.5), suggesting that there might not be benefit of using one inhaled agent over another [75].

#### Other anesthetics and sedatives

Recently, the  $\alpha$ 2-agonist dexmedetomidine has gained more prominence in pediatric sedation practice. Only one animal study has examined its effects on the developing brain and found dexmedetomidine to be devoid of neurotoxic effects [64]. Moreover, the authors noted that dexmedetomidine might be useful in ameliorating isoflurane's deleterious consequences on neonatal brain structure and adult learning [64]. Further studies are needed to investigate whether dexmedetomidine causes neurodegeneration in other models and whether its protective effects extend to other anesthetics.

#### **Opioid analgesics**

Opioid analgesics are another class of potent medications commonly administered to young children before, during,

**Figure 41.3** Neonatal isoflurane exposure significantly increases the number of dead or dying neurons in the neonatal mouse brain (A). Columns represent mean number of brain cells staining positive for the cell death marker Fluoro-Jade B (FJB+) for each brain region 2 h following 6-h exposure to 0.6 MAC of isoflurane (anesthesia, *black bars*) compared with littermates fasted for 6 h (no anesthesia, *white bars*). However, neuronal cell death in neonatal mice immediately following isoflurane exposure does not lead to impairment in spatial learning and memory in adulthood (B–G). Morris water maze place and probe trials in adult mice previously exposed as neonates to 6 h of fasting (no anesthesia, *open circles*) or to 0.6 MAC isoflurane (anesthesia, *black boxes*) using a hidden platform (B–D) or a more difficult reversal platform paradigm (E–G). Both groups significantly improved over the 5-d trial period and performed equally well in the memory retention tasks. Data are shown as mean ± SEM; n = 8–26 for each group; \* $\rho$  < 0.05. Reproduced from Loepke et al [41] with permission from Lippincott Williams and Wilkins.

**Figure 41.4** Representative, high-power magnification photomicrograph, obtained with laser confocal microscopy, demonstrating co-localization of the apoptotic cell death marker activated-caspase 3 (*green*) and the postmitotic neuronal marker NeuN (*red*) in neocortex. Brain section was obtained from a 7-d-old mouse pup following a 6 h to 0.6 MAC of isoflurane, depicting 9  $\mu$ m image stack stained for activated-caspase 3 (*left*) and NeuN-stained single optical sections through each cell body, for clarity (*middle*). Apoptotic neurons, indicated by co-localization of caspase 3 and NeuN in merged images on right, demonstrate degenerative changes, such as dendritic atrophy (*arrows*), dendritic beading (\*), and pyknotic neurons (*arrowheads*), and are surrounded by unaffected neurons; scale bar = 10  $\mu$ m. Reproduced from Istaphanous et al [75] with permission from Lippincott Williams and Wilkins.

and after surgery, often in conjunction with anesthetics and sedatives [76,77]. Since opioids can reduce dose requirements for anesthetics and sedatives, their coadministration could lead to lower anesthetic requirements and thereby potentially assist in mitigating anesthesia-induced cytotoxicity. However, several animal studies have suggested that opioid exposure may also have harmful effects in the developing brain (see Table 41.1) Moreover, opioid co-administration can enhance cell death of immature brain cells triggered by other apoptosisinducing drugs [78]. Specifically, chronic perinatal exposure to morphine, fentanyl or methadone has been shown to induce acute neuronal degeneration in the neonatal animal brain [79], to alter brain opioid receptor density

# Control

# Isoflurane Sevoflurane

**Figure 41.5** Six-hour exposure to desflurane, isoflurane, or sevoflurane similarly increases apoptotic cell death in neonatal mice, compared with fasted, unanesthetized littermates (control). Representative, low-magnification photomicrographs of coronal brain sections, obtained with laser confocal microscopy, demonstrate the pattern of apoptotic neuronal cell death. Brain sections from 7–8-d-old mouse pups were stained for the apoptotic cell death marker activated-caspase 3 (*bright green*) following a 6-h exposure to room air (control) or 0.6 MAC desflurane, isoflurane, or sevoflurane, respectively; arrows mark clusters of dying neurons in neocortical layers II/III; scale bar = 500 µm. Reproduced from Istaphanous et al [75] with permission from Lippincott Williams and Wilkins.

[80–82] and to disrupt nerve growth factor expression as well as dopaminergic, noradrenergic, serotonergic, and cholinergic activity [83,84]. Moreover, perinatal opioid administration can cause long-lasting desensitization to opioid analgesia in adult animals [85] and has also been shown to induce long-term behavioral changes, cognitive deficits, and learning impairment extending into adulthood [13,86–90]. However, as discussed previously, analgesics can diminish the deleterious effects of painful stimulation early in life.

# Putative mechanisms of drug-induced neurotoxicity

The exact mechanisms of neurotoxicity induced by anesthetics, sedatives, and analgesics in the developing brain remain unresolved. Elucidating these mechanisms will be essential in assessing the relevance of toxicity for pediatric anesthesia and neonatal critical care medicine and for devising mitigating therapies, if necessary. The currently prevailing hypothesis suggests that exposure to GABA<sub>A</sub>receptor agonists and/or NMDA-receptor antagonists during a vulnerable period in brain development may cause abnormal neuronal inhibition, triggering cell death in susceptible neurons, which in turn leads to adult learning impairment and decreased neuronal density [37,38,159]. However, several observations cast serious doubt on this hypothesis. While GABA<sub>A</sub>-receptor stimulation results in decreased neuronal activity in the mature brain, it causes excitation in developing neurons [65], thereby contradicting the hypothesis that abnormal neuronal inhibition is the cell death trigger in developing neurons. Accordingly, recent studies in newborn rats have linked the neurotoxic effects of sevoflurane to brain excitatory properties and episodes of epileptic seizures [157]. Isoflurane has also been shown to cause excessive Ca<sup>2+</sup> release from the endoplasmic reticulum via overactivation of inositol 1,4,5-triphosphate receptors (InsP3Rs) in neonatal rats in vivo and in vitro [160]. A similar mechanism may be linked to the production of Alzheimerassociated increases in  $\beta$ -amyloid protein levels [161]. Moreover, while xenon and hypothermia cause neuronal inhibition, they do not appear to exacerbate isofluraneinduced neuronal cell death, as expected by cumulative neuronal inhibition, but rather significantly reduce it [62,63,112].

Importantly, preliminary studies have failed to link the anesthetic and cell death mechanisms. Specifically, while racemic ketamine and S-ketamine both elicit their anesthetic effects via NMDA receptor blockade, S-ketamine induced up to 80% less cell death in vitro when compared with equipotent doses of racemic ketamine [128]. Moreover, concomitant administration of gabazine, a GABA<sub>A</sub>-receptor antagonist, does not attenuate isofluraneinduced neuroapoptosis [64]. Decreases in neuronal activity induced by anesthetics may be less important than the disruption of the neuronal balance of excitation and inhibition, as demonstrated in triggering dendritic morphological changes in postnatal day 15 mice [73,74]. Accordingly, while simultaneous blockade of excitatory and inhibitory activity with tetrodotoxin did not lead to structural changes during synaptogenesis, as expected for a causative relationship between neuronal inhibition and structural damage, administration of GABA<sub>A</sub>-agonistic or NMDA-antagonistic compounds did alter synaptogenesis [73].

Many of the animal studies using GABA-ergic compounds have clearly shown that anesthesia-induced neurodegeneration is not caused by cellular energy failure and necrosis, such as occurring during ischemic stroke, but rather predominantly involves a cellular suicide program, termed apoptosis [66]. Apoptosis, or programmed cell death, represents an inherent, energyconsuming process, which is highly conserved among species and culminates in self-destruction and elimination of cells that are functionally redundant or potentially detrimental to the organism, utilizing a cascade of enzymes called caspases [162]. As such, apoptotic cell death is an integral part of normal development, as demonstrated by the embryonal cell death of interdigital mesenchymal tissue separating the digits of the hands and feet, as well as during ablation of tail tissue as part of tadpole metamorphosis in amphibians. In the central nervous system, cells are also produced in excess and up to 50-70% of developing neurons are eliminated during normal brain development, be it in rodents, primates or humans [163,164]. This physiological apoptotic cell death establishes proper central nervous system structure and function, and any disruption of this process will lead to massive brain malformation and intrauterine demise [165]. However, apoptotic cell death can also be triggered by pathological insults, such as hypoxia and ischemia [166]. It currently remains unknown whether anesthesiainduced cell death hastens physiological neuroapoptosis or whether it eliminates cells not destined to die, i.e. pathological apoptosis. Normal adult neuronal density as observed following isoflurane exposure in neonatal mice may suggest accelerated physiological apoptosis [41] whereas decreased neuronal density demonstrated following a combination of isoflurane, nitrous oxide, and midazolam in neonatal rats supports the concept of anesthesia-induced, pathological apoptosis [38].

Anesthetic exposure has been shown to trigger both the intrinsic and extrinsic pathways of the apoptotic cascade [66] and to be associated with a decrease in brain-derived neurotrophic factor (BDNF) [67], a protein integral to neuronal survival, growth, and differentiation. Recently, exciting work on the cellular mechanism of anesthesiainduced neuronal cell death has highlighted reductions in synaptic tissue plasminogen activation (tPA) release and increases in proBDNF/p75<sup>NTR</sup>-mediated apoptosis following isoflurane exposure in newborn mice [113]. However, it is not entirely clear at this point whether cytotoxicity is a direct effect of the anesthetic exposure or whether it is triggered by anesthetic byproducts or by metabolic and respiratory derangements, such as hypercarbia and acidosis, which have been observed during anesthetic exposure in small rodents [41,43,167]. Importantly, recently published data have demonstrated that hypercarbia can trigger widespread neuronal cell death in unanesthetized neonatal rats, which was in several brain areas quantitatively indistinguishable from neurodegeneration observed in isoflurane-treated littermates, which were also hypercarbic. However, adult neurocognitive impairment was only observed in the isoflurane-exposed animals [43]. Studies by the JevtovicTodorovic and Vutskits laboratories demonstrated prolonged cellular effects of anesthetic exposure beyond neuronal death, albeit with somewhat conflicting results [73,119]. While both studies demonstrated alterations in synaptic plasticity in neonatal animals following anesthetic exposure, Jevtovic-Todorovic et al found a decrease in synaptic density following anesthetic exposure in postnatal day 7 rats [119]. In slightly older, postnatal day 15 mice, however, anesthetic exposure increased density of dendritic spines [73,74]. These contradicting observations may indicate an age-dependent difference in the effects of anesthetics on dendritic morphology.

Regarding the neurodegenerative mechanisms for NMDA-antagonists in the immature brain, three potential causative pathways have been suggested. The first involves upregulation of the NMDA-receptor, whereby prolonged antagonism of the NMDA-receptor by ketamine results in accelerated neurodegeneration and upregulation of the NR1 receptor subunit as demonstrated in rodent and monkey primary neuronal cell cultures [53,55]. This line of investigation stipulates that a 6-h wash-out period after the prolonged exposure to ketamine results in an increased number of NR1 receptors. This upregulation of the NR1 receptor facilitates pathological calcium entry into the neuron, leading to excitotoxicity [51]. These data support an excitotoxic mechanism for ketamineinduced neurodegeneration, demonstrating a dosedependent increase in nuclear translocation of NF-ĸB. Treatment of the neurons with SN-50, a peptide inhibitor of NF-kB translocation, attenuated neuronal cell death. Ketamine also affects other signaling kinases that influence neuronal viability. A second presumptive mechanism involves intracellular signaling by protein kinases. Straiko and colleagues reported that ketamine and propofol individually suppressed phosphorylation of extracellular signal-regulated protein kinase (ERK) and serine/ threonine-specific protein kinase 473 (pAkt<sup>473</sup>) in neonatal mice [72]. They also demonstrated that lithium mitigated the decrease in pERK and neuroapoptotic response.

Lastly, experimental models of neurodegeneration have implicated re-entry of postmitotic neurons into the cell cycle, leading to cell death. These authors have demonstrated that ketamine induces aberrant cell cycle reentry, leading to apoptotic cell death in the developing rat brain [136]. Certainly there are still many other mechanisms that induce neurodegeneration that have not been interrogated in the setting of anesthetic-induced neuroapoptosis [168].

# Interspecies comparison

While abundant experimental evidence is available in developing animals implicating anesthetics and sedatives

in triggering neurotoxicity, such as immediate brain structural damage and long-term neurocognitive impairment, the implications of these findings for clinical practice remain entirely unclear. Unlike animal studies, administration of anesthetics and analgesics in clinical pediatric medicine almost always coincides with significant noxious stimulation, such as during painful procedures and surgical operations. In this setting, some animal models have actually demonstrated therapeutic effects of analgesics or sedatives, without evidence for neurodegeneration [6,13]. Moreover, several studies have demonstrated significant discrepancies between the metabolic and respiratory effects of anesthetic exposure in small rodent species and those in humans, such as extensive hypercarbia, metabolic acidosis, and hypoglycemia in some animals [41,43,167]. Importantly, unlike during pediatric anesthesia, exposure to clinical doses of anesthetics for only 2-4h can be lethal in more than 20% of small rodents [41,43].

These findings seriously limit the immediate applicability of results obtained in small rodents to clinical pediatric anesthesia practice. Moreover, doses needed for injectable anesthetics to cause neuronal degeneration in animals are significantly higher than those used in clinical practice. Animal studies have shown that toxic doses for ketamine are 10 times higher and doses for propofol are up to 20–30 times higher than clinically used doses, using a weight-based comparison. Some of these discrepancies might be related to differences in body size and wholebody metabolic rates among species, resulting in higher dose requirements for smaller animals on a mg/kg basis, compared with larger animals [169]. However, even when allometric scaling is performed to account for differences in body size [170], toxic doses in animal studies still remain higher than clinically used doses for many of these compounds (Table 41.2).

The significant differences of comparative doses used in animal studies and clinical practice are further emphasized by the fact that plasma concentrations of neurotoxic doses for ketamine, as measured in small rodents and monkeys, were approximately 3–10 times higher than those observed during clinical human practice [51,125].

Another important finding from animal studies is the narrow age window during which anesthetics trigger neurotoxicity. According to animal studies, exposure to ketamine or ethanol only inflicts significant damage in the developing brains of rodents aged 5-7 days or in monkeys aged 6 days or younger, but not in older animals [33,35,51]. Similarly, in the study of the cytotoxic effects of isoflurane, neurotoxicity did not seem to occur in 1-day-old animals, peaked in 7-day-olds, and dramatically subsided after 10 days of age [66]. Anesthetic exposure outside this period does not seem to trigger neuronal cell death. On the contrary, in prenatal rats, exposure to clinical doses of isoflurane may actually decrease physiological apoptosis and improve subsequent memory retention [108] whereas only isoflurane doses higher than during clinical anesthesia increase neuroapoptosis in this setting [121].

Given these findings of a narrow window of anesthetic neurotoxicity in animals, it is imperative to identify the corresponding developmental state of the human brain, in order to predict the age range for possible susceptibility in humans (Fig. 41.6). Previously, simple estimations of brain cell numbers and degree of myelination defined this period as spanning from the last trimester of preg-

nancy all the way to the third year of life [159,171,172]. However, using a more up-to-date neuroinformatics approach, the period of maximum neurotoxic susceptibility has been approximated as being closer to the 20th week of gestation until early postnatally (calculator available at www.translatingtime.net) [173]. If these calculations prove correct, susceptibility to anesthesia-induced, neuroapoptotic cell death, if it occurred in humans, may seem more plausible in premature neonates, during fetal surgery, or in neonatal intensive care, and less likely during pediatric anesthesia in term infants and children [174].

# Clinical evidence for anesthetic neurotoxicity

While neurotoxic properties of anesthetics are well documented in developing animals, sound clinical evidence for definitive neurological abnormalities in children following anesthetic exposure is much harder to obtain. Obvious ethical concerns preclude randomization of young children to undergo painful procedures with or without anesthesia and analgesia. Moreover, prolonged anesthetic exposures cannot be justified without any surgical or diagnostic indication. Hence, possible clinical evidence for the neurological effects of anesthetics and sedatives in young children has to be gathered from case reports of inadvertent overdoses, postoperative behavioral studies, epidemiological analyses, or from studies into long-term neurological outcome in children suffering from disorders requiring the administration of anesthetics and sedatives during life-saving surgery and intensive care at a very young age [39,40,49].

#### Postoperative behavioral abnormalities

While many studies investigating behavioral changes immediately postoperatively list the specific anesthetic drugs used and usually involve healthy patient cohorts, their neurological assessment frequently only consists of short-term, parent-reported behavioral questionnaires or observations (Table 41.3). It has long been known that surgery and anesthesia in young children can lead to prolonged behavioral abnormalities [28,175-184]. Reported behavioral abnormalities, such as attention seeking, crying, temper tantrums, sleep disturbance, and anxiety, occur in up to 50% of children early after anesthesia and decrease significantly during the first postoperative month. These symptoms have repeatedly been associated with younger patient age, severity of postoperative pain, and lack of sedation prior to induction of anesthesia [28,177,179,182,184]. While the phenomenon's exact mechanism remains unknown, psychological factors, rather than structural brain abnormalities, are generally believed to be the underlying etiology [175,176,185]. Importantly, the administration of a benzodiazepine prior to general anesthesia did not exacerbate postoperative behavioral abnormalities, as expected for a cytotoxic etiology, but rather significantly reduced abnormal behavioral symptoms [186]. However, since most postoperative behavioral studies rely on parental assessment of the child, no continuing professional observations and long-term neurocognitive assessments were incorporated in any of the behavioral studies. Therefore, the permanence of these neurological abnormalities remains uncertain.

#### Anesthesia in critically ill neonates

A patient population more closely followed with standardized neurodevelopmental tests are previously critically ill neonates, who may have undergone surgical procedures involving general anesthesia, such as ligation of patent ductus arteriosus, repair of esophageal atresia, inguinal hernia repair, neurosurgical operations, laparotomies, or tracheotomies [187-196]. However, none of these studies were designed to study the long-term effects of anesthetic exposure and accordingly, they consistently fail to specify the exact anesthetic agents used and oftentimes involve several potent confounders, such as severe prematurity, prolonged ventilator support, considerable pain and distress, significant co-morbidities, latent episodes of hypoxia or hypoxia-ischemia, and frequently include major surgical procedures with potentially significant postoperative inflammatory response (Table 41.4). In this context, long-term neurodevelopmental impairment, such as a reduction in IQ, increased incidence of cerebral palsy, deafness, or blindness, have frequently been observed [190-194,196]. Greater severity of illness and co-existing, congenital abnormalities were associated with worsening neurological outcome [188,193].

In an attempt to at least partially control for severity of illness, several case-control studies compared neurodevelopmental outcome in survivors of surgical therapy for necrotizing enterocolitis and patent ductus arteriosus with those receiving medical management alone. When compared with age-matched controls or medically treated patients in the same cohort, several investigators noticed an impairment in neurocognitive function in surgically treated survivors of laparotomy or thoracotomy [190-192,194,196] while others were unable to find these differences [187,189,195]. However, it remains difficult to separate the effects of neonatal stress and surgery from the effects of the anesthetics. Moreover, study designs did not include randomized controlled trials, but were rather designed as cohort studies or case-control studies. It therefore seems conceivable that, due to selection bias, some of the extremely premature neonates that needed surgery had more concomitant illnesses and were therefore sicker than their matched controls. This notion is underscored by the fact that some of the studies identified longer periods of hypotension, more common use of inotropic support, and longer periods of total parenteral nutrition in the postsurgical patients [190,192]. Accordingly, a prospective randomized trial of 117 preterm infants with necrotizing enterocolitis who were assigned to either laparotomy or to peritoneal drainage without surgery did not find any difference in patient survival and early outcomes [197].

Table 41.3 (Continued	(L						
Anesthetic agent	Dose or duration	Study design	Number of subjects	Age during exposure	Neurological sequelae on exam	Duration of symptoms and outcome	Reference
Phenobarbital (plus phenytoin)	20–1800 mg/d in mother	Case-control	172	Fetal exposure	Greater need for special education, learnign difficulties, lower intelligence (WAIS), decreased attention on D-2, but not CPT test in adults after fetal exposure vs. controls. No difference in memory tasks (DS, ALT)	Not applicable	Dessens et al [240]
Phenobarbital	2.5-50 mg for 1-540d	Cross-sectional, case-control	28	Neonate	No difference in Kaufman-ABC intelligence and D-2 tests between 8–14 year old children following neonatal treatment with phenobarbital and best-friend controls	Not applicable	Gerstner et al [241]
Ketamine	13–56mg/kg	Case series	õ	0.07–7 years	After inadvertent overdose, prolonged sedation and respiratory depression	Sedation for 3–24 h, no neurological sequelae on follow-up, where available	Green et al [242]
Propofol	200 mg/h for 48 h in utero	Case report	-	Premature neonate 33 wk GA	Prolonged sedation, no other neurological sequelae reported	12h	Bacon et al [243]
Propofol	10.9 mg/kg/h for 11 d	Case report	-	23 months	Restlessness, muscle twitching limbs, functional blindness	Motor function impaired for 2 weeks, blindness for 33 days	Lanigan et al [244]
Propofol	Median infusion 2.7 mg/kg/h for >24 h	Case series	20	Median age 3.3 years	No neurological sequelae	Not applicable	Macrae and James[245]
Propofol	6–18 mg/kg/h for 2–4 d	Case report	2	2.5 and 4 years	Muscle weakness, twitching	9–18 days, full recovery	Trotter et al [246]
Propofol	10 mg/kg/h for 54 min	Case report	-	6 years	Seizure, ataxia, hallucinations starting 44 h after discontinuation of propofol	5d, recovered without overt long-term sequelae	Bendiksen et al [247]

Arnold et al [248]	Kelsall et al [249]	McBeth et al [250]	Sackey et al [251]	Hughes et al [252]	Conreux et al [253]	Vakkuri et al [254]	Constant et al [255]	Nieminen et al [256]	Kain et al [182]	Keaney et al [181] (Continued)
Symptoms responded to treatment advocated for opioid withdrawal	Normal follow-up exam 4–6 weeks after discharge	46h	Resolution of symptoms within 4–5 d	5 d; reportedly normal behavior	Not applicable	Not applicable	Not applicable	Not applicable	Assessment up to 14d postoperatively	Assessment up to 30d postoperatively
Agitation, non-purposeful movement in 50% of patients; all received >70 MAC-hours isoflurane, plus benzodiazepines and opioids	Transient ataxia, agitation, hallucinations, and confusion after isoflurane administration >24 h; no symptoms after benzodiazepines or isoflurane <15 h	Self-limiting, fine tremor in patient with myasthenia	Temporary involuntary movements, myoclonia, brief seizures, and ataxia	Disorientation, hallucinations, agitation, seizure	Seizure-like movement and epileptiform EEG in 10%, no neuro exam	Epileptiform discharge in 88% with controlled ventilation and 20% with spontaneous breathing. No neuro exam	No seizure activity on induction. Neurological exam not performed	No epileptiform EEG activity. Neurological exam not performed	Increased "maladaptive" behavior in children who were younger and whose parents were more anxious on induction	Negative behavioral changes, such as temper tantrums, loss of appetite or sleep disturbance in 38% for up to 30d; no difference between sevoflurane or halothane
0.06–19 years	0.5–10 years	2.5 years	4–11 years	7 years	1.1–8.4 years	2–12 years	2–12 years	3–8 years	3.3±2.1 to 6.9±2.4 years	3.3 ± 2.6 to 4 ± 2.9 years

None, some sibling controls	No exposure to sedation or analgesia	None, comparison with general population	None, comparison with general population	Healthy controls and neonates requiring intensive medical care
General anesthesia for general surgery, ENT, gastroenterology, plastics surgery, orthopedics	Prolonged sedation and/or analgesia for intensive care	General anesthesia for urological procedures	General anesthesia, intensive care for correction of congenital anomalies	General anesthesia, intensive care, ventilator support following major emergency abdominal surgeries
Survey study	Prospective poulation- based study	Retrospective cohort study	Prospective, longitudinal study	Prospective, longitudinal case–control study

birthweight (<1000 g); GMDS, Griffiths Mental Development Scales; INFANIB, Infant Neurological International Battery; LF-CPB, Iow flow-cardiopulmonary bypass; MDI, Bayley Mental Development Index; Movement ABC, Movement Assessment Battery for Children; MPC Mental Composite Score of the Kaufman Assessment Battery for Children; NDI, neurodevelopmental impairment; PDI, Bayley Psychomotor Developmental Index; PDMS, Peabody Developmental Motor Scales; PHBQ, Vernon Post Hospitalization Behavior Questionnaire; PPVT, Peabody Picture Vocabulary Test; SBIS Stanford-Binet Intelligence Scales; TOVA, Test of Variables of Attention; TRF, teacher's report form; VMI, Developmental Test of Visual Motor Integration; WCST, Wisconsin Card Sorting Test of problem solving; WJPB, Woodcock-Johnson Psychoeducational Battery; VLBW, very low birthweight (<1500g); WIAT, Wechsler Individual Achievement Test; WISC 3, Wechsler Intelligence Scale for Children, Third Edition; WSC-RN, Wechsler Intelligence Scale for Children; WPPS-R, Revised Wechsler Preschool and Primary Scales for Intelligence. lowing surgical procedures early in life are neonates and infants undergoing congenital heart surgery, such as for hypoplastic left heart syndrome, transposition of the great arteries, or tetralogy of Fallot [198-208]. Neurocognitive impairment has been documented in many of these studies, compared with the general population [198-206,208] or with "best friend" control subjects [207]. However, the anesthetic regimen was not specified for any of these studies and in many of the patients confounding factors included preoperative neurological lesions, pre-existing or perioperative hypoxia and hypotension, as well as chronic postoperative hypoxemia. Interestingly, in the largest trial, the Boston Circulatory Arrest Trial with patient follow-up for 8 years after arterial switch operation, many outcome measures in a battery of neurodevelopmental tests were within normal population limits, despite major corrective cardiac surgery with anesthesia in the neonatal period [206]. In an important report in this population, Guerra et al studied 95 survivors of neonatal open heart surgery with normal chromosomes. They calculated the cumulative dose, dose per day, and number of days each patient received opioids, benzodiazepines, ketamine, and chloral hydrate in the intensive care unit and OR. They also calculated exposure to anesthetic gas in MAC-hours from end-tidal concentrations, and inspired concentrations in the sweep gas of the cardiopulmonary bypass circuit. At 18-24 months, none of the sedation or anesthetic variables was associated with poor performance on Bayley Scales of Infant Development, or other tests of adaptive behavior and vocabulary [209].

Several case-control studies try to address the neurocognitive implications of prenatal anesthetic exposure in utero [210–212]. Abnormal neurological activity observed in neonates early after delivery included increased motor tone and decreased interaction [212], visual test abnormalities [211] and motor weakness [210]. Interestingly, the incidence of early neurological abnormalities following cesarean section did not differ between neonates exposed to general anesthesia, including thiopental and nitrous oxide, or to maternal epidural analgesia using lidocaine [210]. In a small, 4-year follow-up after prenatal exposure to anesthetics for dental procedures [211], children demonstrated decreased intelligence scores compared with unexposed controls, but demonstrated similar performance on tests of their vocabulary [212]. However, anesthetic exposure was not quantified, spanned from the first to the third trimester of pregnancy, and consisted of such diverse agents as methohexital, sodium thiopental, lidocaine, or carbocaine.

In summary, while several cohort studies in premature and term neonates undergoing major surgical operations involving general anesthesia demonstrate neurodevelopmental impairment later in life, none of these studies specified the anesthetic technique utilized. Moreover, due to design limitations in these studies, the effects of concomitant disease and the impact of the surgical procedure cannot be separated from the effects of anesthesia.

#### **Epidemiological studies**

More recently, several research groups have utilized retrospective reviews of large-scale epidemiological data sets to investigate neurodevelopmental outcome following surgery and anesthesia.

One of these studies used billing codes to identify a birth cohort of children in the New York State Medicaid database who underwent inguinal hernia repair during the first 3 years of life and compared these patients with a sample of more than 5000 age-matched children without the same billing code [225]. After controlling for gender and birth-related complications, such as low birthweight, children who carried an ICD-9 procedure code for inguinal hernia repair were more than twice as likely as their age-matched peers without this procedural code to also possess diagnostic codes for developmental or behavioral disorder. Interestingly, highlighting the importance of co-morbidities in retrospective data sets, surgical patients were more likely to carry secondary diagnoses, including congenital anomalies of the central nervous system (10% of patients), birthweight less than 2500 g (32%), or perinatal hypoxia (17%) and were also more likely to be male and African-American. Accordingly, as the authors correctly pointed out, health and medical care utilization as well as the frequency of mental illness differ in this vulnerable Medicaid study group from the general population [226,227], significantly complicating the generalization of these findings to all patients undergoing surgery with anesthesia.

Two other epidemiological studies in more heterogeneous patient populations investigated the effects of anesthetic exposure either during cesarean delivery or for pediatric surgery prior to age 4 years of age on subsequent learning abilities [228,229]. After adjusting for gestational age, sex, birthweight, and American Society of Anesthesiologists physical status, children who underwent multiple surgical procedures with general anesthesia prior to age 4 were found to be at increased risk for learning disabilities (35% of children), while children who only underwent one operation with anesthesia did not differ from unexposed children (21% learning disabilities) [229]. While listing the anesthetic regimen as predominantly halothane, nitrous oxide, and ketamine, the study was not powered to specifically analyze learning disabilities according to anesthetic drug. The important confounding influence of co-morbidities in this patient cohort was highlighted by the fact that almost half the previously anesthetized patients diagnosed with developmental disability had suffered from serous otitis media prior to age 4, a controversial predictor of neurocognitive disabilities, whereas only one-third of children without learning disabilities had experienced chronic ear infections [230,231]. However, a more definitive analysis including the unanesthetized children will be needed to assess this potential association.

In a second retrospective review, the same research group collected school and health data from almost 5000 children born via vaginal delivery and compared them to almost 200 neonates delivered via cesarean section with either general anesthesia, consisting predominantly of sodium thiopental, halothane, and nitrous oxide, or with about 300 children undergoing cesarean delivery with regional anesthesia [228]. The overall rate of potential learning disability was found to be 26% in this study population and did not differ between those children delivered with or without anesthesia. This finding could not have been easily predicted, because neonates in the general anesthesia group experienced lower birthweights, lower gestational age, and lower Apgar scores. In addition, their delivery was more commonly complicated by hemorrhage and eclampsia/pre-eclampsia, and was more frequently performed due to an emergency indication. Importantly, other risk factors independent from anesthetic exposure, such as male gender and mother's educational status, were strongly correlated with subsequent learning impairment. Children born to mothers with only some high school education were three times more likely to acquire learning disabilities than children from mothers with college education, suggesting powerful genetic and/ or socio-economic confounders. Interestingly, babies born with regional anesthesia were less likely to be diagnosed with a later learning disability than those born vaginally without anesthesia, most likely because their parents also tended to be better educated.

In a pilot study, Kalkman et al tried to control for the fact that there might be a causal relationship between the requirement for surgery and subsequent behavioral and learning impairment independent of anesthetic exposure [219]. They examined behavioral outcome following similar urological procedures, performed either before or after 2 years of age. In this small retrospective study involving fewer than 300 patients, parental evaluations of their children's competencies and behavioral/emotional issues were based on a combination of the child's activities, social relationships, and performance in school. There was a non-significant trend towards a relationship between timing of surgery and the risk for developing behavioral problems, even after adjusting for confounders such as parental education, number of total anesthetic exposures, gestational age, and birthweight. However, the authors correctly point out in their discussion that the indication for the surgery or the timing of the procedure may not be entirely independent of factors that could have also influenced neurobehavioral development, such as co-morbidities. In other words, the decision to operate on a child prior to age 2 years could depend on the severity of symptoms resulting from the anatomical anomaly, which in turn may influence neurobehavioral development independent of anesthetic exposure.

Arguably the most vulnerable group of patients potentially susceptible to the effects of prolonged exposure to anesthetics and sedatives during an immature state of brain developmental is not otherwise healthy pediatric patients undergoing brief, elective surgical procedures, but rather premature infants requiring neonatal intensive care [174]. In this exceptionally vulnerable patient population, Rozé and co-workers employed a prospective population-based study approach to evaluate the effects of prolonged sedation and analgesia on long-term neurological outcome, as measured by a validated, neurocognitive assessment tool [218]. A birth cohort of preterm infants born prior to 33 weeks gestational age who were subjected to mechanical ventilation and/or surgery were examined at 5 years of age using the Kaufman Assessment Battery for Children. While 74% of those treated with sedatives and/or analgesics for less than 7 days or not at all showed no disabilities, only 58% of those treated for more than 7 days were deemed without disability. However, after adjustment for significant confounders, such as birthweight, malformations, complications of pregnancy, characteristics of the delivering hospital, neonatal complications, need for surgery, and postnatal administration of corticosteroids, this association no longer remained statistically significant. While the study did not have the power to detect differences in disability of less than 10%, the long exposure times suggest that effect sizes during comparably briefer surgical anesthesia would be expected to be even smaller.

#### Confounders and anesthetic protection

The presence of powerful, confounding perioperative factors in infants and children undergoing surgery and anesthesia and the lack thereof in animal studies represent a serious limitation of directly applying findings of preclinical studies to humans. Given the overwhelming evidence for pharmacological interference with normal development of the central nervous system and the lack of anesthetics devoid of cytotoxic effects, one could be tempted to limit the use of suspect medications during medical interventions early in life. However, preclinical and human studies, as outlined above, have clearly demonstrated the increased morbidity and developmental abnormalities in animals and children exposed to unmitigated pain and stress. In this deleterious context, anesthetics have demonstrated protective abilities. Similarly, anesthetics may help alleviate the harmful effects from

other perioperative stressors, such as inflammation and hypoxia-ischemia.

#### Inflammatory response

Following physical trauma or surgery, in addition to painful stimulation, neurological impairment of infants may also be related to long-term effects of the inflammatory response to the trauma or due to subsequent bacterial infections. Inflammation plays a major role in the evolution of cerebral injury after cerebral ischemia and traumatic brain injury (TBI). Within hours, transcription factors are activated locally in brain tissue and upregulate proinflammatory genes, including the cytokines, tumor necrosis factor (TNF)-α, interleukin (IL)-1β and chemokines such as IL-8, interferon inducible protein-10, monocyte chemoattractant protein-1, and fractalkine [259]. The production of these inflammatory cytokines promotes the transmigration of the inflammatory cells in the brain parenchyma. Experimental studies in animal models of focal ischemic stroke have suggested that leukocytes play an important role in the development of secondary injury after acute CNS injury [260].

In animal studies, local neonatal inflammation has led to excessive hyperalgesia in adulthood [261]. Chronic persistent inflammation experienced early during development is capable of altering behavior and sensitivity to pain later in life, especially in response to recurrent inflammatory events [262]. Systemic infection, as demonstrated in a mouse model of neonatal injection of live bacteria, leads to sustained increases in microglial activation in the brain [263]. In these animals, cytokine levels are exaggerated following an immune challenge in adulthood, which can lead to impairment in memory function [263]. Injection of lipopolysaccharides during a critical postnatal period can affect adult sensation and pain responses [264] and may also cause long-lasting increases in seizure susceptibility [265].

Several injectable and inhaled anesthetics have been found to modulate immune function. Inhaled anesthetics, such as isoflurane and sevoflurane, were shown to interfere with the leukocyte-mediated immune response, which may lead to immunosuppression following surgical procedures [266]. Ketamine and propofol have also been shown to play a role in modulating inflammatory or immune system function [267,268]. However, postoperative immune function may be influenced by dose and timing of the anesthetic drugs, pain, psychological state, perioperative blood loss, or hypothermia [269]. Similarly opioid analgesics, such as morphine, have been found to suppress natural killer cell activity, inflammatory cytokine production, and mitogen-induced lymphocyte proliferation [270-272]. However, this response is modulated by the presence or absence of noxious stimulation and the type of opioid used.

Importantly, in an adult mouse endotoxemia model, isoflurane anesthesia immediately following the injection of a lethal dose of *Escherichia coli* lipopolysaccharide dramatically improved survival by 300% compared with unanesthetized animals [273]. In these animals, the administration of isoflurane, pentobarbital, or ketamine/ xylazine attenuated serum levels of the inflammatory markers TNF- $\alpha$ , IL-10, and IL-6. These findings suggest that anesthetic administration during endotoxemia may not only improve survival, but also lead to attenuation of the inflammatory process.

In children, abdominal surgery can lead to significant increases in blood levels of the cytokines C-reactive protein and IL-6 [274,275] which have been linked to increased complication rates in adult patients [276]. Moreover, invasive surgery in children has also been shown to depress the patients' immune system [274,277]. Neuromotor abnormalities 6 months following open heart surgery have been correlated with plasma levels of IL-6 that were measured immediately postoperatively [278]. These findings justify further investigations into the long-term effects of anesthetics on cytokine levels and their potential for improved outcome.

#### Hypoxia and hypoxia-ischemia

Due to the brain's limited ischemia tolerance, even relatively brief episodes of inadequate supply of oxygen or nutrients can lead to long-term neurological impairment in critically ill children, irrespective of anesthetic exposure. Several patient populations at increased risk for neurological sequelae, such as infants with congenital heart disease and premature neonates undergoing surgical procedures, have been studied regarding their longterm neurodevelopmental outcome. Many of these studies demonstrate neurobehavioral abnormalities, motor deficiencies, and decreased intelligence in many of these patients [191,205,279–281]. However, none of these studies describes the anesthetic and sedative regimens utilized or discusses their impact on subsequent neurological outcome. Conversely, neonatal animal models have repeatedly confirmed the protective properties of anesthetics when administered during episodes of brain hypoxia-ischemia [282-288]. These findings in immature animals suggest that critically ill human neonates might also benefit from these protective properties during clinical scenarios of neurological injury.

## Co-morbidities and environmental factors

Even patients who do not suffer from life-threatening illnesses may have co-morbidities or be exposed to environmental factors outside the perioperative period that may act as confounders for neurodevelopmental outcome.

#### Chronic otitis media

Relatively subtle medical problems, such as chronic otitis media, have been implicated in causing neurological impairment. While this effect is controversial and the exact mechanism unresolved, some studies suggest impairment in language development, literacy, and school performance following chronic otitis media with persistent middle ear effusions before the age of 3 years, while others were unable to find this association [230,231,289– 292]. A recent epidemiological review of anesthetic exposure in young children suggested a trend towards an association between serous otitis media prior to the age of 4 years and subsequent learning disabilities [229].

#### **Chronic airway obstruction**

In contrast to the contentious effects of chronic otitis media, the deleterious consequences of sleep-disordered breathing on neurocognition are well documented. Children with obstructive sleep apnea may face behavioral abnormalities, lower intelligence, and diminished academic performance, when compared to children with normal breathing patterns [293-295]. In these patients, surgical correction of the obstruction through adenotonsillectomy, which involves exposure to anesthetics, results in improved quality of life, behavior, and cognitive function [296]. Interestingly, even children with a pre-existing neurological condition, such as those with attention deficit hyperactivity disorder, demonstrated improved attention and decreased hyperactivity following surgical correction of mild sleep-disordered breathing, despite the obligatory exposure to surgery and anesthesia [297].

#### **Environmental factors**

Environmental factors and exposures outside the operating room can significantly interfere with normal brain development in humans. In utero, environmental compounds that may negatively influence subsequent neurocognition include such diverse substances as pesticides [298], methyl mercury, manganese, lead, and polychlorinated biphenyls [299]. Fetal exposure to prescription medications has also been found to lead to subsequent neurological sequelae, such as drugs for the treatment of acne [300], antihypertensives [301] and anticoagulants [302]. Prenatal exposure to alcohol and cocaine can impair children's speech, language, hearing, and cognitive development [303]. Intrauterine exposure to antiepileptic drugs, which share many pharmacodynamic properties with anesthetics, have been linked to brain structural abnormalities in young adults [304].

Other "environmental" factors known to affect learning and behavior in children are not as easily measured by subjective standards. Socio-economic aspects related to family dynamics, neighborhoods, and school environments all contribute to development and learning in children. In this context, factors negatively influencing neurodevelopment include economic deprivation, minority and/or immigrant status, exposure to violence, and chronic poverty [305]. Even when providing a strong community and positive family support, differences in school quality and negative encounters with teachers and/or peers can dramatically affect development and learning outcomes [305]. Moreover, negative influences on neurocognition have also been suggested by recreational activities, such as prolonged television viewing or video game play [306-308]. Due to this plethora of confounders, studies into the potential detrimental effects of anesthetic exposures need to take these socio-economic and environmental influences into account.

#### **Genetic predisposition**

Genetic composition can also affect neurodevelopment, even to a greater degree than environmental confounders. Close relationships have been demonstrated between genetic factors and cognitive abilities, including reading and mathematics skills, and intelligence [309]. Moreover, genetic predisposition can influence the effects of environmental stressors and vice versa [310].

Investigating the effects of anesthetic exposure on learning abilities in young children with an emphasis on genetic predisposition, a recent twin study found no causal relationship between anesthetic exposure and cognitive impairment [258]. A review of data from more than 1000 monozygotic twin pairs in The Netherlands Twin Registry demonstrated that, while children exposed to an anesthetic prior to age 3 years scored significantly lower on educational achievement tests and experienced more cognitive problems than children not exposed to anesthesia, cognitive performance of the unexposed co-twin did not differ from that of the exposed twin. These findings seem to suggest that the need for surgery with anesthesia may just represent a marker for subsequent learning abnormalities and not a causative factor leading to the impairment.

#### **Potential alleviating strategies**

While human applicability is not yet confirmed, as discussed above, numerous animal studies have suggested that all currently utilized general anesthetics as well as many analgesics may elicit a neurotoxic response in the immature brain, suggesting the judicious use of these compounds in young children. Conversely, though, inadequate alleviation of pain and distress may equally trigger neurodegenerative effects. Decreasing anesthetic doses by combinations of several deleterious anesthetics or concomitant administration of opioid analgesics may not obviate neurotoxicity, but rather exacerbate it, at least according to animal studies. Accordingly, a few animal studies have tested potentially alleviating strategies, ranging from concomitant administration of other anesthetics or sedatives, other drugs, to naturally occurring hormones. Moreover, whole-body hypothermia has also been proposed in the pursuit of reducing anesthesiainduced neurodegeneration.

Limited studies have found that the NMDA-antagonist xenon [62,63] and the  $\alpha$ 2-agonist dexmedetomidine [311] can reduce isoflurane-induced neuroapoptosis when administered concurrently. When administrated as a single drug, dexmedetomidine did not exhibit any neurotoxic effects in one study [311] whereas xenon demonstrated some neurotoxic properties in one study [63] but not in another [62]. One in vitro study has even suggested that pretreatment with isoflurane can protect from subsequent exposure to higher doses of the same drug [107]. Lithium has been found to alleviate neurodegeneration caused by propofol or ketamine in neonatal mice [72] whereas preliminary data may suggest that pilocarpine reduces neuroapoptosis triggered by the GABA-agonists midazolam or isoflurane [105] while it augments brain damage caused by the NMDA-antagonist phencyclidine [312]. Naturally occurring hormones, such as estradiol [67] and melatonin [68], have been successfully tested in newborn rats to reduce neuronal injury caused by the prolonged, combined administration of midazolam, isoflurane, and nitrous oxide. Head and co-workers have demonstrated that administration of tissue plasminogen activator, plasmin, or pharmacological inhibition of the neurotrophic receptor p75<sup>NTR</sup> reduced neurotoxic effects of isoflurane in neonatal mice [113]. Most recently, it has been proposed that whole-body hypothermia to 24°C may reduce isoflurane-induced neuroapoptosis in neonatal mice [112,313].

While implementation of these proposed strategies during pediatric anesthesia appears premature, given the fact that human applicability of this phenomenon remains highly controversial, the safety of some of the proposed therapies has not been tested in young children. Estradiol may not be a feasible adjuvant prior to puberty or in boys, pilocarpine has demonstrated proconvulsant activity in some animals [314,315], lithium has been labeled as harmful for the human fetus [316] and may cause neurocognitive impairment in young children [317,318], and hypothermia of 24°C may only be feasible in procedures involving hypothermic cardiopulmonary bypass, but not during routine pediatric anesthesia or intensive care. While xenon's scarcity makes it a very expensive treatment, dexmedetomidine may be a valid option for light sedation or as an adjuvant for general anesthetics.

#### **Ongoing and future research**

Whereas animal studies seem to unequivocally demonstrate deleterious brain structural changes immediately following anesthetic exposure, long-term neurological abnormalities are not universally demonstrated. Moreover, human epidemiological studies examining developmental outcomes have returned ambiguous results. However, the potentially immense impact of neurotoxicity induced by anesthetics and sedatives on child health necessitates significant research efforts into this phenomenon. These efforts must include both preclinical studies investigating the exact structural changes, underlying molecular mechanisms, and the affected target cells, as well as carefully designed clinical studies delineating human susceptibility, while taking into full account the above-mentioned perioperative confounding variables. Given the public health impact of the potential neurotoxic effect of anesthetic drugs in pediatric patients, the United States Food and Drug Administration and the International Anesthesia Research Society created a public-private partnership called SmartTots (Strategies to Mitigate Anesthetic Related NeuroToxicity in Tots) to support clinical investigators in this area. (www.smarttots.org). This collaboration has provided funding for ongoing research studies (GAS and PANDA studies).

#### GAS study

This is an international, multi-site, randomized controlled trial, which compares the effects of regional and general anesthesia on neurodevelopmental outcome and apnea in infants in a projected cohort of 660 patients (Dr Andrew Davidson, personal communication, September 2009). The study, under the direction of Dr Andrew Davidson, includes pediatric hospitals in Australia, Canada, France, Italy, New Zealand, the United Kingdom, and the United States and proposes to assess patients' intelligence quotient 2 years following a neonatal inguinal hernia repair performed either with general anesthesia or with caudal or spinal anesthesia [319]. Dr Mary Ellen McCann directs the United States arm of the study and receives funding from the National Institutes of Health and the SAFEKIDS initiative. Advantages of the GAS study, which also enrolls premature neonates born as early as 26 weeks of gestation, include the prospective randomized approach, the use of contemporary anesthesia techniques, and the true separation of the effects of surgery and general anesthesia. The relatively brief exposure period, however, does not allow for the assessment of dose-response relationships. Moreover, neurobehavioral assessment cannot

begin until at least 2 years into the study and definitive results may take even longer to collect [319].

#### **PANDA study**

A different approach of retrospective identification and prospective study of subjects has been taken in the Pediatric Anesthesia and NeuroDevelopmental Assessment (PANDA) study [1]. The PANDA study's aim is to assess the effects of anesthetic exposure for inguinal hernia repair within the first 3 years of life in a retrospectively identified cohort, excluding premature neonates, on prospectively measured neurodevelopmental outcome later in life. Neurodevelopment will be assessed with the NEPSY II (acronym for NEuroPSYchological Assessment, Pearson Education Inc., www.pearsonassessments.com) and the Wechsler Abbreviated Scale of Intelligence instruments and compared with an unexposed sibling control. The study, which is led by Dr Lena Sun at Columbia University, plans to enroll a total of 500 patients and 500 controls and includes several other major pediatric centers throughout the United States, such as in Boston, Chicago, Cincinnati, Iowa, Philadelphia, Pittsburgh, and Nashville. With the PANDA study's approach, neurobehavioral testing starts immediately after enrollment, socioeconomic and genetic confounders are addressed using a sibling control, and anesthetic techniques are still within 10 years of current practice. However, due to the relatively brief surgical time, findings are limited to between 1 and 2h of anesthetic exposure, which might still represent the length of the typical pediatric surgical procedure. However, the measured outcome is a function of both surgery and anesthesia.

#### **Danish Registry**

In an epidemiological approach, Hansen and co-workers are using a database of all 45,000 children who underwent surgical operations in Denmark from 1977 to 1990 before 1 year of age, comparing the academic achievement of exposed children with that of the general Danish population. The researchers are planning to achieve this goal by linking a nationwide demographic database with a national hospital discharge registry and compulsory school completion test scores. While this study is limited by the retrospective nature of an epidemiological approach and the relatively outdated anesthetic methods, the size of the cohort will help to control for many of the confounders discussed in this review [320].

#### Conclusion

In conclusion, neonatal exposure to numerous anesthetics causes widespread neurodegeneration in a dose- and duration-dependent fashion and can lead to long-term neurological impairment following administration of anesthetic combinations in newborn animals. However, the relevance of these findings to pediatric anesthesia is unknown. The phenomenon's exact underlying mechanism has not yet been determined, but does not seem to be entirely explained by anesthetic-induced neuronal inhibition. While animal studies reveal susceptibility to be limited to a very brief stage during brain development, the corresponding human maturational state has not been clearly defined; several lines of evidence point towards the prenatal or early postnatal period. Whereas anesthetic administration in animals differs significantly from pediatric anesthesia practice and numerous confounders exist in humans that do not occur in animal populations, emerging human epidemiological studies do not exclude anesthetics as a factor for impaired learning and neurodevelopment observed following surgical procedures. However, unlike the consistent neurodegeneration and neurological impairment demonstrated in anesthetized animals, neurological sequelae observed in retrospective epidemiological studies seem sporadic and do not affect all exposed individuals to the same degree, suggesting a potential genetic or other influence on this association. Since existing epidemiological studies are unable to establish causality and cannot distinguish between the differential effects of surgery and anesthesia on neurological outcome, further well-designed preclinical and clinical studies are needed to examine the phenomenon's mechanisms and its clinical relevance. Given the serious consequences of unopposed pain for the developing brain, current anesthetic practices should only be changed once results from these future studies become available.

- All currently used anesthetics have been found to be neurotoxic in neonatal animal studies.
- The phenomenon's clinical relevance is unknown.
- Animal and preliminary human studies suggest the maximum potential for susceptibility in humans to occur early in life, potentially prenatally.
- Pain and stress in unanesthetized, immature animals and humans have similarly been found to cause neuronal cell death and neurocognitive impairment.
- More studies into this phenomenon are needed before changes to current anesthetic and sedation practices can be recommended.

#### Introduction

Simulation has taken the medical world by storm but why has this type of approach to teaching, evaluation, and research become so popular in medicine? What does it have to offer us in improving the delivery of pediatric anesthesia care to our patients?

There are many types of simulation, requiring a wide range of facilities and equipment to perform, but all types can be neatly described as creation of an artificial environment that replicates a real-world situation to achieve a particular objective. In re-creating a critical event after the fact, the objective may be the ability to better understand factors that lead to the undesirable outcome. In developing a crisis scenario for an imaginary patient, it may be the training of a new resident in the management of the medical events portrayed. The set of possible goals is as infinite as the human imagination.

In today's world of shrinking budgets, limited hours for trainees, and dispersal of patients from the inpatient to the outpatient setting, the degree of exposure to a wide variety of patients and critical situations for our trainees in medicine has decreased steadily. The challenge, to ensure that our residents and students have the basic tools required to react appropriately to crisis situations or to diagnose rare illnesses, has increased. Private payers, the government, and the public are scrutinizing our medical system, demanding improved patient safety and a decrease in medical errors, and measuring the training and performance of our medical practitioners.

Using simulation, we can focus training hours for our residents and students to elicit the maximum exposure to the types of patients and events deemed critical for complete well-rounded training in any particular field. Skills required by the US Accreditation Council for Graduate Medical Education (ACGME) in communication, professionalism, patient care, and medical knowledge can be practiced and tested. Teams can be drilled on critical actions, helping to ensure that they will act together in appropriate ways when a real situation presents. And we can tease out problems in our care environments, changing processes, protocols, and equipment, prior to exposing our patients to imperfect systems.

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

For all these reasons, it seems clear that simulation in medicine is here to stay. Putting it to good use will ultimately not only benefit our patients, but improve our own mastery of our field as well. This chapter will explore what simulation is, how and why it has grown in medicine, the many ways in which it is applied and finally, the applications and current state of simulation use in pediatric anesthesia.

## History of simulation: development in aviation and beginnings in medicine and anesthesia

In order to remain competitive, increase safety, improve outcomes and become cost effective, the medical system has begun to borrow methods and techniques from successful business models. When dollars are at stake, approaches such as Toyota's "lean" manufacturing principles are used [1]. However, when looking to teach and train for-high risk, high-stakes activities, medicine has borrowed from fields with known extraordinary risks such as nuclear power, aviation, space exploration, and the military. These industries represent high-reliability organizations (HRO), institutions where positive results are consistently delivered with minimal error, despite the need for multiple individuals working together as a team in high-risk situations. Simulation exercises have been used in these areas both to train new practitioners and to expose experienced individuals to critical and rare events.

#### **Development in aviation**

Aviation in particular is often used as a metaphor for the practice of anesthesia. Both require a high degree of vigilance, attention to detail, and periods of relative inactivity interspersed with critical moments when the need to react quickly and effectively is mandatory to avoid poor outcomes. In both fields, lives are at risk if mistakes happen or if practitioners are unable to respond appropriately. Thus, it is helpful to understand the evolution of simulation in that field and to understand how those methods have been adapted to the anesthesia environment.

In aviation, simulation, in the form of mocked-up aircraft controls, was used as early as the manufacturing of the first aircraft, between 1920 and 1927. A more sophisticated, pneumatically driven flight simulator was invented by Edwin Link in 1929 [2]. Improvements have been made over time, and the modern, computer-assisted simulators include high-fidelity computer graphics to create the illusion of the real world outside the cockpit [3]. These simulators are routinely used for both training of new pilots and review of crisis situations for experienced pilots. In fact, it is clear that simulation is an expected part of aviation training in the public mind, when it becomes the norm in cinematic representations. Futuristic flight simulation team training is dramatically depicted in the movie *Star Trek* (2009) [4], when trainee James Tiberius Kirk is subjected to the "Kobayashi Maru" test, a simulation exercise created by "professor" Spock, with the objectives of evaluating a cadet's performance and teaching how to deal with a failure in space.

Not all aviation simulation requires high-tech tools, however. In the military, dunker training, a simulated crash of an aircraft into water, is routinely used as a method both to train recruits in the appropriate reactions to survive such a crash and to weed out individuals that don't have what it takes to respond appropriately in such a situation. The movie *An Officer and a Gentleman* [5] includes a memorable scene with this training for Navy flight cadets, where one of the main characters fails the test. Army flight surgeon training includes a day of simulated water exercises, with long bouts in a pool in full flight gear, jumps from high boards into water, and escape from a simulated "downed helicopter" which flips underwater (personal experience, 1988, Army Aviation Medicine Course, Ft. Rucker, Alabama).

Team training in aviation began in earnest after a series of crashes in the 1970s that were clearly not related to technical or equipment failures. One of the most famous was the Tenerife Airport disaster that occurred in 1977, involving two jet airliners that crashed on the runway at take-off, killing 583 people in all. Review of the crashes clearly demonstrated multiple failures, including problems with communication and team work [6]. Crew resource management (CRM) training, teaching crews to work together through a crisis in a simulated environment, was developed as a method to reduce the system and communication errors inherent in these complex environments [7].

#### Beginnings in medicine and anesthesia

Just as in aviation, simulation in medicine started with simple task trainers and moved to complex high-fidelity simulation environments. Patient simulation was first explored in medicine by Asmund S. Laerdal, with Peter Safar and Bjorn Lind, who created a mannequin, Resusci Anne, for the training of mouth-to-mouth resuscitation [8]. She was introduced as the first patient simulator in 1960; her face was based on the death mask of a young girl pulled from the River Seine at the turn of the century [9]. These first simulation systems were simple and generally task oriented, looking to teach individuals medical skills. High-fidelity patient simulation with the replication of a real-world environment, using interactive mannequins, was introduced to anesthesia in the 1960s and 1970s with the Sim One Anesthesiological Simulator by Abrahamson and Denson [10]. David Gaba created the Virtual Anesthesiology Training Simulation System at the Veterans Affairs Hospital in Palo Alto, California, in 1986 as the first center-based high-fidelity anesthesia simulator environment, allowing a full range of individual and team training, and research into the uses of simulation and the assessment of human performance [11].

In aviation, it took a series of disasters to stimulate the use of simulation and the birth of crew resource management training. In medicine, the widespread use of simulation was stimulated after a pivotal report from the Institutes of Medicine was released in 2000 that shocked the medical world. It publically exposed the high degree of medical error that routinely occurs, stating that between 44,000 and 98,000 patients die in US hospitals due to avoidable medical error each year. The report went on to recommend team training based on both aviation's crew resource management programs and simulation-based education and training in medicine, as a means to create a safer healthcare environment [12]. The widespread acceptance of these techniques and perceived utility in developing and maintaining critical skills are exemplified by the approach taken by Harvard's malpractice insurance carrier: in order to maintain a favorable insurance rate for the anesthesia department, all faculty participate in a simulation event on an annual basis [13]. This approach has since been taken by other malpractice carriers.

#### **Uses of simulation**

As the need for simulation in medicine has grown, its use has moved from specialized simulation centers into actual patient care areas, such as hospitals and clinics. It has also progressed from a focus on single medical specialties to involving all levels of healthcare professionals and disciplines, often working together. In the following section, the application of simulation to education, research, team training, professional evaluation, continuing medical education (CME), and systems evaluation will be reviewed.

#### Education

Medical schools are now using simulation as a regular part of their curricula, responding in part to the ethical dilemma of allowing novice students to learn techniques for the first time on real patients. From part-task trainers, which allow students to place intravenous catheter or sutures, to standardized patient actors who teach students how to approach a patient, communicate, and perform a physical exam, simulation has become an integral part of medical student education. Five factors have been cited by Issenberg and Gaba as contributing to the increased use of simulation in medical school curricula: "a. problems with clinical teaching, b. new technologies for diagnosis and management, c. assessing professional competence, d. medical errors, patient safety and team training, and e. the role of deliberate practice"[14].

This trend toward simulation-based training has not been restricted to medical students. The continued shrinking of residency training hours is a worldwide trend [15]. In the US, it is limited by the ACGME to 80 hours per week, with strict rules about rest time between shifts [16,17]. While this may appear to be enough time to expose residents to the many cases required, the restrictions have been felt across all medical disciplines and reflected in residency programs looking for ways in which to accelerate learning apart from the usual "apprenticeship" model currently practiced [18–23]. More and more, simulation is being used to fill the gap.

In anesthesia training, these tools have been used for many years. The operating room represents a unique environment in medicine, full of complicated technology requiring facility in use for rapid responses when changes in patient status occur. Most medical students have very minimal exposure to this environment prior to residency training. Thus, there is a strong impetus for simulation's use in anesthesia education for development of trainees' skills, both in basic understanding of the equipment and in responding to critical events [23,24].

At Stanford, like many other programs, training for anesthesia residents includes regular simulation training with an increase in the difficulty of scenarios presented at each level of training. Trainees may spend a day in the simulation center, running through a series of simulation crisis scenarios and debriefing sessions, examining their own performance and that of their peers in a formative review [25]. *In situ* training, with short focused simulation events, is also becoming more common (Fig. 42.1).

Attempting to understand human performance factors, which are critical to achieving positive outcomes in crisis

Figure 42.1 Anesthesia trainee intubating a Sim Baby mannequin during an *in situ* simulation scenario in the operating suite.

situations, has been a widely appreciated practice since it became a focus in evaluating a series of severe accidents in the aviation industry in the 1970s. These human performance factors have been heavily studied and described [26]. Recognizing their importance to a wide variety of situations in medicine, many of the factors are also listed as required competencies for all medical residents by the ACGME [27]. Gaba et al have also described a set of skills that correlate with successful performance during a simulated anesthesia crisis (anesthesia crisis resource management - ACRM) [28]. Many of these human performance skills, described as non-technical skills by Flin et al in Safety at the Sharp End: A Guide to Non-Technical Skills, are also noted as essential in team work during crisis for multiple industries [6]. The concurrency in the description of these skills is evident in listing of some of the factors from these three systems - ACGME, ACRM, nontechnical team skills - in Table 42.1. They all have as key components aspects of human behavior and communication which are important in working together well in complex situations.

Simulation courses, such as the ACRM course based on aviation's CRM principles, are geared to help teach these critical human performance factors (see below) [14,29,30]. Simulation, with debriefing focused on these nontechnical skills, can help improve overall competency while raising the awareness of the importance of teamwork skills [31].

Most anesthesia residents may spend very little time in pediatric anesthesia training: often just 2–4 months during their 3 years of residency. The approach to patients and families, the method of preoperative sedation and preparation, the induction techniques, and the types of crisis that occur in pediatrics are very different from those in adult anesthesia. This limited clinical time, with an extensive behavioral knowledge set required, creates an ideal situation for the application of simulation training to enhance the rapid acquisition of this specialized skill set.

The reasons why simulation works as an effective means of education have been studied, with some inconsistent results. Issenberg et al searched the literature to extract the key factors of simulation noted to be associated with effective learning [14], listed in Table 42.2. The most common element seen in 47% of the journal articles they reviewed was "providing feedback." During highfidelity patient simulation (HFPS), this is usually done during a debriefing session that follows the simulated scenario. Effective debriefing allows for a carefully guided introspective review of the scenario, how the event unfolded, and the outcomes, with input from all participants. Other common factors include "repetitive practice," cited in 39% of journal articles, and "curriculum integration" in 25%. These two factors require a standard design to scenario development, which allows for repetition and inclusion in standard curriculum, for standard objectives and goals. Templates have been designed to facilitate standardization of scenario development and consistency in repeated use of single scenarios [32] (see below).

Performance of these types of dynamic interactive and interpersonal human performance skills is difficult to observe and evaluate in the normal testing situation. Simulation provides a venue to demonstrate or practice these skills, allowing feedback on effectiveness of leadership, communication, or decision-making abilities [33,34]. Use of simulation for evaluation of trainee performance has long been an area of considerable interest [35]. While it has been difficult to convincingly link performance measurements in simulation environments to real clinical situations, tools are beginning to be developed that demonstrate improved reliability and validity [36,37].

Finally, another factor driving the increased use of simulation in medical education is the perceived effectiveness of the learning method itself. By using high-fidelity patient simulation, the learner becomes immersed in the educational domain, participating actively in the learning environment rather than passively absorbing information. This type of performance learning has been shown to be more effective for adult learners, and information is retained at a higher rate than information imparted in passive learning sessions [38–41]. The evocation of emotional responses improves the learning process and increases retention as well [41]. Simulation provides just such a learning environment.

#### Research

Simulation's applicability to research is beginning to be fully realized. From answering basic questions in human performance to teasing out ways to improve protocols, procedures, and equipment, simulation can be used to answer multiple questions in practice sessions prior to the real event.

Research in human factors and performance is facilitated with the use of simulation. This has been a particularly fruitful area of investigation, because of the ability to recreate relatively uniform circumstances for testing with more than one practitioner group [42]. Theoretically, questions regarding practice performance can be answered, which otherwise might demand an approach using retroactive reviews of multiple charts, thereby including many uncontrolled assumptions. Investigations have been conducted into human interactions with the environment, fatigue, and response to the stressors inherent in caring for patients during a crisis [43-45]. Looking at the effectiveness of crew co-ordination and the ability to perform to task would be difficult or impossible without the use of a high-fidelity simulated environment in which to create a crisis scenario and elicit a team response [46].

**Table 42.1** Comparison of non-technical and team skill characteristics from three systems: non-technical team skills as described by Flin et al [6], ACRM performance goals, and ACGME trainees' performance criteria (\*includes only the subset of ACRM and ACGME areas for which there was some correlation with the other system behaviors noted)

Factor	No. of citations	% of journals	Description
Providing feedback	51	47%	Educational feedback
Repetitive practice	43	39%	Repeated practice of behavior
Curriculum integration	27	25%	Integration of simulation-based exercises into the standard medical school or postgraduate educational curriculum
Range of difficulty	15	14%	Range of task difficulty level
Multiple learning strategies	11	10%	Adaptability of high-fidelity simulations to multiple learning strategies
Capture clinical variation	11	10%	Capture a wide variety of clinical conditions
Controlled environment	10	9%	Controlled environment where learners can make, detect, and correct errors without adverse consequences
Individual learning	10	9%	Reproducible, standardized, educational experiences where learners are active participants, not passive bystanders
Defined outcomes	7	6%	Clearly stated goals with tangible outcome measures, appropriate to level of training
Simulator validity	4	3%	Degree of realism

 Table 42.2
 Factors noted by Issenberg et al [14] to be associated with effective learning

Finally, not only has HFPS facilitated obtaining answers to many primary research questions, it has also been used by researchers to improve the effectiveness of their clinical trials. Problems in protocol design, procedures, and data collection tools can be exposed prior to the beginning of the trial, saving time and decreasing costs. Also using simulation to train evaluators and co-ordinators can help to decrease errors at the start of the trial, ensuring better compliance with trial rules [47,48].

#### Team training: review of Anesthesia Crisis Resource Management principles

Anesthesia crisis resource management (ACRM) refers to a system of appropriate team and individual responses to a crisis in a patient under anesthesia. This system is based on principles and techniques derived from aviation: crew resource management. Training in these techniques teaches crews to work together through a crisis in a simulated environment, and was developed as a method to reduce the system and communication errors inherent in the complex aviation environment [7,49–51]. The primary goal of crisis management is to detect problems early in their evolution, then mobilize an appropriate response in order to prevent an adverse outcome.

Many of the keys to ACRM revolve around maintenance of situation awareness and effective dynamic decision making. Leadership ability and communication among team members are essential, as is the effective use of all available resources. Figure 42.2, an example of a

#### Crisis Resource Management Key Points

**Figure 42.2** Cognitive aid developed to assist in recall of performance goals using the ACRM framework, by David Gaba, Steven Howard, and Sara Goldhaber-Fiebert (Stanford University School of Medicine and VA Palo Alto Health Care System).

cognitive aid, includes the behaviors that are associated with an improved team response to crisis as taught in ACRM [28].

One of the mechanisms that helps create an effective team is the concept of the "shared mental model"; that is, the mutually agreed upon set of knowledge and processes used to explain or predict events to achieve certain goals safely and effectively [52,53]. While team training began in the military in the 1950s, training based on the "shared mental model" concept was first instituted in the 1990s [29]. Crew resource management, used in aviation for many years, works with shared mental models, using a variety of training methods, including simulation, to teach appropriate team skills. These teamwork functions are fleshed out from work focused on the macrocognitive skill sets required to achieve effective team management of complex tasks [54]. Included are leadership and communication skills such as those outlined in Table 42.1, and others such as adaptability, back-up behavior, mutual trust, and team orientation. Simulation is an effective tool to create a situation in which these skills can be teased out and practiced [50].

#### **Professional evaluation**

The ability to grade performance in medicine has long been fraught with difficulty. Testing paradigms which focus on the ability to regurgitate medical knowledge in board examinations ignore the multiple skill sets known to affect performance in real patient care situations, including communication and professional skills, and ability to work in an acute crisis situation within a team structure. Across healthcare disciplines, simulation has been adopted for training and assessment, because of its ability to demonstrate these critical skill sets [55]. Both standardized patients and mannequin-based simulation have been used for summative assessment, and in some cases, are required to obtain certification and licensure [56,57].

Various simulation modalities, from part task trainers and mannequins to computer-based case management scenarios, have been adopted for professional assessment in anesthesiology. Using simulation, particular situations can be recreated for testing for competence. For limited situations, experts come together to develop checklists, which can be tested for reliability and validity, permitting "credentialing" for that particular situation [36,58–60]. Broadening evaluation in order to comment on a practitioner's ability to practice is fraught with difficulty because of the lack of a widely accepted assessment tool [61]. Despite the challenges, this model is already in place in some countries, and is being used to allow professional accreditation, such as passing of board exams [62]. Testing systems are being investigated and developed for residency training in several fields, including anesthesia [63].

While not being used for evaluation, the American Board of Anesthesia (ABA) has recently added simulation exposure as part of the core CME requirements in the Maintenance of Certification in Anesthesiology (MOCA) system for recertification of anesthesia boards in the US [64]. Understanding the value of exposure to teamwork skills and crisis management is a prime driver for including simulation in CME for anesthesiologists [57].

#### **Continuing medical education**

Exceptional performance and expertise have been shown to be linked both to practice and to repeated exposure to activities with strong teachers who give formative realtime feedback [65,66]. The American Society of Anesthesiologists (ASA) has taken a proactive approach to CME, encouraging both the retention of skills and the acquisition of new expertise in practicing anesthesiologists by the introduction of simulation training in CME requirements for recertification [64]. Simulation offers the opportunity to practice the responses required to any given situation again and again, enabling practice performance assessment and improvement by participants [57,67].

#### Systems evaluation

Simulation methods have been used to evaluate the effectiveness of hospital systems, allowing targeting of system fixes if needed. Team responses to disasters in which multiple patients arrive in the emergency department [68] have been evaluated, as has the ability to respond in a timely and appropriate way to hospital emergency codes [69]. The ability to respond to crisis in the use of extracorporeal membrane oxygenation (ECMO) for neonates has been practiced [70]. Simulation has also been used to review new spaces prior to them being used for patient care, ensuring adequate equipment, space, and familiarization of staff with the environment [71]. Prior to opening the new operating rooms at Lucile Packard Children's Hospital at Stanford University, simulations of the complex information technology systems created to assist with scheduling of surgical cases and recording of surgical care in nursing and anesthesia documentation, and of the ability to perform the anticipated surgical cases, were completed prior to using the new OR suite. All surgical services were used in a simulation session in which a test case was scheduled, all team members required were present, and all equipment and supplies were reviewed and obtained to ensure that no significant gaps remained prior to receiving the first patient. Issues revealed included critical equipment that was discovered to be missing, process and policy problems that interfered with effective communications, and poor patient flow. Identified problems were then addressed proactively, eliminating their possible impact on actual patients (Fig. 42.3).

#### **Types of simulation**

#### **Part task trainers**

Performance of procedures requires technical skills that rely on mechanical facility. An understanding of the basic mechanical steps can be acquired with the use of part task trainers, pieces of the whole picture that represent some part of a patient or physical reality. For instance, a mock arm, with tubing representing vessels, can be used to practice the steps required for starting an IV. A manne-

**Figure 42.3** *In situ* simulation in the Lucile Packard operating room, team training for improved response time to critical events.

quin head, with tongue, pharynx, glottis, larynx, and trachea, can be used to practice mask ventilation and intubation. These trainers can be as simple as a block of gelatin encompassing a target for practice using ultrasound-guided regional blocks to sophisticated computer-driven, sensor-laden systems for practice of laparoscopic surgical manipulations [72,73]. Complex haptic devices are being developed that meld computer-based virtual simulation and hands-on control [74,75].

Just as adult simulation high-tech mannequins have "evolved" to smaller pediatric models, part task trainers are now being created to simulate pediatric patients. Limbs for vascular access, intubate-able neonatal heads, and ultrasound-guided central vascular access trainers are just some of the items that are available. Figure 42.4 represents some of the current pediatric task trainers being marketed. As interest in these systems has grown, the variety and scale of available models have increased greatly.

#### **Computer-based simulation systems**

Sophisticated computer programs have been written to enable practice of various anesthesia tasks and medical crisis scenarios in a virtual format. These types of systems have the advantage of being available at any time to allow learners the chance to practice whenever they have the time [76–78]. Using the input of large amounts of data, from systems such as magnetic resonance images (MRI),

**Figure 42.4** Part task/technical trainers. Clockwise from upper left corner: arm for IV starts (Gaumard Scientific), intraosseous needle placement (Gaumard Scientific), infant head for intubation and mask ventilation, umbilical catheter placement (Laerdal Medical).

models of human anatomy, based on various patients' idiosyncrasies, can finally be realized and used to present learners with the type of variety that they will see in practice [79,80]. Some internet-based systems, based on avatars, facilitate multiple users coming together in a virtual world to act as team members in various clinical scenarios. This keeps facility and material costs down, but relies on scheduling participants appropriately, having multiple access ports available, and a teacher/facilitator to guide the action [81].

Other systems allow for a melding of simulated transparency of functions in real time, enabling a deeper understanding of both mechanical anesthesia systems and simulated patient physiology [82]. Taking virtual systems and task trainers and combining them with a full-scale simulator allows for another twist on increasing the perceived reality of the scenario depicted [83,84].

As pediatric-based systems have yet to be developed and are likely to be difficult to pull together as basic vital signs and responses are so varied in pediatrics based on age and physical status, this area will not be discussed further in this chapter.

#### **High-fidelity patient simulation**

High-fidelity patient simulation (HFPS) refers to simulation scenarios that closely replicate real patients, making it easier for participants to believe in the reality of the situation depicted and thus to apply realistic responses. In any high-fidelity simulation, a learning or evaluative goal is selected, and a scenario is developed to create the opportunity for the goal to be achieved. Using a simulated environment and tools such as high-tech mannequins that both simulate a patient's responses to interventions and allow varying degrees of interaction with the participants, the scenario is played out. Expert facilitators in various roles encourage the participants to react to the cues supplied for the scenario and supply real-time feedback supporting the scenario as it unfolds.

#### **High-tech mannequins**

High-tech mannequins have been developed by several companies for use in simulation. These mannequins are made to represent patients of varying ages, from neonates to adults, and come equipped with mechanical and electrical parts to produce various effects from coughing and wheezing to hypotension and cyanosis. Heart tones, chest wall motion, palpable pulses, and closure of the airway can all be mimicked. Interventions are possible including bag-mask ventilation, tracheal intubation, IV placement, defibrillation, and in some cases chest tube insertion or cricothyrotomy. A vital signs monitor shows the patient's current status and can be manipulated by a technician in response to interventions by the simulation participants (Fig. 42.5).

Figure 42.5 Elements of infant simulation mannequin by Laerdal Medical: mannequin with electrical and mechanical elements, control computer, monitor, remote control device, video camera, and relay box.

Some simulation systems include software which provides automatic realistic responses to interventions, including chest compressions, ventilation, and administered drugs. Table 42.3 provides a review of the features currently available in the more popular pediatric mannequins. Many of the mannequins have common features, which allow for basic interactions to control the airway and respirations. Some mannequins provide the ability to perform a variety of invasive interventions. The "consumable" parts, skin and bone, often need to be replaced after a certain number of uses. Setting some rules of engagement with the mannequins before beginning the simulation can allow for near realistic performance while saving the limited and costly resources of the mannequin parts.

#### Standardized patient actors

When communication skills were made one of the core competencies for ACGME, the central importance of clear and effective communication in medicine was emphasized. Team communication is very important and can be practiced during simulated scenarios involving mannequins, but effective communication with a patient or family member cannot be simulated well with these tools. Thus, standardized patient actors are frequently used in many simulated situations in both medical schools and other educational venues [85].

Using patient actors allows learners to interact with a "patient" or "family member" capable of evoking convincing emotions by improvising and adjusting their response based on the learner's input. This type of high-fidelity simulation can also create complex and subtle interactions, with the ability to practice the most basic features of medicine: effective history taking or developing a caring and empathetic approach. Videotaping of the interactions for review during debriefing also helps the learner to see how they come across and the nonverbal communication cues they may be using unknowingly (Fig. 42.6). This type of simulation has now been

Table 42.3 Comparison of some of the features offered in mannequins created to mimic various pediatric patients, from premature infants to 6 year olds

This table does not represent all the features that these simulators offer. Some features which were common to all the simulators were not included. All these high-fidelity models allow the users to place airway management devices, attach standard ASA monitors, and perform advanced life support interventions. In addition, all models have a vitals signs monitor that can produce a complete gamut of physiological states and a user input device that triggers the simulator to generate various heart sounds, breath sounds, and vocalizations. Some METI and Laerdal models offer a wider variety of advanced airway emergencies such as laryngospasm and airway edema, whereas the Gaumard models have the distinct advantage of being completely tetherless (i.e. not needing to be attached to compressed air source).

**Figure 42.6** Depiction of actor as parent coupled with simulation mannequin in training exercise.

incorporated into Step 2 of the US Medical Licensing Examinations for medical students. Students must effectively interact with trained patient actors to obtain a history and physical, thereby demonstrating not only the technical medical knowledge but also the effective communication and interactive skills critical to becoming a physician [85,86].

#### Hybrid simulation

Hybrid simulations refer to the combination of any two types of simulation, whether the use of a part task trainer combined with a mannequin, or a patient actor and a simulated body part that can be manipulated by the participant to treat the simulated situation. For instance, a part task trainer arm can be attached to a patient actor's arm and used to start an IV, or a delivery task trainer can be combined with a patient actor for simulated infant delivery. The patient actor can then provide active and realistic responses to the participant as they attempt to provide the indicated care. This combination of task training and communication with the "patient," such as suturing of a wound or injection of a local anesthetic, creates a much more instructive and meaningful situation for the learner and allows a substantially greater understanding by an evaluator of the participant's skill set and patient management style. The tasks that are performed on patients never happen in a vacuum. Learning to deal with the patient's reactions to the procedures we perform is critical for effective patient care. This hybrid model allows the integration of these components for a much more realistic and effective training scenario.

#### Organization and running of highfidelity simulation sessions

#### Elements of high-fidelity patient simulation The introduction

Prior to starting a simulation scenario, the participants should be familiarized with the simulation environment, the tools to be used, and the roles they will play, elements critical in enabling a positive learning experience. Just as important is ensuring that all learners understand the goals of the exercise and how their performance will be assessed. Some essential points to cover include goals of the session, who will be participating, who will be facilitating, and how to engage and behave in the environment.

When the simulation scenario is focused on formative rather than summative assessment, removing any sense of threat from the session will help ensure a positive learning frame of mind. Many simulation centers ask the participants to sign a consent that emphasizes the importance of keeping the elements of the session, both the scenario and the performance of individuals, confidential. This can help decrease the concern that an "inadequate" performance will be talked about after the event. In these types of learning sessions, participants are told that there is no penalty for "failing" in a crisis simulation, allowing them to take risks in their interactions and actions during the scenario that will enable their learning.

#### The scenario

A scenario is created, somewhat like a storyboard for a movie, which sets the framework for the simulation session. It is based on both the goals and the anticipated participants. Content experts are critical in designing a realistic scenario, as an understanding of patient responses in various clinical situations is key to playing out any scenario. No matter what framework is set for the situation, the particular participants during the session will bring their own experience and knowledge base to the interpretation of the scenario, and will often react in unexpected ways. Thus, content experts are key during the running of the scenario as well, allowing credible manipulation of patient vital signs and reactions to any actions by the participants.

#### Debriefing

Arguably, the greatest learning from a simulation session occurs during the final section, called the debriefing. Debriefing has its roots in the military and aviation, where a group leader brings the unit together after an

**Figure 42.7** *In situ* team debrief after simulation in the Lucile Packard Children's Hospital operating room, aimed at improving response time and management effectiveness for patient crisis at induction.

event or mission to review outcomes, both positive and negative, and to develop some lessons learned to apply to the next mission. Similarly, in medical simulations, this part of the session allows the team to discuss what occurred during the scenario and develop an understanding of how the crisis or situation unfolded (Fig. 42.7).

The goals of a debriefing session may vary but in ACRM, the technique is used to allow members of the team a chance to review their own performance, to evaluate the team's performance, to understand the drivers in the crisis, and to learn some general principles of crisis management that they may then use more effectively during future critical events [34,41].

Facilitated debriefing is the key to reaching learning goals from a simulation scenario. During a critical event, attention is intensely focused on managing the crisis and completing necessary tasks. It is only in the later analysis that an understanding of all the factors affecting the outcome can be gained. This then leads to learning from the event, its management, and any failures that occurred. A facilitator is important in guiding the debriefing and framing the learning points [41].

Ideally, the facilitator encourages reflective analysis, leading the participants in the crisis through the event, eliciting their own reactions and thus assisting them in developing their own analyses. Material covered in a group discussion is much more likely to be retained than that passively obtained in a lecture type presentation. In addition, when participants provide their own insights and observations, they feel that their input has been heard and then have more of a stake in the discussion and a sense that their ideas become part of the conclusion. These conclusions then become more acceptable and believable to the participants. **Box 42.1** Factors that can facilitate or detract from the effectiveness of the debriefing portion of a simulation session

Thing to do	Things to avoid
Set expectations for crew participation	Don't lecture
Engage the team to facilitate achieving those expectations	Don't provide your own analysis before it is "discovered" by team's analysis
Cover all critical topics	Don't give impression that your observations are the most important
Balance the discussion: draw in quiet participants	Limit interruptions of team discussion
Cover teaching points to be made – integrate into discussion at appropriate times	Don't create the sense of an interrogation
Discuss positive actions and how they affected outcome	Avoid a rigid agenda
Consider using visual cues to track major discussion points	Don't cut sessions short when outcomes are positive

Facilitating a debriefing well takes time and practice. Box 42.1 includes actions that help create a positive learning session and several that can hinder the ability of the group to develop their own conclusions.

Debriefing sessions are most effective when the team members are able to guide their own discussion based on observations of their own, using the facilitator to initiate the discussion by setting the objectives and assist in leading the discussion minimally. Teams that have not previously participated in this type of analysis or group discussion will require much more guidance from the facilitator.

Starting the debriefing session with an introduction that outlines the expectations for the session and the ways in which the team members will participate allows creation of the proper framework for the learning session. Setting a format will then help the team develop an agenda for the session. The facilitator should be sure that all critical items are included in the agenda. Using the basic principles of ACRM to frame the analysis and evaluation can help deflect difficult feelings related to any perceptions of individual inadequate performance among participants. Finally, the lessons learned from the session should be explicitly reviewed and generalized if possible.

Some techniques that encourage active team member participation and in-depth analysis of events include the following.

- Ask questions: what, why, and how?
- Engage all team members in the discussion.
- Reword questions instead of answering allow the team to answer the questions.
- Allow pauses and silence to encourage thoughtful analysis and time for answers.

In summary, debriefing creates the opportunity for members of a team involved in a crisis situation to reflect on their performance, review the elements that were active during the crisis, analyze how these factors affected the outcome, and develop some lessons to be carried away and used in future situations. In addition, basic concepts useful in approaching any crisis can be emphasized during the debriefing, allowing a review of important skills that can then enhance participants' performance in a wider set of circumstances.

#### **Creating scenarios**

The first step in creating a scenario is defining the participants who will be taking part in the scenario and the learning goals to be set. The resources available to run the simulation must also be considered, from location of the simulation to equipment, staffing, and facilitators. The particular clinical situation can then be set. A simple storyline for the scenario, identifying roles to be played by both participants and facilitators/confederates, an outline of the basic clinical situation, the crisis to be dealt with, and the key patient characteristics that will orient the participants to the situation at hand are all key elements to include. It is helpful to try and anticipate the types of reactions from the participants and map out the likely patient responses, vital signs changes, and other changes to those actions. A map is thus created that helps the technician running the mannequin and attached monitor to set the proper circumstances as the scenario plays out (Table 42.4).

Development of the scenario relies on experts, in the clinical situation being portrayed, to ensure realistic patient responses and a reasonable premise. In addition, running of the scenario must include confederate facilitators who are expert as well, allowing the team to modify scenario responses realistically based on the actions of the participants. Thus one of the challenges in creating scenarios that are generally applicable to a wide range of practitioners, particularly for evaluative purposes, is the ability to translate the expertise of one group to the expectations in another. Consensus must be developed around scenarios and performance goals.

## Creating the environment: where simulations are run

Medical simulation training has traditionally occurred in simulation centers, which were designed to recreate spe-

**Figure 42.8** Three-dimensional rendering of the simulation center at Stanford Hospital and Clinics.

cific patient environments such as operating rooms. They were often built with viewing rooms and debriefing conference rooms, allowing post-event review of the video and breakdown of the trainees' performance [11]. Many large academic centers now include a separate simulation center for education, incorporating multidisciplinary approaches and allowing for training of medical personnel at all levels of practice. From Stanford University, where simulation use in anesthesia training was first developed, to Duke University in North Carolina and the University of Florida in Jacksonville, these centers are now an integral part of the fabric of medical education [87-89]. Use of some of these centers is not limited to physician education but includes nursing education as well, partially in response to increased limits of access to patients for their training. Private free-standing centers are also beginning to be seen, a response to the growing demand by hospitals and physicians for reproducible and reliable training and testing (Fig. 42.8).

Taking simulations to the various areas in which actual patient care is provided is called in situ simulation and allows a unique ability not only to test the areas for process and equipment deficiencies, but also to see how the teams work in their usual environment. This helps create a highly realistic milieu for training and eliminates many confounders that otherwise inhibit the normal responses of participants. However, the ability to recreate the positive features available in full-blown simulation centers, including audio-video capture and playback of scenarios, could be a technical challenge. By using a mobile audiovisual cart, simulation can be used in any work environment without giving up video-facilitated debriefing that is used in analyzing center-based simulation scenarios. After experimenting with several prototypes, a system was developed and first demonstrated at

Patient state: trigger	Physiologic parameter: di-dir glenn	Physiologic parameter: down's with repaired av canal, phn	Time	Step required	Team actions	Ideal steps and notes
Anesthetized: immediately after induction	HR 120 BP 80/45 RR 26 SpO2 86	HR 120 BP 80/45 RR 26 SpO2 98	t = 0	chaotic because primary anesthesiologist in extremis	circulating nurse escorts anesthesiologist from room	-
Drapes going up: prepped	HR 120 BP 82/48 RR 26 SpO2 85	HR 120 BP 80/45 RR SpO2 99	t = 2	review of work space, materials etc.	scrub arid surgeon place drapes, patient prepped just as scenario started	Patient ventilated on FiO2 30%
Antibiotic given	HR 122 BP 80/45 RR 26 SpO2 85	HR 122 BP 80/45 RR 26 SpO2 98	t = 3	Already drawn up and labeled on anesthesia machine	surgeon asks if antibiotic given; team proceeds with time out only if anesthesiologist asks for this step	-
Surgeon makes incision	HR 158 BP 100/56 RR SpO2 85	HR 158 BP 100/56 RR SpO2 99	t = 4	patient coughs/moves, requires more anesthetic	Surgeon states, patient is moving, can you give him more anesthesia?	Vitals return to baseline if candidate responds to deepen anesthesia
Desaturation	HR 164 BP RR SpO2 75	HR 164 BP RR SpO2 85	t = 5	Note changes, run through differential, adjust vent	Team continues with surgery unless anesthesiologist states need to stop	no/minimal increase in SpO2 if candidate goes to 100% fiO2
Hypotension	HR 180 BP 50/35 RR SpO2 70	HR 180 BP 50/35 RR SpO2 80	t = 5	Treat wheezing with appropriate meds, Epi vs Albuterol?	Surgeon talks with nurse about fact that has meeting with Dean in one hour, so need to proceed quickly	-
Wheezing and PIPs increase	HR 180 BP RR SpO2 65	HR 180 BP RR SpO2 75	t = 7	Differential, adjust anesthetics, communicate with surgeon	Team continues with surgery unless anesthesiologist states need to stop	-
Hives on torso	HR BP RR SpO2	HR BP RR SpO2	t = 12	narrow differential, work on premise of anahylaxis	Surgeon states notes hives in field	-
? Dysrhythmia and/ or ischemia	HR BP RR SpO2	HR BP RR SpO2	t = 14	Support cardiac function, call code	Nurse brings in code cart, other participants respond when called	ST segment changes then pulseless VT
Management steps: meds, ventilator management, etc.	HR BP RR SpO2	HR BP RR SpO2	t = 15– 20	Management of patient state, attempt to stabilize	Team works with direction of anesthesia leader	-
End of scenario: alive but surgery cancelled and prep for ICU	HR BP RR SpO2	HR BP RR SpO2	t = 15– 20	Patient still with moderate hypotension, poor saturations, holding on but not stable enough to continue surgery	When calling ICU nurse notes antiobiotic allergy on page in chart, different information than on anesthesia preop record	-

#### Table 42.4 Template of Vital Signs Changes for Lost Airway Scenario

**Figure 42.9** *In situ* simulation cart developed at Stanford, Lucile Packard Children's Hospital. Includes mechanical elements for a Sim Baby® (Laerdal Medical) with control computer, monitor, and large screen for display of multiple video and monitor channels to the simulation technical operator during simulations and after for debriefing. Audio elements are also integrated into the unit.

the 2006 Society for Pediatric Anesthesia Annual Winter Meeting by the Stanford Pediatric Anesthesia group [90] (Fig. 42.9). Commercial mobile audiovisual systems are now also available and have been used with positive results at other centers [91].

#### Facilitation: running a scenario

Prior to starting, participants must be briefed on the basic setting for the scenario, helping them to set the proper mental framework in which to play it out. Specific roles are assigned to each participant, allowing them to take part in the scenario as part of the care team. For instance, when the goal is improving medical management of a rare medical crisis in the OR, the learners may be assigned the role of the anesthesiologist, a member of a code team, or a second anesthesiologist responder. However, if the goal is to develop an understanding of team dynamics in the operating rooms, participants may be asked to assume other roles within the team, such as the scrub-tech, which would allow them a different perspective on events as they unfold during the crisis.

Teaching facilitators will take other roles in the clinical team, such as the surgeon or circulating nurse, playing the parts as the scenario unfolds to help present the appropriate cues for the learner. The confederates feed information to the learners at appropriate times, guiding the understanding of the situation for participants or constraining their actions if needed.

A technician is required to run the computer that controls the mannequin throughout the scenario, allowing realistic "patient" responses to the actions of all participants. Communication between the confederates within the scenario and the technician controlling the mannequin is important to ensure the mannequin responses are made in an appropriate and timely manner.

An expert facilitator manages the flow of the scenario throughout, answering queries from the participants when environmental cues are unclear and giving absolute "truths" about the situation, which align with the rules set by the clinical situation being depicted.

#### **Pediatric anesthesia simulation**

### Applications of pediatric anesthesia simulation

Simulation scenarios focused on pediatric anesthesia care can be created to serve many purposes: basic training of medical students or anesthesia residents, advanced training for pediatric anesthesia fellows, and refresher training for non-pediatric attending anesthesiologist or nonanesthesia specialists who might be called to sedate or resuscitate a pediatric patient.

With the continuing trend to centralize the surgical care of pediatric patients to large pediatric centers, anesthesiologists in community hospitals are exposed to fewer and fewer pediatric patients [92–94]. This could increase the demand for simulations related to pediatric care in order to maintain a sense of confidence in caring for these patients. Common crisis scenarios that depict relatively common and potentially critical events could help in this setting.

#### Pediatric anesthesia simulation centers and activities

Centers offering simulation experiences in pediatric anesthesia have multiplied over the last decade. Academic centers across the country have developed pediatricfocused groups, allowing training of fellows and residents, OR teams, and support personnel. Fellow training in pediatric anesthesia includes simulation to varying degrees. With the gradual decline in numbers of cases of neonatal emergency surgery in the past decade, some centers are beginning to develop scenarios targeted at exposing fellows in pediatric anesthesia to these rare cases critical to the complete training of consultants in pediatric anesthesia.

## Factors in creating pediatric-specific anesthesia simulations

There are six major factors that affect the types of anesthesia simulations created for pediatrics versus adults: anatomy, psychology, physiology, procedural locations, types of surgery required, and parental involvement. The first relates simply to the size of the patients: children come in a large variety of sizes as a normal function of growth and development. This requires a whole different range of equipment, including mannequins specialized for the appearance of infants and small children. The second factor is that children present psychological challenges in IV access, co-operation, and the desire to avoid trauma. Therefore, they are frequently anesthetized using an inhalational mask induction, without IV access in place. The third factor relates to the propensity for children to exhibit rapid reactions and decompensation based on their physiology, such as rapid hypoxia following laryngospasm because of low functional residual capacity and high metabolic rate. These reactions present challenges in management, unique to pediatrics. The fourth factor is the relatively wide variety of locations in which anesthetics are administered to children routinely, because of their inability to co-operate with procedures or remain still, such as for diagnostic imaging. The limited equipment and support systems available in these diverse locations create opportunities for interesting scenarios. The fifth factor pertains to the types of surgery required by infants, which are often rare but require a high skill and focused knowledge set to manage well. Finally, the sixth factor acknowledges the parents' relation to and role in their children's lives: they have legal authority for their children and extremely strong emotional bonds. This relationship creates some unique situations ideal for simulation learning. See Box 42.2 for examples of scenarios created at Cincinnati Children's Medical Center.

The early patient simulation mannequins were developed with the adult model in mind. This not only targeted the vast majority of medical care delivered, but the larger mannequin provided more space for the mechanical and electrical components needed to create the various desired physical effects. With advances in computer technology and the miniaturization of components, smaller high-tech mannequins have become possible. Several companies now offer pediatric, newborn, and even premie- sized mannequins with a wide range of realistic

Box 42.2 Topics for some of the scenarios run at the Cincinnati Children's Medical Center, Cincinnati, Ohio (courtesy of Paul Samuels MD)

- Smoke inhalation
- Hemorrhage shock
- Supraventricular tachycardia
- Near drowning
- Head injury requiring RSI
- Status asthmaticus
- Seizures
- Opiate ingestion
- Meningococcal disease
- Anaphylaxis
- Spontaneous pneumothorax
- TCA overdose
- Cardiogenic shock
- Fentanyl reaction
- Ketamine reaction
- FBOA arrest
- Head injury requiring RSI complication
- Malignant hyperthermia (PACU specific)
- · Laryngospasm-induced pulmonary edema
- Pulseless electrical activity (no CPR initially)
- Child burn victim
- Child diabetic ketoacidosis

- Infant heat illness
- Pneumothorax (ECMO)
- Hypovolemia basic (ECMO)
- Infant supraventricular tachycardia
- Airway trach crisis
- Child gunshot wound
- Infant near drowning
- Pediatric blunt trauma
- Infant blunt trauma
- Infant multiple trauma
- Respiratory failure
- VFIB arrest
- Arterial venous malformation
- Calcium channel blocker overdose
- Septic shock
- Hypertensive encephalopathy
- Ventricular tachycardia arrest

CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation; FBOA, foreign body obstructing the airway; PACU, postanesthesia care unit; RSI, rapid sequence intubation; TCA, tricyclic antidepressant; VFIB, ventricular fibrillation. dynamic physical effects and interactive capabilities. For instance, the newborn simulator by Gaumard® (Gaumard Scientific, Miami, FL) not only delivers heart tones, breath sounds, peripheral pulses, and patient phonation, but will exhibit chest wall motion with either spontaneous or positive pressure ventilation, increased peak inspiratory pressures with various pathological conditions being simulated, and random rapid motion of the extremities to simulate a seizure. Advances in wireless signaling allow this mannequin to be picked up and moved without any tethers, allowing for an increased degree of realism and flexibility in creating scenarios, during which an infant might normally be moved from one location to another in a caregiver's arms.

Scenarios based on infants can only be realistically created using these appropriately sized mannequins. Everything in the environment is then appropriately sized as well, allowing the participant learner to more easily "suspend disbelief" and react to the crisis. Indeed, sizing of equipment and materials such as laryngoscopes and endotracheal tubes is one of the key elements in effectively working in any pediatric milieu. For applications in either learning or checking for proficiency, it was essential to overcome this size barrier before pediatric scenarios were possible.

Anatomy, psychology, and physiology affect another fundamental aspect of pediatric anesthesia, which is the induction technique. Pediatric patients have small veins, often masked by copious subcutaneous adipose tissue, making IV access difficult. They do not have the ability to understand the circumstances bringing them to our care, nor to co-operate and follow direction. These characteristics create a situation in which the child can become agitated and combative when attempting an IV start while awake. In addition, their physiology, including a high metabolic rate, heart rate, and respiratory rate, ensures rapid uptake of inhaled anesthetic agents, allowing for rapid induction using a mask technique. For these reasons, inhalation induction is commonly the method of choice when anesthetizing small children. Because there is no IV access for drug delivery yet available, this also creates some unique circumstances in which life-threatening reactions that are difficult to treat can occur during induction. Pediatric scenarios dealing with laryngospasm, bronchospasm, desaturation, bradycardia and hypotension during induction are both realistic and rich in teasing out both technical and non-technical skills for debriefing and learning. A practiced pediatric anesthesiologist becomes facile at the critical steps involved in these types of situations, and working through these reactions and steps in simulation scenarios with anesthesiologists who do not care for children every day or trainees is extremely useful.

The basic physiology in children is fundamentally different from that of adults in many ways, as noted above. In neonates, particularly if born prematurely, the airway reflexes are immaturely innervated, creating the propensity for apnea, laryngospasm, and bronchospasm, at times with no clear stimulation. Desaturation occurs very rapidly due to the limited functional residual capacity and rapid metabolic rate. Bradycardia is a common sequela of desaturation and, as opposed to adults, is commonly accompanied by significant hypotension due to the fixed ejection fraction of the still developing heart. These combined circumstances allow for a varied set of crises to deal with in simulated scenarios, often simply manipulating the patient's vital signs to create very realistic sequences. Also, the crisis can be attributed to minor triggers in healthy patients without major pathology, enabling a quick, rich scenario with full recovery of the patient and a sense of positive engagement and reinforcement for the learners.

When designing pediatric anesthetic scenarios, the full range of hospital locations can be utilized. Unlike the adult population, children often require anesthesia for painless imaging studies or minimally invasive procedures. As a result, it is common to anesthetize pediatric patients in various venues, such as MRI suites, radiation therapy rooms, endoscopic suites, and dental offices. Scenarios based on some of these remote locations can take advantage of the variable constellation of equipment available, unfamiliar personnel on hand, and unique environmental concerns. For example, one common scenario involves anesthetizing patients in the MRI suite, which requires special precautions around the magnetic field. Resuscitation cannot occur within the magnet, so the simulated patient must be removed to an adjacent locale for treatment.

In these remote locations, the availability of back-up support or help in the event of a crisis is likely to be markedly different as well. A focus on the system requirements in these locations during debriefing of these scenarios can open the participants' minds to the safeguards that have been put in place in their usual work environment and what might in fact be missing.

Pediatrics includes many types of surgery and procedures that are not seen in adults. Some of these operations are becoming rarer so it can be more difficult to acquire the skills needed to successfully navigate the appropriate anesthetic and to develop an understanding of the physiological aberrations that are commonly seen. Emergency operations in neonates, such as tracheo-esophageal fistula (TEF) repair, congenital diaphragmatic hernia repair, omphalocele and gastroschisis repair, are becoming less and less frequent. This, coupled with the increasing use of thoracoscopic and laparoscopic surgical approaches, which adds challenges for the anesthetic management, creates an ideal circumstance for the use of simulation training. For example, physiological aberrations, such as end-tidal  $CO_2$  levels greater than 100 mmHg during thoracoscopic repair of TEF in a neonate, must often be tolerated. Simulation scenarios created to mimic normal circumstances in these rare operations can be used both for fellow trainees and for maintenance of skill in senior faculty.

Using high-fidelity simulation for this type of scenario can be extremely useful to practice the interdisciplinary communication and co-ordination that are key to successful management during these cases, whether sharing the airway with the otolaryngologist during a direct laryngoscopy and bronchoscopy or intermittently ventilating both lungs during a TEF repair, forcing a pause in the surgery for stabilization of the patient.

Finally, as children are minors and unable to consent to their medical care without an adult, working with the parents or guardians is a normal part of every pediatric anesthetic plan. Parents must be counseled for consent to proceed, co-opted to assist with the preparation of the patient, and at times assist the anesthesiologist with the patient through induction. Their own anxieties in facing the procedure or surgery for their child are often extreme.

Scenarios that incorporate a parental presence not only add a great deal of realism to pediatric simulations but can be used to create the crisis or circumstance that is the learning objective. Whether practicing effective communication before, during or after an event or successfully disengaging a parent as a crisis begins to unfold, much realism can be gained by adding this element. Scenarios are often derived from the real-world experiences of faculty members. One such case involved a parent-present induction in which the parent became panicked as the child went into laryngospasm on induction and fled with the baby from the operating room. In our adapted scenario, the patient developed a dysrhythmia and hypotension, forcing our participant-learner to effectively communicate with the parent, engage the team members for assistance in managing the crisis, and direct a team member to assist the parent out of the room, all while beginning effective management of the patient.

#### Pediatric-specific simulation equipment

An essential element of high-fidelity patient simulation is the creation of a realistic environment with appropriate equipment and props. Pediatric anesthesia simulations had to await the production of mannequins sized to approximate pediatric age ranges. Challenges in developing components small enough to fit into an infant mannequin delayed introduction of an infant mannequin for many years. In 1999, METI (Medical Education Technologies Inc., Sarasota, FL) was the first to introduce a pediatric mannequin known as the PediaSIM, approxi-

Figure 42.10 Gaumard wireless simulator created to mimic a premature infant.

Figure 42.11 METI® infant simulator, created to mimic an infant 1–2 years of age.

Case title ( <u>not</u> to be read to participants)	Management of anaphylaxis in patient with congenital cardiac disease for hernia repair: inaccurate paperwork causes confusion about allergies, and wrong med given Note: scenario is preliminary for follow up scenario in which the "hot seat" anesthesiologist must disclose the events to the patient's mother			
Patient information	Name: Baby Sim Packard	Age: 13m	Gender: Male	
MRN (will be changed)	Weight: 14Kg	Height: 90cm	Race: Caucasian	
Case presentation (to be read to participants)	13 month-old-boy, scheduled for hernia repair one week after difficult reduction of incarcerated hernia			
Past medical/surgical/family history	Original surgery planned for day of hernia reduction but patient with Down Syndrome, h/o AV Canal repair with small PFO, mild PHN, therefore surgery delayed for cardiac consult, now one week later, consult states patient is stable with no active cardiac symptoms and OK for surgery, "avoid hypotension and hypoxia"; URI and OM 2 weeks prior, no other medical history, family history negative for problems with anesthetics			
Diagnostic tools	ASA monitors			
Narrative case description (describe how the case unfolds, including major patient trends and conse- quences of interventions)	Patient in the OR and anesthesia already induced when "hot seat" participant comes in to take over care – original anesthesiologist acutely severely ill (chest pain, presyncopal); patient is stable at the time of handoff, immediately after intubation; surgeon is impatient to begin, draping completed and surgeon asks for antibiotics, which are already drawn up (Cefazolin), antibiotics given by hot-seat participant, surgeon states that patient moves with incision and anesthetic deepened, shortly thereafter desaturation and hypotension occur. Congenital cardiac disease, causes confusion about immediate diagnosis in OR, "red herring"/complicating factor. Wheezing, increased PIP's, and hives appear within next few minutes. Anaphylaxis treatment ensues, with patient not responding completely, requiring pressors/remain intubated, transfer to ICU for observation and treatment; the primary circulating nurse is not in the room at "time-out" to relay new allergy information to team, she presents this information when clear that allergic reaction is occurring and asks what antibiotic was given, this information does not correlate with information on anesthesia preop assessment form. Surgery cancelled with incision already made, transfer to ICU. Surgeon states will go speak with mother while team takes patient to ICU.			
Clinical diagnosis and "correct"	1. Recognize signs and symptoms of anaphylaxis			
treatment	2. Understand likely manifestations of congenital heart condition

**Figure 42.12** An example of a template used to capture and organize the critical elements in a scenario, from a short description of the basic clinical situation being depicted, to the staffing and equipment needs and the learning goals and objectives. Adapted from the Duke University Simulation Scenario Development Template available at http://simcenter.duke.edu/support.html and the Scenario-Preparation and Script by P. Dieckmann and M. Rall, TuPASS Germany, published in the IMSH 2008 Instructor Training Course manual [88].

mately the size of a 5–7-year-old child. In 2005, both Laerdal (Laerdal Medical, Stavanger, Norway) and METI brought infant mannequins to the market [92]. Their many features and the availability of connected vital sign monitors allowed for creation of complex and realistic scenarios. Now other companies, such as Gaumard, have also created infant and neonatal models (Figs 42.10, 42.11). Again, refer to Table 42.3 for a list of high-fidelity simulator mannequins, age ranges simulated, and features available.

#### Creating pediatric anesthesia scenarios

Various templates have been used to organize the diverse elements required to create and re-create a given scenario for high-fidelity patient simulation. All templates include the basic premise for the scenario to be acted out with a description of the patient's condition, the procedure or circumstance in which the patient is found, and the sequence of events that is planned to occur. This plan is created to specifically test the skills and teamwork of the participants, targeting particular learning goals. The roles for facilitators and participants must be carefully delineated. The supporting equipment required, either to create a realistic environment or for use in responding appropriately to the scenario, must be listed. Expected reactions to the script and the typical physiological responses are planned as well, so that any actions taken by participants will give realistic consequences. Figure 42.12 depicts a typical short template for a scenario, listing all critical elements required. The longer format adds detail to each element or includes references to support reactions depicted in various steps of the scenario. A "map" for the technician, to help guide them through the expected physiological reactions to different steps in the scenario, can also be included (see Fig. 42.8). Learning objectives are spelled out to ensure their inclusion during the debriefing section of the simulation.

#### Conclusion

Medical simulation has become a standard in education in medical schools and resident training, used for research, systems evaluations, and human performance evaluation. With the development of pediatric sized equipment, the use of simulation has been introduced to the area of pediatric anesthesia, with multiple and varied applications. It seems clear that these tools will continue to be developed and expand within medicine to improve education and ultimately patient care.

#### Introduction

Databases are playing an increasingly important role in research about care of patients, and this chapter will provide a background to what databases are and how they are used. We will then review some important anesthesia-related databases, and finally we will examine the growing importance of outcomes research and look at the approaches used in outcomes research. An important role for databases is in the evaluation of care and the quality and cost of care, and we will begin with an examination of this topic.

#### Introduction to medical databases

In the past the assessment of the quality of care provided by institutions and by individual physicians was based on word of mouth information, on subjective appraisals of physician–patient interactions and on the reputation of institutions and physicians. This method of evaluation is in the process of change, and society is moving toward attempts at objective measures of the quality of health systems and of physicians. As a result, physicians and healthcare systems are being challenged to provide objective measures of quality and safety. We are just in the infancy of using data to measure the quality of results produced by the healthcare system and also the performance of physician groups and individual physicians. Given that it is difficult for physicians to define quality in healthcare, the task of developing objective measures of a largely subjective concept is proving challenging.

There are several reasons for the drive toward objective measures of quality and performance. Beside the desire to select healthcare professionals based on the quality of the care that they provide, the ability to control costs, the elimination of unnecessary care and perhaps other motivations are involved. We are a long way from measurement systems that are equivalent to those available for the purchase of consumer goods such as automobiles, but

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

the process is well under way. In this climate it is important that physicians are involved in the design of measurement tools so that the measurements will be meaningful and not based on inaccurate or biased data.

In evaluating the quality of care, one can use process measures or outcome measures. Process measures are activities that are carried out during the care of a patient. They might include whether we use a mask or intravenous induction, whether antibiotics are given, whether a surgical safety checklist is followed, or other similar items. Outcome measures, on the other hand, look at what happens to the patient; in the above examples, was the induction smooth and non-traumatic for the child or did the patient experience a surgical site infection? Because the outcomes of patients that anesthesiologists care for in the operating room depend to a great extent on both surgical care and anesthesia care, it is difficult to develop good outcome measures for anesthesia alone. The result is that process measures are often used as a measure of the quality of anesthesia care.

As an example of what is happening and of the difficulties involved, the 2006 Tax Relief and Health Care Act established a physician quality reporting initiative (PQRI) for physicians caring for patients in the Medicare program [1]. Since it is difficult to find objective measures that relate specifically to outcomes of anesthesia care, the measures developed so far are process measures and are inadequate measures of the quality of anesthesia. The current measures are timely administration of antibiotics, maintenance of patient temperature, and use of standard protocols during insertion of central venous catheters, all of which are important but do not by themselves define the quality of anesthesia care.

Since the number of measures for anesthesiology is so small and limited, it is likely that other more sophisticated tools will be used to measure the influence of anesthesia on patient outcomes. This process of evaluation will likely involve the use of data in databases and sophisticated statistical techniques to measure the influence of anesthesia on patient outcomes. In order to ensure that the measurements are meaningful and appropriately measure the quality of care, it is important to know from where the data that will be used in the measurements came and how the data are manipulated. Since most data used for these purposes are stored in databases, a basic understanding of databases is important for practicing physicians.

#### Database terminology

A number of terms are used in relation to management and storage of data. A *database* is defined as a large collection of data organized especially for rapid search and retrieval. Data in a database are obtained not by planned scientific experiment but come from data maintained for clinical care or other purposes. Medical databases are a logically coherent collection (which is often computerized) of observations and related information about a group of patients. Databases are designed to manage and archive large amounts of information that can be accessed or retrieved, and they help with collecting information in a standard format, which decreases redundancy of the data and reduces repeated data entry. Databases also improve data security and provide a means for retrieval of the data using query languages. The term data warehouse is often used. A data warehouse is a collection of a large amount of data. Data get into a data warehouse from one or more sources after the data are cleaned (cross-checked and corrected), transformed and catalogued.

Database management systems are a collection of software programs that allow users to define, construct and manipulate databases for various applications. Data can be extracted from data warehouses using so-called data mining techniques or other analytical processing techniques using database management systems. The structure of the stored data is maintained in a *data dictionary*, which provides information about data such as meaning, relationships to other data, origin, usage, and format. The data dictionary typically includes the names and description of various tables and fields in each database, plus additional details, such as the type and length of each data element.

#### **Classification of databases**

There are several ways in which databases can be classified. One way is classification based on the function they perform.

- *Analytical* databases are primarily used to keep track of statistics. They are used in online analytical processing, which provides improved speed compared to a relational database. Analytical databases differ from relational databases in their ability to look within the database at specific elements in which the end-user is interested.
- *Operational* databases are databases that let the user modify the data. These databases can store and update data such as employee personal information, employee training status, and previous work history and this information is updatable and retrievable across the company. An example of an operational database is a database used by a store to take orders, track completion of the order, and keep track of the inventory. Thus the user would change the database when an order is sent to a customer

Another way of classifying databases is by their data model. A data model describes how the data are stored in and retrieved from a database.

- *Flat-file database model*. In this system the data are stored in numerous files that are not linked. This type of database can perform basic record keeping of a limited number of data elements; for example, an Excel spreadsheet is a flat-file database model.
- *Hierarchical database model*. This system consists of a series of databases that are grouped together to resemble a family tree. The top database in the hierarchical model is called the parent database. The databases under it are called child databases. The child databases are all connected to the parent database via links creating a one-to-many ratio.
- Network database model. This model is designed to allow for links between the child databases but these kinds of databases are harder to use and maintain. A network database model is similar to the hierarchical database but the network model allows for multiple parent databases. Hierarchical and network databases have largely been replaced by relational databases which offer a higher degree of flexibility.
- *Relational database model*. In this model data are stored in any number of separate databases that are connected by a "key" field. The same key field is present in each dataset and allows for the tables to be related to each other. Use of a relational database makes it easy to extract data. Many of the commonly used databases such as Access, Oracle and MySQL are relational databases.
- *Object-oriented database model*. Object-oriented database models let databases store and manipulate text, sounds, images, and all sorts of media clips. Examples are Java and C++.
- *Client/server databases*. Client/server databases are the databases that are used for the Internet and for the World Wide Web

#### Administrative data versus clinical data

In the medical field, administrative data are usually collected from billing information that hospitals submit to payers, whereas clinical data are extracted from information used to care for a patient [2,3]. Administrative data have major problems when used for purposes for which they were not intended. They may lack clinically important information, such as significant pre-existing illnesses and other problems that might make one patient a higher risk than another. The primary and secondary diagnosis codes are based on the interpretation of the person entering the codes for billing purposes, and billers may not interpret medical issues correctly. Since higher severity of illness often results in higher payments, there could be a bias toward including insignificant or trivial diagnoses, but since there are penalties for "upcoding" there may be a bias to downcode some of the data elements in an administrative database. In addition, administrative data may not distinguish between conditions that were present on admission and those that occurred during the hospitalization.

Some other concerns that have been raised include such issues as data collection and sampling procedures, missing data, and erroneous data. In addition, more technical issues related to data distribution, data independence, data quality management, data integration, data access and data privacy may also be involved [4]. Analytical problems when using large administrative datasets include issues related to multiple testing on a particular dataset which increases the likelihood of observing a statistically significant result due to chance, making comparisons using datasets from different sources with data that may be represented differently. Finally, there is the problem of differentiating the statistically significant from the scientifically significant.

The accuracy and validity of the data used to calculate a measure's value are primarily determined by the match between the purpose for which the data were entered and the meaning ascribed to that data element when generating a report [5,6]. Using administrative data from billing systems to deduce clinical context can produce misleading results [6]. As an example of the problems associated with the use of administrative data, consider the measurement of the data element "complications of anesthesia." If a surgeon is doing a case with local anesthesia and administers an overdose of local anesthetic, that error would be labeled as a "complication of anesthesia" and could be attributed to the anesthesia department, when in fact no anesthesia provider was involved in the case.

Another problem with administrative data is the issue of risk adjustment [7]. If one group of patients is healthier than another before comparable operations, we would expect the healthier patients to have better outcomes. The differences in expected outcome because of differing prior health can be minimized by risk adjustment; that is, by using scoring systems to adjust expected outcome for the risk of the patient. For example, the risk of complications during an anesthetic for hernia repair is presumably greater in a 1500 g premature infant compared to a healthy 8-year-old child. If the quality of care were to be compared in this case, risk adjustment would use statistical techniques to take into account the difference in risk and expected outcomes of the two patients. The validity of risk adjustment systems that use only administrative data has been challenged and there is a need for additional data to increase the accuracy of predicting a patient's risk. The previously mentioned problems with coding of coexisting illness and other factors tends to make risk adjustment with administrative data difficult, but in some cases risk adjustment may appear to produce the expected results. The advantage of administrative data is the fact that they are readily available in electronic form, whereas clinical data may be scattered in many places, collected in different ways and may even use different definitions for the same concept. When good clinical data are available, though, it would seem preferable to use them. There are some robust clinical databases available such as those which collect data from cardiac surgery patients.

The value of good clinical data compared to administrative data has been shown by Welke et al [8] who compared mortality rates using administrative data with those of the Congenital Heart Surgeons Society and the Society for Thoracic Surgeons databases. They found that mortality rates based on data from administrative sources were higher than from those based on good clinical data. But sometimes administrative data may produce the expected result. Aylin et al [9] were concerned that administrative datasets might not have sufficient information for appropriate risk adjustment. They compared risk adjustment for mortality in coronary artery bypass grafting, repair of aortic aneurysm and colorectal procedures using administrative data and compared the results to those obtained when using clinical data and found that risk adjustment was equivalent. Since there is no validated comparison, though, their findings could mean that neither system did a good job with risk adjustment.

#### Limitations of databases

Database systems are complex, difficult, and timeconsuming to design and involve substantial hardware and software start-up costs. They also involve initial training for users and continued manpower to maintain the database and facilitate data entry, check data accuracy and provide means for data extraction. There may be problems or limitations with the quality of the data that go into the database and the research based on databases is only as good as the data in the database. In addition, to some extent the interpretation of the results of database research depends on the assumptions used in generating the information. In evaluating research based on databases, it is important to understand how the data were obtained, how they were extracted, and how they were interpreted.

#### Privacy laws and data sharing

Research using databases depends on using scientific data over a period of time to support scientific observations. The use of these data has to comply with a host of regulatory directives at different levels (federal, state, local) [10]. The Privacy Rule in the US Health Insurance Portability and Accountability Act of 1996 (HIPAA) both created new procedural requirements for the use of protected health information (PHI) and defined PHI more broadly. The HIPAA rule requires that certain personal identifiers be stripped from a dataset prior to sharing. These include explicit identifiers (e.g. names), quasiidentifiers (e.g. dates and geocodes), and traceable elements (e.g. medical record numbers). An alternative to the use of data with these identifiers is to use a limited dataset, which allows sharing of some detailed data but requires the data recipient to enter into a contract that prohibits them from reidentification of a patient [11].

#### **Uses of databases**

In addition to attempts to measure quality of care, databases have been used in a number of ways. As we will discuss in more detail below, databases have been used for quality improvement, as in the National Surgical Quality Improvement Program. The have also been used in research on diseases and treatments, one notable example being cystic fibrosis. Other uses have been evaluation of risks of various treatments and techniques, especially with the anesthesia Closed Claims Project and the Pediatric Perioperative Cardiac Arrest Registry (POCA). Finally outcomes research, which we will discuss below, is another use of databases. The next section will review several initiatives involving databases in order to provide examples of how databases have been used.

#### Anesthesia databases

Two databases, the Closed Claims Project and the Pediatric Perioperative Cardiac Arrest Registry, have contributed to the safety of anesthesia, and it is important to discuss these before covering current and future anesthesia databases.

#### American Society of Anesthesiologists Closed Claims Project

The Closed Claims Project was an effort begun by Richard J. Ward MD and Ellison Pierce Jr MD, working with the American Society of Anesthesiologists Committee on Professional Liability. Under the direction of Frederick W. Cheney MD, the initiative was begun in 1984. In this initiative the researchers received clinical information from insurance companies on anesthesia malpractice claims that had been settled or adjudicated. Expert anesthesiologists reviewed the claims to analyze the cases and to look for errors in care, and the results of their reviews were entered into a database. It was then possible to use the database to analyze relatively rare but serious events [12,13]. The results of these analyses were published in a series of papers.

One of the first reports was by Caplan et al in 1988 [14]. From a review of the closed claims data, they found 14 cases of unexpected cardiac arrest during spinal anesthesia in ASA 1 or 2 patients undergoing relatively minor surgical procedures. These arrests appeared to occur in spite of what was judged to be adequate anesthesia care, and did not appear to be related to inappropriate care. In approximately half of the cases the reviewers found that the arrest was associated with sedation sufficiently deep to result in verbal unresponsiveness, and they felt that unrecognized respiratory insufficiency might have been the cause of the arrest. In the other half of the patients, it was assumed that an unexpectedly high sympathetic block was involved, and that the vasodilation might have interfered with resuscitation. The authors pointed out that recognition of this condition was important and they recommended that epinephrine be administered in cases of sudden bradycardia or cardiac arrest in this setting.

In 1990 the group reported on adverse outcomes related to respiratory events [15]. At the time of the review there were 1541 claims in the database, and of these 522 or 34% were classified as being respiratory in origin. The most common causes of respiratory problems were inadequate ventilation, esophageal intubation, and difficult tracheal intubation. Reviewers concluded that better monitoring could have prevented 72% of the events. Most of these events occurred before the widespread use of pulse oximetry and capnography and the results presented in this paper were important in demonstrating even to the most skeptical the value of routine pulse oximetry and capnography. One other important observation was the apparent presence of breath sounds in a significant number of cases of esophageal intubation.

Further reports followed, examining less common respiratory events (airway trauma, pneumothorax, airway obstruction, aspiration and bronchospasm) [16]. In the cases of airway trauma, 58% were not associated with difficult intubation. Some of the injuries noted were injury to pharynx or esophagus leading to mediastinitis. There were a number of injuries to the larynx in patients in whom intubation was thought to be routine. Pneumothorax was associated with blocks (mostly supraclavicular or intercostal) in 40% of cases, and also with airway management or barotrauma.

Another report from Caplan [17] focused on adverse outcomes related to malfunction or misuse of gas delivery equipment. This group comprised only 2% of events included in the closed claims database, and the majority were due to misuse of the equipment, not failure. Approximately 10% of the events were due to switches of oxygen lines. Most of the events were judged to be preventable with better monitoring, such as high airway pressure alarms.

Morray et al [18] compared pediatric closed claims with adult claims. Respiratory events, particularly those associated with inadequate ventilation, were more common in the pediatric cases than in adult cases, and mortality rate was higher. They found more claims in the group of patients under 6 months of age than in any of the other age groups. More of those claims were thought to be preventable than in adult claims. Jimenez [19] provided an update on pediatric closed claims, looking at trends over time. She found that although there was a decrease in proportion of claims due to death or events with respiratory causes, nevertheless cardiovascular and respiratory causes were still major contributors to claims in the later period. There was an increase in the proportion of claims in younger children, and inadequate ventilation decreased from 26% of claims to 3% of claims, presumably as a result of the introduction of pulse oximetry and capnography. Cardiovascular events increased to 26% of claims in this later report, and the most common of these events involved blood loss and fluid resuscitation.

While closed claims analysis led to a significant number of findings and reports which initiated changes in anesthetic practice, there are limitations to this sort of research. These limitations include the lack of a denominator which prevents any determination of incidence of these adverse events. Another limitation was that the reviewers knew the outcomes and this fact led to bias in assessment of responsibility [20]. A further problem was that the only cases available to reviewers were those that came to litigation, and these represented only a limited sample of adverse events. Finally data collection was retrospective and some important data may have been missing or subject to misinterpretation.

#### Pediatric Perioperative Cardiac Arrest Registry

The Pediatric Perioperative Cardiac Arrest Registry (POCA) is a pediatric database that followed the Closed Claims Project. POCA was formed in 1994 in an attempt to determine the clinical factors and outcomes associated with cardiac arrest in anesthetized children [21]. Some institutions that provide anesthesia for children voluntarily enrolled in the POCA registry, and the investigators created a database of information about cardiac arrests that occurred in children. To create the database, a representative from each participating institution anonymously submitted a standardized data form for each cardiac arrest. Cardiac arrest for this registry was defined as the need for chest compressions or as death in anesthetized children 18 years or younger. The investigators used the database to try to determine the causes of the cardiac arrests, and published a series of reports. In the first 4 years of the POCA registry, 63 institutions enrolled and submitted 289 cases of cardiac arrest.

The Pediatric Perioperative Cardiac Arrest Registry provides an interesting example of changes in causes of cardiac arrest in children over time, presumably related to changes in anesthestic practice. The initial report in 2000 by Morray et al [21] divided the arrests into groups:
medication related, cardiovasular causes, respiratory events, and equipment related. Of the medication-related arrests, halothane-induced cardiovascular depression was the most common cause of arrest and significantly, a large number of these arrests occurred in patients who were ASA 1 or 2 status. The incidence of cardiac arrest was found to be  $1.4 \pm 0.45$  per 10,000 anesthetics, calculated using the reported cardiac arrests as numerator and total number of anesthestics at participating institutions as denominator. A later report by Bhananker et al [22] showed a decrease in arrests due to halothane, presumably due to the replacement of halothane by sevoflurane as the most common induction agent. In the report by Bhananker, cardiovascular causes became more common, particularly hypovolemia from blood loss and hyperkalemia associated with transfusion of blood.

A final report detailed the higher risk surrounding cardiac arrest in children with heart disease. Ramamoorthy et al [23] compared findings associated with cardiac arrest in patients with heart disease with those who did not have heart disease. Ninety-two percent of the patients with heart disease were ASA 3 or higher, and 63% of the patients were less than 2 years of age; 54% of the arrests occurred in cases in which the operative procedure was non-cardiac. In looking at causes, the reviewers felt that cardiovascular depression was a contributing factor in some cases and that myocardial ischemia was a contributing factor in some cases.

The POCA registry has made some significant observations but as with the Closed Claims Project, it has some methodological weaknesses. POCA depended on voluntary reporting and for a variety of reasons, underreporting is likely. Selection bias is also possible, in that unexpected cardiac arrests or highly sensitive cases might not get reported. Furthermore, since the participants were for the most part large academic institutions, they may not be representative of all institutions that provide anesthesia care for children. This preponderance of large institutions could result in skewed statistics that are not representative of the actual population [21].

#### Other pediatric anesthesia databases

As with any good study, many questions arose after POCA, including questions about the incidence of cardiac arrest, and several institutions used local databases to provide more information about pediatric cardiac arrests. The use of databases for research often begins with a local database maintained by individual departments, and as the reports below indicate, it is possible for departments to maintain an effective database and to extract meaningful information from it. Several institutions have maintained databases are appearing in the scientific literature. Different types of data are maintained, and different structures often make comparing information from one database to another difficult. On the other hand, an advantage of local databases is the ability to maintain more control over the data, and to enter more extensive and specific data. Several of these databases are discussed below to point out some of the attractive features of local databases and to enumerate some of their limitations. This is not meant to be an exhaustive discussion of local anesthesia-related databases.

The cardiac anesthesia service at Boston Children's Hospital has maintained a database relating to anesthesia care of cardiac patients since January 2000. Extensive data including diagnosis, demographics, procedure, anesthetic technique and details of cardiopulmonary bypass were maintained on every case. Data on cardiac arrests were reported in 2007 by Odegard et al [24] who assessed procedures with and without cardiopulmonary bypass and also whether the arrests were anesthesia related or not. The incidence of cardiac arrest in this group was 79 per 10,000; 26.8% were possibly related to anesthesia. The anesthesia-related causes include airway management, monitoring issues, medication-related issues, and myocardial ischemia.

The Mayo clinic has maintained a quality assurance database since November 1988, and in a recent report the data were used to determine the incidence of cardiac arrest in children undergoing anesthesia [25]. They analyzed a total of 92,881 anesthetics, for both cardiac and non-cardiac procedures. In the non-cardiac cases the incidence of cardiac arrest was 2.9 per 10,000 anesthetics, while for cardiac cases the rate was 127 per 10,000. Most of the arrests were due to factors not related to anesthesia.

Baum [26] used the University Hospital Consortium (UHC) database to examine the influence of congenital heart disease on mortality after non-cardiac surgery in children. UHC is a group of more than 60 university hospitals in the US that share data in a database. They found increased mortality in those patients with congenital heart disease, especially in the youngest patients, and in those patients with more severe cardiac disease.

# Current and future database research in anesthesia

The findings of the Closed Claims Project and POCA provided useful data about problems in the administration of anesthesia but they raised a number of questions that cannot be answered with the data available from these sorts of databases. For this reason and for the reasons discussed above relating to quality and outcomes measurement, a number of databases have been and are being developed that will be important in the future of anesthesia research.

The Congenital Cardiac Anesthesia Society is working with the Society for Thoracic Surgeons (STS) to include anesthesia-specific data in the STS Congenital Database. This database will be an important step forward as it will include both surgical and anesthesia information in a common database [27,28] (Table 43.1). Pediatric cardiac cases represent a specific subset of pediatric cases and a specialized database is important for understanding outcomes with this group of patients. The group is developing common definitions of events and complications, and also methods to track patients if one patient receives care from multiple institutions. As data are collected the common definitions and quality control of data should provide a valuable resource for understanding the contribution of anesthesia to outcomes in pediatric cardiac surgery patients.

#### **Pediatric Sedation Research Consortium**

Several other initiatives in pediatric anesthesia are collecting data for the purpose of conducting research. The Pediatric Sedation Research Consortium (PSRC) was created in 2003 in an effort to improve pediatric sedation process and outcomes [29]. It initially was a collaboration of 35 institutions that wanted a more comprehensive approach to the study of the safety and reliability of pediatric sedation. Only 26 institutions actually submitted data to the database before the first publication of the data in 2006. The consortium wanted the participating institutions to share their prospective observational outcome data on procedural encounters. As of October 2010, there were more than 200,000 encounters in the database [30]. There are no selection criteria for participation and, as a result, the PSRC consists of data from sedation administered by a mix of anesthesiologists, pediatric medical subspecialists, emergency physicians, pediatric intensivists, nurses, physician assistants, and healthcare research personnel. The data are collected through a self-report system. The National Patient Safety Foundation supports the development and management of the database [31]. The future analysis of the database will focus on evaluating the association of adverse outcomes with various provider types, monitoring standards, and medications used [32].

The Sedation Consortium reported on the use of propofol for sedation or anesthesia in 49,836 procedures outside the operating room (OR). There were no deaths and cardiopulmonary resuscitation (CPR) was required twice. Apnea or airway obstruction occurred in 575 per 10,000 cases. The group concluded that propofol sedation is unlikely to yield serious adverse outcomes in the settings in which it was used in the study, that is, in highly motivated institutions with established protocols and with training for the providers of sedation. These factors of motivation and training limit the degree to which the findings in this study are generalizable to other situations. Furthermore, there is no assurance that all adverse outcomes are reported. Leaders of the consortium have tried to address this issue by using blinded data submission [32].

#### **Pediatric Regional Anesthesia Network**

The Pediatric Regional Anesthesia Network (PRAN) was organized in 2006 in an effort to facilitate multiinstitutional studies of regional anesthesia in children. The goal of this group is to create an online data collection network that can facilitate the conduct of large-scale multi-institutional studies involving regional anesthesia in infants and children. The network began with six pilot sites, after which one withdrew from the project and five continued. All regional anesthetics performed at each institution by an anesthesiologist are entered into the database on a self-report system. Blocks performed by surgeons are excluded from the database. In addition to the details of the block, any intraoperative and postoperative complications are recorded as well as age, gender, and ASA physical status [33]. Completeness and accuracy of data submission are verified by the investigator at each institution through a monthly random audit of 10% of charts that are checked against the submitted data [34]. As of October 2010, there were more than 17,000 regional anesthetics in the database. Data from the PRAN are now being utilized to strengthen recommendations for regional anesthesia in children, for example the safety of epidural catheter placement under general anesthesia [35].

#### Wake Up Safe

Wake Up Safe is a quality improvement initiative sponsored by the Society for Pediatric Anesthesia (SPA) and founded in 2006. The database is a registry of serious adverse events, an analysis of why the event occurred, and in addition, demographic data on all anesthetics at participating institutions. Initially 10 institutions participated in the start-up phase, and as of December 2010, 14 institutions participate with approximately 250,000 anesthetics per year.

Almost immediately after data collection began, five cases of wrong side procedure were reported, three surgical cases and two anesthesia blocks. In the analysis it was determined that no "time out" occurred prior to the blocks. For the surgical procedures, there were protocols in place to protect against wrong side/site procedures, but the protocols were not followed. For example, one case occurred when the site was marked but the marking was not visible when the patient was prepped and draped for the procedure. Information about the wrong side procedures was transmitted to the members of the Society Table 43.1 Anesthesia fields for the Congenital Cardiac Anesthesia Society-Society of Thoracic Surgeons joint congenital heart surgery database

Patient Information	
Location of procedure	
Primary Anesthesiology attending	Name
Secondary Anesthesiology attending	Name
Fellow or Resident present	Yes/No
CRNA/SRNA present	Yes/No
Patient body surface area	Calculated
Preoperative medications	
Preoperative medications	Drop down list of common medications patient is on for 24 hours prior to OR
Preoperative sedation	Yes/No; medication used
Time of transport from ICU/Floor	Hours:Minutes (HH:MM)
Time of induction	Hours:Minutes (HH:MM)
Monitoring	
Preoperative baseline oxygen saturation	%
Arterial line	Percutaneous/Cutdown/None
Central pressure monitoring	Percutaneous/Cutdown/Transthoracic/None
Neurologic monitoring	None/BIS/NIRS/TCD/SSEP/EEG
Lowest recorded core intraoperative temperature	Degrees Celsius
Transesophageal echocardiography	Yes/No
Anesthetic technique	
Induction	Inhalation/Intravenous/Intramuscular
Primary induction agent	List of medications
Primary maintenance agent	List of medications
Regional anesthetic	Yes/No: type (caudal/epidural/spinal); single/continuous
Airway	
Airway type	None/Nasal cannula/Endotracheal tube (ETT)/Double lumen endobronchial tube (EBT)/Laryngeal mask airway (LMA)/Other
Airway size	
Cuffed	
Airway site	None/Oral/Nasal/Tracheostomy
Transfusion	No/Yes (if Yes than continue below)
Packed red blood cells (PRBC)	Volume or units
Platelets	Volume or units
Fresh frozen plasma (FFP)	Volume or units
Cryoprecipitate	Volume or units
Whole blood	Volume or units
Activated Factor VII	Yes/No

#### Table 43.1 (Continued)

Intraoperative pharmacology	
Drop down list of medications	All common intraoperative/intraprocedural medications
Pharmacology at transfer to ICU/PACU	
Drop down list of medications	All common intraoperative/intraprocedural medications
ICU/PACU care	
Time of ICU/PACU arrival	Hours:Minutes (HH:MM)
Initial FiO2	
ECMO	Yes/No
Initial pH	
Initial SpO2	%
Temperature on arrival	Degrees Celsius
Need for pacemaker	Yes/No
Morbidity/Mortality	
None	No/Yes (if Yes than continue below)
Anesthesia-related morbidity	(only events occurring during time of anesthetic care or related directly to anesthetic care)
Airway – pulmonary	Dental injury
	Respiratory arrest either pre-operatively, intra- or post-operatively requiring unanticipated airway support
	Unanticipated difficult intubation/reintubation
	Post-extubation stridor or sub-glottic stenosis requiring therapy
	Unintended extubation in Operating Room or during patient transfer
	Endotracheal tube migration requiring repositioning
	Airway/pulmonary injury related to ventilation
Vascular	Arrhythmia during central venous line placement requiring therapy
	Difficult vascular access (> one hour of attempted access)
	Hematoma requiring cancellation or additional surgical exploration
	Inadvertent arterial puncture with hematoma or hemodynamic consequence
	Myocardial perforation or injury with central venous line placement
	Vascular compromise secondary to line placement (such as blue leg or venous obstruction)
	Pneumothorax during central venous line placement
Regional anesthetic	Bleeding at site or with aspiration
	Inadvertent intrathecal puncture
	Local anesthetic toxicity
	Neurologic injury
Pharmacology	Anaphylaxis/anaphylactoid reaction
	Non-allergic drug reaction
	Inadvertent drug administration (wrong drug)
	(Continued)

#### Table 43.1 (Continued)

	Inadvertent drug dosing (right drug, wrong dose)
	Intraoperative recall
	Malignant hyperthermia
	Protamine reaction requiring pharmacologic intervention
Cardiac*	Cardiac arrest after admit to operating room and prior to incision
	Unexpected cardiac arrest not related to surgical manipulation
	*Cardiac arrest defined as the sudden abrupt loss of heart function
Transesophageal echocardiography	Esophageal bleeding or rupture during transesophageal echocardiographic probe placement or manipulation
	Esophageal chemical burn
	Airway or vascular compromise during transesophageal echocardiographic probe placement/ manipulation requiring removal of transesophageal echocardiographic probe
	Accidental extubation during transesophageal echocardiographic probe manipulation
Positioning	Patient falling out of either transport bed or Operating Room table to floor
	Neurologic injury resulting from patient positioning during anesthetic care

Reproduced from Vener et al [28] with permission from Cambridge University Press. See text for full explanation.

for Pediatric Anesthesia with recommendations for ways to avoid wrong side/site procedures [36]. Another early finding from Wake Up Safe was a warning concerning syringe swaps; that is, using one syringe mistaking it for another with a different drug, particularly with non-color coded pharmacy-produced syringes [37].

Wake Up Safe plans to increase the number of institutions participating, and to use the reports of adverse events to develop quality improvement initiatives to decrease the frequency of occurrence of serious adverse events.

#### Other anesthesia databases

Other anesthesia subspecialty societies are also starting databases to examine outcomes.

The Society for Ambulatory Anesthesia (SAMBA) was founded in 1985 in an effort to advance the field of ambulatory anesthesia. In 2009, the society announced the launching of the SAMBA Clinical Outcomes Registry or SCOR. The goal is to develop a registry that will serve to build a national database of patient outcomes in both ambulatory surgical centers and office-based surgical suites. The society hopes to use the database to establish benchmarks for accepted standards of care, for example, best practices to deal with postoperative nausea and vomiting, delayed awakening, and perioperative glucose management [38,39]. It is collecting a large number of data elements including information about the type of ambulatory center, the anesthesia provider model, demographic information on patients, co-morbidities, and type of anesthesia. It will also collect current "pay for performance" elements and operational data such as operative times. For outcomes, it will track emesis, use of pain medications, urinary retention and significant adverse events such as death, cardiac arrest and sentinel events. It will also collect information about readmission or emergency room visits, pain and patient satisfaction.

The Society for Obstetric Anesthesia and Perinatology (SOAP) started the Serious Complication Repository Project (SCORE) in 2005 to track adverse complications in obstetric anesthesiology. The society recognized that characteristics associated with rare complications can best be identified using a large population base rather than from prospective clinical studies that typically enroll few patients. Furthermore, the goal was to avoid assessing the incidence of complications at any individual institution because this may be more indicative of practice patterns unique to that institution and may occur more or less frequently than in the general population. The ultimate goals of the repository are to reliably estimate the incidences of serious complications and to improve patient safety by identifying factors associated with each complication. The data are collected by a self-report mechanism and institutional confidentiality is maintained by pooling all the data [40].

The American Society for Regional Anesthesia/Pain Medicine (ASRA) is also in the process of starting a database. It will collect basic demographic information on all patients, information about surgeon and anesthesiologist, type of anesthesia, and discharge information. With regard to regional anesthesia, it will collect information about the modalities used, the effectiveness of pain therapy and side-effects, follow-up information such as pain at home and major complications and will also ask the important question of whether the patient would want the same technique for a subsequent procedure [41].

The Malignant Hyperthermia Association of the United States (MHAUS) was founded in 1981 to educate the medical and lay communities about malignant hyperthermia (MH) and serve as a resource for families affected. In an effort to start a database, MHAUS merged with the North American MH Registry in 1995. The Registry, originally established in 1987, collected and recorded information about clinical episodes and the results of laboratory tests concerning MH in order to learn about the manifestations of the disorder [42]. As a result of these two organizations, a wealth of information has been obtained and recorded from clinical experiences. The data are obtained by self-report and the database is unique in that data are mostly collected while the crisis is occurring. When there is a case of malignant hyperthermia, a caller rings the MH hotline, where an expert will help the caller manage the situation that is occurring. All calls are logged at the time of the initial contact. There is attempted follow-up for each call, but this is difficult to obtain for every case. As a result, in most cases entered into the database, the final diagnosis is never known.

The Anesthesia Patient Safety Foundation (APSF), developed in 1985, has also been an advocate for outcomes research specifically in the field of anesthesia and has recognized the need for aggregate databases. A major initiative by this foundation started in 2001 when the APSF endorsed the use of anesthesia information management systems (AIMS) as a means of collecting data in order to easily review patient records for the purpose of research and practice analysis. It soon encountered a barrier to meeting the goal when it discovered that there is a lack of standardization for terms in different AIMS systems, and this problem inhibits the sharing of data across institutions. This was the same barrier that the National Center for Clinical Outcomes Research (NCCOR) encountered in the late 1990s when that organization embarked on the same mission of developing a data warehouse to which participants would send their perioperative records. In 2002, the APSF announced the

launch of the Data Dictionary Task Force (DDTF) to define and address the problem of consistency and communication in surgical anesthesia. The long-term goal is to develop an active data dictionary that will direct database systems to obtain outcome data and to link to computerbased anesthesia record keepers nationwide [43].

The most recent investment by the specialty of anesthesiology in making a national clinical database has been made by the American Society of Anesthesiologists (ASA). This organization announced the launch of the Anesthesia Quality Institute (AQI) in October 2008. The mission of the AQI is to develop and maintain an ongoing registry of case data that helps anesthesiologists assess and improve patient care. The eventual goal is to provide a resource for anesthesiologists to obtain patient safety and quality management data and to meet regulatory requirements designed to improve patient care. The data will be useful for activities ranging from education to outcomes measurement to emerging federal efforts to ensure performance improvement [44].

The impetus for the formation of this quality database came from several quarters. Not only was there a desire to form a national database to permit research about clinical quality, but the ASA wanted to respond to the growing need for objective measures of anesthesia performance. As the public desire for transparency grows, the drive for reporting performance data increases. The AQI has accepted the responsibility to determine that the metrics by which the public and government judge anesthesiologists are legitimate and meaningful. The belief is that individual anesthesiologists or groups of anesthesiologists will need to document their performance metrics and outcomes against benchmark data. Therefore, a strong and validated anesthesia process and outcome database will become a necessity for future practice [45].

The AQI national database is called the National Anesthesia Clinical Outcomes Registry (NACOR). The NACOR goal is to eventually capture data on all of the anesthetics and pain clinic procedures performed each year by anesthesiologists in the United States. These data will be evaluated and analyzed by the AQI, and then the information will be reported back to the providers in an effort to guide approaches to anesthesia. After the data are assimilated, the information will be disseminated to the wider anesthesia community for education purposes.

# Electronic anesthesia information system and databases

The electronic anesthesia information management system (AIMS), although utilized currently in less than

50% of anesthesia departments, is expected to gain more widespread use fairly quickly in the next several years [46] (see Chapter 44 for a complete discussion of AIMS). The collection of electronic anesthesia records, pre- and postoperative anesthesia documentation into larger databases with computerized search capabilities has made both clinical and outcomes research possible, as demonstrated by recent publications.

Kraemer et al [47] assessed the incidence of bradycardia and hypotension during sevoflurane induction in children with Down syndrome, with a case-control retrospective analysis. Using an electronic anesthesia record-keeping system (Compurecord, Phillips Healthcare, Bothell, WA), they searched for patients meeting study criteria with Down syndrome and sevoflurane induction. They selected a control group of patients without Down syndrome. They then used the database's computerized searching capabilities to assess the incidence of bradycardia, using predefined criteria, in the first 360 sec of administration of sevoflurane, in the electronic data which were stored every 15 sec. They then used the search capabilities to extract additional data, including sevoflurane end-tidal concentrations, other drugs administered, demographic data, co-existing conditions, and ASA physical status. They determined that bradycardia and hypotension were significantly more frequent with Down syndrome (57% versus 12%), and that Down syndrome conferred a relative risk ratio of 54 (95% confidence interval 14–206, p < 0.001), after multivariable analysis.

Large-scale anesthesia and perioperative outcomes research has now become possible with pooled AIMS databases from multiple institutions [48]. One such effort is the Multicenter Perioperative Outcomes Group (MPOG), formed in 2008 by the University of Michigan Department of Anesthesiology and several other large departments with well-developed AIMS [49]. Requirements for membership include deployment of an AIMS system capable of collecting a minimum electronic data set, contribution of at least 10,000 anesthetic cases to the consortium, obtaining local institutional review board approval for collection and transmission of data, developing and configuring electronic data interfaces to transfer data, and completing data transfer agreements with MPOG. Over 40 institutions are now participating, including several large children's hospital departments of anesthesia. Research projects can be initiated by individuals or institutions with permission of the MPOG leadership. This approach has the potential to pool tens or even hundreds of thousands of anesthetics, with complete electronic data for objective assessment, for high-quality outcomes research in anesthesia in response to specific research questions.

#### **Perioperative databases**

#### National Surgical Quality Improvement Program (NSQIP)

The National Surgical Quality Improvement Program (NSQIP) is an important database run by the American College of Surgeons (ACS). This program grew out of a congressionally mandated requirement that the Veterans Administration (VA) compare its surgical outcomes with national norms [50]. As a result, in the early 1990s VA nurses collected numerous preoperative, intraoperative and postoperative data points on surgical patients. After risk adjustment of presurgery status, the data were used to compare actual outcome with expected outcome developed from performance of the group as a whole. These data allowed risk-adjusted analysis of surgical outcomes. Those hospitals with poor outcomes were able to take steps to improve their outcomes [51].

The success of the VA program led to interest in the private sector, and a pilot group of 14 hospitals began to collect data. With these data the hospitals attempted to improve in areas where their actual outcomes were not as good as the expected outcomes. A study of the hospitals who adopted the program demonstrated reductions in morbidity, surgical site infections, and renal complications [51]. Seeing the successful results of the study in 14 hospitals, in the mid/late 1990s the ACS developed the NSQIP. Currently NSQIP collects 136 variables in a rigidly defined sample of both inpatient and outpatient surgical patients in participating hospitals. The data include demographic data, preoperative risk factors, laboratory values, operative information, and outcome data. What makes this database important is that the data are clinical data, and that they are collected carefully, and rigid data quality monitoring is carried out. Data gatherers are extensively trained, and periodic audits of data gathering are conducted on site [51]. Tests of inter-rater reliability are carried out periodically. Another benefit is that the data include 30-day outcomes, not just outcomes while the patient is in the hospital.

From the data, using statistical methods, the program determines expected risk-adjusted outcomes and determines the observed/expected ratio. This information provides risk-adjusted outcomes and allows comparison of a hospital's outcomes with external benchmarks. These data can then be used in programs to improve the quality of care. The value of NSQIP has been reported by Hall et al [52]. They looked at whether the observed/expected ratios reduced over time. In 118 hospitals 66% of hospitals had improvement of O/E ratios over 3 years.

Once the database had been established with reliable clinical data, many useful clinical studies were completed. One of the values of this database is that it represents everyday clinical practice and not the somewhat unusual circumstances often seen with patients involved in clinical trials. For example, Kiran et al [53] compared surgical site infection rates after colorectal surgery using open surgical approaches and laparoscopic approaches. They studied 3414 laparoscopic cases and 7565 open cases submitted in 2006–07 to the ACS NSQIP. The overall infection rate was 9.5% for laparoscopic cases and 16.1% for open cases. An interesting finding that is available because of the extensive data in the database is that the risk based on co-morbidities was higher in those patients with open procedures, presumably because sicker patients were offered open surgery more often.

Page et al [54] used the database to examine whether the laparoscopic approach to appendectomy has benefits over the open approach. In this situation, the benefits of laparoscopy are not as clear, as the complication rate with open procedures is relatively small and a large number of cases is required to demonstrate the superior technique. Page et al studied data from 17,199 patients who underwent appendectomy, 3025 open and 14,174 laparoscopic. Laparoscopic patients had shorter length of stay, lower incidence of wound disruptions, and lower perioperative mortality.

Another use of a database such as NSQIP is to prioritize quality improvement efforts. One group carried out such an effort in orthopedic surgery [55]. They reasoned that it is important to direct quality improvement efforts to those areas where the need is greatest, as defined as those procedures that generate the greatest number of adverse events. They examined the database first to find orthopedic procedures and then to find those procedures that contributed most to the occurrence of adverse events and to excess length of stay in hospital. They found that 10 procedures (hip fractures, total hips and knees, and others) accounted for 70% of adverse events and 65% of excess hospital days. They recommend that orthopedic surgeons and hospitals use these data to focus quality improvement efforts toward those areas that will benefit the most.

Merkow et al [56] examined variability in reoperation rates as a target for quality improvement efforts. Using NSQIP data, they examined reoperation rates in patients who had colorectal procedures. Reoperations occurred more often than expected in 16 hospitals and less often than expected in seven. The following factors were associated with a higher risk of reoperation: higher ASA class, male gender, contaminated wounds, surgical extent, surgical indication, and smoking.

### Pediatric National Surgical Quality Improvement Program

The patients whose data have been submitted to NSQIP have largely been adults, but recently several pediatric

hospitals have joined NSQIP in a pediatric model. As of October 2010, 27 institutions are submitting pediatric data, using a sampling model that is similar to adult NSQIP. The program is currently in a  $\beta$ -test mode. The pediatric model samples patients under 18 years of age and it is different from the adult NSQIP in that it includes more subspecialty cases. Thus, it includes cases from general surgery, thoracic surgery, orthopedic, ENT, urology, plastic surgery, and neurosurgery. It does not include trauma. Data from the  $\alpha$ -test were published in 2010 [57]. The purpose of the report was to provide a summary of phase I results, identify variables associated with postoperative occurrences, and outline potential areas of focus as the ACS NSQIP Pediatric moves toward the use of data for surgical quality improvement.

A total of 7287 patients were evaluated during the initial phase. There were 22 deaths captured (0.3%). A total of 287 patients (3.9%) had one or more postoperative complications. These complications were four times more likely in patients undergoing inpatient procedures versus outpatient procedures. Factors associated with a higher likelihood of postoperative occurrences included a nutritional or immune history such as preoperative weight loss or chronic steroid use and a history of physiological compromise, such as sepsis or inotrope use before surgery. Operative factors associated with occurrences included multiple procedures under the same anesthetic and ASA classification category 4 or 5 versus 1. Variability in outcomes was demonstrated across participating sites as well as across surgical specialties. This finding supported the potential of the project to identify improvement targets in the future, although risk-adjusted performance evaluation of the small number of pilot sites was not attempted.

Several specific challenges to developing a quality improvement program for children's surgery were identified in this preliminary report. First, mortality and morbidity event rates after surgery are low in the pediatric patient population. A second challenge to measuring surgical quality in children is that the procedures for which morbidity and mortality are high are uncommon. The last challenge to measuring surgical quality in children involves the data burden associated with data collection, the number of variables needed for risk adjustment, and the duration of follow-up [57].

While the adult NSQIP data are being effectively used for evaluation of surgical care, and there is promise with pediatric data, less is being done with anesthesia care. As noted above, the AQI is still in the start-up phase, and anesthesia comparative effectiveness research has had to rely on other, administrative databases.

# Outcomes and effectiveness research using databases

Outcomes research was established in 1988 when the Health Care Financing Administration (HCFA) of the US Department of Health and Human Services proposed an "Effectiveness Initiative." In this case, the initiative was in response to work on geographic variations in medical practice, appropriateness of care, the poor quality of medical evidence, congressional reluctance to fund health services research, and Medicare costs [58]. The initiative was the first attempt at finding a solution to these interrelated problems.

To start the initiative, the HCFA requested that the Institute of Medicine, National Academy of Sciences recommend those clinical conditions that should receive initial priority attention. The first five high-priority medical conditions that the outcomes research initiative focused on were acute myocardial infarction, angina (stable and unstable), breast cancer, congestive heart failure, and hip fracture. The goal of the initiative was to assess the success of different interventions in treating the identified clinical conditions in an effort to guide clinicians in the management of patients and to aid policy makers in allocating Medicare resources. In return, the HCFA would make the information gathered in its database available to the medical community for analysis of effectiveness. Any new information gathered from clinical demonstrations or trials would be available for review. As a result, the first outcomes research national database was established.

One goal of a national program is to collect information in a common database in order to conduct comparative effectiveness research. The definition of outcomes and effectiveness research has been described in numerous ways. One group reviewed all seminal and contemporary descriptions of outcomes and effectiveness research in order to arrive at an encompassing definition of the topic. The definition they arrived at was as follows.

Outcomes and effectiveness research evaluates the impact of healthcare (including discrete interventions such as particular drugs, medical devices, and procedures as well as broader programmatic or system interventions) on the health outcomes of patients and populations. It may include evaluation of economic impacts linked to health outcomes, such as cost effectiveness and cost utility. Outcomes and effectiveness research emphasizes health problem- (or disease-) oriented evaluations of care delivered in general, "realworld" settings; multidisciplinary teams; and a wide range of outcomes, including mortality, morbidity, functional status, mental well-being, and other aspects of health-related quality of life. Outcomes and effectiveness research may entail any in a range of primary data collection methods and secondary (or "synthetic") methods that combine data from primary studies [59].

The importance of this definition is that it encompasses all aspects of a patient's care. The definition includes evaluating whether a traditional biomedical measure, such as the result of a laboratory test, determines if a health intervention is necessary or successful, but it goes beyond that. This research also measures how people function and the patient's experiences with care. These outcomes are sometimes what matter most to patients. This is the key to understanding how to improve the quality of care.

In 1989, the initiative took legislative form in a law called the Omnibus Budget Reconciliation Act (OBRA). This law created the Agency for Health Care Policy and Research (AHCPR) which accepted the primary responsibility for carrying the initiative forward. The mandate was that the AHCPR would focus heavily on researching the outcomes and effectiveness of medical care and on the development and dissemination of practice guidelines. This represented an important hypothesis: guidance for optimal medical practice could be gleaned from analysis of data routinely gathered in the process of delivering and paying for patient care. This was the start of the trend in thinking that evidence instead of opinion should guide clinical decision making [58].

Essentially, a decade later, in 1999, the AHCPR was renamed the Agency for Healthcare Research and Quality (AHRQ). "Policy" was explicitly removed from the name because the agency did not want to be viewed as a regulatory body. Today, the AHRQ still makes advances towards its mission to improve the quality, safety, efficiency, and effectiveness of the nation's healthcare system. One of its successes has been through the Healthcare Cost and Utilization Project (HCUP) which has created a family of healthcare databases that focus on the data collection efforts of state data organizations, hospital associations, private data organizations, and the federal government to create a national information resource on patient care [60]. The HCUP includes the largest collection of longitudinal hospital care data in the United States, dating as far back as 1988. It contains six databases, three at the national level and three at the state level.

The Nationwide Inpatient Sample (NIS) collects inpatient data from over 1000 hospitals. It is the largest allpayer inpatient database in the US, dating back to 1988, and contains more than 100 clinical and non-clinical elements per hospital stay. These include, but are not limited to, primary and secondary diagnoses, primary and secondary procedures, admission and discharge status, patient demographics (e.g. gender, age, race, median income for ZIP code), expected payment source, total charges, length of stay, hospital characteristics (e.g. ownership, size, teaching status). The data are administrative data. The NIS is based on the data collection efforts of data organizations in participating states that maintain state-wide data systems and that have partnered with AHRQ.

The data are most commonly used to examine trends in healthcare costs, access, practice variation, and quality of care. Lee and Morell noted the limitations in using such a database to evaluate quality of care. For example, they reviewed two papers recently published using the NIS database about the rare complication of postoperative visual loss (POVL). While the strengths of the national database are the volume of entries and the breadth of sampling, limitations for this study of the database include incomplete data entry, lack of any intraoperative data from the anesthesia record, inability to verify POVL diagnosis, and inability to determine whether a condition was pre-existing. The process of how the data are collected and entered into the database merits scrutiny if used for something like evaluating quality of care. For example, commonly there are hospital employees who review hospital records to look for codes that may upgrade a patient's acuity status for reimbursement purposes. Hypothetically, this could result in the diagnoses of hypotension and POVL being entered in the patient's medical record, which could lead to potential conclusions that are arbitrary. It may be implied that intraoperative hypotension caused the POVL, without considering the baseline blood pressure or associated factors during the surgery. The search for associated factors in the medical record is much more intense when a complication arises [61].

The Kids' Inpatient Database (KID) [62] is the only allpayer inpatient care database for children in the United States. The KID contained data from 2–3 million hospital discharges for children. There has been greater success with data collection as the years have passed. The 1997 KID contained data drawn from 22 state inpatient databases on children 18 years of age and younger. By 2006, KID contained data drawn from 38 state inpatient databases on children 20 years of age and younger. The disadvantage for medical research purposes is that the KID database consists of administrative data. The data are collected in the same way as the NIS database and record the same 100 non-clinical and clinical elements.

The last national database developed through this project is the Nationwide Emergency Department Sample (NEDS). The NEDS is the largest all-payer emergency (ED) database in the United States. It was constructed using records from both the HCUP state emergency department databases (SEDD) and the state inpatient databases (SID). The SEDD captures information on ED visits that do not result in an admission (i.e. treat-and-release visits and transfers to another hospital). The SID contains information on patients initially seen in the emergency room and then admitted to the same hospital [63]. This is an administrative database that records elements like primary and secondary ICD-9-CM diagnoses, primary and secondary ICD-9-CM and CPT-4 procedures, discharge status from the ED, patient demographics (e.g. gender, age, median income for ZIP code), expected payment source, total ED charges (for ED visits) and total hospital charges (for inpatient stays for those visits that result in admission), hospital characteristics (e.g. region, trauma center indicator, urban-rural location, teaching status).

The three state-level databases are the SID, SEDD, and the state ambulatory surgery database (SASD). The SID and SEDD database information contribute to make up the NEDS database.

The SID contains inpatient discharge abstracts in participating states, translated into a uniform format to facilitate multi-state comparisons and analyses. It is well suited for research that requires complete enumeration of hospitals and discharges within market areas or states. Researchers and policy makers use the SID to investigate questions unique to one state; to compare data from two or more states; to conduct market area research or small area variation analyses; and to identify state-specific trends in inpatient care utilization, access, charges, and outcomes. For example, one article that used the SID as a resource was published by Coben et al [64]. They compared motorcycle-related hospitalizations across states with differing helmet laws, looking at hospital discharge data from 33 states. Results revealed that motorcyclists hospitalized from states without universal helmet laws are more likely to die during the hospitalization, sustain severe traumatic brain injury, be discharged to long-term care facilities, and lack private health insurance. However, a major limitation to this study was the lack of specific helmet use information on individual cases.

The SEDD is an administrative database that captures discharge information on all emergency department visits that do not result in an admission. It has not been used as frequently as the SID for publishing thus far. Potential areas of research include injury surveillance, access to healthcare in a changing healthcare marketplace, trends and correlations between emergency department use and environmental events, emerging infections, occurrence of non-fatal, preventable illness, and community assessment and planning.

The state ambulatory surgery databases (SASD) are a powerful set of databases, from data organizations in participating States, that capture surgeries performed on the same day in which patients are admitted and released. It is an administrative database that has not been used as much as the SID for publishing thus far. However, it has potential to aid in areas needed to identify state-specific trends in ambulatory surgery utilization, access, charges, and outcomes [61].

Another national administrative database is managed by the National Association of Children's Hospitals and Related Institutions (NACHRI). This organization is made up of children's hospitals with members from the United States, Canada, Australia, the United Kingdom, Italy, China, and Mexico. In addition to hospitals, this organization also has representation from large pediatric units of medical centers and related health systems, including those that specialize in rehabilitative care of children with serious chronic or congenital illnesses. The purpose of the association is to provide a voice for health systems to ensure children's access to healthcare and the continuing ability of children's hospitals to provide services needed by children. To accomplish this, the NACHRI developed the Case Mix Comparative Data Program, a pediatric inpatient discharge database for children's hospitals in the United States [65].

Historically, the only indicator to monitor quality of care and utilization of services in the hospital setting was diagnosis-related groups (DRGs). However, DRGs have been criticized because they do not take into account the acuity of patients. For example, a child who is admitted with pneumonia and also had cystic fibrosis would be simply listed as having a diagnosis of pneumonia despite the significant co-morbidity. The NACHRI has developed all-patient refined DRGs (APR-DRGs) which take into account severity of illness and risk of mortality. In doing so, the NACHRI APR-DRG case mix comparative database now has the ability to separate out acuity levels within a diagnosis. The result is a sensitive tool to determine variances in care [66]. Using the only pediatric acuity measures available, the database helps target quality improvement activities, enhance hospital utilization, develop pricing strategies and evaluate the likely effects of alternative prospective payment systems.

An example of how the NACHRI database has been used in a real setting was demonstrated at the University of Michigan Mott Children's Hospital (UMMCH). Sedman et al [66] reported using the NACHRI APR-DRG case mix comparative database to research non-complicated asthma cases (level 1 severity). The data showed that the UMMCH average length of hospital stay was longer than the NACHRI data for the same population (2.16 days versus 2.14 days). Also, the UMMCH cost per case was higher (\$2824 versus \$2738). Furthermore, their cases of moderate, major, and extreme severity were lower than the national aggregate. This showed that the APR-DRG system is sensitive enough to distinguish variances of care within a diagnosis according to severity level. The UMMCH went on to redesign its clinical processes to improve quality in the level 1 severity group.

Another database for practice improvement has come from the Virtual Pediatric Intensive Care Unit (VPICU) that started in 1997. The VPICU was started with the vision of creating a common information space for the international community of caregivers providing critical care for children. After the VPICU was initiated, it collaborated with the NACHRI to develop a database to define, understand, and improve pediatric critical care. Today, there are over 250,000 patient admissions to the database. The database is unique in that it utilizes severity of illness adjustment tools in an effort to insure that patients with similar severity of illnesses are compared. The core purpose of the prospective data collection is quality improvement. This effort includes comparative data reporting and the availability of comprehensive quality reports and tracking for individual institutions [67].

A recent trend in perioperative safety research is to look at not just issues traditionally associated with anesthesia but the entire encounter. As anesthesia becomes safer, it is important to look at potential contributions of anesthesia to the healing and recovery process. This sort of research is an important part of comparative effectiveness research, and extends the concept to looking at what happens in everyday practice as opposed to what happens in controlled clinical trials, where as many factors as possible are controlled [48]. Memtsoudis et al [68] examined perioperative outcomes after unilateral and bilateral total knee arthroplasty. The question is if a patient needs bilateral total knees, is it best to do them together, staged during the same hospitalization, or totally separately? Memtsoudis et al used the national inpatient sample to examine this question and found that there were worse outcomes with simultaneous procedures or procedures done during the same hospitalization. Kheterpal uses this as an example of the kinds of research that anesthesiologists should start getting involved in [48].

The important question is, does anesthesia have effects on recovery and later outcomes that we are not currently tracking? For pediatrics, one important current question is: is there an impact of anesthetic exposure by neonates on longer term neural and cognitive development? The use of databases has the potential to shed some light on these issues. See Chapter 41 for a complete discussion of anesthesia neurotoxicity.

#### Study design issues for outcomes research: comparison of non-inferiority (equivalence) statistics to traditional superiority statistics

Compared to a superiority trial whose aim is to determine if one intervention is superior to another (control) intervention, non-inferiority trials aim to determine if one intervention is similar to another [69]. In superiority trials, the null hypothesis is that the treatments are equally effective and the alternative hypothesis is that they differ. In a non-inferiority or equivalence trial, the null hypothesis is that the treatments differ and the alternative hypothesis is that they are equally effective [70] (Fig. 43.1). An important point is that a superiority trial should not conclude that the groups are equivalent if the null hypothesis is true. If the primary objective of a study is to prove equivalence then the study design, conduct, and data analysis should be based on the null hypothesis that the treatments differ.

Non-inferiority designs are useful when the new treatment is more favorable than standard therapy in other ways than the one being tested (economic benefit, ease of use, etc.). In this case, even showing that the two treatments are equivalent would justify the use of the new treatment. For example, an equivalence trial comparing hydroxyethyl starch (HES) and hetastarch showed that the two treatments are equally effective as plasma

Figure 43.1 Possible scenarios of observed treatment differences for adverse outcomes (harms) in non-inferiority trials. Error bars indicate two-sided 85% confidence intervals (CIs). Tinted area indicates zone of inferiority. (A) If the CI lies wholly to the left of zero, the new treatment is superior. (B,C) If the CI lies to the left of  $\Delta$  and includes zero, the new treatment is non-inferior but not shown to be superior. (D) If the CI lies wholly to the left of  $\Delta$  and wholly to the right of zero, the new treatment is non-inferior in the sense already defined, but it is also inferior in the sense that a null treatment difference is excluded. This puzzling case is rare, since it requires a very large sample size. It can also result from having too wide a non-inferiority margin. (E,F) If the CI includes  $\Delta$  and zero, the difference is non-significant but the result regarding noninferiority is inconclusive. (G) If the CI includes  $\Delta$  and is wholly to the right of zero, the difference is statistically significant but the result is inconclusive regarding possible inferiority of magnitude  $\Delta$  or worse. (H) If the CI is wholly above  $\Delta$ , the new treatment is inferior. Reproduced from Piaggio et al [70] with permission from the American Medical Association.

volume substitutes but HES has less of an effect on coagulation [71].

It is important when reviewing outcomes and effectiveness research to understand who is influencing the drive behind the research and who is interpreting the results. Organizations may serve as producers, consumers, or sponsors of research. The nature and intensity of this involvement vary dramatically as a function of the type, size, commitment, and history of the organization. This overlap of interest becomes apparent, for instance, when a managed care plan funds its own research for use in internal policy decisions. The interest of each group drives production in what areas will be researched. It is for this reason that the topics of research in the public and private sectors do not significantly overlap. The research is used in a focused way to promote business goals and other organizational objectives.

# Departmental and institutional requirements for database participation

As noted throughout this chapter, information collected in the course of routine clinical anesthetic care is often not in a form that is organized and accessible for databases, and thus not useful for clinical or outcomes research. Databases, whether organized from data entered by clinicians or researchers or collected automatically from AIMS, require significant institutional and departmental commitments in the form of infrastructure (hardware and software), information technology expertise, a clear strategy and standards for entering and auditing data, and personnel to maintain the systems. Most of these elements are not provided for in routine clinical care, and the additional financial and personnel resources require a long-term commitment. The benefit to patient care, quality and outcomes, and contribution to research in these areas need to be demonstrated to department and hospital leadership. Box 43.1 lists the components needed for departmental participation in anesthesia and perioperative databases.

#### Conclusion

Databases for pediatric anesthesiology are in their infancy. New initiatives within the subspecialty and participation in larger anesthesiology and perioperative databases are increasing, and hold promise to hasten the pace of datadriven improvement in care and outcomes, with properly performed studies with valid data in adequate numbers of patients to draw valid conclusions. As a subspecialty, pediatric anesthesiology will need to commit to acquiring expertise in databases to maximally affect the improvements available in this rapidly advancing field. **Box 43.1** Necessary components for departmental and institutional participation in anesthesia databases

- Leadership
  - Departmental vision and strategy for databases; anesthesiologist expertise in database design, management, maintenance
  - Strategies and processes for integration with institutional databases and hospital electronic medical records
- Information technology expertise
  - Database designers working with clinical and research staff to maximize efficiency and accuracy of data entry according to purpose of database; collect data over and above standard clinical and administrative databases
- Anesthesia information management systems
  - Interface for collection of clinical data into research database; search capabilities of clinical database for research and outcomes projects
- Computer hardware and software
  - Proper software to collect and organize data locally and allow connection to local networks and databases as well as transmission to national data warehouses
  - Hardware, including adequate computing power and speed, and high-capacity redundant data storage capacity
- HIPAA , legal, and IRB compliance
  - Patient permission for data collection for research, appropriate deidentified data, IRB approval for research
  - Compliance with hospital, institutional, local, state, and federal requirements for data collection and sharing
- Participation in national databases
  - Institutional legal agreements for participation, financial costs of participation, permission for research projects, benchmarking of institutional data versus de-identified data from outside institutions
- Local database personnel to enter data
- Clinicians (attendings, fellows, residents, OR nurses, research nurses and other personnel)
- Audit procedures
  - Well-defined criteria for auditing or correcting data before analysis or transmission to national data consortia
- Financial resources
  - Realistic budget and business plan; calculated return on investment in databases: quality and outcomes, research, financial

### Medical electronic databases: usefulness, drawbacks

Documentation in medicine is moving inexorably from the paper to the electronic realm. An electronic medical record (EMR) is the legal record created by a hospital or health care institution. The EMR is the data source for the electronic health record (EHR) and is a different concept [1]. The EHR represents the vehicle by which medical information can be shared between stakeholders and will allow a patient's information to follow them through the various areas of their care. Stakeholders include patients, providers, employers, and third party payers.

Anesthesia documentation is also moving in the direction of electronic records, but perhaps more slowly than in other areas of medicine, despite being advocated for over 20 years ago [2]. To reflect the fact that these systems have potential that goes beyond simply documentation, the term commonly used is anesthesia information management system (AIMS). The relatively slow progress in converting anesthesia to an electronic system is because there are some very specific aspects of anesthesia documentation that make conversion from the paper to the electronic medium particularly challenging. This chapter discusses the overall movement of health documentation to the electronic realm, with special focus on anesthesia records.

Computers are the tools used to implement electronic systems and have actually been used in medicine for several decades. In the era of mainframe computers in the 1960s, a decision support system was developed at the University of Leeds to aid in the diagnosis of acute abdominal pain. In the 1970s, the minicomputer arrived, and significant computing power was available at the level of clinical departments. The personal computing era arrived in the 1980s and individual physicians have had access to computers of ever increasing power and at decreasing cost.

With this computational ability, many individuals and departments developed and used home-grown electronic record systems in their practice. However, the healthcare industry as a whole has been relatively slow to adopt

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

enterprise-wide electronic systems for managing health information. Even now, less than 5% of healthcare institutions have enterprise-wide electronic medical documentation, and only 17% have computerized physician order entry (CPOE) for medications [3]. The penetration for electronic records has increased over the past few years and the pace of change will likely accelerate [4]. Powerful external forces are driving the adoption of electronic systems in healthcare.

There is a strong, though not yet well-substantiated belief that use of electronic systems such as CPOE systems will improve quality of care and patient safety. As a result, there is encouragement (in some cases a mandate) at both the federal and state level for healthcare institutions to adopt electronic information systems.

In 2004, then President George W. Bush ordered the Department of Health and Human Services to develop a national health information network [5]. The task was to be complete within 10 years and was allocated to a newly created entity, the Office of the National Coordinator for Health Information Technology. In 2009 President Barack Obama called for a national system of electronic health records by 2014. The Health Information Technology for Economic and Clinical Health Act (HITECH) of 2009 was a part of the American Recovery and Reinvestment Act (ARRA). This "stimulus" bill authorized incentive payments to hospitals that used EHRs in a "meaningful" way [6].

It is unlikely that a national system will be in place by 2014. In the meantime, regional networks of electronic health information are being created [7]. These regional networks will then feed into state networks which will in turn feed into the proposed national database. This patchwork approach raises the question of "interoperability," i.e. how well these various systems interact. This question is receiving a lot of national attention, but the problems are far from solved [5,7].

In addition to these outside forces, our own professional bodies, such as the Anesthesia Patient Safety Foundation (APSF), endorse the use of electronic records: "The APSF endorses and advocates the use of automated record keeping in the perioperative period and the subsequent retrieval and analysis of the data to improve patient safety." Finally, major purchasers of healthcare, such as the Leapfrog Group (an alliance of large corporations), have strongly advocated the use of CPOE systems. In the not too distant future, payments for services will be linked to use of electronic information systems.

### Why convert from paper to electronic records?

By and large, clinicians are comfortable with the systems that they use every day. Where the systems don't work well, people have developed workarounds. Most clini
 Table 44.1 Paper versus electronic records: comparison of cardinal properties

	Paper	Electronic
Legibility	Variable, often poor	Excellent
Accessibility	One location only	Multiple access points
Reliability	May be lost	Backed up
Clinician comfort	High – familiarity	Wariness for change
Training required	Minimal	May be extensive
Data entry	Very unstructured	Structured
Viewing options	Limited	Extensive
Searching records	Labor intensive	Easy after initial set-up

cians use and are familiar and comfortable with paper records; less than 25% have used electronic documentation [3]. Consequently, clinicians may have a hard time giving up paper. To help make the case for electronic records, it is worth comparing the strengths of paper and electronic records.

#### Paper and electronic records compared

First, let's consider paper records (Table 44.1). They are familiar, probably the property that makes change most difficult. Data can be entered quickly and simply, the process of data entry is very flexible plus the whole record can be viewed easily. No special training is required. Finally, paper records do not break, i.e. they do not go "down" like electronic systems can.

On the downside, paper records are available in only one location, and this may not be where they are needed. Paper records can also be lost irretrievably, as was the personal experience of the current Surgeon General Regina Benjamin from Alabama after a destructive hurricane [8]. Legibility may be poor, space to enter information is restricted, there is no systematic standardized format of data entry, and ability to collect, monitor, and analyze information is poor [3]. The unused record looks pristine (Fig. 44.1A), but that property is lost as soon as documentation is started (Fig. 44.1B). This is an example of a real (de-identified) patient paper record at the University of California San Francisco. All the problems listed above are clearly demonstrated.

While a paper record is the traditional method of record keeping, it cannot be considered a "gold standard." The accuracy and completeness of data entry on a paper record are often inadequate [9], and the deficiencies are independent of the experience of the clinician [10]. In addition, adverse events are commonly under-reported on paper records [11]. Many of these deficiencies can be alleviated with electronic record keeping (Box 44.1). While an electronic record does not cram as much information on a single page as a paper record, the ability to

**Figure 44.1** (A) Paper record before any entries are made. It appears well structured and clear. (B) The apparent structure of the empty record has disappeared. Many entries are barely legible. There is little space for entries, such as laboratory results. Someone looking at the record for the first time would not know where to find items such as antibiotics or a consistent description of procedures, events, etc. Many critical elements, such as pulse oximetry values, are entered only every 15 min.

**Box 44.1** The specific data elements that constitute protected health information (PHI)

- Names
- All geographic subdivisions smaller than a state
- All elements of dates and the age of patients over 89
- Telephone numbers
- Fax numbers
- Email addresses
- Social Security numbers
- Medical record numbers
- Health plan beneficiary numbers
- Account numbers
- Certificate/license numbers
- Vehicle identifiers and serial numbers
- Device identifiers and serial numbers
- Web Uniform Resource Locators (URLs)
- Internet protocol (IP) address numbers
- Biometric identifiers, including finger and voice prints
- Full-face or comparable photographic images
- Any other identifying number, characteristic (e.g. a tattoo), or code

view multiple screens allows for better legibility and data presentation (Fig. 44.2).

Electronic records are accessible from many locations, allow structured and standardized data input, allow multiple views and trending of the data, are legible, can link to other hospital systems, and allow for ongoing monitoring and systematic analysis of data [11–16]. Electronic records can be backed up in multiple locations so that they are never lost. Disadvantages of these records are that they are unfamiliar to many clinicians, require training, need ongoing support, and can go "down" for a variety of technical reasons. However, the eventual adoption of electronic records is inevitable and it is important that clinicians have influence in the process of choosing and implementing an electronic record-keeping system that they, the clinicians, must use.

# Reasons to adopt an electronic anesthesia system

#### Enhance quality of patient care

This should always be the number 1 criterion driving change. It is easy to justify electronic medical record keeping on this one issue alone. Safety is enhanced by the easy accessibility and legibility of previous records, and by the ability to track outcomes and improve record keeping for quality improvement initiatives [17–19]. Electronic record keeping is a necessary first step in the move towards evidence-based practice and decision support. A good example of enhanced safety comes from the Children's Hospital of Philadelphia. Their electronic tracking of adverse events, specifically bronchos-

pasm, led the clinicians to stop using rapacuronium 8 months before it was withdrawn from the market by the company [20].

#### Increased provider satisfaction

With few exceptions, anesthesia providers embrace technology and believe that electronic records are an indication that they are working in a modern facility. Medical records are more readily available, data can be entered directly from other hospital systems, and the amount of time devoted to record keeping is decreased [21]. This leads to a perception that the overall quality of work is improved [16].

#### The financial case

Electronic information systems are very expensive to install and maintain, and it is difficult to demonstrate financial gains to offset these costs [22]. As described above, patient safety is enhanced and this has real but hard-to-quantify financial benefit [22]. Within anesthesia, the areas where financial benefits may be quantifiable are revenue and costs.

#### Increased revenue

Automated electronic error detection systems enhance anesthesia professional fee billing [23]. The identification of additional diagnoses and co-morbidities from an electronic anesthesia preoperative evaluation system allowed the use of additional ICD-9 codes in 12% of cases that increased hospital revenue 1.5% [24]. Additional areas of increased revenue are enhanced charge capture for specific high-cost drugs and for technical fees for anesthesia services.

#### **Decreased costs**

There is clear evidence that giving providers feedback on their drug costs, compared to those of their colleagues or other institutions, can bring down the average cost per case by 20% [12,13]. The problem is that the effect is transient and reverts to previous costs after 3 months without reinforcement. There is no way, using paper records, that the effort of gathering and disseminating drug use information to individuals can be sustained. In contrast, generating recurring drug and supply use reports is simple with electronic information systems [14]. Finally, there is accumulating evidence that electronic records decrease medico-legal liability and costs [25].

# Potential problems with an electronic anesthesia system

The disadvantages of an electronic system relate mostly to costs, effort, and resources needed for implementation, maintenance, and upgrading. In addition, if data entry imposes significant additional workload on the clinician

#### (A)

**Figure 44.2** These illustrations are taken from the AIMS used at the University of California San Francisco. Their use in this figure does not imply an endorsement of the product. (A) This is an example of the default home screen in an electronic anesthesia system. All entries are legible and vital signs data are displayed at a 5-min resolution. The data display can be compressed by increasing the interval to 30 min, allowing for a summary view of a long case. Alternatively, the resolution can be increased to every 10 sec to allow very close inspection of rapidly changing events. Data are actually saved to the database at 1-min intervals. (B) Computer screens do not display the totality of information as a paper record does. Rather different pages are used to view different data summaries. This is a medication summary review. All the medications administered can be viewed by individual doses and totals. (C) This screen is a summary view of all fluids administered during the procedure. Individual totals and current fluid balance are automatically calculated by the application. (D) This shows a summary of procedures, e.g. airway management, performed by the anesthesia provider. In this example, all the entries are in structured data fields and so can be searched after the fact for purposes of analysis and reporting.

Figure 44.2 (Continued)

or the electronic infrastructure is unstable and the system goes down frequently, clinicians will soon become dissatisfied. Computers, screens, and keyboards may take up very valuable space within the clinical workspace (Fig. 44.3). Finally, it is possible to generate more paper after implementation of an electronic system due to printouts, and a specific printout may be required for your own institution [26].

#### **Computers in medicine**

Computers are the vehicles used to enable electronic documentation. Perhaps the most compelling reason to incorporate computer-based electronic information systems in anesthesia and medicine is that it is the only way to manage and effectively utilize the already large and rapidly increasing amount of information available. A simple example is the proliferation of medications and the information on their interactions. An individual physician cannot keep details of drugs and their interactions in their head the way an earlier generation once did. There are more tests and services available and more tests performed on patients than ever before. Turnover of patients in hospitals has increased, and resident work hours require multiple transfers of care in a single day. The only way to manage the array of data and to pass it on safely between the members of the care team is by electronic means.

#### Standards

The use of computers to manage and share information has many consequences. The first of these is that common standards of information transfer need to be developed.

**Figure 44.3** An electronic information system takes up a significant amount of real estate in the usually tight confines of the anesthesia workspace. In addition, the devices need network connection to the central database. This is a tough environment with risks to the equipment of damage from impact, fluids, and electrical interference. A good inventory of readily available spare parts, mouse, keyboards, cables, etc. is essential to keep the system up and running.

A simple definition of what constitutes a standard is that it is "what most people do." Standards familiar to most clinicians are the ICD-9 (International Classification of Diseases, version 9) and the CPT-4 (Current Procedural Terminology version 4) standards for describing diseases and medical procedures, respectively. Standards may be developed in several ways. The first and simplest way is that the dominant vendor in an area sets the standard. An example of this is the iPhone operating system. Second, a government agency, such as the Centers for Medicare and Medicaid Services (CMS) or National Institute for Standards and Technology (NIST), may mandate the use of an existing system. Finally, groups of interested parties can meet and develop standards independently. If the process has been sufficiently open and rigorous, these recommendations are adopted as standards, for example the Health Level 7 (HL7) standard for clinical data interchange.

There are many areas where standards have been developed and adopted in medicine, but there are several crucial areas, including AIMS, where there are no standards [26]. The most complex problem is perhaps that of medical terminology. Take, for example, the terms "heart attack," "cardiac infarction," "myocardial infarction." To a clinician they all mean the same thing but to a computer they are three different entities. Structured systems such as the Unified Medical Language System (UMLS) and Systemized Nomenclature of Human and Veterinary Medicine (SNOMED) exist, but none has gained universal acceptance. Within the SNOMED systems, a subgroup of anesthesia-related terms is under development [27]. Developing standardized terminology is compounded by the problem that systems of nomenclature are required for all areas of healthcare, e.g. nursing, and in all applicable languages. Terminology must not just be standardized within a system; it must also be standardized across systems in different areas of healthcare.

# Devices: why electronic anesthesia systems are different

There are two characteristics of anesthesia documentation that separate it from other areas in medicine. The first is that data are directly recorded in real time from devices, for example vital signs monitors and mechanical ventilators [28]. The second is that these devices and the associated computer workstation are connected to and can be linked with only one patient at a time. Consequently, if the system develops a problem, one cannot delay data entry or go to another workstation to enter the data. These characteristics impose unique demands for high data transfer capabilities, the reliability of the system, and the need for 24/7 immediate technical support.

### **Medical records**

What is the medical record in the electronic world? The legal definition of the health record is "the composite documentation of healthcare services provided to an individual during any aspect of healthcare delivery in any type of healthcare organization." When all documentation was on paper and x-ray images were all on film, identifying the legal health record was easy. The contents of the paper chart (including the paper anesthesia record) plus x-rays formed the healthcare provider's legal business (medical) record. The advent of the EHR has complicated matters considerably.

Now the legal health record comprises a wide variety of individually identifiable data stored on any medium, electronic, paper or a hybrid. The purpose of the legal record remains the same: to support decisions made in the patient's care, to provide justification for revenue claims to payers, and to support legal testimony pertinent to both of these. The legal health record is not the totality of the patient's EHR; rather, it is a subset of records, which serves as the legal business record for the organization.

#### Medico-legal issues in electronic records

Concerns over electronic record systems and medical liability were raised back in 1997 at a time when very few institutions had electronic medical records. At the time, the question did not generate much urgency [29]. However, with the rapid expansion of the use of EHRs, the question is now receiving a lot of attention [30]. From a medicolegal perspective, EHRs confer both benefit and risk.

#### Discoverability and electronic records

Since the legal health record is now a subset of a potentially much larger dataset comprising the full EHR, the legal issue arises of how much of the EHR is discoverable. The courts are in the process of defining limits to discoverability, but many issues remain unsettled. Some areas have been identified that generally are not discoverable in litigation. Examples include fragmented information on hard drives, items that are temporary, such as cookies, and other transient information that would require extraordinary efforts to preserve. Exceptions can be made when justified, but the courts will likely discourage "fishing expeditions" through the EHR by attorneys.

Another question relates to the format in which the 'discoverable" data will be produced. In the days of paper records this was simple; the patient's chart or a photocopy of the original record could be produced. It is a very different situation with an electronic record. With paper, what constitutes the anesthesia record is obvious. With an AIMS, there are tens of thousands of individual electronic data elements stored in every patient's record. In what format should that be produced for litigation? In practical

terms, most AIMS include some form of clinical summary of the record that can be read much as a paper record would be. While it will depend on an individual institution's policies and procedures, and on some degree of negotiation between parties to the litigation, it is most likely that this is the form of the record that would be produced for discovery [31].

#### Medico-legal benefit of electronic records

As described earlier, electronic records are more legible than paper records, documentation is standardized and likely to be more complete, and other information, such as pertinent laboratory results, is likely to be included. A survey by the Medical Records Institute of practitioners using EHRs found that 50% felt they were better protected against malpractice claims, and 20% reported a reduction in their malpractice premiums. Of the anesthesia departments that were using an AIMS and were also involved in a malpractice lawsuit, the majority viewed the electronic record as helpful [25].

# Areas of possible medico-legal risk with electronic records

An inevitable area of risk with electronic records is the privacy and security of the patient's protected health information (PHI). These risks will be covered more fully in the following section on privacy. Specifically in the realm of anesthesia, it is common to print summaries of the preoperative evaluation or anesthesia record for easier reading, or as an *aide-memoire*. Since these printouts no longer go into the patient chart, it is easy to discard them in an unsecure way, e.g. left lying around in a lounge. This is a clear violation of the Health Insurance Portability and Accountability Act (HIPAA), and one of which anesthesia providers should be very aware.

Anesthesia information management systems incorporate audit trails so all entries into the record bear a stamp of the time of the entry and the electronic identity of the person logged into the system. Providers should be very careful to annotate any significant alterations to the record with an explanation for the change. Likewise, any information entered after the fact may require explanation.

Errors in, or omission of, required documentation is very obvious in an electronic anesthesia record. Asynchronous timelines of events, e.g. anesthetic induction recorded as occurring before the patient entered the operating room, will create medico-legal problems down the road. Clinicians are heavily reliant on the AIMS for automatically documenting vital signs. If, for example, any vital signs values are not recorded and this is not noticed, then the record appears deficient and non-compliant with standard of care [32].

In conclusion, the medico-legal issues around EMRs and AIMS are in a phase of development and definition.

The overall consensus is that an AIMS will decrease medico-legal liability, but as with anything in anesthesia, attention to detail, vigilance, and proper training are keys to success [33].

#### Implementing an AIMS at your hospital

The majority of hospitals do not have an AIMS and, as mentioned earlier, there is a great deal of pressure to adopt electronic records in medicine. Consequently, it is likely that many anesthesiologists will be involved in or even lead the implementation of an AIMS at their institution some time in the next few years. It is vital to the ultimate success of electronic documentation that the clinicians who will be the end users are involved in the choice and design of the system [34]. Useful guidelines to help in the implementation of AIMS are already available as original articles or online reports [35,36]. It is vital that clinicians drive the process, since there are significant differences in the priorities for the medical documentation process between hospitals and medical professionals [37].

Should you find yourself leading or otherwise being involved in a project to implement an electronic anesthesia record system, you are in an enviable position because you will be leading your colleagues on a major step into the future of anesthesia practice. It is also a difficult position because of the number of headaches that are in your own future. Before considering the challenge, you should ask yourself a couple of questions.

First, are you passionate about the need for electronic record-keeping systems? You will be leading a significant cultural change and you need to feel committed to it. Second, do you feel you can recruit the support of sufficient numbers of your colleagues to give the project enough momentum to overcome some inevitable clinician opposition? The answer to both questions should be yes.

#### Criteria for evaluating a system

There are several electronic anesthesia record systems on the market. The choice should take into account the needs of both the clinicians and the institution. The following is a brief overview of priorities in evaluation; the order of priority will not be the same for all institutions.

• *Enhance quality of patient care.* This should always be the number 1 criterion. It is not difficult to justify electronic medical record keeping on this one issue alone. Safety is enhanced by the easy accessibility and legibility of old records and the ability to track outcomes and improve record keeping for quality improvement initiatives. In addition, electronic systems are a necessary first step in the move towards evidence-based practice and decision support.

- *Vendor history.* These systems must be robust and reliable. The best guarantee of this is a vendor with a long track record in the field, a commitment to the future of their products, and the successful implementation of the system in many centers similar to your own.
- *Interoperability.* The system should integrate with other hospital systems. One of the principal advantages of an electronic anesthesia system (easy access to all the patient's medical data) is lost in "stand-alone" systems that do not have outside connectivity. In particular, the system should link with the operating room scheduling and management system, with the hospital admission, discharge and transfer (ADT) system, and with the clinical laboratory (Fig. 44.4). The Centers for Medicare & Medicaid Services (CMS) and the Joint Commission (TJC) are particularly concerned by the phenomenon of the "fractured" medical record. This is where a hospital has put in multiple different systems that do not communicate, and clinicians are limited in their ability to access the totality of a patient's record.
- Accessibility (information retrieval). The system should be easily accessible from many locations, including outside the operating room. Many systems now have web-based front ends to allow such accessibility, but the need to protect patients' medical information is paramount. Although enhanced accessibility of patient medical information was an important core goal in the original intention of the HIPAA legislation, it has sadly been largely ignored in the pursuit of privacy and security.
- *Scalability.* The system should be capable of adapting easily to operating suites of different sizes. A system that requires a large up-front investment for infrastructure and technology may be financially unjustifiable for a small institution. The initial cost and maintenance costs should be in rough proportion to the size of installation.
- *Improve compliance*. Because electronic systems encourage standardization of data entry and record keeping, there is significant potential to enhance compliance for billing and regulatory agencies.
- *Analytical tools.* Part of the power of electronic systems is their ability to analyze data to improve billing and compliance, to monitor outcomes, and to improve efficiency. Such analysis tools may or may not be provided with the system. At the very least, the system must be capable of interfacing with the reporting and analysis tools used by the hospital.

#### Forming the project group

It is unlikely that clinicians have sufficient expertise in information technology, budgeting, project management, etc. to put together an AIMS proposal by themselves. Your principal role is to provide clinical insights and to

Figure 44.4 Anesthesia information systems do not exist in isolation. Hospitals have many electronic systems, both clinical and administrative. An AIMS would exist as a subsystem in the section of "Patient Care" under "Perioperative Services\*" and/or "Clinical Departments\*." It is easy to see why there is always competition for IT resources, and why issues that are priorities for clinical departments such as anesthesia may not get the attention we think they deserve.

set clinical needs and priorities. Clinicians should insist that the hospital put together a project group that will oversee the project. The following are key members of this group.

- *Clinician colleague.* There should be at least one other clinician on the group to ensure representation of more than just your views. This colleague should be someone who has the respect of you and your colleagues.
- *Information technology.* The committee should have a representative from the hospital information technology department who can address issues such as the state of the existing or planned IT infrastructure, available human resources, etc.
- Hospital administration. A high-level representative of hospital administration is required to give the support needed to champion the project through to completion. One of the principal reasons why initiatives fail is because the project lacks support in the high levels of the administration.
- *Project manager.* In an ideal world the hospital has a department dedicated to project management. An individual from this group should be appointed to organize the resources and shepherd the project from inception to completion. If such an individual is not available, someone from information technology or the hospital administration will often act in this capacity.

- *Business/finance.* Since much of the financial justification of the project will be improved billing, enhanced compliance, and increased efficiency, a representative of the business side of the administration is very useful to the project.
- *Others.* The above comprises the core members of the group. If the project is to involve integration with other systems, such as the OR management/scheduling system, then someone from those projects should be closely involved from the beginning.

#### Setting the scope

The first crucial goal for the project group is to define the scope of the project. Will the system be used only in the main operating room suite? Will it be used in remote areas, e.g. interventional radiology, labor and delivery? Will it be an operating room system only or will it have a preoperative evaluation and a postanesthesia care unit (PACU) component? Will the new system require the upgrading of all the existing monitoring systems? What are the essential interfaces that will be required: the hospital ADT system, clinical labs, pharmacy, materials management, and billing? All are desirable, but all cost dollars and human resources. The scope should be settled pretty firmly before the project moves forward. It is really important to involve your clinical colleagues in discussion about the scope and what they see as essential

requirements for the system versus functions that would be merely "nice to have."

# Determining what systems are out there Personal contacts

There are several avenues to follow to determine what systems are available and which might best suit your needs. You, your colleagues or members of the information technology unit may know individuals in institutions with electronic anesthesia systems already installed. Personal contacts may provide information about a system, the vendor, and the implementation process that cannot be obtained easily from other sources.

#### **Professional publications**

There are several publications in the area of medical information technology. While they often have a significant industry bias, they can be useful because they have sections listing all the vendors in a particular area. The medical and anesthesia literature will occasionally have reviews related to medical information systems.

#### The internet

Simply typing "anesthesia information systems" into Google will bring up many sites for vendors of interest. Browsing these sites will often give background information (albeit slanted towards putting their system in a favorable light) about the system's capabilities.

#### Formal requests for information

You can make formal requests to vendors for information and proposal for a system or even a quotation for cost. Institutions usually have rules about soliciting such information. The IT department or a specific contracting group within the hospital may be the ones to make the contact. Before asking for this information, you should have specified your needs and the scope of the project.

#### **Evaluating systems**

Close attention must be paid to several areas when evaluating systems and vendors. These include the software itself, the quality of vendor support and responsiveness, and the level of resources needed to install and maintain the system. The IT representatives on your steering group will have had experience installing other hospital systems and should guide this process.

#### References

The prospective vendor should provide information about systems that have been installed in institutions comparable to yours. They should be able to provide names of individuals from the IT and clinical side of the system who are willing to talk with you and describe their experience.

#### Site visit

It is also very informative to visit sites that have the prospective systems installed. A very eager vendor might offer to pay the expenses for such a visit but this is not the norm and may violate conflict of interest and ethical guidelines at your institution.

#### Summary

Anesthesiologists will be involved one way or another with an AIMS implementation over the next few years. Installing a system and gathering the vast amount of data generated by these systems are just the first steps [38]. Whether you are a passionate advocate for electronic record keeping or not, it is important that, as a clinician, you have input into the process. If you are a leader in the project, you will have a great influence on the future practice of your colleagues, the majority of whom will much prefer an AIMS to paper [16]. You will also be embarking on a significant personal learning experience. It will probably take more effort and a greater commitment of time than you realize. Make sure to negotiate support from the hospital for the significant time commitment this will require of you.

### **Protecting electronic information**

The use of computers for collecting, storing and exchanging patient information opens up the possibility of those data falling into the wrong hands. All clinicians have an obligation to ensure that the data are only available to those for whom it is appropriate to access patient information. An example of a breach of privacy would be prurient examination of the medical information of a "celebrity patient" by curious healthcare workers. A quote by Hippocrates is apposite.

Whatever, in connection with my professional practice or not in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret. (Hippocrates 400 BCE, translated by Francis Adams)

In a somewhat chilling piece of legislation, the state of California has made healthcare providers individually liable up to \$250,000 for breaches of patient privacy. The individual's employer or malpractice insurance carrier does not cover this liability! In addition, in April 2010 a former employee at the University of California Los Angeles became the first person in the country sentenced to federal prison for a violation of HIPAA.

# Heath Insurance Portability and Accountability Act

In the United States 12 cents of every insurance premium dollar goes to support the insurance company; in Canada it is 1 cent. Healthcare providers in the US spend about 20% of total revenues on billing and administrative costs related to dealing with the very large number of insurance entities. In 1991, President Bush reached an agreement with the insurance industry that they would *voluntarily* convert to a system of standardized transactions. This did not happen!

In 1993 the Clinton administration introduced legislation to provide standardized transactions. Because such simplification would make patient-identifiable information more accessible, Congress argued for the inclusion of provisions for added privacy and security. The HIPAA was passed into law on 21 August 1996.

Amongst its many provisions are several relating to the use of electronic healthcare information. The requirements of the HIPAA apply to all "covered entities." A covered entity is one in which any patient information is transmitted electronically, no matter how small a proportion it represents of the overall data management by the entity. Thus, hospitals, physicians, other healthcare providers, health plans, plus their employees are covered entities. That means any clinician using any electronic means to use or access patient information is covered by the HIPAA and requires some basic knowledge of its provisions. The two areas of most relevance are privacy and security.

The HIPAA covers three areas: insurance portability, fraud, and administrative simplification. It is administrative simplification that is addressed in this chapter. Under administrative simplification the topics relevant to this discussion are privacy, security and standardized transactions.

#### Privacy

If a covered entity transmits any data electronically, then all protected health information (PHI), whether electronic or not, must be handled in accordance with the privacy rule. This means essentially that every healthcare establishment falls under the HIPAA regulations. PHI includes all information that can be matched to a patient, is created in the process of caring for the patient, and is kept or used in any manner, written, oral, or electronic. For a list of all information that is PHI, see Box 44.1. Research records of patient care are also PHI. If all the identifiers listed in Box 44.1 are removed then the material is no longer PHI.

All patients must be provided with an official notice of privacy rights and practices, and a good faith attempt must be made to obtain a written acknowledgment of receipt of these materials. It is usually not the responsibility of an anesthesia provider to give this notice and obtain consent. Thereafter, routine use of PHI for treatment, payment or healthcare operations is permitted, without further consents being necessary.

Authorization is required for release of specific elements of PHI for specific purposes outside routine use or disclosure, e.g. application for insurance coverage, for an employment physical examination, for marketing or fundraising, or for clinical research. The authorization document must be signed by the patient and specify an expiration date or event. Authorization is required for any clinical research that involves access to or collection of PHI.

The clinician may both use (share data within the institution) and disclose (share data outside the institution) PHI. An example of the former is looking up results of tests in the clinical laboratory database. An example of the latter would be communicating with a patient's primary physician outside your institution. The Minimum Necessary Standard covers many exchanges of data, i.e. do not transmit more information than is absolutely necessary. However, this standard does not apply to treatment-related exchanges between healthcare providers. As an anesthesia provider, you have full access to any part of a patient's medical record (in any medium) that you consider necessary to provide care.

#### **Business associate contract**

An entity is not responsible for monitoring compliance of other entities with which it shares PHI. It must, however, have a contract with the other entity stating that the entity will comply with the Privacy Rule. As an anesthesia provider, you may be involved with industry representatives regarding devices, equipment, etc. The HIPAA applies to all interactions you have, and you should be aware of the requirement to ensure that the proper agreements are in place if those representatives will have any exposure to PHI.

#### Patients' rights under the HIPAA

Patients have an unlimited right to restrict or amend the use or disclosure of PHI. However, the clinician is under no obligation to treat that patient if the restrictions are considered to compromise the quality of care delivery. Patients have a right to access their records if they are part of a designated record set. A designated set is defined as any data that were used to make a decision about an individual. This applies to records held by the entity and by any business associate.

#### Security

Strong security is required to ensure that persons not authorized to have access to it cannot obtain PHI. A good security system emphasizes three areas: confidentiality, integrity, and availability. Confidentiality means that only appropriately authorized individuals have access to PHI. **Box 44.2** Questions to ask yourself about your own approach to data security

- Do you store any patient information in publicly accessible areas? Is it posted where the public can see it?
- Do you send any patient information over email or fax?
- Do you share any patient information with anyone over the phone?
- Do you store any patient information on paper? Is it in a secure area?
- Are patient data stored on your computer or on a server?
- Can anyone access patient information on your computer without your permission?
- Do you send patient information to anyone outside your institution?
- Can you track who accesses your databases and what they view?

Integrity means that data can be altered only by those authorized to do so. Availability means that data are readily accessible by those who need them.

The basis of strong security lies in creating both a culture and an infrastructure that make security possible. The world of electronics has opened up many new opportunities for breaches of PHI security. Box 44.2 lists the questions you should ask yourself if you handle, store or transmit any PHI (paper or electronic). Your hospital or clinical department should have IT professionals who can advise you how to make your data as secure as possible. Some states, such as California, take security of PHI so seriously that they have laws making individuals (not their employer) personally liable for breaches of PHI security.

Security starts with an appropriate culture of human behavior (Box 44.3); this leads to an appropriate computer policy, which in turn determines the technical mechanisms (infrastructure) to be used. Inappropriate individual behavior will defeat even the best electronic security systems. An example of human behavior that will defeat the system might be a physician who carries unprotected PHI in a personal digital assistant that is then left in a public place. Another example is careless discussion about patients by providers in public areas (such as elevators). Unless the human/organizational culture changes first, technical solutions will fail to provide security.

### **Standardized transactions** Transactions

The intention of the HIPAA was that simplification brought about by having standards for transactions and codes, should decrease administrative overheads in healthcare. The standards apply to all health plans, clearing houses and any providers that transmit electronic data under the umbrella of the HIPAA. A standard is simply "what most people use." For example, Health Level 7 (HL7) is a current standard for clinical data interBox 44.3 Good practices to safeguard the security of PHI

- Do not share passwords under any circumstances
- Always use a "strong" password (at least 6 characters with at least 3 of them being a capital letter, number or symbol), and change it at least every 90 days
- Log off computer stations when finished with use
- Destroy all papers containing PHI in shredder or locked disposal bins (never in a trash can)
- Do not leave PHI, in any form, lying around
- Do not send PHI over an unsecured email system (e.g. to outside physicians)
- Do not send PHI to an unsecured fax machine
- Do not leave PHI messages on voicemail
- Password protect all electronic devices with PHI

change and the Institute of Electrical and Electronics Engineers (IEEE) publish standards for clinical instruments. These are the data transmission standards used when connecting vital signs monitors to an AIMS.

#### **Code sets**

Several code sets are mandated for use in electronic transactions. For diseases, the *International Classification of Diseases*, 9th edition, clinical modification (ICD-9-CM) will be used. For physician services, e.g. surgical procedures, the Current Procedural Terminology, 4th edition (CPT-4) is used. These code sets will also change over time. ICD-10-CM has recently been released in the United States, and the Department of Health and Human Services has mandated that it be used to replace the ICD-9-CM codes effective October 1, 2013.

#### **Identifiers**

An initial intention of the HIPAA was to introduce unique identifiers for individuals, providers, employers and health plans. Because of a strong negative response from the public, implementation of the individual identifier has been postponed indefinitely. This was a significant setback for any attempt to create a national data repository of patient healthcare information. The unique national provider identifier (NPI) is a 10-digit number issued to healthcare providers under the National Plan and Provider Enumeration System (NPPES) mandated under the HIPAA. For a healthcare organization, the identifier is their income tax code.

#### Patient care

One of the earliest questions asked about electronic systems was whether they enhance or detract from patient care [39]. The detractors will contend that poorly designed or unreliable systems take more time and are a distraction

from patient care; this is indeed true [40]. They will argue also that manual entry of vital signs on a paper record requires the clinician to actually pay some attention to the monitors and recorded values; this also is a valid argument [41]. Proponents of electronic documentation take the position that more attention can be paid to direct observation of the patient by the clinician who is freed from the task of writing on a paper record and that this occurs without loss of vigilance [42]. They will contend that data recording is more timely and complete, and that electronic systems enhance evidence-based practice and decision support [27,43].

#### Compliance

One of the most onerous tasks facing anesthesia practitioners is keeping up with the increasing mandates for documentation needed to comply with the requirements of the various regulatory agencies and payers. Not only must these required elements be documented, but compliance must also be tracked and reported. Many elements of performance must be documented in a very specific and complete manner. An example would be the requirements for insertion of a central venous catheter. There are elements of performance that constitute good clinical practice, and the clinician must not only adhere to the practice guidelines, but must document the individual elements performed. Using an AIMS can facilitate data entry, tracking, and reporting if the elements are built into the protocol for that procedure in the record (Fig. 44.5) [44,45].

#### **Enhanced documentation**

Electronic systems can provide automated reminders for necessary documentation or intervention. This enhances patient care by, for example, improved documentation of allergies or timing of antibiotic administration (Fig. 44.6) [46–48]. Real-time recording of data is important for accuracy and completeness, but timely documentation is

**Figure 44.5** Electronic systems can greatly enhance the clinician's ability to fulfill regulatory requirements for following, tracking and reporting compliance with clinical guidelines. This shows a screen allowing checkbox documentation of the required elements for inserting a central venous catheter using good clinical practice. The checkboxes serve as an *aide mémoire* to good practice, and are in a highly structured data format that can be easily tracked and reported on, and modified as guidelines and regulations change. This illustration is taken from the AIMS used at the University of California San Francisco. Its use in this figure does not imply an endorsement of the product.

**Figure 44.6** Electronic systems can also incorporate reminders to the clinician to perform certain tasks. In this illustration, the red box in the cefazolin row shows that prophylactic antibiotic has not been given. Once the antibiotic is charted, the red box disappears. If the procedure goes on sufficiently long, then a red box will reappear at the appropriate interval to prompt redosing of the antibiotic. In a similar manner, prompts can be given for required data entries, e.g. an attending signature, or to draw attention to events that are out of chronological order. This illustration is taken from the AIMS used at the University of California San Francisco. Its use in this figure does not imply an endorsement of the product.

often impossible, for example, in crisis situations. Speechactivated recording to an AIMS has now reached a level of functionality that makes its use practical for crisis situations in the operating room [49]. Outside the operating room, hand-held devices can be used to link directly to the AIMS and allow data entry by clinicians during preoperative evaluations or anesthesia rounds [50].

#### Data retrieval

It goes without saying that information in an AIMS or EMR should be easily available to the clinician who needs it. There are two main obstacles to achieving this desired state. First is the fact that only about 1% of hospitals have a truly integrated EHR so that all data in the record are available through a single source. Most hospitals have a multitude of different systems, all with different levels of security, usernames, passwords, and types of workstations on which they are available. This is a problem of real concern when the universal system, which is the paper record, is replaced by multiple and poorly interacting electronic systems. The ideal data retrieval system would tailor information to specific providers (e.g. residents on specialties) and provide it on media (e.g. PDA, tablet) most useful to the provider. In addition, it should be available wherever the provider happens to be working. We are a long way from achieving that vision in any widespread sense.

Data retrieval can also be affected by the stability and speed of the underlying system. Systems that go down frequently or function slowly significantly impair the clinician's ability to retrieve data. Lack of ability to retrieve data can actually lead to patient harm, and a particularly vulnerable time is when a new system is implemented and clinicians are not yet comfortable and competent with it [51].

#### **Evidence-based medicine**

Evidence-based medicine (EBM) has been defined as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research" [52]. The optimal application of EBM requires two things. The first is clinical expertise in the acquiring of information from the patient via history, physical examination and performance of appropriate tests. The second is combining those results with the best available external knowledge (the medical literature) and applying this information to the patient's diagnosis and treatment. EBM gives less importance to intuition and more to a systematized approach to healthcare. This does not devalue individual clinical expertise, but rather supplements it.

Clinicians can perform their own *ad hoc* searches for clinical guidelines and evidence-based recommendations. The American College of Cardiology, American Heart Association, and Anesthesia Patient Safety Foundation all have websites that provide evidence-based guidelines for preoperative cardiac assessment and perioperative  $\beta$ -blockade management. However, the information on different sites may at times be conflicting and outdated. Evidence-based practice with an AIMS works best if the institution arrives at a consensus practice for the areas where there is strong and current evidence for best practice and embeds those into the EMR and even the AIMS.

#### **Decision support**

There are two general categories of information – patientspecific information and knowledge-based information. Patient-specific information is generated from the care of an individual patient. This comprises a careful, thorough history and physical examination plus the results of all tests and interventions. In the computerized world this information resides in the electronic medical record. The other category is knowledge-based information which consists of the scientific literature of healthcare. Computers provide the means for information retrieval and evidencebased medicine. When those two information systems are combined you have a decision support system. Decision support can also be defined as "the application of information from knowledge-based systems to an individual patient."

While clinicians may initially be wary of such systems, there are design characteristics that encourage acceptance [53]. The system should guide practice, not coerce it. The systems should not block nor lock out the physician. Systems should be perceived as being helpful in compensating for human failure. Computer-based clinical decision support systems can enhance drug dosing, reduce errors, enhance safety, and improve compliance with clinical guidelines [17,18,54]. To date, the preponderance of evidence suggests that computerized clinical decision support systems improve practitioner performance [55]. However, improved patient outcome from use of these systems is yet to be convincingly demonstrated [55].

Protocols for anesthesia technique can be built into the AIMS. For example, this might automatically load all the required drugs, fluids, and monitors that would be used in a given case. Included in this, for example, might be practice guidelines for prophylactic antibiotic administration. Such systems have been shown to improve timeliness in the administration of preoperative antibiotics [56]. The system can also be automated to include reminders to redose intraoperative antibiotics (see Fig. 44.6). Other protocols might include a set of advanced cardiac life support guidelines to facilitate resuscitation procedures.

There are significant consequences to implementing clinical guidelines and recommended best practices. They require constant maintenance to keep up with advancing knowledge and changing regulations. There must be acceptance that the clinician has the ultimate authority to determine the care for an individual patient. Inherent in this principle is the clear understanding that deciding to adopt a plan different from the guideline or protocol is not *per se* practicing below normal standard of care.

#### Using the system for perioperative management support

Installing a system and gathering the vast amounts of electronic data available are just the first steps. Greater advantage is obtained from the system if it is used to analyze the information and to guide perioperative management decisions.

#### Staffing plans

An example of this might be in optimizing human resource use. Operating rooms do not keep regular hours, and planning how many providers are required at different times of the day is a difficult problem. Programs exist that use case start and end times to analyze and project staffing needs at different times of the day [57]. Enhanced scheduling of staff may be a significant advantage of the installation of the electronic information system.

#### Quality improvement

Anesthesia-related adverse events are under-reported chronically [11,58]. Voluntary reporting can be facilitated by building it into normal workflow as an integral part of the EMR. Clinicians in general support such a system [45,59]. Electronic information systems can increase the detection of some adverse events by automated scanning and extraction [60,61]. There is a strong association between adverse events and in-hospital mortality [58], so improved detection of and corrective measures for adverse events should lead to enhanced quality of care.

# Potential pitfalls with electronic documentation

#### Documenting on wrong patient

It is very difficult with a paper record to enter information under the wrong patient name. Usually the record is blank and the correct name will be written or stamped on the paper by the clinician. Should a mistake be made, the record can be corrected by judicious scoring out of the erroneous data and appropriate correction made. The situation is not so simple with an electronic record. If the wrong patient is selected at the beginning of the record entry, then thousands of pieces of data will be entered into the wrong record. Retrieving and reassigning data inthis case are very difficult. The easiest fix is usually to delete the electronic record entirely and create a paper record instead, a far from elegant solution.

#### Data entry errors

Garbage in, garbage out is the operative phrase here. All AIMS require a significant amount of manually entered data, drug doses, descriptions of procedures, perhaps laboratory values, etc. Some systems use checkboxes to document events, and it is easy to check the wrong box. Such errors may go unnoticed since many data entry pages exist in the background, and once the entry is made they will not be looked at again.

#### Artifacts

It is the nature of clinical monitoring that many values are clearly incorrect. Such artifacts may be due to electrical interference with, for example, the ECG, movement artifact with the pulse oximeter reading, or incorrect arterial blood pressure readings when the line is flushed [62]. With a paper record, these values were simply not recorded, but with automatic electronic data collection they may be. It is possible to automatically filter some but not all of these artifacts [62]. Other options include deleting the value, altering the value, or annotating the record to explain the artifacts. The authors recommend the annotation approach rather than deletion or alteration. In an electronic system, all entries, modifications, and deletions are tracked and retained in the record. Deletions or alterations may be hard to defend (especially if not explained), while a simple annotation of the reason for the artifact will leave the issue quite clear.

#### Missing data

Data enter the electronic record in two ways. First, they are automatically transmitted from devices, vital signs monitors, and interfaces with other systems, e.g. ADT. While usually robust, the data flow may be interrupted and not noticed by the clinician for a period of time. This can lead to vital sign data being absent from the record and creates medico-legal liability [32]. Second, the clinician is required to enter many data elements manually. When this is not done records are often incomplete [63]. Designing manual data entry in logical sequences and providing prompts to enter the data where possible can mitigate, but probably not eliminate this problem.

#### Self-population of entries

One of the real advantages of an AIMS is that "boilerplate" type documentation can be entered automatically by the system. One of the consequences of living in a world obsessed with regulatory requirements is that every single element of care must be documented, or it is considered never to have happened. A simple example might be the meeting with the patient in the preoperative holding area. Providers will, for example, check the patient's identity, confirm the surgery, ask about NPO status, examine the airway, discuss the anesthesia plan, and obtain informed consent. Each of these interactions must be documented individually. With an electronic system, one press of a key or click on an icon and all the necessary statements are entered in the record. This is now complete and standardized, and fulfils compliance requirements. Of course, each of the items that are documented should in fact have been done. Overuse of automatic data entry can lead to problems if some of the documented interventions have not actually been performed.

#### Cloning

This is a term for the process whereby old data entries are replicated uncritically and automatically from one record to the next. Electronic records enable "copy forward" procedures and this is in many cases valid and useful. However, incorrect information may be promulgated, and items that should be updated are left unchanged. Unless this process is controlled by professional behavior or electronic means, there is a potential for what amounts to documentation fraud.

### Research

#### **Information retrieval**

One advantage of hospitals with an EMR and AIMS is that computer workstations are usually easily accessible. As a consequence, the clinician who wishes to search the literature has access to a vast array of online data. There are two major pitfalls. The first is searching in such a way that the actual information you seek will be found in a short period of time. The second is judging the quality of the information retrieved. When planning a search, the goal should be to optimize both the sensitivity of the search (i.e. the chance of finding what you want) and the specificity (i.e. avoid being inundated with nonrelevant information).

The simplest way of finding information is to go to one of the many websites that offer clinically relevant information directly. Sites such as MDConsult (mdconsult. com), UpTodate (uptodate.com) and AccessMedicine (accessmedicine.com) are invaluable tools in finding answers to basic clinical care questions. In anesthesia there are many sites that specifically give expert practical information. Examples (out of many such sites) are directions on placing regional blocks (nysora.com) or performing a bronchoscopy (thoracic-anesthesia.com). Navigating these sites is simple, and the information is to a large degree vetted by experts and therefore reliable. The process gets a lot more complicated when you start to search the online medical literature.

#### **Online literature search strategies**

A good strategy for efficient searching is to start in a site that has a focus on the type of information that you seek. For the medical science literature, PubMed (www.ncbi.nlm.nih.gov/pubmed/) is still the definitive source. If your question involves specifically evidencebased medicine, then the Cochrane Library (www. cochrane.org), the Agency for Health Care Research and Quality (www.ahrq.gov) and the National Guidelines Clearing House (www.guidelines.gov) are excellent resources. Scirus (www.sciris.com) limits itself to searches of science-specific web pages. Alternatively, you can start your search at a site that deals with the specific disease entity or organ system in which you are interested, for example, the National Cancer Institute: CancerNet (www.cancer.gov). Finally you can start at specific subspecialty websites. For example, the website for the American Society of Anesthesiologists (www.asahq.org) has up-to-date information on standards, guidelines, consensus statements, etc. related specifically to the practice of anesthesiology.

If you use general web search engines, Google for example, there is so much information available (much of it non-scientific) that it is quite possible to be inundated by both useful and non-useful data. It will save a lot of time if you plan your search before starting. For example, in Google, typing in the query *awareness under anesthesia* will generate over 4 million hits. Switching to the Google Scholar search engine decreases this number to a mere 102,000 hits. Putting quotation marks around the phrase limits the search to the exact phrase only and reduces the number of hits to about 370. Other modifiers such as preceding the search phrase in Google with "allintitle:" further limits the search to web pages with the exact title and results in only 18 hits.

The order in which the hits are presented may not exactly match the quality of the content. Judging the quality of the information recovered in searches is a necessary skill in this era when vast quantities of information are so easily available [64]. A comprehensive description of methods for analyzing and validating scientific papers is beyond the scope of this chapter, but an online guide to evaluating the literature (www.vetmed.wsu.edu/ courses-jmgay/EvalGuide.htm) that was produced by the College of Veterinary Medicine at Washington State University is a good place to start.

A more in-depth discussion is provided in the excellent series of papers by Trisha Greenhalgh published in the *British Medical Journal* and gathered in a book entitled *How to Read a Paper: The Basics of Evidence Based Medicine* [65]. Since the publication of these articles in 1997 [66,67], much has changed in the world of medical literature. The internet, as we know it, and e-publishing did not exist when the articles were first published. The explosive growth of non-peer reviewed articles has made it more important than ever that the reader critically assess the validity of the work, and the principles espoused by Greenhalgh are as relevant as ever.

#### **Data repositories**

The proliferation of electronic data capture facilitates the creation of large data repositories that provide opportunities for new avenues of outcomes research. Multicenter outcomes research in anesthesia is not new; in fact, in 1954 Beecher and Todd published the first such study on deaths associated with anesthesia and surgery [68]. However, with manually collected and recorded data, the effort and resources involved in such multicenter studies limited the number and scope that could be performed. The advent of AIMS and EMRs has provided the opportunity to ask many more and wider-ranging outcome questions from data automatically uploaded into large data repositories from many sources.

There are several efforts under way to create anesthesia data repositories. Some individual institutions, such as the Cleveland Clinic, already have their own extensive clinical information data repositories. In other areas, national anesthesia data repositories are being created.

The Multicenter Perioperative Outcomes Group (MPOG) was formed by a group of academic anesthesia departments that use an AIMS. Its purpose is to "promote multi-institutional collaboration on outcomes research to advance knowledge and improve patient care in

perioperative medicine." Leaders of the University of Michigan Department of Anesthesia initiated the project, and the MPOG data repository is hosted at the University of Michigan.

In 2008, the American Society of Anesthesiologists (ASA) created the Anesthesia Quality Institute (AQI). Under AQI, the National Anesthesia Clinical Outcomes Registry (NACOR) was created. The aim of the NACOR is to cast a very wide net, essentially to take all available electronic data elements from any anesthesia practitioner willing to upload it. The gathering of small amounts of data from wide-ranging sources by AQI complements the MPOG's gathering of rich datasets from a limited number of institutions.

#### Informatics

Managing the vast amount of data in these repositories involves the science of informatics. The term is a contraction of "information science" and is defined by the Merriam-Webster dictionary as "the collection, classification, storage, retrieval, and dissemination of recorded knowledge treated both as a pure and as an applied science." Medical or health informatics is the science of informatics as it relates to the fields within healthcare and biomedicine. Medical informatics is a relatively new science; the term was first coined in the late 1970s. There are several subcategories under the general umbrella of medical informatics, and one of the most recently created is "anesthesia informatics" [69].

The pure science of medical informatics relates to theoretical aspects of information and knowledge management, and is not within the scope of this chapter [70]. The applied component deals with how information is used in the service of patients and clinicians. It makes more sense when you realize that fundamentally, clinicians gather information and use their knowledge to make diagnoses and decide on interventions. The amounts of both information and knowledge are increasing beyond the capacity of individuals to manage them. Therefore, medical informatics is a vital tool for optimizing this process and for analyzing the vast amounts of data to create useful information for the clinician [71]. The judicious use of informatics in medicine promises, amongst other things, the possibility of decreasing medical errors [17].

Healthcare professionals with knowledge of informatics raise the quality of information processing, and the quality of information processing influences the quality of healthcare itself. This is particularly true in anesthesia where only anesthesia professionals who can speak the languages of both informatics and clinical care can optimize design of the information-gathering, data retrieval, and decision support systems to function in the real-time, immediate environment of anesthesia practice.

### **CHAPTER 45**

# Operating Room Safety, Communication, and Teamwork

### Thomas L. Shaw & Stephen A. Stayer

Department of Anesthesiology and Pediatrics, Baylor College of Medicine, and Texas Children's Hospital, Houston, TX, USA

Introduction, 1279 Non-technical skills, 1279 Medical team training, 1280 Anesthesia Crisis Resource Management, 1280 TeamSTEPPS<sup>®</sup>, 1281 Hand-offs, 1284 Checklists, 1286 Medication safety, 1287 Incidence, 1288 Types of medication errors, 1288 Risk factors, 1289 Prevention, 1289 Pay-for-performance, 1289 Safe systems in the operating room, 1289 Conclusion, 1291 Annotated references, 1291

### Introduction

"In solo or group practice, teamwork is a major part of the anesthesiologist's life. Whether a vital part of a surgical team, a member of an interdisciplinary group of diagnosticians at a pain clinic, or a partner on a research team or teaching faculty, an anesthesiologist works continuously with a variety of medical professionals" [1]. This quote from the American Society of Anesthesiologists career information webpage summarizes the importance of teamwork in the daily life of all anesthesiologists. Teamwork can be defined as "the ability of team members to work together, communicate effectively, anticipate and meet one another's demands, and inspire confidence resulting in a co-ordinated collective action" [2]. In 1999, the Institute of Medicine published a report entitled To Err Is Human: Building a Safer Health System [3]. This highlighted the fact that systemic failures in healthcare delivery account for more errors than poor performance by individuals. The Institute of Medicine recommended interdisciplinary team training to reduce the incidence of such medical errors. Effective teamwork can provide a safety net that can often prevent human errors from becoming a patient safety issue. This chapter will review the basic principles of operating room and anesthesia safety as they apply to pediatric patients, emphasizing the non-technical skills of communication and teamwork as crucial to patient outcomes.

### **Non-technical skills**

In the 1970s, the investigation of several airplane crashes concluded that no mechanical failure of the aircraft or technical failure of the pilot had occurred. So why did these planes crash? The investigators blamed deficits in other human factors, characterized as non-technical skills [4]. Non-technical skills are defined as "the cognitive, social, and personal resource skills that complement technical skills, and contribute to safe and efficient task performance" [5]. These skills do not directly relate to medical knowledge, technical expertise, drugs, or equipment. For example, a surgeon could demonstrate excellent technical skills during the amputation of the wrong foot (lack of situational awareness). Non-technical skills have been increasingly recognized as crucial to maintaining patient safety. Non-technical skills can be classified as (i) cognitive and mental skills (such as decision making, planning, and situation awareness) and (ii) social and interpersonal skills (such as communication, teamwork, and leadership) [6]. Traditionally, medical training has not formally taught these skills and deficiencies in these skills have

been reported amongst anesthesiologists [6,7]. Medical team training focuses on the cultivation of these non-technical skills.

## Medical team training

Clinical training usually focuses on the individual execution of tasks. Safe and efficient patient care requires the co-ordination of activity amongst physicians, nurses, respiratory therapists, pharmacists, and other healthcare professionals. However, all of these team members are rarely trained together. Effective teamwork is not reliably learned without formal training and cultivation. Team training teaches a set of tools and strategies that requires a mental shift from an individual perspective to a team perspective, as shown in Figure 45.1.

Several different medical team training programs have been developed. Medical team training programs can be categorized into high-fidelity simulator-based programs and classroom-based programs. The high-fidelity simulator-based programs rely upon patient simulators and include courses such as anesthesia crisis resource management (ACRM) [7] and team-oriented medical simulation (TOMS) [8]. The classroom-based team training programs rely upon lectures, videos, demonstrations, and role play. Classroom-based programs include TeamSTEPPS<sup>®</sup> (Team Strategies and Tools to Enhance Performance and Patient Safety) [9], MedTeams<sup>®</sup> [10], medical team management, Lifewings<sup>™</sup>, and geriatric interdisciplinary team training.

There is considerable overlap between all of these training programs, and there is no evidence that one training program or method is superior to another. Advocates of high-fidelity simulator-based programs list several advantages [11]. Simulators provide hands-on training in a realistic environment. The environment mandates the integration of decision skills, procedural skills, and teamwork skills in a scenario that actually challenges and stresses the clinician. Advocates of classroom-based programs highlight the lower cost, mobility, and ability to train large numbers of students simultaneously [12]. A detailed discussion of ACRM and TeamSTEPPS<sup>®</sup> follows.

### **Anesthesia Crisis Resource Management**

In 1989, David Gaba and his colleagues at Stanford University and the Palo Alto Veterans Affairs Medical Center pioneered the adaptation of aviation crew resource management to the practice of anesthesiology, resulting in the curriculum for anesthesia crisis resource management (ACRM) [7]. The phrases "crew resource management," "crisis resource management," and "cockpit resource management" are used interchangeably throughout the literature. Crew resource management can be defined as a management system which makes optimum use of all available resources (equipment, procedures, and people) to promote safety and focuses on teaching nontechnical skills. The ACRM course begins with didactic presentations regarding anesthesia safety, decision making, specific anesthesiology crisis scenarios, and system-related failures that affect patient safety and human performance. Also, course participants critically analyze a video of an aviation accident. The bulk of the course consists of simulations followed by detailed debriefings. The simulator sessions feature a realistic patient simulator in an operating room environment in which each participant is the primary anesthesiologist managing critical event scenarios. Significant interaction between nursing and surgical personnel (role-played by instructors) is required during the scenarios. Emphasis is placed on working more effectively with different leadership, followership, and communication styles. The simulation sessions are video recorded and analyzed by the team during debriefing sessions with the help of an

instructor. The key points emphasized in ACRM are listed in Box 45.1. See Chapter 42 for a more detailed discussion of simulation in pediatric anesthesiology.

## **TeamSTEPPS®**

TeamSTEPPS® (Team Strategies and Tools to Enhance Performance and Patient Safety) is another resource for training healthcare professionals in better teamwork practices. The Patient Safety Program of the Department of Defense and the Agency for Healthcare Research and Quality collaborated for 20 years to explore the field of medical teamwork. TeamSTEPPS® is an evidence-based teamwork training system focusing on four complementary competency areas: leadership, situation monitoring, mutual support, and communication [9]. These are all teachable and learnable skills and should not be viewed as skills that a person "either has or does not have." TeamSTEPPS<sup>®</sup> offers a free public domain toolkit that can be tailored to any healthcare setting [13]. The free educational material on the TeamSTEPPS® website includes presentations, group exercises, and videos. The Agency for Healthcare Research and Quality also offers a free TeamSTEPPS® instructor course so that an institution can develop in-house expertise on team training. TeamSTEPPS® can be used by all healthcare organizations and all medical specialties. This open availability may allow the entire medical field to begin using a common language and approach to team training.

TeamSTEPPS<sup>®</sup> teaches specific tools and strategies to overcome barriers to team effectiveness. The tools and strategies are intimately linked to the four core competencies of the TeamSTEPPS<sup>®</sup> framework: team leadership, situation monitoring, mutual support, and communication, shown in Figure 45.2.

#### Leadership

"Leadership is the ability to direct and co-ordinate activities of team members, assess team performance, assign tasks, develop team knowledge and skills, motivate team members, plan and organize, and establish a positive team atmosphere" [14]. Effective team leaders organize the team, articulate clear goals, and make decisions through the collective input of members. They also delegate tasks, empower members to speak up and ask questions, actively promote and facilitate good teamwork, and are skillful at conflict resolution. Three strategies that leaders use to promote team information sharing are briefs, huddles, and debriefs.

A brief, also known as a team meeting, is held for planning purposes and lets everyone on the team know what is planned and why. It is a short planning session to discuss subjects such as a patient's current condition, diagnosis, the role of team members, team goals, potential complications, and back-up plans. Briefs open the lines of communication so that everyone can contribute their unique knowledge to the task. The team leader usually initiates the briefing, but any member of the team can do so. A huddle is an ad hoc discussion that focuses on problem solving. Huddles provide team members with an opportunity to update each other on changes in the status of the patient so that all team members can adapt. Huddles are used to re-establish situation awareness, reinforce plans already in place, and assess the need to adjust the plan. A debrief takes place after a procedure or event and focuses on process improvement. It is an informal information exchange session designed to improve team performance and effectiveness. Debriefs are most effective in an environment where

**Figure 45.3** Continuum of situation monitoring, situation awareness, and a shared mental model. Reproduced from Agency for Healthcare Research and Quality [13].

honest mistakes are viewed as learning opportunities and the focus is not placed on individual blame.

#### Situation monitoring

Situation monitoring is the process of continually scanning and assessing what is going on around you to maintain situation awareness [14]. Situation awareness is "knowing what is going on around you." When everyone maintains their situation awareness and shares relevant facts to ensure that all team members are "on the same page," a shared mental model is formed. There is a continuum that begins with the individual skill of situation monitoring that leads to situation awareness and collectively results in a shared understanding of the situation (referred to as a shared mental model) (Fig. 45.3).

Situation awareness can be undermined by one team member's failure to share information, request information, and direct information to specific team members. Cross-monitoring involves monitoring the actions of other team members and provides a safety net within a team. It involves "watching each other's back." Crossmonitoring can help catch mistakes early before they compromise patient safety. The STEP mnemonic (Fig. 45.4) is a situation monitoring tool that is a mental reminder to constantly monitor the Status of the patient, Team members, Environment, and Progress towards goal.

## Mutual support

Mutual support (or back-up behavior) is the ability to anticipate other team members' needs and to shift workload among members to achieve balance. Task assistance is a form of mutual support where team members protect each other from work overload situations. Some medical professionals are conditioned to avoid asking for help due to the fear of suggesting a lack of knowledge or con-

**Figure 45.4** The STEP mnemonic for situation monitoring. Reproduced from Agency for Healthcare Research and Quality [13].

fidence. Effective teams place all offers and requests for assistance in the context of patient safety and team members foster a climate where it is expected that assistance will be actively sought and offered.

Feedback is another type of mutual support. Feedback provides information to improve team performance. Effective feedback is timely (the behavior is still fresh in the mind of the receiver), respectful (should not be personal and should focus on behavior and not personality), specific (should relate to a specific situation), and directed (goals are set for improvement). Feedback can also be used to reinforce positive behaviors. Personal feedback is more effective when it is given in private as it causes less defensiveness on the part of the recipient.

Advocacy and assertion tools and strategies should be used when a team member's viewpoint does not coincide with that of the decision maker. The team member thus has the opportunity to correct errors or the loss of situation awareness. Failure to advocate and assert is frequently identified as a primary contributor to malpractice cases, sentinel events, and aviation disasters. If the safety of the patient is at risk, even an unpopular viewpoint that questions authority should be advocated. The twochallenge rule was initially developed to help airline pilots prevent disasters caused by momentary lapses in judgment. The two-challenge rule states that if there is concern for potential harm to a patient, that concern should be asserted at least twice. If after two attempts the concern is still disregarded, a stronger course of action should be taken using the chain of command. This overcomes the natural tendency to believe that the team leader must always be right. It is the responsibility of the person challenged to acknowledge the safety concerns and resolve any safety issues. Leaders must foster an environment where all team members feel empowered to speak up when they notice a safety issue, knowing that their inputs are welcomed.

The healthcare environment is susceptible to frequent and sometimes disruptive conflict. This is not surprising given that it is an environment with a number of highly educated, experienced individuals with different training, backgrounds, and priorities. TeamSTEPPS® teaches two basic conflict resolution strategies. Two different scripts are taught that can aid communication during times of conflict. The CUS (Concerned, Uncomfortable, Safety) script uses signal words to catch an individual's attention. First, a *concern* is stated, next the speaker states why they are *uncomfortable*, and finally they state that they believe there is a safety issue. The DESC (Describe, Express, Suggest, Consequences) script can be used to communicate effectively during all types of conflict. The specific situation is described. Concerns about the action are expressed. Other alternatives are suggested. Finally, potential consequences are stated. A private discussion between the individuals who have conflict will lead to more focus on resolving the conflict instead of a focus on saving face. The focus should be on what is right, not who is right. When resolving conflict, the goal should be to achieve collaboration, which means working together to achieve a mutually satisfying solution yielding a win-win situation.

#### Communication

Communication includes the efficient exchange of information and consultation with other team members. Communication is defined as the "exchange of information between sender and a receiver . . . the process by which information is clearly and accurately exchanged between two or more team members in the prescribed manner and with proper terminology and the ability to clarify or acknowledge the receipt of information" [15]. Communication is the lifeline of an effective team and the glue that holds all the team skills together. Improving the quality of information exchange decreases communicationrelated errors. In order for communication to be effective, it must be complete, clear, concise, and timely. How does communication relate to the other team skills? Effective leaders must communicate clear information so that team members are aware of their roles and responsibilities. Team members monitor situations and communicate any changes to keep the team informed. Finally, communication facilitates a culture of mutual support.

The Joint Commission on Accreditation of Healthcare Organizations (now officially the Joint Commission) has set specific safety goals related to communication, including the need for standardized hand-offs with the opportunity to ask and respond to questions. Closed-loop communication is highly recommended and is defined as information exchange behavior whereby a sender initiates a message, a receiver acknowledges the message, and the message is verified by the initial sender, as depicted in Figure 45.5.

Figure 45.5 Closed-loop communication. Reproduced from Agency for Healthcare Research and Quality [13].

TeamSTEPPS® teaches four communication strategies and tools that have the potential to reduce errors associated with miscommunication. SBAR communication is described as one effective tool. SBAR is a mnemonic that stands for situation, background, assessment, and recommendation. SBAR was originally developed by the United States Navy and adapted for use in the medical setting [16]. Many leading healthcare institutions support the use of SBAR, including the Institute for Healthcare Improvement and the Joint Commission. SBAR is a standardized communication technique that allows the speaker to be clear and concise. Call-out is a communication strategy exemplified when a team member verbally states what they are doing, observing, or thinking in real time. A call-out is used to communicate important or critical information during a crisis so that all team members know what is occurring. Examples of call-outs include stating the ability to visualize the larynx during emergency laryngoscopy and intubation, or announcing "clear!" before defibrillation during cardiac arrest. A read-back (checkback) is a process of employing closed-loop communication to ensure that information conveyed by the sender is understood by the receiver as intended. Read-backs avoid orders being given without being acknowledged and ensure proper understanding of orders. Hand-offs are emphasized as important communication processes that can result in patient harm if performed ineffectively. Hand-offs are discussed in detail in the following section.

Many barriers to effective communication exist. These include language barriers, distractions, varying communication styles, workload, and conflict. The teamwork tools and strategies can be used to overcome these barriers to effective communication. Figure 45.6 summarizes the barriers to team effectiveness, the tools and strategies

BARRIERS	TOOLS and STRATEGIES	OUTCOMES
<ul> <li>Inconsistency in Team Membership</li> <li>Lack of Time</li> <li>Lack of Information Sharing</li> <li>Hierarchy</li> <li>Defensiveness</li> <li>Conventional Thinking</li> <li>Complacency</li> <li>Varying Communication Styles</li> <li>Conflict</li> <li>Lack of Coordination and Follow-Up with Co-Workers</li> <li>Distractions</li> </ul>	STRATEGIES Brief Huddle Debrief STEP Cross Monitoring Feedback Advocacy and Assertion Two-Challenge Rule CUS DESC Script Collaboration SBAR	<ul> <li>Shared Mental Model</li> <li>Adaptability</li> <li>Team Orientation</li> <li>Mutual Trust</li> <li>Team Performance</li> <li>Patient Safety!!</li> </ul>

**Barriers to Team Effectiveness** 

Figure 45.6 Barriers to team effectiveness. Tools and strategies to overcome these barriers, and the desired team outcomes. Reproduced from Agency for Healthcare Research and Quality [13].

**Figure 45.7** Frequency of communication problems as the root cause of sentinel events. Reproduced from Joint Commission on Accreditation of Healthcare Organizations [19].

to mitigate these barriers, and the desired outcomes of team training as taught by TeamSTEPPS<sup>®</sup>.

## **Hand-offs**

A sentinel event is defined by the Joint Commission as "an unexpected occurrence involving death or serious physical or psychological injury" [17]. Examples of sentinel events include surgery on the wrong body part or the unintended retention of a foreign body such as a surgical instrument. The Joint Commission determined that between 1995 and 2006, nearly 70% of all sentinel events were caused by communication problems [18,19] (Fig. 45.7). More than half of the communication problems analyzed by the Joint Commission occurred during hand-offs. An analysis of one closed claim database showed that 40% of communication problems occurred during hand-offs [20].

A hand-off (also referred to as a handover, sign-out, transition, or sign-over) is defined as the transfer of accountability and responsibility of a patient from one healthcare provider to another. The Joint Commission states that the "primary objective of a hand-off is to provide accurate information about a patient's care, treatment, and services, current condition and any recent or anticipated changes. The information communicated during a hand-off must be accurate in order to meet patient safety goals" [18]. The daily workflow of anesthesiologists involves hand-offs to and from other anesthetists, surgeons, neonatologists, critical care physicians, emergency physicians, respiratory therapists, and perioperative nurses. Pediatric patients are particularly vulnerable to ineffective hand-offs due to their reduced capacity to advocate for themselves and provide information regarding their medical history [21]. Surprisingly, anesthesiologists are seldom formally taught how to perform this duty effectively.

Many specialties including anesthesiologists, surgeons, pediatricians, internists, and emergency medicine physicians have undertaken the qualitative evaluation of hand-offs, finding that they frequently lack a formalized structure [22–30]. They also note frequent omissions and distortions of important information. One study noted that pediatric interns overestimate the effectiveness of the hand-offs that they give [29]. The same study showed that almost 40% of the recipients felt that the most important information about the patient was not reported.

The Joint Commission has commented on the negative consequences of ineffective hand-offs based on the relationship with sentinel events. Analysis of closed claims databases has also demonstrated the contribution of ineffective hand-offs to wrong site surgery, wrong patient surgery, and unintended retention of foreign bodies [20,31]. Ineffective hand-offs have also been shown to result in medication errors, delays in diagnosis and treatment [32], completely missed diagnoses [33], and omission of handed over tasks [25]. Studies have also demonstrated the frequent inability of the incoming physician to find the missing information by means of the medical record [26].

There are many barriers to effective hand-offs. Most important is the lack of formal teaching of the handoff process. Other barriers include interruptions, noise, distractions, and the time constraints on performing hand-offs in a busy practice [21,34,35]. Outgoing physician fatigue also can decrease the quality of a hand-off. Social hierarchy can also have a negative impact on the quality of a hand-off. It is commonly noted that when receiving a hand-off from a more senior person, the more junior person is reluctant to ask questions and ask for clarification [21,34,36]. This is because the junior person fears the perception that they are questioning a superior.

Controversy exists amongst anesthesiologists regarding whether hand-offs should be formally structured. One survey of anesthesiologists reflected the perspective that standardization is burdensome and not needed, arguing that extra paperwork is an impediment to clinical care [37]. Another group of surveyed anesthesiologists felt that standardization would be valuable [38,39].

Regardless of the desire for or perceived need for standardization of the hand-off process, it is clear that standardization and inclusion of a written and verbal component decreases omissions and distortions, and improves recipient satisfaction with hand off quality [22-25,27,28,34,40]. Another feature of high-quality hand-offs is the inclusion of a read-back (also referred to as a checkback) [21,35,41-44]. A read-back takes place when the incoming provider (recipient of the hand-off) repeats what they heard during the hand-off to the outgoing practitioner who confirms accuracy or clarifies errors. This two-way feedback technique double-checks information accuracy and verifies that the recipient was actually listening during the hand-off. Finally, face-to-face communication during a hand-off is ideal due to the nonverbal information that can be conveyed via facial expressions, body language, gestures, and eye contact. Box 45.2 summarizes the characteristics of effective hand-offs [30,35,44].

It may be useful for an institution to consistently use one mnemonic throughout the hospital so that when surgeons, nurses, anesthesiologists, neonatologists, critical care physicians, and emergency medicine physicians communicate, they utilize a similar communication struc-

#### Box 45.2 Characteristics of effective hand-offs

- Format is standardized
- Contains a verbal and written component
- Read-back used to verify understanding
- Allows the opportunity to ask questions
- Pending studies are emphasized
- Hierarchy is flattened
- Interactive
- Information is up to date
- Contingency plans discussed
- Free of interruptions
- Quiet environment
- Face to face

#### Box 45.3 Sample protocol for hand-off in SBAR format

Receiving/incoming provider is first given ample time to review the preoperative evaluation, intraoperative record, and surgical note before the hand-off begins

- Situation
  - Patient age, weight, diagnosis, and medical/surgical procedure stated
- Background
- Allergies, medications, medical history, and surgical history stated
- Assessment
  - Airway/breathing: baseline respiratory status, airway management details
  - Circulation: hemodynamic stability, vasoactive infusions
  - Central nervous system: opioid doses, muscle relaxants, regional anesthesia techniques
  - Fluids/electrolytes/nutrition: aspiration risk, dextrose-containing fluids, electrolytes
  - Hematology: last hematocrit, estimated blood loss, blood availability
  - Infectious disease: antibiotic schedule, contact precautions
  - Renal: urine output
- Lines: intravenous access, central lines, arterial lines
- Recommendations
  - Pending tasks and studies are emphasized
  - Recommendations for further management given
  - Read-back performed
  - Questions are solicited and encouraged from receiving/incoming provider

ture. At least 24 different mnemonics for hand-offs have been described in the medical literature [45]. SBAR is the most frequently cited mnemonic. SBAR is one format that can be used to standardize hand-offs. Box 45.3 displays a sample hand-off protocol in SBAR format.

Effective team members are expected to ensure that their colleagues are well informed when sharing the care of a patient. Providing an effective standardized hand-off prevents lapses in information that can lead to mistakes.

## Checklists

In 1978, a study revealed that 14% of anesthetic mishaps could be attributed to failure of the anesthesia machine [46]. In 1987, the American Society of Anesthesiologists and the United States Food and Drug Administration collaborated to produce a generic anesthesia machine checklist to increase detection of malfunctions.

A checklist is a simple tool designed to reduce error and encourage compliance with best practice. Checklists are memory aids that list action items or criteria that have been determined to be essential to the success of a process or procedure. Indeed, "a short pencil is better than a long memory." Utilization of checklists is considered essential to safety in the industries of aviation, nuclear power, construction, and manufacturing [47]. Recent studies have also demonstrated positive applications in the medical field. Checklists are a proven component of interventions to reduce the incidence of central venous line-associated bloodstream infections, intensive care unit length of stay, and surgical morbidity and mortality.

Central venous line-associated bloodstream infections occur frequently, may result in death, and are considered mostly preventable [48]. In 2001, Pronovost and colleagues undertook a quality improvement project aimed at reducing the incidence of central line-associated infections [49]. The project included a checklist designed to ensure adherence to the infection control protocol. The checklist contained infection control guidelines that most practitioners recognize, but do not always follow. Use of the checklist resulted in a reduction in the mean rate of infections from 7.7 per 1000 catheter-days to 1.4 per 1000 catheter-days. Subsequent studies have reproduced these results, showing significant reductions in line-associated infection rates when a checklist is used [50–54]. Typical components of a central line insertion checklist are shown in Box 45.4.

Box 45.4 Central venous line insertion checklist

- Equipment assembled and supplies verified before procedure begins
- Nurse observes procedure and is empowered to intervene to ensure compliance
- Provider washes hands with antibacterial soap or waterless hand
   cleaner
- Provider wears hat, mask, sterile gown, and sterile gloves
- Insertion site scrubbed with 2% chlorhexidine (age >2 months) or povidone iodine (<2 months)</li>
- Patient covered from head to toe with sterile drape
- Sterile dressing applied and dated immediately after procedure

The intensive care unit is an environment where multidisciplinary co-ordination and communication are vital to patient safety and throughput. The entire care team must clearly understand the goals of care, list of tasks, and communication plan. The intensive care unit daily goals form is a type of checklist designed to improve communication between team members [55–57]. The top two priorities of the daily goals form are the conditions necessary to discharge the patient from the intensive care unit and reducing the patient's greatest safety risk. Several studies have demonstrated that the use of this form results in significant improvements in team understanding of the daily goals for a patient and significant reductions in patient length of stay [55,57,58].

The World Health Organization (WHO) recognizes that surgical complications are common and often preventable. It has been estimated that over 230 million major surgeries take place per year [59]. Of these, 7 million major complications occur, including 1 million deaths. A team of experts created the WHO Surgical Safety Checklist, designed to improve teamwork and prevent common causes of perioperative morbidity and mortality (Fig. 45.8). The WHO Surgical Safety Checklist promotes and facilitates good teamwork by helping the team develop a shared mental model with the use of a brief before anesthesia induction and a time out before skin incision. Before the procedure begins, the entire team introduces themselves by name in order to flatten hierarchy. The checklist also empowers team members to speak up if they notice any safety concerns.

Several components of the WHO Surgical Safety Checklist are related to the practice of anesthesiologists. The Checklist specifically encourages vigilance related to the presence of a difficult airway, risk of aspiration, risk of significant blood loss, the presence of allergies, and timely administration of prophylactic antibiotics.

The effect of the Checklist was evaluated in eight hospitals across the world, including several in developing nations and others in highly developed academic teaching settings. Implementation of the Checklist resulted in a reduction of death from 1.5% to 0.8% and a reduction in inpatient complications from 11.0% to 7.0% [60]. Considering the high volume of worldwide surgeries and the high complication rates [59], global implementation of the WHO Surgical Safety Checklist could lead to substantial reductions in surgical mortality and morbidity. One criticism of this landmark safety study is that although there was improvement in all hospitals, more of the improvement in outcome could be attributed to the hospitals in developing nations.

A recent study of a comprehensive perioperative safety checklist was conducted in six intervention hospitals and five control hospitals in The Netherlands, all tertiary care and academic hospitals with previously demonstrated

high standards and quality of care [61]. In 3760 patients studied before implementation of the checklist and 3820 patients after implementation, the total number of complications decreased from 27.3 to 16.5 per 100 patients (p < 0.001), and in-hospital mortality decreased from 1.5% to 0.8% (p < 0.001). These outcomes did not change in the control hospitals. Surgical safety checklists should be modified according to local institutional needs, including those of a children's hospital, where the surgical briefing may need to be done in the preoperative holding area with the parent present. One such modification is shown in Figure 45.9.

Checklists are important components of comprehensive patient safety interventions. It would be an oversimplification to state that checklists alone reduce central venous line-associated infections, ICU length of stay, and surgical morbidity [62]. Team education must first take place to build faith in the practices reinforced by the checklist. Barriers to the use of the checklist must be identified and eliminated or the checklist will often be left unused. Outcomes must be measured and feedback should be provided. Institutions should customize checklists to fit the needs and culture of their own organization.

One survey revealed that some physicians remain skeptical about whether or not checklists truly improve patient safety. The fact that almost all of those same skeptics wanted the checklist used if they themselves were having surgery speaks for itself [47]. The use of checklists that have shown evidence in improvements in patient outcomes should be embraced.

## **Medication safety**

The practice of anesthesia requires titration of multiple medications in order to safely produce the anesthetized state while maintaining hemodynamic and respiratory stability. Anesthesia providers also must have multiple medications immediately available to treat potential emergency situations that may develop during surgery. The environment is frequently chaotic and requires effective focus and skills in multitasking to avoid potentially lifethreatening medication errors. In modern medical systems,

# Texas Children's Hospital Surgical Safety Checklist- (VERSION 6.6)

**Figure 45.9** The Texas Children's Hospital Surgical Safety Checklist. The surgical briefing is done in the holding area or intensive care unit bedside, and initiated by the anesthesiologist with the parent present to verify information. The surgeon must be present for the briefing or have communicated to the anesthesiologist verbally or via written communication his/her plans and concerns for the case.

the anesthesiologist is in a unique situation with regard to medication administration: single-handedly responsible for ordering, preparing, and administering medications without a second person to cross-check. Pediatric patients are particularly vulnerable to medication dosing errors since most medications are administered on a dose per weight basis and incorrect measurement of weight, recording of weight, or calculation of dose can lead to significant overdosing or underdosing of medications.

## Incidence

Medication errors are common in healthcare systems and are reported to be the seventh most common cause of death overall. In 1999 the Institute of Medicine (IOM) issued a report indicating that 44,000–98,000 patients die each year as a result of medical errors, and a large portion are medication related [3,63]. A survey of members of the Canadian Society of Anaesthesiologists reported that 85% of respondents had experienced at least one drug error or near miss [64]. Similarly, 89% of respondents to a survey of anesthesiologists in New Zealand reported making a drug administration error at some stage of their career and 12.5% had actually harmed the patient [65]. Several prospective studies have found the incidence of drug errors during anesthesia to be between one per 133 anesthetics and one per 274 anesthetics, with major morbidities being rare [66–68].

## Types of medication errors

Various groups have classified medication errors, and Table 45.1 is a classification scheme proposed by Webster et al [66].

A report from the ASA Closed Claims Project compared medication error claims between 1990 and 2001, finding that pediatric patients had a higher proportion of claims compared to adults and incorrect dosing was the most

Type of medication error	Definition
Omission	Drug not given
Repetition	Extra dose of an intended drug
Substitution	Incorrect drug instead of the desired drug: a swap
• Insertion	A drug that was not intended to be given at a particular time or at any time
• Incorrect dose	Wrong dose of an intended drug
Incorrect route	Wrong route of an intended drug
• Others	Usually a more complex event, not fitting the above categories

Tab	le 45.1	Classification	scheme	proposed	by	Webster	et a	l [66]
-----	---------	----------------	--------	----------	----	---------	------	--------

common type of error (44% of errors) [69]. A recent report from New Zealand also found the most common type of error to be incorrect dosing [66].

### **Risk factors**

The large study from New Zealand evaluated many contributing factors to medication errors, finding a failure to check to be the most common (23%), followed by distraction (16%), inattention (13%), and haste or production pressure (10%) [66]. Interestingly, several studies have evaluated the risk of emergency surgery and this does not appear to be a contributing factor with medication errors.

#### Prevention

Webster and colleagues evaluated the baseline incidence of medication errors in two hospitals, both of which used a standard color-coding labeling system for medications used by anesthesiologists [66]. They evaluated the effect of implementing a new system designed to reduce such errors in one of the hospitals. This system included:

- labels with the class and generic name of each drug in large, clear lettering and incorporating a barcode
- alerts for known allergies and expired drugs
- custom software and a barcode scanner to allow a drug-identity cross-check before each administration, by redisplay of the drug name and its international color code on a computer screen and an auditory announcement of the drug name
- reorganization of the workspace using syringe trays and a color-coded drug tray, prefilled, standardized syringes for many commonly used medications
- a complete, automated anesthetic record
- operational rules designed to decrease human error and facilitate safe practice. The two principal operating rules were: to scan each drug before administration

and to retain used ampules and syringes in designated zones on the new trays as a physical "record" of what had been given

• additional labeling system for the accurate preparation of infusion drugs.

On 26 January 2010, the Anesthesia Patient Safety Foundation (APSF) convened a consensus conference of 100 stakeholders from many different backgrounds to develop new strategies for "predictable prompt improvement" of medication safety in the operating room. Their recommendations are summarized in Box 45.5 [70].

## **Pay-for-performance**

Many evidence-based clinical processes that are known to improve patient outcomes are not consistently achieved or are implemented slowly [71]. In the United States, Medicare and many other healthcare plans have adopted pay-for-performance (P4P) methods to incentivize reporting of quality data and achieving quality goals. P4P initiatives create financial incentives for physicians to achieve quality goals by linking a portion of payments to performance on quality measures. The quality goals are based on evidence (or consensus in the absence of data) and strive for the efficient use of resources. For example, the Physician Quality Reporting Initiative was established by the Centers for Medicare and Medicaid Services. This was done to incentivize physicians to report data on various quality measures. By doing so, a group practice may qualify to earn an incentive payment equal to 2% of their total Medicare allowed charges. Currently, participation in Medicare P4P initiatives is voluntary and only requires the reporting of quality data to achieve financial incentives. The ASA has developed a set of five proposed "quality incentives" that can be the basis for performance measures [72]. These ASA measures parallel several Medicare measures [73] and are shown in Box 45.6.

Pay-for-performance initiatives are in the early phases of adoption. The actual effect that P4P has on quality improvement is currently unclear. Studies have generally shown that P4P initiatives have no effect or minimal effect on improving quality measures [74–77]. Even as many third party payers are moving forward with P4P initiatives, caution may be warranted due to the fact that the data regarding effectiveness are weak at best.

## Safe systems in the operating room

Operating room (OR) safety can potentially be improved through the application of technology and knowledge. Recent advances in technology have moved the traditional surgical suite toward one that is more efficient Box 45.5 Consensus recommendations for improving medication safety in the operating room.

#### Standardization

- High alert drugs (such as phenylephrine and epinephrine) should be available in standardized concentrations/diluents prepared by pharmacy in a ready-to-use (bolus or infusion) form that is appropriate for both adult and pediatric patients. Infusions should be delivered by an electronically-controlled smart device containing a drug library.
- Ready-to-use syringes and infusions should have standardized fully compliant machine-readable labels.
- Additional ideas
  - Interdisciplinary and uniform curriculum for medication administration safety to be available to all training programs and facilities.
  - No concentrated versions of any potentially lethal agents in the operating room.
  - Required read-back in an environment for extremely high alert drugs such as heparin.
  - Standardized placement of drugs within all anesthesia workstations in an institution.
  - Convenient required method to save all used syringes and drug containers until case concluded.
  - Standardized infusion libraries/protocols throughout an institution.
  - Standardized route-specific connectors for tubing (IV, arterial, epidural, enteral).

#### Technology

- Every anesthetizing location should have a mechanism to identify medications before drawing up or administering them (bar code reader) and a mechanism to provide feedback, decision support, and documentation (automated information system).
- 2. Additional ideas
  - a. Technology training and device education for all users, possibly requiring formal certification.
  - b. Improved and standardized user interfaces on infusion pumps.

**Box 45.6** Proposed anesthesiology pay-for-performance measures

#### American Society of Anesthesiologists recommended quality incentives

- **1.** Timely administration of antibiotic prophylaxis
- **2.** Perioperative normothermia
- 3. Comprehensive planning for
- chronic pain management4. Prevention of ventilator-
- associated pneumonia5. Prevention of catheter-related
- bloodstream infections

### 2010 Physician Quality Reporting Initiative List (Medicare)

- **1.** Timely administration of antibiotic prophylaxis
- 2. Perioperative temperature management
- **3.** Pain assessment prior to initiation of patient therapy
- 4. Venous thromboembolism
- prophylaxis 5. Prevention of catheter-related
- bloodstream infections

and safe. However, the practice in most operating rooms does not differ greatly from operating rooms 50 years ago. The Health Information Technology for Economic and Clinical Health (HITECH) Act as part of the American

c. Mandatory safety checklists incorporated into all operating room systems.

#### Pharmacy/prefilled/premixed

- 1. Routine provider-prepared medications should be discontinued whenever possible.
- 2. Clinical pharmacists should be part of the perioperative/operating room team.
- **3.** Standardized pre-prepared medication kits by case type should be used whenever possible.
- 4. Additional ideas
  - a. Interdisciplinary and uniform curriculum for medication administration safety for all anesthesia professionals and pharmacists.
  - b. Enhanced training of operating room pharmacists specifically as perioperative consultants.
  - c. Deployment of ubiquitous automated dispensing machines in the operating room suite (with communication to central pharmacy and its information management system).

#### Culture

- **1.** Establish a "*just culture*" for reporting errors (including near misses) and discussion of lessons learned.
- Establish a culture of education, understanding, and accountability via a required curriculum and CME and dissemination of dramatic stories in the *APSF Newsletter* and educational videos.
- **3.** Establish a culture of cooperation and recognition of the benefits of STPC within and between institutions, professional organizations, and accreditation agencies.

Reproduced from Eichhorn [70] with permission from the Anesthesia Patient Safety Foundation.

CME, continuing medical eduation; APSF, Anesthesia Patient Safety Foundation; STPC, Standardization, Technology, Pharmacy/Prefiled/Premixed, and Culture.

Recovery and Reinvestment Act (ARRA) of 2009 pledges billions of dollars to improve access to data through technology and improve overall quality of care [78,79]. Yet, to date, electronic information systems do not have a common platform and do not effectively share data elements (pertinent patient information). Effective anesthesia information systems (AIMS) should enhance patient care by more than simply providing a legible record. In fact, although legible, most current information systems produce records that will automatically add data and descriptive text with the push of a button. Such a record may actually lead to inaccurate data entry, or produce a lengthy record that will fatigue users in the same way that sorting through a voluminous paper chart is inefficient. Also, the addition of complex technology to the operating room can increase hazards by distracting the anesthesiologist from the patient and surgical procedure. An effective anesthesia information system is easy to use and provides decision support to the user in order to enhance patient care (Box 45.7) [80]. See Chapter 44 for a more detailed presentation of the electronic anesthesia record.

**Box 45.7** Examples of decision support from anesthesia information management systems

- Quality assurance
  - Maintenance of normothermia notifications
  - Presurgical antibiotic management notifications
- Medication support
  - Drug–drug interaction checking
- Drug–dose calculations
- Drug re-dosing reminders
- Drug–allergy checking
- Regulatory and compliance support
  - Concurrency checking
  - Ensuring electronic records contain elements required for billing
- Attending physician attestation statements
- Case times (start of anesthesia care, end of anesthesia care)
- Case type (general/monitored anesthesia care/regional)
- Patient details (ASA physical status)
- Support around critical events
  - Algorithm display and guidance (malignant hyperthermia, advanced cardiac life support, ASA difficult airway algorithm)
  - Critical event detection
    - 1. Chaotic electrocardiogram + no pulse-ox wave form → consider ventricular fibrillation
    - ↓Blood pressure + 1heart rate + ↓end-tidal CO<sub>2</sub> → consider ↓cardiac output from hypovolemia

Other technologies that are being tested in the operating room to improve patient safety include the use of barcodes, radiofrequency identification (RFID), and smart imaging. As described above, barcodes can be used to perform as a second check on medication administration. Additionally, they can track instruments used in the surgical field.

Most commercial warehouses and supermarkets track their inventories more effectively than healthcare providers do in the perioperative environment. Modern retailers easily track the inventory of inexpensive items, while a charge nurse in a typical operating suite might have to search for a \$20,000 ultrasound machine. RFID can be used to track, plan, and send shared equipment for operating room procedures, thereby improving efficiency. RFID can be inexpensively incorporated into the patient's armband so that when the patient enters the operating room, the most recent labs, images, planned surgical procedure, ordered antibiotics, and allergies are automatically displayed on a common screen. Adding RFID tags to surgical sponges and instruments could potentially eliminate retained foreign material in the surgical wound, and an RFID label on blood products could identify an incorrect unit as it is brought into the operating room. At the time of this writing, these technologies remain in the early phases of development.

## Conclusion

The Institute of Medicine's seminal report *To Err is Human*, first published in 1999 [3], started the patient safety revolution in healthcare that continues to this day. That study used previously collected data from large population-based studies to determine that there were between 44,000 and 98,000 preventable hospital deaths, and up to 1 million patient injuries each year in the United States during the decade of the 1990s. In a recent report retrospectively reviewing adverse events from 2002 to 2007 in 10 randomly selected North Carolina general acute care hospitals, there was no reduction in patient harms on an annual basis over the 6 years of the study [81], averaging 25.1 harms per 100 admissions. The perioperative period was a significant source of patient harms.

These new data demonstrate that despite all the recent emphasis on patient safety and improving outcomes, medical error is still common and there is still a very significant amount of work to be done. The Institute of Medicine's stated goal of 50% reduction in medical error has clearly not been met. Although data specific to pediatric care are sparse, the same issues are identified in pediatric practice as in medical care in general. Pediatric anesthesiologists are in a unique position, interfacing with all members of the perioperative care team, to take a leadership role in teamwork, communication, and patient safety, to prevent adverse events and deaths in our vulnerable pediatric population.

# APPENDIX A

# Pediatric Anesthesia Drugs and Other Treatments in the Perioperative Period

# Dean B. Andropoulos

Department of Anesthesiology and Pediatrics, Baylor College of Medicine, and Texas Children's Hospital, Houston, TX, USA

Drug doses and treatments are those commonly recommended; each patient's treatment must be individualized, drug doses double-checked for accuracy, and drug concentrations and modes of administration used according to local guidelines. Information is current at the time of publication; however, the practitioner must always be aware of new recommendations, and is responsible for determining the best course of treatment. Consult the textbook, hospital formulary, or authoritative internet resources for a complete listing of indications, contraindications, interval dosing schedules, and side-effects of these drugs and treatments. All drugs are intravenous unless otherwise noted. Drugs denoted with an asterisk (\*) are not US FDA approved as of August 2011. Source for dosing information is the Texas Children's Hospital Drug Formulary, current as of August 2011, except where otherwise noted in the references.

# 1294 Appendix A

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Anesthetic, sedative, and an	algesic agents		
Opioids	Fentanyl	1–10µg/kg; 50–200µg/kg total dose	5–20 µg/kg/h
	Remifentanil	0.25–1µg/kg	0.05–2 µg/kg/min
	Sufentanil	0.1–5µg/kg	0.1–3 µg/kg/h
	Morphine	0.03–0.2 mg/kg	0.01–0.05 mg/kg/h
	Meperidine (shivering)	1-2 mg/kg	NA
	Methadone	0.1 mg/kg	NA
	Hydromorphone	0.02 mg/kg	0.006 mg/kg/h
Benzodiazepines	Midazolam IV	0.03–0.1 mg/kg	0.05–0.1 mg/kg/h
	Midazolam PO	0.5–1 mg/kg	NA
	Lorazepam	0.25–0.1 mg/kg	NA
	Diazepam IV	0.05–0.3 mg/kg, max 10 mg	NA
	Diazepam PO	0.04–0.3 mg/kg, max 10 mg	NA
Barbiturates	Thiopental	1–6 mg/kg	NA
	Pentobarbital	1–6 mg/kg	NA
	Methohexital	1–3 mg/kg	NA
Other sedative/analgesic	Ketamine IV	1–2 mg/kg	NA
agents	Ketamine IM	5–10 mg/kg	NA
	Etomidate	0.1–0.3 mg/kg	NA
	Propofol	1-3 mg/kg	50–200 µg/kg/min
	Scopolamine	10µg/kg	NA
	Dexmedetomidine	0.3–1 µg/kg	0.3–0.7 μg/kg/h
Neuromuscular blocking	Vecuronium	0.1–0.3 mg/kg	0.05–0.1 mg/kg/h
drugs and reversals	Rocuronium IV	0.6–1.2 mg/kg	NA
	Rocuronium IM	2 mg/kg	NA
	Atracurium	0.4–0.5 mg/kg	NA
	Cisatracurium	0.15–0.2 mg/kg	NA
	Pancuronium	0.1–0.2 mg/kg	NA
	Succinylcholine IV	1–2 mg/kg	NA
	Succinylcholine IM	4 mg/kg	NA
	Neostigmine	40–80 µg/kg	NA
	Glycopyrrolate	8–16µg/kg	NA
	Sugammadex*[1]	2–4 mg/kg	NA

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Vasoactive drugs			
Inotropes/vasoconstrictors	Epinephrine	0.5–10µg/kg	0.03–0.1 µg/kg/min
	Atropine IV	10–20µg/kg	NA
	Atropine IM	20–40 µg/kg	NA
	Phenylephrine	0.5–3µg/kg	0.05–0.5µg/kg/min
	Ephedrine	0.05–0.2 mg/kg	NA
	Calcium chloride	10 mg/kg	5–10 mg/kg/h
	Calcium gluconate	30 mg/kg	NA
	Dopamine	NA	3–20µg/kg/min
	Dobutamine	NA	3–20µg/kg/min
	Milrinone	25–75μg/kg	0.25–0.75 µg/kg/min
	Norepinephrine	NA	0.05–0.1 µg/kg/min
	Vasopressin	NA	0.02–0.05 units/kg/h
	Isoproterenol	NA	0.01–0.1µg/kg/min
	Levosimendan [2-4]	6–12 µg/kg	0.1–0.2 µg/kg/min
	Tri-iodothyronine (T3)[5]	NA	0.05 µg/kg/h
Vasodilators/	Sodium nitroprusside	NA	0.3–5μg/kg/min
antihypertensives	Nitroglycerine	NA	0.3–5µg/kg/min
	Prostaglandin E1	NA	0.0125–0.05 µg/kg/min
	Prostacyclin (Flolan, epoprostenol, PGI2)	NA	2–5 ng/kg/min
	Nesiritide	NA	0.01–0.03 µg/kg/min
	Fenoldopam	NA	0.025–0.3 μg/kg/min initially, titrate to max 1.6 μg/kg/min
	Nicardipine	NA	0.1–0.3 mg/kg/h, max 15 mg/h
	Hydralazine	0.1–0.2 mg/kg	NA
	Phentolamine	0.1–0.2 mg/kg on CPB	NA
	Phenoxybenzamine	0.25–1 mg/kg on CPB	
	Labetalol	0.25–0.5 mg/kg	NA
	Enalaprilat	5–10µg/kg	NA
	Sildenafil [6,7]	0.35–0.44 mg/kg over 1–3 h	0.067 mg/kg/h (Continued)

# 1296 Appendix A

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Antiarrhythmics/β-blockers	Lidocaine	1-2 mg/kg	20–50 µg/kg/min
	Procainamide	10–15 mg/kg	20–80 µg/kg/min
	Esmolol	250–500µg/kg	50–300 µg/kg/min
	Propranolol	0.01–0.1 mg/kg	NA
	Amiodarone	5 mg/kg over 10–15 min, may repeat × 2 to max 15 mg/kg	NA
	Verapamil	0.1–0.3 mg/kg	NA
	Adenosine	$25-50\mu$ g/kg, double if ineffective	NA
	Magnesium sulfate	25–50 mg/kg over 30–60 min	NA
	Digoxin	8–10µg/kg 1st loading dose	NA
Antibiotics	Cefazolin	25 mg/kg, max 1 g	NA
	Ampicillin	50 mg/kg, max 1 g	NA
	Vancomycin	15 mg/kg, max 1 g	NA
	Gentamicin	2.5 mg/kg, max 120 mg	NA
	Nafcillin	50 mg/kg, max 2 g	NA
	Clindamycin	10 mg/kg	NA
	Cefuroxime	25–30 mg/kg	NA
	Cefoxitin	30–40 mg/kg, max 2 g	NA
	Pipericillin/tazobactam	100 mg/kg piperacillin component, max 4g	
Non-steroidal anti-	Ketorolac	0.5 mg/kg, max 30 mg	NA
inflammatory drugs/ non-opioid analgesics	Acetaminophen PO	15 mg/kg, max 1000 mg	NA
	Acetaminophen PR	20–30 mg/kg (one time)	NA
	Acetaminophen IV	12.5–15 mg/kg, max 1000 mg	NA
	Ibuprofen IV	5–10 mg/kg, max 400 mg	NA
	Ibuprofen PO	5–10 mg/kg, max 400 mg	NA
Malignant hyperthermia treatment	Dantrolene	2.5 mg/kg; may repeat × 3 up to 10 mg/kg	NA
Local anesthetics	Lidocaine	Max 5mg/kg	NA
	Bupivacaine	Max 2.5 mg/kg	NA
	Levobupivacaine	Max 2.5 mg/kg	NA
	Ropivacaine	Max 2 mg/kg	NA
	Tetracaine (spinal – infants <6 months)	0.4–0.8 mg/kg	NA
Local anesthetic toxicity	20% Intralipid [8]	1 ml/kg; repeat $\times$ 2 to max 3 mL/kg	0.25 mL/kg/min
Corticosteroids	Methylprednisolone	1–30 mg/kg depending on indication	5.4 mg/kg/h × 23 h for spinal cord injury
	Dexamethasone	0.25–1 mg/kg, max 20 mg	NA
	Hydrocortisone	1–2 mg/kg	NA

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Anticoagulants	Heparin	CPB: 300–400 units/kg	NA
	Bivalirudin [9,10]	Interventional cardiac cath: 0.75mg/ kg CPB: 1mg/kg, plus 1mg/kg CPB prime	Cath: 1.75 mg/kg/h CPB: 2.5 mg/kg/h
	Argatroban	CPB: 35–100µg/kg (ACT > 400 sec)	2–10 µg/kg/min
	Antithrombin III	50 units/kg; target levels 80–120% of normal	NA
Hemostasis agents	ε-Aminocaproic acid	75 mg/kg patient; 75 mg/kg CPB prime	75 mg/kg/h
	Tranexamic acid	10–100 mg/kg	1–10 mg/kg/h
	Recombinant factor VIIa	$30-90\mu g/kg;$ may repeat $ imes$ 2	
Diuretics	Furosemide	0.5–1 mg/kg, max 40 mg	0.1–0.4 mg/kg/h
	Bumetanide	0.015–0.1 mg/kg, max 2.5 mg	NA
	Mannitol	0.25–1 g/kg	NA
Perioperative nausea and	Ondansetron	0.1 mg/kg, max 4 mg	NA
vomiting/ gastrointestinal	Granisetron	10–20µg/kg	NA
prophylaxis	Metoclopramide	0.1–0.2 mg/kg, max 10 mg	NA
	Promethazine (over age 2 years only)	0.25–0.5 mg/kg, max 25 mg	
	Sodium citrate PO	30 mL	NA
Antihistamines	Diphenhydramine	1–2 mg/kg, max 50 mg	NA
	Ranitidine	1 mg/kg, max 50 mg	NA
	Famotidine	0.5 mg/kg, max 40 mg	NA
Alkalinizing agents	Sodium bicarbonate (dilute 1:1 sterile H <sub>2</sub> O for neonates)	1–2 meq/kg	NA
	Tromethamine (THAM) 0.3 M solution	3–6 mL/kg	NA
Inhaled agents/			Inspired dose
bronchodilators	Sevoflurane		1–8%
	Isoflurane		0.5–3%
	Desflurane		2–12%
	Nitrous oxide (N <sub>2</sub> O)		50–75%
	Nitric oxide (NO)		5–20 ppm
	Levalbuterol	8–12 MDI puffs per ETT; 0.075– 0.15 mg/kg nebulized in 3 mL normal saline	NA
	Racemic epinephrine	0.25–0.5 mL of 2.25% racemic epinephrine in 3 mL normal saline	NA
	Prostacyclin (lloprost, PGI2) [11]	2.5–5μg nebulized in 3 mL normal saline	NA (Continued)

## 1298 Appendix A

Category	Drug/treatment	Bolus/loading dose	Infusion/continuous dose
Electrolytes/dextrose	25% Dextrose in water (50% dextrose diluted 1:1)	0.25–0.5 mL/kg	NA
	Potassium chloride (KCl)	0.5–1 meq/kg	NA
	3% NaCl	3–5 mL/kg	NA
Insulin (regular)	Dose based on plasma glucose levels	0.02–0.1 units/kg	0.02–0.1 units/kg/h
Sedation/analgesia	Naloxone	1–10µg/kg	NA
reversal	Flumazenil	1–5μg/kg; repeat as needed, max dose 1 mg	NA
Immunosuppressants (transplant)	Basiliximab	<35kg: 10mg >35kg: 20mg	NA
	Mycophenolate	15 mg/kg, max 1.5 g	NA
Miscellaneous drugs	Caffeine citrate	10–20 mg/kg	NA
Transfusions	Packed red blood cells	10–15 mL/kg	NA
	Whole blood	10–15 mL/kg	NA
	Platelets	1 unit/5 kg will increase platelet count by 50,000; 1 pheresis unit = 6 random donor units	NA
	Cryoprecipitate	1 unit per 5kg, max 4 units	NA
	Fresh frozen plasma	10–20 mL/kg	NA
Intravascular volume	5% albumin	10–20 mL/kg	NA
expansion	25% albumin	2–4 mL/kg; 0.5–1 g/kg	NA
	6% hetastarch	10–20 mL/kg, max 15 ml/kg/24 h	NA
Direct current cardioversion/	External synchronized cardioversion	0.5 J/kg; increase to max 1 J/kg; max 100 kg	NA
defibrillation	External defibrillation	2–5 J/kg; increase if ineffective; max 200J biphasic, 360J monophasic	NA
	Internal defibrillation	5 J; increase to 10 if ineffective	NA
	Internal synchronized cardioversion	2 J; increase to 5 J if ineffective	NA

ACT, activated clotting time; CPB, cardiopulmonary bypass; ETT, endotracheal tube; IM, intramuscular; IV, intravenous; J, joules; µg, microgram; max, maximum; MDI, metered dose inhaler; meq, milliequivalents; mg, milligram; NA, not applicable; ng, nanogram; PO, oral (per os).

# APPENDIX B Pediatric Normal Laboratory Values

## Dean B. Andropoulos

Department of Anesthesiology and Pediatrics, Baylor College of Medicine, and Texas Children's Hospital, Houston, TX, USA

For conversion of conventional (US) units to SI units, see: www.soc-bdr.org/rds/authors/unit\_tables\_ conversions\_and\_genetic\_dictionaries/e5196/index\_ en.html Values are reference values from Texas Children's Hospital Clinical Laboratory, current as of August 2011. All practitioners are urged to consult the normal laboratory values for their local laboratory, as these may differ from those listed below. They are also advised to continually check for updated normal ranges.

# APPENDIX B Pediatric Normal Laboratory Values

## Dean B. Andropoulos

Department of Anesthesiology and Pediatrics, Baylor College of Medicine, and Texas Children's Hospital, Houston, TX, USA

For conversion of conventional (US) units to SI units, see: www.soc-bdr.org/rds/authors/unit\_tables\_ conversions\_and\_genetic\_dictionaries/e5196/index\_ en.html Values are reference values from Texas Children's Hospital Clinical Laboratory, current as of August 2011. All practitioners are urged to consult the normal laboratory values for their local laboratory, as these may differ from those listed below. They are also advised to continually check for updated normal ranges.
