Most children do not like needles or injections. Small, frightened children are unlikely to keep still unless well sedated. Thus LA techniques alone are not usually used in children under about 8–10 years of age. After that age, a co-operative child who has had the procedure explained may tolerate a block for such procedures as suturing lacerations, reduction of a fracture or minor procedures on an extremity. Adequate sedation and/or the presence of a reassuring parent facilitates the procedure. New methods of giving sedatives, opioids, and LAs transdermally will be of great benefit to peripheral LA techniques in the conscious child.

If the use of a nerve stimulator is planned, the child will need to be well sedated. A nerve stimulator will facilitate the use of neural blockade in an anxious child, since motor responses can be obtained without causing discomfort if sedation is adequate. The use of ultrasonography alone is helpful to perform peripheral blocks in an awake child, due to the lack of elicited motor responses.

# With general anesthesia

In children, regional anesthesia is often combined with light general anesthesia, but there must be justifiable advantages to the child. Such potential advantages are summarized above. In addition, general anesthesia decreases central nervous system (CNS) toxicity and dysrhythmias caused by LAs [50,51]. The decision to intubate the trachea or to use a laryngeal mask airway should be based on the usual criteria, such as a full stomach, upper abdominal surgery or the need to maintain adequate ventilation. If indicated, the trachea should be intubated before the block is begun.

# Techniques for performing regional anesthesia

# **Patient monitoring**

Monitors should be applied and functions tested before the block is performed. In particular, the electrocardiogram should be adjusted so that the P wave, QRS complex, and upright T wave can be seen clearly. Baseline systolic blood pressure and heart rates should be noted.

# Skin preparation

Bacterial colonization of epidural and caudal catheters in children occurs at a rate of 6–35%. Gram-positive organisms are most common, though gram-negative colonization may also occur, particularly with caudal catheters. Children under 3 years of age are also most likely to have colonization of caudal catheters. Despite high rates of colonization, serious epidural infections are exceedingly rare. Chlorhexidine may be better than povidone-iodine for reducing the risk of catheter colonization in children [52].

### Test dose

While placement of regional blocks under general anesthesia is considered standard practice in children, the

search for the ideal "test dose" to reduce the risk of inadvertent intravascular injection continues. The original "test dose" described an increase in heart rate and blood pressure following intravenous administration of epinephrine 0.5µg/kg, which is equivalent to 0.1mL/kg IV injection of LA with epinephrine 1:200,000. In children these hemodynamic changes vary with the anesthetic agent used (halothane, sevoflurane or isoflurane) and whether prior atropine has been administered. However, an increase in heart rate of 10 beats per minute above baseline occurring within 1 min of injection of 0.1 mL/kg of LA with 1:200,000 epinephrine is a reasonable predictor of intravascular injection for children anesthetized with sevoflurane. Monitoring the ECG changes, i.e. >25% change in Twave or ST segment changes irrespective of the lead chosen, is considered by some to be more specific and more reliable [53].

These changes have been questioned recently as it seems that similar changes in heart rate, blood pressure, and Twave may be seen following a painful stimulus (surgical incision). The temporal relationship is important and a secondary decrease in pulse rate detected after intravenous epinephrine distinguishes this from the response seen after a painful stimulus [54]. Nonetheless, LA solution should be administered slowly over a period of at least 60–120 sec, irrespective of the type of block, with repeated aspirations.

### Sympathetic blockade

A clinically significant decrease in blood pressure related to sympathectomy from central neuraxial blocks is rare in children younger than 8 years of age [5]. Volume loading before such blocks, commonly practiced in adults, is unnecessary in this age group. In older patients, the sympathetic block results in a slight (20–25%) but consistent decrease in blood pressure. Even in adolescents, however, fluids or vasopressors are rarely required to treat the hemodynamic effects of central neuraxial blocks.

#### Contraindications

Contraindications to central neuraxial blocks are few and similar to those in adults. They include coagulopathy, infection at the insertion site, true LA allergy, and abnormal superficial landmarks or lumbosacral myelomeningocele because of the risk of malposition of the cord or dural sac. Progressive neurological disease is a relative contraindication primarily because of medico-legal concerns. The safety of central neuraxial techniques in the presence of a ventriculoperitoneal shunt has not been studied. Risks and benefits in these patients should be carefully considered on an individual basis.

Though it is rare to encounter opposition to the use of peripheral nerve blocks, certain conditions may call for a judicious avoidance of them. Relative contraindications include local infection, generalized sepsis, coagulopathy, predisposition to compartment syndrome, and parental or child dissent.

### **Nerve stimulator**

Though not a substitute for anatomical knowledge, a nerve stimulator is useful to localize peripheral motor nerves in anesthetized children. In addition, the surface mapping of peripheral nerves with a nerve stimulator is helpful in children [55]. Because paresthesia cannot be elicited in an anesthetized child, the use of a nerve stimulator may decrease the potential for nerve damage. A nerve stimulator capable of delivering low voltage is preferred [56]. The stimulator should deliver electric current in short pulses lasting 50-100 msec of a constant intensity adjusted from 1.5mA to 0.7mA (0.5mA if awake), and emitted at a frequency of 1-2 Hz. The sheathed needle is connected to the negative polarity of the generator, whereas the skin electrode is connected to the anode. Before injection, the appropriate muscular contractions should be obtained for a minimal intensity. An aspiration test should be done preceding each injection. When this has been identified, 1-2mL of local anesthetic agent is injected. Immediate abolition of muscle movement indicates correct placement of the needle.

# Impact of ultrasound on regional anesthesia

A significant problem in regional anesthesia is that a large number of techniques still do not achieve a success rate of close to 100%. Indeed, the key to successful regional anesthesia has always been the accuracy of needle and LA placement in relation to the nerve structures to be blocked. In 1994, Kapral introduced ultrasound guidance into regional anesthesia [57]. About 10 years later, Marhofer introduced this technique into pediatric regional anesthesia practice [58]. Real-time ultrasound guidance allows the demonstration of the target, whether it is nerve, fascial plane or anatomical space, and the monitoring of the distribution of the injected LA. Furthermore, ultrasound guidance allows the anesthesiologist to reposition the needle in the case of maldistribution of the LA.

There is some evidence to support ultrasound for various outcomes in pediatric regional anesthesia (Table 18.3) [59]. More randomized controlled studies with significant outcomes are required to further support these findings and to evaluate the potential for ultrasound to reduce complications of regional anesthesia in children. In addition, there are still two large obstacles to be overcome before this technique can attain the position of "gold standard" for the performance of regional anesthesia in infants and children. First, department heads and hospital managers need to make the necessary funds available to purchase ultrasound equipment. Second, training in the use of ultrasound-guided techniques is not easy. Dedicated efforts must be made to allow at least key individuals to attend focused training, so that these people can start to use and teach these techniques in their own institutions. Although the ultrasound-guided techniques will predominate in the future [60,61], more traditional techniques should not be forgotten.

# **Central neuraxial blocks**

# **Caudal block**

This is the most useful pediatric central block, as it is widely applicable and technically simple. It can provide analgesia for surgery up to and including the umbilicus. This technique can be used successfully in neonatal rectal surgery [62].

**Performance of a caudal block** (see Video clip 18.1) The anesthetic agent is injected through the sacral hiatus, which is formed by failure of fusion of the fifth sacral vertebral arch. The hiatus is easily palpated in children as a triangular-shaped depression bounded on either side by the sacral cornua (Fig. 18.4). Following induction of general anesthesia, the child is placed in the lateral position with the knees drawn up, the upper knee being flexed more than the lower. The best approach to the sacral hiatus is found at the apex of an equilateral triangle based on a line drawn between the two posterior superior iliac spines (Fig. 18.5). A short beveled 22 gauge needle is inserted at 45° to the skin. When the needle pierces the sacrococcygeal membrane and enters the sacral canal, a distinct "pop" is felt. Then the needle is advanced an additional 0.5-1 cm, depending on the child's age, on a plane parallel to the spinal axis. After aspiration to exclude bone marrow, dural puncture or venepuncture, incremental doses of LA should be injected.

When there is difficulty identifying the sacral hiatus, the technique of intervertebral sacral blockade has been described in children. The puncture of the ligamentum flavum is performed in the S2–3 interspace, which is easily identified because it is the interspace just below the level of the posterior superior iliac spines.

On the other hand, we do not recommend the use of caudal epidural catheters because of the risk of sepsis due to the proximity of the anus. Therefore, caudal block is a single-shot technique. The lumbar epidural route is preferred if reinjection is needed, or in children weighing more than 20–25 kg to reduce the total amount of LA used. In this group of patients, we may use the lumbar epidural block as a single-shot technique. Moreover, if we

want to prolong caudal block and to avoid a lumbar catheter, it is possible to use clonidine.

# Local anesthetic dosage

Several dosage regimes have been recommended, but the author prefers the bodyweight method. Thus, 0.25% bupivacaine 0.5 mL/kg for lumbosacral areas (i.e. orthopedic surgery of lower limb) and 1 mL/kgfor the thoracolumbar area (i.e. herniorrhaphy and orchidopexy) is administered [63]. Recently, it has been shown that caudal analgesia with a larger volume of diluted ropivacaine (0.15%), i.e. 1.5mL/kg, provides better quality and longer duration after discharge than a smaller volume of more concentrated ropivacaine [64].

## Use of ultrasound guidance

Ultrasound can be used to identify the sacral hiatus in obese children and can also be used to monitor whether the LA solution is injected in the correct anatomical place. It is also feasible to monitor the cephalad spread of local

Figure 18.4 Cutaneous landmarks and needle injection for a caudal block. See text for futher details.

Figure 18.5 Bony landmarks for a caudal block. See text for futher details.

anesthetics within the caudal–epidural space [65]. However, so far there are no published data to suggest that ultrasound assistance does in fact provide any substantial benefits compared with a traditional landmarkbased technique. The results of future prospective randomized studies on the possible benefits of ultrasound assistance in this context are awaited with anticipation.

# **Epidural block**

The greatest advantage of epidural block is the long-term analgesia following major surgery of the chest and abdomen and some orthopedic procedures, with continuous LA injection combined with administration of opioids or clonidine [2,66,67].

# Performance of an epidural block

As described above with the caudal block, general anesthesia is introduced first. The technique of lumbar epidural anesthesia in children is similar to that in adults. The smaller the patient, the narrower the epidural space, and modifications of equipment are required if the epidural needle and catheter are to be safely placed and dural puncture avoided. The midline approach is preferred. However, the distance between skin and epidural space depends on the age of the child. We use an 18 gauge Tuohy needle (10cm length) with a 20 gauge epidural catheter in children older than 4 years and a 19 gauge Tuohy needle (5 cm length) with a 21 gauge epidural catheter in children younger than 4 years. The puncture is performed at the L3-4 or L4-5 interspace in order to decrease the potential risk of trauma to the spinal cord. Indeed, in infants the spinal cord may extend lower than the L2–3 interspace. The correct positioning of the Tuohy needle is ascertained by the loss-of-resistance technique with an air-filled syringe instead of saline to avoid diluting the very small volumes of anesthetics used. Nonetheless, a patchy analgesia has been reported with use of a large volume of air [68] and case reports of venous air embolism cause many pediatric anesthesiologists to prefer the saline loss-of-resistance method [69]. The catheter should be threaded with minimal resistance, and the tip should be placed as close as possible to the spinal nerves innervating the area of the surgical field, with no more than 2–4 cm of catheter inserted into the epidural space, as measured from the end of the needle. Tsui and colleagues have developed a novel approach to confirm cephalad advancement of catheters by use of electrical nerve stimulation directly through the catheter [70]. Other groups with an acceptably rapid learning curve should confirm these results. Luer-Lok adapters with bacteriostatic filters are connected to the free end of the catheter.

Thoracic epidural analgesia may be provided for upper abdominal and thoracic surgery, with the catheter tip placed at the level of the spinal dermatome innervating the area of the incision. After induction of general anesthesia and positioning the patient in the lateral decubitus position, the thoracic spine should be extended maximally by drawing knees to chest and flexing the cervical spine with chin to chest (paying attention to airway patency), with an assistant steadying the patient with a hand on the sternum to provide counterpressure during needle placement. Because of the more acute caudad angulation of the spinous processes of the thoracic vertebrae compared to the lumbar vertebrae, a more cephalad angulation of the epidural needle is required to pass between the spinous processes. A midline approach is used, and very careful attention paid to progress of needle excursion in the interspinous ligaments and ligamentum flavum. Because of lack of calcification of these ligaments, especially in younger children, the loss of resistance felt when passing through the ligamentum flavum is not as distinct. These features in younger children, coupled with the small distances involved and the presence of the spinal cord during thoracic epidural anesthesia, make ultrasound guidance potentially a very important technique to improve accuracy of placement [59,60].

#### Local anesthetic dosage

A dose of 0.5mL/kg (0.75mL/kg for infants below 18 months old) is used for initial loading, and 0.25mL/kg for subsequent "top-up" in order to obtain intraoperative analgesia. After injection into the epidural space, the epidural space seems to protect patients: indeed, absorption into the bloodstream follows a biphasic process. The buffering properties of the epidural space are important and prevent a rapid rise in concentration. Sometimes, in order to have better muscle relaxation, it is possible to use the local anesthetic in combination with intravenous muscle relaxants.

The useful dosage of bupivacaine to obtain pain relief in the postoperative period may be supplied by giving a continuous infusion (0.1–0.125% bupivacaine, 0.3–0.4 mL/ kg/h) [71]. The disadvantages of continuous bupivacaine epidural infusion are a high risk of urinary retention and motor block of the legs. The latter can cause anxiety in children between 4 and 8 years old, who may not understand why they cannot move their legs. The use of ropivacaine or levobupivacaine could help to decrease the risk of motor blockade [72].

#### Use of ultrasound guidance

Willschke and colleagues have investigated the potential usefulness of ultrasound assistance when performing epidural anesthesia in infants and children [73,74]. In addition, they compared epidural catheter placement using either the traditional landmark-based technique or ultrasound assistance and found a reduction in performance time by visualization of the skin–epidural space [75] and fewer episodes of bone contact when using ultrasound. The described technique does, however, require a very skilled assistant handling the ultrasound probe and, apart from the need for a "skilled third arm," there is also interference between the operator and the ultrasound probe. Recently, Karmakar et al reported the use of ultrasoundassisted epidural blockade using a spring-loaded syringe in adults [76]. Such a modification of the technique makes it possible to for a single operator perform the block (holding the ultrasound probe in one hand and the Touhy needle/spring-loaded syringe in the other). This may represent a modification of this approach that makes ultrasound assistance clinically valuable in the context of epidural blockade, also.

# **Spinal block**

This block is a useful technique in the ex-premature infant scheduled for inguinal herniorrhaphy because it is the only form of pediatric regional anesthesia in which the block is routinely performed and the operation carried out on a conscious patient. It is well known that expremature infants are more prone to complications, such as apnea, hypoxia and bradycardia, during the first postoperative hours following general anesthesia [42,77]. Moreover, premature infants with a history of bronchopulmonary dysplasia may be at even further risk of developing postanesthetic complications because of the depressant effects of halogenated agents on intercostal muscles, lung volumes, and chemo- and baroreceptor responses. Avoiding general anesthesia is very useful.

**Performance of a spinal block** (see Video clip 18.2) As discussed with epidural block, the subarachnoid puncture should be made caudal to L3 to avoid possible damage to the spinal cord. The puncture is performed with the child turned in the lateral position with lower extremities flexed and the neck extended. Indeed, it has been shown that hypoxemia occurs during lumbar puncture in the sick neonate when the infant's neck was flexed for the spinal tap [78]. A 22-gauge, 3.5 cm styletted (or 25 gauge 1.5 cm) lumbar puncture needle is inserted in a midline position. An unstyletted needle increases the risk of development of an epidermoid tumor. The needle is advanced slowly, and the stylet is frequently removed in order to watch for the free-flowing return of CSF.

# Local anesthetic used

Tetracaine 0.5% with 5% dextrose is the most common local anesthetic used: 0.13 mL/kg in infants weighing less than 4kg and 0.07 mL/kg in infants weighing more than 4kg [77]. Hyperbaric bupivacaine, isobaric levobupivacaine or ropivacaine can also be used [79,80]. Duration of spinal block is shorter in infants than in adults, probably due to the larger volume of CSF. Indeed, a relationship between duration of motor blockade and age has been reported [5]. In addition, the timing in relation to the baby's feeding requirements is important for two reasons. First of all, the crying of a hungry baby renders a hernia repair much more difficult. Therefore, a pacifier can usually keep the baby quiet and the upper limb should be immobilized. Secondly, hypotension from the sympa-

thetic block following the spinal anesthesia can occur if the fasting is prolonged [81].

In older children, there are few indications for spinal block, due to the short duration of postoperative analgesia. Nonetheless, the child with a full stomach scheduled for a testicular torsion should be a good candidate for a spinal block without sedation. The usual dosage of 1% tetracaine plus 10% glucose is 1 mg per year of age (below 3 years: 0.2 mg/kg). The other LA can also be used in older children.

# Use of ultrasound guidance

Recently, caudal anesthesia was shown to be technically less difficult than spinal anesthesia and to have a higher success rate. Its application as an awake regional anesthesia technique in these patients seems more appropriate than spinal anesthesia [82]. However, theoretically, ultrasound could be used to help predict or determine (if using in real time) the depth to reach either the subarachnoid space or some depth within the spinal canal. However, there is no published literature directly related to ultrasound imaging for spinal anesthesia in pediatrics.

# **Peripheral nerve blocks**

## **Brachial plexus and branches**

Fractures of the upper extremity, especially at the elbow and wrist, are common injuries during the summer months when children are outside playing on jungle gyms and skateboards. These patients often present in the late afternoon or early evening, having eaten just prior to the traumatic event. Surgery focuses on reduction and realignment procedures with hardware insertion and casting. Use of sedation may complicate the anesthetic considerations of a full stomach. Brachial plexus blockade may be established with a variety of effective techniques. In addition, ultrasound guidance is very useful [83,84].

#### Interscalene approach

There are few indications for interscalene brachial plexus blocks in the pediatric population. Blockade of the brachial plexus high in the neck by an interscalene approach is relatively simple in children because of the lack of fat and ease with which the scalenus and medius can be palpated with the index and middle fingers. The groove between these muscles runs parallel to the posterior border of the sternocleidomastoid, and is identified when the palpating fingers fall off the posterior portion of the sternocleidomastoid at the level of the cricoid cartilage. The groove may also be identified at the point where the external jugular vein crosses the sternocleidomastoid. The sheathed needle is inserted between the palpating fingers with the tip directed towards the sternal notch and angled posteriorly towards the transverse process of the vertebral body and not the vertebral artery. The use of a nerve stimulator may be of assistance in the performance of this block.

### Use of ultrasound guidance

Few case reports have been published describing ultrasound-guided interscalene block in children [85]. With the patient positioned supine and head turned slightly to the contralateral side, in a transverse oblique plane at the level of the cricoid, the anechoic compressible internal jugular vein and pulsatile carotid artery are visualized medial to the anterior scalene muscle and deep to the triangular-shaped sternocleidomastoid muscle. The roots of the brachial plexus appear as distinct hypoechoic oval or round bodies arranged in a cephalocaudal orientation in between the bulky anterior and middle scalene muscles (Fig. 18.6).

#### Periclavicular blocks

The *parascalene approach* to the brachial plexus has been described by Dalens et al and is recommended for elective or emergency surgery of the upper limb when lesions are located above the elbow or when the limb cannot be

**Figure 18.6** Sonoanatomy of interscalene region. The ultrasound probe is depicted at the top of the figure. The roots of the brachial plexus appear as distinct hypoechoic oval or round bodies arranged in a cephalocaudal orientation in between the bulky anterior and middle scalene muscles, depicted here in yellow. VA, vertebral artery. See text for futher details. moved, either because of severe pain or because of the nature of the lesion itself [86]. Specific contraindications are acute or chronic respiratory insufficiency or whenever the surgery mandates bilateral supraclavicular block, due to the possibility of phrenic block. Some side-effects can occur: stellate ganglion block with a Horner syndrome, risk of damage to the vertebral artery or the large blood vessels of the neck, or pneumothorax.

The patient position is supine with the head turned away from the side to be blocked, the arms extended along the sides of the body, and the shoulders raised with a roll sheet. The anatomical landmarks are the midpoint of the clavicle and Chassaignac's tubercle (anterior tubercle of the transverse process of the sixth cervical vertebra) which is projected on the skin at the intersection of the sternocleidomastoid, with the transverse plane passing through the cricoid cartilage. The point of puncture is situated at the junction of the upper two-thirds and lower one-third of the line joining the midpoint of the clavicle and Chassaignac's tubercle. The sheathed needle is inserted perpendicularly to the skin in an anteroposterior plane, until muscle twitches are elicited. If the needle is too lateral, muscle contractions of the shoulder are seen when the supraclavicular nerve, which lies outside the plexus, is stimulated. If the needle is too medial or too deep, the phrenic nerve may be stimulated, leading to contractions of the diaphragm. In either case, the needle should be withdrawn up to the subcutaneous tissue and redirected correctly.

In contrast to the parascalene and interscalene techniques described above, Winnie's subclavian perivascular approach to the brachial plexus is not often used in pediatrics. In the same way, the optimal injection site for the infraclavicular approach to the brachial plexus in children is still a subject of debate. Some authors argue that the vertical infraclavicular brachial plexus block, which is very popular in adults, is dangerous in children because of its proximity to the cervical pleura. A more lateral approach was described in 1981 [87]; Kapral et al modified this coracoid block and advocated a vertical variant called the lateral vertical coracoid block [88]. The main advantage of this block is the greater distance between the puncture site and the dome of the cervical pleura. This technique was later reported by Fleischmann et al to be a safe and highly effective approach to the brachial plexus in children when compared with the axillary approach [89].

# Use of ultrasound guidance (see Video clip 18.3)

Because of the high risk of potentially serious side-effects, most anesthesiologists have avoided the supraclavicular and infraclavicular approaches in children, in whom the anatomical relations are even closer than in adults [90]. With the introduction of ultrasound guidance, the supraclavicular approach to the brachial plexus is once again becoming popular in children. The probe is first placed in a coronal oblique plane at the lateral end of and just above the upper border of the clavicle. It is then moved medially until an image of the subclavian artery appears on the middle of the screen (Fig. 18.7). At this point, the plexus is located superior and lateral to the artery, and the neurovascular structures are noted to be above the first rib. In the supraclavicular fossa, the divisions of the brachial plexus are visualized as a cluster of hypoechoic nodules immediately cephalad and lateral to the anechoic pulsative subclavian artery and above the first rib. In a prospective, randomized study, Marhofer et al compared ultrasound-guided and nerve stimulator-guided infraclavicular brachial plexus blocks in children with upper extremity fractures [91]. Not only was the ultrasoundguided technique associated with less pain during the performance of the block but it was also found to produce a faster onset time (9 versus 15 min) and a longer duration of the block (384 min versus 310 min). Furthermore, the sensory and motor block characteristics were better in the ultrasound-guided group at 10min after the completion of the block procedure.

Recently, De José María et al demonstrated that ultrasound-guided supraclavicular plexus block is as effective as an ultrasound-guided infraclavicular plexus block in children aged 5–15 years [92]. However, the supraclavicular plexus block appeared to be associated with

**Figure 18.7** Sonoanatomy of supraclavicular region. The ultrasound probe is depicted at the top of the figure. The subclavian artery appears on the middle of the screen. At this location, the plexus is located superior and lateral to the artery, and the neurovascular structures are noted to be above the first rib. A, subclavian artery. See text for futher details.

fewer failed blocks when compared with the infraclavicular approach. These data imply that in experienced hands, a supraclavicular block is a safe and useful alternative for pediatric hand and arm surgery.

### **Axillary approach**

The axillary approach to the brachial plexus was introduced into pediatric regional anesthesia in 1960 and is frequently used because of its low complication rate [93]. The indication for an axillary approach is for elective or emergency surgery on the forearm and hand. The specific contraindications are axillary lymphadenopathy or when the situation requires that the limb be immobile, such as with intense pain or an unstable fracture.

The positioning of the patient is determined by the patient's ability to co-operate, which may be limited by pain or enhanced by a light plane of general anesthesia. The arm should be abducted 45-90° and externally rotated. The correct position is determined by the operator's ability to identify the axillary arterial pulsation and to trace it beneath pectoralis major towards the apex of the axilla. The anatomical landmarks are the axillary artery, major pectoral muscle, and the coracobrachialis muscle. The point of puncture is situated at the intersection where the pectoralis major muscle crosses the coracobrachialis muscle, at the upper border of the axillary artery. The needle is introduced at an angle of 45° at the upper margin of the axillary artery with the needle pointing toward the midpoint of the clavicle. A characteristic pop is felt as the needle enters the periplexus sheath and the axillary artery pulsations are transmitted to the needle. Muscle twitches are seen in the forearm and the hand.

Once the correct position of the needle is confirmed, the injection can begin. At least three major nerves (median,

radial and musculocutaneous) have to be located to obtain a complete forearm and hand block in 90% of the patients within 20-30 min in adults. Only one nerve, median or radial, should be assessed due to the excellent diffusion in the periplexus sheath. Indeed, Carre et al showed in a double-blind, prospective study that a multiple injection technique provides no benefit for children with regard to the quality of sensory and motor block as long as an LA volume of 0.5 mL/kg is used [94]. A volume of 0.3-0.5mL/kg is used (do not use over 35mL). If a tourniquet is necessary for the surgical procedure and in order to have good tolerance of it, a subcutaneous infiltration of local anesthetic solution at the puncture point may be needed to block the cutaneous medial nerve. Catheters can be tunneled away from the insertion site if a long implantation is expected, or merely sutured in place and the site covered with a clear plastic dressing to facilitate daily inspections for disconnection, erythema, drainage or other signs of infection. This approach in pediatric patients yields success near 100%, and a high benefit/ risk ratio.

### Use of ultrasound guidance

There is no original report of ultrasound-guided axillary block in children. The patient is positioned supine with the arm abducted to 90° and flexed at the elbow. With the probe placed perpendicular to the anterior axillary fold, a short-axis view of the neurovascular bundle can be obtained (Fig. 18.8). The nerves are pictured as distinct hypoechoic nodules with internal hyperechoic punctuations typically situated lateral (median nerve), medial (ulnar nerve), and posterior (radial nerve) to the anechoic pulsatile axillary artery. It is noteworthy that the location of these three nerves relative to the axillary artery can be highly variable. This block could be performed with

**Figure 18.8** Sonoanatomy of axillary region. The ultrasound probe is depicted at the top of the left figure. The right figure is a magnified view. The nerves are pictured as distinct hypoechoic nodules with internal hyperechoic punctuations typically situated lateral (median nerve), medial (ulnar nerve), and posterior (radial nerve) to the anechoic pulsatile axillary artery. A, axillary artery; V, axillary vein; MC, musculocutaneous nerve; M, median nerve; U, ulnar nerve; R, radial nerve. See text for futher details.

similar techniques used in adults. Multiple punctures will not be necessary to anesthetize all the relevant nerves for many surgical procedures [95] and possibly musculocutaneous nerves will require separate blockade. In addition, topographic variations of the four main nerves at the axilla were found to be numerous [96,97]; this is a reason to use ultrasound guidance.

# Lumbar plexus and branches

The innervation of the skin, muscles, periosteum, and joints of the hip, thigh, and knee make the blockade of the lumbar plexus particularly useful in pediatric patients. Analgesia for lower extremity procedures in children frequently involves areas innervated by branches of the lumbar plexus. Procedures involving joint or bone realignment, especially with insertion of hardware, are common, particularly in disabled children where the ability to sit upright in a wheelchair or to manage transfers from chair to bed and vice versa is vital to reducing their dependence on the family or nursing staff. In those with cerebral palsy, lengthening of muscle and tendons is equally important. Unfortunately, these children may suffer from long periods of muscle spasm and pain following surgery. Due to their disabilities, communication regarding the efficacy of pain relief may be very difficult. Regional techniques, which effectively block the development of muscle spasm, eliminate the need for benzodiazepines and their supposed muscle relaxant effect. A clearer sensorium facilitates care delivery and assessment of pain relief. Congenital hip dislocation, which does not respond to immobilization in plaster, may require open reduction. In this setting, unilateral blockade of the lumbar plexus or bilateral blockade from a central approach makes life easier for all concerned.

#### **Psoas compartment block**

Posterior lumbar plexus block represents one of the most challenging techniques in terms of both ultrasound imaging and needle guidance. The use of nerve stimulation in addition to ultrasound imaging is still recommended to confirm correct needle placement. It should therefore only be performed or supervised by experienced clinicians. The clinical value of this technique has not yet been studied systematically. The well-recognized advantage of a posterior approach to lumbar plexus is a reliable block of the femoral nerve, obturator nerve, and lateral cutaneous nerve of the thigh with a single injection.

One concern about this technique is that systemic LA toxicity might occur because of the rapid absorption of large volumes or because of inadvertent injection into one of the large paravertebral blood vessels [35]. Bilateral spread is also a known side-effect of posterior lumbar plexus block.

### **Femoral block**

The area anesthetized by a femoral block will be the quadriceps group of muscles, the periostium of the shaft of femur, skin on the anterior aspect of the thigh, the medial part of the leg and a small portion of the foot. The indications are analgesia in patients with fracture of the femur [98] and surgery on the thigh and analgesia for knee and leg surgery with a sciatic block combined.

The anatomical landmarks in a patient supine with the lower limb abducted, the knee slightly flexed, and the lateral border of the feet in contact with the bed is the inguinal ligament, which extends from the anterosuperior iliac spine to the pubic tubercle and the femoral artery, which can be palpated just below the inguinal ligament. The femoral nerve compartment lies two layers of fascia below the skin, inferior to the inguinal ligament and lateral to the femoral artery pulse. The site of puncture is 0.5–1.0 cm below the inguinal ligament and lateral to the femoral artery. The needle (length 25mm under 25 kg, 50 mm over 25 kg) is inserted perpendicular to the skin surface or with a slight upward tilt until muscle twitches of the rectus femoris are seen. Sometimes the correct insertion of a short-bevel needle will yield two fascial "pops" as it penetrates the fascia iliaca and fascia lata to enter the nerve compartment. A volume of 0.3- $0.5 \,\mathrm{mL/kg}$  is used (do not use over  $35 \,\mathrm{mL}$ ).

**Use of ultrasound guidance** (see Video clip 18.4) As when using conventional techniques, the femoral artery is the key landmark when using ultrasound guidance for femoral nerve blockade (Fig. 18.9). With the probe placed perpendicular to the nerve axis (i.e. coronal oblique) at the level of and parallel to the inguinal crease,

**Figure 18.9** Sonoanatomy of femoral region. With the probe placed perpendicular to the nerve axis (i.e. coronal oblique) at the level of and parallel to the inguinal crease, the nerve appears lateral to the large, circular, and anechoic femoral artery. F, femoral nerve; A, femoral artery; V, femoral vein. See text for futher details.

the nerve appears lateral to the large, circular, and anechoic femoral artery. When compared with nerve stimulation, Oberndorfer et al showed that ultrasound guidance is associated with a prolonged duration of blockade in children receiving femoral and sciatic nerve blocks [99]. This could also be achieved with smaller volumes of local anesthetics than with the nerve stimulator-guided nerve blocks.

#### Fascia iliaca compartment block

The fascia iliaca compartment block blocks the femoral nerve in all cases, the lateral cutaneous nerve of the thigh and the obturator nerve (75 % of cases) [100]. The anatomical landmark in a patient supine with a slight abduction of the thigh is the inguinal ligament, which extends from the anterosuperior iliac spine to the pubic tubercle and the femoral artery. The site of puncture is 0.5–1.0 cm below the junction of the lateral one-third and the medial two-thirds of the inguinal ligament lateral to the femoral artery. The needle is introduced at right angles to the skin. A first loss of resistance is felt when the needle pierces the fascia lata, and the second is felt as it penetrates the fascia iliaca. For this block, the use of a nerve stimulator is not needed. In addition, a catheter for continuous infusion of local anesthetic can be used, as with femoral block.

#### Sciatic nerve

With contributions from the lumbar roots (L4, L5) and the sacral roots (S1, S2, S3), the sciatic nerve is the largest in the body. The indications for sciatic nerve block include analgesia for trauma of the leg and foot. In elective surgery, a sciatic nerve block can be performed for surgery on the foot and with a femoral nerve block combined. Thus, any operations on the lower limb can be performed. In addition, pediatric orthopedic procedures on the lower extremity below the knee relate primarily to congenital deformities such as talipes equino varus and structural imbalances caused by cerebral palsy. Leg length discrepancy may also require prolonged treatment with an external fixator. In this setting, any length, which can be gained early with excellent analgesia from regional blockade, will shorten the hospitalization and reduce the associated expenses.

The *anterior approach* to the sciatic nerve relies on the path of the sciatic nerve between the ischial tuberosity and the greater trochanter of the femur. The patient lies supine with the leg in a neutral position. After a sterile prep and drape, two parallel lines are drawn with a perpendicular dropped between them. The first line follows the inguinal ligament from the anterior superior iliac spine to the pubic tubercle. The perpendicular is drawn from the intersection of the medial one-third and lateral two-thirds of the first line. The second line is drawn from the greater trochanter parallel to the inguinal ligament until it intersects the perpendicular. At this point, a shortbevel needle is inserted until the surface of the femur is reached. The needle is then withdrawn and redirected to pass behind the lesser trochanter and enters the neurovascular sheath containing the sciatic nerve, the sciatic artery, and the inferior gluteal veins. The use of a nerve stimulator is mandatory in order to achieve dorsiflexion of the foot and eversion (tibial nerve) or plantarflexion of the foot and inversion (common peroneal nerve).

The *posterior approach* to the sciatic nerve identifies the nerve at the same level as the anterior approach described above. In this setting, the patient is placed in the lateral position with the upper leg flexed at the hip. At the midpoint of a line drawn from the ischial tuberosity to the greater trochanter, a short-bevel needle is inserted with a nerve stimulator attached (length 25mm under 10kg, 50 mm until 25 kg, 100 mm over 25 kg). The depth at which twitches are seen depends on the age (16-60mm). When the chosen endpoint is found, the injection of 1 mL of local anesthetic will abolish the stimulation muscle activity, i.e. dorsiflexion of the foot and eversion (tibial nerve) or plantarflexion of the foot and inversion (common peroneal nerve). The volume is 0.5 mL/kg (do not use over 35 mL). When a femoral nerve block is combined with a sciatic nerve block, the total dose is reduced by one-third for each block.

In the *lateral approach* to the sciatic nerve, the patient position is supine with, if possible, the leg lightly rotated externally. The point of puncture is located on the lateral aspect of the thigh (1–2 cm depending on age) below the greater trochanter. The needle is inserted perpendicular to the long axis of the limb in the horizontal plane directed toward the position bordering the femur and the ischial tuberosity. If the needle touches bone, it is withdrawn and reinserted more dorsally, under the femur. The depth at which the sciatic nerve is found depends on age. Lateral sciatic nerve block is simple and the child does not need to be moved.

For the *medial popliteal nerve approach*, the indication is foot surgery except the medial aspect of the thigh that will be blocked with a saphenous nerve block. The patient position is prone in which case the legs are flexed at about 30° with a rolled towel underneath the ankles. The anatomical landmarks are between the tendons of the biceps femoris and the semitendinosus, the intercondylar line, and the bissector of the angle created with the summit of the popliteal fossa. The point of puncture is located 1 cm lateral to the bissector, at the junction of the upper-third and the lower two-thirds of the segment extending from the summit of the popliteal fossa and the intercondylar line. The needle is inserted at right angles to the posterior aspect of the popliteal fossa until muscle twitches are elicited in the flexor muscles of the foot. The volume (0.5 mL/kg) injected should be less than 35 mL and reduced by one-third if combined with a femoral block.

Use of ultrasound guidance (see Video clip 18.5) Subgluteal and popliteal approaches are commonly used for sciatic nerve blockade in children with the use of ultrasound guidance. In the subgluteal region, the sciatic nerve appears predominantly hyperechoic and is often elliptical in a short-axis view. On the other hand, a caudalto-cephalad scan can effectively locate the sciatic nerve in the posterior popliteal fossa at a location where the tibial and common peroneal components have yet to separate. At the popliteal crease, a transversely positioned linear probe captures the tibial and common peroneal nerves, the former located medially and lateral to the adjacent popliteal vessels (Fig. 18.10). The tibial nerve is often located in close proximity to the tibial artery and the tibial vein. The nerves appear round to oval and hyperechoic compared with the surrounding musculature. The hyperechoic border of the femur (condyles) may be apparent. Gray et al published the first report on ultrasound-guided peripheral nerve block in children in 2003, in which they

performed sciatic nerve block in the subgluteal region of a 7 year old [101]. More recently, studies with ultrasoundguided sciatic nerve blockade using a subgluteal approach have been published [99,102].

# **Continuous peripheral nerve blocks**

Single-shot peripheral blocks are widely used in children but they provide analgesia only for a few hours. These blocks are even safer than central ones but few studies describe this technique in children, except recently infraclavicular block [103] and sciatic block [46,103]. The indications for a catheter for continuous peripheral nerve blocks are severe pain, long intraoperative time requiring re-dosing, and pain control necessary for many days. Otherwise, painful rehabilitation and physiotherapy are probably the main indication because good rehabilitation can only be performed if pain is under control. Indeed, in adults, it has become daily clinical practice supported by a large quantity of data, providing effective analgesia and allowing active physiotherapy, essential to achieving optimal functional recovery. Catheters can be maintained in position for several days and even if so far there are only reports from adults being sent home with a catheter infusion, in the future this method will also be applied in children.

A recent study has reported the efficacy of continuous peripheral nerve blocks with elastomeric disposable pumps associated with initial Bier blocks for the treatment of recurrent complex regional pain syndrome in children [104]. All the studies published so far underline the efficacy and safety of analgesia via a peripheral catheter, and no complications or side-effects linked to the long-term infusions have been described, with only a few accidental removals and some drug leakage [105]. They are at least as efficient as epidural analgesia, but produce fewer side-effects [104]. Sometimes a combination of peripheral blocks as a continuous sciatic block with a single shot 3-in-1 block for tourniquet pain and light general anesthesia provides good intraoperative conditions for leg and foot surgery and adequate postoperative pain relief [106]. Additional sedation to minimize the discomfort of a cast may be a consideration in the first 24h [102].

As continuous regional analgesia is considered a safe and efficacious technique for postoperative pain relief in children after lower limb surgery, the feasibility of patientcontrolled regional analgesia in a similar acute pain situation was recently evaluated. Both techniques are efficacious and satisfactory. However, patient-controlled regional analgesia with ropivacaine 0.2% can provide adequate postoperative analgesia for pediatric orthopedic procedures with smaller doses of ropivacaine and lower total plasma concentrations of ropivacaine than with continuous regional analgesia [107].

**Figure 18.11** Anatomy, landmarks and needle approach for a penile block. The anatomical landmark is the pubic symphysis. After gently pulling the penis downward, the two points are marked just below the pubic symphysis, each pubic ramus about 0.5–1.0 cm on either side of the pubic symphysis. The puncture is performed with a 22 gauge needle, 30 mm in length. See text for futher details.

# **Other nerve blocks**

# Penile nerve block

The indication is surgery on the foreskin (phimosis, paraphimosis, circumcision). The anatomical landmark is the pubic symphysis (Fig. 18.11) [108]. The puncture is performed with a 22 gauge needle, 30 mm in length. After gently pulling the penis downward, the two symmetric puncture sites are identified immediately below the pubic symphysis at a distance of 0.5 to 1 cm from the midline. The needle is introduced at the puncture site, perpendicular to the skin. The penetration is stopped in the subpubic space, after distinct elastic recoil is felt, corresponding to the crossing of the deep membranous layer of the superficial fascia. The depth of insertion correlates with age (8 mm for a newborn, 30 mm for a young adult). The same procedure is repeated on the opposite side. The volume should be 0.1 mL/kg for each side with 0.5 % ropivacaine or levobupivacaine without epinephrine [109]. Epinephrine is absolutely contraindicated because it can lead to a spasm of the dorsal arteries of the penis, with subsequent ischemia and necrosis of the gland. In addition, the midline puncture, the old technique, can injure the dorsal artery of the penis, leading to a compressive hematoma, possibly resulting in gland necrosis.

### Use of ultrasound guidance

By placing a probe sagittally along the shaft of the penis, the subpubic space can be located as a triangle containing the deep penile fascia (inferiorly), the pubic symphysis (superiorly), and the membranous layer of the superficial (Scarpa's) fascia. Ultrasound-guided penile nerve block improved the efficacy of the block in terms of the early postoperative pain [110].

# Ilio-inguinal iliohypogastric nerve block (II/IH block)

The main indication is hernia repair. The anatomical landmark is the anterior superior iliac spine. A short-bevel 22 gauge needle is to be inserted just below and medial to the anterior superior iliac spine (ASIS). The medial distance depends on the size of the child, being 0.5 cm in the infant and 2 cm in the adolescent. The needle is slowly advanced until there is a loss of resistance, which occurs as the aponeurosis of the external oblique is being pierced. The needle is then immobilized in this position. A volume of 0.4–0.5 mL/kg with 0.5% levobupivacaine or 0.5% ropivacaine without epinephrine is used.

#### Use of ultrasound guidance

This peripheral nerve block is one of the best studied with regard to the use of ultrasound guidance [111-115]. After placement of a linear probe or a hockey stick probe along the ASIS with the probe oriented toward the umbilicus, the three layers of the abdominal wall muscles can be recognized. The ilio-inguinal and iliohypogastric nerves are seen as two hypoechoic structures between the internal oblique and transversus abdominis muscles (Fig. 18.12). A short-bevel needle (e.g. 22 gauge, 40 mm with facette tip) is used. Indeed, a reliable endpoint for the inexperienced practitioner of ultrasound-guided II/IH nerve block may be the transversus abdominis/internal oblique plane where the nerves are reported to be found in 100% of cases [114]. By postinjection ultrasonographic control, Weintraud et al were able to show that the use of the classic landmark-based approach resulted in only 14% of the injections being made at the correct anatomical location [113]. Not surprisingly, the overall success rate of

**Figure 18.12** Sonoanatomy of abdominal region. After placement of a linear probe or a hockey stick ultrasound probe along the anterior superior iliac spine with the probe oriented toward the umbilicus, the three layers of the abdominal wall muscles can be recognized. The ilio-inguinal and iliohypogastric nerves are seen as two hypoechoic structures between the internal oblique and transversus abdominis muscles. II, ilio-inguinal nerve; IH, iliohypogastric nerve. See text for futher details.

the II/IH nerve block was found to be only 61% in this study.

In a prospective randomized study by Willschke et al, the efficacy of an ultrasound-guided II/IH nerve block was compared with the landmark-based approach [111]. It was clearly demonstrated that use of the ultrasoundguided technique was associated with a significantly higher success rate, as evidenced by a reduced hemodynamic reaction to skin incision (4% versus 24%) and a considerable reduction in the number of patients needing supplemental analgesia in the recovery room (6% versus 40%). In a further study by the same authors, they showed that a substantial reduction in the volume of LA (traditionally recommended volume  $0.4-0.5 \,\mathrm{mL/kg}$ ) is possible when using ultrasound guidance. Using a modified up/ down technique, they found that an effective II/IH nerve block can be achieved using a volume of LA as low as 0.075 mL/kg when using ultrasound guidance [112].

Weintraud and colleagues have recently published a study in which plasma concentrations following either landmark-based or ultrasound-guided II/IH nerve block was analyzed following the administration of equal volumes and amounts of ropivacaine (0.25 mL/kg of 0.5% ropivacaine) [115]. Somewhat surprisingly, the maximum plasma concentration ( $C_{max}$ ) was found to be higher and the time to maximum concentration ( $T_{max}$ ) shorter when ultrasound guidance was used, indicating more rapid absorption when the LA was injected at the correct anatomical position. The most likely explanation for this

unanticipated finding is that when the LA is deposited between the fasciae of the internal oblique and transversus abdominis muscles, the area of absorption will increase substantially compared with when the drug is mainly injected intramuscularly.

# Transversus abdominis plane block

The transversus abdominis plane (TAP) block is increasingly being used to provide analgesia after surgery involving the abdominal wall. Rafi introduced this block technique in 2001 as a landmark technique [116]. The block requires injection of LA into a plane between the transversus abdominis and internal oblique muscles. Recently, a cadaver study demonstrated that with an ultrasound-guided single injection of 20mL of aniline blue dye in the TAP, the ninth thoracic nerve (T9) was not surrounded by the injectate, whereas the segmental nerves T10, T11, T12 and L1 were surrounded by the injected dye in 50%, 100%, 100% and 93% of the cases, respectively [117]. Ultrasound can help the practioner readily visualize the muscle layers at the lateral abdominal wall, though not allowing clear distinction between the individual muscles. Linear and parallel hyperechoic striations are apparent, beneath which lies a hypoechoicappearing region representing the peritoneum [118]. The external oblique abdominal muscle will lie superficial, overlying the internal oblique and transversus abdominis muscles. As for the rectus sheath and umbilical blocks, the nerves (in this block, the lower thoracic and first lumbar spinal nerves) will not be viewed with clarity because they would appear with similar echogenicity as the muscle layers and travel tangentially to the ultrasound beam axis at this location. A short-bevel needle (e.g. 22 gauge, 80–100 mm with facette tip) is used. Finally, only a few case series of children have been published [119–121]; all other publications deal with the adult use of this block.

Transversus abdominis plane block represents an interesting and effective regional anesthetic technique for the provision of pain relief after abdominal surgery. Future studies should define its risks and benefits, and compare them with epidural techniques, which can be considered the "gold standard" for the provision of abdominal analgesia.

# **Rectus sheath block and umbilical block**

To perform the rectus sheath block, the probe is placed just below the umbilicus (i.e. above the arcuate line). The anterior and posterior aspects of the rectus sheath and the enclosed rectus abdominis muscle are visualized. The sheath appears hyperechoic with multiple linear layers, lying on the anterior and posterior aspects of the rectus muscle. Willschke et al [121] and De José María et al [122] stated that their injection site was situated at the location where an optimal view of the posterior sheath was obtained. A short-bevel needle (e.g. 22 gauge, 40 mm with facette tip) was inserted in an in-plane approach at the inferior edge of a linear probe, using an angle most suitable for the depth of the sheath. The needle tip was placed just inside the rectus sheath near the posterior aspect of the rectus abdominis muscle.

### **Paravertebral block**

Paravertebal block has been used to provide postoperative pain relief for adults and children in a variety of settings [123]. Satisfactory pain relief has been demonstrated for unilateral thoracotomies and urological surgery. The percutaneous insertion can be performed with equipment found in most epidural trays, in a patient placed in the lateral decubitus position. Because of the variation of size in children, the use of a loss-of-resistance technique to find the space is better than judging the location by depth alone. Potential complications are pneumothorax and vascular puncture; hypotension is rare due to the lack of sympathectomy [124].

#### Use of ultrasound guidance

Ultrasonographically, the transverse process of the thoracic vertebra and rib is identified at the appropriate thoracic level [125]. The transducer is moved cranially until an intercostal ultrasound view is obtained, indicated by visualization of the parietal pleura. An in-plane needle insertion approach from lateral to medial is used, and a total of 0.2–0.3 mL/kg of LA is injected through the needle and a subsequently threaded catheter, while the spread of LA is observed. An ultrasound-guided out-of-plane paravertebral block with the ultrasound probe positioned longitudinally to the paravertebral area has also been described.

# Infraorbital nerve block

The infraorbital nerve is the terminal branch of the second division of the trigeminal nerve and is purely sensory. It leaves the skull through the foramen rotundum and enters the pterygopalatine fossa. There it exits the infraorbital foramen, dividing into four branches: inferior palpebral, external nasal, internal nasal, and superior labial. These branches innervate the lower lid, the lateral inferior portion of the nose and its vestibule, the upper lip, the mucosa along the upper lip, and the vermilion border. This block can be used to provide postoperative analgesia and to favor early feeding resumption after cleft lip repair in infants [126,127]. It can also be used for nasal septal reconstruction, rhinoplasty, and in patients undergoing endoscopic sinus surgery.

Different approaches are used, including intraoral and extraoral; recently a suprazygomatic approach has been described [127]. For the intraoral approach, after palpation of the infraorbital foramen, the upper lip is folded back and a 27 gauge needle is advanced to the infraorbital foramen parallel to the maxillary premolar [126]. By placing a finger at the level of the infraorbital foramen, the cephalad progression of the needle is checked. A volume of 0.5–1 mL of 0.25% levobupivacaine with 1:200,000 epinephrine is injected after careful aspiration.

# Complications of blocks and their treatment

Performing a regional block may result in different complications, most of which can be avoided by learning the correct technique, using an appropriate device, and applying the basic safety rules. Despite the fact that most regional anesthetic techniques are performed under sedation or general anesthesia, large prospective and retrospective studies have demonstrated a low complication rate, particularly with peripheral nerve blocks, and fewer long-term sequelae when compared with adults having the same procedure.

#### Complications related to the device used

Block needles are used blindly and may thus damage a nerve trunk, especially when they are inserted without careful regard for nerve anatomy. Vascular lesions may lead to compressive hematoma and, at spinal levels, definitive paraplegia. If a spinal hematoma is suspected, a diagnosis must be established urgently by magnetic resonance imaging or computed tomography, and surgical treatment must follow immediately. Attempted peripheral nerve blocks can produce other injuries such as arterial wounds and pneumothorax, the presenting symptoms of which can be delayed by several hours.

The technique of determining the nerve/space location may produce complications. These include nerve damage while seeking paresthesias, and complications related to the medium used for the loss-of-resistance technique while locating the epidural space. These include dilution and increase in the injected volume of local anesthetic with saline headache, patchy anesthesia, lumbar compression, multiradicular syndrome, subcutaneous cervical emphysema or venous air embolism. Headache is the most common complication of dural puncture in adults; its occurrence is less common in children. The treatment includes keeping the patient in supine position, hydration with intravenous fluids, analgesia, and an autologous epidural blood patch (0.3 mL/kg) [128] which is not always free of complications. Failure to respond to the blood patch warrants further investigation. The use of caffeine or sumatriptan (5-HT<sub>1D</sub> receptor agonist) has not been reported in children.

#### **Complications of catheters**

Insertion of an epidural catheter can lead to several complications: misplacement, kinking, knotting, rupture (especially if attempts are made to withdraw the catheter through the epidural needle). Secondary migrations into the subarachnoid space, a blood vessel, the subdural space or the paravertebral space are sometimes reported. Leakage around the puncture point occurs in approximately 10% of cases, and inadvertent removal is not infrequent; also, several pediatric cases of catheter infection have been reported. Some complications, such as cutting and knotting, become apparent only on removal of the catheter; in most cases, they are directly related to the length of catheter introduced into the epidural space, which usually should not exceed 2-4 cm. The frequency of catheter-related complications has been noted to be as high as 11% in a pediatric series [129]. Malfunctioning of infusion pumps is not uncommon.

#### Complications related to faulty technique

Epidural abscess, meningitis, arachnoiditis, radiculopathies, discitis, and vertebral osteitis have been reported following central blocks. Interposed bacterial filters are effective in preventing contamination. Inadvertent dural puncture with subsequent intrathecal injection of an epidural dose of local anesthetic results in total spinal anesthesia, the clinical expression of which is almost immediate respiratory arrest requiring rapid control of ventilation and, in adolescents, cardiovascular collapse. Subdural injection results in a delayed (20 min) and shortduration (60min) block with an extensive distribution of analgesia (involving cranial nerves up to the fifth pair) but with no or minimal motor and sympathetic blockade. The injection of large volumes may result in excessive spread of the local anesthetic, which can reach distant nerves, or in too high levels of epidural/spinal anesthesia with subsequent respiratory failure due to intercostal muscle paralysis (above T4) or even in diaphragmatic paralysis (C4). Interscalene brachial plexus, lumbar plexus, and intercostal nerve blocks may lead to the same complications.

# Complications due to the local anesthetic solution

The use of wrong solutions or additives can lead to definitive neurological damage; a highly effective way to avoid syringe mismatch consists of using a specific cart for regional block procedures. Interruption of blood flow in the artery of Adamkiewicz, due either to the surgical procedure or, hypothetically, to vasoconstriction resulting from the administration of local anesthetics with epinephrine, may result in anterior spinal artery syndrome, which combines definitive loss of lower limb motor function with, at least partially, intact sensory function. Epidural anesthesia has been implicated in the flaring of latent infections (herpes, neuroimmunological diseases such as Guillain-Barré syndrome). Of greater concern is the risk of unmasking latent neurological diseases such as spinal cord compression, cerebral tumors, angiomas or an epidural abscesses. Allergy to aminoamides is rare, and most adverse reactions are related to adrenaline.

Treatment of LA convulsions consists of supplementing the child with oxygen and providing respiratory assistance; if convulsions persist after oxygenation, it is recommended that small intravenous doses of benzodiazepines (diazepam 0.1 mg/kg, midazolam 0.05 mg/kg) or thiopental 4 mg/kg be administered. Persistent convulsions require muscle relaxation (succinylcholine injection 1.5– 2 mg/kg), intubation, and assisted pulmonary ventilation to prevent acidosis.

Treatment of LA cardiac arrest: immediate treatment is required, including oxygen supplementation, ventilation and, if appropriate, external cardiac massage, sodium bicarbonate, and inotropic support. Ventricular tachycardia or fibrillation requires electrical defibrillation; 20% Intralipid bolus of 1.5mL/kg and then an infusion of 0.5–1mL/kg/min is also indicated. See Chapter 40 for more detailed discussion of treatment of LA toxicity, including cardiac arrest.

# **Epidemiology of complications**

Complications were rare and similar in both ADARPEF studies [1,3]. As reported in the literature, they were more frequent (four times in the recent ADARPEF study) in children aged <6 months than in children aged >6 months. Central regional anesthesia has the highest incidence of complications (seven times higher than peripheral). The incidence was low despite an increase in the use of central neuraxial blockade in the 12 last years. Significant complications are rare, as indicated by results from a UK audit (5 years, 10,633 epidurals performed) reporting permanent residual neurological deficit in a child aged 3 months (1 year follow-up), two epidural abscesses, one case of meningitis, one postdural puncture

headache requiring active blood patching, and one drug error resulting in cauda equina syndrome. The UK audit also reported five cases of severe neuropathy/ radiculopathy which resolved over a period of 4–10 months using pharmacological therapy in a pain clinic. Thus, in this study the incidence of serious complications was 0.09% [2]. The recent ADARPEF study [3] records a very low overall morbidity, almost six times lower than in central regional anesthesia. This result should encourage anesthesiologists to use peripheral rather than neuraxial (including caudal) blocks as often as possible when appropriate.

The use of catheters does not seem to increase the occurrence of complications, even if cardiac toxicity following a secondary injection through a catheter is due to an inadvertent displacement of the catheter. Some complications (drug error, wrong side, block of the upper limbs due to an extended spinal anesthesia) were avoidable. In the recent ADARPEF study, LA toxicity resulted in one case of convulsions [3] while the UK audit only reported two respiratory arrests and one seizure following central regional anesthesia [2]. None of these complications required lipid rescue treatment. Some other complications (prolonged duration of spinal anesthesia in two premature infants, one drug error, and a case of cardiac toxicity without cardiac arrest) were probably also avoidable. It is thus possible to improve the safety of pediatric regional anesthesia provided basic precautions are followed.

#### Safety and ultrasound guidance

Despite the theoretical advantages of ultrasound imaging during the performance of nerve blocks, no large prospective studies in pediatrics have so far been published in support of the notion that the use of ultrasound does in

 Table 18.4
 Reduction of local anesthetic volume with ultrasound guidance

Technique	Ultrasound guidance dosages	Landmarks dosages
Supraclavicular block [92]	0.3 mL/kg	0.5 mL/kg
Infraclavicular block [91]	0.2 mL/kg	0.5 mL/kg
Sciatic block [99]	0.2 mL/kg	0.3 mL/kg
Femoral block [99]	0.15 mL/kg	0.3 mL/kg
Rectus sheath block [122]	0.1 mL/kg each side	0.3 mL/kg
llio-inguinal block [112]	0.1 mL/kg each side	0.4 mL/kg

fact reduce the incidence of complications compared with alternative nerve blocking techniques. The possibility of visualizing the nerve structures as well as important nearby anatomical structures (e.g. vessels, pleura and peritoneum) most likely reduces the incidence of inadvertent complication due to misplacement of the tip of the blocking needle. The reduced volume of local anesthetic needed to produce an adequate block should also reduce the risk of systemic toxicity due to rapid absorption of local anesthetics from the injection site (Table 18.4). Indeed, using a conventional up/down technique and measuring the cross-sectional area of the ulnar nerve in the proximal part of the forearm [130] and of the sciatic nerve [131] in adults, a 95% median effective dose for an effective ulnar nerve block with 1% mepivacaine can be as low as 0.11 mL/mm<sup>2</sup> nerve, corresponding to a total volume of 0.7 mL, and a 99% median effective dose can be 0.10 mL/mm<sup>2</sup>. Thus, there is good evidence that effective peripheral nerve blocks can be achieved by using considerably smaller volumes of local anesthetics when using ultrasound guidance.

Because serious complications luckily are very rare following peripheral nerve blockade in infants and children [1,3], it is unlikely that even large-scale studies will prove ultrasound guidance to be superior to other approaches with regard to the rate of complications. However, it does not seem reasonable to expect that the use of ultrasound should result in an increased rate of complications.

# Conclusions

The goal of regional anesthesia in the pediatric population must always be the provision of effective, safe analgesia with low rates of morbidity and low risk of adverse side-effects. Indeed, safety concerns are prominent because most children coming for surgery and anesthesia are healthy and tolerate systemic opioids with a good safety margin.

Studies have demonstrated a diminished stress response, fewer episodes of hypoxia, greater cardiovascular stability, faster return of gastrointestinal function, a reduced need for postoperative ventilation and a shorter stay in intensive care in children who have had surgery performed under regional anesthesia.

In this era of evidence-based medicine, purists would claim that further prospective studies with larger sample sizes are necessary to demonstrate that regional anesthesia has significant benefits and offers a better outcome than other forms of analgesia in children.

Finally, ultrasound guidance has been shown to improve the block characteristics and probably the safety of regional anesthesia in pediatrics.

# CASE STUDY

A 7-year-old child was scheduled for primary, elective, unilateral metatarsal osteotomy which was expected to require a lengthy administration of potent analgesics, and a hospitalization of 4–5 days. The anesthetic procedure was combined general anesthesia and regional anesthesia with continuous popliteal sciatic catheter, on an ambulatory basis. Therefore the parents were required to:

- live within a 1-h drive from the hospital
- be able to contact medical staff or nurses 24h a day
- be able to return to the hospital quickly if required
- understand a visual analog scale
- provide rescue oral analgesics
- observe the analgesic device (catheter and elastomeric pump) and the skin under the dressing
- screen possible local anesthetic-related complications.

A peripheral nerve catheter was placed in the child under general anesthesia just before surgery. After premedication with oral midazolam, anesthesia was induced and maintained using sevoflurane, oxygen, and nitrous oxygen via a facemask. Intravenous saline solution, at a rate of 5–10 mL/kg/h, was infused throughout the procedure. The child received an antibiotic and antiemetic prophylaxis (0.2 mg/kg dexamethasone). With the child in lateral position, ultrasound-guided placement of a peripheral nerve sciatic catheter was performed. As described by Koscielniak-Nielsen et al [132], we were able to view the catheter exiting the needle tip and during advancement while using longaxis views of the nerves [131].

After confirming the nerve identity using a long-axis plane, the probe was rotated 90° and the needle and catheter were introduced in-plane with a tangential angle. Injection of local anesthetic confirmed the needle tip and catheter location. The catheter was introduced 15 mm beyond the introducer cannula, affixed securely to the skin by a "U" stitch, covered by transparent dressing, and taped onto the thigh. After negative aspiration, 0.2 mL/kg of ropivacaine 5 mg/mL was injected in divided doses via the catheter, with gentle aspiration every 2 mL. During the surgical procedure, if intravenous opioid rescue was required, the blockade was considered ineffective and the catheter would be removed. Since the surgery lasted more than 1 h, an additional injection of 0.1 mL/kg of the same local anesthetic solution was administered hourly.

For the surgical procedure, a tourniquet was applied at the thigh and inflated according to the surgeon's discretion. In the postanesthetic care unit, the sensory and motor blockade of the foot was evaluated. As soon as the child's toe motor function recovered, the sciatic popliteal catheter was connected to a multirate, disposable infusion elastomeric pump (Infusor LV, Baxter, Deerfield, IL, USA), containing 200 mL of 0.2% ropivacaine, with  $1.5 \mu g/mL$  clonidine (mainly for its sedative effect in children), giving a fixed infusion rate according to the child's weight (0.1 mL/ kg, i.e. 2.5 mL/h; infusor rate possibilities 0.5–5 mL/h). In the hospital, if pain control was considered insufficient, intravenous acetaminophen or opioids was given as rescue. The criteria for discharge from the hospital depended on the presence of a plaster splint (observation day 1 in hospital) and the absence of local postoperative complications. Totally efficient continuous sciatic nerve block, i.e. the ability to ambulate with crutches without assistance or dizziness, and urinary voiding were also required before home discharge.

Before home discharge, nurses gave the parents the following training: extensive explanation about the use of the visual analog scale to diagnose pain, elastomeric device surveillance, and evaluation of sensory and motor blockade, spontaneous mobility, and short delay in capillary refill after pressure on the child's test toes. When the child fulfilled the criteria for discharge, the medical staff checked both the child's and parents' comprehension of the provided instructions. The parents agreed never to leave their child alone, and to record (four times daily, at breakfast, lunch, dinner, and bedtime) the following items: changes in behavior, sleep disturbance, quality of appetite, play activity, the occurrence of any adverse effects and technical problems possibly related to the analgesic technique, temperature, evaluation of the blockade and the integrity of the child's dressing, episodes of pain, and the use of an oral rescue analgesic (acetaminophen twice a day, or a combination of acetaminophen and codeine at bedtime). Instructions were provided regarding protection of the anesthetized limb, signs of local anesthetic toxicity, a direct return to the hospital if needed, and 24-h contact information. The elastomeric pump was filled before discharge. At the end of the procedure, the child returned to hospital and met with the medical staff. The parents shared their feelings and observations about the postoperative period at home, and their overall satisfaction. The catheter was then removed, and its distal portion was sent for bacteriological analysis.

A total of 47 children were treated with this protocol in a recent prospective feasibility study [134]. The main finding of this observational study is that analgesia at home by continuous sciatic nerve block with an infusion elastomeric pump is effective, with pain control rated excellent or good in 89% of patients. It is also feasible and associated with no major complications in this study, and enables children to experience ambulatory or shortened hospital stays [133]. Another interesting point is that parents trained by nurses readily understood the method of pain screening, and managed the analgesic device well.

# Introduction

Sir (Albert) William Liley, a New Zealand perinatologist, was the first to demonstrate that fetal diagnosis and treatment were possible when he treated Rh diseaseinduced fetal hydrops (erythroblastosis fetalis) with intraperitoneal blood transfusion [1]. He had determined the correlation between the severity of rhesus isoimmunization and the bilirubin-induced deviation of the spectral absorption curve of amniotic fluid. Amniocentesis is now a standard procedure in obstetric practice. Others attempted exchange transfusion by directly cannulating fetal vessels through a small uterine incision. Early results were not encouraging and further attempts at fetal surgery were abandoned [2]. A decade later G.C. Liggins, another New Zealand perinatologist, demonstrated the beneficial effects of maternal glucocorticoid administration to augment fetal surfactant production in fetuses at risk for respiratory distress syndrome of prematurity [2]. In the early 1980s, after careful experimentation and practice in sheep [3–5] and monkeys [6], the first successful human fetal surgery was performed at the University of California San Francisco by Michael Harrison to treat lower urinary tract obstruction-induced bilateral hydronephrosis by creating a vesicostomy [7].

Fetal surgery would not have been possible without the improvements in sonographic resolution that occurred in the early 1980s. Curvilinear or convex abdominal transducers that better fit the obstetric abdomen provided wider fields of view at greater distances from the transducer. Improvements in digital signaling processing and extensive use of wide aperture transducers, coherent image processing, and harmonic imaging improved spatial and contrast resolution, background noise reduction, dynamic range, and near and far field visualization. Advances in prenatal diagnosis substantially improved the ability to recognize and more precisely delineate fetal anatomy and anomalies.

Associated with these advances in imaging were advances in amniocentesis that permitted analysis of amniotic fluid for detection of many metabolic disorders and chromosomal abnormalities, assessment of fetal pulmonary maturity, and severity of fetal hemolytic anemia. Advances in fetoscopy have allowed direct visualization of the fetus and the ability to obtain samples from organs and tissue. They also allowed fetal blood sampling, but this was replaced by ultrasound-guided percutaneous umbilical blood sampling (PUBS).

Serial sonographic examinations of fetuses facilitated delineation of the pathophysiology and natural history of

congenital diaphragmatic hernia, hydrocephalus, nonimmune hydrops, and obstructive hydronephrosis. However, most anatomical malformations diagnosed *in utero* are unsuitable for antenatal intervention and surgery.

Fetal surgery would also not be possible without the information sharing and collective conceptualization among physicians from a wide variety of disciplines who are interested in fetal diagnosis and therapy. This was greatly facilitated by Harrison's early (1981) organization of a symposium with worldwide experts [8]. A registry for fetal interventions was established and ethical guidelines adopted, leading to the creation of the International Fetal Medicine and Surgery Society and subsequently to the journal Fetal Diagnosis and Therapy. The pioneering work from a few medical centers spawned the field of fetal medicine worldwide. Fetal treatment centers around the world now rely on the expertise of radiologists, geneticists, perinatologists, pediatric cardiologists, neonatologists, social workers, support staff, and many others, as well as fetal surgeons and anesthesiologists.

Before undertaking fetal surgery, its feasibility, safety, and efficacy must be assured. Fetal surgery requires a normal fetal karyotype and a selected, accurately diagnosed and isolated anomaly that has a high probability of resulting in death, severe disability or irreversible harm before fetal lung maturity occurs, and for which removing the lesion might allow development to proceed relatively normally. Accurate and complete diagnosis is required to avoid interventions that would be futile or when the fetus is so mildly affected that postnatal treatment would be equally effective. There should be a good physiological rationale that was tested in animals and in controlled human trials that established efficacy and safety of the procedure. Family counseling for risks and potential benefits must be comprehensive and must include options for elective termination of pregnancy or continuation of pregnancy without therapy. Consent must also include a discussion that the surgery and potential benefits for the fetus might incur risks for the mother. Maternal risk must be small, and careful preoperative assessment is mandatory to ensure that the risk is acceptably low [9,10].

Fetal surgical interventions are broadly categorized into three different kinds of procedures. "Open procedures" involve maternal laparotomy and hysterotomy and uterine stapling to seal membranes to the endometrium and provide hemostasis. Most myelomeningocele repairs and resections of congenital cystic adenomatoid malformations and saccrococcygeal teratomas are performed "open." Open procedures are technically more complicated and entail the most maternal and fetal risk, particularly for postoperative membrane separation, preterm labor, rupture of membranes, and preterm delivery. Chorio-amniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise [11]. Preterm delivery causes significant morbidity and mortality for fetuses that otherwise might benefit from these interventions. Consequently, preoperative, intraoperative, and postoperative tocolysis is crucial. Inadequate postoperative tocolysis and preterm rupture of membranes is a major hindrance to fetal surgery. Fortunately, overall maternal risks are minimal but include blood loss, blood transfusion, infection, placental abruption, and pulmonary edema from tocolysis [12]. Location and orientation of the uterine incision mandates cesarean delivery for this and all subsequent pregnancies after open procedures.

The second type of fetal surgery is "minimally invasive or percutaneous" that involves uterine puncture with needles or trocars to perform endoscopic or sonographically guided procedures. Minimally invasive procedures are less risky than open procedures but preterm rupture of membranes is still a major problem. These techniques are employed for fetal blood sampling, treatment of fetal anemia by intrauterine transfusion, treatment of unbalanced blood flow between monochorionic twins, radiofrequency ablation of umbilical blood flow of a non-viable twin, and tracheal occlusion by endoluminal balloon placement to treat congenital diaphragmatic hernia. The trend in fetal surgery is to develop minimally invasive techniques to avoid open procedures.

The third type of fetal surgical intervention, the ex utero intrapartum treatment (EXIT) procedure, is a modification of cesarean section [13]. EXIT procedures provide time to secure a difficult airway by tracheal intubation, bronchoscopy or tracheostomy for conditions that would make newborn tracheal intubation unfeasible or very difficult (e.g. embryonic cervical tumors such as cystic hygromas, cervical teratomas). The EXIT procedure is also used for thoracotomy to treat cystic adenomatoid malformation, transitioning from placental gas exchange to extracorporeal membrane oxygenation (ECMO) for anticipated pulmonary insufficiency or complete resection of a giant cervical teratoma. EXIT preserves placental gas exchange during surgery. This has allowed us to perform several surgical procedures that lasted more than 2.5h and maintain placental circulation without causing hypercarbia or acidosis at delivery [14].

# Fetal surgery: indications, procedures, and outcomes

The following sections summarize the rationale for fetal intervention and provide a description of both surgical and anesthetic considerations for each procedure, and a review of outcome data. Details of anesthetic techniques are presented.

# **Congenital diaphragmatic hernia**

Approximately 1 in 2000–5000 neonates have a congenital diaphragmatic hernia (CDH) [15,16]. Incomplete fetal diaphragm formation allows the abdominal contents to enter the thoracic cavity and produce varying degrees of pulmonary parenchymal and vascular hypoplasia. Pathophysiological changes include decreased alveoli number, thickened interstitial tissue and alveolar walls, decreased surface area for gas exchange, reduced lung compliance, and decreased pulmonary vasculature that has medial hyperplasia and adventitial thickening [17]. After birth, hypoxia, hypercarbia, and acidosis induce further pulmonary vasculature constriction and pulmonary hypertension. This increases right-to-left shunting of blood and causes further hypoxia and acidosis.

The majority of CDHs are left-sided and more than half are associated with other birth defects [18]. The rate of mortality varies by center but is frequently greater than 60%. Mortality is associated with the degree of pulmonary insufficiency and pulmonary hypertension [19,20]. Survival of patients with CDH has improved in tertiary care centers by:

- removing the herniated abdominal contents from the chest and closing the diaphragm defect
- ventilation techniques that cause less barotrauma (high-frequency oscillation)
- administration of surfactant
- ECMO.

Although advanced ventilation techniques and ECMO were not of benefit in randomized prospective trials, centers utilizing these methods report improved outcomes among neonates who have a poor initial prognosis [19,21]. Postnatal CDH survival now occurs in 60–85% of patients, but it is significantly affected by the presence of other defects and by disease severity. Outcomes vary widely among centers [22–24].

It was postulated that correction of CDH in utero might improve fetal lung development and significantly reduce the degree of pulmonary hypoplasia present at birth. In controlled trials, fetal lamb models of CDH confirmed the benefit of in utero repair in that progression of pulmonary hypoplasia and pulmonary vascular changes were less severe, and newborn survival improved [3]. Although removing the abdominal contents from the chest and repairing the defect is technically feasible, it is difficult in human fetuses, and intervention for those with severe disease had limited success [25]. A lesson learned from these patients was the need to place an abdominal patch to prevent increases in intra-abdominal pressure and the associated compromise of the ductus venosus blood flow. In addition, it was found both thoracic and abdominal incisions were needed to facilitate both removal of the liver from the chest and placement of the diaphragmatic patch. However, replacing the liver

in the abdomen often caused acute and severe decreases in cardiac preload and intraoperative fetal mortality [25]. Problems with blood loss from the uterine incision and amniotic fluid leaks after uterine closure were solved. However, preterm labor remained a significant problem after surgery and caused neonatal morbidity and mortality. Results from a small prospective trial of open fetal surgical intervention comparing *in utero* repair with surgical repair after birth failed to demonstrate that fetal surgical intervention improved outcomes [20].

Given the difficulties encountered with primary repair of CDH in utero, another strategy was pursued. It was known that fetal lungs secrete about 125 mL/kg/day of fluid that normally exits the fetal trachea and mouth into the amniotic fluid. Since fetuses with congenital high airway obstruction cannot expel the fluid, they develop hyperplastic lungs [26]. It was reasoned that reversibly obstructing the trachea would cause lung fluid accumulation, lung expansion and growth, and decrease the amount of pulmonary hypoplasia. The concept of "plug the lung until it grows" (PLUG) was tested in fetal lambs and shown to decrease pulmonary hypoplasia and herniation of abdominal contents and to improve neonatal respiratory function [27-29]. Although in utero tracheal occlusion decreases much of the pulmonary hypoplasia and hypertension, there are fewer type II pneumocytes and less secreted surfactant. Removing the tracheal obstruction before delivery may reduce this unwanted effect [30,31].

The initial method of creating a reversible, controlled tracheal occlusion during open fetal surgery required both maternal laparotomy and hysterotomy, and involved application of either an internal tracheal plug or external tracheal clip [32]. The large water-impermeable foam plug used initially to block the fetal trachea reduced pulmonary hypoplasia but was difficult to remove and caused tracheal malacia. A smaller plug was easier to remove but did not completely occlude the trachea and failed to improve the fetus' pulmonary status. Next, an external tracheal metallic clip was placed around the trachea after meticulous dissection and attempts to avoid injuring the recurrent laryngeal and vagus nerves. Since the clip or plug had to be removed surgically, the EXIT procedure was developed (see below).

Unfortunately, few patients survived these initial open procedures. Of the first 13 fetuses undergoing this treatment, only 15% survived compared to 38% of fetuses receiving standard postnatal treatment [33]. Preterm labor occurred at  $30 \pm 0.6$  weeks' gestation and was a major cause of mortality in the treated group; the nontreated group was born at  $37.5 \pm 0.5$  weeks. A second series of 15 fetuses with CDH treated with external clips at the Children's Hospital of Philadelphia also had a 30% survival rate [34], but tracheal occlusion did not consistently improve the lung hypoplasia or postnatal pulmonary function.

Improvements in endoscopic and ultrasound imaging techniques allowed refinement of minimally invasive techniques for tracheal occlusion. These video-assisted fetal endoscopic (FETENDO) techniques replaced open surgical procedures for tracheal occlusion. Application of external fetal tracheal clips by FETENDO improved survival to 75% in eight fetuses [33]. To reduce fetal laryngeal nerve and tracheal trauma, a small balloon was placed in the trachea by percutaneous endoscopic endotracheal intubation in utero at University of California San Francisco (UCSF). The balloon, which is typically used for endovascular occlusion of intracranial aneurysms, is inflated to occlude the tracheal lumen, detached, and left in place until delivery via EXIT procedure (Figs 19.1, 19.2). The balloon is deflated and removed by endoscopy prior to birth.

A prospective randomized controlled trial (1999–2001) compared fetal tracheal occlusion (n = 11) for intrauterine treatment of severe CDH with repair after birth (n = 13) [35]. Eligibility included 22–28 weeks' gestation, a left-sided CDH, herniation of the liver into the left hemithorax, normal karyotype, and a low lung to head ratio (LHR) <1.4. LHR is the ratio of cross-sectional area of the contralateral lung to the head circumference as determined by two-dimensional ultrasound and is a good indicator of the severity of pulmonary hypoplasia and the likelihood of survival [36]. The trial was stopped due to an unexpectedly high survival rate in the control arm (77% versus 73%). Secondary measures of neonatal mor-

bidity were not different between groups, but premature rupture of membranes and preterm delivery were more common in the fetal treatment group (gestational age 30.8 weeks versus 37.0 weeks) [35]. A reason for the lack of difference in morbidity at 90 days may have been overly broad LHR inclusion criteria. In fetuses with liver herniation into the chest, at 22–28 weeks' gestation LHR predicts fetal survival, which is inversely proportional to LHR [37]. Using a LHR of 1.4 likely allowed inclusion of many fetuses who would survive with standard care. Table 19.1 compares outcomes of expectant and treated fetuses with left-sided CDH and liver herniation.

Minimally invasive fetoscopy for tracheal occlusion and prenatal tracheal balloon removal 24 or more hours before delivery may improve lung growth, minimize effects on type II alveolar cells [38], and potentially avoid morbid EXIT procedures. Comparison of the EXIT procedure to predelivery balloon removal in 24 fetuses with severe CDH (LHR ≤1.0 plus intrathoracic liver) that underwent fetal endoscopic tracheal occlusion (FETO) at 26-28 weeks' gestation demonstrated improved 28-day survival (p = 0.013) in the balloon reversal group (83%) compared to the EXIT group (33%) [39]. There was no maternal hemorrhage, pulmonary edema or infection. This "plug-unplug sequence" may be more ideal in that the cyclical occlusion and release may allow pulmonary structural maturation, pulmonary artery remodeling, and pneumocyte maturation [39]. An ongoing multicenter European study is determining survival of FETO on fetuses with severe left-sided CDH (LHR <1.0) and intrathoracic liver herniation [40]. A detachable tracheal

balloon is endoscopically placed in the trachea and is removed prenatally by either fetal endoscopic tracheoscopy or by ultrasound-guided needle puncture. An EXIT procedure is occasionally required. Postnatal therapy includes neonatal tracheal intubation, high-frequency ventilation, and nitric oxide or ECMO if needed. Survival data from this study are displayed in Table 19.1. Patients with severe CDH who underwent FETO showed improved survival compared to those treated with expectant management [40]. An increased LHR was associated with increased survival. Improvements in occlusion device are needed to allow complete, sustained tracheal occlusion throughout gestation without damaging the trachea or surrounding structures. Further trials are required to determine the optimal timing, duration, and protocol for occlusion to improve fetal survival. Future studies should not only address survival but also morbidity and quality of life for survivors of this treatment.

# Ex utero intrapartum treatment procedure

The EXIT procedure was developed to allow adequate time to manage and secure the airway of fetuses at birth who had undergone *in utero* tracheal occlusion or PLUG [13]. The EXIT procedure is widely used for cases in which the neonatal airway may be difficult or impossible to manage, i.e. fetal neck masses and congenital high airway obstruction (CHAOS). It is also used for other surgical procedures, such as a thoracotomy to excise large cystic adenomatoid malformations, for separation of conjoined twins or for transition to ECMO. It is also useful for severe lung hypoplasia (e.g. unilateral pulmonary agenesis) and selected cardiac lesions ("blue babies") for transition to ventilatory support and/or ECMO when resuscitation could otherwise be jeopardized by compromised oxygenation [41,42].

During the EXIT procedure, the neonate is partially delivered by cesarean section and the connection between fetus, placenta, and mother remains intact. This allows gas exchange (including maternally inhaled anesthetic agents) through the placenta rather than the fetal lungs. Uterine relaxation is necessary to prevent uterine contractions, separation of the placenta from the endometrium or the compromise of uterine blood flow. Some EXIT procedures have lasted more than 2.5h. During this time, placental circulation was adequate, as demonstrated by normal umbilical cord blood gases and absence of fetal acidosis at delivery [14].

For fetal surgery to be successful, a multidisciplinary team of fetal surgeons, anesthesiologists, ultrasonographers, maternal-fetal medicine specialists, and dedicated operating room nurses is needed. Maternal considerations, positioning, induction of anesthesia, and tracheal intubation are similar to those with general anesthesia for cesarean deliveries. (See Anesthesia for open fetal procedures below.)

Often >2 minimum alveolar concentration (MAC) of halogenated vapor is required to maintain profound uterine relaxation and prevent placental separation from the uterine endometrium. In some cases, periodic boluses of intravenous nitroglycerine ( $50-200\mu g$ ) or a continuous infusion of nitroglycerine ( $1-20\mu g/kg/min$ ) are required in addition to or instead of a halogenated vapor to provide adequate uterine relaxation. In certain cases EXIT has been successfully accomplished with neuraxial blockade and nitroglycerine [43]. Although nitroglycerine crosses the placenta, it causes minimal fetal effects because much of the nitroglycerine is metabolized at the placental interface [43,44].

The use of high MAC levels often decreases maternal cardiac output and uteroplacental blood flow and causes vasodilation and hypotension. Close hemodynamic monitoring is, therefore, required. Vasopressors, such as phenylephrine and/or ephedrine, are given as needed and are preferred to volume expansion, which may cause maternal pulmonary edema.

The uterus must be flaccid and atonic for hysterotomy. The location of the placenta and fetus is determined by ultrasound, the uterine incision avoids the placenta, and a stapling device is used to ensure hemostasis [45]. Some early EXIT procedures were terminated for uncontrolled maternal bleeding [46]. Following hysterotomy, the fetal head and upper torso are brought outside the uterus. Keeping part of the fetus in utero helps maintain uterine volume and facilitates fetal warmth. A sterile pulse oximeter probe is applied to the fetal hand for monitoring heart rate and oxygen saturation. Occasionally partial delivery of the fetus causes fetal bradycardia from occult umbilical cord compression and full delivery of the fetus is necessary. Partial delivery allows placental-fetal gas exchange to continue while the airway is secured or surgery is performed (Fig. 19.3). Anesthetic is transferred to the fetus via the placenta; muscle relaxant, opioid or resuscitation drugs are given by fetal intramuscular injec-

**Figure 19.3** Partial delivery during EXIT procedure with airway secured and pulse oximeter monitor placed on left hand and occluded from light with foil. Courtesy of UCSF Fetal Treatment Center.

tion (see Anesthesia for open fetal procedures). Fetal wellbeing is continuously monitored by pulse oximetry (see Fig. 19.3) and by periodic echocardiography. The mother breathes at least 50% inspired oxygen to improve fetal oxygenation [47]. Typical fetal saturations are 40–60%; 30–40% saturation is considered adequate. Despite maternal PaO<sub>2</sub>s >600 mmHg, fetal arterial pO<sub>2</sub>s are <60 mmHg due to the nature of placental oxygen transfer [48]. Decreases in fetal heart rate or arterial saturation can result from maternal hypotension, placental abruption, umbilical cord compression or kinking, or from loss of uterine relaxation. Anesthesiologists play a key role in monitoring the fetus and ensuring its safety by maintaining adequate uterine relaxation and appropriate maternal hemodynamics.

When the EXIT procedure is used for delivery of a fetus with CDH after in utero tracheal occlusion, fetal bronchoscopy is performed to pierce the tracheal occlusive balloon and retrieve it. Oral tracheal intubation is accomplished by direct laryngoscopy with a 3.0-3.5 tracheal tube. After the trachea is intubated, surfactant is usually administered and the lungs are ventilated with oxygen. Peak inspiratory pressures are monitored with a manometer and maintained at the lowest pressures required for adequate pulmonary ventilation. Typically a positive endexpiratory pressure of 5cmH<sub>2</sub>O is used to increase functional residual volume. Before delivery and termination of "placental support," endotracheal tube placement is confirmed by direct observation, breath sounds, and end-tidal CO<sub>2</sub>. Fetal pulmonary ventilation typically increases arterial oxygen saturation to >90%. After the baby's oxygen saturation increases, the cord is clamped, the baby is delivered, and the neonatologists provide further resuscitation as needed.

Failure of fetal arterial oxygen saturation to rise above 90% with pulmonary ventilation has been used to initiate ECMO before delivery [49]. This allows time to insert vascular cannulas and initiate ECMO before the fetus is removed from placental gas exchange. In other cases, fetal ascites or cystic masses can be decompressed before securing the airway; this makes it easier to manipulate the head and upper airway and ventilate the fetal lungs. For longer surgeries or when intravascular fetal volume or red blood cell mass must be increased, a fetal intravenous catheter is inserted into an upper extremity vein.

Immediately after cord clamping and fetal delivery, the halogenated anesthetic is reduced or discontinued and oxytocin is administered to antagonize uterine relaxation and initiate and maintain normal postpartum uterine tone. Other agents, such as methergine, prostaglandin-F2 $\alpha$  or prostaglandin-E are used if uterine atony persists. Oxytocin is often continued for 4h postpartum to minimize uterine atony. As the concentration of halogenated anesthetic is reduced or discontinued, intravenous opioids are administered and the concentration of inspired nitrous oxide is increased to provide maternal anesthesia to complete surgery.

Six case series (4–52 patients) of EXIT have determined neonatal outcome [50]. Ninety-seven to 100% of infants were born alive. Average blood loss was 850–1150 mL and the mean time on uteroplacental circulation following hysterotomy was 28–45 min. Long-term outcomes of these neonates depended on the severity of the pathology necessitating the EXIT procedure. Maternal outcomes after EXIT procedures have been excellent. Whenever possible, low transverse uterine incisions are used to decrease the risk of uterine rupture with subsequent pregnancies. Noah et al compared complications in 34 mothers who underwent EXIT procedures to 52 women who underwent cesarean delivery prior to labor [51], and found small increases in both wound complication rates and estimated blood loss in the EXIT procedure group but no difference in maternal transfusion requirements, postoperative hematocrit levels, and length of hospital stay [51].

#### Twin-twin transfusion syndrome

The majority of monochorionic twins have abnormal chorionic blood vessel connections in the placenta, which can result in twin–twin transfusion syndrome (TTTS). Normally, the umbilical artery carries deoxygenated blood to the surface of the placenta where it branches, traverses the placental surface, and then descends into capillary divisions where gas and nutrients are exchanged with the maternal circulation. The returning "paired" system consists of a vein that lies directly next to an artery as it returns to the umbilical cord (Fig. 19.4). This vascular configuration is associated with placental cotyledons and represents normal fetal placental vascular anatomy.

In TTTS, a branch from the umbilical artery travels along the surface of the placenta and descends into the cotyledon where, instead of connecting with a paired vein, it connects with an *unpaired* vein that now carries blood to its twin [52] (Fig. 19.5).

Figure 19.4 (A) Normal angio-architecture (cotyledon). (B) Superficial view of bidirectional flow into and out of a cotyledon. (C) Normal arteriovenous pair on placental pathology specimen. Reproduced from Rand and Lee. Clin Perinatol 2009; 36: 417–30 with permission from Elsevier.

(C) AV anastomosis seen superficially on placental pathology specimen. Reproduced from Rand and Lee. Clin Perinatol 2009; 36: 417–30 with permission from Elsevier.

Figure 19.6 (A) AA anastomosis. (B) Superficial view of bidirectional flow in AA anastomosis. (C) Superficial view of AA anastomosis (*arrows*) between cord insertions (both marginal) on placental pathology specimen. Reproduced from Rand and Lee. Clin Perinatol 2009; 36: 417–30 with permission from Elsevier.

In monochorionic twins, blood moves unidirectionally from one twin to the other via this abnormal arterialvenous (AV) connection. Whether the flow goes to or from either fetus depends on which one contributes the arterial vascular connection. These one-way AV connections are common in monochorionic placentas [52], yet only about 10% of monochorionic pregnancies have TTTS, which suggests that the abnormal AV connections and overall blood flow are relatively balanced between most fetuses.

The unequal chronic blood flow distribution between the twins causes the symptoms of TTTS [53]. Artery-toartery (AA) and vein-to-vein (VV) end-to-end anastomoses also occur in monochorionic placentas (Fig. 19.6).
These connections remain on the placental surface and cause turbulent bidirectional flow. An AA connection protects against TTTS if it equalizes overall resistances and blood flow between the twins. AA anastomoses are associated with nine times less TTTS [54]. Placental sharing, vasoactive mediators, and abnormal cord insertion may also influence the development of TTTS [55]. This syndrome usually presents at 15–26 weeks' gestation [56] in approximately 9–10% of monochorionic twin pregnancies [57]. TTTS results in  $\geq$ 80% mortality if untreated and a 15–50% risk of morbidity (e.g. cardiac, renal, neurological, gastrointestinal) in survivors [58].

The unbalanced flow of TTTS causes hypovolemia, oliguria, oligohydramnios, and intrauterine growth restriction in the donor twin (often referred to as a "stuck" or "pump" twin). This twin is at risk of developing neonatal renal failure, renal tubular dysgenesis and dysfunction, and high cardiac output-induced hydrops fetalis. Part of the mechanism of TTTS may be hypovolemiainduced upregulation of the renin synthesis system, increased angiotensin II, aldosterone, and antidiuretic hormone, which causes further fetal vasoconstriction and reduction of placental blood flow in the donor fetus [59]. The recipient twin has polycythemia, polyuria, polyhydramnios and hypertrophic cardiomyopathy and is at risk for hydrops fetalis and fetal death.

A major threat to both twins is polyhydramniosinduced preterm rupture of the membranes and preterm labor. For unclear reasons, survivors of TTTS are at risk for CNS white matter lesions and long-term disability. The increased risk of impaired neurodevelopment is associated with higher gestational age at intervention, increased severity stage of TTTS, and lower gestational ages at birth [60]. In the past, the diagnosis of TTTS was based on a  $\geq 20\%$  difference in birthweight and a >5g/dLdifference in cord hemoglobin concentrations. Current diagnostic criteria are based on ultrasound findings, including size discordance, which is not always present and is not necessary for the diagnosis [61]. These ultrasound-based criteria focus on discrepancy between amniotic fluid sac volumes, umbilical cord size, presence of cardiac dysfunction in the recipient twin, abnormal umbilical artery or ductus venosus blood flow velocity, and significant fetal size discordance [55]. In addition, multiple staging systems have been developed that are based on progression of size discordance and abnormal changes in the twins. These staging systems are helpful for prognosis of outcome, treatment options, and communication between physicians and centers [55].

A variety of treatment strategies for TTTS have been devised. Each is intended to decrease morbidity and improve survival of one or both twins. These include serial amnioreduction to control polyhydramnios and decrease preterm labor; surgical microseptostomy of the inter-twin amnion membrane to equalize amniotic pressures; selective fetoscopic laser photocoagulation (SFLP) of selected abnormal inter-twin vascular anastomoses to equalize the resistance and blood flow between the twins; and fetoscopic cord coagulation to selectively terminate the unhealthy recipient twin to improve survival of the donor.

# Amnioreduction

Serial amnioreduction was the first treatment utilized for TTTS and was designed to decrease the morbidity from polyhydramnios in the recipient twin. Amnioreduction decreased preterm delivery and improved uteroplacental perfusion by reducing intrauterine pressure [62]. Mari et al used international registry data to examine the effects of amnioreduction on 223 sets of twins diagnosed with TTTS before 28 weeks' gestation [63]. They reported medians of two amnioreductions, 3550 mL of fluid removed, and a gestational age at delivery of 29 weeks. Intrauterine death occurred in 18% of recipients and 26% for donors, with an overall survival rate at birth of 78%. By 4 weeks of age, only 60% of infants were alive; 65% of recipients and 55% of donors survived [63]. Possible complications from amnioreduction included infection, placental abruption, premature rupture of membranes, and preterm labor.

## Microseptostomy

Microseptostomy was developed to improve uteroplacental blood flow by equalizing pressures between the two amniotic cavities. Eighty-three percent of 12 patients with TTTS undergoing microseptostomy survived [64]. In a prospective randomized trial, 73 women with TTTS were treated with either serial amnioreduction or septostomy. No difference was found in either overall perinatal survival (64% versus 70%) or survival of at least one infant during pregnancy (78% versus 80%) [65]. Microseptostomy is seldom used today because if a single amniotic cavity is inadvertently created, there is a risk of umbilical cord entanglement.

#### Selective fetoscopic laser photocoagulation

In utero SFLP is a minimally invasive procedure that coagulates abnormal communicating vessels between the twins. A Nd:YAG or diode laser is introduced through a semi-flexible ≤2.0mm diameter endoscope. Typically, the fetoscope and laser are inserted percutaneously into the recipient twin's amniotic sac that has polyhydramnios (Fig. 19.7). Neuraxial blockade is commonly employed for anesthesia, but infiltration of local anesthesia into the trocar insertion site in the myometrium is also effective. Fetoscope placement is determined by placental location and is guided by ultrasonography. Vascular anastomoses on the surface of the placenta are directly visualized.

**Figure 19.7** Direct insertion of the fetoscope through the sheath – without cannula (*left*). An anterior placenta, with the use of a curved sheath and a flexible cannula (*right*). A photo of flexible cannula in place (*insert*). Use of a cannula allows change of instruments, with only a minimal increase in diameter. Reproduced from Deprest et al. Curr Opin Anaesthesiol 2008; 21: 298–307 with permission from Lippincott Williams and Wilkins.

Identification of the connecting vessels and their oxygen status is possible because the arteries crossing on top of the veins are a darker red color due to oxyhemoglobin desaturation [56]. Using the fetoscope, chorionic plate vessels that cross the membrane separating the amniotic sacs are visually traced to each fetal umbilical cord insertion. Based on their angio-architecture, abnormal vessels are identified [52] and selectively coagulated with laser. Due to the location of the fetuses, placenta, and cord insertions, many procedures require some non-selective coagulation. Non-selective ablation of vessels is associated with higher rates of intrauterine deaths from acute placental insufficiency [66]. Frequently, some of the abnormal twin-twin anastomoses are not visualized and remain intact after laser therapy. Complete obliteration of all connecting vessels is unnecessary for successful outcomes [67,68]. Following laser ablation, an amnioreduction is often done when the fetoscope is removed to reduce the polyhydramniotic sac to a normal or slightly lower volume. Fetal monitoring and periodic ultrasound imaging are performed for 24–48h after surgery.

A multicenter prospective randomized trial compared endoscopic laser surgery to serial amnioreduction for TTTS that was diagnosed before 26 weeks' gestation. The study was stopped early because interim analysis demonstrated a benefit of the laser treatment group [69]. The laser group had a greater likelihood of at least one twin surviving at both 28 days (76% versus 56%, p < 0.01) and 6 months of age (76% versus 51%, p = 0.002) [69]. The laser treatment group also had significantly fewer neurological complications at 6 months of extra-uterine life. Another prospective randomized multicenter trial of amnioreduction and SFLP found no difference in 30-day mortality for either the recipient or donor twin [54]. Fetal "recipient" mortality was increased for SFLP but was offset by an increase in neonatal "recipient" mortality in the amnioreduction group [54]. The hypertensive cardiomyopathy of the "recipient" twin was an important factor in survival, which might be the result of vasoactive hormones (renin-angiotensin system) from the "donor" that compromise the recipient.

A recent meta-analysis of literature from 1997–2007 that compared laser therapy with amnioreduction concluded that fetuses treated with laser therapy were more likely to survive [70]. The same group found a significant difference (p < 0.001) in overall survival rate between donors (60%) and recipients (70%), with no difference in neurological morbidity between groups [71].

The most common complication of laser therapy for TTTS is preterm rupture of membranes, but risks also include transplacental entry of the trocar, spontaneous preterm labor, infection, and hemorrhage.

In summary, randomized controlled trials and metaanalysis suggest that fetoscopic laser ablation is superior to serial amnioreduction and should be considered as treatment for TTTS to improve both neonatal survival and outcome. This conclusion is echoed by a Cochrane review of the subject [72].

#### Fetoscopic cord coagulation

In cases where salvage of the recipient twin is unlikely, fetoscopic cord coagulation (FCC) or ligation can be used. It attempts to significantly improve the outcome of the remaining fetus by stopping twin–twin blood flow and its associated morbidities. FCC has also been used following SLEP if the laser therapy worsened the fetal condition [54].

# Twin reversed arterial perfusion sequence

In monochorionic twin pregnancies, retrograde blood flow through AA anastomoses that allows blood to flow from one twin to the other is known as the twin reversed arterial perfusion (TRAP) sequence. The twin receiving the retrograde flow has a non-functioning heart or acardia. This condition is associated with other lethal anomalies that include acephalus. The acardiac twin receives all of its blood flow from the normal or "pump twin" and has no direct placental connection. Blood flows retrograde to the acardiac twin via the umbilical artery and returns from the acardiac twin via the umbilical vein. Instead of entering the placenta, this blood bypasses the placenta and flows into the normal twin via a VV connection [73]. This puts the normal twin at risk for high-output congestive heart failure, preterm birth, and polyhydramnios [74]. The incidence of TRAP is about 1 in 35,000 livebirths, affecting about 1% of monochorionic twins and 3% of monochorionic triplets [75,76]. The risk of death for the pump twin is >50% if the condition remains untreated and 90% if the acardiac twin is >75% of the size of the normal twin [77]. Additionally, there is a linear relationship between the size ratio of the acardiac-to-pump twin and the risk of mortality in the normal twin [77].

Early diagnosis is beneficial for optimal management. Unfortunately, both twins can have cardiac activity and still have the diagnosis of TRAP if the "acardiac" twin has a malformed cardiac mass without effective pumping. The diagnosis is confirmed by documenting retrograde flow to the acardiac twin by ultrasound Doppler imaging.

The primary goal of treatment is to stop blood flow between the twins by interrupting the connecting vasculature. Initially, this was accomplished by extracting the acardiac twin through an open hysterotomy (Fig. 19.8). Currently, either percutaneous endoscopic laser ablation of placental vascular anastomoses or image-guided percutaneous radiofrequency coagulation of the umbilical cord is employed [78–80]. A retrospective study of 60 TRAP cases (mean gestational age 18.3 weeks) from three European centers which used fetoscopic laser coagulation of the placental vascular anastomoses or of the umbilical cord reported 80% survival rate and a mean gestational age at birth of 37.4 weeks for the pump twin [81].

Radiofrequency ablation (RFA) is used to thermally coagulate the base of the acardiac twin's umbilical cord [79]. At UCSF, RFA is performed by inserting a

Figure 19.8 Open selective extraction of an acardiac twin. Courtesy of UCSF Fetal Treatment Center.

radiofrequency generator to the acardiac fetal abdominal wall through a 17 gauge needle under ultrasound guidance and coagulating the insertion site of the umbilical cord. As with other minimally invasive techniques, maternal anesthesia can be produced by infiltrating the skin with local anesthetic or by neuraxial blockade and intravenous sedation. RFA endpoints include reaching a predetermined impedance level or temperature. At 110°C, a 2cm diameter area of tissue coagulation is produced. Absence of flow to the acardiac twin is confirmed by ultrasound color Doppler at the end of the procedure and on postoperative day 1. In a single-institution retrospective review of 26 cases of monochorionic diamniotic twins with TRAP who were treated with RFA, there was 92% survival of the pump twins who on average were born at 35.6 weeks [79].

# Myelomeningocele

Open spina bifida or myelomeningocele (MMC) is a nonlethal neural tube defect that occurs early in gestation and results in protrusion and exposure of meninges and spinal cord through a spinal defect. These neural elements may be injured by exposure to amniotic fluid during gestation, making possible early fetal repair attractive. The definitive cause of MMC remains unknown, but is likely multifactorial. Taking folate during pregnancy has decreased the incidence of this lesion to 1 in 2000 livebirths.

Animal studies suggest that part of the ultimate neural damage arises from chemical neurotoxicity and secondary neural destruction by components of amniotic fluid or meconium [82]. In sheep, covering the MMC neural defect decreased neurological morbidity and increased the likelihood of normal anal sphincter function [83]. Using somatosensory evoked potentials, Julia demonstrated decreased neurological sequelae following *in utero* repair of a surgically created MMC in rabbits [84]. Examination of fetuses with MMC early in gestation showed an open but undamaged spinal cord. Examination of stillborn fetuses at later gestations demonstrated recent neural injury and tissue loss [82]. Direct trauma to the exposed cord and mutations in the *PAX3* gene have also been implicated in causing MMC [85].

 $\alpha$ -Fetoprotein screening of maternal blood detects MMC during the first trimester and affords the option of pregnancy termination. The 5-year mortality of MMC is about 8% of livebirths [86]. Secondary complications include hydrocephalus, Arnold–Chiari II malformation, motor and sensory nerve deficits (including paraplegia), bowel and bladder incontinence, spinal cord tethering, sexual dysfunction, and cognitive impairment [87]. Approximately 80% of children with MMC require ventriculoperitoneal shunting for the treatment of hydrocephalus [88]. The primary purpose of fetal treatment of MMC is to cover the fetal neural contents early in gestation to prevent additional damage by prolonged exposure to the uterine environment.

Initial attempts at in utero repair of MMC were done endoscopically and used a maternal split-thickness skin graft to cover the defect [89]. Unfortunately, the success of these initial attempts was poor [90]. Subsequently, open fetal surgery has been used to correct this lesion in utero (Fig. 19.9) using either a primary closure (Fig. 19.10) or a dermal patch (Fig. 19.11), depending on the size of the defect. Investigators at Vanderbilt University compared 26 patients corrected in utero to historic controls and reported a significant reduction in hindbrain herniation (4% versus 50%) and a decrease in shunt-dependent hydrocephalus (58% versus 92%) [91]. However, lower extremity motor function closely matched the level of the mean anatomical lesion in both groups. A retrospective chart review of 54 children who underwent in utero repair of MMC at the Children's Hospital of Philadelphia found better neonatal neuromotor function of the legs than predicted by prenatal ultrasound [92]. The recent analysis and publication of a randomized unmasked trial comparing outcomes from in utero myelomeningocele repair versus postnatal repair demonstrated the efficacy of prenatal intervention [218]. The primary outcome measures for the management of myelomeningocele study (MOMS) included a composite of fetal or neonatal death, the need for cerebral spinal fluid shunt placement by 12 months of age, and mental development and motor function assessed at 30 months of age. The study was stopped early for efficacy as it showed fetal surgery significantly reduced the need for shunts as well as improved motor function. However, prenatal intervention was associated with increased risk of preterm birth and uterine dehiscence. Based on these results, it is likely the incidence of open fetal myelomeningocele repair will increase in the future. Specific maternal and fetal considerations for open repair of MMC are detailed in the section on anesthesia for open fetal procedures.

# Congenital cystic adenomatoid malformation

Congenital cystic adenomatoid malformation (CCAM) is a discrete pulmonary mass that contains both solid and cystic components that are <1 mm to several cm in diameter. CCAMs have been previously classified by size or by histology [93,94] (see Chapter 24). Recently, they have been classified into two types based on ultrasound imaging and size [95]. Malformations containing single or multiple cysts >5mm in diameter on ultrasound are

Figure 19.9 Open repair of fetal myelomeningocele. Courtesy of UCSF Fetal Treatment Center.

Figure 19.10 Primary closure of fetal myelomeningocele. Courtesy of UCSF Fetal Treatment Center.

Figure 19.11 Closure of fetal myelomeningocele with dermal patch. Courtesy of UCSF Fetal Treatment Center.

termed "macrocystic"; they may develop into large solitary cysts of several centimeters in diameter. Smaller lesions with cysts <5mm diameter are termed "microcystic"; they appear as solid images by ultrasound. The incidence of CCAM is estimated to be 1 in 25,000 pregnancies [96]. CCAMs are distinguished from other fetal lung masses based on five histological characteristics: mucosal polypoid projections; more cystic wall smooth muscle and elastic tissue; a lack of cartilage; presence of mucus-secreting cells; and no inflammatory markers [95]. The differential diagnosis of CCAM includes bronchopulmonary sequestration, congenital lobar emphysema, peripheral bronchial atresia, and mixed lesions that include CCAM [97].

The overall fetal outcome depends on CCAM size, tumor growth characteristics, presence of hydrops, and secondary morbidity from large masses that cause a fetal mediastinal shift, pulmonary hypoplasia or polyhydramnios [98,99]. Smaller CCAMs detected *in utero* are resected after birth, usually by excising the affected pulmonary lobe. The CCAM volume ratio (CVR) is the quotient of the calculated CCAM volume and the fetal head circumference normalized for gestational age as determined by ultrasound imaging [100]. A CVR >1.6 is associated with greater risk of fetal hydrops. Bilateral fetal masses or the presence of hydrops are associated with poor outcomes [100,101]. Periodic ultrasound surveillance of these masses is critical since they can grow rapidly and unpredictably.

Possible fetal surgical strategies include aspiration and drainage of cysts, thoracoamniotic shunt placement, percutaneous laser ablation, and resection of the mass during open fetal surgery [102]. Aspiration of cysts may improve the fetus' condition temporarily, but the fluid often reaccumulates. Placement of shunts can produce sustained decompression and resolution of hydrops in utero, and allow definitive treatment after birth [103]. Without intervention, large CCAMs may cause significant pleural effusions and pulmonary hypoplasia. Unfortunately, some cystic lesions are compartmentalized and cannot be successfully drained. Thoracoamniotic shunts may be displaced, malfunction or occlude, and may cause fetal hemorrhage, placental abruption, preterm labor, and chorio-amnionitis [100,102]. Administration of betametasone to fetuses with CCAMs and hydrops can improve outcomes [104].

Solid microcystic CCAMs or other large masses not amenable to drainage or shunting can be resected during open fetal surgery (Fig. 19.12). The lobe containing the lesion is resected during a hysterotomy and fetal thoracotomy [105]. Anesthetic considerations are described in the section on anesthesia for open fetal procedures. A retrospective review of 30 fetuses at UCSF who had large CCAMs and hydrops showed a 50% 30-day survival after birth following open surgical resection [106]. Only 3% (1 of 33) of fetuses with similar CCAMs survived without surgical intervention.

Improved selection criteria and the potential for minimally invasive video-assisted thorascopic radiofrequency ablation of the tumor hold promise for improved outcomes [102].

### Sacrococcygeal teratoma

Fetuses with sacrococcygeal teratoma (SCT) are typically diagnosed in the second trimester of pregnancy; the incidence of SCT is 1 in 40,000 livebirths [107,108]. The lesions can grow to 500-1000 cubic centimeters [109]. Perinatal mortality is high due to massive tumor enlargement, hydrops, and placentomegaly. The perinatal mortality of 23 fetuses with SCT was 43% [109]. These tumors also cause significant arteriovenous shunting, and the resultant high-output cardiac failure is often the cause of fetal death. Fetal hydrops may be associated with "mirror syndrome" in which the mother develops a hyperdynamic high cardiac output state similar to that of the fetus and has superimposed symptoms of pre-eclampsia [110]. Fetuses with large lesions are at risk for intrapartum dystocia, tumor rupture and hemorrhage, and bladder outlet obstruction. They are born by cesarean section.

Several SCTs have been successfully removed *in utero* with resolution of hydrops noted in the weeks following the procedure [14]. Successful operations for large sacro-coccygeal teratomas require catheterization of a fetal hand or umbilical cord vein to allow blood and fluid resuscitation during tumor resection. To date, outcome of hydropic fetuses with SCT has not been improved by surgery. Minimally invasive surgery using RFA and thermocoagulation attempts to reduce the tumor's blood supply and improve outcomes, although it is unclear whether or not this happens [14].

# Fetal urinary tract obstruction

Urinary tract obstructions are detected by ultrasound in approximately 1% of pregnancies [111]. The great majority of these abnormalities have no significant clinical consequence. Only 1 in 1000 pregnancies has congenital obstructive uropathy (see Chapter 29) [112]. The clinical morbidity from fetal urinary tract obstruction depends on the location of the obstruction, severity, duration, age at onset, and gender of the fetus [111]. Congenital bilateral hydronephrosis from obstruction of the fetal urethra has a worse prognosis than unilateral upper urinary tract obstructions. Although the exact etiology may vary, posterior urethral valves are often the cause of bilateral hydronephrosis in male fetuses. Other possible causes include obstruction of the ureteropelvic and ureterovesical junctions, ectopic ureter, ureterocele, megacystis megaureter, multicystic kidney or more complex pathologies [113]. These anomalies are easily detected by ultrasonography

Figure 19.12 (A) Open resection of fetal congenital cystic adenomatoid malformation (CCAM) with fetal thoracotomy shown. (B) Resected CCAM mass. (C) Primary closure of fetal thoracotomy. (D) Pathology specimen of resected CCAM mass. Courtesy of UCSF Fetal Treatment Center.

and commonly result in oligohydramnios. Before 16 weeks' gestation, a transudate of maternal plasma forms the amniotic fluid; after 16 weeks, fetal urine is its primary source. An ultrasound grading system based on fetal renal pelvis anteroposterior diameter is commonly used to assess the severity of prenatal hydronephrosis [114]. Not only should an extensive ultrasound evaluation of the entire urinary tract be done, cardiac or neural tube defects should also be sought because they occur more commonly in fetuses with lower urinary tract obstructions [111]. Occasionally, amnio-infusion of warmed isotonic solution may be needed to improve imaging conditions.

Severe urinary tract obstruction causes oligohydramnios, hydroureteronephrosis, and bladder distension, which in turn cause pulmonary hypoplasia, facial and extremity deformations, renal dysplasia and dysfunction, and deficiencies of abdominal muscle (Fig. 19.13) [115]. These problems significantly reduce postnatal survival, primarily by causing lung hypoplasia.

Placement of a double pigtail catheter between the fetal bladder and amniotic cavity allows decompression and drainage of the bladder *in utero*. This reduces oligohydramnios and its associated morbidities (pulmonary hypoplasia and umbilical cord compression) and improves renal development. The first intervention for congenital hydronephrosis was performed by open hysterotomy at UCSF. The neonate was born at 35 weeks' gestational age and died from lung hypoplasia [115]. Improved selection

Figure 19.13 Developmental consequences of fetal urethral obstruction. Severe urinary tract obstruction results in significant fetal sequelae that can reduce postnatal survival. Reproduced from Harrison et al [115] with permission from the American Medical Association.

and placement of vesicoamniotic shunts allowed successful treatment of congenital hydronephrosis [7]. An algorithm with specific criteria was proposed to improve fetal candidate selection and outcome [116]. Components of the algorithm included fetal karyotype, an ultrasound examination looking for additional anatomical abnormalities, and fetal urine sampling to determine the amount of renal dysfunction. Fetal intervention requires a male karyotype (females often have more complex urinary abnormalities), absence of other structural abnormalities that affect outcome, and the presence of oligohydramnios or decreasing amniotic fluid volume. Serial sampling of fetal urine on 3-5 occasions, complete bladder drainage, 24-48-h intervals between samples, and assessment of sodium, chloride, calcium, osmolality, protein, and β2microglobulin improves fetal outcome prediction [111,117]. Increased levels of these components of fetal urine are associated with advanced renal damage and a poor prognosis [118]. Detection of lesions early in gestation, the degree of oligohydramnios, and the presence of additional abnormalities all predict worse outcomes.

Vesicoamniotic catheter shunt placement is often difficult because oligohydramnios compromises ultrasound imaging. Potential complications of catheter insertion include catheter occlusion or displacement, chorioamnionitis, premature rupture of membranes, fetal trauma, abdominal wall defects (gastroschisis), placental separation and hemorrhage, preterm labor, and maternal leakage of amniotic fluid [111]. This minimally invasive intervention requires neuraxial anesthesia or infiltration of local anesthetic into the maternal abdominal wall and uterine musculature. The neonate will require definitive repair of the underlying problem after birth.

A single-institution, retrospective review of 34 vesicoamniotic shunt placements for heterogeneous causes of obstructive uropathy between 1987 and 1996 reported 50% survival to at least 2 years of age; 43% of survivors had normal renal function [119]. A recent retrospective review of 20 pregnancies with male fetuses with lower urinary tract obstruction reported overall 1-year survival of 90% and only two neonatal deaths from pulmonary hypoplasia [120]. Eight children had normal renal function, 11 had normal bladder function with spontaneous voiding, and eight had respiratory difficulty [120]. Currently, a multicenter randomized controlled trial is comparing survival and renal function in fetuses with lower urinary tract obstruction treated with either vesicoamniotic shunting or conservative therapy [121]. Minimally invasive percutaneous cystoscopy with laser ablation of the posterior urethral valves may reverse pulmonary and renal morbidity, but its efficacy is uncertain at this time [122,123].

#### Fetal cardiac anomalies

Congenital cardiac anomalies occur in 0.08–0.1% (8– 10/1000) of livebirths [124]. About 3.4–4 per 1000 livebirths require surgical or interventional treatment for these anomalies in infancy [125]. Significant improvement in ultrasound imaging allows *in utero* diagnosis of cardiac abnormalities as early as 12–14 weeks' gestation. It also allows better determination of the physiological relevance of the anomaly for the fetus [126]. *In utero* interventional cardiac catheterization has been done in an attempt to reverse detrimental consequences of cardiac lesions before they cause irreversible damage [127].

This technique has been used for aortic and pulmonary valvuloplasty to treat aortic and pulmonary valvular stenoses. Significant aortic stenosis causes fetal blood to flow primarily through the low-resistance foramen

ovale, which diminishes left ventricular growth and causes hypoplastic left heart syndrome (HLHS). In severe cases, biventricular cardiac function is so reduced that neonatal palliative univentricular surgery or heart transplantation are the only options [126]. Fetal aortic valvuloplasty for severe aortic stenosis carries a high risk for HLHS, and fetal intervention has been shown to reverse hydrops and heart failure, and improve cardiac hemodynamics [128-130]. Hypoplastic right heart syndrome occurs with severe fetal pulmonary valvular stenosis or atresia. Significant tricuspid regurgitation produces high central venous pressures and hydrops [127]. In utero intervention for pulmonary stenosis has had mixed success [127,131,132]. The criteria and optimal gestational age at which in utero intervention should occur are uncertain. Guidelines for patient selection for in utero aortic vavuloplasty include degree of stenosis, left ventricular length, left-to-right shunting, and reversal of aortic arch flow [133]. Guidelines for in utero pulmonary valvuloplasty include biventricular output, degree of stenosis, estimated right ventricular pressures, and presence of hydrops [134].

Open fetal cardiac methods have been used to optimally position the fetus for cardiac catheterization. However, minimally invasive techniques are preferred because they decrease maternal morbidity and premature labor. A small laparotomy may be required when the fetal position is suboptimal, when maternal obesity limits visualization or when an anterior-lying placenta prevents direct needle trajectory [127]. The initial percutaneous approach for aortic valvular repair was described by Maxwell [135]. Currently, ultrasound imaging is used to visualize the fetus while it is positioned with the left chest anterior to allow unobstructed visualization and a cannula path that is parallel with the fetal aortic outflow tract [136]. A small cannula (≤19 gauge) is passed percutaneously through the maternal abdomen and fetal chest wall, into the left ventricle, and through the aortic valve. The valvuloplasty is performed with a high-pressure small (e.g. 2mm) balloon-tipped catheter. Similar techniques have been used for right heart valvuloplasty and atrial septoplasty [127]. Fetal intervention also has been suggested to treat complete heart block that is unresponsive to other forms of therapy, especially when it is thought that cardiac output is insufficient to sustain fetal life [137].

Infiltration of local anesthetic or neuraxial anesthesia with supplemental intravenous sedation is appropriate for these procedures. Intramuscular narcotics and muscle relaxants are given to the fetus (see Minimally invasive and percutaneous procedures). Fetal resuscitation drugs should be readily available to treat bradycardia or other arrhythmias. Other complications include valvular insufficiency, pericardial effusions, infection, and preterm labor.

# Anesthetic management of fetal procedures

Anesthetic management of fetal surgical procedures is similar to anesthesia for non-obstetric surgery during pregnancy. Although the anesthesiologist must optimize fetal well-being and the conditions required for successful surgical and fetal outcomes, the paramount focus must be maternal safety. Consequently, anesthesiologists must participate in determining potential maternal risk compared to potential fetal benefit and exclude women in whom the benefit/risk ratio is low. Pregnancy-induced hormonal changes, mechanical effects of a growing uterus, and, changes in maternal physiology have important implications for administration of anesthesia. To ensure maternal and fetal safety, the anesthesiologist must understand these physiological changes and how they affect anesthetic management, and must take an active role in perioperative management of both patients.

Unlike other surgical procedures performed during pregnancy for maternal indications (e.g. appendectomy) where the fetus is an innocent bystander, fetal surgery involves two surgical patients and the anesthesiologist must balance the needs of both. For fetal procedures, the anesthesiologist must consider the fetus' requirements for anesthesia (see below) and the perioperative control of uterine tone.

# Physiological changes of pregnancy and anesthetic implications

During pregnancy, women undergo fundamental changes in anatomy and physiology [138,139]. These changes and the associated morbidities of the fetal procedure place mothers at significantly greater risk for complications during anesthesia than non-pregnant women. A detailed understanding of these changes and their anesthetic implications is required to prepare for and respond immediately to complications such as fetal distress and maternal hemorrhage. Although the physiological changes of pregnancy affect all organ systems, this section only focuses on cardiovascular, respiratory, and gastrointestinal changes and their anesthetic implications in the perioperative period. A more detailed discourse on this subject is found in obstetric anesthesia texts [139].

# Maternal cardiovascular system Hematology

Maternal intravascular volume begins to increase in the first trimester of pregnancy. Larger increases in plasma volume (45%) than in erythrocyte volume (20%) cause physiological (dilutional) anemia of pregnancy. The hemoglobin concentration is normally 11 g/dL or greater during pregnancy [138].

Pregnancy induces a hypercoagulable state. Factors I, VII, VIII, IX, X, and XII increase and factors XI, XIII, and antithrombin III decrease. These changes reduce both prothrombin (PT) and partial thromboplastin time (PTT) by 20%. Platelet levels are normal or reduced by 10%, and the leukocyte count is commonly elevated.

#### Cardiac output

Cardiac output increases 10% above the pre-pregnant state by 10 weeks' gestation and by 40–50% by the third trimester. Increases in both heart rate (15-25%) and stroke volume (25-30%) are responsible for this rise. During labor, maternal cardiac output increases further. Each uterine contraction autotransfuses 300-500 mL of blood into the maternal central circulation. The greatest increase in cardiac output occurs immediately after delivery, when it is elevated by as much as 80% above predelivery levels. This abrupt increase in cardiac output is secondary to removal of aortocaval compression, autotransfusion from the contracted uterus, and decreased venous pressure in the lower extremities [140]. These changes in cardiac output are a significant risk for patients with major cardiac disease, e.g. fixed valvular lesions or left ventricular outflow tract obstruction.

#### Aortocaval compression

The gravid uterus may decrease preload, cardiac output, and maternal blood pressure by compressing the vena cava of supine pregnant women, especially at term. Venous blood from the lower extremities is redirected to the heart via the azygos, epidural, and vertebral veins. When supine, significant aortoiliac artery compression occurs in 15–20% of pregnant women. Vena cava compression is universal and often occurs as early as 13–16 weeks of gestation. Approximately 15% of women experience significant hypotension in the supine position late in gestation. In addition, symptoms of nausea, vomiting, diaphoresis, and decreased mental status may accompany the reduction in blood pressure.

#### Anesthetic implications

The majority of pregnant women experience minimal supine hypotension because they increase systemic vascular resistance to compensate for reduced venous return. Anesthetic interventions that diminish sympathetic tone (e.g. neuraxial blockade, general anesthesia) exacerbate the effects of vena cava compression and hypotension in supine mothers. Compression of the abdominal aorta by the gravid uterus can also produce lower extremity hypotension and reduced uterine and fetal blood flow that may not be reflected by upper extremity maternal blood pressures. Therefore supine positioning is to be avoided during the perioperative period in the second and third trimesters of pregnancy. To help preserve uterine blood flow and fetal circulation, the right hip is elevated 10–15 cm with a wedge or lateral table tilt. A >25% decrease in maternal blood pressure for >10–15 min may cause fetal hypoperfusion and progressive fetal acidosis.

Vena cava compression contributes to lower extremity venous stasis and increases the risk of venous thrombosis and pulmonary embolus. The venous stasis and hypercoagulable state of pregnancy require deep venous thrombosis prophylaxis in the postoperative period (sequential compression devices, low molecular weight heparin, encourage mobility). In addition, vena cava compression causes epidural veins to dilate, and this increases the risk of accidentally placing an epidural catheter in a vein and injecting local anesthetic intravenously. Vascular injection or accidental intrathecal injection of a dose of local anesthetic that is appropriate for epidural anesthesia may have grave maternal and fetal consequences (e.g. seizures, hemodynamic collapse, death). Consequently a "test dose" of 3 mL of 1.5% lidocaine with 1:200,000 epinephrine is injected prior to giving larger (therapeutic) doses of local anesthetic through an epidural catheter. Increases in heart rate and blood pressure in excess of 20% (intravascular injection) or a rapid loss of lower extremity sensation and onset of motor block (intrathecal injection) are evidence of a misplaced epidural catheter.

# Maternal airway and pulmonary systems Upper airway

During pregnancy, the pharynx, larynx, and trachea have increased capillary engorgement and tissue friability, making both laryngoscopy and tracheal intubation more challenging. It is frequently appropriate to use smaller cuffed endotracheal tubes (6.0 and 6.5 mm internal diameter) because the larynx may be edematous and narrowed. Because of increased tissue friability, oropharyngeal suctioning and airway instrumentation may induce bleeding. Routine use of nasogastric tubes is contraindicated.

# Ventilation and oxygenation

At term, minute ventilation is increased approximately 50% and oxygen consumption more than 20%; functional residual capacity is decreased 20%. Resting maternal  $CO_2$  decreases from 40 mmHg to 30–32 mmHg in the first trimester of pregnancy. Arterial pH is slightly alkalotic (7.42–7.44) due to decreased concentrations of bicarbonate (compensatory metabolic acidosis)

# Anesthetic implications

Airway management by facemask, laryngeal mask or tracheal intubation can be technically difficult in pregnant women because of their increased anteroposterior chest diameter, enlarged breasts, and laryngeal narrowing. The increased oxygen consumption and decreased oxygen reserve allow more rapid oxygen desaturation during hypoventilation, apnea, and general anesthesia. Obesity this desaturation. Pregnancy-induced exacerbates changes in both airway and respiratory physiology make ventilation and tracheal intubation more difficult and increase the potential for complications. During general anesthesia and controlled ventilation for fetal surgery, the maternal arterial CO<sub>2</sub> should be maintained at physiological levels (30-32 mmHg). Alkalosis reduces uterine blood flow and causes fetal acid-base abnormalities. Excessive positive pressure ventilation can increase maternal mean intrathoracic pressure and decrease cardiac preload, cardiac output, and uterine blood flow [141]. Severe hypocapnia shifts the oxyhemoglobin dissociation curve leftward, increasing maternal hemoglobin affinity for oxygen. Lastly, arterial pCO<sub>2</sub> of <20 mmHg can decrease umbilical blood flow [142] and jeopardize the fetus.

# Maternal gastrointestinal system

Women beyond 20 weeks' gestation are at risk for regurgitation and aspiration of gastric content during the induction of anesthesia or with deep sedation. The gravid uterus displaces the stomach cephalad and anteriorly and the pylorus cephalad and posteriorly. The normally intraabdominal portion of the esophagus is elevated into the thorax, decreasing the competence of the esophageal sphincter. Elevated progesterone and estrogen levels during pregnancy reduce esophageal sphincter tone. The gravid uterus increases gastric pressure, and placental gastrin secretion lowers gastric fluid pH. Consequently, maternal symptoms of gastric reflux increase with increasing duration of pregnancy in most pregnant women [143]. Although gastric emptying is not delayed until the onset of labor, systemic or neuraxial boluses of opioids during surgery can delay gastric emptying and further increase the risk of aspiration [144].

#### Anesthetic implications

Beyond midgestation, or earlier if there are symptoms of gastric reflux, women are at increased risk for pulmonary aspiration of acidic gastric contents. Regardless of when the last ingestion of food occurred, pregnant women should be considered as having a full stomach and assumed to have increased risk for pulmonary aspiration of gastric contents. A non-particulate antacid, such as sodium citrate 30 mL, is used as premedication for all procedures. Rapid-sequence induction of anesthesia and tracheal intubation, utilizing cricoid pressure and a styleted, cuffed tracheal tube, is routinely employed during induction of general anesthesia in pregnant women after midgestation. The risk of aspiration during tracheal extubation is similar to that during induction of anesthesia [145]. Consequently, the trachea is not extubated until protective airway reflexes have returned. Metoclopramide (10 mg IV), when given at least 15 min before the start of anesthesia, decreases the risk of aspiration at both induction of anesthesia and tracheal extubation. However, prior opioid administration reduces the effectiveness of metoclopramide and may cause extrapyramidal signs [146]. H<sub>2</sub> receptor antagonists also effectively increase gastric pH and are recommended by some practitioners [147].

#### Maternal central nervous system

The MAC of volatile anesthetics decreases 30–40% during pregnancy. In addition, pregnant women are more sensitive to local anesthetics, which decreases the local anesthetic dose requirement for epidural or spinal anesthesia. This increased sensitivity begins in the first trimester, before there is significant aortocaval compression, suggesting a role for biochemical changes (progesterone mediated) [148,149]. Engorgement of epidural veins and the corresponding decrease in the size of the epidural space with advancing gestation may facilitate the spread of local anesthetics.

#### Anesthetic implications

The decreased MAC in pregnant women increases the possibility of anesthetic overdose. Alveolar concentrations of inhaled anesthetics that may not anesthetize nonpregnant women can produce unconsciousness in pregnant women. This degree of central nervous system depression can impair protective upper airway reflexes and increase the risk of pulmonary aspiration. To obtain a similar level of surgical block, the dose of local anesthetic used for neuraxial blocks should be reduced by approximately one-third of that used for non-pregnant patients.

# Uteroplacental and fetal physiology Uterine blood flow

Uterine blood flow increases from approximately 100 mL/ min in the non-pregnant state to about 700 mL/min (about 10% of cardiac output) at term. The placenta receives about 80% of the uterine blood flow (UBF) and the myometrium 20%. Uterine vasculature has limited autoregulation and is essentially maximally dilated throughout pregnancy.

Reduced uterine perfusion pressure or increased arterial resistance reduces maternal UBF. Decreased perfusion pressure results from systemic hypotension (hypovolemia, aortocaval compression) and neuraxial or general anesthesia. Arterial  $CO_2$  below 20 mmHg, stress-induced endogenous catecholamines, and exogenous vasopressors also increase the resistance of the uterine arteries and can decrease UBF.

#### Placental exchange and fetal circulation

The placenta is the interface between the fetal and maternal circulatory systems. Maternal blood is delivered to the placenta by the uterine arteries. Oxygen-poor fetal blood arrives at the placenta via two umbilical arteries, and oxygen- and nutrient-rich blood returns from the placenta to the fetus through a single umbilical vein.

Oxygen transfer to the fetus depends on a variety of factors including ratio of maternal UBF to fetal umbilical blood flow; oxygen partial pressure gradient; respective hemoglobin concentrations and affinities; placental diffusing capacity; and acid–base status of the fetal and maternal blood (Bohr effect). The fetal oxyhemoglobin dissociation curve is left-shifted (greater oxygen affinity) while the maternal hemoglobin dissociation curve is right-shifted (decreased oxygen affinity). This facilitates oxygen transfer to the fetus. After the first trimester, the fetal-placental blood volume is 120–160 mL/kg, depending on the gestational age [150].

Fetal hypovolemia reduces fetal organ perfusion because the immature sympathetic nervous system and baroreceptor activity are unable to compensate by vasoconstriction. The fetus also has limited capacity to increase cardiac output in response to stresses. Fetuses also become rapidly hypothermic when outside the uterus because of transdermal heat loss and immature thermoregulatory vasoconstriction. They produce their own coagulation factors (which do not cross the placenta). The concentration of these factors increases with gestational age. Despite this increase, fetuses clot less well than adults.

Maternal-fetal exchange of most drugs and other substances of <1000 daltons is principally by diffusion. Transfer of substances across the placenta to the fetus depends on maternal-to-fetal concentration gradients; maternal protein binding; molecular weight of the substance; lipid solubility; and the degree of substance ionization. In most instances, the drug concentration in maternal blood is the major determinant of how much drug ultimately reaches the fetus.

Fetal uptake of substances that cross the placenta is facilitated by the more acidic pH (0.1 unit) of fetal compared to maternal blood. Weakly basic drugs (local anesthetics, opioids) that cross the placenta in the non-ionized form are ionized in the fetal circulation and accumulate against a concentration gradient (ion trapping). Therefore, distressed acidotic fetuses can accumulate high concentrations of local anesthetic. If there is an inadvertent maternal intravascular local anesthetic injection, the fetus often develops bradycardia, ventricular arrhythmia, acidosis, and severe cardiac depression.

The anatomy of the fetal circulation helps decrease fetal exposure to potentially high concentrations of drugs in umbilical venous blood. Approximately 75% of umbilical venous blood initially passes through the fetal liver,

which may result in significant drug metabolism before the drug reaches the fetal heart and brain (first-pass metabolism) if the enzymes for metabolism are present (see Chapter 9). Fetal/neonatal enzyme system activities are lower than those of adults, but most drugs can be metabolized. In addition, drugs entering the fetal inferior vena cava via the ductus venosus are initially diluted by drug-free blood returning from the fetal lower extremities and pelvic viscera. These characteristics of the fetal circulation markedly decrease fetal plasma drug concentrations compared to maternal concentrations.

#### Anesthetic implications

Adequate uterine blood flow and oxygenation are critical to fetal well-being. Because asphyxiated fetuses cannot increase oxygen extraction, they compensate by redistributing blood flow from the periphery to vital organs. Both hypercapnia and hypocapnia reduce uterine blood flow, which causes fetal acidosis. In addition to left uterine displacement, eucarbia for the mother (30mmHg endtidal CO<sub>2</sub>) should be maintained during general anesthesia. When regional or general anesthesia techniques are used, a  $FiO_2$  of 0.5 or higher is recommended during the procedure. In addition, maintenance of maternal blood pressure near baseline values is critical to fetal well-being. Use of vasopressors and judicious fluid administration are frequently required to maintain normal maternal blood pressure. Despite the historical use of ephedrine as the vasopressor of choice, phenylephrine ( $\alpha$ -adrenergic) has proven to be extremely useful for treatment of maternal hypotension that is associated with neuraxial anesthesia [151-153].

### Teratogenicity

Many drugs, including anesthetics, are known teratogens in at least one animal species. Organogenesis occurs primarily between 15 and 56 days of gestation in humans. Most fetal procedures are performed well beyond this critical period. At the present time, there is no evidence that any currently used anesthetic administered during pregnancy is teratogenic in humans. However, anesthetics cause neurodegeneration and widespread apoptosis in neonatal animals. A few studies also demonstrate cognitive impairment in adult animals who were exposed to anesthetics as neonates. Unfortunately, these data in animals cannot be extrapolated to humans. Clinical evidence is still scarce and amounts to an associative and not causal relationship [154].

#### Impact of anesthesia on the fetus

In addition to decreased uterine blood flow and potential fetal compromise, certain anesthetics depress the fetal cardiovascular and central nervous systems or increase the risk of preterm labor and delivery. Anesthetics typi-

cally used for induction of anesthesia, such as thiopental (4-6 mg/kg) and propofol (2.0-2.5 mg/kg), are highly lipid soluble, render the pregnant patient unconscious within 30 sec, and have peak concentrations in the fetal circulation within minutes after administration to the mother. Etomidate also has a quick onset of action and rapidly crosses the placenta. Unlike thiopental and propofol, etomidate has minimal cardiovascular effects in the mother but is painful on injection, can cause involuntary muscle tremors, causes significant nausea and vomiting, and can decrease seizure thresholds and increase the risk of seizures. At typical induction doses (0.3 mg/kg), maternal etomidate administration decreases neonatal cortisol production in <6h but the clinical significance of this remains uncertain [155]. Induction of anesthesia with ketamine can increase uterine tone and uterine contractions, and compromise uteroplacental perfusion. Therefore, it is rarely used.

Volatile anesthetics are rapidly transferred across the placenta because they are non-ionized, highly lipidsoluble, low molecular weight substances. By causing some uterine vasodilation and relaxation, modest amounts of maternal hypotension can be compensated for and uterine perfusion maintained. Fetal concentrations of these agents depend directly on the concentration and duration of anesthetic in the mother. Halogenated agents (≥2 MAC) depress fetal myocardium and lead to progressive fetal acidosis [156]. Yet even the high concentrations (2–3 MAC) used with the EXIT procedure appear well tolerated if maternal arterial blood pressure is maintained.

Placental transfer of local anesthetics and opioids is facilitated by their relatively low molecular weights. Most systemic anesthetics and opioids decrease fetal heart rate variability and may have minimal effects on baseline fetal heart rate, but do not cause fetal heart rate decelerations or bradycardia.

Succinylcholine has a low molecular weight, is highly ionized, and does not readily cross the placenta unless it is given in large doses (4 mg/kg) or repeatedly. The high molecular weight and poor lipid solubility of nondepolarizing neuromuscular agents prevent them from entering the fetal circulation in significant quantities. Thus, during general anesthesia for fetal procedures, fetuses remain unparalyzed by muscle relaxants given into the maternal circulation.

Neostigmine, glycopyrrolate, and heparin also have limited placental transfer, but atropine and esmolol easily diffuse into the fetal circulation and cause fetal tachycardia and bradycardia respectively. In general, drugs that readily cross the blood–brain barrier also cross the placenta.

#### Fetal pain and anesthesia

Whether or when fetuses experience pain and whether they require or benefit from anesthesia for surgical intervention are inadequately understood and controversial. Surgical pain is defined as an unpleasant sensory and emotional response to tissue damage and a subjective experience involving cognition, sensation and affective processes [157]. Although pain is commonly associated with physical noxious stimuli, it is clearly more than nociception or the simple reflex activity of a withdrawal response [158]. Pain is fundamentally a psychological construct that can exist in the absence of physical stimuli (e.g. phantom limb pain). The psychological nature of pain distinguishes it from nociception, which involves activation of nociceptive pathways without the subjective emotional experience of pain. Most definitions of pain suggest that the experience is highly subjective, organized into a conceptual framework, and based on previous painful injuries [157]. While the ability to experience pain must begin at some point and is clearly present in neonates, it is unclear when fetuses actually first feel pain.

Reflex movements and biochemical evidence of a "stress response" can be triggered by a noxious stimulus without involving the cerebral cortex and without conscious pain perception. An example is withdrawal from a noxious stimulus mediated in the spinal cord without conscious perception of pain (Fig. 19.14). This occurs by about 18 weeks' gestation. Peripheral sensory receptor nociception is transmitted by afferent fibers that synapse on interneurons in the spinal cord and then synapse on spinal cord motor neurons. These motor neurons trigger muscle contractions that cause limb flexion and movement. The stress response can be mediated in the spinal cord, brainstem or basal ganglia without cortical involvement (see Chapter 7).

It is generally accepted that experiencing pain requires higher cognitive functioning and cortical recognition that the stimulus is unpleasant. This requires intact neural pathways from the periphery, through the spinal cord, to the thalamus, which relays the stimulus to the primary sensory cortex, the insular cortex, and the anterior cingulated cortex (Fig. 19.15). Peripheral sensory receptor afferents also synapse on spinal cord neurons that project to the thalamus, which relays afferent stimuli to the cerebral cortex and activates many different cortical regions. Sensory receptors and spinal cord synapses required for nociception develop earlier than the thalamocortical pathways required for conscious perception of pain. It is doubtful that fetal perception of pain is possible before there are pathways from the periphery to the brain and before cortical structures develop and become functional. However, the stage of gestation at which fetal pain perception is possible and whether the fetus must be awake or aware of its surroundings to perceive pain is unknown.

Nerve terminals for detection of touch, temperature, and vibration (not pain) are present deep in human skin by 6 weeks of gestation and become more numerous and

**Figure 19.14** Early in development, reflex responses to noxious stimuli occur before thalamocortical circuits are functional; noxious stimuli trigger reflex movement without cortical involvement. Activated by a noxious stimulus (1), a peripheral sensory neuron (2) synapses on a dorsal horn interneuron (3) that in turn synapses on a ventral horn motor neuron (4), leading to reflex muscle contraction and limb withdrawal (5). Reproduced from Lee et al [158] with permission from the American Medical Association.

**Figure 19.15** Later in development, noxious stimuli (1) activate peripheral sensory neurons (2) that synapse on spinothalamic tract neurons (3), the axons of which extend up the spinal cord as the spinothalamic tract (4) to synapse on neurons of the thalamus (5). From here, thalamocortical axons (6) synapse on cortical neurons, resulting in the conscious perception of pain (7). Reproduced from Lee et al [158] with permission from the American Medical Association.

have extended towards the skin surface by 10 weeks [159]. Immature skin nociceptors are probably present by 10 weeks and definitely present by 17 weeks [160]. Nociceptors develop slightly later in internal organs.

Peripheral nerve fibers that control movement first grow into the spinal cord at about 8 weeks of gestation. When these fibers connect with nociceptors is unknown but in other mammals this is more delayed than other sensory inputs. One human study suggests that nerve fibers from nociceptors do not enter the spinal cord before about 19 weeks [161]. The cerebral cortex develops after the fetal spinal cord and brainstem.

The developing cerebral wall consists of transient fetal zones where neuronal proliferation, cell migration, apoptosis, axonal outgrowth and synaptogenesis occur according to a highly specific timetable. Early in development, the cerebral cortex is a smooth layer without sulci and gyri and, like the thalamus, has no internal cellular organization [159]. The insular cortex starts developing in humans around 15 weeks' gestation, and the cortical subplate develops about 13 weeks. The subplate is a temporary structure located one layer deep to the cortical plate. The subplate recedes after 32–34 weeks' gestation and the cortical plate develops into the six layers of the cerebral cortex [162–164]. The subplate is crucial in cortex development because it serves as a waiting zone for various afferents, including thalamic afferents that are en route to the developing cortex. The subplate is also critical for establishing connections between the thalamus and cortex and for precise organization and laminar relocation of these afferent pathways.

The first fibers from the thalamus reach the subplate by 12 and 18 weeks' gestation and remain in the subplate until maturation of the cortical plate. By 24 weeks, substantial thalamocortical fibers have amassed in the subplate and have grown into the maturing cortex by 24 and 32 weeks. The gestational age at which thalamic pain fibers reach the human cortex can only be estimated from histological studies of other thalamocortical circuits. Thalamic projections reach the visual subplate at 20-22 weeks [163,165], the visual cortex at 23–27 weeks [166], and the auditory cortical plate at about 26-28 weeks' gestation [167]. The subplate thins in the insula and in areas of the brain where cortical folding occurs early. It disappears after a period of rapid relocation of fibers to the cortex at around 34 weeks' gestation. Massive brain growth and maturation occur after 34 weeks' gestation. This results in the typical cortical sulci and gyri and in development of extensive intracortical pathways and pathways from the cortex to the thalamus, midbrain, and spinal cord.

Given the development of pain pathways and interpretation of cortical function, it is unlikely that fetuses experience pain before 24 weeks' gestation (and perhaps significantly later) because the cortex must subsequently undergo considerable development and establish enormously complex and highly integrated neural networking, with dendritic and synaptic rearrangements that occur during late fetal life and infancy and continue into early childhood.

Although development of neural pathways from the periphery to the cortex is important, development of the cortex itself is probably necessary for fetuses to experience pain. The neural networking must also be functional. Although there are no specific electroencephalographic patterns for fetal pain, EEG studies provide some evidence for functionality. Studies at 24 weeks' gestation show the presence of cortical electrical activity only 2% of the time, with bursts that last about 20 sec and inactive periods that last up to 8 min [168]. By 30 weeks, EEG patterns are similar to those of wakefulness and sleep, but they are not continuous and are discordant with fetal behavior. By 34 weeks, electrical activity is present 80% of the time and EEG patterns become more distinct [169–172].

Can the fetus experience pain before there are connections from the periphery to cortex or before there is significant brain electrical activity? Some investigators have postulated that nociceptive information may be transmitted earlier through neurological connections from peripheral tissue through the brainstem and thalamus to the subplate. They argue that the midbrain reticular system is responsible for "consciousness" rather than the thalamocortical system [173]. Although midbrain systems are crucial for the waking state, instincts, orienting, goaldirected control, and purposeful behavior, consciousness is widely regarded as a very complex phenomenon for which the cerebral cortex is indispensable. Awareness and wakefulness are different phenomena.

Preterm neonates who undergo surgery with minimal anesthesia have circulatory, sympathoadrenal, and pituitary adrenal responses that are characteristic of stress. These include release of catecholamines, growth hormone, glucagon, cortisol, aldosterone, and other corticosteroids, as well as decreased insulin secretion [174,175]. Anesthesia blunts the neonatal stress response [176]. Opioids also improve the outcome of preterm neonates by attenuating the stress response [177].

In the human fetus, inserting a needle into the intrahepatic vein for blood transfusion induces the stress response, while needling the insensate umbilical cord does not. This response includes increased plasma  $\beta$ endorphin and cortisol concentrations and decreased Doppler-determined middle cerebral artery pulsatility index. The latter is consistent with redistribution of blood flow to vital organs, including the brain [178]. The stress response to intrahepatic vein needling is blunted by  $10\mu g/kg$  of fentanyl [179]. Human fetuses elaborate pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 18 weeks' gestation [180–183]. During late gestation, fetuses respond to environmental stimuli (e.g. noises, light, music, pressure, touch, and cold) [184]. However, these physiological stress related responses or reflex responses to external stimuli are not necessarily equivalent to the multidimensional, subjective phenomenon we call pain. Reduction in stress hormones is not necessarily indicative of adequate analgesia [185]. The stress response is largely mediated in the spinal cord, brainstem or basal ganglia, not the cortex.

Two studies used near-infrared spectroscopy to measure changes in cerebral oxygenation over the somatosensory cortex and demonstrated that noxious stimulation of preterm infants caused cortical responses that differed from those of non-noxious stimulation. They concluded that noxious information can be transmitted to the infant cortex from 24 weeks' gestation onward [186,187]. Preterm neonates have cortical evoked potentials after heel lancing [188]. Although these studies provide evidence of functional neural activity in the sensory cortex of 24-week-old preterm neonates, the primary sensory cortex is not the only brain area that mediates painful experiences; continued development and organization of the cortex are likely necessary. These were preterm neonates, not fetuses. In utero, the low level of oxygen alone may preclude awareness and the ability to experience pain. Furthermore, endogenous neuroinhibitors produced in the placenta (e.g. adenosine, allopregnanolone, pregnanolone, prostaglandin-D2, various placental peptide inhibitors) sustain fetal sleep and suppress fetal awareness [189]. Late-gestation fetuses oscillate between REM and NREM sleep 95% of the time. Data suggest that the other 5% of the time they are in a form of indeterminate transitional sleep, suggesting that the fetus is always asleep [190]. Unlike neonates, noxious stimuli do not appear to cause cortical arousal to a wakeful state in fetuses. Wakefulness is a state of arousal mediated by the brainstem and thalamus in communication with the cortex. It must be understood that wakefulness does not equal awareness. Thus, the intrauterine environment might keep the fetus from being awake, aware, and from experiencing pain. Maybe awareness is only possible after birth.

Although noxious stimulation might not affect fetal consciousness, it might influence neurological or behavioral development. Circumcision of a non-anesthetized neonate increases the infant's pain response to injections 6 months later, and fetal stress has long-term adverse hormonal effects in young monkeys [191,192]. Consequently, it is possible that noxious stimuli can have adverse long-term neurodevelopmental consequences that could be attenuated or blocked by anesthesia [173]. Of course, these effects later in life do not prove that the causal event was experienced as pain.

#### Anesthetic implications

Because it is unclear when fetuses feel pain, it seems best to err on the side of providing adequate fetal anesthesia [193]. Altogether, clinical observations of fetal and neonatal behavior, information about the development of mechanisms of pain perception, and studies of fetal and neonatal responses to noxious stimuli provide a compelling physiological and philosophical rationale for providing adequate fetal anesthesia, especially after 24-26 weeks' gestation. Although we do not know whether or when fetuses actually experience pain, noxious stimulation during fetal life causes a stress response, which could have short- and long-term adverse effects on the developing CNS. The link between the stress response and pain is not always predictable, but the threshold for pain relief is reliably well below the threshold for stress response ablation. Furthermore, the stress response to noxious stimulation is clear evidence that the fetal nervous system is reactive [194].

Despite ongoing debate regarding fetal capacity for pain perception, fetal anesthesia and analgesia are warranted for fetal surgical procedures. Evidence of fetal pain is unnecessary to justify providing fetal analgesia or anesthesia because doing so serves other purposes, including inhibition of fetal movement during a procedure; prevention of hormonal stress responses associated with poor surgical outcomes in neonates; prevention of possible adverse effects on long-term neurodevelopment and behavior; and for open procedures, to ensure profound uterine relaxation to prevent contractions and placental separation during open procedures. Anesthesia has been administered to fetuses undergoing *in utero* procedures since the inception of fetal surgery in 1981, and it is now practiced worldwide [195].

# Perioperative and procedural considerations

# Preoperative assessment and considerations

The anesthesiologist must conduct a thorough preoperative assessment of both the mother and fetus. In addition to a standard preoperative history and physical examination, specific details should be obtained regarding how the pregnancy is affecting this mother. A thorough respiratory and circulatory evaluation should include questions about shortness of breath, episodes of syncope or feeling lightheaded, and severity of gastric reflux. Imaging studies should be reviewed because they provide placental location and anatomical information about the fetal lesion. This information may alter the surgical approach and patient positioning and necessitate modification of the anesthetic plan. In certain circumstances, general anesthesia is chosen over neuraxial or local anesthesia if the maternal position compromises her safety or the duration of the surgery will be protracted. Most minimally invasive procedures can be performed with just a maternal type and screen of blood, while readily available, cross-matched blood is required for open procedures because the risk of hemorrhage is greater. In addition, type O-negative, leukocyte-depleted, irradiated, CMV-negative blood that is cross-matched against the mother should be readily available for fetuses undergoing open procedures. Maternal IgG antibodies cross the placenta.

## **Risks and benefits**

The primary goal of *in utero* surgery is to improve neonatal outcomes over those possible when surgical or medical interventions are performed after preterm or term birth. The intrauterine environment offers quicker wound healing, decreased scar formation, and an ideal postoperative recovery environment because the placental/fetal circulation provides all the fetus' nutritional, metabolic, and oxygen requirements.

Risks to the fetus (renal failure, fetal demise, CNS injuries, postoperative amniotic fluid leaks, membrane separation, preterm rupture of membranes, preterm labor, and preterm delivery) are relatively high. Chorio-amniotic membrane separation can cause amniotic bands, umbilical cord strangulation, and fetal demise. Preterm delivery carries significant morbidity and mortality for fetuses that might otherwise benefit from therapeutic interventions if they were born at term.

Maternal safety must be considered when developing an appropriate fetal management plan. The vast majority of fetal conditions that might benefit from fetal surgery pose no direct risk to the mother, but the procedure itself or medications administered may have risk for her, as does postoperative pain and discomfort. Although the potential for significant maternal morbidity is always present, fortunately maternal morbidity is relatively minimal or uncommon [9,10]. In a retrospective review of 87 hysterotomies performed at UCSF between 1989 and 2003, 28% of mothers had pulmonary edema, 52% had premature rupture of membranes, 13% required blood products, 9% had chorio-amnionitis, and the risk of preterm delivery was high and occurred at a mean gestational age of 30 weeks [9]. These risks include hemorrhage, wound infection or chorio-amnionitis, placental abruption, uterine rupture, and side-effects of tocolytics (including pulmonary edema) [12,196]. In addition, the risks of pulmonary aspiration, difficult ventilation/tracheal intubation, and hemodynamic compromise are increased during pregnancy. Open fetal procedures involve a hysterotomy incision that is away from the uterine segment. This necessitates cesarean delivery of the current and all future pregnancies of patients that have undergone an open fetal procedure. Future reproductive capabilities do not seem to be compromised [197]. Maternal safety and welfare must be balanced against the risk of fetal death or caring for a child with a significant morbidity.

# Interdisciplinary team

Perioperative care by a multidisciplinary team is essential for success of fetal surgical procedures and care of the mothers. In addition to the anesthesiologist's preoperative assessment, a typical case requires input from ultrasonographers and radiologists regarding ultrasound and MRI imaging to confirm diagnosis, detail the abnormal anatomy, and rule out other pathological lesions. Maternal-fetal medicine physicians, geneticists, and neonatologists provide patient counseling, fetal karyotyping and information about the likely condition of the newborn with or without in utero intervention. Fetal surgeons provide details of the procedure and associated risks and outcome potential to the family, and social workers and nurse co-ordinators address unique family situations, logistics and concerns, and potential psychological issues. Maternal partners must be involved in the process to alleviate potential perceptions of guilt or coercion, depending on the mother's final decision. Regular interdisciplinary meetings with obstetric anesthesiologists, obstetricians, fetal surgeons, neonatologists, maternalfetal medicine experts, ultrasonographers, operating room staff, nurse co-ordinators, and social workers allow team communication and provide awareness of patient developments by all caregivers. This maximizes the chance of successful outcomes for both mothers and fetuses. Before undertaking any fetal procedure, members of all disciplines should meet to ensure that a complete, detailed, and appropriate plan is in place and the necessary equipment and personnel are available.

# General intraoperative and postoperative considerations

Maternal analgesia/anesthesia for fetal surgery can be provided with local infiltration of the skin and uterine wall, intravenous maternal sedation, neuraxial anesthesia, general anesthesia or a combination of techniques.

In addition to the maternal anesthetic plan and the fetal surgical procedure, strategies must be developed for fetal monitoring, fetal analgesia and/or neuromuscular relaxation, management of unanticipated fetal or maternal distress, postoperative fetal and uterine monitoring, and maternal postoperative analgesia. The anesthesiologist must consider the anesthetic requirements of the fetus and appropriate intraoperative fetal monitoring (ultrasound, doptones, fetal oximetry), and the potential need for fetal intravenous access for fluid resuscitation or blood transfusion. Fetal analgesia and anesthesia can be provided by direct intravenous or intramuscular administration of drugs to the fetus, or placental transfer of maternal intravenous agents or general anesthetics. Many anesthetic compounds readily cross the placenta (e.g. induction agents, halogenated anesthetics, nitrous oxide, opioids, benzodiazepines), but only small amounts of muscle relaxants do so.

Fetal surgery necessitates control of uterine tone and profound uterine relaxation is required for open procedures. Concern for increased uterine tone and initiation of premature labor requires continuous or intermittent postoperative fetal heart rate and uterine activity monitoring, sometimes for days. Maternal postoperative analgesia includes intrathecal narcotics, continuous epidural analgesia, patient-controlled intravenous analgesia (PCA) or oral medications.

Finally, the anesthesiologist should be prepared, if the need arises, for emergency fetal delivery or uterine evacuation. If maternal cardiac arrest is precipitated by local anesthetic overdose, total spinal or severe hemorrhage, and resuscitation cannot be accomplished in 4 min, the fetus should be delivered as an emergency. Emergency cesarean delivery relieves aortocaval compression, improves the effectiveness of resuscitation, and increases the maternal and possibly the fetal chances for survival [198].

The following sections are generic descriptions of anesthetic approaches for both minimally invasive and open fetal procedures, and of postoperative management used at the University of California San Francisco. Our colleagues at other fetal treatment centers in the United States and Europe may employ variations on these techniques. The EXIT procedure is described previously and in the case study at the end of this chapter. Basic anesthetic considerations are similar to those for any woman undergoing surgery during pregnancy [199,200].

# Minimally invasive and percutaneous procedures

Amniocentesis, cordocentesis, intrauterine blood transfusion, needle aspiration of cysts, shunt placement into the fetal bladder or thorax, or SFLP for TTTS are typically defined as minimally invasive. These procedures are performed using an ultrasound-guided needle or by inserting a single, small-diameter sheath or cannula that allows insertion of an endoscope. Local anesthetic infiltration of the abdominal wall or neuraxial anesthesia is usually adequate for these procedures. If the procedure involves multiple needle punctures at various locations, large instruments or a mini laparotomy, neuraxial anesthesia often provides better maternal comfort. Choice of anesthesia technique is based on the surgical approach, anticipated duration of the procedure, and need for postoperative analgesia. Typically, the anesthetic is supplemented by conscious sedation. General anesthesia is rarely necessary unless placental location makes uterine exteriorization necessary. General anesthesia provides maternal comfort and prevents increased uterine tone during uterine manipulation. Before the procedure starts, the mother should be appropriately fasted, receive prophylaxis against aspiration, have adequate intravenous access, and be fully monitored. The technique used is similar to that described in the following section on open fetal procedures.

Use of local or neuraxial anesthesia does not provide fetal analgesia or immobility. Supplemental analgesia (opioids), anxiolysis (midazolam), and sedation (lowdose propofol infusion) provided to the mother will sedate her and may provide minimal fetal immobility and some analgesia following placental transfer. A randomized, blinded, controlled trial demonstrated that remifentanil ( $0.1 \mu g/kg/min$ ) resulted in more fetal immobility and better surgical operating conditions [201]. Any maternal sedation regime must assure that the mother remains within a level of "conscious sedation" to minimize maternal respiratory depression, loss of maternal airway reflexes, and pulmonary aspiration.

Fetal immobilization is unnecessary for certain minimally invasive fetal procedures, such as laser surgery of the chorionic plate (e.g. SFLP for TTTS). However, fetal movement may compromise the success of certain procedures by making them technically difficult or impossible. As an example, in the case of intrauterine transfusion or blood sampling, fetal movement may be hazardous because displacement of the needle or catheter may cause trauma, bleeding or compromise of the umbilical circulation and require emergency delivery. If the procedure requires fetal immobility and/or analgesia, muscle relaxants and/or opioids can be administered directly to the fetus. Non-depolarizing neuromuscular blocking agents, such as pancuronium or vecuronium, can be administered to the fetus by ultrasound-guided intramuscular (0.3 mg/kg) or umbilical venous (0.1–0.25 mg/kg) injection [202,203]. Pancuronium might be preferred for its longer duration of action and its vagolytic effect on fetal heart rate. Fetal paralysis with either agent occurs in 2-5 min. Vecuronium is often chosen when only 1-2h of fetal immobility are desired.

For procedures involving noxious stimulation of the fetus (e.g. shunt catheter placement, cardiac septoplasty), intramuscular or intravascular opioid (e.g. fentanyl 10– $25\mu g/kg$ ) can be administered to the fetus [179,199]. If general anesthesia is administered to the mother, placental transfer of inhaled anesthetic is sufficient to adequately immobilize and anesthetize the fetus.

A plan should be in place for treatment of fetal distress and should include having available weight-appropriate doses of drugs for fetal resuscitation (e.g. atropine, epinephrine). This plan may range from supportive or palliative therapy to emergency delivery. Cordocentesis occasionally causes prolonged fetal bradycardia, especially if the needle punctures the umbilical artery rather than the umbilical vein. Persistent fetal bradycardia in this situation or during other minimally invasive procedures may require an emergency cesarean section if the gestational age is compatible with extrauterine viability. Consequently, the anesthesiologist must be prepared to emergently provide general anesthesia if it is required.

# **Open fetal surgical procedures**

In utero procedures that require a maternal laparotomy and hysterotomy (e.g. myelomeningocele repair, sacrococcygeal teratoma resection) are typically performed using general anesthesia. In addition to anesthetic considerations required for minimally invasive fetal surgery and for surgery for maternal indications, open fetal procedures have some unique issues. These include the need for profound uterine relaxation; increased potential for significant maternal or fetal blood loss or fluid shifts; intraoperative fetal monitoring, fetal anesthesia, and the potential need for fetal resuscitation; and postoperative maternal analgesia and uterine quiescence. Box 19.1 details specific considerations that must be addressed before undertaking open fetal surgery. The majority of these items are also useful when planning for minimally invasive and EXIT procedures.

A non-particulate antacid is given preoperatively for prophylaxis against aspiration, rectal indometacin is placed for prophylactic tocolysis, and an epidural catheter inserted for postoperative analgesia. Type and crossmatched blood products are obtained for both mother and fetus. Sequential compression devices are placed on the mother's lower extremities to minimize the risk of deep venous thrombosis. Minimal preanesthetic medication (opioids or anxiolytics) is used so as not to increase hypotension when maximal doses of a volatile halogenated agent are administered. Similar to what occurs when any general anesthetic is administered after about 20 weeks of gestation, the patient is positioned with left uterine displacement, is adequately preoxygenated, and rapid-sequence induction and tracheal intubation are performed during cricoid pressure. Prior to incision, anesthesia is typically maintained with low concentrations of volatile agent. During this time, the ultrasonographer determines fetal presentation and placental location, additional large-bore vascular access is obtained, the urinary bladder is catheterized, and prophylactic antibiotics are administered.

For both open and EXIT procedures, 2–3 MAC of volatile anesthetic agent is used to provide maternal and fetal anesthesia and the surgical tocolysis (uterine atony) required for the procedure. Volatile anesthetic agents inhibit myometrial contractility by calcium-sensitive potassium channel modulation [204]. The human uterus has a thick, muscular layer that is sensitive to stimulation Box 19.1 Considerations for open fetal surgery

#### **Preoperative considerations**

- 1. Maternal counseling by multidisciplinary team
- 2. Complete maternal history and physical exam
- 3. Imaging studies to define fetal lesion and placental location
- Complete fetal work-up to exclude other anomalies or karyotype abnormalities
- 5. Surgical meeting or "time out" with all team members prior to starting
- 6. Prophylactic premedication: non-particulate antacid (aspiration) and rectal indometacin (tocolysis)
- 7. Blood products typed and cross-matched for potential maternal and fetal transfusion
- 8. Epidural catheter placement for postoperative analgesia
- 9. Sequential compression devices on lower extremities for thrombosis prophylaxis
- **10.** Fetal resuscitation drugs transferred to scrub nurse in unit doses

#### Intraoperative considerations

- 1. Left uterine displacement and standard monitors
- 2. Preoxygenate for 3 min prior to induction
- 3. Rapid-sequence induction and intubation
- **4.** Maintain maternal FiO<sub>2</sub> at  $\geq$ 50% and end-tidal CO<sub>2</sub> 26–28 mmHg
- 5. Ultrasonography to determine fetal and placental positioning
- **6.** Urinary catheter placed and additional large-bore intravenous access obtained
- 7. Administer prophylactic antibiotics
- Following incision, initiate high concentrations of volatile anesthetics (2–3 MAC)
- 9. Consider intravenous nitroglycerine if uterine tone remains increased
- 10. Maintain blood pressure with IV phenylephrine or ephedrine
- **11.** Intramuscular administration of fetal opioid and paralytic with ultrasound guidance or by direct vision
- **12.** Place fetal pulse oximeter and use periodic ultrasound for fetal monitoring
- 13. Obtain fetal vascular access if significant fetal blood loss expected
- **14.** Restrict maternal maintenance fluids to <2L to decrease risk of pulmonary edema
- **15.** Administer loading dose of IV magnesium sulfate when uterine closure begins
- **16.** Discontinue halogenated agents after magnesium sulfate bolus complete
- Activate epidural for conclusion of surgery and postoperative analgesia
- **18.** Administer nitrous oxide and opioids to supplement epidural anesthesia
- Monitor neuromuscular blockers carefully due to potentiation of magnesium sulfate
- 20. Extubate trachea when patient fully awake

#### Early postoperative considerations

- 1. Continue tocolytic therapy
- 2. Patient-controlled epidural analgesia
- 3. Monitor uterine activity and fetal heart rate
- 4. Ongoing fetal evaluation (ultrasonography, etc.)

or manipulation. Thus, uterine incision and stimulation may produce strong uterine contractions. Halogenated anesthetics cause dose-dependent inhibition of uterine contractions and myometrial tone. Complete uterine relaxation is essential because increased tone compromises uterine perfusion, especially during uterine manipulation, and increases the risk for partial placental separation. High intravenous doses of nitroglycerine may also be used as a supplemental or primary agent for intraoperative uterine relaxation [44].

Prior to hysterotomy, the volatile agent is increased (>2 MAC) and the uterus is assessed for increased tone. Fetal uptake and distribution of maternal anesthetic gases take longer than the mother, but fetal MAC is lower [205]. If increased uterine tone is noted before or after incision, the halogenated agent can be increased (up to 3 MAC) or additional small boluses of IV nitroglycerine can be given (50-200µg intravenously) or by continuous infusion. If nitroglycerine is used without high concentrations of volatile anesthetic, an infusion of up to  $20\mu g/kg/min$  IV may be required. Although nitroglycerine crosses to the fetal circulation, fetal effects are minimal because there is significant metabolism of nitroglycerine by the placenta [44]. Arterial blood pressure is maintained with IV phenylephrine or ephedrine as needed to maintain adequate mean arterial pressures (>65mmHg). Maternal monitoring by arterial line and central venous catheter is not typically used.

Brief fetal exposure to more than 2–3 MAC of inhaled anesthetic appears to be safe. However, the combined impact of adequate fetal anesthesia with a halogenated agent, intrauterine manipulation, and fetal stress on fetal cardiovascular stability and regional blood flow is unknown. Recent animal studies have demonstrated neuronal apoptosis in the developing brain when a variety of agents are administered to induce and maintain general anesthesia [154,206]. Implications for the fetus and neonate from brief anesthetic exposures are currently unknown, due to lack of human studies and difficulties extrapolating animal study methods to humans. In our experience at the University of California San Francisco, long and deep maternal inhalation anesthesia has not caused fetal hypoxia, hypercarbia or acidosis, even after 2h of exposure. However, others have reported acidosis after only 45 min of fetal anesthesia [207].

Cross-matched blood for the mother and O-negative, CMV-negative, leuko-reduced, irradiated blood for fetal transfusion should be readily available in the operating room. For open procedures with the potential for significant fetal blood loss (e.g. sacrococcygeal teratoma resection), close attention to fetal monitoring and estimated fetal blood loss is required. It may be necessary to insert a fetal intravenous catheter to transfuse blood. Vascular access is obtained in a fetal hand or arm vein, or by surgical cut-down on the internal jugular vein. Intraoperative ultrasound is used to determine placental location and fetal position. Uterine incision is made away from the placenta but in a position that allows for appropriate exposure of the fetal part. A stapling device with absorbable lactomer staples is used to prevent excessive bleeding and seal the membranes to the endometrium [208]. During surgery, the exposed fetus and uterus are bathed with warm fluids and intrauterine temperature monitored.

With ultrasound guidance or direct vision, opioid (e.g. fentanyl 10–25 $\mu$ g/kg) and muscle relaxant (e.g. pancuronium or vecuronium 0.1–0.3 mg/kg) are administered intramuscularly before the fetal incision [199,209]. However, these agents are seldom required when the mother is anesthetized with a general anesthetic. Drugs for fetal resuscitation (atropine 0.02 mg/kg, epinephrine 1 $\mu$ g/kg, and crystalloid 10 mL/kg) are sterilely transferred to the scrub nurse for administration (if needed) under direction of the anesthesiologist. Each syringe is prepared with a single, unit weight-based dose and appropriately labeled. Multiple dose syringes should be avoided to reduce the risk of accidental overdosing.

Maternal and fetal anesthesia, uterine incision, fetal manipulation, and surgical stress may adversely affect uteroplacental and fetoplacental circulation by several mechanisms. Maternal hypotension increases uterine activity and causes maternal hyperventilation and hypocarbia, which impair uteroplacental and/or umbilical blood flow. Manipulation of the fetus may affect cardiac output, regional distribution of cardiac output, and/or umbilical blood flow. Direct compression of the umbilical cord, inferior vena cava and/or mediastinum adversely affects fetal circulation. Fetal well-being is assessed by continuous fetal pulse oximetry, periodic fetal heart rate (FHR) monitoring by intraoperative ultrasonography, fetal echocardiography for assessment of ventricular contractility, and/or direct fetal ECG. The predictive value of pulse oximetry may be superior to FHR monitoring. In fetal lambs, bradycardia was found to be a late sign of fetal distress following umbilical cord compression [210]. However, in our experience and that of others [211], bradycardia can precede oxygen desaturation during human fetal surgery. Ultrasonography can assess fetal heart rate by either direct visualization of heart motion or by Doppler assessment of umbilical cord blood flow. Echocardiography can be used to assess fetal cardiac contractility and filling volume. Unfortunately, the sterile transducer cannot be left in position continuously because it interferes with surgery. Under specific circumstances, capillary or umbilical venous blood samples can be obtained for blood gas, pH, electrolyte, and glucose determinations. One significant limitation is the inability to monitor fetal blood pressure easily. In the future, placental vessels might be catheterized for continuous blood

pressure monitoring and blood gas determinations. Fetal ECG waveform analysis might also provide additional useful information.

During surgical closure, a loading dose of magnesium sulfate is administered (4-6g) intravenously over 20min and is followed by an intravenous infusion of 1-2g/h to (hopefully) maintain uterine atony and prevent postoperative contractions. Intraoperatively, maternal intravenous fluids are normally restricted to minimize the risk of postoperative pulmonary edema that is associated with the use of tocolytic agents [9,212]. Inspired concentrations of halogenated agents are significantly decreased or discontinued once the magnesium sulfate bolus has been administered. Maternal anesthesia can be maintained with a combination of IV fentanyl, nitrous oxide in oxygen, and activation of epidural anesthesia after first carefully testing for catheter position. Discontinuing the high-dose volatile agent at the beginning of surgical closure allows more time for the elimination of volatile halogenated agent from tissues. This regimen facilitates timely tracheal extubation of a fully awake patient and minimizes the likelihood of coughing or straining and jeopardizing the integrity of the uterine closure. The epidural allows the patient to emerge pain free. If neuromuscular agents are utilized, the absence of neuromuscular blockade should be determined prior to tracheal extubation, since magnesium sulfate potentiates neuromuscular blockade. When utilized, neuromuscular agents must be carefully titrated in anticipation of later administration of magnesium.

Whatever anesthetic technique is used for open fetal surgery, it must ensure adequate uteroplacental perfusion, profound uterine relaxation, maternal hemodynamic stability, fetal anesthesia and immobility, and minimal fetal myocardial depression and compromise.

#### **Postoperative management**

Management of postoperative preterm labor has been one of the most difficult aspects of fetal surgery [32], but prevention and treatment of uterine contractions are essential for optimal fetal outcomes. Postoperative tocolysis has included a variety of agents, including magnesium sulfate, β-adrenergics, indometacin, and calcium-entry blockers. Magnesium likely competes with calcium at voltage-operated calcium-sensitive potassium channels by an action similar to volatile anesthetics [204]. Indometacin blocks the synthesis of prostaglandins, and β-adrenergic agents act directly on the uterus by activating adenylate cyclase and thereby reducing intracellular calcium. The relative inefficacy of tocolytic agents and their adverse side-effects have made this aspect of postoperative management challenging. Tocolysis is normally unnecessary after cordocentesis or intrauterine transfusion but for more invasive percutaneous procedures (e.g. shunt catheter placement, endoscopic techniques), postoperative tocolytics are used at most centers.

With open fetal procedures, early postoperative uterine contractions are expected and tocolysis is provided by a continuous infusion of magnesium sulfate for approximately 24h. This is supplemented with indometacin and occasionally with terbutaline or nifedipine as indicated.

Postoperative analgesia can be provided by several days of continuous epidural analgesia or by intravenous opioids by PCA. Effective analgesia may help prevent preterm labor by decreasing plasma oxytocin levels [213]. In addition to preterm labor, other postoperative concerns include rupture of membranes, infection, and fetal complications that include heart failure, intracranial hemorrhage, indometacin-induced constriction of the ductus arteriosus, and fetal demise. Uterine activity and FHR are monitored closely during the first few postoperative days. The fetus is evaluated daily by ultrasonography and echocardiography, looking for ductal narrowing, cardiac valvular function, and oligohydramnios. In some cases, magnetic resonance imaging is used to determine the presence of intracranial hemorrhage.

# Future of fetal therapy and surgery

The future of fetal diagnosis and therapy is bright and provides many opportunities for advances that benefit the fetus and perhaps adults with diseases that originate during fetal development. Fetal tissue engineering may provide perinatal treatment of congenital anomalies. For example, neural stem cells can mediate repair of postnatal spinal cord impairments in experimental animals, suggesting that stem cells might be used to promote fetal spinal cord repair for myelomeningocele [214–216]. Prenatal gene therapy with viral vectors or naked DNA, combined with microbubble-enhanced ultrasound, holds promise for possible treatment of hemophilia disorders, cystic fibrosis, and muscular dystrophy [217].

The future for fetal surgical intervention is that the majority of interventions will be performed percutaneously, using imaging or endoscopic guidance. Further miniaturization of surgical tools and improvements in endoscopes will facilitate this. Although use of minimally invasive techniques will simplify anesthetic management, many issues remain unresolved because research in this area is difficult. Potential neurotoxicity of anesthetic agents in the fetal and neonatal brain, impact of surgical stress on the fetus and/or later in life, and optimal anesthetic techniques are among the many issues that require further evaluation. Future advances in fetal therapy and surgery require careful consideration of potential fetal benefit and fetal risk and, most importantly, maternal risk. Maternal safety remains a paramount concern for the anesthesiologist.

# CASE STUDY

Ultrasound diagnosis of a large (>6cm) fetal neck mass, consistent with a cervical teratoma, was made in a 25-yearold, gravida 1 woman at 32 weeks' gestation. The mother was otherwise healthy, and no other anatomical abnormalities were detected in the fetus. The ultrasound images and patient's history were discussed at the weekly, multidisciplinary fetal treatment conference and it was decided to re-evaluate the fetus in 2 weeks. The delivery strategy was by EXIT procedure at 38 weeks' gestation after confirming fetal lung maturity by amniocentesis. Concern was expressed that it would not be possible to intubate the trachea by laryngoscopy during the EXIT procedure, given the massive size of the lesion. No significant changes occurred in the mother during the ensuing 2 weeks, and she was admitted at 38 weeks' gestation for amniocentesis. Measurement of surfactant phospholipids secreted by the fetal lungs revealed a favorable lecithin/sphingomyelin ratio and presence of phosphatidylglycerol (PG) and gave assurance of lung maturation. The EXIT procedure was scheduled for the following morning. All team members were notified and their availability confirmed by the perinatologists who performed the amniocentesis. The fetal surgery team included pediatric surgeons (fetal surgeons), radiologists (ultrasonographers), neonatologists, anesthesiologists, and nurses.

Before entering the operating room, all team members participated in a pre-procedure conference to ensure the availability and readiness of all necessary equipment and personnel, and to discuss the surgical plan, issues specific to the case, and potential complications that might arise. In preparation for the procedure, the anesthesiologists checked their anesthesia machine, maternal and fetal drugs and their doses, and ensured that a manometer, sterile hand ventilation bag, and separate source of oxygen supply were available for ventilating the fetal lungs once an airway was established. The anesthesiologists had a second pulse oximeter and sterile probe for fetal monitoring. They also prepared a combination of paralytic agent and opioid to administer to the fetus and transferred the sterile "cocktail" to the scrub nurse. Similarly, two doses of atropine and two doses of epinephrine were prepared in labeled, 1mL syringes for emergency administration to the fetus, if needed. Each labeled 1mL syringe was prepared by unit weight-based dosing so excessive doses could not be mistakenly given from a multidose syringe during an emergency. The scrub nurse ensured the appropriate surgical equipment was available, as well as sterile laryngoscopes, bronchoscopes, a Jackson-Rees non-rebreathing circuit, endotracheal tubes, cables and sensors for pulse oximetry, including transparent adhesive medical dressing to secure the oximeter and an opaque cover to shield the oximeter sensor from the surgical lights.

The mother was premedicated with 30 mL of sodium citrate before entering the operating room. A 'time-out" was completed, and an epidural catheter was placed for postoperative pain control. The mother was then positioned supine and left uterine displacement was initiated to prevent aortocaval compression by the gravid uterus; 100% oxygen was administered by tight-fitting facemask while pulse oximeter, arterial blood pressure cuff, and electrocardiogram leads were applied. The fetus was evaluated by ultrasonography and was noted to be in a cephalic presentation; the fetal heart rate was 130 beats per minute with appropriate variability. After denitrogenation of the mother's lungs and application of cricoid pressure, rapidsequence induction of anesthesia was performed with propofol and succinvlcholine and the trachea was rapidly intubated. Once tracheal intubation was confirmed by auscultation and by normal-appearing carbon dioxide endtidal waveform tracings, sevoflurane was administered. A urinary catheter and a second large-bore intravenous catheter were placed. Prophylactic antibiotics were administered, and the abdomen was prepped and draped. The fetal surgeon, perinatologist, and neonatologist positioned themselves around the surgical table, and the equipment was readied. The neonatologist passed the oxygen supply line to the fetal breathing circuit and an additional catheter for connection to the manometer over the drape to the anesthesiologist. Together, they ensured the integrity and dynamics of the circuit, with a pop-off valve set for 20 cmH<sub>2</sub>O to avoid iatrogenic pneumothorax when fetal ventilation was initiated. The pulse oximeter cable was passed over the drape and connected to the second oximeter. The sensor was tested to ensure all connections were intact.

Following a Pfannenstiel incision, the sevoflurane concentration was increased, and was 1.9 MAC when the hysterotomy occurred. No vasopressor support was required to maintain the mean arterial pressures above 65 mmHg. The uterus was visualized and palpated to assess tone. Since it was not sufficiently relaxed, the inspired concentration of sevoflurane was increased. The ultrasonographer determined the edges of the placenta so the surgeons could avoid it during hysterotomy. After 5 min, the end-tidal sevoflurane concentration was 2.6 MAC, the mother's vital signs were stable, the fetal heart rate was about 130 beats/ min, and the uterus was appropriately soft. A purse-string suture was placed in the uterine wall and an incision was made that was just large enough to insert a uterine stapler to divide the myometrium and membranes and to apply absorbable staples to seal the edges of the hysterotomy and provide hemostatsis. Given the somewhat anterior location of the placenta, the hysterotomy was performed towards the uterine fundus using the "classic" uterine incision, which will require all future babies to be delivered by cesarean section without having undergone labor.

Once the uterus was opened, a "cocktail" of 3mg morphine and 0.4 mg pancuronium was administered into the fetus' left triceps muscle. The fetal head and upper thorax were delivered, and the pulse oximeter was placed across the fetus' left palm and secured with a transparent adhesive dressing and covered with an opaque dressing to shield the sensor from the surgical lights. The pediatric surgeon, neonatologist, and anesthesiologist were unable to visualize airway structures by laryngoscopy and bronchoscopy (Fig. 19.16). Initially, a decision was made to perform a tracheostomy, but this was considered unwise given the size of the neck lesion. Instead, during the next 2h the teratoma was excised while the fetus was maintained on placental support and monitored by pulse oximetry. Peripheral venous access was obtained in the left arm (Fig. 19.17). After the teratoma was resected, it was necessary to perform a tracheostomy. After the airway was secured, positive pressure ventilation was initiated with peak pressures of 20 cmH<sub>2</sub>O and a positive end-expiratory pressure of 4cmH<sub>2</sub>O. The fetal oxygen saturation rapidly rose and when it exceeded 90%, the umbilical cord was clamped and cut, and the newborn was delivered to the awaiting neonatal resuscitation team for further care. Blood gases from a doubly clamped segment of the umbilical cord were normal and showed no evidence of acidosis.

After cord clamping, sevoflurane was discontinued, an infusion of oxytocin (30 units) was started, the mother's lungs were ventilated with 70% nitrous oxide in oxygen, intravenous fentanyl (100µg) was administered, and a test dose was given through the epidural catheter. When it was determined that the catheter was not in a vein or subarachnoid, epidural lidocaine 2% was administered. The perinatologist closed the uterus and abdomen, and the patient awakened without pain. She received 2L of crystalloid, no colloid or blood, had 150 mL of urine output, and an estimated blood loss of 650 mL. Fluids were purposely minimized to decrease the risk of pulmonary compromise. Over the first 36 postoperative hours, analgesia was provided with an infusion of bupivacaine 0.1% into the epidural space using patient-controlled epidural analgesia. The mother did well. The pathology confirmed a teratoma, and the neonate did well.

#### **Key points**

- **1.** Successful EXIT procedures are a multidisciplinary team effort in which detailed preoperative planning and discussion among all team members are crucial.
- **2.** Detailed anatomical information regarding airway mass and placental position is needed for appropriate patient selection and optimal outcome.
- **3.** Thorough preparation and planning for unanticipated emergency events (e.g. fetal bradycardia, maternal hemorrhage, failed fetal tracheal intubation) are critical to successful outcome.
- **4.** Prolonged exposure to anesthesia does not lead to fetal acidosis.

- 3. Harrison MR, Bressack MA, Churg AM et al. Correction of congenital diaphragmatic hernia in utero. II. Simulated correction permits fetal lung growth with survival at birth. Surgery 1980; 88: 260-8. This is one of the earliest studies demonstrating the rationale for fetal surgery. The investigators created a model of a progressively enlarging intrathoracic mass in the sheep fetus using a conical silicone rubber balloon to produce severe pulmonary hypoplasia, simulating the pathophysiology of congenital diaphragmatic hernia. This study demonstrated that simulated correction later in gestation by balloon decompression allowed sufficient lung growth and development to alleviate the respiratory insufficiency and allow neonatal survival. Lambs without simulated correction died. Those with simulated correction had increased lung weight, air capacity, compliance, and area of the pulmonary vascular bed. Efficacy of in utero correction of an anatomical defect was confirmed.

Although fetal surgery had been successful in the ovine and other lower animal models, the gravid uterus of the primate is more sensitive to surgical stimulation and induction of preterm labor. Surgical, anesthetic and tocolytic techniques were refined in monkeys to allow fetal surgery in the late second and early third trimesters without increasing maternal or fetal-neonatal mortality.
- Harrison MR, Golbus MS, Filly RA et al. Fetal surgery for congenital hydronephrosis. N Engl J Med 1982; 306: 591–3. This is a case report of the first open fetal surgery; bilateral ureterostomies were performed at 21 weeks' gestation for bilateral hydronephrosis.
- 13. Mychaliska GB, Bealer JF, Graf JL et al. Operating on placental support: the *ex utero* intrapartum treatment procedure. J Pediatr Surg 1997; 32: 227–30; discussion 30–1. To address the clinical problem of neonatal airway obstruction created by temporary tracheal occlusion for treatment of congenital diaphragmatic hernia, the *ex utero* intrapartum treatment (EXIT) procedure was established. EXIT allows fetal treatment to be performed while maintaining the fetoplacental circulation until the neonatal airway is secured. Use of this technique rapidly expanded to include many other causes of prenatally diagnosed airway obstruction.
- Jani J, Gratacos E, Greenough A et al. Percutaneous fetal endoscopic tracheal occlusion (FETO) for severe left-sided congenital diaphragmatic hernia. Clin Obstet Gynecol 2005; 48: 910–22. These investiga-

tors from Leuven, Belgium, pioneered advances in minimally invasive fetal surgical techniques. This paper reports the evolution of their fetoscopic tracheal occlusion technique for fetuses with severe congenital diaphragmatic hernia. Rather than restoration of airway patency by EXIT, they employed a technique of *in utero* reversal of occlusion (plug–unplug sequence), based on data showing less deterioration of alveolar type II cell counts and to avoid the need for hysterotomy (EXIT).

- 158. Lee SJ, Ralston HJ, Drey EA et al. Fetal pain: a systematic multidisciplinary review of the evidence. JAMA 2005; 294: 947–54. The human fetus can mount a hormonal stress response to noxious stimulation, but whether the fetus can experience pain remains controversial. This paper reviews the evidence regarding the capacity for fetal pain based on neurodevelopment.
- 178. Giannakoulopoulos X, Sepulveda W, Kourtis P et al. Fetal plasma cortisol and beta-endorphin response to intrauterine needling. Lancet 1994; 344(8915): 77–81. This landmark study clearly demonstrated that the human fetus has a hormonal stress response to noxious stimulation, raising the possibility that the fetus feels pain *in utero* and may benefit from anesthesia. Cortisol and β-endorphin concentrations increased with prolonged fetal abdominal needling (to access the intrahepatic vein), but not with needling the placental cord insertion, which is not innervated.
- 179. Fisk NM, Gitau R, Teixeira JM et al. Effect of direct fetal opioid analgesia on fetal hormonal and hemodynamic stress response to intrauterine needling. Anesthesiology 2001; 95: 828–35. In another important study, these investigators demonstrate that the hormonal stress response of the human fetus to abdominal needling can be attenuated by intravenous fentanyl. Whether the fetus can experience pain remains controversial, but this study demonstrates that the hormonal stress response can be modified by fetal anesthetic administration
- 189. Mellor DJ, Diesch TJ, Gunn AJ et al. The importance of 'awareness' for understanding fetal pain. Brain Res Brain Res Rev 2005; 49: 455–71. Understanding whether the fetus can experience pain based on neurodevelopment alone may be inadequate. This provocative paper examines the role of endogenous neuroinhibitors, such as adenosine and pregnanolone, that are produced by the fetoplacental unit and contribute to fetal sleep states, suppressing fetal awareness.
- 205. Gregory GA, Wade JG, Beihl DR et al. Fetal anesthetic requirement (MAC) for halothane. Anesth Analg 1983; 62: 9–14. In a novel set of experiments, these investigators demonstrated that the MAC of the sheep fetus was significantly lower than that of the pregnant ewe. This has significant implications for fetal surgery and anesthesia.

# Introduction

Respiratory manifestations, 477

Preoperative evaluation of premature neonates is the most important part of anesthesia. During this time the anesthetist determines what abnormalities are present, gathers information from the intensive care nursery (ICN) team, and makes plans to care for the infant during the perioperative period. The following pages provide information about premature infants, preoperative evaluation, and provision of anesthesia. This information is the basis for understanding the physiology and pathophysiology of preterm neonates, which is necessary for effective evaluation of these patients for surgery and for providing appropriate care for them.

# Background

Six percent of infants are born prematurely, i.e. <37 weeks' gestation. The more immature they are at birth, the more likely they are to die during the neonatal period and to have serious complications. Great strides have been made

in reducing this mortality rate, even in very small infants. It is now expected that at least 60–70% of infants weighing <750 g at birth will survive [1]. With this increased survival has come a host of complications that often require surgery, including patent ductus arteriosus (PDA), retinopathy of prematurity (ROP), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH) with hydrocephalus, and inguinal hernias, to name a few.

Most body organs undergo continuous structural and functional development during the last 3 months of gestation. Infants born prematurely have inadequately developed organs that are required to perform functions that may be beyond their capacity. Consequently, preterm infants are less able to maintain their body temperature, suck, swallow, eat, and sustain breathing. Many of them experience asphyxia at or just before birth, predisposing them to central nervous system injury, intraventricular hemorrhage, necrotizing enterocolitis, myocardial dysfunction, and the respiratory distress syndrome (RDS).

Preterm infants can be divided into three groups: borderline premature (36–37 weeks' gestation); moderately premature (31–35 weeks' gestation); and severely

premature ("micropremies", 24–30 weeks' gestation). The problems of each group increase in number and severity with decreasing gestational age [2].

#### **Borderline prematurity**

Sixteen percent of all livebirths are borderline premature and can usually be cared for in the normal neonatal nursery. However, they do require close observation for the first 12h of life, because, as a group, they have more difficulty maintaining their body temperature without added external heat, and they may not suck and feed well. If feeding is a problem, gavage feeding may be required for a few days, and they may be slow to regain their birthweight, especially if they have RDS. Eight percent of borderline premature infants born by cesarean section have RDS versus 1% of those born vaginally, probably because those born vaginally more effectively remove water from the lungs [3].

Because they are predisposed to respiratory distress, the respiratory system of near-term infants must be carefully evaluated during the preoperative visit. Intercostal retractions, tachypnea, grunting respirations, and cyanosis suggest RDS but also may be signs of meconium aspiration, pneumothorax or pneumonia in these large preterm infants. Temperature instability and hyperbilirubinemia suggest sepsis but are usually just manifestations of prematurity.

#### Moderate prematurity

Moderately premature infants (31–36 weeks' gestation) account for 6–7% of all births. The neonatal mortality of infants born at 31 weeks' gestation is below 5% whereas it is nearly zero at 36 weeks' gestation if there are no congenital anomalies. The major causes of death are intracranial hemorrhage, sepsis, and RDS.

# Extremely premature infants (micropremies)

Infants of 24–30 weeks' gestation make up about 1% of all liveborn infants. However, they account for more than 70% of neonatal mortality. They also account for a major portion of neurologically damaged infants later in life. The causes of death include birth asphyxia, acidosis, and respiratory failure (congestive heart failure, patent ductus arteriosus, RDS, infections, especially  $\beta$ -streptococcus and listeria), necrotizing enterocolitis, and intracranial hemorrhage. All the problems of prematurity are exaggerated in these very immature infants.

About one out of 200 term infants, one out of 20 moderately premature infants, and one out of two infants weighing less than 1kg at birth suffer birth asphyxia. Preterm fetuses are more prone to asphyxia than term fetuses because the preterm infant's blood oxygen content is lower (due to lower hemoglobin concentrations) than that of term infants. Slight degrees of stress lead to anaerobic metabolism and metabolic acidosis, which in turn reduce cardiac output and increase cerebral blood flow. The latter may damage the central nervous system (CNS) if it causes the fragile vessels of the periventricular areas of the brain to bleed [4,5]. Causes of asphyxia include antepartum hemorrhage, intrauterine infections, breech delivery, and RDS. Treatment of birth asphyxia has been described elsewhere [6].

Most severely premature infants are asphyxiated at birth and often require tracheal intubation and assisted ventilation or nasal continuous positive pressure breathing (nCPAP) as part of delivery room resuscitation. It is hoped that early application of nCPAP will avoid some of the complications of tracheal intubation and mechanical ventilation, although this is unproven [7]. However, early nCPAP does reduce the number infants who require mechanical ventilation by approximately 50% [8]. These infants frequently have both metabolic and respiratory acidosis and require mechanical ventilation, blood volume expansion and, if necessary, a slow, cautious infusion of enough sodium bicarbonate or tris(hydroxymethyl)aminomethane (THAM) to correct their pH to 7.3.

During resuscitation, ventilation should be controlled during sodium bicarbonate infusion and should never be infused more rapidly than 1mEq/kg/min. Rapid infusion of bicarbonate may quickly expand the intravascular volume, raise the arterial blood pressure, and increase the PaCO<sub>2</sub>, all of which can cause intracranial hemorrhage in premature neonates. Fifty mL of sodium bicarbonate (50 meq) produces 1250 cc of CO<sub>2</sub> when the bicarbonate is fully reacted with hydrogen ions. This is of little consequence if the lungs are normal and can easily excrete the additional CO<sub>2</sub>. If the lungs are abnormal, the PaCO<sub>2</sub> may rise rapidly and cause IVH or cardiac arrest. Artificial ventilation is one way to prevent these complications. What is considered an "adequate" PaCO<sub>2</sub> has changed over the years. Many preterm neonates now undergo "permissive hypercapnia" with PaCO<sub>2</sub> as high as 70 mmHg if the pH is 7.2 or above [9]. Compensation for the hypercapnia includes bicarbonate retention and a positive base excess. If the PaCO<sub>2</sub> is reduced to normal, the pH increases and cerebral blood flow decreases. This alkalosis may also decrease the ionized calcium concentration, myocardial function, and arterial blood pressure.

In the past, hypoglycemia was partly responsible for the increased incidence of CNS damage in small preterm infants [10]. Fortunately, hypoglycemia is less common today because blood glucose concentrations are maintained between 50 and 90 mg/dL, not 20–40 mg/dL as in the past. Hyperglycemia is also to be avoided because fewer hyperglycemic patients can be resuscitated from a cardiac arrest and those who are resuscitated have more CNS damage [11]. Hyperglycemia also causes an osmotic diuresis and can cause hypovolemia. Unlike older patients, premature infants spill glucose in their urine with blood sugar concentrations as low as 125 mg/dL.

# Common problems associated with prematurity

The following are some problems associated with prematurity. While they are covered more fully in other chapters, they are presented here to give an overview of the problems and to provide a means of organizing one's thoughts when planning anesthesia for a preterm infant.

In general, anesthesia for premature infants is fraught with problems because they often have multisystem disease and respond poorly to anesthesia. To reduce the risk, it is important to garner as much information preoperatively as possible. A common mistake, especially among novice anesthetists, is to ignore the fact that those caring for the infant in the NICU have considered the patient's problems over an extended period of time and have come to a plan of therapy based on an understanding of these problems. It is neither appropriate nor sensible to alter this plan, unless there is an urgent reason to do so, without thorough discussions with the neonatologists.

# **Temperature regulation**

Hypothermia, or even exposure to a cold environment, increases the metabolic rate and oxygen consumption of preterm infants, which can cause hypoxemia, acidosis, apnea or respiratory distress and is a risk factor for infant mortality [12]. The minimal oxygen consumption of preterm infants is 4.3–5.4 cc/kg/min on day 1 and 8–9 cc/ kg/min by 2 weeks of age [13]. As the oxygen consumption increases, so do the ventilation and caloric requirements. Body heat is dissipated by conduction, convection, radiation, and evaporation. During mechanical ventilation, heat and liquid are lost from the lungs, especially when dry gases are used in the operating room. This can be avoided by using warmed, humidified gases. The surface/volume ratio of preterm infants is high, and their flaccid, open posture tends to increase heat loss rather than conserve it. The preterm neonate's lack of insulating fat allows more heat loss from the core to the surface.

Evaporative heat loss accounts for approximately 25% of the heat lost in term neonates and adults. Brück [14] showed that preterm neonates can vasoconstrict and increase heat production when exposed to cold, but they still lose heat because they lack insulation and their overall heat production is lower. The rise in metabolic rate in preterm neonates is approximately linear between

28° and 36°C [13]. Extremely low birthweight neonates do not peripherally vasoconstrict, which is a problem in cold operating rooms [15].

Young infants become agitated and move more in response to cold. Serum norepinephrine concentrations increase, which stimulates brown fat metabolism and heat production. The increased heat produced warms the CNS and vital organs [16]. Primitive brown fat cells begin to differentiate from reticular cells at 26–30 weeks' gestation [17] and increase in size and number for 3–6 weeks after birth. Infants born before the cells fully develop have more difficulty maintaining their body temperature when exposed to cold environments, as do hypoglycemic infants and those with CNS damage.

Because small premature infants lose heat and water through their thin, transparent skin, they easily become dehydrated, especially when cared for under a radiant warmer and are fluid restricted. Covering the premature infant's body with clear plastic film, and the head with a cap significantly reduces both heat and water loss, as does warming and fully humidifying the inspired gases to 34–37°C [18,19]. The addition of forced air warming systems, circulating water blankets, and room temperature of 30°C provide maximal efficiency in reducing dry heat loss [20].

The clinical consequences of chilling include periodic breathing or apnea, bradycardia, metabolic acidosis, hyperglycemia, and aspiration of gastric contents. Fewer infants nursed in non-neutral thermal environments survive [21]. Those who survive gain weight more slowly. Maternal anesthesia (general) and neonatal fentanyl analgesia cause hypothermia in some infants, while morphine or conduction anesthesia does not [22].

# **Respiratory manifestations** Respiratory distress

Respiratory distress is common in preterm infants. It occurs three times more often after cesarean section than after a vaginal birth. The less mature the infant, the more severe the disease tends to be, although some very immature infants escape this affliction, especially if given surfactant shortly after birth or if there was chorio-amnionitis [23]. Survival of preterm infants depends on their size and gestational age. Moderately premature babies (1500-2500 g) with RDS require more support of ventilation and fewer of them survive than their larger counterparts. Despite their small size, more than 95% of the former should survive. Eighty-five percent of those weighing less than 1000g and about 80% of those weighing less than 750 g now survive. Administration of exogenous pulmonary surfactant at birth has increased survival and decreased serious complications [24,25]. This rapidly improves lung function, which can lead to pulmonary gas leaks and lung injury if ventilation pressures are not decreased appropriately. The increased lung compliance improves oxygenation, which increases the likelihood of both ROP (see below) and inflammatory lung damage. Thus the Fio<sub>2</sub> must also be rapidly reduced to acceptable levels.

In addition to surfactant administration, in recent years ventilation strategies have changed in premature infants with RDS in an attempt to reduce the incidence and severity of bronchopulmonary dysplasia (BPD - see below). Targeting lower SpO<sub>2</sub> of 87-94% instead of 95-98%, employing nCPAP instead of endotracheal intubation, and limiting positive pressure ventilation by allowing permissive hypercapnia have all been demonstrated to reduce the severity of RDS and the incidence of BPD. In contrast, high-frequency oscillatory ventilation does not improve RDS or reduce incidence of BPD. Routine treatment with dexamethasone resulted in a lower severity of lung disease and less BPD; however, it is associated with increased risk of intestinal perforation, cerebral palsy, and neurodevelopmental impairment so its use has greatly diminished in recent years [26]. Finally, inhaled nitric oxide in infants less than 1250g, when administered for 14 days, resulted in significantly greater BPD-free survival in one large multicenter study, and did not adversely affect long-term neurodevelopmental outcomes [27].

#### **Bronchopulmonary dysplasia**

Many preterm infants develop chronic lung disease (BPD) as a result of mechanical ventilation, oxygen administration, infection, inflammation or a combination of these factors [28]. The number of infants with BPD is increasing because more 500-750g infants now survive [29,30]. Today's BPD differs from that described by Northway et al [31]. Many of today's preterm infants have no oxygen requirement above that of room air and normal lung function for a few days after birth, probably because of prenatal steroids and/or the administration of surface-active material after birth. Lung function then deteriorates, often in association with pulmonary infections [32], and the oxygen requirements increase and respiratory failure develops. The deterioration is made worse if the child has a PDA [33]. Furthermore, the chronic lung disease (CLD) of today's smaller infants has changed [34]. Today's CLD consists of simplified lungs, increased alveolar size, decreased alveolar number, and dysplastic pulmonary vasculature [35]. The end-result of these lung abnormalities is maldistribution of ventilation and perfusion, hypercarbia, hypoxemia, and occasionally the need for prolonged mechanical ventilation. Later in life, if they require surgery, their lung function [36] and gas transfer will be reduced [37]. Positive end-expiratory pressure (PEEP) and furosemide 0.5-1 mg/kg every 6-12h are frequently used to treat pulmonary edema and improve gas exchange. However, furosemide often causes metabolic

Figure 20.1 The effects of alkalosis on mean arterial pressure in premature infants. Ventilation was maintained constant and  $CO_2$  was added to raise the PaCO<sub>2</sub>, to normal.

alkalosis, especially if these babies are not given sufficient potassium and chloride.  $CO_2$  is retained to compensate for the alkalosis. Reducing the PaCO<sub>2</sub> may cause severe alkalosis, reduced arterial blood pressure, and reduced cerebral blood flow (Fig. 20.1). Some preterm infants require higher ventilator pressures (tidal volumes) and oxygen concentrations during surgery, but many have improved ventilation and reduced oxygen requirements. During surgery, many infants can be ventilated with room air to maintain appropriate oxygen saturations. Although an oxygen saturation of 87–94% is felt (hoped) to be safe, the infant's PaO<sub>2</sub> would be 30–40 mmHg were they still *in utero*.

### Apnea

Periodic breathing (cessation of breathing for <15 sec) and apnea (cessation of breathing for >20 sec or <20 sec with a decrease in SaO<sub>2</sub> plus bradycardia) are common in preterm infants, especially after the first week of life [38]. The incidence of apnea is inversely related to postconceptual age [39]. The causes of apnea are multiple and include anemia (hematocrit <30%), hypo- and hyperthermia, hypo- and hyperglycemia, hypo- and hypercalcemia, hypo- and hypervolemia, anemia, decreased functional residual capacity, patent ductus arteriosus, constipation, hypothyroidism, poorly developed control of respiration, excessive handling and stimulation, birth trauma, maternal drugs (narcotics), seizures, infections, and congenital heart disease. However, the primary cause of apnea of prematurity is immaturity of the central nervous system. Repeated apnea increases the likelihood of CNS damage due to repeated episodes of hypoxemia [40]. Infants who had apneic spells in the ICN usually must be ventilated from the time anesthesia is induced. Giving caffeine 5 or 10 mg/kg IV before surgery reduces or prevents postoperative apnea and oxygen desaturation, especially in patients who have had previous apneic spells, a hemoglobin concentration below 10g/dL or pre-existing CNS injury [41].

Moderately premature infants, especially those recovering from RDS and those requiring mechanical ventilation, may have chronic lung disease. If they do, the PaCO<sub>2</sub> is frequently elevated and the PaO<sub>2</sub> or SaO<sub>2</sub> decreased during room air breathing. Care should be taken not to overexpand the lungs of premature infants, as this may lead to severe lung injury [42,43].

#### Patent ductus arteriosus

Fifty percent of full-term infants close their ductus arteriosus by 24h of age and almost all of them do so after 72h [44]. Most preterm infants of 30 weeks' gestation or more close their ductus arteriosus by 96h of age. However, the ductus arteriosus of smaller preterm infants often remains open [45] and symptoms of a PDA often appear between the third to fifth day after birth [46]. Infants treated with surfactant at or near birth may have a significant PDA within a few hours of birth as the lungs expand and pulmonary vascular resistance decreases. A PDA murmur is usually heard at the left upper sternal border and is often continuous. It is loudest during exhalation or apnea, and its intensity is increased by hyperventilation. Patients with a PDA have bounding pulses and a widened pulse pressure (Fig. 20.2). A gallop rhythm may be present.

As the left-to-right shunt increases, so does the pulmonary blood flow. If the heart cannot keep up with the increased demand for cardiac output, congestive heart failure (CHF), manifested by increased respiratory failure (intercostal retractions, diminished breath sounds, poor air entry, rales), tachycardia, and a gallop rhythm develop. The PaO<sub>2</sub> decreases and the PaCO<sub>2</sub> rises. Apnea, increasing requirements for oxygen and mechanical ventilation, and a widened pulse pressure are often the earliest signs of a PDA. Signs of failure often appear before a murmur is heard [47] and if the ductus arteriosus is very large, no murmur is heard. In this case, a PDA is usually detected

**Figure 20.2** Aortic blood pressure of a preterm infant during periods when a PDA was present and was absent. Note the widening of the pulse pressure and elevated arterial pressure when the murmur was present. Courtesy of Dr Joseph A. Kitterman.

by changes in oxygenation, increased need for mechanical ventilation, and an echocardiogram.

The initial treatment of a PDA is medical, which includes fluid restriction [48,49] (occasionally to the point of dehydration) and administration of cyclo-oxygenase inhibitors, indometacin and ibuprofen [50,51] and diuretics. Indometacin has greatly reduced the number of patients requiring surgical closure of a ductus arteriosus, but it has not reduced the incidence of CLD or CNS injury [52].

If fluid restriction prevents adequate calorie intake, surgical ligation of the ductus arteriosus is usually undertaken. Early closure of the ductus arteriosus (either with indometacin or surgically) allows earlier weaning from mechanical ventilation and initiation of feeding within a few days after surgery.

A second reason to close a patent PDA early is to reduce the incidence of necrotizing enterocolitis [53]. A large PDA shunts as much as 80% of the cardiac output away from the systemic circulation and into the lungs, leaving little blood for the remaining body. Because the gut is one of the first organs to be deprived of blood, it is the shock organ in neonates. The use of prostaglandin synthetase inhibitors has not increased the incidence of necrotizing enterocolitis, but early ligation of the PDA may do so.

#### **Central nervous system injury**

Premature infants have two predominant forms of CNS injury. The most common in very premature infants is periventricular white matter injury, which is a leading cause of later cerebral palsy. The pathophysiology is incompletely understood, but the immature oligodendrocyte precursors are exquisitely sensitive to a number of common insults, including hypoxemia, hypotension, and inflammation [26]. The arterial supply to these areas is not fully developed, leading to vulnerability to ischemia. In addition, because of the fragile state of the developing vascular supply in the germinal matrix, these vessels are prone to rupture, causing the common complication of intraventricular hemorrhage (IVH). Grade I IVH is confined to the germinal matrix, grade II IVH occurs when bleeding extends to the cerebral ventricles, grade III IVH involves ventricular dilation, and grade IV IVH includes parenchymal extension of the bleed. Grades III and IV IVH may lead to hydrocephalus requiring ventricularperitoneal shunting, a common procedure in premature neonates. Chapters 7 and 23 discuss pathogenesis and treatment of these disorders in more detail.

# Infection

Infections (e.g. pneumonia, sepsis, and meningitis) are common in preterm infants, especially those who are moderately or severely preterm, because both their cellular and tissue immunity are reduced. Although the

signs of sepsis are often subtle, sepsis is suspected if the infant is hypo- or hyperthermic (despite a neutral thermal environment), lethargic, mottled, gray or apneic. If despite a constant infusion of glucose, the serum glucose concentration increases, sepsis should be suspected. Laboratory examinations may be helpful but preterm infants are often septic without positive blood cultures, elevated white blood cell (WBC) counts or fevers. In fact, this is more often true than not. The presence of an abnormal WBC count, whether increased or decreased, is diagnostically helpful (Table 20.1). A shift to the left toward neutrophil predominance is also helpful, but this is not always present. Band counts in excess of 15% are abnormal and are a good indicator of infection in preterm infants [54]. Cerebrospinal fluid (CSF) should contain fewer than 1 WBC per 200 red blood cells (RBCs), although an absolute count of 70 WBC/mm<sup>3</sup> may be normal [55]. The concentration of glucose in the CSF should be at least 50-60% of that in the blood. Urine should contain fewer than 5 WBCs per high-power field. A bladder tap urine specimen should be devoid of WBCs.

Preterm infants respond appropriately to antibiotics, although the dosage and interval between doses often must be altered (see Appendix A). Aminoglycosides may cause muscle weakness or paralysis and act synergistically with non-depolarizing muscle relaxants to increase their effect.

# **Necrotizing enterocolitis**

Necrotizing enterocolitis is a common surgical emergency, especially in tiny preterm infants [53,56], and 10–50% of patients with this problem die [57]. The most common associations with NEC are prematurity, feeding per os,

excess feeding, and overgrowth of the bowel with nonnormal bacterial flora [58,59]. An infant who suddenly develops abdominal distension, vomiting, bloody stools, reducing substances in the stool, and shock should be suspected of having NEC. Shock occurs because large amounts of fluid are translocated into the peritoneal cavity, gut, and other tissues and because of bacterial toxins. Radiographs of the abdomen demonstrate distended loops of bowel, air in the bowel wall and, if the bowel has perforated (which occurs about one-third of the time), free air in the peritoneal cavity. Such infants are extremely ill (often moribund), hypovolemic, and require fluid resuscitation with blood, colloid, and large volumes of saline or lactated Ringer's solution prior to surgery if they are to survive. Administering the quantity of fluid needed to accomplish volume resuscitation often worsens any respiratory failure and increases their need for mechanical ventilation. Infants with NEC should be started on IV broad-spectrum antibiotics preoperatively. Most survive, although about 10% of those who survive have short gut syndrome [60]. Many infants with NEC have cerebral palsy, severe neurological delay, and mental retardation, which may complicate anesthesia later in life [61].

## **Hematological manifestations**

Preterm infants are frequently anemic because their ability to produce RBCs is reduced and because their caregivers frequently take blood for tests. Compensatory responses include tachycardia, increased cardiac output, and increased extraction of oxygen from blood. If the oxygen demand is unmet, lactic acidosis occurs. Low iron stores and inadequate iron intake worsen the anemia. As long as preterm infants have respiratory or

cardiovascular problems, their hemoglobin levels should probably be maintained at or above 10g/dL by blood transfusions from a limited number of units of packed RBCs and by the administration of epoetin alfa. A hemoglobin concentration of 14-15g/dL is more likely to reduce the number of apneic spells and the CHF associated with a PDA than a hemoglobin of 8-10g/dL. One study found that limiting transfusion was associated with higher rates of CNS hemorrhage, periventricular leukomalacia, and apnea [62] but another study failed to find these problems [63]. It is probably unwise to begin surgery for preterm infants if their hemoglobin concentration is <10g/dL unless forced to do so by an absolute emergency. Transfusion of blood with adult hemoglobin, besides raising the hematocrit, shifts the oxygen dissociation curve to the right, which improves oxygen delivery to the tissues.

The WBC count of normal preterm infants is shown in Table 20.1. At birth, the WBC is higher than at later ages; it decreases over the first week of life. Stress can elevate the WBC count to 40,000–50,000/mm<sup>3</sup>. Septic neonates either increase or decrease their WBC.

Erythropoietin (EPO) is produced in the liver and regulates erythropoiesis. Growing fetuses have high levels of erythropoiesis, a relatively high hematocrit, and predominant synthesis of hemoglobin F (fetal hemoglobin). The high concentrations of EPO present at birth decline relatively rapidly. The concentration of hemoglobin decreases over time and causes many preterm infants to be anemic. Phibbs et al [64] showed that giving  $100 \mu g/kg$  of recombinant human erythropoietin intravenously to anemic preterm infants twice weekly for 6 weeks increased the reticulocyte counts (and RBCs) faster than a placebo and did not suppress subsequent release of endogenous EPO. The need for blood transfusions was reduced.

On rare occasions, premature infants are polycythemic. If the hematocrit exceeds 65%, an exchange transfusion may be required before surgery to prevent occlusion of their renal, portal or cerebral veins, especially if the patient becomes hypovolemic and/or hypotensive during surgery. If it is necessary to operate on a polycythemic child, sufficient fluid must be administered during surgery to maintain a normal or slightly increased intravascular volume. Hypotension must be treated immediately.

# **Nutrition and growth**

Premature infants frequently have difficulty sucking effectively for some time after birth and require intermittent or continuous gavage feedings. While their gastric capacity and gastrointestinal motility are adequate to accept the instilled food, they often have difficulty absorbing their feeds. As a result, intravenous fluids and nutrition are commonly required. Infants who will not be fed orally for 3 or 4 days after birth usually receive intravenous feedings with glucose 12.5%, protein (amino acids) 2–3g/kg/day, and lipids 3g/kg/day within the first few hours of life [65]. From this diet they derive 80-100 kcal/ kg/day, depending on the volume of fluid infused, which is usually sufficient to maintain positive nitrogen balance, prevent tissue breakdown, and allow some growth (albeit inadequate). Attempts to feed asphyxiated infants early are often associated with NEC or abdominal distension and regurgitation of gastric contents. When this occurs, oral feedings are usually delayed for 5-6 days. While enough free water is required to maintain normal intraand extravascular fluid volumes, administering more than 130-150 mL/kg/day increases the likelihood of a PDA, congestive heart failure, and the risk for NEC. Electrolytes (3mEq/kg sodium, 2mEq/kg potassium, 200-500 mg/kg calcium gluconate), and vitamins (including vitamin E) should be administered in the maintenance fluids. Because antibiotics kill gut flora, vitamin K 0.2 mg is administered twice weekly as long as the patient is receiving antibiotics [66]. Failure to do this increases the risk of bleeding during surgery.

# Serum chemistry determinations Calcium

During the last trimester of pregnancy, fetal concentrations of calcium exceed those of the mother [67]. At birth, the maternal supply of calcium is withdrawn and the baby's serum calcium concentration decreases, often to 7.5–8.5 mg/dL. If the baby takes in sufficient calcium, the levels increase after several days. Despite the low concentrations of total calcium, ionized calcium concentrations are normal (because serum protein concentrations are lower, at 3–4.5 g/dL). Consequently, total serum calcium concentrations above 7 mg/dL are adequate if ionized calcium concentrations are normal [68]. Phosphate and magnesium concentrations are similar to those of term infants.

If the patient has symptoms of hypocalcemia (e.g. twitching, seizures, hypotension), calcium gluconate 10–30 mg/kg is administered slowly intravenously. Hyperventilation decreases the unbound fraction of calcium, which can lower the seizure threshold. Despite the presence of hypocalcemia, the electrocardiogram (ECG) is usually normal.

#### Sodium

The serum sodium concentrations of tiny preterm infants are labile. They rise quickly with dehydration and decrease just as quickly with overhydration. Hypernatremia can damage the CNS, and hyponatremia (<120 mEq/L) can cause seizures. Water intoxication is usually associated with persistent hyponatremia.

Hypertonic saline is seldom required to correct hyponatremia; fluid restriction usually suffices.

# Glucose

Most neonatologists attempt to maintain the postnatal nutrition of preterm infants at or above their requirements during fetal life in the hope of maintaining normal growth. This goal is seldom met for many reasons [69]. Glucose provides most of the energy for many organs, including the brain. Most non-anesthetized larger preterm infants tolerate an infusion of 5-7 mg/kg/min of glucose without developing hyperglycemia, glucosuria, polyuria or dehydration, but many extremely low birthweight infants (23-25 weeks' gestation) require at least 10 mg/ kg/min to maintain normoglycemia and growth. The only way to know the serum glucose concentrations is to measure them frequently, especially in the operating room. Excessively high serum glucose concentrations (>200 mg/dL) can cause an osmotic diuresis, hypovolemia, and possibly CNS injury [70,71]. With adequate nutrition, preterm infants gain 25-30 g/day and increase their head circumference by 0.8-1 cm/wk. It may, however, be difficult to provide sufficient nutrition to achieve this growth for myriad reasons. The level of nutrition and weight gain should be determined carefully before surgery because infants with poor preoperative nutritional states often tolerate anesthesia and surgery less well.

The blood glucose concentrations of many preterm infants are below 40 mg/dL, which constitutes hypoglycemia. If present, hypoglycemia should be corrected with 10-20% dextrose 2-5 mL/kg over 5 min and with a continuous infusion of sufficient dextrose to maintain the glucose concentration between 50 and 90 mg/dL. Many preterm infants have an SaO<sub>2</sub> of 80–90%. However, if they are hypoglycemic and anemic in addition to having their SaO<sub>2</sub> at these low levels, their growth rates are often reduced [72].

#### Bilirubin

Because they conjugate substances less well, preterm infants often have higher serum bilirubin concentrations, especially those who are bruised, polycythemic or have intracranial, gastrointestinal or pulmonary hemorrhage. The relative hypoproteinemia, the decreased effectiveness of the blood–brain barrier, and the often-present acidemia increase their susceptibility to kernicterus – brain injury secondary to the direct neurotoxic effects of prolonged high serum uncongugated bilirubin concentrations . Even low concentrations of bilirubin (10–15 mg/ dL) are sufficient to produce kernicterus in acidotic infants [73,74]. It may be necessary to do a two-volume exchange transfusion before surgery if the patient's indirect bilirubin concentration is elevated and if time permits, Table 20.2 Serum bilirubin concentrations for exchange transfusion

Birth weight (g)	Serum bilirubin concentrations for exchange transfusion (mg/dL)		
	Norma/infants <sup>†</sup>	Abnormal infants <sup>‡</sup>	
<1,000	10.0	10.0 <sup>§</sup>	
1,001-1,250	13.0	10.0 <sup>§</sup>	
1,251-1,500	15.0	13.0	
1,501-2,000	17.0	15.0	
2,001-2,500	18.0	17.0	
>2,500	20.0	18.0	

\*These guidelines have not been validated.

<sup>+</sup>There have been case reports of basal ganglion staining at concentrations considerably lower than 10 mg.

<sup>+</sup>Normal infants are defined for this purpose as having none of the problem listed below.

<sup>§</sup>Abnormal infants have one or more of the following problems: perinatal asphyxia prolonged hypoxemia, acidemia, persistent hypothermia, hypoalbuminemia, hemolysis, sepsis, hyperglycemia, elevated free fatty acids or presence of drugs that compete for bilirubin binding, and signs of clinical or central nervous system deterioration.

Data from American Academy of Pediatrics, Committee on Fetus and Newborns Standards and Recommendations for Hospital Care of Newborn Infants, 6th ed. Evanston, IL, American Academy of Pediatrics, 1977.

because intraoperative hypoxemia and acidosis may prove disastrous (Table 20.2).

### **Retinopathy of prematurity**

Fifty percent of infants weighing 1000–1500 g at birth have some degree of ROP [75]. Seventy-eight percent of those weighing 750–999 g have ROP, and more than 90% of those weighing less than 750 g have some degree of ROP. ROP is rare in term infants. Retinopathy of prematurity is divided into five stages [76].

- Stage 1: a thin white line separates the posterior vascularized portion of the retina from the anterior avascular retina.
- Stage 2: the demarcation line increases in volume and elevates. At this point it is known as the "ridge." The changes found in stage 1 and 2 regress in 80% of patients. Between 5% and 10% of premature infants with stage 1 and 2 disease progress to stage 3 [77].
- Stage 3: tissue proliferation develops from the ridge, usually posteriorly. Stage 3 can be mild, moderate or severe, depending on the volume of the extraretinal tissue [76].
- Stage 4: partial retinal detachment occurs with the macula still attached (stage 4a). The macula is detached in stage 4b.
- Stage 5: total retinal detachment occurs in stages 4 and 5.

Retinopathy of prematurity begins with retinal blood vessel constriction, reduced vascular endothelial growth factor (VEGF), and retinal hypoxia [78]. The retinal hypoxia stimulates VEGF production and vascular proliferation, hemorrhage, and (in the worst cases) retinal detachment. While oxygen is a major contributing factor to the development of ROP, it is not the only factor [61]. It is unknown what levels of oxygenation cause ROP, but a PaO<sub>2</sub> of 150 mmHg for as little as 1–2h (the length of many surgical procedures) has done so. It is also possible that ROP might develop at considerably lower PaO<sub>2</sub> because the retinas of preterm infants, were they still in utero, would be exposed to a PaO<sub>2</sub> of 30-40 mmHg, not 50mmHg or more, as often occurs after birth. Preterm infants whose SaO2 was maintained between 80% and 96% for the first several postnatal weeks had less ROP than those with higher  $SaO_2$  [78]. Interestingly, after 31 weeks' gestation, an  $SaO_2\ of\ 94\mathchar`-99\%$  was required to reduce the risk of further retinal damage. At this age the lower oxygen concentrations and mild hypoxia were adding to the retinal hypoxia. After discussion with the neonatologist, it may be appropriate to maintain higher oxygen saturations in this specific group of patients during surgery.

The left-shifted oxygen dissociation curve of fetal hemoglobin (HbF) releases less oxygen to the tissues, which may protect the retina. Transfusion with adult blood may increase the risk of developing ROP because the right-shifted oxygen dissociation curve releases more oxygen. Chorio-amnionitis and neonatal systemic inflammatory disease also increase ROP [79].

Vitamin E and omega-3 fish oils may protect against ROP by their membrane-stabilizing and antioxidant actions [80,81]. While vitamin E concentrations normally decrease rapidly after birth, due to inadequate intake and storage of vitamin E, administering more than physiological amounts of vitamin E to premature infants has little beneficial effect and may increase the incidence of necrotizing enterocolitis and infection [82,83].

Approximately 85% of acute ROP undergoes spontaneous regression [84]. Grades 1 and 2 regress in 2–3 months, while grade 3 regresses in 6 months or more. Most grade 4 and 5 ROP results in blindness or limited vision in approximately 25% in infants who were at high risk for retinal detachment [85].

Patients with ROP come to the anesthetist's attention because they require an eye examination, photocoagulation or scleral buckling under anesthesia. It is unknown if exposure to increased oxygen concentrations during anesthesia worsens pre-existing ROP. Because we do not know, it is better to keep the SaO<sub>2</sub> during anesthesia at the same levels used in the ICN, usually between 87% and 92% [86]. Because many of these patients also have chronic lung disease and maldistribution of ventilation and perfusion, their SaO<sub>2</sub> can rapidly decrease with the induction of anesthesia. Adding a small amount of PEEP (2–5 cmH<sub>2</sub>O) often improves both the match of ventilationperfusion and oxygenation. Excessive PEEP may overdistend the ventilated portions of the lung and decrease oxygenation. Aoyama et al have published a sensible plan for anesthetizing patients with ROP [87]. They point out that many patients require postoperative mechanical ventilation and ICU care after surgery, even if they did not require them preoperatively. Because the surgeons often inject air into the eye during surgery, it is best to avoid nitrous oxide and use air as the carrier gas for the inhaled anesthetic.

# **Preoperative preparation**

#### History

During the preoperative visit, the patient's chart must be read, understood, and thoroughly discussed with the physicians and nurses caring for the patient. It is the nurses who stand at the bedside 24h a day and provide the patient's minute-to-minute care. They know the idiosyncrasies of each patient. For example, the nurses may know that very brief periods of apnea cause severe hypoxemia and cyanosis or that the patient's perfusion decreases when his blood glucose concentration is <40 mg/dL or when the ionized calcium concentration is below 0.9 mmol/L.

Both the fetal and birth histories are important when planning an anesthetic for preterm infants. If the infant was asphyxiated before or at birth, the effects of asphyxia (right ventricular dysfunction, coagulation abnormalities, etc.) may still be present. Autoregulation of the cerebral circulation may be absent [5,88,89]; if so, sudden increases in arterial pressure may rupture fragile cerebral vessels and cause intracranial hemorrhage [90].

Myocardial function may still be depressed and the heart may show signs of hypoxic strain, including insufficiency of the tricuspid valve. Blood flow to the gut may be reduced. Both the blood volume and the hemoglobin concentration may be low if they were not corrected. These abnormalities can persist for several days after birth.

A maternal medication history should be sought in every case because many pregnant women take prescription or non-prescription drugs. A few use illicit drugs, and the baby may be undergoing drug withdrawal at the time of surgery. The symptoms of narcotic withdrawal include agitation, tremors, poor feeding, vomiting, and occasionally seizures. Infants withdrawing from barbiturates, diazepam or methadone may only do so at 5–10 days of age. Fetuses who are repeatedly exposed to cocaine, which causes premature delivery, may also have pulmonary hypertension and bowel perforation. Infants born after maternal ingestion of large doses of aspirin or acetaminophen may have pulmonary hypertension and persistent fetal circulation (PFC) during the first few days of life [91,92]. PFC must be considered in any severely hypoxemic infant.

# **Systems review and examination** Head, eyes, ears, nose, and throat

Congenital anomalies of the face and mouth are common, either as part of a syndrome or as a lone entity. A cleft palate may be missed when infants are mechanically ventilated from birth. If the anesthetist must reintubate the patient's trachea, a cleft palate may make this more difficult because the tongue cannot be fixed against the palate and flops over the laryngoscope blade, obstructing the anesthetist's view of the glottis. The small mouth and the relatively large tongue of preterm infants frequently obstruct breathing, especially when pressure is applied to the submental triangle while holding an anesthesia mask on the patient's face. Even slight pressure in this area can completely obstruct the airway. Anesthesia masks with large air-filled cuffs are dangerous if they slip off the bridge of the nose and compress the nares while the mouth is being held closed. Most babies are obligatory nasal breathers for several months after birth [93]. A nasogastric tube (NGT) obstructs half of the unintubated infant's upper airway when the mouth is closed. This often increases respiratory work and leads to apnea during the induction of anesthesia. Nasogastric tubes should be removed and reinserted orally if necessary. Atropine, if administered to patients with some types of cataracts or with glaucoma, may increase the intraocular pressure and further damage the eye (see Chapter 31).

## **Pulmonary system**

As stated above, pulmonary dysfunction is common in preterm infants. Therefore, the pulmonary system must be evaluated carefully before anesthesia and surgery. Answers should be sought to the following questions.

 Does the patient now have or is he/she recovering from RDS? If so, how much support of breathing is required? What are the ventilator rates, pressures (peak-inspired and end-expiratory), inspired oxygen concentrations, and inspiratory times? Is the patient breathing spontaneously during mechanical ventilation? Is he/she triggering inspiration by the ventilator? What SaO<sub>2</sub>, blood gas, and pH values do spontaneous breathing or the ventilator settings occasion? How labile are the blood gases? Do the blood gases and pH change when the patient is moved from side to side or onto the back or abdomen[94], when the trachea is suctioned or when the chest is percussed [95]? It may be a problem if the patient must be turned into the lateral position for surgery and this position causes deterioration of the blood gases and pH.

- Has the patient had a pulmonary hemorrhage? If so, has the bleeding stopped?
- Is pneumonia present? Pneumonia may be difficult to differentiate from RDS, pulmonary edema or chronic lung disease on radiograph. A WBC count, a differential WBC count, and a smear of the tracheal secretions may be helpful in making this differentiation. If the infant has pneumonia, the tracheal smear will show both WBCs and bacteria. Either finding alone is seldom significant.
- Is the endotracheal tube (ETT) fixed securely in place? Accidental extubation of the trachea on the way to the operating room is disconcerting. Tape used to hold the ETT in place should not completely encircle the infant's head to prevent brainstem hemorrhage [96].
- Does the infant have intercostal retractions? Most preterm infants have grade 1-of-4 to 2-of-4 retractions because their chest walls are not fully developed. Those with pulmonary disease have grade 3-of-4 to 4-of-4 retractions. Retractions indicate increased work of breathing, decreased lung compliance, increased airway resistance or all three.
- Can rales be heard? Most preterm infants have occasional rales. Moist rales indicate intra-alveolar fluid, usually associated with pulmonary edema or infection. Dry rales are usually associated with atelectasis. Rhonchi are also common, especially after several days of tracheal intubation.
- Are there secretions? White or clear secretions are seldom significant. Yellow, green or brown secretions often indicate infection. Frothy, pink or blood-tinged secretions are usually indicative of pulmonary edema or pulmonary hemorrhage.

Preterm infants normally breathe 30–60 times per minute. However, those with lung disease can have respiratory rates of 150 breaths/min or more, especially when lung compliance is reduced. Babies "choose" to breathe rapidly and shallowly rather than slowly and deeply, probably because the metabolic cost of breathing rapidly and shallowly is less. Rapid respirations help maintain the functional residual capacity by not allowing sufficient time for complete exhalation. Unless PEEP is applied, slow respiratory rates decrease functional residual capacity (Fig. 20.3) [97].

Evaluating blood gas and oxygen saturation data gives important clues to the patient's responses to ventilatory maneuvers. Preterm infants normally have lower  $PaO_2$ than term babies (Tables 20.3, 20.4). Therefore, small changes in  $PaO_2$  cause large changes in oxygen saturation and in oxygen content [98]. Brief periods of apnea lead to hypoxemia. Is the patient having apneic spells (see above)? Apneic spells are often indicative of other problems. If the infant is having or has had apnea, he/she may have postoperative apnea and require mechanical ventilation for a variable amount of time (see Chapter 21). Figure 20.4 shows the chest radiographs of a normal infant and one with hyaline membrane disease.

### Cardiovascular system

Many preterm infants have problems with their cardiovascular systems (including patent ductus arteriosus, hypotension, shock) [99,100] but congenital heart disease is less common. Because the bulk of muscle is laid down in the pulmonary arteries during the third trimester of pregnancy, infants born earlier have less muscle and are prone to develop a PDA and increased left-to-right shunting of blood through the ductus arteriosus earlier in life (3–5 days of age) than in term infants (7–14 days of age). The net result is increased pulmonary blood flow, pulmonary edema, congestive heart failure, reduced lung compliance, hypoxemia, and  $CO_2$  retention. Surfactant administration establishes the functional residual capacity (FRC) more quickly, which is associated with a PDA and left-to-right shunting of blood within a few hours after birth.

Congestive heart failure may not be heralded by tachycardia in preterm infants, as it is in older patients. In fact, the heart rate is often monotonously regular and usually within normal limits (120–160 beats/min) (Table 20.5). A third heart sound (gallop) may be present but may be difficult to hear because of the rapid heart rate and

Table 20.5 Heart rate in preterm infants with patent ductus arteriosus

Condition	Heart rate (bpm)
Normal cardiac function	150 ± 18
Congestive heart failure	148 ± 22
Postligation ductus arteriosus	146 ± 18

environmental noise (e.g. mechanical ventilators, alarms, monitors, people). Murmurs can be difficult to hear for the same reason. Two murmurs are commonly present in preterm infants, that of a PDA and that of tricuspid insufficiency. The PDA murmur is a systolic ejection murmur that is best heard along the upper left sternal border when the ductal flow is small. When it is large, the murmur extends into diastole, is continuous, and is heard throughout the chest. The "machinery murmur" described in older patients is seldom heard. The murmur of tricuspid insufficiency is systolic in nature and is best heard along the right sternal border. It seldom radiates far, and it disappears after several days of life as ventricular function improves.

Congestive heart failure reduces peripheral perfusion and slows capillary filling. The pulses are decreased, except in patients with a PDA. Peripheral edema is common, in part because serum protein concentrations are low (see above). Edema usually appears first in the eyelids. Pitting edema of the feet and shins is uncommon in other than the sickest babies. Puffiness of the feet, however, is common.

The chest radiographs of preterm infants with CHF are frequently difficult to differentiate from those of infants with RDS. The former usually show central fluffiness and slightly larger markings than those of RDS (Fig. 20.5).

The liver size is a good indicator of right-sided heart failure and of CHF in preterm infants because their livers are very distensible. The inferior margin is normally sharp and located 1–2 cm below the right costal margin; with CHF, the liver can quickly distend into the pelvis. Just as quickly, it returns to its normal position with appropriate therapy. Applying excessive pressure when examining the abdomen may push the liver up into the thoracic cavity and make the liver appear smaller than it really is. The position of the liver edge can usually be determined by gently running one's fingertips over the right upper abdomen or by percussing the abdomen. Percussion is especially useful when the abdomen is distended. Enlarged livers often extend across the midline, which may make it difficult to differentiate from the spleen, which also is often enlarged during CHF.

# Abdomen

The abdomen of preterm infants is normally protuberant and soft. The venous pattern of the abdominal wall is prominent and is exaggerated with liver disease. Intraabdominal organs are generally easy to palpate. The spleen is usually palpable below the left costal margin in patients who have erythroblastosis fetalis, systemic infections, liver disease or fluid overload. The ascites of erythroblastotic infants may interfere with ventilation of the lungs and make it necessary to remove some of the fluid by paracentesis to allow adequate ventilation of the infant's lungs. In some cases paracentesis may be required before the induction of anesthesia.

The preterm infant's kidneys are easily palpable as small masses in the retroperitoneum. They may be enlarged by renal vein thromboses or by renal, ureteral or bladder anomalies. The urinary bladder is usually felt as a round mass extending above the pelvic rim. Obstruction of the urethra can cause the bladder to distend above the umbilicus. The ureters are occasionally palpable as cords running longitudinally in the retroperitoneum.

It is often possible to see loops of distended bowel through the abdominal wall. Abdominal distension is seldom a cause of abdominal tenderness unless peritonitis is present. Then the abdomen is tender, rigid, and edematous enough to leave one's fingerprints on the skin. Intraperitoneal fluid often passes through the inguinal canals and distends the scrota. As a consequence, inguinal hernias occur in about 30% of premature male infants. Redness around the umbilicus is often a sign of systemic or intra-abdominal infections.

One should ascertain patency of the anus before the infant undergoes surgery. Occasionally an imperforate anus is missed in very sick infants. Nothing (including thermometers) should be inserted more than 0.5 cm into the rectum to avoid perforating the bowel.

#### Central nervous system

The incidence of CNS injury increases with increasing degrees of prematurity and asphyxia (see Chapter 23). CNS injury is usually manifested as flaccidity, hypertonia, hypotonia or a difference in tone between the upper and lower or between the right and left sides of the body. Deep tendon reflexes and the grasp reflex are often absent. Normal preterm infants normally have a positive Babinski sign. The back, neck, and sacral area should be examined for evidence of a meningomyelocele. Again, these lesions can be missed preoperatively when very ill infants are placed on their backs and left there for days because of the extent of their illness.

# State of hydration

The hydration state of preterm infants should be carefully assessed during the preoperative visit. Their large surface/volume ratio, thin skin, rapid respiratory rates, relatively large minute volumes, and infrared warmers increase water losses [101]. Failure to replace these losses adequately leads to dehydration. Covering the baby with clear plastic film significantly reduces water and heat losses. Reducing fluid intake to less than 130 mL/kg/day to decrease the incidence of PDA in preterm infants occasionally leads to severe fluid and calorie restriction [49]. Restricting fluid and caloric intake may cause infants to be dehydrated and undernourished when they present for surgery. Administration of potent diuretics, such as furosemide, can cause further dehydration. Preterm infants third space fluids more easily than older patients because the preterm infant's capillaries leak easily, serum protein levels are lower and the oncotic pressure is reduced [102,103]. As a consequence, infants with sepsis or shock lose large amounts of fluid into the peritoneal cavity. These patients commonly gain 20-50% of their bodyweight, despite being intravascular volume depleted.

#### Laboratory findings

Most sick preterm infants undergo a multitude of laboratory tests, the results of which must be reviewed and understood before anesthesia is induced.

#### Hematology

In well infants, a hemoglobin concentration above 7 g/dL is usually adequate. In infants with cardiorespiratory disease, the concentration of hemoglobin should exceed 9g/dL to ensure adequate oxygen-carrying capacity. As discussed above, the hemoglobin (Hgb) concentration decreases rapidly after birth, frequently because caregivers extract large volumes of blood for tests.

Besides knowing the  $PaO_2$  and  $SaO_2$ , it is important to determine the oxygen content of the patient's blood:

([
$$\{1.36 \text{ mL oxygen/g Hgb} \times \text{Hgb g/dL}\} \times \text{SaO}_2$$
]  
+0.003×PaO<sub>2</sub>).

0.003 is the solubility coefficient of oxygen in plasma. If the hemoglobin concentration were 10g, the oxygen content would be about 13.1 cc oxygen/100 mL of blood. The entire body extracts about 5 volumes percent of oxygen from the blood. However, the heart extracts 12 volumes percent from blood passing through it. There is barely enough oxygen present to meet cardiac demands. If the Hb concentration were 5g, the oxygen content of the arterial blood would be about 6.5 cc/100 mL of blood, which is insufficient to meet cardiac demands, unless coronary blood flow increases and cardiac oxygen
requirements remain constant or decrease while the oxygen extraction from blood increases. This is a precarious position in which to begin surgery. Infants with low hemoglobin concentrations should be transfused before surgery if possible to normalize their blood oxygen content.

#### Electrolytes

The concentrations of the serum electrolytes vary more in preterm infants than in older patients because premature infants are affected more severely by small changes in fluid and electrolyte intake, by fluid and electrolyte losses, and by their environment. A single electrolyte value can be misleading; serial values are much more helpful. A rise in serum sodium is usually a result of either dehydration or excessive sodium administration. The latter is associated with peripheral edema. Although hyperkalemia is common, it seldom affects the ECG. Hypokalemia (<3mEq/L) is also common, especially when preterm infants are given potent diuretics. Inadvertent hyperventilation and alkalosis further reduce the serum potassium concentration when potassium moves into the cells in exchange for hydrogen ions. The serum concentration of chloride is normally higher in preterm infants (105–115 mEq/L) than in older children, which in part accounts for the commonly present metabolic acidosis.

The total calcium concentration is usually lower than that of term infants (see above), but the ionized calcium concentrations of the two groups are similar. Hyperventilation may reduce the ionized calcium concentration to unacceptable levels. The tendency of most neonatologists is to maintain the total serum calcium concentration above 7 mg/dL if the ionized calcium concentrations are normal for age [68].

#### **Coagulation status**

At birth, the levels of coagulation factors are approximately 50% of adult values, although babies seldom bleed because of this [104-106]. Their platelet counts are similar to those of normal adults, but their platelets probably function less well. Does the infant have a bleeding diathesis? Infants who are asphyxiated at birth have depression of factors V, VII, and VIII, which return to normal within 3-4 days if the infants are resuscitated quickly [107]. These levels may not return to normal for a week or more if the hypoxia is prolonged. The latter infants are frequently thrombocytopenic, often below 10,000/mm<sup>3</sup>. Even at these levels, bleeding seldom occurs in the absence of surgery or injury. Therefore, it is seldom necessary to transfuse platelets to premature infants unless they require surgery or their platelet count is below 5000/ mm<sup>3</sup>, especially when their other clotting parameters are normal and there is no evidence of bleeding. When surgery is required, platelets should be transfused to raise their concentration to 50,000/mm<sup>3</sup> or greater. If the surgical procedure lasts for several hours, another platelet transfusion may be required. If the patient has not received vitamin K after birth, has been nil per os (NPO) and has received IV antibiotics, vitamin K 0.3 mg/kg should be administered preoperatively to preterm infants [106].

Bleeding disorders, such as disseminated intravascular coagulation (DIC), must be corrected preoperatively with fresh frozen plasma, cryoprecipitate or factor VIIa. If both the clotting factors and the platelets are decreased, the patient will benefit from fresh whole blood because it contains all of the clotting factors, platelets, proteins, and RBCs required.

#### **Preoperative plan**

For very ill preterm infants, it is advisable to have the help of a second anesthetist during surgery. It is difficult for one person to ventilate the patient's lungs, give fluids and blood, watch the surgical field and monitors, and keep the anesthesia record at the same time (although automatic record keeping has made this easier - see Chapter 44). In an attempt to prevent hypothermia, the operating room should be warmed to 37°C or above before the patient arrives and a servo-controlled infrared heater should be placed over the operating table. A watercirculated heating blanket should be placed under the sheet covering the table and maintained at 35-37°C. Pressure transducers used to monitor arterial and central venous pressure should be set up and calibrated if needed. Intravenous solutions are made up if they differ from those being infused in the nursery. Patients often receive 5% dextrose in 0.2 normal saline in the ICN. This solution should not be used to replace fluid losses during surgery. Ringer's lactate or normal saline is used for this purpose. Fluid should be warmed and delivered through an infusion pump when possible. If a drip chamber is used, it should never contain more fluid than is safe to give in 1h. This avoids accidental overhydration if the IV infusion runs wide open.

Before transport to the operating room, an exchange of information between the ICN physician and nurse and the anesthesiologist should occur, summarizing current status and any special concerns the team has. Transporting preterm infants to and from the operating room can be dangerous. During transport, the anesthetist should always accompany sick infants to reduce this risk. The patient is connected to batteryoperated arterial blood pressure, ECG, and oxygen saturation monitor during transport. Infusion pumps should continue to infuse fluids and drugs, especially vasoactive drugs. Ventilation is supported during Table 20.6 Body temperature of preterm infants during transport to and from the operating room

Time	Body temperature (°C)
Preoperative: nursery	36.4 ± 0.5
Preoperative: operating room	35.7 ± 0.7
End of surgery	36.4 ± 1.0
Postoperative: nursery	35.9 ± 1.7

transport, usually with a Jackson-Reese device, and a portable air-oxygen blender. Sufficient oxygen should be administered to keep the oxygen saturation between 87% and 92% [98].

The inspired oxygen concentration should not be 100% during transport or in the operating room unless that concentration of oxygen is needed to maintain the desired oxygen saturation. Otherwise, the FiO<sub>2</sub> should be kept as low as possible while providing appropriate oxygen saturations. Use of an air-oxygen blender is required during transport to the operating room so the Fio<sub>2</sub> can be properly adjusted.

Keeping the patient warm is a major problem during transport. Table 20.6 shows the changes in body temperature of preterm infants being transported to and from the operating room for surgery. Note the loss of nearly a degree of body temperature during this short period. Their body temperature increased to normal in the operating room and decreased again during the trip back to the nursery. These heat losses can usually be prevented by covering the baby's body with clear plastic film and warm blankets, covering the infant's head with a cap, and placing a chemical heating pad under the patient (Porta-Warm, Allegiance Health Care Corp.). Elevators should be waiting for the patient, not vice versa. The operating room should be warm, and the infant should go directly into the operating room and be immediately placed under a servo-controlled radiant warmer.

In most instances, it is better to ligate a PDA, insert a Broviac catheter or treat necrotizing enterocolitis in the NICU rather than transport the child to the operating room. This allows the patient's mechanical ventilator and monitors to be used during surgery. The infection rates of patients undergoing surgery in the ICN are the same as those of patients undergoing surgery in an operating room [108].

## Induction of anesthesia

Although preterm infants require anesthesia [109], their requirements are lower than those of older patients [110,111]. Failure to provide adequate anesthesia

predisposes them to hypertension and intracranial hemorrhage if their cerebral vascular autoregulation is absent, which it commonly is [112]. When this occurs, increases or decreases in arterial blood pressure increase or decrease cerebral blood flow. Adequate anesthesia prevents or attenuates these changes in pressure. Because deep anesthesia reduces the arterial blood pressure of infants and children more than it does that of adults [113], arterial blood pressure must be supported with fluid and vasopressors when necessary. Increases in heart rate and arterial blood pressure are usually signs of light anesthesia. However, the heart rate often does not change during hypotension because the baroreceptors of preterm infants are obtunded by even light levels of anesthesia [113]. Seventy percent nitrous oxide reduces the baroresponse to the same extent as halothane [114]. Fentanyl 10µg/kg also depresses the baroreceptor reflex significantly [115] though this does not cause hypotension. Anand and associates showed that inadequate anesthesia induces a stress response in preterm infants [109] and that underanesthetized infants have a 10-fold greater complication rate.

Inserting an ETT without anesthesia or analgesia increases arterial and intracranial pressures [116]. Obviously, some patients are too ill to anesthetize before inserting an ETT, but this is uncommon after the immediate neonatal period.

Anesthesia is often induced with inhaled anesthetics (usually sevoflurane) and sufficient oxygen to maintain the desired SaO<sub>2</sub>. If controlled ventilation is required during the induction of anesthesia, the anesthetic concentration must be reduced to prevent sudden, severe hypotension [117]. An alternative anesthetic technique employs propofol 1-2mg/kg or fentanyl 10- $30\mu g/kg$  intravenously given over 1–2min [110]. Once the eyelid reflexes are lost, an ETT can be inserted. If an assistant places a finger in the patient's suprasternal notch, the tip of the ETT can be felt as it encounters the finger. At this point the tube tip is in the mid-trachea and advancement of the tube can be stopped and the tube fixed in place. This reduces inadvertent endobronchial intubation. If necessary, the patient can be paralyzed with pancuronium bromide 0.1 mg/kg or rocuronium 0.3-1.0 mg/kg. Pancuronium is often preferred for premature infants because it increases the heart rate and prevents bradycardia, which better maintains cardiac output.

## Maintenance of anesthesia

There are few data on the anesthetic requirements of preterm infants, especially extremely premature infants [111]. However, experience suggests that premature 
 Table 20.7 Relation between heart rate and systolic blood pressure in preterm infants anesthetized with halothane for ligation of a patent ductus arteriosus

Condition	Heart rate (bpm)	Systolic pressure (mmHg)
Preinduction	146 ± 20	62 ± 16
Before ductal ligation	143 ± 17	48 ± 16
After ductal ligation	145 ± 16	66 ± 15

infants require less anesthesia than their healthy full-term counterparts. The sevoflurane requirement for infants undergoing ligation of PDA is approximately 50–80% of that of term infants. At that dosage, no change occurs in either heart rate or arterial blood pressure with skin incision [111].

Preterm infants anesthetized with inhaled anesthetics are more often hypotensive than older patients [118], probably because there is less response of peripheral vessels to catecholamines [113], myocardial depression, and loss of baroresponse [119]. Because preterm infants depend heavily on tachycardia for cardiac output, loss of baroresponses makes it difficult for them to respond appropriately to hypotension. Table 20.7 shows the heart rate and arterial blood pressures of preterm infants anesthetized with halothane for ligation of a patent ductus arteriosus. Note the heart rate did not increase when the blood pressure decreased or increased, so baroreceptor function was reduced. Similar data are unavailable for sevoflurane, but the changes are almost certainly similar.

To avoid anesthesia-induced hypotension, fentanyl has been used to anesthetize preterm infants [110,120]. Administering  $10-30 \mu g/kg$  of fentanyl prevents changes in both heart rate and arterial blood pressure with a skin incision. When the blood volume is adequate, fentanyl administration seldom causes hypotension. Patients regularly receiving fentanyl in the NICU may require much higher doses of fentanyl for surgery, often more than  $50 \mu g/kg$ . As with all drugs, fentanyl should be titrated to the desired clinical effect. Muscle relaxants are often used to prevent movement and to reduce anesthetic requirements. Paralyzed premature infants must, however, be anesthetized! Nitrous oxide, like other anesthetics, can cause hypotension and cardiac arrest in hypovolemic patients.

The lungs of preterm infants should be mechanically ventilated during anesthesia and surgery. Operating room mechanical ventilators are poor substitutes for those used in the ICN, but ICN ventilators cannot deliver inhaled anesthetics. If an ICN ventilator is used, a narcotic-based anesthetic will provide adequate anesthesia. No ventilator adequately compensates for changes in compliance and resistance of the lungs induced by retractors, packs, and hands. Consequently, the lungs of small preterm infants are often ventilated by hand while observing the surgical field and chest expansion. The lowest pressures and tidal volumes possible should be used to normally expand the chest and lungs. If the neonate required PEEP in the NICU, he/she will require it during anesthesia and surgery. The initial ventilator settings used during anesthesia should mimic those determined by the physicians, nurses, and respiratory therapists in the NICU to produce the best blood gases and oxygen saturations. These variables can be adjusted as needed. In the operating room, the lungs of premature infants are mechanically ventilated. To avoid administering high oxygen concentration, it must be possible to adjust the FiO<sub>2</sub> between 0.21 to 1.0 during surgery. Administering high oxygen concentrations to preterm infants who do not need them unnecessarily exposes the infants to the risk of ROP (see above).

Actively determining and replacing the premature infant's blood losses with blood and fluid is crucial because the blood volumes of premature infants are small, 85–100 mL/kg. Consequently, in a 1 kg infant a loss of 10mL of blood is equivalent to a 10% loss of blood volume. It is often difficult to accurately determine blood losses during surgery. Weighing the used sponges is a more accurate method of doing so than merely looking at them and guessing how much blood is in them. A 1g increase in sponge weight equals 1 mL of blood. Suctioned blood should be collected in small bottles to more accurately determine blood losses. Volumes of flush solutions must be accurately recorded so they can be subtracted from the amount of fluid in the blood collection bottle. The most difficult part of estimating blood loss is determining how much blood is lost into the surgical drapes and into the tissues. Because of these inadequacies in blood loss determinations, it is often necessary to increase the estimated blood loss by 25-50% and to administer that amount of blood or an appropriate volume of crystalloid while monitoring intravascular pressures, heart rate, and determining serial hematocrits. Low hematocrits are corrected with packed RBCs.

The volume of fluid administered depends in great part on the amount of surgical trauma occurring. Abdominal or thoracic procedures are more traumatic than peripheral procedures and therefore require 8–12mL/kg/h or more of lactated Ringer's solution. Replacing fluid losses with 0.2 or 0.3 normal saline is dangerous because it leads to hyponatremia, water overload, and occasionally death. Infusing approximately 5–7mg/kg/min of glucose is a good starting dose under anesthesia, unless the patient was receiving higher concentrations of glucose in the ICN. The blood glucose concentration should be

Figure 20.6 Systolic, diastolic, and mean arterial blood pressures and pulse pressures of infants between 610 and 4200g. Reproduced from Versmold et al [121] with permission from American Pediatrics Association.

 Table 20.8

measured frequently and maintained between 50 and 90 mg/dL. Giving more glucose may cause hyperglycemia (Tables 20.8–20.10).

Additional fluid should consist of lactated Ringer's solution (without glucose), 5% albumin, blood or a combination of these. Intravenous alimentation fluid is *never* used to replace fluid losses during surgery because doing so causes severe hyperglycemia and possibly CNS damage. Instead, the anesthetist should infuse hyperalimentation fluids at their preoperative rate and provide additional fluid needs with plain lactated Ringer's solution. The blood glucose concentration can be determined during surgery with a glucometer and the infusion rates of dextrose altered as needed.

Adequate replacement of colloid and crystalloid is aided by measuring central venous pressure (CVP), mean arterial pressure (MAP), and urine output. Mean arterial blood pressure is a good indicator of intravascular volume. An arterial blood pressure that is two standard deviations below normal for that age group [121] indicates hypotension and suggests hypovolemia (Fig. 20.6). Infusing adequate fluid usually returns the blood pressure to normal. CVP is also a useful measurement of intravascular volume status. A CVP below 3 cmH<sub>2</sub>O suggests hypovolemia.

Urine output is also a good indicator of intravascular volume. It should exceed 0.75 mL/kg/h. The urine specific gravity of normal neonates is usually less than 1.005 [122]. A urine specific gravity in excess of 1.009 usually indicates that the patient is conserving fluid (see above). If the skin over the fontanelle is below the inner table of the skull, and the baby is not crying, he is probably hypovolemic.

Body temperature is maintained between 36°C and 37°C to avoid postoperative hypoventilation, delayed awakening from anesthesia, atelectasis, respiratory and metabolic acidosis, infection, poor feeding, and aspiration of gastric contents. The body temperature is maintained in the normal range by warming the operating room and the inspired gases. Intravenous fluids and blood can be warmed using a conventional fluid warmer set to 38–41°C, and leaving only a short length of tubing to the patient's IV catheter, so that the fluid will not cool in a long length of tubing. The short segment of tubing must be visible so air bubbles can be detected and removed. Even small air bubbles (0.1 cc) can be lethal if they lodge in a coronary or cerebral artery

because the foramen ovale is patent in most of these neonates.

### **Recovery from anesthesia**

Emergence from anesthesia can be as dangerous as induction of anesthesia. There is often pressure to quickly remove the patient from the operating room so that the next case can start. This pressure must be resisted while careful preparations are made to transport the patient to the recovery area, usually the ICN. Before the patient leaves the operating room, it must be known that the ICN nurses are available and ready to receive and care for the patient. The ICN should be informed of the FiO<sub>2</sub>, ventilator settings, body temperature, and planned postoperative pain therapy before the patient leaves the operating room. After transport to the ICN, a complete verbal exchange of information from the anesthesia team and surgeons to the ICN nursing and physician team is important, to inform them of intraoperative events.

In most instances the lungs of preterm infants should be ventilated on the way to and in the ICN. It can then be decided whether mechanical ventilation is required postoperatively or not. Muscle relaxants must be reversed and adequate spontaneous ventilation established before an ETT is removed.

Many preterm infants who are less than 44 weeks' gestation develop postoperative apnea [123,124]. The incidence of apnea is related inversely to the gestational age at birth [125]. Although the cause of apnea is unknown, it may be due to persistence of small amounts of anesthetic in the CNS that affect the autonomic nervous system [126] or it might be related to an incompletely developed CNS [127]. Most postoperative apnea occurs during the first 4h after surgery but may occur 12 or more hours after surgery [128]. Patients who are <46 weeks' gestation are usually monitored for apnea and SaO<sub>2</sub> in hospital for 12-24h after surgery due to their high risk for apnea. Those with gestational ages of 47-60 weeks' gestation are evaluated carefully for 6h postoperatively. If there is no evidence of apnea, bradycardia or oxygen desaturation, they can be discharged home, all else being normal. Those older than 60 weeks' gestation can be treated as normal term infants and can be discharged home after surgery if there are no other problems. Infants who develop postoperative apnea may require mechanical ventilation for several hours to several days. This possibility usually precludes outpatient surgery for infants who are less than 50 weeks postconceptual age, although one study disputes this conclusion [129].

Welborn and associates found that ex-premature infants whose hematocrit was below 30% had an increased incidence of apnea [130]. Eighty-nine percent of the infants with low hematocrits were apneic after surgery while only 21% of those with a hematocrit of greater than 30% were apneic.

The same authors found less apnea in infants treated with spinal anesthesia than in those anesthetized with general anesthesia [131]. No instances of apnea occurred with spinal anesthesia unless the patients were also sedated. Eight of nine infants premedicated with ketamine had significant apnea while five of 16 had postoperative apnea if not given the drug. Although spinal anesthesia caused fewer instances of postoperative apnea [132], apnea and total spinal anesthesia have occurred [133,134]. Kunst et al found no difference in the rate of apnea in patients who received either form of anesthesia [135]. Patients undergoing general anesthesia were more likely to have oxygen desaturation and bradycardia than those undergoing spinal anesthetic. Tashiro and associates [136] found that gestational age, birthweight, postconceptual age, and use of aminophylline preoperatively were associated with a need for postoperative ventilation. Approximately one-third of the infants undergoing hernia repairs had postoperative apnea [137]. Welborn et al found that IV caffeine 5 mg/kg prevented life-threatening postoperative apnea and eliminated the need for mechanical ventilation [138]. It had no effect on lesser degrees of apnea. By delaying surgery until the patient is more than 44 weeks' postconceptual age, most postoperative apnea can be avoided. Patients who require surgery before 44 weeks' gestation should receive intravenous caffeine.

## Anesthesia for micropremies

The marked improvement in the survival of very premature infants ("micropremies," i.e. 400–1000 g at birth) over the past few years has resulted in many surgeries before discharge from hospital. Some of these patients have poor neurological and developmental outcomes. Evidence suggests that only 67–71% of 24–25-week gestation infants are neurologically normal compared to 89% of those born at 26 weeks' gestation (Table 20.11). An additional 22% of 24-week gestation infants have neurological examinations that are suspicious for injury [139,140].

Table 20.11 Neurological and developmental outcome of micropremies

	24 Weeks	25 Weeks	26 Weeks
No. of infants followed	18	30	38
Neurologically normal	12 (67%)	22 (73%)	34 (89%)
Neurologically suspicious	4 (22%)	2 (7%)	0
Cerebral palsy	2 (11%)	6 (20%)	4 (11%)
Normal cognitive development	5 (28%)	14 (47%)	27 (71%)
Borderline cognitive development	6 (33%)	7 (23%)	7 (18%)
Deficient cognitive development	7 (39%)	9 (30%)	4 (11%)

\* Data are presented as n (%).

<sup>+</sup>Kruskal-Wallis  $\chi^2 = 10.6542$ , p = 0.005 for cognitive outcome and gestational age.

Reproduced from Piecuch et al [140], with permission from Lippincott, Williams & Wilkins.

Only 28% of neonates born at 24 weeks' gestation have normal cognitive development at 4.5–7 years of age. Eleven percent of 24–27-week gestation infants had cerebral palsy. The outcome of small infants was significantly improved by delaying their birth until 26 weeks' gestation. Infants with CNS injuries are more likely to have hypotension and bradycardia with anesthesia.

The problems of micropremies are similar to those of larger premature infants, but worse. Because they are so immature, micropremies do not have true alveoli and the distance between their capillaries and their gas exchange units is greater, making oxygenation more difficult. The high surface/volume ratio and the thin fragile skin increase fluid loss and make it more difficult to maintain their body temperature. Removing tape or monitor pads often removes their skin and leaves large weeping abrasions.

To maintain hydration and prevent/treat hypotension, it is often necessary to administer very large volumes of fluid (often >200 mL/kg/day) and vasopressors. Failure to do so results in dehydration and hypotension. However, administering these volumes of fluid may cause a PDA, heart failure, and pulmonary edema.

The normal mean arterial blood pressure for infants of 24–26 weeks' gestation infants is debatable but is grossly the same as the gestational age. Blood pressures measured by non-invasive means are often higher than those measured intravascularly (Table 20.12). Consequently, micropremies may be hypotensive despite having non-invasive mean arterial blood pressures that would be considered normal for gestational age. Determining the state of hydration is more difficult in these patients because they have little or no subcutaneous tissue, their skin is paper thin, and their pulses are frequently difficult to feel. The skin over their fontanelles is level with the outer table of the skull. Their urine output is usually more than 1 mL/kg/h and the specific gravity <1.005.

The anesthesia requirement of micropremies is unknown. However, from previous data it appears that the MAC for halothane is less than 0.55. The dose of sevoflurane is about 60% of that of term infants. Opioids in adequate doses provide anesthesia for these infants; their arterial pressures are more stable than during

Table 20.13 Vital signs during fentanyl and halothane anesthesia (23-26 weeks' gestation)

inhaled anesthesia (Table 20.13). Since these children are often mechanically ventilated after surgery, muscle paralysis with pancuronium 0.1 mg/kg and anesthesia with fentanyl 10–50µg/kg provides adequate conditions for any surgery. Although small premature infants have cerebrovascular autoregulation, it is very fragile and easily disrupted. This increases the likelihood of intracranial hemorrhage and central nervous system injury if the anesthesia is inadequate.

Micropremies have high fluid requirements during surgery. Failure to provide the required amount of fluid results in hypotension and/or shock. All fluid should be administered via calibrated pumps when possible to avoid excess fluid administration. Where should the surgery for micropremies be performed? Many institutions do it in the NICU because it is easier to take nurses, doctors, and technicians to the NICU than it is to take the patients to the operating room. The infection rate is no different whether the patient undergoes surgery in the ICN or the operating room.

Common surgical problems of micropremies are described elsewhere in this book. Patent ductus arteriosus is covered in Chapter 25, thoracotomy for pulmonary resection in Chapter 24, hydrocephalus in Chapter 23, and necrotizing enterocolitis and inguinal hernia in Chapter 28. The following is a case study that illustrates and integrates many of the points discussed above.

## CASE STUDY

The infant was 5 days old at the time we were asked to evaluate him for anesthesia and surgery for NEC. He was born after 29 weeks' gestation and weighed 980g at birth. On the day of surgery his weight was 840g, a 15% weight loss from birth. He was severely asphyxiated at birth and required immediate tracheal intubation and assisted ventilation.

His initial blood gas values were pH 7.00,  $PaCO_2$  63 mmHg, and  $PaO_2$  43 mmHg (SaO<sub>2</sub> 91%) despite ventilation with 100% oxygen. His mean arterial blood pressure was 16 mmHg at 5 min of age. Ventilation was continued, and 10 mL of whole blood were administered over 5 min, which brought his mean arterial blood pressure to 28 mmHg. His blood gases improved following the transfusion. By 25 min of age the PaO<sub>2</sub> was 165 mmHg (SaO<sub>2</sub> 100%), the PaCO<sub>2</sub> 33 mmHg, and the pH 7.34. He was transferred to the NICU after the PaO<sub>2</sub> had been reduced to 63 mmHg (SaO<sub>2</sub> 97%) by progressively decreasing the FiO<sub>2</sub> to 0.67. A chest radiograph demonstrated classic RDS.

During the next 4 days, the RDS improved and the NICU staff reduced the level of assisted ventilation. On day 1 he received 5% dextrose in water, equal to 50mL/kg/day, plus electrolytes. This rate was increased to 70mL/kg/day thereafter. He was covered with clear plastic film to reduce

evaporative heat loss. The baby was started on ampicillin and gentamicin shortly after birth because it was uncertain if sepsis was present. When the blood, urine, and CSF cultures failed to demonstrate bacteria on day 3, the antibiotics were discontinued. The initial hemoglobin value was 12.5 g/dL. Because of blood sampling, the hemoglobin concentration decreased to 9.5 g/dL. He was transfused to increase it to 11.2 g/dL on the third day of extrauterine life.

On day 5, the infant developed abdominal distension, vomiting, and bloody stools following attempts to feed him with breast milk. His respiratory distress, which had been improving, now worsened. He required higher ventilator rates and pressures and a higher FiO<sub>2</sub>. An abdominal radiograph showed free air in the peritoneal cavity and a diagnosis of necrotizing enterocolitis was made. At this point, he was scheduled for surgery.

A review of the records and his physical examination demonstrated the following.

#### Hydration

His skin was pale and mottled and failed to return to its resting position for 8 sec after being tented up. The fontanelle was sunken below the inner table of his skull. It took more than 6 sec for the skin of his fingers and toes to fill with blood after they were blanched. His extremities were cold from the groins and axillae outward. There were no pulses in his feet or wrists and his groin pulses were markedly diminished. The pulse rate was 150 beats per minute (bpm) and the arterial pressure 40/15 mmHg, with a mean pressure of 23 mmHg. There had been no urine output for 6h and only 2 mL of urine during the 4h previous to that. The urine specific gravity of his last sample was 1.028.

#### Chest findings

He had bilateral rales that did not clear when the ETT was suctioned. Air entry into the upper lobes of the lungs was appropriate but was decreased in the bases. An ETT was in place in the mid-trachea and was fixed securely. The  $PaO_2$  was 72 mmHg (SaO\_2 98%), the  $PaCO_2$  30 mmHg, and the pH 7.21. His base deficit was -15 mEq/L. He was ventilated 20 times per minute with peak pressures of  $30 \text{ cmH}_2O$ , and PEEP of  $5 \text{ cmH}_2O$ .

#### **Cardiovascular findings**

His heart rate was normal (150bpm) and there was no murmur or gallop. The point of maximal cardiac impulse was in the fourth interspace anteriorly. His pulses were as above.

#### Abdominal findings

His abdomen was grossly distended. Loops of bowel were visible through the anterior abdominal wall, which was edematous, warm, and tender. Bowel sounds were absent. The liver was not palpable, but it could be percussed 1 cm below the right costal margin.

#### Laboratory data

His WBC count was 29,300/mm<sup>3</sup> with a shift to the left. Fifteen percent of these cells were bands. His hemoglobin was 14.5g/dL. His electrolytes showed a sodium concentration of 147 mEq/L, potassium 5.3 mEq/L, chloride 120 mEq/L, and bicarbonate 17 mEq/L. His serum calcium concentration was 6.3 mg/dL and his ionized calcium was 1.0 mmol/L. The total protein concentration was 4.5 mg/dL.

Discussions with the nurses indicated that the infant would become severely cyanotic and his  $SaO_2$  would abruptly decline to 80–88% when the ETT was disconnected for tracheal suctioning. They also pointed out that his body temperature was labile and that he required increasing amounts of exogenous heat to maintain his body temperature in the normal range.

#### **Preoperative preparation**

On the basis of the above information, it was clear that the infant was severely intravascular volume depleted, although his bodyweight had not changed over the past 12h. His peripheral perfusion and arterial blood pressure were decreased. The lack of urine output for 6h indicated not only that the intravascular volume was decreased but also that he had more than a 70% chance of becoming hypotensive with the induction of anesthesia. The rise in his hemoglobin concentration also indicated intravascular volume depletion. A central venous line was inserted with local anesthesia and was connected to a pressure transducer. The CVP was 0 cmH<sub>2</sub>O. Lactated Ringer's solution 10 mL/kg was infused over 15 min which increased his CVP to 2cmH<sub>2</sub>O. Additional lactated Ringer's solution 10 mL/kg raised the CVP to  $5 \text{ cmH}_2\text{O}$ . With this increase, the peripheral perfusion improved and the mean arterial pressure rose to 32mmHg. His urine output increased to 2mL/kg/h, and the urine specific gravity decreased to 1.006. He needed less mechanical ventilation because the  $PaO_2$  rose to 123 mmHg (SaO<sub>2</sub> 100%) and the PaCO<sub>2</sub> decreased to 18mmHg. His base deficit rose to -5meq/L without infusing sodium bicarbonate. His blood glucose concentration was now 128 mg/dL. Calcium gluconate 150 mg/kg was administered to treat the hypocalcemia. Repeat electrolyte determinations showed a calcium concentration of 8.1 mg/dL and ionized calcium of 1.02 mmol/L, a sodium concentration of 140 mEq/L, a potassium concentration of 4.5 mEq/L, and a chloride concentration of 115 mEq/L. His hemoglobin concentration had decreased to 11.0g/dL after rehydration.

After 90 min of preparation, the patient was transported to the operating room while being manually ventilated at the same pressures, rates, and inspired oxygen concentration used in the nursery.

#### Surgery

The patient was anesthetized and operated on in his intensive care bed. Anesthesia was induced with fentanyl 20µg/ kg, and he was paralyzed with pancuronium 0.1 mg/kg. Surgery began within 5 min of his arrival in the operating room. The inspired oxygen was maintained at a level that kept the PaO<sub>2</sub> between 50 and 70 mmHg (SaO<sub>2</sub> 91–96%) by using air as the carrier gas and adding oxygen as needed. Oxygen saturation was measured continuously with a pulse oximeter, and the blood gases and pH were measured intermittently, as was the serum glucose. The total calcium concentration was determined once during the 2-h procedure and was found to be 6.9 mg/dL. The concentration of ionized calcium was 1.01 mmol/L. Calcium gluconate 20 mg was given slowly through the central venous line. A blood loss of 15 mL was replaced with packed RBCs, bringing the hemoglobin to 15 g/dL. His IV fluids included 5% dextrose in lactated Ringer's solution 4mL/h and lactated Ringer's solution without glucose 6mL/h, which maintained the blood glucose concentration and the arterial and central venous pressures within normal limits. The bowel Continued was resected and an end-to-end anastomosis performed in addition to a diverting colostomy.

His body temperature was maintained within normal limits by wrapping the extremities with sheet wadding, covering his head with a cap, placing a warming pad under him, warming and humidifying the inspired gases to 37°C, warming the infused fluids, and placing him on a forced air warming blanket. At the end of the procedure he was covered with warm blankets and clear plastic film. His ventilation was controlled during transport to the NICU. Mechanical ventilation and paralysis were continued in the postoperative period. Once we were sure that the vital signs and ventilation were adequate, his care was transferred to the NICU staff after a complete report of intraoperative events.

His condition continued to improve over the next week, and he was weaned from mechanical ventilation and fed intravenously through the central venous line. He was discharged from the hospital at 2 months of age neurologically intact and eating well. At 4 months of age, his colostomy was closed, and he has done well since.

#### Conclusion

This case illustrates how severely dehydrated such premature patients can be and how well they respond to fluid replacement. It also shows how stable they can become once the deficits are replaced.

## Introduction

More premature babies are surviving and presenting for surgery in early life with residual effects of prematurity, complications of prematurity and neonatal intensive care and co-morbidities. The risk of perioperative apnea has been elucidated and anesthetic techniques with modern volatile agents or using awake regional anesthesia have been developed to try to minimize this risk, particularly for inguinal hernia repair. For more major congenital abnormalities such as tracheo-esophageal fistula (TEF), abdominal wall defects and congenital diaphragmatic hernia, the principles of neonatal anesthesia are described in general, with particular refinements of technique for each of these major lesions described in detail. The dilemma for the anesthesiologist of having to provide anesthesia for a muscle biopsy in an infant is also discussed. The current neonatal resuscitation algorithm is discussed with information from recent trials of techniques aimed at trying to improve outcomes.

# Residua and complications of prematurity

With advances in obstetric and neonatal care, a higher proportion of premature babies are surviving and presenting for anesthesia and surgery in early life [1–3]. Often the survivors have one or more residua of prematurity (Box 21.1) or complications of prematurity or neonatal intensive care unit (NICU) management. The incidence and severity of disabilities tend to be in

proportion to the degree of prematurity and length of NICU stay [2,4].

#### **Chronic lung disease**

Significant chronic lung disease, or bronchopulmonary dysplasia (BPD), persists in up to 10% of ex-premature infants. The severity and incidence have been ameliorated by antenatal maternal steroid therapy, exogenous surfactant treatment, new ventilatory support strategies to minimize barotrauma and volutrauma and improved monitoring to prevent oxygen toxicity (see Chapter 20). However, because a higher proportion of premature babies are surviving, the number of babies presenting for surgery and anesthesia with some degree of lung disease has tended to increase over the last 10 years.

The mechanisms leading to chronic lung disease are detailed in Chapter 20 but a useful clinical classification of severity of BPD [5] highlights for the anesthesiologist those at particular risk of perioperative pulmonary complications such as pneumothorax, interstitial emphysema, bronchospasm, hypoxemia and pulmonary hypertension. For babies born at less than 32 weeks' gestational age who are assessed at hospital discharge or 36 weeks' postconceptional age as having needed supplemental oxygen for at least 28 days, the severity of BPD is *mild* if the baby is now breathing room air, *moderate* if the baby is now needing less than 30% oxygen and severe if the baby now needs 30% oxygen or more and/or positive pressure ventilation or nasal continuous positive airway pressure (CPAP) [5]. To minimize perioperative deterioration in lung function, strategies for the anesthesiologist include use of awake regional anesthesia techniques where feasible (see below) or, for those who need general anesthesia, tracheal intubation with controlled ventilation is usually recommended with administration of the minimum effective inspired oxygen concentration to maintain arterial oxyhemoglobin saturation between 92% and 96%, use of minimum effective peak inspiratory pressures, application of low levels of positive end-expiratory pressure (PEEP) to minimize airway collapse, permissive hypercapnia and relatively slow ventilatory frequency with shorter inspiratory:expiratory (I:E) ratio to minimize gas trapping and overinflation of lung segments. Bronchodilator medication should be continued on the day of surgery and postoperatively. For severe BPD cases, elective postoperative ventilatory support may well be required, although with good regional analgesia, early extubation may be possible for certain operative procedures.

#### **Airway problems**

Subglottic stenosis, tracheal stenosis, tracheomalacia and bronchomalacia may occur in up to 10% of ex-premature babies.

Subglottic stenosis at the level of the cricoid ring is most often due to repeated tracheal intubation, use of too large a tracheal tube or where tracheal intubation has been needed for a very long time. It may also be associated with gastro-esophageal reflux with repeated spillover of acid or bile into the airway. It may well be that in an infant presenting for elective surgery, consideration should be given to therapy for the subglottic stenosis as a higher priority, depending on its severity, but this decision requires careful discussion. Where anesthesia has to be given, a much smaller tracheal tube diameter than expected may be required and elective steroid therapy given prior to extubation to minimize mucosal edema.

Tracheomalacia may be primary or secondary to extrinsic compression (e.g. vascular ring) or prolonged positive pressure ventilation. The tracheal cartilages may be underdeveloped and the membranous part of the trachea posteriorly may be widened. Tracheal collapse typically occurs on expiration, giving expiratory stridor, a seal-like cough and expiratory wheeze. A similar pattern may be seen with bronchomalacia which may be primary or secondary to extrinsic compression, for example from a large pulmonary artery or left atrium. Bronchomalacia may lead to unilateral lung collapse or hyperinflation. Care must be exercised on starting positive pressure ventilation to ensure sufficient end-expiratory pressure to splint the collapsible large airways open on expiration to avoid stacking of breaths and gross hyperinflation of the lung. On extubation of the trachea, babies with tracheobronchomalacia benefit from postextubation CPAP or bilevel positive airway pressure (BiPAP) to minimize postoperative lung collapse and respiratory failure.

#### Apnea

The mechanisms of apnea in the premature and expremature infant are described in detail in Chapter 20. Apnea has been recognized as an issue for such babies for over 40 years [6] and soon after this was reported, the use of xanthine derivatives such as aminophylline [7] or theo-

phylline [8,9] and their active metabolite caffeine [8–14] as therapy was elucidated. Anesthesiologists became aware of this work when the problem of postoperative apnea was highlighted by landmark reports during the 1980s [15–20] and key dose-finding studies of caffeine as prophylaxis [21,22]. Around this time, there was also interest in the use of "awake" regional anesthesia as an alternative to general anesthesia for such cases, particularly for inguinal surgery (see below). Comparative trials of general with regional anesthesia were undertaken (see below) and risk factors for postoperative apnea were further elucidated [23-28], most notably in a combined analysis by Coté et al [29]. This made clear that the main risk factors are young postconceptual age, anemia (hematocrit <30%) and nature of the surgery [29]. The importance of this analysis for clinical practice has been immeasurable in helping clarify risks for all ex-premature infants up to 60 weeks' postconceptual age, allowing guidance for monitoring and postoperative care to be developed and helping decision making about day care and time of discharge [29].

In summary, the risk/benefit ratio suggests a default position of considering admission for monitoring of all ex-premature infants who are younger than 60 weeks' postconceptual age as the postoperative apnea risk is around 1 in 200 for non-anemic infants who have not exhibited apnea in the postanesthesia care unit (PACU) until around 55 weeks postconceptional age (PCA) (Fig. 21.1).

For those with co-morbidities, those for more major surgery, who are anemic with hematocrit <30% or who become apneic in the PACU, admission for at least 12h after the last apneic episode, and caffeine 10 mg/kg intravenously are recommended [30,31]. These guidelines apply whatever anesthetic technique has been used, including awake regional anesthesia, although some authors have questioned this recently based on their own local expert practice [32,33] (see below). There have been reports of postoperative apnea in full-term neonates [34– 37] and it is prudent therefore to admit and monitor fullterm infants of less than 44 weeks PCA who show any respiratory abnormality during recovery from anesthesia for monitoring for at least 12 apnea-free hours.

#### Cerebral damage

Residual cerebral damage may occur from birth asphyxia, intraventicular hemorrhage, periventricular leukomalacia, hydrocephalus or seizures. The mechanisms of cerebral damage are detailed in Chapter 20. The clinical effects are manifest as cerebral palsy, cognitive and behavioral deficits, hearing loss and visual impairment. Longer term follow-up published in 2005 showed that around 1 in 5 very premature babies had severe disabilities at age 5 years and only 1 in 4 exhibited normal development [38]. More recent analyses [39] suggest that some centers are

**Figure 21.1** (A) Postoperative apnea risk showing variation among centers. (B) Postoperative apnea risk by gestational age and postconceptual age and influence of apnea. Reproduced from Coté et al [29] with permission from Lippincott Williams and Wilkins.

achieving much lower prevalence rates of cerebral palsy (as low as 1.9% in very preterm infants born at 20–27 weeks' gestation) and rates of hearing and vision loss as low as 1% [39].

The anesthesiologist should make a detailed preoperative assessment of residual neurological impairment and document this baseline carefully, noting the pathology underlying the deficit, presence of hydrocephalus and/or a ventriculoperitoneal shunt, seizures and their pattern and frequency, and antiseizure medication. These findings may affect choice of anesthetic agent and technique, use of central regional blockade, need for perioperative antibiotics and decisions about early extubation or elective postoperative ventilatory support. The documentation is also important from a medico-legal perspective to minimize the risk of subsequently being accused of causing neurological damage by anesthetic agents, techniques or procedures. Anesthetic goals should be to maintain a normal range of blood pressure, carbon dioxide levels and arterial oxyhemoglobin saturation in the range 92-96% and in particular to minimize episodes of fluctuation above and below these norms for age.

#### Eye problems

The mechanisms of retinopathy of prematurity (ROP) are described in Chapter 20. Residual eye problems occur in

up to 50% of ex-premature babies [40] and the anesthesiologist needs to be aware of the importance of avoiding hypoxia and hyperoxia and thereby potentially exacerbating the retinal damage. Thus titrating oxygen delivery to maintain stable arterial oxyhemoglobin saturation values of 92–96% and avoiding major fluctuations is recommended [41].

#### Anemia

The full-term neonate usually has a high hematocrit of 45-55%, depending on the degree of placental autotransfusion at delivery, and this level starts to fall within the first week of life. In response to increased oxygen saturation after birth, the levels of erythropoietin decrease and so replacement of short half-life red blood cells containing fetal hemoglobin with longer half-life cells containing adult hemoglobin is delayed. This results in a low point of hematocrit of 24-30% at around 2-3 months of age. In the premature baby, this low point of hematocrit often occurs earlier (1-2 months of age) and is more profound (21-27%) due to repeated blood sampling and nutritional deficiencies of iron, folic acid and vitamin E. Many neonatal intensive care units (NICU) aim to maintain the hematocrit in the range 36–45%, especially in the sickest infants with severe lung disease, low arterial oxyhemoglobin saturations and low cardiac output states.

A study of preterm babies weighing between 500 and 1300 g showed that restricting blood transfusion resulted in more medical complications (brain hemorrhage, periventricular leukomalacia and apnea) [42]. Use of exogenous erythropoietin as therapy to increase hematocrit levels in the NICU showed initial promise but resulted in an increased incidence of retinopathy of prematurity, although this only occurs when very large doses of erythropoietin are given [43]. For anesthesia, it is important to optimize oxygen delivery. Transfusion with blood containing adult hemoglobin, which releases oxygen to tissues more readily, may be required. There is an important association between the incidence and severity of perioperative apnea and anemia (see above) [24,29]. For individual cases, transfusion triggers will depend on the starting hematocrit, the likelihood of blood losses, the risk of apnea and the presence and severity of co-morbidities such as BPD and cardiac disease [44].

#### Patent ductus arteriosus

Patent ductus arteriosus (PDA) is common amongst expremature babies and the prevalence has increased with improved survival rates and as a concurrent effect of exogenous surfactant therapy. PDA may still be present when an ex-premature baby presents for other surgery, especially emergency surgery. For elective surgery, consideration should be given to closure of the duct first either by medical therapy (e.g. with indometacin or ibuprofen [45]), transcatheter device closure, thoracoscopic duct ligation/clipping or open duct ligation/clipping, as appropriate. The presence of a PDA adds risks because of left-to-right shunting with increased lung water, decreased lung compliance, pulmonary hypertension, congestive heart failure, potential for shunt reversal and increased risk of hypotension, especially diastolic hypotension due to excessive run-off into the pulmonary circuit. Coronary arterial hypoperfusion with myocardial ischemia can occur. The low diastolic blood pressure can also result in splanchnic hypoperfusion. Cardiac output reserves are also diminished for the ill baby, for example with necrotizing enterocolitis or if bleeding occurs during surgery, and severe hypotension may occur in such cases.

#### **Difficult vascular access**

Ex-premature infants may present serious difficulties with peripheral and central venous access and sometimes also arterial access, particularly if they have had a long and complicated NICU stay. Peripheral veins may have been used repeatedly for blood sampling or cannulated for intravenous fluid and drug administration or for central venous access using a peripherally inserted central catheter (PICC). Central veins may have become thrombosed and this often induces collateral venous channels to expand, which can be very difficult to cannulate, catheterize and sustain.

## Altered pain perception and responses and tolerance to analgesics and sedatives

Most premature babies are exposed to multiple painful procedures in early life and these can alter sensory perception, including that for pain, and also induce long-term changes in sensory responses and behavior [46–54]. This can manifest clinically as increased sensitivity to pain [46] and increased analgesic requirements or, alternatively, reduced sensitivity to pain [54] so for the anesthesiologist, this emphasizes the importance of individualizing pain assessment and management. In addition, premature babies may have had considerable exposure to sedative and analgesic drugs during their NICU stay and may have developed tolerance with important effects on their individual dose requirements [55–58].

## Operating room environment for the neonate

The operating room (OR) environment for the neonate must carry a range of appropriate equipment drugs and fluids and must have appropriate means of maintaining the baby's temperature to minimize heat losses to the environment. The ambient room temperature should be increased to around 23–25°C (80–85°F), anesthetic inspired

gases should be warmed and humidified, IV fluids should be delivered via a warming device and a forced warm air delivery device and/or warming blanket used. The exposure of the baby to the ambient environment should be minimized to avoid heat losses.

For awake regional anesthesia, the ambient light level should be lowered and monitor alarm volumes reduced to a minimum. Monitoring equipment should comply with current standards and include electrocardiogram (ECG), stethoscope, arterial blood pressure (BP), temperature, pulse oximetry, anesthetic agent monitor and capnography. Appropriate sizes of pulse oximeter probes and provision to monitor pre- and postductal saturations should be available. The anesthetic machine should be able to deliver air and oxygen to allow titration of inspired oxygen to avoid hypoxia or hyperoxia and should have a ventilator capable of supporting small infants, including delivery of PEEP if needed. Many pediatric anesthesiologists prefer non-rebreathing circuits but circle systems are now being used more widely. Technological advances allow improved gas monitoring, including accurate tidal volume and pressure measurement, which can be very helpful. Invasive pressure monitoring should be readily available. A full range of airway equipment appropriate for small infants must be immediately available including facemasks, oral airways, laryngeal mask airways (LMAs), suction catheters, stylets, tracheal tubes and laryngoscope blades. A full range of anesthetic, analgesic, muscle relaxant and resuscitation drugs and IV fluids (including dextrose 10%) should be immediately available. Peripheral and central venous cannulas of appropriate size and length should be immediately to hand and small size intraosseous needles also. Many ORs will construct a neonatal cart which is checked regularly to ensure all equipment is present in case of an emergency. Where difficult intubation is anticipated, an appropriate sized fiberoptic bronchoscope, videolaryngoscope, and intubation aids such as guidewires and airway exchange catheters should be available.

## Postoperative extubation versus postoperative ventilation

For the neonate undergoing surgery under endotracheal general anesthesia, the question of whether to extubate or not at the end of surgery is a common dilemma. For some infants with major co-morbidity undergoing major surgery, the decision may be clear but for others it may be more difficult. Newborn and ex-premature infants differ physiologically from older children with regard to certain aspects of their respiratory physiology and this has some bearing on the decision (see Chapter 20). Minute ventilation and therefore the relative work of breathing in the neonate is 3–4 times greater than in adults because of much higher oxygen consumption [59]. During normal tidal ventilation, neonatal lungs are close to closing volume [60]. This means more rapid desaturation during apneic episodes. Furthermore, respiratory control mechanisms are not fully mature and hypoxia can result in short periods of hyperventilation followed by apnea [61]. An immature respiratory center is also sensitive to the effects of volatile anesthetics, sedative and opioid drugs. These factors mean that for all but the shortest and nonstimulating procedures, tracheal intubation and controlled ventilation are appropriate.

In general, the attainment of normal physiological parameters is a prerequisite prior to extubation of the expremature or term neonate following general anesthesia. The infant should be awake and able to flex the hips and lift the arms. Muscle relaxation should be fully reversed and there should be a regular respiratory pattern with adequate minute ventilation and a satisfactory PaCO<sub>2</sub>. The infant should also be normothermic as the consequences of hypothermia include delayed drug metabolism, hypoxia and apnea (see above) [6]. Apnea risk is a particularly important factor in those <44 weeks PCA [28] with a lesser but not insignificant risk in those infants born at less than 37 weeks where the risk persists until 60 weeks PCA [29]. Prophylactic respiratory stimulants such as caffeine or theophylline are highly recommended in these groups, particularly if early extubation is being considered [30,31,62]. Anemia in the immediate postoperative period should be corrected as a hemoglobin level of <10g/dL has also been shown to significantly increase the risk of postoperative apneic episodes [24].

Opioid administration is a factor which must also be considered. The less well-developed neonatal bloodbrain barrier allows greater penetration of opioids into the cerebrospinal fluid in the newborn [63]. Moreover, an immature respiratory center is more sensitive to the respiratory depressant effects of opioid drugs [64]. The use of shorter acting opioids such as alfentanil or remifentanil may facilitate extubation but transition to ongoing analgesia can be difficult to manage. Care must be exercised, however, with the use of morphine which has a much longer half-life and its active metabolite morphine-6-glucuronide is excreted renally. Immature renal tubular function in the term and ex-premature infant therefore means that there is reduced clearance of morphine, thus prolonging its effect. For the neonate undergoing surgery, intubation and postoperative ventilation may be mandatory, for example in the case of repair of congenital diaphragmatic hernia or in long-gap esophageal atresia (EA). Significant hypothermia, hypoglycemia, hypocalcemia or other uncorrected biochemical abnormalities are also indications for postoperative ventilation. Similarly, there is rarely reason to consider extubation in the syndromic

infant or in the case of major thoracic, abdominal or airway surgery. However, early extubation, either in the operating room or within 3h, has found feasibility in some neonates undergoing cardiac surgery [65]. The advantages are thought to be reduced postoperative complications, a shorter hospital stay and reduced costs. This is only achievable in some centers and with a dedicated and highly involved multidisciplinary team approach.

For infants undergoing some abdominal or thoracic procedures, the choice of anesthetic technique can influence the decision to extubate post procedure. Desflurane, with its low blood/gas and tissues/gas solubility coefficients, has a very rapid offset and while it may be irritant and unsuitable for spontaneous ventilation, it is a very useful agent in the ventilated neonate and is the volatile agent of choice when extubation is required. The addition of local anesthetic techniques to supplement general anesthesia may reduce or eliminate the need for opioids. Inguinal hernia repair, for example, can be achieved easily without opioids by either supplemental ilioinguinal nerve blockade or caudal epidural anesthesia. Epidural techniques (see Chapter 18) are appropriate in many scenarios and often allow a reduction in opioid administration. Caudally sited epidural anesthesia is a straightforward procedure and is useful for both abdominal and thoracic surgery, depending on level. In esophageal atresia repair, it has been shown to reduce the need for postoperative ventilatory support [66].

Because of their size and relative physiological immaturity, neonates and ex-premature infants require careful consideration for postoperative extubation. They are sensitive to many environmental, physiological and pharmacological factors and before the decision to extubate is taken, the anesthesiologist must take all these factors into account.

### **Inguinal hernia**

Inguinal hernias are frequently found in up to one-third of ex-premature neonates [67] and it is recommended that they are repaired surgically in early life because of the risks of incarceration of bowel in the hernia sac (bowel obstruction, bowel infarction) and the risk of testicular infarction. The need for early surgery has to be balanced against the risks of anesthesia, perioperative apnea and medical co-morbidities, including the residual effects of prematurity (see above). The optimal timing of surgery [68] has to be decided on an individual case basis but some need urgent repair, particularly irreducible hernias, those associated with frank signs of bowel obstruction or very large hernias where the testicular blood supply may be compressed or compromised. The decision-making process has been affected by recent concerns about developmental neurotoxicity of general anesthetic and sedative agents [69–71]. This has led to renewed interest in awake regional anesthesia techniques [72–87]. A large multicenter comparative trial of neurodevelopmental outcome after regional or general anesthesia is in process (GAS study) [69]. Some units now favor delaying repair but the risks of leaving hernias unrepaired are significant in an already vulnerable population [68]. Surgical techniques and attitudes to prophylactic repair of the contralateral side are evolving with the advent of laparoscopy [88,89]. Many centers now undertake these procedures entirely laparoscopically, while others use the technology to inspect the contralateral side. Open repair is still widely practiced and gives good results.

All surgical repair techniques have complications (infection, bleeding, testicular infarction, bowel perforation, hernia recurrence) and opinion is still divided as to whether open surgery or laparoscopy has a lower incidence of these various problems [89]. Often the hernia repair is scheduled towards the end of the baby's hospital stay prior to discharge home from the NICU or specialist children's center, although some babies go home first and are then readmitted at a slightly later stage if the hernias are deemed to be low risk.

The baby should be assessed for residual effects or complications of prematurity or NICU care as noted above and in particular assessed for the known risk factors related to PCA, anemia, co-morbidities [29] and nature of the hernia (elective, emergency, unilateral, bilateral, very large, incarcerated or complex) and surgical technique (open, laparoscopic, open with contralateral inspection) [89]. Whichever anesthetic technique is used, general anesthesia or awake regional anesthesia, the guidance above about monitoring and aftercare should be used. Consider the use of caffeine 10 mg/kg IV if the baby is not already receiving it. The choice of anesthetic technique should be discussed in detail with the surgical team and with the parents and informed consent obtained.

#### Anesthetic and analgesic techniques

There are two main groups of techniques, both with a considerable evidence base behind them, namely awake regional anesthesia and general endotracheal anesthesia (usually with a regional analgesic component).

#### Awake regional anesthesia

This may be provided by a single-shot spinal (subarachnoid) injection of local anesthetic [32,72–76,83,84,87,90– 101], a single-shot caudal (epidural) injection of local anesthetic [20,76,77,84,87,102,103], a combination of these (see Case Study below) or a catheter-based caudal anesthetic (single or multiple shots and/or continuous infusion of local anesthetic) [79,80]. Plain local anesthetic solutions are preferred for ex-premature and term

Local anesthetic	Concentration	Dose (mg/kg)	Reference
Spinal anesthesia			
Tetracaine	10 mg/mL hyperbaric	1	[93]
Bupivacaine	5 mg/mL hyperbaric	0.3	[75]
Bupivacaine	5 mg/mL isobaric	1	[109]
Levobupivacaine	5 mg/mL isobaric	1.2	[109]
Ropivacaine	5 mg/mL	1	[101, 109]
Caudal anesthesia			
Bupivacaine	2.5 mg/mL	2	[87]
Levobupivacaine	2.5 mg/mL	2	[110]
Ropivacaine	2 mg/mL	2	[110]

Table 21.1 Recommended doses of local anesthetic agents for awake regional anesthesia for inguinal hernia repair in neonates

neonates because additives such as clonidine can produce an increased apnea risk [104–108]. However, epinephrine has been shown to prolong spinal anesthesia with tetracaine by about one-third. The local anesthetic agents used include tetracaine [93], bupivacaine [74,75,109], ropivacaine [101,109] and levobupivacaine [109] (see Table 21.1).

Spinal anesthesia has the advantage of quicker onset than a caudal but duration may be shorter and the institution of the block can be technically challenging, with a failure rate of up to 10%. The doses in Table 21.1 typically give a block adequate for inguinal surgery lasting around 1h but a tetracaine spinal may extend this by a further hour [87]. Supplementation of the spinal block with any sedative or anesthetic agent results in loss of the benefits in terms of reduced apnea. Sucrose analgesia is a useful adjunct and often helps settle a restless baby [111]. Some authors feel that a caudal is more likely to succeed and more anesthesiologists are familiar with caudal blocks so the disadvantage of slow onset is countered by improved reliability and longer duration of action [87].

#### **General anesthesia**

General endotracheal anesthesia could be regarded as the standard technique but early study results were confounded by use of older volatile agents such as halothane [93]. With newer volatile agents such as sevoflurane and desflurane showing promise for infant anesthesia in terms of speed of recovery and low incidence of postoperative respiratory complications [112–114], a head-tohead study of spinal with sevoflurane anesthesia for hernia repair in ex-premature infants [97] favored spinal anesthesia in terms of reduced early respiratory adverse events but there were a number of failures to secure a spinal block which gave cause for concern.

So general anesthesia with modern volatile agents, supplemented by local anesthetic infiltration, peripheral nerve block or a caudal is a more reliable and flexible technique and may be essential in certain cases, in particular incarcerated, complex or very large bilateral hernias. With an increasing trend towards laparoscopic repair, it may well be that general anesthesia for such cases will be needed more often in the future.

## Abdominal wall defects

Abdominal wall defects are congenital abnormalities that are usually detected antenatally by fetal ultrasonography. Gastroschisis and omphalocele are the most common defects resulting in herniation of viscera through a defect in the upper or lower abdominal wall [115,116]. Although the anesthetic management of these conditions is essentially the same, these two conditions have significant embryological and clinical differences [117].

#### Gastroschisis

Gastroschisis is a congenital defect of the abdominal wall resulting in herniation of the abdominal contents, most commonly the small and large intestine (Fig. 21.2). The incidence of gastroschisis is approximately 1 in 3000–8000 livebirths. It is more common in mothers aged <20 years, the babies tend to be born prematurely with a low birthweight and in recent years the incidence has been rising, for reasons unknown [118–120]. Specialist antenatal and postnatal care results in a survival rate of over 90%.

The defect is usually on the right side of a normally developed and positioned umbilical cord and the viscera are not enclosed in a peritoneal sac. The vertical opening is approximately 2–5 cm in length, making herniation of other organs, such as the liver, unusual. The herniated intestine often appears dilated, foreshortened, and edematous and is covered in a thick inflammatory fibrin peel, probably due to exposure to amniotic fluid *in utero*. The intestine is often functionally abnormal and this may be complicated by the presence of intestinal atresia, stenosis

Figure 21.2 (A) Gastroschisis. (B) Silo for gastroschisis

or malrotation [121]. Associated congenital anomalies are uncommon in gastroschisis, but initial routine investigations should aim to exclude potential cardiac abnormalities. The etiology of gastroschisis is not certain but is thought to involve vascular disruption of either the right umbilical vein or right omphalomesenteric artery. The result is paraumbilical ischemia and atrophy of the layers that form the anterior abdominal wall at the base of the umbilicus [122].

Following delivery, the initial priorities for gastroschisis must focus on ensuring that the newborn has a safe and patent airway, ventilation and oxygenation are not compromised by the defect, the exposed bowel is protected, and that fluid and heat loss are minimized and adequately managed. Reduction of the abdominal contents should take place urgently within hours of delivery to minimize the risk of volvulus, ischemia and infection. A nasogastric tube should be inserted to decompress the bowel, minimizing any splinting of the diaphragm and reducing the risk of regurgitation and aspiration. If signs of respiratory distress are evident or the newborn requires large volumes of fluid resuscitation then endotracheal intubation and ventilation are necessary.

The exposed bowel should be covered and supported using a sterile plastic wrap or a clear polythene bag to cover the lower limbs and abdomen to minimize fluid and heat loss.

The newborn should be dried and then placed under a radiant heater or in a heated incubator. Patients with gastroschisis should be nursed on their right side in a lateral decubitus position to enhance venous return from the gut and avoid vascular compromise. In patients with a large omphalocele, the position of the viscera and liver may compress the inferior vena cava in the supine position and so preferentially these infants should be nursed on their left side. Intravenous access is required early to allow fluid resuscitation, administration of broadspectrum antibiotics, blood sampling and cross-match if going to surgery. Umbilical vessel catheterization is contraindicated. Third space losses in gastroschisis or ruptured omphalocele can be substantial and require fluid resuscitation with isotonic solutions: 0.9% normal saline, Hartmann solution, 5% albumin, blood or blood products. Boluses of 20mL/kg should be given and the adequacy of resuscitation regularly monitored. Regular assessment of capillary refill, core-peripheral temperature gradients, heart rate, urine output and evidence of correction of acid-base disturbance will help guide the resuscitation efforts. Insertion of a peripheral arterial line is invaluable for repeated sampling to detect acid-base or electrolyte changes during the resuscitation and perioperative period.

Surgical management of the newborn depends on the size of the defect. Small defects can be closed by primary closure in the OR under general anesthesia or in the NICU without an anesthetic. If the defect is large then concerns arise from the effects of returning the abdominal viscera into a relatively small abdominal cavity, resulting in raised intra-abdominal pressure and abdominal compartment syndrome (ACS). Raised intra-abdominal pressure reduces venous return from compression of the inferior vena cava, decreasing cardiac output. Perfusion of the renal and splanchnic circulation is impaired, potentially leading to renal failure and bowel ischemia, causing intestinal perforation, necrotizing enterocolitis and a metabolic acidosis. Raised intra-abdominal pressure increases tension on the wound, causing dehiscence, and also results in splinting of the diaphragm, causing respiratory failure. The safety of primary closure can be assessed intraoperatively by measurement of intragastric, bladder,

and central venous pressures or changes in ventilatory pressures as an indirect way of measuring intra-abdominal pressure. Intragastric or intravesical pressures less than 20mmHg were found to result in successful primary closure and no ACS in neonates with gastroschisis [123,124]. Peak plateau respiratory pressures should be kept below 25 cmH<sub>2</sub>O [125]. Gastric tonometry and pulse oximetry have also been used to help predict the onset of ACS [126,127]. If the surgeon is unable to perform a primary closure then a staged reduction is undertaken. The neonate is initially taken to the OR and fitted with a protective silastic silo. This is suspended above the incubator, allowing gravity to ease the viscera back into the abdominal cavity over the next 5-7 days. Each day the silo is gradually reduced in size, minimizing the risk of ACS. Once reduced, the neonate is returned to theater for surgical closure of the abdominal wall defect.

Important anesthetic considerations include the following.

- Ensure the baby is adequately resuscitated and preoperative tests are performed before coming to the OR.
- Actively warm the neonate during transfer to the OR in their incubator and on arrival in the OR with overhead radiant heaters, warm air blankets on the OR table, intravenous fluid warmers and humidified and warmed anesthetic gases. Monitor core and peripheral temperatures perioperatively.
- Aspirate the nasogastric tube preinduction in left and right lateral, prone and supine positions.
- Induction may be a rapid-sequence induction (RSI) or modified RSI. Sevoflurane gas induction may be performed and atracurium or vecuronium used for muscle relaxation prior to intubation.
- Nitrous oxide should be avoided to prevent further intestinal distension.
- Analgesia with morphine or fentanyl and, for smaller defects where early extubation is anticipated, a regional block technique may be used.
- Maintenance fluids (containing 10% dextrose) supplemented with boluses of albumin 5% or other isotonic solutions should be titrated according to the cardiovascular status of the neonate.
- In addition to routine monitoring, intragastric or intravesical pressures and urine output should be measured to assist in deciding whether a primary closure is possible.
- An intra-arterial cannula is useful for regular blood sampling and acid-base monitoring. Central venous cannulation, either conventional via internal jugular or subclavian routes or PICC lines, is necessary for large defects where repeat procedures or prolonged total parenteral nutrition (TPN) are required.

• The majority of neonates are returned to the NICU intubated, ventilated, paralyzed and sedated for further monitoring and ongoing management. They are ventilated until the bowel has settled back into the abdomen. TPN feeds, antibiotics and muscle relaxants are given.

In some centers, reduction may take place in the NICU without general anesthesia. NICU reduction is carried out in newborns who are stable and uncomplicated, i.e. absence of perforations, volvulus, atresias and obstruction [128,129]. The introduction of a spring-loaded silo that can be fitted at the bedside without any sutures or anesthesia has permitted staged closure in the NICU. When the reduction is complete the umbilicus is often used to plug the defect.

Outcome in gastroschisis is generally good unless complicated by intestinal atresia, stenosis, perforation, NEC, volvulus, sepsis, rare associated cardiac abnormalities or problems relating to prematurity (respiratory distress syndrome, intraventricular hemorrhages) [121].

#### **Omphalocele**

Omphalocele has an incidence of 1 in 5000 livebirths. It is an abdominal wall defect where the abdominal viscera herniate into the base of the umbilical cord through the umbilical ring. It is thought to result from failure of the midgut to return to the abdominal cavity around week 10 of gestation, causing incomplete closure of the anterior abdominal wall around the umbilicus. Unlike gastroschisis, the viscera are covered by a membrane and the bowel looks normal. Occasionally the peritoneal sac may rupture and can resemble gastroschisis although examination of the intestine helps differentiate these two conditions. The herniation may be a small defect 2-5cm in diameter (exomphalos minor) or may be large (greater than 10 cm) involving liver and spleen, with poorly developed abdominal and thoracic cavities and pulmonary hypoplasia (exomphalos major) (Fig. 21.3).

Figure 21.3 Omphalocele (exomphalos major).

Associated congenital abnormalities are much more common than in gastroschisis, with at least 60% of infants born with omphalocele having at least one associated anomaly. These may be cardiac in origin (30-40%), chromosomal abnormalities (trisomy 13, 18 or 21), cloacal or bladder extrophy, or Beckwith-Wiedemann syndrome (macroglossia, organomegaly, hypoglycemia, giantism, and congenital heart disease) [130]. Rarely, omphalocele may be part of the thoraco-abdominal pentalogy of Cantrell with a cleft sternum, anterior diaphragmatic hernia, heart defects and an absent pericardium [131]. Given that associated anomalies are more common in this condition, a thorough preoperative examination with appropriate investigations (chest x-ray, cardiac echo, renal ultrasound and routine blood investigations) should be performed before surgical correction.

Anesthetic management of omphalocele is very similar to that for gastroschisis. Unless the membrane is ruptured, omphalocele repair is less urgent. Defects without rupture of the membranous sac may be allowed to epithelialize on the ward using topical agents (silver sulfadiazine or antibiotic preparations) and a silo, avoiding any surgical intervention in the initial stages. This may take several weeks to months after which the infant will return to surgery for repair of the ventral hernia defect [132]. Care must be taken for cases that come to the OR for reduction or silo fitting if the liver is herniated. Damage to the liver parenchyma or compression of the hepatic veins can result in dramatic periods of cardiovascular instability.

Outcome in omphalocele is mainly dependent on the severity of additional abnormalities and chromosomal defects. Infection, surgical complications, low birthweight, hernia rupture and intestinal obstruction also contribute to mortality rates.

## Esophageal atresia and tracheoesophageal fistula

Esophageal atresia encompasses a group of congenital anomalies in which there is interruption of the continuity of the esophagus. In 86% of cases this co-exists with a distal tracheo-esophageal fistula, while in 7% there is no fistulous connection. In 4% of cases there is a tracheoesophageal fistula but without esophageal atresia. Esophageal atresia occurs in around 1 in 2500–3000 livebirths. In less than half of these, the condition exists in isolation while more than 50% occur in the presence of other congenital anomalies, the most common being one or more of those associated with the VACTERL group of anomalies (vertebral, anorectal, cardiac, tracheoesophageal, renal and limb defects). The presence of a major cardiac anomaly reduces an almost complete survival rate to around 80%. Low birthweight is also associated with a survival rate of around 80% while the presence of both of these risk factors together reduces survival to 30–50% [133]. Respiratory insufficiency, however, is the single most significant risk factor affecting outcome [134]. Together, these factors provide a significant challenge to the anesthesiologist.

#### **Clinical features**

Two classification systems are in use today, the first being that proposed by Vogt in 1929, later modified by Gross in 1953. These can be summarized as shown in Table 21.2.

The most commonly occurring defect is Gross type C (Vogt 3B) which accounts for 86% of esophageal atresias (Fig. 21.4). These classification systems are, however, not comprehensive and variations other than those described can occur.

#### Diagnosis

Suspicion may be raised by antenatal ultrasound scan at around 18 weeks' gestation. This may show an absent or small gastric bubble. The incidence of esophageal atresia is also increased in the presence of polyhydramnios. The diagnosis may be confirmed at birth in these babies by failure to pass a nasogastric tube beyond 9–10 cm from the mouth. This is usually confirmed by a plain abdominal and chest radiograph. This may reveal other associ-

 Table 21.2
 Classification of esophageal atresia and tracheo-esophageal fistula

Gross	Vogt	Description
-	Type I	Esophageal agenesis (not included by Gross). No fistula present
Туре А	Type 2	Proximal and distal esophageal stumps with a missing mid segment. No fistula present
Туре В	Туре ЗА	Proximal esophagus meets lower trachea with distal esophageal stump
Туре С	Type 3B	Proximal esophageal atresia. Esophagus ends in blind loop superior to sternal angle with the distal esophagus arising from the lower trachea or carina
Type D	Type 3C	Proximal esophagus terminates on lower trachea or carina with distal esophagus arising from carina
Type E (or Type H)		Type D variant where the esophagus is continuous but the presence of a fistula creates the appearance of the letter H
Type F		Esophageal stenosis

**Figure 21.4** Esophageal atresia and tracheo-esophageal fistula variants. (A) The most common arrangement with a blind upper esophageal pouch and a distal TEF (Gross type C, Vogt type 3B). (B) Proximal and distal esophageal stumps with a missing segment and no TEF (Gross type A, Vogt type 2). (C) H-type fistula (Gross type E). (D) Proximal esophagus meets distal trachea with distal esophageal stump (Gross type B, Vogt type 3A). (E) Proximal esophagus terminates on lower trachea with distal esophagus arising from carina (Gross type D, Vogt type 3C).

ated anomalies such as vertebral or rib abnormalities or the "double bubble" associated with duodenal atresia. However, if not suspected prenatally, esophageal atresia may not manifest itself until feeding begins, whereupon the baby may cough, choke and become cyanosed. Failure to recognize the condition swiftly can result in the development of aspiration pneumonitis and dehydration can result due to accumulation of saliva and disturbed swallowing. Initial preoperative surgical management involves the passage of a suction catheter, often a radiopaque double-lumen tube (Replogle tube) into the blindending pouch for continuous irrigation and suction.

#### **Preoperative evaluation**

The baby with esophageal atresia/tracheo-esophageal fistula presents many challenges for the anesthesiologist. First, due to the large variation in the anatomy of these lesions, correct placement of the endotracheal tube may be difficult. Furthermore, prematurity of 34 weeks' gestation or less is present in 12% of babies with esophageal atresia [135] and may result in moderate-to-severe neonatal respiratory distress syndrome. Associated anomalies may also significantly affect both the difficulty of the anesthetic and the outcome for the patient. Cardiovascular anomalies account for 29% [136] and have been shown to be the single most common mortality-related association in esophageal atresia [137]. Of the other associated anomalies, anorectal defects comprise 14%, genitourinary 14%, gastrointestinal 13%, vertebral/skeletal 10%, respiratory 6%, genetic 4%, and others 11% [136].

Preoperative evaluation of infants with esophageal atresia should include a detailed history of the neonatal course, including delivery. A history of polyhydramnios may also indicate possible renal anomalies and is more common where there are associated chromosomal abnormalities such as Down syndrome or Edwards syndrome. Major neurological anomalies may impair fetal swallowing, also resulting in polyhydramnios. If there is no antenatal suspicion and the infant presents later then a feeding history should be obtained, with special attention being paid to episodes of cyanosis or choking, which may indicate aspiration and the possible development of aspiration pnuemonitis.

Preoperative preparation by this time will have established a blind-ending esophagus, with continual suction and irrigation of the pouch being provided, preferably by a Replogle tube. A full anesthetic history should also be obtained from the parents regarding any significant family reactions to anesthesia. A plain radiograph of the chest and abdomen will confirm the tip of the suction catheter proceeding no further than the upper mediastinum while gas in the stomach is significant in that it confirms the presence of a tracheo-esophageal fistula. Absence of gas suggests an isolated atresia. A clinical examination of the neonate should have established any dysmorphic features and indicated the presence of any major cardiac anomaly; however, cardiac echo is required routinely as a preoperative investigation in these cases. This will define any structural abnormality of the heart but may also reveal a right-sided aortic arch which occurs in 2.5%. This has implications for patient positioning and surgical approach [138] and may also significantly affect ventilation.

A congenital cardiac lesion producing high pulmonary blood flows is unlikely to pose significant physiological problems during the first few days after birth as pulmonary vascular resistance remains high initially. These patients can usually proceed safely for surgical correction. However, patients who have lesions with significant right- or left-sided obstructive components may have either a systemic or pulmonary circulation which is ductus arteriosus dependent. Babies with duct-dependent circulation have been shown to have a significantly increased risk of mortality [139]. In these cases the duct can be kept open with an infusion of prostaglandin E1 and if the baby remains stable and in good condition, surgery may proceed. A small number of patients will present in poor condition with a closed or closing duct. In these cases resuscitation is often required and surgery needs to be delayed. Rarely, such babies will require a palliative shunting procedure or cardiac repair prior to surgery for esophageal atresia [140]. A renal tract ultrasound scan is required due to the associated incidence of genitourinary anomalies. Blood biochemistry and

hematology should be ascertained and blood should be cross-matched for surgery. Assessment of the respiratory system is paramount. The presence of respiratory distress is a significant prognostic indicator [134] and has an important bearing on the conduct of anesthesia, in particular with regard to the principle of maintaining low airway pressures. Preoperative oxygen saturation should be measured and increased oxygen requirement noted.

#### **Conduct of general anesthesia**

Preparation of the operating environment is as for any other small baby but particular attention needs to be paid to the ambient temperature. This may need to be increased in the case of the premature infant. A heated warming mattress, heated and humidified breathing circuit and warmed intravenous and irrigation fluids will help to prevent heat loss. Intravenous access would ordinarily have been established prior to surgery as these babies are unable to feed. This can be used for maintenance fluids with 5-10% glucose where required. A second IV line is required for replacement therapy, and this should be of sufficient caliber to allow for rapid replacement of blood loss if required. In addition to the application of standard monitoring, invasive arterial pressure monitoring is invaluable as it allows for real-time measurement. This is especially so in the case of aberrant cardiac or great vessel anatomy where surgical access may cause hemodynamic compromise. It also allows for easy blood sampling intraoperatively. This can be particularly useful where significant respiratory compromise exists and allows for rapid and accurate assessment of gas exchange and acid-base status. Central venous access is not usually required but may be necessary in the event of failure to establish adequate peripheral intravenous access.

The major consideration of both anesthetic and surgical management of the neonate with esophageal atresia and tracheo-esophageal fistula is ventilation of the lungs without ventilation of the fistula. Endotracheal tube misplacement can lead to undesirable consequences such as massive gastric distension and resulting respiratory and cardiovascular compromise. Even with a correctly placed endotracheal tube, poorly compliant lungs and a large distal fistula can result in selective passage of anesthetic gases into the gastrointestinal tract, leading to hypoventilation and hypercarbia [141]. The interplay between the variable anatomy of the defect, pre-existing co-morbidity and anesthetic technique may be unpredictable. As a result, techniques have focused on the avoidance of muscle relaxants and positive pressure ventilation until ligation of the fistula is achieved [142]. Traditionally, intubation may have been performed awake but in the preterm neonate, this is associated with an increased risk of intraventricular hemorrhage [143].

One recognized technique is induction of general anesthesia by inhalation with the patient in a semi-supine position. Once adequate depth of anesthesia is achieved and with the patient spontaneously ventilating, laryngoscopy should be performed and the vocal cords sprayed with no more than 3mg/kg of lidocaine. An appropriately sized endotracheal tube is then passed through the cords and beyond the carina, aiming for endobronchial intubation. This is then confirmed by auscultation and the tube is then withdrawn until ventilation is just heard on both sides. At this point, it is possible to confirm the position of the endotracheal tube by passage of a flexible bronchoscope through it. If all is well then a muscle relaxant may be administered and the patient positioned for surgical repair. This technique is limited, however, by the assumption that the fistula is proximal enough to allow passage of the endotracheal tube beyond it. It also may not be an adequate technique where there is a large fistula. In one series, 11% of fistulae were at or below the carina, with a further 22% being within 1cm of it [144]. Even with such a lesion, it may be possible to achieve adequate ventilation initially, with problems only being encountered on repositioning of the patient or during surgical manipulation, particularly compression of the right lung. Additionally the patient's condition may preclude spontaneous ventilation, requiring that muscle relaxation be instituted followed by gentle positive pressure ventilation. It is, however, in the preterm neonate with respiratory distress that this is most problematic. Poorly compliant lungs and a large distal fistula can mean an easy egress of ventilatory gases into the stomach with resultant compromise in ventilation [141]. With progressively increasing gastric distension, the stomach may rupture, resulting in a tension pneumoperitoneum which further impairs ventilation [145]. The traditional approach in this instance would be to perform an emergency gastrostomy. However, this often worsens the situation as the sudden reduction in intragastric pressure further facilitates escape of ventilatory gas through the fistula. Resuscitation in this instance is often ineffective until leakage of gas through the esophagus is controlled [146].

Placement of a 2Fr or 3Fr Fogarty embolectomy catheter (Baxter Healthcare Corporation, Irvine, CA, USA) through a rigid bronchoscope to occlude the fistula in a neonate with severe respiratory compromise was first described in 1982 [147]. Since then routine rigid bronchoscopy has become standard practice for some as part of the airway management in tracheo-esophageal fistula, with 18% of patients in a retrospective review requiring the insertion of a Fogarty catheter [142]. In this same series, ventilation difficulty was only encountered with a fisutula >3mm in diameter at or near the carina. Smaller fistulas or those more than 5mm above the carina were not associated with ventilation problems. Routine preoperative rigid bronchoscopy has also been found to be useful in the diagnosis of abnormal variants and unsuspected findings [134,148]. However, rigid bronchoscopy in the newborn can be technically difficult, often resulting in arterial desaturation, and in those preterm neonates weighing less than 1500g who have severe respiratory compromise, it may be impossible altogether.

More recently, tracheoscopy-assisted repair of tracheoesophageal fistula has been reported [149]. The technique described involves passage of a narrow-diameter fiberoptic bronchoscope through the endotracheal tube in a neonate who is intubated with established muscle paralysis and low-pressure intermittent positive pressure ventilation (IPPV). The aim is for gentle ventilation with the tip of the endotracheal tube sitting above the fistula so that identification and repair of the fistula take place under direct visual control. In 47 cases over a 10-year period, no adverse events related to the tube being positioned above the fistula occurred. The authors suggest that mandatory positive pressure ventilation with their technique avoids hypercapnia, hypoxia and respiratory acidosis that can result in a potentially disastrous return to fetal circulation. With this technique, unlike rigid bronchoscopy, visualization of the airway can take place at any point during the surgical repair.

In the past, the infant with TEF/EA often underwent an initial surgical gastrostomy, sometimes under local anesthesia, with the thought that this would decompress the stomach and minimize ventilatory problems. The thoracotomy was then performed several days later. However, as noted above, a gastrostomy may allow egress of ventilatory volume through the fistula and out of the gastrostomy. In modern practice the gastrostomy is rarely performed primarily, and usually not at all except in cases of long-gap EA where prolonged healing is required.

In recent years thoracoscopic repair of esophageal atresia with or without TEF has been accomplished. McKinlay described a series of 26 neonates, 20 with TEF/ EA and six with isolated EA [150]. Anesthetic technique is described as standard tracheal intubation without bronchial blocker or other special technique. Three thoracoscopic ports are inserted in the right hemithorax with insufflation of CO<sub>2</sub> to a pressure of 6mmHg, which is often accompanied by hypercarbia and arterial desaturation, requiring adjustment of ventilation as the lung collapses to afford the surgeon a view of the field. The TEF is suture ligated and the esophageal pouches dissected, mobilized, and anastomosed with 5-0 vicryl sutures (Fig. 21.5). The anesthetic techniques were not described in detail, but no severe ventilation problems were apparently encountered. Patient weights were 1.4-3.9kg and gestational ages 31-41 weeks. There were two early

**Figure 21.5** (A) Neonate in semi-prone position, with tip of scapula and three port sites for thoracoscopic instruments marked. (B) Port sites and instrument position for surgeon and assistant. (C) Esophageal anastomosis completed with azygous vein intact; note collapsed right lung at lower right quadrant of picture. Reproduced from McKinlay et al [150] with permission from Elsevier.

deaths (one patient with trisomy 18 and another with associated congenital diaphragmatic hernia), and one late death from congenital heart disease. There were seven minor esophageal anastomotic leaks managed conservatively, one recurrent TEF managed thoracoscopically, and nine anastomotic strictures. Further details on the anesthetic management of thoracoscopic surgery are discussed in Chapter 24.

Because of the many different approaches to TEF/EA repair, and even variation within institutions, a thorough preoperative discussion with the surgeon, focusing on airway and ventilation management strategies and contingency plan in case of severe ventilatory compromise, must be held when approaching these patients.

#### Postoperative anesthetic care

Postoperative ventilation is mandatory in neonates weighing less than 2000 g [59] and in those with respiratory distress or significant cardiac pathology. Repair of the esophageal anastomosis under tension is also an indication for postoperative ventilation, usually for a period of 5 days [133,151]. Furthermore, it has been proposed that safe awake extubation may affect every anastomosis to some degree, whether or not it is a "long-gap" anastomosis under tension, and that emergent reintubation may have catastrophic consequences for an anastomosis [152]. This latter problem leads some institutions to routinely leave the trachea intubated in all these patients, until it is clear that the threat of respiratory insufficiency has passed. Tension at the anastomotic site is recognized to be the most important factor contributing to anastomotic complications, but it is very difficult to assess and measure and should therefore be assumed [153]. Analgesia both intra- and postoperatively can be provided by a longacting opioid such as morphine. This can be given by intravenous bolus at surgery and continued by infusion in the intensive care unit.

Although postoperative ventilation should be the norm where staffing and facilities exist to provide it, there may be occasion when extubation is planned at the end of surgery. Avoidance of opioids or minimizing their use is desirable although it may be necessary to use a short-acting opioid such as alfentanil or remifentanil. Regional anesthesia may be provided by a caudal catheter technique with insertion to T6–7 level, or supplementary local anesthetic can be injected by the surgeon. If morphine is required postoperatively then it must be used with extreme vigilance.

## **Congenital diaphragmatic hernia**

Congenital diaphragmatic hernia (CDH) occurs with an incidence of approximately 1 in 3000 births and was first

described by Bochdalek in 1848. The most common leftsided form bears his name and accounts for approximately 80% of CDH cases. The embryological development of CDH is incompletely understood but it is thought that the defect may result from failure of closure of the pleuroperitoneal canals. Animal studies using rats exposed to the teratogenic herbicide Nitrofen showed that the defect is formed very early in the embryonic period with early ingrowth of the liver through the defect [154]. At a cellular level, there may be abnormalities of epithelial and mesenchymal growth and differentiation which may also have implications for lung development [155]. Further rat studies have suggested that lung hypoplasia as a result of fibroblast growth factor deficiency may precede the development CDH and lend support to the theory of a global mesenchymal embryopathy [156].

Infants presenting with the condition are often born at full term and weigh in excess of 3kg [157]. Around half of infants with CDH will have other congenital anomalies, with the heart being commonly affected; 4–16% will have chromosomal abnormalities. Survival is often severely affected by the presence of associated anomalies. In the infant with CDH, abdominal viscera, most commonly bowel, herniate through the defect into the thoracic cavity, effectively acting as a space-occupying mass. This is accompanied by abnormal pulmonary development, particularly on the affected side, but mediastinal shift can prevent normal growth and development of the contralateral lung. Despite the apparent simplicity of the anatomical defect, the pathophysiology of the condition is complex. The lungs show a decreased number of bronchopulmonary segments, decreased alveolar surface area and abnormal pulmonary vasculature [158]. There is also a thickening of arteriolar smooth muscle that extends to affect the alveolar capillaries. This impairs pulmonary function further by increasing pulmonary artery pressure that can lead to right-to-left shunting.

#### Diagnosis

The majority of infants with CDH are discovered at prenatal maternal ultrasound scan. This provides an opportunity to arrange for both delivery of the infant in an appropriate center for management and prenatal counseling for the parents and family. It may also allow fetuses with poor outcome to be identified. Ultrasound is, however, dependent on equipment, expertise and experience and may fail to detect the condition prenatally in up to 50% of cases [159].

Two parameters have been shown to be of some prognostic value. First, if there is herniation of the liver into the thoracic cavity, the likelihood of survival is halved [160]. Second, at 24–26 weeks' gestation it is possible to measure the cross-sectional area of the contralateral lung and to compare it with the head circumference. A lungto-head ratio (LHR) of >1.4 is associated with no mortality compared to a LHR of <0.8 which carries a 100% mortality rate [161]. With the advent of three-dimensional ultrasound, some centers are now able to assess LHR usefully from 24–34 weeks' gestation. Furthermore, fetal magnetic resonance imaging (MRI) has also been found to be a useful modality in the prenatal assessment of CDH [162].

Following prenatal diagnosis, a birth at or as close to term as possible is preferred as preterm delivery is associated with a worse outcome [163]. The infant born with CDH usually presents with a scaphoid abdomen and an unusually prominent ipsilateral chest with an increased anteroposterior diameter. Breath sounds are diminished on the side of the lesion and heart sounds may be deviated towards the contralateral side. Diagnosis may be confirmed with a plain chest radiograph which demonstrates air-filled intestinal loops in the affected side of the thorax and a paucity of intestine in the abdominal cavity. There may also be mediastinal shift with a resultant deviation of heart sounds (Fig. 21.6).

#### **Postnatal management**

At or shortly after birth, the majority of infants will develop signs of respiratory distress. If the defect is large then severe hypoxia and respiratory acidosis will be present and the infant will require immediate resuscitation, including endotracheal intubation and mechanical ventilatory assistance. A naso- or orogastric tube is passed to decompress the gut. Pulmonary hypertension may

**Figure 21.6** Chest radiograph of left congenital diaphragmatic hernia. Note liver and intestines in left hemithorax with heart displaced to right.

worsen the situation and can result in a persistent fetal circulation with shunting of blood from right to left through the ductus arteriosus and foramen ovale. This further exacerbates hypoxia and hypercarbia and a decrease in systemic oxygenation results in a metabolic acidosis. However, a small minority of infants are born asymptomatic and remain so for the first day of life. In these cases the defect is small and physiologically much less significant. This group usually has an uneventful course following surgical repair.

In the past CDH was considered a surgical emergency and infants were rushed to the operating room but the last decade has seen a change to preoperative stabilization of the infant prior to surgery [164,165]. In particular, stabilization strategies have been aimed at preserving extrapartum circulation and minimizing acidosis with avoidance of further damage to the lungs. Current practice involves transfer of the infant to an intensive care unit and institution of gentle ventilation aimed at minimizing barotrauma [166,167]. Strategies include permissive hypercapnia to a pCO<sub>2</sub> of no greater than 7.8 kPa (60 mmHg) [168]. However, with the frequent association of pulmonary hypertension, this level of hypercarbia is sometimes not tolerated. An oxygen saturation of no less than 80% on 60% inspired oxygen is considered an indication for alternative forms of ventilation or respiratory support [169].

Typically, the stabilization period may range from 24h to a number of days, depending on the condition of the child. Current practice may allow for stabilization of the sick infant, thus allowing a potentially less fraught perioperative course. However, in a recent large multi-study review, no difference in outcome was demonstrated when delayed repair after stabilization was compared to both repair within 24h and repair immediately after birth [170]. The availability of extracorporeal membrane oxygenation (ECMO) has become widespread in line with the advent of delayed surgery in these infants. It has been shown that the overall survival rate for infants requiring ECMO is 52.9% versus 77.3% (p < 0.001) for non-ECMO infants. However, in those who were deemed to have a mortality risk of 80% or more, it is associated with improved outcome. Furthermore, in infants with additional risk factors it may worsen outcome [171]. Highfrequency oscillatory ventilation (HFOV) and inhaled nitric oxide (iNO) are also frequently used when failure of conventional ventilatory support occurs. HFOV and iNO are both aimed at improving oxygenation. HFOV achieves improved ventilation with a reduction in barotrauma [172] while iNO is used as a selective pulmonary vasodilator aimed at reducing pulmonary vascular resistance. Neither modality has been shown to have any conclusive effect on outcome in infants with CDH [169]. Surfactant and prenatal steroids have found vogue in

recent years. Although steroids are a recognized and valuable treatment for immature lungs, they are of unproven benefit in CDH. Similarly, surfactant has been found to be of little value [169].

## Anesthetic care for congential diaphragmatic hernia repair

Immediately after birth, the infant with CDH may be in acute respiratory distress and will need to be intubated as an emergency. Where possible, bag and mask ventilation should be avoided to prevent gaseous distension of the stomach. A naso- or orogastric tube should then be placed to provide intestinal decompression. The infant will then need to be transferred to a NICU for assessment and stabilization.

When it is deemed appropriate to undertake repair, there are several anesthetic concerns. First, pulmonary hypoplasia and the resulting pulmonary hypertension can make the maintenance of adequate oxygenation challenging. Hypoxia, hypercarbia and acidosis all act to increase the pulmonary vascular resistance further [173,174]. Instrumentation of the airway may also result in a dangerous increase in pulmonary vascular resistance [175] and so an opioid such as fentanyl should be given at the beginning of the procedure and can be repeated as necessary. A dose of  $25\mu g/kg$  has been shown to abolish the stress response to airway instrumentation [176]. The operating room should be prepared as for any neonate requiring major surgery. Standard monitoring is applied. Good venous access is mandatory and central venous access is highly desirable for both the measurement of central venous pressure and the administration of inotropes such as dopamine. Invasive arterial blood pressure monitoring is also required as it provides real-time measurement of intra-arterial pressure. This is particularly useful as surgical access (Fig. 21.7) may result in acute compression of the great vessels, leading to sudden acute

**Figure 21.7** Operative appearance of congenital diaphragmatic hernia via left thoracoabdominal incision. Liver is being reduced through large diaphragmatic defect.

hypotension. The surgical approach usually involves a left thoracoabdominal incision, reduction of the intrathoracic intestinal viscera and liver, and repair of the diaphragm, often with a patch made of synthetic material. Furthermore, the changes in pressure that may be seen during the cycling of ventilation can indicate hypovolemia. A urinary catheter is useful to monitor urine output.

The goals of anesthetic management are to provide adequate analgesia and depth of anesthesia with minimal impact on pulmonary vascular resistance and myocardial function. Therefore great care must be exercised with the maintenance of anesthesia. Volatile anesthetic agents are known to attenuate hypoxic pulmonary vasoconstriction [176]. However, they may cause systemic hypotension if not used carefully. For this reason a fentanyl-based anesthetic may be preferable. Nitrous oxide has been shown to have little effect on pulmonary vasculature in infants [177]. However, it should be avoided because of its effect on alveolar PaO<sub>2</sub> and its propensity to worsen bowel distension. Muscle relaxation may be provided by competineuromuscular blockade. Vecuronium tive and rocuronium are appropriate. Pancuronium is best avoided because of its intrinsic sympathomimetic activity. Mechanical ventilatory parameters should be set to allow for adequate oxygenation. A degree of hypercarbia is acceptable as high inflation pressures should be avoided, again being mindful of pulmonary hypertension. If the infant has been stabilized prior to surgery then preoperative PaO<sub>2</sub> and PaCO<sub>2</sub> levels serve as a guide to aim for. Throughout the procedure, the anesthesiologist must be prepared to treat a sudden pulmonary hypertensive crisis. In this event, moderate hyperventilation, often manual, may be required with 100% oxygen. The cardiac output may require support and adequate preload should be ensured. Selective pulmonary vasodilators such as inhaled nitric oxide should be available in addition to appropriate inotropic support which may include drugs such as phenylephrine, epinephrine, dopamine, and milrinone. On occasion, it is necessary to repair CDH with the patient supported by either HFOV or ECMO. This makes patient transfer hazardous and in this situation repair is undertaken in the NICU.

#### Meningomyelocele

Meningomyelocele is a form of neural tube defect occurring in 0.5–1 per 1000 livebirths and is usually diagnosed antenatally. The spinal cord and meninges are exposed to the intrauterine environment and this results in a central sac filled with cerebrospinal fluid, damaged spinal cord, and nerve roots. Invariably this defect is associated with the Arnold–Chiari malformation and hydrocephalus. The cerebellar vermis, fourth ventricle and lower brainstem are herniated downwards below the level of the foramen magnum. Primary closure is usual within the first 2 days to minimize infection. Treatment of hydrocephalus is individualized but a concurrent ventriculoperitoneal (VP) shunt placement may be needed. Fetal repair has been undertaken with reduced need for VP shunting at age 1 year but no improvement in neurological deficits [178].

Problems for the anesthesiologist are positioning for induction, solved by use of pads or a circular gel ring to protect the fragile sac; prone positioning for surgery; awareness of preventing latex allergy by use of a latexfree environment and equipment; the potential for large intraoperative blood losses due to dissection of skin flaps to gain coverage of the defect; and postoperative respiratory problems associated with Arnold–Chiari malformation. These babies may have reduced or absent response to hypoxia and hypercarbia and may have impaired swallowing and gag reflexes [179–181]. See Chapter 23 for further discussion of anesthetic care for patients with this lesion.

## **Muscle biopsy**

Muscle biopsy in an infant usually requires a general anesthetic supplemented by local anesthetic infiltration at the biopsy site. This presents a dilemma for the pediatric anesthesiologist who is being asked to provide anesthesia in a child without a definitive diagnosis and therefore a degree of uncertainty about the individual's response to anesthetic and other drugs. A muscle biopsy is often required for definitive diagnosis of a wide range of disorders (Box 21.2) and supplements information from family history, symptoms and signs, biochemistry, genetic tests and electromyography.

Clinically the infant will usually present with hypotonia or floppiness which may be associated with swallowing difficulties, gastroesophageal reflux and failure to thrive. If reflux is significant, episodes of aspiration may

have caused significant lung damage. Try to assess the degree and extent of muscle weakness and any evidence of respiratory compromise as these infants often have reduced respiratory reserve and may need postoperative respiratory support even for a short procedure such as muscle biopsy. Avoid sedative premedication and opioids if at all possible. A preoperative ECG and echocardiogram are recommended to check for cardiac involvement, for example in Duchenne muscular dystrophy or mitochondrial myopathy. Avoid prolonged fasting as infants with hypotonia often are prone to hypoglycemia and consider giving IV dextrose from the start of the fluid fast period and continuing intra-and postoperatively. Inhalational anesthesia with sevoflurane with or without tracheal intubation and ventilatory support as appropriate to the individual child are indicated along with local anesthesia of the biopsy site by the surgeon and simple analgesia thereafter with acetaminophen and or non-steroidal antiinflammatory drugs (NSAIDs). If possible, avoid muscle relaxants and certainly succinylcholine, which can cause dangerous hyperkalemia in some of these disorders. If a non-depolarizing neuromuscular blocking agent is needed, then titrate carefully against neuromuscular monitoring and ensure complete reversal at the end of the procedure. The possibility of malignant hyperthermia is a concern and dantrolene should be available but not administered prophylactically as it can itself exacerbate muscle weakness in some of these disorders. Even after a short procedure, postoperative monitoring should be extended and ventilatory support must be available as required. This may be best carried out in an intensive care setting.

## **Resuscitation of the newborn**

During the transition from intrauterine to extrauterine life, the neonate will undergo a significant and complex physiological change from the fetal circulation to the adult circulation, with a period of time in a transitional circulation. At birth, the neonatal systemic blood pressure increases after the cord is clamped. The first breath of air needs to expand fluid-filled alveoli and for this may require negative intrapleural pressures of up to 70 cmH<sub>2</sub>0. Oxygen causes the pulmonary vascular resistance to fall because of a reduction in hypoxic pulmonary vasoconstriction and also causes the ductus arteriosus to constrict, thus making the pulmonary artery the route of least resistance from the right ventricle. Flow through the foramen ovale ceases due to the rise in pressures in the left side of the heart. The left ventricle, which is of a similar size at birth, will gradually increase in its function of compliance and contractility.

The World Health Organization estimates that 19% of neonatal deaths worldwide are caused by birth asphyxia

[182]. That equates to nearly 1 million deaths annually. However, the vast majority of newborn infants do not require any form of resuscitation other than drying and being kept warm by being given to their mother, often skin to skin. Approximately 10% of newborns require some assistance to begin breathing at birth, with 1% needing extensive resuscitation [183]. Other studies have estimated that between 5% and 10% of neonates need resuscitation at birth, from simple stimulation to assisted ventilation [184]. Resuscitation of the newborn is commonly managed by the obstetrician or midwife but if there is an anticipated sick neonate, cesarean section or preterm delivery, then neonatologists and occasionally anaesthesiologists are involved.

The following is based on current practice and evidence as well as guidelines produced by the Neonatal Resuscitation Program (NRP) in association with the American Heart Association (AHA) for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) of pediatric and neonatal patients [183]. Although neonatologists and pediatricians generally manage newborn resuscitation, the techniques that are set out in the neonatal resuscitation algorithm could be extrapolated to form competencies relevant for any neonatal resuscitation, especially for those patients in their first few weeks of life and those who are preterm. Important trials and studies looking at aspects of neonatal resuscitation have caused recent and significant changes in the therapeutic algorithm. There are also related studies that may change care in the future. These include the use of supplemental oxygen as part of initial resuscitation and therapeutic cooling which aims to decrease the neurological damaged caused by asphyxia at birth. These will be discussed briefly.

Anticipating the need for resuscitation as well as the preparation of appropriate equipment, environment and trained staff are crucial to a successful outcome.

The algorithm shown in Figure 21.8 is taken from guidelines produced by the American Academy of Pediatrics and the AHA. It is divided into four broad categories: A – Assessment and initial care and observations, B – Ventilation, C – Chest compressions, D – Drug and fluid administration. These will be discussed with the emphasis on current significant evidence and recent trials.

#### Assessment and initial care

Immediate assessment and initial care include drying and stimulating the baby, clearing and positioning the airway, which includes suctioning and positioning the head in the "sniffing" position. Intrapartum suction of meconium has been shown not to improve outcome, so this is no longer recommended by the NRP. There should also be some way of providing a source of warmth during resuscitation and this is normally done under a radiant heat source. Preterm infants and neonates with a very low birthweight

**Figure 21.8** Neonatal resuscitation algorithm. <sup>a</sup>Endotracheal intubation may be considered at several steps. Please refer to full guidelines [183] for details. Reproduced from AHA/AAP [183] with permission from the American Heart Association.

(<1500 g) are recommended to have the additional warming technique of being placed in a plastic wrapping, as well as being placed under a radiant heat source. This has been shown to decrease heat loss without hindering ongoing resuscitative measures [183,185,186].

The immediate assessment is of respiratory effort, muscle tone, heart rate, and color. This in practice also includes saturation monitoring. The first major sign of tissue hypoxia in newborns is bradycardia (heart rate <100 as per the guidelines). Bradycardic episodes normally respond well to a brief period of positive pressure ventilation. This is done via a bag and mask, T-piece or manually operated, gas-powered, pressure-regulated resuscitator (Neo-puff<sup>TM</sup>, Fisher and Paykel Healthcare, Auckland, New Zealand). The NRP guidelines then recommend giving supplemental oxygen. There are many studies comparing the risks and benefits of using oxygen to resuscitate neonates.

#### Oxygen versus air

Firstly, there is evidence linking ventilation of neonates on high concentrations of oxygen, even for short periods of time, to retinopathy of prematurity (ROP), chronic lung disease, oxygen free radical disease of the neonate, infection, and leukemia. Studies comparing initial resuscitation with air and varying concentrations of oxygen are beginning to show some evidence that using air alone can have outcomes comparable to using oxygen supplementation, therefore preventing the risks associated with oxygen therapy. But there is as yet insufficient evidence to resolve all questions [187].

Although some studies have shown that room air may be superior to 100% oxygen as the initial choice for resuscitation [188], it seems standard practice to give 100% oxygen initially during resuscitation. At present, there is insufficient evidence to recommend starting resuscitation with room air over oxygen or oxygen over room air. However, recent changes to the algorithm do state that it is recommended to decrease the oxygen concentration as saturations rise over 95%. It is also stated that it is reasonable practice to start resuscitation with room air if that is the clinician's preference, if there is supplemental oxygen available should it be needed. The AHA guidelines do recommend supplemental oxygen when giving positive pressure ventilation and free flow oxygen to those spontaneously breathing with central cyanosis. Some studies suggest a compromise, aiming for 30-40% oxygen [189]. The use of oxygen blenders with either T-pieces or Neopuff<sup>TM</sup> apparatus is recommended.

## Temperature control: therapeutic hypothermia

A recent review of literature looking at hypoxic ischemic encephalopathy of newborn infants found that there is now some evidence from trials to show that induced hypothermia helps to improve survival and development at 18 months for, specifically, term babies at risk of brain damage [190]. It should be pointed out that this is not yet a recommended therapeutic intervention as per the NRP guidelines, but is expected to be in the near future. A great deal more research is needed into methods of cooling, whether it is isolated to the head or whole-body therapeutic hypothermia. There is also the difficulty of patient selection. It is unclear which patients would benefit from cooling and also to what temperature and for how long. There are still many important, specific and as yet unanswered questions.

#### Ventilation

Improving bradycardia is the first sign that effective ventilation is being conducted during resuscitation. Improving color and muscle tone, with a return to spontaneous and regular breathing, normally follows this. Effective ventilation is achieved using a T-piece or self-inflating Ambubag®; however, many centers now use the Neo-puff<sup>TM</sup> as it has an oxygen blender as part of its design.  $CO_2$  monitoring is the gold standard method of confirming correct placement of the endotracheal tube.

Studies looking at resuscitation of asphyxiated neonates at birth have shown that term babies often require around 30 cmH<sub>2</sub>O as an initial inflation pressure [191], with preterm and low-birthweight babies needing higher inflation pressures due to their underdeveloped lungs. Largevolume inflations can cause injury [192] but the inclusion of PEEP has been shown to have a protective effect against lung injury as well as improving lung compliance and gas exchange [193,194].

#### **Chest compressions**

Good ventilation strategies are the most effective way of successfully resuscitating a neonate. Chest compressions are only indicated if there is a continuing bradycardia <60bpm in the face of adequate ventilation and oxygenation. Chest compressions should be started after approximately 1 min of resuscitation as per the algorithm. There should be a period of at least 30 sec where adequate assisted ventilation is delivered before starting chest compressions. The two thumb-encircling hands technique is recommended by the AHA for chest compressions as this should generate higher peak systolic and coronary artery perfusion pressures [182]. The two-finger technique should probably be used if access to the umbilicus is needed for umbilical catheter insertion during resuscitation.

#### Drugs

If bradycardia persists despite good ventilatory resuscitation with poor perfusion and no improvement in color, muscle tone or saturations then volume expansion and administration of specific drugs, especially epinephrine, are indicated. Emergency umbilical vein access, where the catheter is inserted only 3–5 cm until blood return is obtained, is the preferred route for administration of emergency drugs and fluids [195]. The concentration of epinephrine used is 1:10,000 (0.1 mg/mL).

There is a lack of data on the effectiveness of endotracheal epinephrine but it can be used as a route of access while IV access is being obtained. The dose used for endotracheal epinephrine is 0.1 mg/kg. This is a 10-fold increase in the recommended dose for IV administration. The recommended IV dose is 0.01-0.03 mg/kg per dose. Higher doses are not used as they can cause a paradoxical decrease in myocardial function due to exaggerated hypertensive responses with a subsequent effect of poorer neurological outcome [196]. Other drugs are used during resuscitation but rarely. Naloxone or other narcotic antagonists are not recommended due to a lack of clinical evidence during initial resuscitation and also as they may precipitate withdrawal seizures in newborns of mothers taking regular opioids. The Resuscitation Council (UK) does recommend the administration of sodium bicarbonate when there is no effective cardiac output, or virtually none, prior to a second dose of adrenaline. There are no well-powered studies to support the beneficial effects of sodium bicarbonate use.

## CASE STUDY

This case study illustrates the principles of anesthetic management of the ex-premature infant as detailed in this and the previous chapter.

This baby boy weighing 2kg presented for surgical repair of a unilateral large but easily reducible inguinal hernia at 44 weeks' PCA, having been born at 28 weeks PCA by cesarean section after his mother went into premature labor with premature rupture of membranes. The mother had been given predelivery steroids to encourage lung maturation and surfactant production in the baby's lungs but the baby showed signs of in utero fetal distress and a decision was made to deliver early. The birthweight was 1kg and the baby required exogenous surfactant therapy, intubation and ventilatory support for 2 weeks using high-frequency oscillation for severe neonatal respiratory distress syndrome complicated by group B streptococcal septicemia. Weaning from ventilatory support was slow and it became evident that the baby had a patent ductus arteriosus. Medical treatment with nasogastric ibuprofen was unsuccessful and the PDA was clipped via a left mini-thoracotomy performed in the NICU. The baby's lung function improved but he continued to require oxygen therapy for several weeks. A right inguinal hernia was noted but was easily reducible.

After discussion with the surgical team and parents and because the baby lived locally, it was agreed to allow him home and readmit at around 44 weeks' PCA when he had grown a bit more and been weaned from oxygen therapy for a number of weeks. He had no residual cerebral damage and echocardiography revealed normal cardiac anatomy with no residual ductal flow. His blood work-up prior to the hernia repair was normal except for a hemoglobin level of 9 g/dL.

Thus, this baby presents as an ex-preterm infant of 44 weeks' PCA with mild bronchopulmonary dysplasia and preoperative anemia. He therefore does have a significant risk of postoperative apnea and arrangements were therefore made to admit him after his inguinal herniotomy to the high-dependency area adjacent to the NICU for monitoring overnight even though he was being considered as suitable for an awake regional block technique. The anesthetic options, benefits and risks and postoperative moni-

toring and analgesia management were discussed with the parents and it was mutually agreed to use a spinal anesthetic supplemented by a single-shot caudal block. The parents were initially concerned that their baby would be upset by being awake in the OR environment but were reassured by discussion about the use of oral sucrose, topical local anesthesia for the spinal injection and IV cannula sites and the use of a quiet warm OR environment.

The possibilities of failure of the technique or the need to supplement with or convert to general anesthesia were covered and the anesthesiologist discussed his personal results for this technique, which were a failure rate of around 5% overall. The parents agreed to this option and to the postoperative plan for overnight admission for monitoring and ongoing pain control with intravenous or oral acetaminophen. The anemia was also discussed as it is an added risk factor for apnea but the parents were not keen on further blood transfusion if this could possibly be avoided. On balance, it was felt that leaving this untreated was an acceptable risk. The anesthesiologist recommended that the baby should be given caffeine intravenously to help further reduce the propensity for apneic spells and this was agreed. The anesthesiologist discussed this plan with the surgeon who was used to operating on these babies under regional blockade and preferred to do open rather than laparoscopic repairs in small infants.

The baby was scheduled as the first case of the morning and the OR was prepared for a neonate with appropriate equipment, drugs and fluids available for a full general anesthetic as well as regional block in case of block failure. The ambient temperature was set to 23°C. A warm air system and warming mattress were set up and the baby was given a breast feed 4h in advance of the scheduled time and a clear fluid drink 2h in advance. Tetracaine gel was applied to the back of each hand and to the lumbar region 30 min in advance of the procedure. The baby was brought into the OR and an IV cannula was sited and maintenance fluids were commenced at a rate of 8 mL/h. Caffeine 10 mg/kg was administered slowly IV. A neonatal pulse oximetry probe was placed on the right hand and ECG leads applied.

The local anesthesia tray was then prepared for a spinal and caudal block and the anesthetic machine and equipment were also made ready for a 2kg baby, including facemask, oropharyngeal airways, tracheal tubes, anesthetic and muscle relaxant drugs, atropine and intravenous acetaminophen 7.5 mg/kg. For the spinal/caudal block, full aseptic technique was used including surgical scrub, gown, gloves and mask, skin prep and sterile drapes, equipment and drugs. The local anesthetic used was isobaric levobupivacaine 5mg/mL concentration at a dose of 1mg/kg (0.2mL/kg). An additional 0.1mL was added to allow for the dead space of the needle and its hub. So, for this 2kg baby that was a volume of 0.4 + 0.1 mL = 0.5 mL drawn into a 1mL syringe. A 25G neonatal lumbar puncture needle was used at the L5-S1 interspace with the baby sitting supported by a trained assistant who paid particular attention to supporting the baby's chin to avoid flexion of the head and neck on the trunk which can cause airway obstruction (this baby was too young to have head control) (Fig. 21.9A,B).

After the spinal injection the baby was immediately placed in the left lateral position and a caudal cannula (22 G) inserted via the sacral hiatus (Fig. 21.9C–F). Levobupivacaine at a concentration of 2.5 mg/mL was slowly injected to a dose of 2 mg/kg (0.8 mL/kg) via the sacral hiatus which was a volume of 1.6 mL for this baby. The caudal cannula was then removed and small dressings

applied to the spinal and caudal puncture sites and the electrocautery grounding plate was applied to the baby's back. The baby was then turned supine and a blood pressure cuff was applied to a lower limb and skin temperature probe applied to a toe. A pacifier with dextrose was given to the baby (50% dextrose via a pinhole made in the nipple), who fell asleep (Fig. 21.9G). The legs were straightened out and stayed straight and gentle skin pinch testing showed a block to just above the umbilical level. The room lights were dimmed, noise levels were kept to a minimum and monitor alarm volumes were minimized.

After surgical prep and draping of the operation field, an open herniotomy was performed in conventional fashion via a 1.5 cm skin incision. The baby did not respond to the incision and showed slight signs of arousal during dissection of the hernia sac but settled after sucking further on the pacifier. Oxygen saturation, respiratory rate, pulse and blood pressure were stable throughout. The operation lasted a total of 20 min from prep to dressing. The spinal/ caudal took a total of 20 min from patient arrival in the OR to start of skin prep for surgery. The baby was taken straight to the high-dependency unit and monitoring was applied. No apneic episodes were observed overnight and the baby resumed breast feeding 1 h postoperatively. Acetaminophen was administered orally twice before discharge the following day after surgical review. The parents were delighted and felt this had been a very good option for their baby.

**Figure 21.9** Case study sequence of awake spinal-caudal anesthesia. (A) Baby supported in sitting position by trained assistant with head held in neutral position avoiding neck flexion, arms contained and spine curved gently forward to open up the intervertebral spaces. (B) View of the back with the vertebral column in straight alignment. (C) Spinal injection using 25 G needle and 1 mL syringe at L5–S1 interspace. (D) Baby immediately placed in left lateral position for caudal injection. (E) Caudal cannulation using 22 G cannula. (F) Caudal injection of local anesthetic. (G) Pacifier with microdrip feed of 50% dextrose delivered via pinhole in the nipple.

## Introduction

Adolescence, defined as the time between puberty and adulthood, roughly 13-19 years of age, is a time of significant change for children, even for those without significant health problems. Chronic diseases beginning in infancy and childhood may further complicate the transition to adulthood. The pediatric anesthesiologist cares for patients in both categories and may face a number of challenges in these patients. This chapter first reviews developmental and behavioral issues in adolescents, and then addresses reproductive issues of adolescents as they relate to anesthesia care. Then, common chronic adolescent and young adult illnesses are discussed, including cystic fibrosis, congenital heart disease, cancer, sickle cell anemia, diabetes, inflammatory bowel disease, and developmental disabilities and autism, emphasizing anesthetic care. Finally, obesity and bariatric surgery in the adolescent will be reviewed.

# Developmental/behavioral issues in the adolescent

Adolescence, a transitional period between childhood and adulthood, is generally characterized by ongoing cognitive development, greater emotional lability, increased risk-taking behavior, and inconsistencies in behavior modulation [1,2]. Non-compliance with medication administration and other medical treatment regimens, including subspecialty follow-up, is a form of risk-taking behavior. From an evolutionary perspective, while this period prepares the person for independent survival, it also is a period of vulnerability. The social environment is changing. More time is often spent with peers than adult family members. Peer influence is greater and may also influence emotional reactivity. Most of the time these changes are positive but of the 13,000 adolescent deaths in the US annually, about 70% result from risk-taking behavior, including automobile accidents, unintentional trauma, homicide, and suicide.

Several neurobiological hypotheses have been advanced to explain these changes; many have cited increased growth and activity in the prefrontal regions of the brain as the reason for progressively greater cognitive control and affective modulation as a person grows into adulthood. Newer theories implicate the subcortical limbic areas (nucleus accumbens and amygdala) as likely causes of engaging in risky behavior as teenagers, versus adults or younger children. The dopaminergic (DA) system has been linked to reinforcement learning and to highlevel cognitive processes and control. The DA system,

**Figure 22.1** Structural changes in gray matter over time derived from serial MRI studies in children, adolescents, and young adults. Right lateral and top views of the dynamic sequence of gray matter maturation over the cortical surface. The side bar shows a color representation in units of gray matter volume. Fifty-two scans from 13 subjects each scanned four times at approximately 2-year intervals. The developmental trajectory of cortical gray matter follows a regionally specific pattern with areas subserving primary functions, such as motor and sensory systems, maturing earliest and higher order association areas, which integrate those primary functions, maturing later. For example, in the temporal lobes the part to reach adult levels latest is the superior temporal gyrus/ sulcus which integrates memory, audio-visual input, and object recognition functions. Reproduced from Lenroot and Giedd [3] with permission from Elsevier.

including levels of the neurotransmitter and receptors, undergoes rapid changes during adolescence and some theories postulate that DA activity is greater in the frontal cortex of adolescents, which may result in greater propensity for riskier (and perceived greater reward) behavior. This neurobiological underpinning substantiates the clinical knowledge that, despite their physical size and physiological (i.e. cardiac and pulmonary physiology) similarity to a mature adult and the tendency for healthcare providers to treat them like adults, adolescents have substantial emotional and behavioral differences that may affect anesthetic care [3] (Fig. 22.1).

Substance abuse and "recreational" use of alcohol and drugs (both legal and illegal) is one area of difference between the adolescent and mature adult. Prevalence of alcohol use (any lifetime use) among 10th graders in the US (age 15–16) was estimated at 59.1% in 2009, and any use of illicit drugs, such as marijuana, cocaine, and methamphetamines, was 36.0% [4]. Substance misuse is defined as a maladaptive pattern of use leading to clinically important impairment or distress that is manifested by persistent or recurrent use of the substance despite interference with important functions, such as school,

home life and interpersonal relationships, and issues such as legal problems and use in physically hazardous situations [5]. Substance dependence is much more limited, with daily use of alcohol reported by 1.1% and daily marijuana use by 2.8% of 10th graders [4]. This condition is equivalent to addiction and usually is accompanied by physiological changes related to chronic drug administration, including tolerance, withdrawal, unsuccessful efforts to stop using the drug, interference with important daily activities, and spending a great deal of time and effort obtaining the drug.

Alcohol and drug use and misuse in adolescence have important neurodevelopmental consequences. Functional magnetic resonance imaging (MRI) studies of adults dependent on cocaine have shown abnormal responses in the prefrontal cortex and basal ganglia, including the nucleus accumbens and related structures, and that the clinical effect of cocaine ingestion coincides with rapid saturation of dopamine transporters in the basal ganglia [5]. Other neuroimaging studies have found a smaller prefrontal cortex and hippocampus in young adults who had been dependent on alcohol during adolescence. Large epidemiological studies of US adults found that those who had their first alcoholic drink before age 14 or first drug use before age 15 were three times more likely to develop alcohol or drug dependence than those whose first use was at an older age. Regular use of marijuana before age 15 may be linked with increased risk of subsequent psychosis [5]. As noted above, executive functions are developing in the adolescent and recent research has confirmed associations between poor development of these functions and adolescents who are at high risk of developing alcohol/substance abuse. In addition, there is a familial or genetic component to substance abuse behaviors [6].

Where there is concern that alcohol or substance use may affect the course of the anesthetic, the best course is often to ask the parent or guardian if the anesthesiologist can ask the patient a few questions in private, and then take a history of drug or alcohol use by asking direct questions in a non-threatening, non-accusatory manner, emphasizing that this is necessary to provide the best possible care. In urgent or emergency surgery, where the patient is suspected to be under the influence of alcohol or drugs, it is important to ascertain what drugs were ingested, if possible. Acutely, central nervous system depressants will decrease minimum alveolar concentration (MAC) and other anesthetic requirements, whereas central nervous system (CNS) stimulants often have sympathomimetic effects and increase anesthetic requirements and exaggerate hemodynamic responses, i.e. dangerous hypertension and tachycardia are possible. Chronic use of opioids increases requirements for these drugs, and chronic use of alcohol and other CNS depressants will increase MAC [7-9].

## Teen cigarette smoking

Recent US national surveys show that about 20% of 12th graders smoked on at least 1 day in the last month; 8.1% smoked at least 20 days in the last month. This represents a decline of almost 40% since the late 1990s [10]. In the adolescent undergoing anesthesia and surgery, several potential adverse effects of smoking are possible. General anesthesia-related airway and respiratory events are more common in smokers. In a large prospective study of over 26,000 anesthetics, adverse events were compared in 7100 smokers and 19,000 non-smokers, including patients as young as 16 years of age. Respiratory events, including bronchospasm (most frequent event), laryngospasm, hypoxemia, and other events were 2.3 times more common in young smokers [11]. It is well known that carbon monoxide levels in the blood of heavy smokers may exceed 10%, impairing oxygen-carrying capacity and delivery. Cigarettes function as a means to rapidly deliver nicotine to the CNS. Nicotine activates several types of acetylcholine receptors, predominately in the CNS, and is postulated to modulate neurotransmitter release, including dopamine. Despite its potential effects on pain modulation and acute withdrawal of nicotine in the postoperative period, several studies in adults have demonstrated that nicotine withdrawal symptoms are minimal, and thus perhaps this is an opportunity to achieve sustained abstinence from tobacco [12]. An important effect of tobacco smoke exposure is its ability to exacerbate asthma symptoms and to precipitate bronchospasm; since the incidence of asthma is at its peak during adolescence, any teenager with asthma who smokes should be strongly encouraged to quit [13].

## Pregnancy/reproductive issues in the adolescent and young adult

Teenage pregnancy testing before anesthesia is a controversial topic but recent data and publications offer some guidance for pediatric anesthesiologists [14,15]. In 2006 in the US, 750,000 women younger than 20 years of age became pregnant. The pregnancy rate was 71.5 pregnancies per 1000 women aged 15-19, meaning pregnancies occurred among about 7% of women in this age group. In general, the teen pregnancy rate has declined for the past 30 years and in 2005, the US teenage pregnancy rate reached its lowest point in more than 30 years (69.5 per 1000), down 41% since its peak in 1990 (116.9). There was a 3% increase in 2006, the first such increase in more than a decade [16]. The teenage birthrate in 2006 was 41.9 births per 1000 women, a total of over 435,000 births. This was 32% lower than the peak rate of 61.8 reached in 1991, but 4% higher than in 2005. From 1986 to 2006, the proportion of teenage pregnancies ending in abortion declined almost one-third, from 46% to 32% of pregnancies among 15–19 year olds. About 18% of the US female population was estimated to become a teen mother in 2006 [17].

These interesting data make the point that teenage pregnancy is not a rare condition, and indicate that the anesthesiologist must consider the possibility that the patient is pregnant when caring for adolescent females. Taking a history about possible pregnancy and missed menstrual periods is known to be inaccurate, so many pediatric anesthesia departments have instituted policies for routine urine human chorionic gonadotropin (HCG) testing in menstruating females before anesthesia. At Texas Children's Hospital (TCH), parents are told that this urine pregnancy testing is routine, but exceptions can be made at the discretion of the anesthesiologist based on medical or cultural grounds. Positive tests are rare, but when pregnancy is detected by serum HCG testing, the surgeon, anesthesiologist, and social worker inform the parent after obtaining permission from the patient. Elective surgery is cancelled because of the potential effects of anesthetics, including benzodiazepines, halogenated anesthetic agents, and nitrous oxide, on early fetal development. Emergency surgery proceeds, but agents that may be implicated in fetal malformations are avoided. At TCH, in 2008-2010, of over 91,000 anesthetics, approximately 9% were performed in menstruating females. During this period, only four of more than 6000 urine HCG tests were positive.

Before implementing a policy concerning preoperative urine pregnancy testing, institutional, local, and state laws and regulations must be consulted. In general, reproductive confidentiality laws mandate that the pregnant teen under the age of 18 has the right to be informed first of a positive test and to decide whether parents are to be notified. In practice, this situation is rare, and the involvement of experts in social work, behavioral health, and adolescent medicine is highly desirable in this complicated situation.

## Chronic diseases in the adolescent and young adult, and transition to adult care

Pediatric anesthesiologists care for many patients for procedures caused by chronic diseases that are congenital or start in infancy or early childhood and continue through adolescence, into adulthood. Very often, these patients and their parents are very attached to their caregivers in the pediatric environment and have developed great trust and confidence in them. The expertise in a specialized pediatric field, such as congenital heart disease, is not widely available in the adult care environment, and many of these patients are understandably anxious about changing to providers in an adult setting.

Because over 90% of children with chronic diseases now survive into adolescence and early adulthood, the concept of transition of care to the adult environment has assumed increasing importance in recent years. In a study of 283 patients aged 14-25 years with chronic conditions that spanned a range of subspecialties and had not yet transferred their care to adult healthcare, 50% of patients thought the best age to transfer care was 18-19 years, while 14% felt that 20 years or older was best. Thirty-nine percent of respondents felt that chronological age was the most important factor in deciding when to transfer care, and 34% said that feeling too old to see a pediatric specialist was the most important factor. Only 11% believed that their relationship with the pediatric specialist was a factor, and 3.5% felt that the severity of the chronic disease was important. Barriers to transition included feeling at ease with the pediatric specialist (45%), anxiety because of not knowing the adult specialist (20%), and lack of information about adult services (18%) [18]. This ambivalence on the part of patients, parents, and pediatric caregivers leads to many young adults being cared for in the pediatric setting and to variable policies about age limits for pediatric care, which are often different for different services in the same institution. In a study of 73 pediatric emergency departments (ED) in the US, 79% had age limits for treatment, with 18 and 21 years the most often cited age cut-offs. Those EDs with age limits over 21 years were most often associated with free-standing children's hospitals. There were many subspecialty-specific exceptions to the age policy that allowed older patients to be cared for by pediatricians, with cystic fibrosis (64%), congenital heart disease (56%), and sickle cell disease (53%) the most common. Interestingly, allowing care in the adult environment for patients less than 18 years was most frequent for teen pregnancy (79%), burn patients (50%), and psychiatric patients (40%). Only 18% of institutions had a specific transition of care policy [19].

Recommendations for transition of care for pediatric patients include starting education of the patient and family about transition several years in advance, having the patient acquire increasing age-appropriate information about the disease, and taking increasing responsibility for their own care, i.e. medication administration and insurance information, and having them understand the differences between the adult and pediatric systems [20]. It should also be noted that mentally competent young adult patients (18 years in the US) legally must sign their own consent for treatments.

Several of the most common chronic disease states presenting for anesthesia care occur in the transition period from adolescence to adulthood and will be discussed below.

### **Cystic fibrosis**

Cystic fibrosis (CF) is an autosomal recessive disease that primarily affects the respiratory and gastrointestinal systems. Historically, CF was a uniformly fatal disease of childhood, but has become more a disease of adolescents and adulthood with the mean age of survival now being 37 years. This improvement in mortality is the direct result of more aggressive, standardized treatment involving many disciplines [21–24].

In the past, CF was considered a disease of the Caucasian population. We now know that the incidence of CF in Caucasian, Hispanics, and African American births is 1 in 2500, 1 in 12,000, and 1 in 15,000 respectively. One thousand patients are newly diagnosed with CF each year in the US. The prevalence is growing quickly, due to the increase in median survival age.

The fundamental defect in CF is a gene mutation on the long arm of chromosome 7 that encodes a protein, cystic fibrosis transmembrane receptor (CFTR), in the apical membrane of epithelial cells in submucosal glands. CFTR is important for the regulation of airway surface liquid. The CFTR mutation causes defective chloride secretion and excessive sodium reabsorption that results in loss of airway surface liquid [25,26]. Beyond the problems of regulating surface liquid, a profound inflammatory response is present in patients with CF that is only partially explained by ongoing infection. The cumulative effect of the inflammatory response is persistent progressive symptoms and irreversible lung damage.

More than 1000 known mutations in the CFTR gene have been identified, but genotype and phenotype correlate poorly, especially regarding the severity of lung disease. Certain genotypes are closely tied to development of CF liver disease and portal hypertension (SERPINA1 A allele), while other genotypes increase the risk of developing type 2 diabetes with CF (TCF7L2) or of developing pancreatic insufficiency [27,28].

Pulmonary disease causes 90% of the morbidity and mortality associated with CF. Pulmonary goblet cells exude a thick tenacious mucus that overwhelms mucociliary clearance. Patients develop a severe unremitting cough to try and remove these secretions. The accumulation of secretions leads to airway occlusion, atelectasis, and hypoxemia. Retained viscid mucus is a fertile growth medium for bacteria, especially *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Pulmonary disease begins at a very early age with evidence of lower tract respiratory infections, neutrophilic inflammation, elevated interleukin (IL)-8, and elastase present in infants (median age 3.6 months). *Pseudomonas* can be cultured from over 50% of asymptomatic children. Cough is a poor indicator of
*Pseudomonas* carriage. Left undetected or untreated, *P. aeruginosa* leads to increased inflammatory cytokine response and poorer clinical status, which are all made worse by the concomitant presence of *Staph. aureus*. In older patients, airway contamination with the fungus *Aspergillus fumigatus* and *Stenotrophomonas maltophilia*, an aerobic motile gram-negative rod of low virulence, develops as a consequence of repeated courses of antibiotics [26]. The infections trigger a neutrophilic inflammatory response that damages airways and eventually causes bronchiectasis and bronchomalacia.

The chest roentgenogram may show hyperinflation and flattened diaphragms, bronchiectasis, and cyst formation. Tram-track radiodensities are parallel lines from advanced peribronchial cuffing and bronchial wall thickening. Computed tomography (CT) scans reveal the extent of pulmonary involvement but may overestimate severity of disease based on exercise tolerance.

Airway reactivity is common and may worsen in adolescence. The response to  $\beta$ -agonist bronchodilators may worsen expiratory flow due to progressive loss of airway cartilaginous support. The airway becomes more dependent on muscle tone for patency, and the airways become floppy and similar to bronchomalacia. Further smooth muscle relaxation by bronchodilators increases airway obstruction.

Pulmonary function tests (PFTs) reveal severe airway obstruction that may be poorly responsive to or worsen with bronchodilators. While PFTs typically demonstrate increased residual volume/total lung volume (RV/TLV) ratios and decreased forced expiratory volume during 25–75% of expiration (FEV<sub>25-75</sub>), the reduction in forced expiratory volume in 1 sec (FEV<sub>1</sub>) correlates with reduced survival [21]. Outcome predictors are rapid loss of pulmonary function, poor nutritional status, presence of *Pseudomonas*, persistent rales on pulmonary examination, and frequent clinical illness from infections [29].

Progressive bronchiectasis and airflow obstruction ultimately lead to hypoxemia and hypercarbia. Destruction of pulmonary architecture and chronic hypoxia cause pulmonary hypertension, right ventricular hypertrophy, and eventually cor pulmonale. Patients may feel better with home oxygen and non-invasive ventilation support with continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). These adjuvants may be very helpful during postoperative care.

All mucosal cells are affected by the defective CFTR and the associated generalized mucosal hypertrophy. Nasal mucosal hyperplasia causes chronic sinusitis. Pedunculated nasal polyps are found in nearly half of patients and occur most commonly during adolescence. Although surgical removal of polyps may be necessary, the use of rehydration therapy with hypertonic saline irrigation, topical or inhaled nasal rhDNase, and glucocorticoids may be helpful. The presence of nasal polyposis makes the use of nasopharyngeal airways or nasal tracheal tubes a higher risk than normal.

Pancreatic exocrine function is reduced in 90% of patients. The dysfunctional chloride–bicarbonate exchanger induced by the absent CFTR impairs bicarbonate secretion. Consequently, the volume and pH of pancreatic secretions are reduced. Pancreatic enzymes plug the pancreatic duct; retention of those enzymes causes inflammation and autodigestion of the pancreas.

Antenatal accumulation of viscid secretions causes meconium ileus, a bowel obstruction in neonates that is caused by inspissated secretions derived from the intestinal mucosa glands. Adolescents and adults may have recurrent gastrointestinal obstruction, a meconium ileus equivalent, through a similar mechanism. This condition is better termed distal intestinal obstruction syndrome because it may occur in the colon or the ileum. Advanced pancreatic disease, dehydration, irregular use of pancreatic enzyme supplements, and use of medications that slow intestinal transport are precipitating factors of this condition.

Tenacious secretions obstruct pancreatic exocrine ducts, reducing overall pancreatic secretion of lipase, an enzyme necessary for the hydrolysis and subsequent absorption of fat. Inadequate absorption of fat-soluble vitamins (vitamins A, D, E, and K) worsens the patient's nutritional state and overall quality of life. Vitamin D deficiency leads to fractures due to inadequate calcification of bones. Vitamin K deficiency, caused by either malabsorption or reduced enteral bacterial synthesis of vitamin K synthesis as a result of chronic antibiotic use, causes coagulopathy. Vitamin E deficiency results in ataxia, decreased sensation to vibration, lack of reflexes, and paralysis of eve muscles. A decline in cognitive function is an early sign of vitamin E deficiency, particularly in the preteen years. Vitamin A deficiency causes predominantly eye and skin problems, while excessive supplementation of vitamin A may harm the respiratory and skeletal systems of children. A Cochrane review found no studies that showed that regular vitamin A consumption is beneficial for people with cystic fibrosis [30].

Enteric-coated pancreatic enzyme supplements (Creon®, a delayed release form of pancrelipase, Pancrease (lipase, amylase, and protease)) and fat-soluble vitamin supplements are essential elements of supportive care.

Pancreatic endocrine dysfunction gradually develops from the progressive autodigestion of the pancreas. The loss of islet cell function may trigger diabetes. Curiously, insulin resistance may also be present and further complicate glucose homeostasis. Preparation for intraoperative care requires skilled management of both hyper- and hypoglycemia. Microvascular deterioration of the retina, kidneys, and peripheral nerves is more frequent with prolonged poor glucose management.

The younger the age at diagnosis, the greater is the liver and pancreatic compromise. One-third of patients will have liver dysfunction, fatty infiltration, cirrhosis, and portal hypertension. Death from cirrhosis is the second most common cause of death in patients with CF. This progression typically occurs in specific histocompatibility complex genotypes, with male gender, or when nutrition is poor. If liver disease is suspected from function tests, preoperative evaluations for biliary fibrosis and cirrhosis may be necessary, since they may cause coagulopathy and altered drug metabolism.

Bone demineralization is common in patients with CF. Poor nutritional status, malabsorption of vitamin D, and the administration of steroids are precipitating factors for both fractures and scoliosis. In addition, chronic pulmonary infections increase serum cytokines that stimulate bone resorption. Scoliosis and/or kyphosis is present in 75% of female and over 30% of male patients older than 15 years. Prevention of skeletal degeneration includes aggressive nutritional support, pancreatic enzyme supplements, fat-soluble vitamins, and treatment with growth hormone, calcium, and sex steroids.

Congenital absence of the vas deferens with obstructive azoospermia causes infertility in 95% of males. Menstrual irregularity from chronic disease and thick cervical secretions reduces fertility in females. The natural history of cystic fibrosis is one of progressive deterioration of the condition. It is important to carefully monitor the qualityof-life indicators, the presence of depression, and patients' ability to cope, as these will directly affect a patient's compliance with treatment [31].

#### Treatment of cystic fibrosis

Inhaled hypertonic saline acutely increases mucociliary clearance and is a safe, inexpensive means of clearing secretions. Chest physiotherapy, employing percussion with exhalation flutter valves or direct chest compression, improves the efficacy of the patient's cough.

Even though used clinically for decades, the effectiveness of inhaled N-acetylcysteine (NAD) (Mucomyst®) has recently been questioned. NAD is thought to reduce mucus viscosity by splitting the disulfide bonds of mucoproteins, but evidence that this improves mucus clearance is absent [32]. However, high-dose oral NAD is thought to modulate inflammation in patients with CF and may counter the intertwined redox and inflammatory imbalances present [33].

Aerosolized antibiotics (i.e. tobramycin, aztreonam) decrease the population of *P. aeruginosa*, thereby reducing

hospitalization and the rate of pulmonary deterioration. Even short-term use of inhaled aztreonam improves lung function [34] and quality-of-life indicators.

Oral azithromycin, an acid-stable derivative of the macrolide antibiotic erythromycin, is a recent addition to standardized maintenance therapy for patients with cystic fibrosis. The drug's principal effects appear to be unrelated to its antibiotic effect but acts through modulation of the proinflammation effects of bacterial infection and alteration of the virulence of Pseudomonas. Azithromycin interferes with neutrophil recruitment, chemotaxis, and oxidative bursts, all of which injure airways during infections. With protracted use, azithromycin is associated with gradual improvements in FEV<sub>1</sub> and forced vital capacity (FVC). It appears especially useful in patients with persistent Pseudomonas infection, an effect that may not be the result of its antibiotic potential. Subinhibitory concentration of azithromycin can be bactericidal to P. aeruginosa when exposed for protracted periods [35].

Bacterial growth in biofilms is associated with reduced sensitivity to antibiotics. Biofilm formation is iron dependent, and iron chelation therapy combined with antibiotics reduces biofilm formation and enhances antibiotic susceptibility of *P. aeruginosa* [36].

Deoxyribonuclease I (DNase), a bovine recombinant enzyme, and its recombinant twin rhDNase (Pulmozyme<sup>®</sup>) catalyze the hydrolytic cleavage of phosphodiester linkages in the DNA in white blood cells that accumulate in the mucus. Hydrolysis of white cell DNA reduces "stickiness" of the mucus, which makes it much easier to clear mucus from the lungs. The net effect is to reduce air trapping, improve FEV<sub>1</sub>, and reduce the frequency of clinical infections. Although rhDNase efficaciously reduces atelectasis, hyperinflation, and mediastinal shift over a period of 3 days, its use in the hyperacute setting of the operating room has not been demonstrated. Prolonged use of rhDNase does not reduce pulmonary bacterial colonization, and the timing of its administration to chest percussion is a subject of considerable debate.

A new treatment option is to increase the amount of functioning CFTR at the cell surface. Miglustat (Zavesca®), a drug used for patients with type I Gaucher disease, has a CFTR corrector effect when given by inhalation. Miglustat activates CFTR-dependent chloride transport in mice that have a similar mutation [37]. Another new agent, spiperone, is a psychoactive butyrophenone that activates the specific genetic defect in the chloride channel in airway epithelium. Prolonged use of the long-acting  $\beta_2$  adrenoreceptor salmeterol acts via the CFTR as a potent chloride secretagogue. Interestingly, it appears to act by reducing the internalization of the  $\beta_2$  adrenoreceptor, thereby restoring chloride secretion and airway surface liquid [38].

#### Sinus surgery in cystic fibrosis

The paranasal sinuses become infected before pulmonary contamination and infection begin. As patients age, they are more likely to have infection in both their upper and lower airways. Bacteria spread from the sinuses to the lungs of patients with CF [39]. Because the upper and lower respiratory tracts have the same mucosal lining, improvements in sinus health reduce the frequency and severity of lower tract infections.

Nasal obstruction and chronic rhinosinusitis (CRS) are common otorhinological manifestations of CF. The altered viscoelastic properties of mucus result in impaired ciliary function and obstruction of sinus ostia. Chronic sinusitis and mucosal edema lead to sinonasal polyposis and nasal obstruction in nearly all adolescent and adult patients. Sinonasal disease increases the risks of pneumonia, the bacterial origin of which is the paranasal sinuses [40].

The prevalence of nasal polyposis in children with CF is between 6% and 48% [40]. Nasal polyps begin as an edematous growth of mucosa that is a consequence of inflammatory mucosal reaction in the paranasal sinuses. Polyps are commonly found bilaterally and lead to septal deviation, bulging of the nasal dorsum, and even hypertelorism [41].

Almost all patients with CF have CT abnormalities of their sinuses, but the findings do not correlate well with symptom severity. Surgical intervention for sinus disease is based on management of symptoms, pulmonary status, and frequency of infection. Endoscopic sinus surgery is safe and at least temporarily effective at reducing these complications. Grading the severity of nasal polyposis can help predict the need for future sinus surgery [42].

Chronic high-dose ibuprofen appears to effectively manage nasal polyposis in young adults with CF [43]. Hypertonic saline lavages improve clearance of viscid secretions. Despite aggressive medical management, approximately one-quarter of patients with CF will require sinus surgery. Paranasal sinus surgery in pediatric and young adult patients with CF can be safely performed and improves individual rhinosinusitis symptoms (less facial pain, headache, nasal obstruction, postnasal drip and rhinorrhea). While combined medical and surgical management may yield symptomatic relief, the infections, obstruction, and nasal polyposis can recur because CF is a chronic, unremitting disease.

Intraoperative management of patients with CF undergoing open or endoscopic sinus surgery includes appreciation of the degree of nasal airway obstruction, avoiding instrumentation of nares with tracheal tubes and nasal airways, management of vitamin K-deficient coagulopathy, and having readily available equipment to suction tenacious mucus from the lungs.

#### **Portosystemic shunts**

Liver disease occurs in over one-quarter of patients with CF and is the second most common cause of death in these patients [44]. The purported pathophysiological mechanism of liver injury is focal inspissation of bile due to its abnormal viscosity, decreased bile flow, and high concentrations of bile in the liver tissue. Decreased bile flow obstructs small biliary ductules and induces collagen deposition in the portal tracts [45]. The spectrum of clinical liver disease in patients with CF runs from cholestasis to focal biliary cirrhosis to multilobular cirrhosis, and finally to portal hypertension. In its most severe clinical states, portal hypertension occurs in 7% of patients, with a preponderance of male gender. It causes massive splenomegaly, ascites, and bleeding from esophageal varices [46]. Initial management of variceal bleeding may include sclerotherapy, but one of the various forms of portosystemic shunts (Fig. 22.2) is often required to provide more definitive relief of portal hypertension and of its complications [47].

#### Pulmonary surgery in cystic fibrosis

Pulmonary surgery in patients with CF requires special comment. Surgical treatment of bronchiectasis, whether segmental or diffuse, may be indicated to reduce cough and sputum production, and to decrease formation of new areas of bronchiectasis. Pulmonary function is affected very little by the lung resection, since the area of diseased lung contributes little to respiratory function. Lung resection may reduce the severity of symptoms and improve oxygenation. Even large resections may be tolerated.

In severe or recurring cases of pneumothorax, bleb resection and/or multiple treatments with talc pleurodesis may be necessary. Talc creates an enhanced plural reaction and causes the parietal and visceral pleural surfaces to adhere, thereby reducing the frequency of pneumothorax. This technique is particularly helpful in patients with bleb formation. Unfortunately, future surgical procedures (i.e. lobe resections, lung transplants) are made more difficult by this procedure.

Cystic fibrosis is the third most common indication for pulmonary transplantation in adolescents and adults. The criteria for transplantation are a calculated survival of less than 50%, typically marked by a FEV<sub>1</sub> less than 30%, a PaO<sub>2</sub> of less than 50mmHg, and a PaCO<sub>2</sub> greater than 55mmHg. The most common precipitating conditions for transplantation are progressive loss of FEV<sub>1</sub> to <30%, severe hypoxemia and hypercarbia, increasing frequency of hospitalization, and hemoptysis. When transplantation is a consideration, bilateral lung transplants are usually required to avoid crosscontamination of the good lung. A review of 9 years of pulmonary transplantation revealed that the

**Figure 22.2** The four major types of portocaval shunts. PV, portal vein; CV, cardiac vein; SV, splenic vein; IMV, inferior mesenteric vein; LRV, left renal vein; SMV, superior mesenteric vein; IVC, inferior vena cava; SGV, short gastric veins. Reproduced from Lillegard et al [47] with permission.

cumulative survival of older patients is better than that of younger patients [48]. Older patients have fewer infections, less bronchiolitis obliterans, and fewer graft rejections. Transplantation in patients 6–10 years of age for CF has similar overall survival to patients of the same age being transplanted for other reasons. Evidencebased decision aids help to improve expectations of lung transplantation and prepare patients for the posttransplantation experience [49]. See Chapter 27 for a detailed discussion of the anesthetic management of lung transplantation.

#### Anesthetic management in cystic fibrosis

Perioperative evaluation depends on the severity of the clinical disease and the extent of the operative intervention planned. Routine chemistries, liver profile, and coagulation assessments are warranted. Exercise tolerance is a good prognostic indicator of the risk for postoperative pulmonary complications. Preoperative arterial blood gases (ABGs) help determine the severity of disease and may help guide postoperative care.

The anesthetic should be designed to facilitate early tracheal extubation and avoid prolonged mechanical ventilation. Volatile agent anesthetics may benefit patients with bronchodilator-responsive bronchospastic disease. Total intravenous anesthesia (TIVA) may be well suited for patients whose degree of airway obstruction worsens with bronchodilators or when vapor diffusion is severely affected by the extent of pulmonary disease.

Propofol normally has 30% first-pass metabolism in the lungs, but clearance of this drug may be substantially increased by the presence of an active inflammatory lung process like cystic fibrosis. Consequently, much larger doses of propofol may be required to achieve adequate anesthesia. Inadequate insulin supply plus resistance to insulin makes intraoperative glucose monitoring imperative. Tracheal tube size should be as large as feasible to facilitate tracheal suctioning. Because of nasal mucosa hypertrophy and the potential for nasal polyps, nasal airway devices should be avoided if possible. Inspired anesthetic gases should be warmed and humidified; frequent airway suctioning, with or without bronchodilators, may be required.

Use of neuromuscular blockade (NMB) may complicate ventilation of patients who rely on muscle tone for airway patency. Avoiding prolonged administration of NMB, particularly in combination with adrenocorticosteroids, is essential to avoid muscle weakness, prolonged ventilation support, and additional pulmonary infections.

Prior to tracheal extubation, tracheal suctioning, with or without aerosolized hypertonic saline, and lung recruitment maneuvers help restore pulmonary function. Patients may need longer periods of observation postoperatively to effectively balance analgesia needs with the need for additional oxygen support.

Non-invasive support of ventilation (CPAP, BiPAP) is helpful postoperatively. Aggressive pulmonary toilet that includes percussion, postural drainage, and flutter valve therapy improves postoperative lung function. Inhaled hypertonic saline or rhDNase may facilitate clearance of secretions and efficaciously treat atelectasis.

Postoperative pain control should not be provided exclusively with opioids because of their effect on intestinal transit and the potential to initiate distal intestinal obstruction syndrome. Acceptable analgesic adjuvants include non-steroidal anti-inflammatory drugs, continuous IV infusion of lidocaine (because of its ability to reduce inflammation), and low-dose ketamine (for modulation of pain via the NMDA receptor). If the procedure and parameters permit, regional or neuroaxial anesthesia may lower the risks of altered drug metabolism and excretion.

#### **Congenital heart disease**

Congenital heart disease (CHD) is present in 8 per 1000 births in the US and Europe and is the most common birth

defect requiring treatment. Because of improved survival rates (>90%) after neonatal and infant cardiac surgery for complex cardiac lesions, the vast majority of these patients survive into adolescence and adulthood and will present for both cardiac and non-cardiac surgery for the same range of procedures found in patients without CHD. In the US there are approximately 1 million children and 1 million adults over the age of 18 living with CHD. Of these survivors, 55% have simple disease, 30% moderately complex, and 15% complex lesions [50]. In patients with CHD, having current, accurate information about the status of their cardiac condition and repair is crucial. Patients with complex and moderately complex lesions must have a recent evaluation by a cardiologist who has expertise in congenital heart disease, and must have their medical condition optimized for the surgery and anesthetic [51]. Patients with significant potential for cardiovascular instability and need of specialized care should undergo anesthesia whenever possible only in facilities where such expertise is readily available. Infective endocarditis prophylaxis guidelines must be followed [52]. For more detail about the preanesthetic evaluation and anesthetic management of patients with CHD for both cardiac and non-cardiac surgery, see Chapter 25.

#### Cancer

The most common new cancers diagnosed in the adolescent population, in the 10–14 and 15–19 year age groups, are:

- leukemias (32 and 33 per million)
- lymphomas (25 and 47 per million)
- brain and spinal neoplasms (37 and 43 per million)
- malignant bone tumors (13 and 14 per million)
- soft tissue and other extraosseous sarcomas (13 and 17 per million) [53].

Five-year survival for all cancers in childhood, 1999–2006, is 79.8%, with leukemias and lymphomas having the best survival at 80–90%, and malignant bone and CNS cancer the lowest survival at 60–70% [54].

These adolescent cancer patients require anesthesia for a wide variety of procedures, including primary and secondary tumor resections (sometimes after initial chemotherapy) and metastatic lesions, vascular access procedures, bone marrow aspirations, and many others. The reader is referred to chapters elsewhere in this book for a discussion of anesthetic management of procedures in specific organ systems. Radiation therapy is common in these patients. Emergency radiation therapy in patients with a lymphoma or leukemia and an anterior mediastinal mass and airway obstruction is a rare occurrence, but when present is fraught with the dangers of managing the airway and transporting the patient to a remote location. See Chapter 24 for a discussion of the anesthetic management of the patient with a mediastinal mass. Many patients require follow-up imaging procedures, including MRI, CT, positron emission tomography/CT (PET/CT), and ultrasound; in the vast majority of adolescent patients, these procedures can be done without anesthesia or sedation.

As with many other congenital and acquired conditions in childhood, survival from childhood cancers has increased dramatically over the past several decades, and many of these patients require anesthesia care for follow-up or treatment of their cancer or for completely unrelated issues. It is important for the anesthesiologist to understand the residual medical and psychological problems that can be present in these adolescents [55]. It also is important to understand the past treatments of these patients, particularly chemotherapy and radiation therapy, which can have severe effects on cardiac and pulmonary function (Table 22.1). For example, anthracycline chemotherapy may cause cardiomyopathy. Consequently, routine follow-up with echocardiography is performed on all these patients. Pulmonary and renal toxicity should also be determined and the anesthetic planned accordingly. Cranial irradiation is used commonly to treat leukemia and CNS tumors. This therapy is associated with a significant incidence of neurodevelopmental disability.

As with many chronic illnesses, survivors of childhood cancer have an increased incidence of psychological problems. In a review of psychological and quality-of-life studies in over 7000 adolescent and young adult cancer survivors, it was found that cancer survivors were 80% more likely to report clinically relevant impairments in mental health, and twice as likely to report emotional distress [56]. Those with particularly high levels of anxiety and depression are patients with CNS tumors, bone tumors, leukemia and lymphoma, and those who have undergone cranial irradiation. Chronic pain may also be an important component of the residual medical problems of cancer survivors.

#### Sickle cell disease

Sickle cell disease (SCD) is an autosomal dominant condition caused by the substitution of valine for glutamate at the sixth position of the  $\beta$ -globin chain of hemoglobin; this produces hemoglobin S instead of hemoglobin A. Sickle cell anemia is most common in populations whose origins are Africa, South or Central America (especially Panama), Caribbean islands, Mediterranean countries (Turkey, Greece, and Italy), India, and Saudi Arabia. In the US, an estimated 70,000–100,000 children and adults have sickle cell anemia, mainly African Americans. The disease occurs in about 1 out of every 500 African American births and in more than 1 out of every 36,000 Hispanic American births. More than 2 million Americans have sickle cell trait (homozygous hemoglobin AS); this Table 22.1 Long-term effects of childhood cancer

System	Risk factor	Potential effect
Cardiac	Radiation therapy Anthracyclines	Valvular disease Pericarditis Myocardial infarction Congestive heart failure Sudden death
Pulmonary	Radiation therapy Carmustine/Lomustine Bleomycin	Restrictive lung disease Exercise intolerance
Renal/ urological	Radiation therapy Platinums Ifosfamide and cyclophosphamide Ciclosporin A Nephrectomy	Atrophy or hypertrophy Renal insufficiency or failure Hydronephrosis Chronic cystitis
Endocrine	Radiation therapy Alkylating agents	Growth failure Pituitary, thyroid, and adrenal disease Ovarian or testicular failure Delayed secondary sex characteristics Infertility
Central nervous system	Radiation therapy Intrathecal chemotherapy	Learning disabilities
Psychosocial	Childhood cancer	Post-traumatic stress disorder Employment and educational difficulties Insurance discrimination Adaptation and problem-solving difficulties Difficulties with transition to independence
Second malignancies	Radiation therapy Alkylating agents Epipodophyllotoxins Type of primary malignancy	Solid tumors Leukemia Lymphoma Brain tumors

Reproduced from Henderson et al [55] with permission from the American Academy of Pediatrics.

condition occurs in about 1 in 12 African Americans [57]. Homozygous hemoglobin SS causes abnormal aggregation of hemoglobin under conditions of low oxygen tension or acidosis, which results in reduced red cell elasticity and the characteristic sickle shape of erythrocytes

**Figure 22.3** Sickle cell disease complications by age. Width and color of arrow shaft signifies the relative incidence of the complication. Reproduced from Redding-Lallinger and Knoll [58] with permission from Elsevier.

seen with homozygous sickle cell disease. This in turn impedes passage of the deformed erythrocytes through capillaries of all organs and results in the myriad problems seen with this disease. (Fig. 22.3). Red cell survival is shortened, which leads to hemolysis and anemia; most patients maintain hemoglobin concentrations of 7-9g/ dL. Homozygous SS patients have hemoglobin S concentrations that exceed 80% and are usually significantly affected by the disease. In the US about two-thirds of sickle cell disease patients have this genotype. Other variants, such as hemoglobin SC disease or hemoglobin S-βthalassemia, are also frequently encountered. In terms of severity of disease, hemoglobin SS and S- $\beta^{\circ}$  thalassemia genotypes generally are most affected, although symptoms are variable. Heterozygous carriers with one copy of the hemoglobin S gene are usually relatively asymptomatic [58].

Problems of particular importance for adolescents with SCD are acute painful crises and chronic pain, strokes, priapism, cholelithiasis, and avascular necrosis of the hip and other joints. Acute chest syndrome episodes that result in pulmonary hypertension are also seen in this age group.

Current therapy for SCD often includes chronic transfusion therapy to maintain higher levels of hemoglobin A and lower levels of hemoglobin S. This therapy has been demonstrated to reduce episodes of painful crisis, stroke, priapism, and acute chest syndrome, and to reduce risk for chronic pain and pulmonary hypertension. However, it also increases the risk of transfusion reactions. In recent years treatment with hydroxyurea has been shown to increase the percentage of hemoglobin F (fetal hemoglobin) and decrease hemoglobin S. This results in fewer episodes of painful crises and acute chest syndrome. Leukopenia and thrombocytopenia are possible side-effects of hydroxyurea treatment. Packed red blood cell transfusion or exchange transfusion is used for acute problems, such as acute chest syndrome, painful crises, priapism, and acute stroke. Erythrocytes for transfusion should be sickle negative, leukocyte poor, and matched for C, E, c, e and Kell antigens, as well as Rh D and ABO (extended cross-matching or partial phenotypic matching). This reduces the risk of alloantibody sensitization against the many antigens the patient is likely to be exposed to during future transfusion therapy. Hematopoietic stem cell transplantation in children with SCD is 85% effective in curing the disease.

The goal of perioperative anesthetic management in patients with SCD is prevention of excessive sickling of abnormal cells and thus prevention of significant complications, such as acute chest syndrome, painful crises, stroke, and other major problems. The cornerstones of management are avoidance of known precipitating factors for sickling, including hypoxemia, hypovolemia, acidosis, and hypothermia, which induce a vicious cycle of red cell adherence to endothelium, vaso-occlusion, further tissue hypoxia and ischemia, inflammation, activation of coagulation, and further vasoconstriction (Fig. 22.4).

Among the most common surgical procedures that adolescents with SCD require are cholecystectomy for chronic hemolysis-induced cholelithiasis, tonsillectomy, orthopedic procedures for avascular necrosis, and priapism. Case reports and case series of other major procedures, including cardiac surgery with cardiopulmonary bypass, have also been published [59-61]. The most recent consensus guidelines about perioperative management of SCD patients were published in 2002 by the US National Institutes of Health National Heart, Lung, and Blood Institute [62] (Box 22.1). Besides strict attention to preoperative hydration, oxygenation, temperature maintenance with warmed intravenous (IV) fluids, forced-air warming, and avoidance of acidosis and hypovolemia, transfusion to a minimum hemoglobin of 10g/dL is recommended for all but the simplest procedures. This includes tonsillectomy, open cholecystectomy, major orthopedic procedures, and other major surgery. Laparoscopic cholecystectomy has been performed without problems with hydration alone in one series of 13 patients [61]. Exchange transfusion is indicated only for very severely affected patients or for open heart surgery.

Perioperative analgesia is critically important to prevent severe pain, stress, catecholamine release, and

Figure 22.4 Elements of the pathophysiology of sickle cell disease and interactions between them. Reproduced from Redding-Lallinger and Knoll [58] with permission from Elsevier.

precipitation of further acute events. Consequently, provision of intraoperative and postoperative pain relief must be carefully considered. Patient-controlled analgesia is often very effective in the adolescent sickle cell population. It is important to maintain high oxygen saturations with supplemental oxygen in the recovery period. For any sickle cell patient undergoing anesthesia and surgery, consultation with the patient's hematologist for perioperative recommendations is key for providing optimal care and outcomes. See Chapter 11 for more discussion of the perioperative management of patients with sickle cell disease.

#### **Diabetes mellitus**

In the adolescent population, diabetes mellitus is usually type 1, although the incidence of type 2 diabetes is increasing in this population (see below under Obesity). Approximately 186,000 children aged 0–19 had a diagnosis of diabetes mellitus in 2007 in the US, or 0.2% of this population; 80% of the diabetes was type 1. In the 10–19 year age group, 85% of new diabetes in the non-Hispanic white population in the US was type 1, while in African American and Hispanic populations the proportion of new type 1 versus type 2 cases was 50:50; in the Asian Pacific Islander and Native American populations, new cases are predominantly type 2 [63]. Onset of type 1 diabetes usually occurs during childhood or adolescence and arises from T-cell mediated autoimmune destruction of pancreatic  $\beta$  cells, which causes failure of insulin production, and hyperglycemia.

The incidence of type 1 diabetes is also increasing in many parts of the world. Associated risk factors include genetics, diet, lifestyle, and immune responses to viral infection, with enterovirus most frequently implicated. Insulin therapy is the cornerstone of treatment for type 1 diabetes [64]. Type 2 diabetes is the result of resistance to **Box 22.1** US NHLBI recommendations for perioperative care of the sickle cell disease patient (2002)

- Make sure the operating and anesthesia teams are aware of the diagnosis of a sickle cell syndrome and the need for special attention.
- In patients with SCD-SS and SCD-S  $\beta^{\circ}$ -thalassemia, simple transfusion to achieve a hemoglobin of 10 g/dL should be performed before all but the lowest-risk procedures.
- For patients with SCD-SC, exchange transfusions may be needed to avoid complications associated with hyperviscosity.
- Alloimmunization should be minimized by giving antigen-matched blood (matched K, C, E, S, Fy, and Jk antigens).
- Patients with SCD, regardless of genotype, should all receive careful attention, with preoperative monitoring of intake and output, hematocrit, peripheral perfusion, and oxygenation status.
- Intraoperative monitoring of blood pressure, cardiac rhythm and rate, and oxygenation should be conducted for all surgical procedures.
- Postoperative care should include attention to hydration, oxygen administration with careful monitoring, and respiratory therapy.

Reproduced from Guidelines for Perioperative Management of Sickle Cell Disease [62] with permission from NHLBI.

the effects of insulin, which causes hyperglycemia. Obesity, particularly adipose tissue deposits in the abdomen and non-alcoholic fatty liver disease, is associated with this disease in adolescents. Treatment is primarily by diet, exercise and, in some cases, oral hypoglycemic drugs, such as metformin, sulfonylureas or thiazolidinediones; insulin is rarely necessary in adolescence [65].

The secondary complications of diabetes, i.e. nephropathy, are rare in adolescents. Most patients with diabetes present for anesthesia because they require the standard surgical procedures seen in patients in this age group. For those who are insulin dependent, there are many insulin types available, ranging from short, medium, to longacting insulin; dosing occurs one, two or more times per day or on a sliding scale. Insulin pumps that provide continuous basal rates of subcutaneous insulin infusion plus programmable boluses at mealtimes or in response to hyperglycemia are also used [66]. An understanding of the patient's insulin regimen, history of diabetic ketoacidosis or hospitalization, and degree of glycemic control (hemoglobin A1C <7.5%) is important, as is co-ordination with the patient's endocrinologist [67].

Whenever possible, insulin-dependent patients should be scheduled as the first case of the day. Generally, the night before surgery, the patient's normal meal and insulin regimen should be followed. Fasting guidelines are not different from patients without diabetes for a morning case, i.e. nil per os (NPO) for solid food and non-clear liquids for 6h preoperatively and clear liquids for up to 2h preoperatively. For afternoon cases, a light early breakfast may be preferable in those who are insulin dependent. For patients on twice-daily or more frequent insulin administration, the current recommendations are to omit short-acting insulin and to give only 50% of the intermediate insulin dose in the morning. After measuring a baseline blood glucose, an infusion of 5% dextrose in 1/2 normal saline is begun at maintenance rates 2h preoperatively or as soon as the patient arrives for an early morning case (1500 mL per 24h, plus an additional 20mL/kg/24h for each kg over 20kg, maximum 2000 mL/24 h, i.e. 83 mL/h for a 50 kg patient). Also start an insulin infusion with 1 unit regular insulin per 1 mL normal saline, at 0.025–0.1 unit/kg/h, depending on the baseline glucose. Glucose must be measured every hour while receiving an insulin infusion and the insulin rate must be adjusted accordingly with the goal of maintaining blood glucose concentrations of 90-180 mg/ dL. Additional boluses of IV regular insulin, of 0.025-0.1 unit/kg, are given for glucose values above 180 mg/ dL. Serum electrolytes, i.e. sodium and potassium, are measured at regular intervals and potassium replaced if needed.

After surgery, the glucose and insulin infusion are continued, with the addition of potassium chloride at 20 mEq/L in the IV fluid if the patient remains NPO. If oral intake is allowed, the IV dextrose and insulin can be weaned, and the patient's normal evening meal and insulin regimen can be resumed if glycemic control is adequate. Patients with infusion pumps must be managed in close consultation with the endocrinologist. Pump use may be continued during anesthesia. These recommendations are summarized in Box 22.2. For type 2 diabetes patients on insulin, the guidelines are the same as above. If the patient with type 2 diabetes is taking metformin, discontinue it 24h before elective surgery. If taking sulfonylureas or thiazolidinediones, these are stopped on the day of surgery.

#### Adolescent gynecological surgery

Adolescent gynecology is a growing field and because of this, more of these patients are presenting for surgery. Most of these procedures are done laparoscopically. Indications for laparoscopic surgery in females of this age include congenital anomalies, such as Mullerian anomalies and disorders of sex development, which may require diagnosis and treatment. Adnexal masses, such as ovarian torsion, tumors or tubo-ovarian abscess, are also diagnosed and treated with laparoscopy. Other less frequent indications include diagnosis and treatment of endometriosis or pelvic inflammatory disease, and procedures to preserve ovarian function before pelvic irradiation [68,69]. See Chapter 28 for a discussion of the anesthetic management of patients undergoing laparoscopy. **Box 22.2** Guidelines for perioperative management of patients with insulin-dependent diabetes

NPO guidelines	6 h preoperatively for solid food, non-clear liquids 2 h preoperatively for clear liquids
IV fluids	D5 ½ normal saline 2 h preoperatively at 1500 mL/24 h plus 20 mL/kg for every kg over 20 kg, maximum 2000 mL/24 h
Insulin regimen	No change the evening before surgery Omit short-acting AM insulin, give 50% of usual medium-acting insulin dose
Insulin infusion	Start at 0.025–0.1 unit/kg/h depending on baseline glucose
Glucose measurement	Q 1 h during insulin infusion
Glycemic control	Goal: 90–180 mg/dL; increase or decrease insulin infusion accordingly; may give regular insulin IV 0.025–0.1 unit/kg bolus for values >180 mg/dL, or stop insulin infusion briefly for values below 60 mg/ dL
Insulin pump patients	Consult endocrinologist for plan
Postoperative treatment	Continue insulin and glucose infusion if NPO; add KCI 20mEq/L to IV fluids Wean insulin and glucose and resume normal evening meal and insulin regimen if taking food

#### Inflammatory bowel disease

Inflammatory bowel disease (IBD) is classified as either Crohn's disease or ulcerative colitis, and the overlapping clinical features of these diseases often lead to lack of clarity in diagnosis in adolescents (see Chapter 28) [70]. Twenty to 30% of patients with IBD are less than 20 years of age, and the prevalence of this disease in this age group worldwide has been estimated to be 4–7 per 100,000 [71].

Crohn's disease is a transmural inflammatory disease of the mucosa with episodic progression that can involve any part of the gastrointestinal tract from the mouth to the anus. However, it is often concentrated in the small bowel. Ulcerative colitis is a non-transmural inflammatory disease with episodic progression that is limited to the colon. The clinical features of the IBD depend on its localization and often include diarrhea, abdominal pain, fever, ileus, and the passage of blood and mucus per rectum. Patients with Crohn's disease are less likely to have bloody diarrhea, but rather have abdominal pain or non-specific abdominal symptoms. About 25% have perianal disease. Growth failure is common in both children and adolescents. IBDs are autoimmune diseases that are associated with susceptibility regions on at least 12 different chromosomes. Other associations include ethnic origin, with northern European descent predominant, lifestyle, and geographic factors. Extraintestinal manifestations include joint and skin involvement (15-25% in Crohn's disease, 2-16% in ulcerative colitis) [72]. Medical treatment of IBD is similar for both Crohn's disease and ulcerative colitis: oral or rectal mesalamine, corticosteroids, purine analogs (6-mercaptopurine, azathioprine), methotrexate in varying combinations, depending on severity of disease and acute relapse status. Newer treatments also include anti-tumor necrosis factor-α antibody drugs (infliximab, adalimumab) or, in severe cases, cyclosporin. In addition, patients with Crohn's disease are usually receiving antibiotics (metronidazole, ciprofloxacin).

Adolescents with IBD often present for surgery for complications of the disease or failed medical management. Indications include bowel perforation/abscess, obstruction, stricture, perianal fistula, toxic megacolon or malignancy. Over 50% of IBD patients ultimately require bowel resection. Recurrence of disease and reoperation are frequent, so bowel conservation is very important for avoiding the complications of short bowel syndrome and long-term dependence on total parenteral nutrition. Ostomy formation may be necessary for more severe cases. Complications after surgery for IBD include wound infection, anastomotic leak, anastomotic stricture, fistula, recurrence of disease, small bowel obstruction, and bleeding; these complications are seen particularly following surgery for Crohn's disease. For ulcerative colitis, total proctocolectomy is curative. The procedure done depends on the clinical status of the patient but usually involves a total colectomy, with or without an ileostomy. Creation of a small bowel reservoir with ileo-anal anastomosis is the definitive procedure. These patients also present frequently for upper and lower gastrointestinal endoscopy for diagnosis and treatment of their disease, and for cancer surveillance that may require sedation or anesthesia provided by the pediatric anesthesiologist.

Preanesthetic evaluation and care must consider nutritional status, chronic pain, medications (including corticosteroids and other immunosuppressant drugs), and history of anesthesia and surgery. Extraintestinal manifestations of the disease must be carefully sought out. As with any chronic disease in the teenage population, psychosocial distress is common in patients with IBD, and anesthetic care must take this into consideration.

#### **Developmental disabilities/autism**

Chapter 38 contains an extensive listing of the genetic causes of developmental delay, including autism spectrum disorder. Acquired causes of developmental delay include hypoxic-ischemic brain injury from cardiac or respiratory arrest secondary to a disease state, hypoxemic insults from cardiopulmonary bypass or the perioperative period for congenital heart surgery, trauma, neardrowning, cranial irradiation, toxic exposures, and many other etiologies. Clearly, it is important to understand fully the patient's history and level of functioning and communication; thus the parent or other caregiver is essential in the preoperative evaluation and preparation and approach to the anesthetic. Developmentally delayed adolescents present for a variety of procedures, including dental care, orthopedic procedures, brain imaging, and many others. Having the parent present during IV placement or mask induction of anesthesia may be extremely helpful. Premedication, either oral (benzodiazepines, barbiturates) or intramuscular (ketamine or midazolam), may be necessary to accomplish induction of anesthesia in large, unco-operative, developmentally delayed adolescents.

## **Obesity in the adolescent**

Obesity in children and adolescents is defined in a variety of ways, but one commonly used definition is that of the US Centers for Disease Control: a Body Mass Index (BMI) above the 95th percentile for age, as defined by the 2000 CDC growth charts for normal children [73].

Using this definition, the prevalence of adolescent obesity has increased dramatically in the US between 1976-80 and 2007-08, from 5.0% to 18.1% in patients aged 12-19 years (Fig. 22.5). For boys and girls respectively, this corresponds to a BMI of 24-25 at age 12, 27-28 at age 15, and 29-30 at age 18. Morbid obesity is often defined in adults as a BMI >40. Epidemiological studies suggest that over 90% of cases of adolescent obesity are not accompanied by an underlying medical condition or syndrome but primarily represent excess intake of calories, relative lack of physical activity, and often social/ psychological factors, genetic and environmental factors, and possibly a deficiency of the hormone leptin in some cases. About 5% of obese adolescents have an accompanying genetic syndrome, including Prader-Willi and Laurence-Moon-Biedl (a glycogen storage disease), or medical cause such as chronic corticosteroid administration, or physical inactivity, such as accompanies severe muscular dystrophy [74].

Obesity is a complex endocrine state in which the adipose tissue communicates with the brain and peripheral tissues by releasing hormones and cytokines, such as leptin, C-reactive protein (CRP), IL-6, tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), lipoproteinlipase, renin, and adiponectin. Significant obesity leads first to insulin resistance and, if well established, to the metabolic syndrome, which

**Figure 22.5** Prevalence of obesity by race/ethnicity: United States, 1988–1994 and 2007–2008. (A) Boys aged 12–19 years. (B) Girls aged 12–19 years. Reproduced from National Center for Health Statistics [73] with permission from CDC.

consists of central obesity, hyperinsulinemia, systemic hypertension, and hypertriglyceridemia. Obesity is a chronic inflammatory state. Multisystem complications of obesity include respiratory (asthma, obstructive sleep apnea, atelectasis, hypoxemia), cardiovascular (systemic hypertension, left ventricular hypertrophy, pulmonary hypertension), endocrine (insulin resistance and type 2 diabetes, polycystic ovary syndrome), gastrointestinal (delayed gastric emptying, gastroesophageal reflux, nonalcoholic fatty liver disease), and psychological (depression, poor body image, loss of self-esteem) problems. Diet and behavioral therapy are always attempted, but achieve variable success rates. Drug therapy is sometimes attempted (orlistat to reduce fat absorption). Bariatric surgery is increasingly recommended for morbid obesity in older adolescents after other measures have failed (see below).

Overweight adolescents present for surgery and anesthesia for a range of disorders, including Blount disease or tibia vara and slipped capital femoral epiphysis [75], cholecystectomy from cholesterol-induced cholelithiasis, tonsillectomy for obstructive sleep apnea, and bariatric surgery. Preoperative evaluation must carefully search for co-morbid disease, especially obstructive sleep apnea (OSA). Some adolescents require BiPAP, especially at night.

Obesity is a known significant risk factor for OSA. See Chapter 31 for a detailed discussion of the perioperative patient with OSA. If the patient is managed with BiPAP, BiPAP should be reinstituted in the postanesthesia recovery area if the trachea is extubated, and BiPAP should be maintained until the patient is awake and can maintain a patent airway. Patients with moderate or severe OSA should be admitted to hospital after anesthesia, even after a minor procedure, and may require intensive care unit (ICU) observation [76,77]. Severe pulmonary hypertension merits very careful planning of the anesthetic in consultation with the patient's cardiologist or pulmonologist; ICU admission should be arranged for these patients prior to surgery. See Chapter 25 for anesthetic management of patients with pulmonary hypertension. Airway management may also be complicated by adipose tissue in the tongue, pharynx, and neck, which can collapse with decreased muscle tone and cause airway obstruction. Most often, this can be managed with an oral airway and mask ventilation. In the vast majority of obese teens, mask ventilation, direct laryngoscopy, and tracheal intubation are not difficult. See Chapter 14 for a discussion of management of the difficult airway. Vascular access may be difficult in obese adolescents but it is often possible to place a small peripheral intravenous catheter preoperatively (often in the ventral surface of the wrist) and a larger intravenous catheter after induction of anesthesia. Gastroesophageal reflux disease is common in obese teenagers. Consideration can be given to prophylaxis for gastroesophageal reflux if the patient is not already on therapy, including oral clear antacids, intravenous histamine-2 blocking agents, and gastrointestinal motility agents.

Intravenous drug dosing is problematic and there are no clear data offering definitive guidance on administering drug doses based on actual versus ideal bodyweight; this may be different for lipophilic drugs such as propofol and ionized drugs such as non-depolarizing muscle relaxants. Often the best practice is to start with doses based on ideal bodyweight and titrate additional doses based on the individual patient's pharmacodynamic response (see Chapter 15).

#### Bariatric surgery in the adolescent

In the mature, morbidly obese adolescent, when diet, exercise programs, and behavioral interventions have failed, there is increasing evidence that bariatric surgery effectively increases weight loss and reverses significant co-morbidities, including type 2 diabetes, OSA, nonalcoholic fatty liver disease, pseudotumor cerebri, quality of life, and depression [78]. Selection criteria for this Table 22.2 Selection criteria for bariatric surgery in adolescents

BMI (kg/m²)	Co-morbidities
>35	Serious: Type 2 diabetes mellitus, moderate or severe obstructive sleep apnea (AHI >15 events/h), pseudotumor cerebri, and severe steatohepatitis
>40	Other: Mild obstructive sleep apnea (AHI ≥5 events/h); hypertension, insulin resistance, glucose intolerance, dyslipidemia, impaired quality of life or activities of daily living, among others
Eligibility criteriaª	
Tanner stage	IV or V (unless severe co-morbidities indicate WLS earlier)
Skeletal maturity	Completed at least 95% of estimated growth (only if planning a diversional or malabsorptive operation, including RYGB)
Lifestyle changes	Demonstrates ability to understand what dietary and physical activity changes will be required for optimal postoperative outcomes
Psychosocial	Evidence for mature decision making, with appropriate understanding of potential risks and benefits of surgery
	Evidence for appropriate social support without evidence of abuse or neglect
	If psychiatric condition (e.g. depression, anxiety, or binge eating disorder) is present, it is under treatment
	Evidence that family and patient have the ability and motivation to comply with recommended treatments pre- and postoperatively, including consistent use of micronutrient supplements. Evidence may include a history of reliable attendance at office with for which
	management and compliance with other medical needs

AHI, apnea-hypopnea index; RYGB, Roux-en-Y gastric bypass; WLS, weight loss surgery.

<sup>a</sup>All of the eligibility criteria must be fulfilled.

Reproduced from Pratt et al [78] with permission from Nature.

surgery are very important, and all must be met before offering bariatric surgery to adolescent patients. (Table 22.2). The most important criteria are BMI >35 with serious co-morbidities, or >40 with milder comorbidities, skeletal maturity, and stable and mature psychosocial evaluation, with parental support and high likelihood of compliance with diet and medical followup regimens. A multidisciplinary team evaluation consisting of gastroenterologists, dieticians, nurse specialists, surgeons, psychologists, and social workers is the standard of care.

Several forms of bariatric surgery have evidence of positive outcomes and low complication rates in adolescents (Fig. 22.6). The first was the Roux-en-Y gastric bypass that was initially performed as an open procedure but is now performed laparoscopically by experienced surgeons. This operation involves creation of a small gastric pouch of 10-30 mL, division of the small intestine and creation of a jejunojenostomy, and finally connection of the gastric pouch to the Roux limb (gastrojejunostomy). Most of the stomach is bypassed, and weight loss occurs mostly through restriction of caloric intake from the small gastric pouch. It is intended as a one-time intervention. In recent adolescent case series, there were no perioperative deaths and fewer complications than in adults. The second operation is the adjustable gastric band, also performed laparoscopically, which involves placing an inflatable silicone band with an inner inflatable balloon around the top of the stomach; this creates a virtual gastric pouch 1-2 cm below the gastroesophageal junction. A catheter leads from the balloon to an implanted subcutaneous pouch, which allows adjustment of balloon size by adding or removing saline. The US Food and Drug Administration has not approved this device for patients under the age of 18. Therefore, any use of the device in adolescent patients should be done in the context of Investigational Device Exemption studies for the purposes of reporting clinical safety and outcomes [79]. In recent adolescent series, complication rates were 6–10%, with no deaths. Reoperation rates, including band removal, were 8–10%. Other operations, such as biliopancreatic diversion, with or without duodenal switch, or laparoscopic sleeve gastrectomy, are not recommended in adolescents.

# Conclusion

Adolescence is a time of rapid growth and change, and a number of anesthetic challenges occur that are unique to this age group. Knowledge of physiological and psychosocial development and of the disease processes and procedures common in these patients is important to maximize favorable outcomes. A direct, honest, positive approach to these patients that is distinct from that

**Figure 22.6** (A) The Roux-en-Y gastric bypass procedure involves creating a stomach pouch out of a small portion of the stomach and attaching it directly to the small intestine, bypassing a large part of the stomach and duodenum. Not only is the stomach pouch too small to hold large amounts of food, but by skipping the duodenum, fat absorption is substantially reduced. Reproduced from National Library of Medicine [80] with permission from the National Institutes of Health. (B) Adjustable gastric band. Restrictive gastric operations, such as an adjustable gastric banding procedure, serve only to restrict and decrease food intake and do not interfere with the normal digestive process. In this procedure, a hollow band made of special material is placed around the stomach near its upper end, creating the small pouch and a narrow passage into the larger remaining portion of the stomach. This small passage delays the emptying of food from the pouch and causes a feeling of fullness. The band can be tightened or loosened over time to change the size of the passage. Initially, the pouch holds about 1 ounce of food and later expands to 2–3 ounces. Reproduced from National Library of Medicine [81] with permission from the National Institutes of Health.

of the younger child, yet empathetic to the adolescent's developmental stage and disease process, is usually greatly appreciated by these patients and their parents. This approach also facilitates establishing trust with the anesthesiologist in the often brief time for preoperative evaluation and preparation. Transition of patients with chronic pediatric diseases, such as congenital heart disease and cystic fibrosis, to adult care is variable, but the pediatric anesthesiologist should be prepared to care for young adults with these conditions.

#### CASE STUDY

The patient was a 16-year-old girl presenting for laparoscopic Roux-en-Y gastrojejunostomy. Current BMI was 47.8 (165 cm tall, 130 kg). In reviewing her growth charts, the patient had been above the 99th percentile on the US Centers for Disease Control 2000 growth charts since age 10 and had attempted diet and behavioral therapy for the past 4 years without success. Co-morbidities included type 2 diabetes treated with metformin, gastroesophageal reflux disease treated with pantoprazole, OSA with apneahypopnea index of 9 (moderately severe OSA) on sleep study that was treated with BiPAP 10 cm at night by nasal mask. She also had early polycystic ovary syndrome, with facial acne and mild hirsutism. After a full evaluation by the bariatric surgery team, including a psychological evaluation, full explanation of the procedure and follow-up required, and signed contract by the patient and parents to adhere to the follow-up guidelines, the patient was accepted for surgery. She had not had anesthesia or surgery previously, there was no family history of anesthetic problems, and there were no medication allergies. She did not smoke, drink alcohol or use illegal drugs. Menses were irregular, with her last menstrual period occurring 6 weeks prior to surgery.

Physical examination revealed an alert, anxious, morbidly obese teenager. Room air SpO2 was 94% without BiPAP, heart rate 80 beats per minute, respiratory rate 16 breaths per minute, and arterial blood pressure 145/86. Airway examination revealed a Mallampati Class II examination, full range of neck motion, and intact dentition. Lung examination revealed no respiratory distress, distant clear breath sounds, and decreased breath sounds at both bases. Cardiac examination revealed regular rate and rhythm and no murmurs. Peripheral veins were difficult to identify. Preoperative laboratory values included hemoglobin 14g/dL, hematocrit 42%, white blood cell count 8500/mm<sup>3</sup> with a normal differential white count. Electrolytes were normal, blood urea nitrogen 18 mg/dL, creatinine 1.0 mg/dL, and fasting blood glucose 125 mg/ dL. The urine human chorionic gonadotropin test was negative. Chest radiograph revealed mild cardiomegaly and clear lung fields, with the exception of some volume loss at both bases. The patient was informed of the anesthetic procedures and that the plan would be to extubate her trachea in the operating room when she was awake and able to follow commands and that she would have her BiPAP reinstituted in the postanesthesia care unit (PACU). Furthermore, she was told that she would have patientcontrolled analgesia (PCA).

A 20 gauge peripheral IV was started in the dorsum of the left hand on the second attempt. Metformin had been discontinued 2 days preoperatively. Oral sodium citrate and IV metoclopramide and pantoprazole were given in the holding area, along with IV midazolam 2mg, which provided anxiolysis. The patient was transported to the operating room (OR) where she was positioned on the OR table with a foam wedge under the back and shoulders to optimize airway alignment. Difficult airway adjuncts were available in the OR, including a videolaryngoscope, large adult intubating laryngeal mask airway, and a fiber-optic bronchoscope. After application of standard monitors and preoxygenation for a full 5 min, IV induction of anesthesia was achieved with fentanyl 100 µg and propofol 150 mg IV, which was 2 mg/kg, based on an ideal bodyweight of 75kg. Her eyelash reflex was lost in 45 sec and mask ventilation was easy once an oral airway was inserted. Rocuronium 80mg was given to facilitate tracheal intubation, which was accomplished easily using a MacIntosh 3 blade. The view was a grade I Cormack and Lehane view of the larynx. Anesthesia was maintained with desflurane, 6-12% end-tidal concentration. Positive end-expiratory pressure of 8 cmH<sub>2</sub>O was used to prevent atelectasis, and the patient's lungs were ventilated with tidal volumes of 750 mL and an FIO<sub>2</sub> of 0.5. An air-oxygen mixture was used to achieve an SpO<sub>2</sub> of 95-98% during the surgery. An 18g IV was placed after induction of anesthesia.

Laparoscopic Roux-en-Y-gastrojejunostomy proceeded via five separate incisions for ports and instruments, and sufficient  $CO_2$  was insufflated to achieve an intraperitoneal pressure of 15–20 cmH<sub>2</sub>O. The patient was hemodynamically stable throughout the procedure; minute ventilation had to be increased during the  $CO_2$  insufflation to achieve end-tidal  $CO_2$  of 35–40 mmHg. This was done by increasing the respiratory rate. After 3h and 15 min of operating time (estimated blood loss 15mL) and achieving an excellent surgical result and hemostasis, the incisions were closed *Continued* 

after infiltrating the fascia, subcutaneous tissue, and skin with a total of 30 mL of 0.25% bupivacaine. Ketorolac 30 mg IV, morphine 6 mg IV, and ondansetron 4 mg IV were given during the last hour of the procedure. Neuromuscular blockade was reversed and the patient's respirations were assisted with pressure support ventilation of  $15 \text{ cmH}_2\text{O}$ .

When she was awake, following commands, and taking unassisted tidal volume breaths of 500 mL or more, the trachea was extubated with the patient in semi-Fowler position with her head elevated 45°. Ventilation was assisted with facemask CPAP, achieving good tidal volumes and SpO<sub>2</sub> of 94–96% without distress. She was then transported to the PACU, where her BiPAP was instituted at end-expiratory pressure of 10 cmH<sub>2</sub>O, and inspiratory pressures of 15 cmH<sub>2</sub>O. Patient-controlled analgesia with morphine was instituted in the PACU without a basal rate and with a PCA dose of 1.5 mg morphine with 10 min lockout interval. Ketorolac 30 mg IV Q 6h × five additional doses, and ondansteron were also ordered. Pneumatic sequential compression stockings for deep vein thrombosis prophylaxis were fitted in the PACU.

After 2h of monitoring in the PACU, with several visits by the anesthesiologist to ensure satisfactory airway, pulmonary, and pain control status, the patient was transferred to an intermediate care monitored unit. She was mobilized out of bed and into a chair on the night of surgery, and every 4h during the first postoperative day. Incentive spirometry exercises commenced the first night after surgery. On the second postoperative day, she was assisted out of bed every 4h and walked around her room. Pain control was adequate, with visual analog scale scores 3–5 on a 10-point scale (10 is maximum), with a total of 22.5 mg morphine used during the first 24h. Respiratory status was adequate, with no episodes of OSA or oxygen desaturation below an SpO<sub>2</sub> of 90%. After 24h she was able to discontinue the BiPAP while awake, thereafter using it only while sleeping. Clear liquid intake and metformin and pantoprazole were commenced orally on postoperative day 1. Serum glucose was adequately controlled at 120– 200 mg/dL. She was discharged to the surgical ward on postoperative day 3, transitioned to oral pain medication with acetaminophen/hydrocodone oral solution, and discharged home on postoperative day 4.

At 6-month follow-up the patient was doing well, had lost 25kg, and was compliant with her diet regimen and clinic follow-up visits. Her blood pressure had decreased to 130/80 mmHg. Her endocrinologist was considering discontinuing the metformin.

#### Conclusions

This case illustrates the principles of preanesthetic evaluation of morbidly obese teenage patients and the comorbidities they suffer, including OSA and type 2 diabetes. Careful preoperative preparation for a possible difficult airway, gastrointestinal prophylaxis preoperatively to prevent aspiration of acid gastric contents, and proper patient positioning to facilitate laryngoscopy allowed appropriate airway management. Dosing lipid-soluble induction agents (propofol) based initially on ideal bodyweight, maintaining functional residual capacity with positive end-expiratory pressure during laparoscopy and CO<sub>2</sub> insufflation, using an insoluble anesthetic gas (desflurane) to minimize uptake by adipose tissue that would delay emergence from anesthesia, minimizing intraoperative opioids, using local anesthesia and non-steroidal antiinflammatory agent, extubating the trachea with the patient awake, and instituting BiPAP immediately after tracheal extubation helped avoid obstructive apnea and hypoxemia. A pain management regimen of PCA without a basal rate, continued ketorolac administration, and early mobilization and ambulation all aided in avoiding pulmonary and airway morbidity in this patient.

# Introduction

Anesthesia for neurosurgery presents an interesting challenge to the anesthesiologist [1]. One has little control over the patient's primary lesion, but the selection of anesthetic technique and the recognition of perioperative events and changes may profoundly reduce or prevent significant morbidity. Current neuroanesthetic practice is based on the understanding of cerebral physiology and how it can be manipulated in the presence of intracranial pathology (see Chapter 7). The pediatric neuroanesthesiologist also must contend with the physiological differences in developing children. In addition to the common problems of administering anesthesia to the general pediatric population, special consideration must be given to the effects of anesthesia on the central nervous system (CNS) of children with neurological diseases. This chapter reviews the fundamentals of the clinical management in neurosurgical patients. Discussion of specific neurosurgical conditions and their respective anesthetic

management is designed to highlight the common and sometimes unique problems encountered by the pediatric neuroanesthesiologist.

# Neuropharmacology

#### **General principles**

Evidence from animals suggests that the lethal dose in 50% of the animals (LD50) for many medications is significantly lower in the neonatal and infancy periods than in adults [2]. The sensitivity of the human newborn to most of the sedatives, hypnotics, and opioids is increased, probably owing to increased brain immaturity (incomplete myelination and blood–brain barrier) and to increased permeability for some medications (i.e. the lipid-soluble drugs used in anesthesia) [3]. In addition, the effect of volatile anesthetic agents is influenced by the age of the patient. The minimal alveolar concentration (MAC)

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

<sup>© 2012</sup> Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

in the neonate (0–31 days) is much lower than in infants aged 30–180 days [4]. Although there is an increase in anesthetic requirements in infancy, it must be emphasized that there is a smaller margin of safety between adequate anesthesia and severe cardiopulmonary depression in the infant and child compared with the adult [5]. Therefore, drug dosages must be appropriately calculated and therapeutic effects must be monitored to avoid inadvertent adverse clinical consequences and prolonged effects.

#### Inhalational anesthetic agents

All currently used inhalational anesthetic agents have variable degrees of cerebrovascular effects. Historically used agents will not be discussed, in favor of focusing on those agents most widely used in current clinical practice.

#### Isoflurane

Isoflurane is the most popular of the volatile anesthetics for neuroanesthesia. Its popularity is based on the fact that it affects cerebral blood flow less than halothane at equivalent MAC doses [6] and on the belief that isoflurane may provide cerebral protection [7]. Recent studies have suggested multiple synergistic mechanisms by which isoflurane and other volatile agents succeed in providing neuroprotection [8].

Compared to other volatile anesthetics, isoflurane has less effect on cerebral vascular autoregulation [6] and cerebrospinal fluid (CSF) production/resorption [9]. Studies in children suggest that an end-tidal concentration of isoflurane between 0.5 MAC and 1.5 MAC did not change cerebral blood flow velocity and had minimal effects on the cerebrovascular reactivity to  $CO_2$  [10]. Furthermore, there were no time-response effects of 1 MAC isoflurane on cerebral blood flow velocity in anesthetized children [11–13]. Interestingly, despite their dissimilar effects on cerebral blood flow, both isoflurane and halothane have been shown to similarly increase intracranial pressure (ICP) in animal models of brain injury [14].

#### Sevoflurane

Sevoflurane is similar to isoflurane with regard to its effects on cerebral blood flow, cerebral metabolic rate of  $O_2$  (CMRO<sub>2</sub>) and ICP in adults [15]. In children, there appears to be no effect on cerebral blood flow during hypo- and normocapnia when 1 MAC concentrations of sevoflurane are used [16]. There was no difference between isoflurane and sevoflurane regarding their relative increases in ICP and reduction in arterial blood pressure resulting in clinically similar reduction in cerebral perfusion pressure [17]. Furthermore, it is suggested that sevoflurane has a protective effect during incomplete ischemia, compared with fentanyl and nitrous oxide techniques in rodents [18].

#### Desflurane

Desflurane increases cerebral blood flow and decreases CMRO<sub>2</sub> in animals. One MAC desflurane has been shown to increase ICP significantly in neurosurgical patients with supratentorial mass lesions, despite hypocapnia [19] although larger studies have not demonstrated this finding [20]. Data in children are limited, though Sponheim et al demonstrated only a modest rise in ICP and a greater reduction in blood pressure which resulted in a decrease in calculated cerebral perfusion pressure compared to isoflurane and sevoflurane [17]. This reduction in mean arterial pressure is perhaps most problematic for managing neurosurgical patients with obvious and subtle issues of increased ICP. Whether this makes intravenous anesthesia a safer option over volatile anesthesia remains a subject of debate [17].

#### Nitrous oxide

The effect of nitrous oxide (N<sub>2</sub>O) on cerebral circulation and its use in neuroanesthesia remain controversial. The reported variability of its effects on cerebral blood flow and ICP is probably due to differences in experimental species, background anesthesia and control of respiration. Subanesthetic doses of N<sub>2</sub>O (60-70%) cause excitement, cerebral metabolic stimulation, and increased cerebral blood flow [21]. In infants and children, Leon and Bissonnette showed that 70% N<sub>2</sub>O in oxygen with fentanyl-diazepam-caudal epidural anesthesia increased cerebral blood flow significantly compared with an air/ O<sub>2</sub> mixture [22]. This increase in cerebral blood flow was not associated with significant changes in mean arterial pressure (MAP), heart rate or cerebrovascular resistance. However, other studies have suggested a direct effect of N<sub>2</sub>O on increasing CMRO<sub>2</sub> in both animals and humans. Clinically, N<sub>2</sub>O has been shown to increase cerebral blood flow and ICP in adults and children [23-25], although the co-administration of intravenous agents (with or without induced hypocapnia) can mitigate these N2O-induced increases in cerebral blood flow [26,27]. In contrast, volatile agents can further increase cerebral blood flow [28]. Although N<sub>2</sub>O is commonly used in neuroanesthesia, it may be prudent to discontinue its administration if the brain is tight. Furthermore, because of its ability to increase CMRO2, it would be unwise to continue N2O administration when cerebral perfusion is reduced.

## Intravenous anesthetic agents Barbiturates

Barbiturates are a broad class of drugs that bind to the  $\gamma$ -aminobutyric acid (GABA) receptor on the  $\alpha$  subunit, creating sedation and amnesia. In addition, barbiturates reduce epileptiform activity, lower ICP, lower cerebral blood flow and reduce CMRO<sub>2</sub> in a dose-dependent

manner [29,30]. A major problem with barbiturates is that they can significantly reduce myocardial contractility, systemic arterial blood pressure, and cerebral perfusion pressure (CPP) [31]. In non-clinical doses (10–55 mg/kg), thiopental produces an isoelectric EEG and decreases the CMRO<sub>2</sub> by 50% [31]. Barbiturates can prevent an increase in ICP [32] during laryngoscopy and tracheal intubation owing to their ability to decrease cerebral blood flow. Cerebral autoregulation and cerebrovascular reactivity to  $CO_2$  are preserved with barbiturates. Production and reabsorption of CSF are not altered [33]. As mentioned, barbiturates are effective in controlling epileptiform activity, except methohexital, which may activate seizure foci in patients [34].

#### **Etomidate**

Etomidate is a carboxylated imidazole that binds to the GABA receptors, resulting in hypnosis and amnesia with a reduction of cerebral blood flow (34%) and CMRO<sub>2</sub> (45%) [35]. Etomidate appears to directly vasoconstrict the cerebral vasculature, even before the metabolism is suppressed [36]. Thus, administration of etomidate can potentially lower ICP by reducing cerebral blood volume while augmenting or maintaining CPP. Studies of etomidate administration have primarily been undertaken in adults while studies in children are limited. However, the clinical applicability of etomidate was perhaps best illustrated in a small clinical study of intubated pediatric patients with traumatic brain injury with elevated ICP (>20 mmHg for over 5 min). After intravenous etomidate administration, all patients had an increase in MAP from baseline, with a significant lowering of measured ICP and improvement in CPP [37]. Other studies have demonstrated that cerebrovascular reactivity to CO2 is maintained following administration of etomidate [35].

Although etomidate has a great advantage over other intravenous agents, like barbiturates, because of minimal cardiovascular depression, it has two significant disadavantages that limit its usage outside airway management: suppression of the adrenocortical response to stress, and increased myoclonic activity, especially after prolonged infusion [38].

#### Propofol

Propofol is a rapidly acting GABA agent that reduces cerebral blood flow and CMRO<sub>2</sub> [39]. Although administration of propofol either by bolus or infusion can reduce ICP, the cardiovascular effects of a dose-dependent reduction in MAP may have a net result of lowering CPP in the patient with traumatic brain injury [40]. Although CO<sub>2</sub> cerebrovascular responsiveness is maintained during propofol anesthesia, the observed reduction in cerebral blood flow and cerebral blood volume is not augmented by hyperventilation (end-tidal CO<sub>2</sub> <30 mmHg) in normal children [41]. Although routinely a part of neuroanesthetic management in children and adults, the use of propofol outside the operating room in critically ill pediatric patients is limited by concerns about morbidity and mortality related to propofol infusion syndrome [42].

#### **Benzodiazepines**

Benzodiazepines bind to the GABA receptor, resulting in amnesia and anxiolysis. In addition, benzodiazepine administration has been reported to decrease cerebral blood flow by a 25% decrease in CMRO<sub>2</sub>, reduce ICP, and slow seizure foci [43–45]. However, the sedating effects and relative short duration of action (compared to barbiturates) encourage their widespread usage in patients in both the operating room and intensive care unit. The benzodiazepine antagonist flumazenil has been demonstrated to reverse the beneficial effects of benzodiazepines on cerebral blood flow, CMRO<sub>2</sub>, and ICP. Consequently, administration of flumazenil should be undertaken with caution in neurological patients with high ICP, abnormal intracranial elastance, and/or a predisposition to seizure [46].

#### **Opioid analgesics**

The opioid agents have little or no effect on cerebral blood flow, CMRO<sub>2</sub>, and ICP [47]. However, if patients are experiencing pain, opioids cause a modest reduction in these variables through indirect effects on the sympathetic nervous system [48]. Fentanyl combined with nitrous oxide decreases cerebral blood flow and CMRO<sub>2</sub> by 47% and 18%, respectively [30]. Cerebrovascular reactivity to CO<sub>2</sub> and cerebral autoregulation are preserved with opioids. Finally, fentanyl has no effect on CSF production, but it reduces CSF reabsorption by at least 50% [49]. Fentanyl has no effects on the cerebral circulation of neonatal animals, but alfentanil increases CSF pressure in patients with brain tumors [50]. This effect was less than that observed with sufentanil but greater than that observed with fentanyl. Alfentanil has the greatest effect on MAP and CPP [51]. Some studies reported a decrease in cerebral blood flow and CMRO<sub>2</sub> [52] whereas others suggested an increase in cerebral blood flow and ICP [53]. Remifentanil, with an ultra-short elimination half-life, offers the advantage over other opioids of not delaying perioperative neurological assessment [54]. Equipotent infusions of remifentanil and fentanyl were studied in patients undergoing supratentorial tumor surgery in combination with a balanced inhalational anesthetic. Remifentanil appeared to have the same preservative effects as fentanyl on cerebral blood flow (CBF) and cerebrovascular reactivity [55,56].

#### Ketamine

Ketamine is a mixed N-methyl-D-aspartate (NMDA) receptor agonist/antagonist that causes a dissociative

anesthetic state [57]. The effect of ketamine on the cerebral vasculature appears to create potent cerebral vasodilation capable of increasing cerebral blood flow by 60% in normocapnic humans, and thus an increase in ICP [58]. Studies have reported clinical deterioration in patients with increased ICP after ketamine administration [32]. Despite alterations in cerebral tone and CBF, ketamine has a negligible effect on the CMRO<sub>2</sub>. Although it is suggested that ketamine may have some cerebral protective effects, recent studies in animal models of brain development have shown that it increases neuronal apoptosis even in the absence of brain injury [59]. Regardless, the use of ketamine is generally contraindicated in neuroanesthesia.

#### Dexmedetomidine

Dexmedetomidine, an  $\alpha$ 2-adrenergic agonist, causes a unique kind of sedation, acting on the subcortical areas, which resembles natural sleep without respiratory depression. The most common cardiovascular effects are bradycardia and transient hypotension [60]. All effects are typically responsive to slowing the infusion and/or bolusing fluid with or without a vagolytic (i.e. atropine). Experimental data demonstrate both cerebral vasoconstriction and vasodilation, depending on the model and dose studied [61]. In clinically relevant dosages that produce sedation, dexmedetomidine has been shown to reduce CBF in humans and animals unrelated to hemodynamic changes.

In early animal investigations, CMRO<sub>2</sub> was unchanged, suggesting the possibility of increasing cerebral vascular resistance [62]. However, additional studies in humans and animals demonstrate that dexmedetomidine maintains a decrease in CBF proportional to its effect on decreasing CMRO<sub>2</sub>. Further, it appears that CO<sub>2</sub> reactivity of the cerebral vasculature is unaffected by dexmedetomidine. In a study of healthy adults, the relative middle cerebral artery blood flow velocity to CBF and CMRO<sub>2</sub> relationship was unchanged following dexmedetomidine administration [63]. Using clinically relevant doses, the authors confirmed that dexmedetomidine decreases CBF and CMRO<sub>2</sub> proportionally in healthy humans. In adult patients with brain injury, it appears that dexmedetomidine is more effective than propofol in causing sedation while providing functionality [64].

Clinical experience with dexmedetomidine use in functional neurosurgery is limited to small case series [65]. However, these reports suggest that use of dexmedetomidine does not appear to interfere with electrophysiological monitoring, and have permitted brain mapping during awake craniotomy and microelectrode recording during implantation of deep brain stimulators in adults [66] and children [67]. Studies are under way to investigate the pharmacokinetics and pharmacodynamics of dexmedetomidine in infants and children.

#### **Muscle relaxants**

Muscle relaxants have little effect on cerebral circulation.

#### Succinylcholine

Succinylcholine produces an initial reduction in ICP followed by a rise, especially in patients with decreased intracranial compliance resulting from increased cerebral blood flow [68,69]. The increase in ICP is probably related to cerebral stimulation caused by increases in afferent muscle spindle activity [70]. The increase in ICP and cerebral blood flow with succinylcholine is reduced by prior administration of deep general anesthesia or by precurarization [71]. However, the benefits to pediatric patients with increased ICP from rapid control of the airway and hyperventilation offset the slight increase in ICP caused by succinylcholine. It is important to remember that lifethreatening hyperkalemia may occur after administration of succinylcholine to patients with closed head injury even though they do not have conditions classically associated with this adverse effect, including motor deficits, severe cerebral hypoxia [72], subarachnoid hemorrhage [73], cerebrovascular accident with loss of brain substance [74], and paraplegia [75].

#### Rocuronium

Rocuronium offers an alternative to succinylcholine for rapid-sequence intubation but it does delay the return of spontaneous respiration and neurological assessment provided by succinylcholine [76,77]. However, the availability of sugammadex in some countries, including the European Union and Japan, for reversal of neuromuscular blockade by non-depolarizing agents may make this issue moot [78,79]. Like the other neuromuscular blocking agents, rocuronium has no effect on cerebral blood flow or hemodynamics [80].

#### Pancuronium, atracurium, and cis-atracurium

These agents have no effect on cerebral blood volume, ICP or CMRO<sub>2</sub> in the presence of volatile anesthetics [81]. Large doses of *d*-tubocurarine, atracurium or metocurine may release histamine and cause transient cerebrovascular dilation, which could account for a slight increase in ICP. However, a slight decrease in MAP may offset any change in intracerebral blood volume [82]. Use of *cis*-atracurium should not result in histamine release, and has demonstrated improved cardiovascular stability. In addition, the metabolism of the agent by Hoffman degradation allows for its rapid clearance in patients with impaired renal and hepatic function [83]. Studies in healthy adults have shown that rocuronium and *cis*-atracurium have no effect on cerebral blood flow [80].

#### Vecuronium

Vecuronium is known for its cardiovascular stability and its relatively short duration of action. In patients with reduced intracranial compliance, vecuronium slightly decreased ICP, probably because there was a concomitant decrease in central venous pressure (CVP) [84].

# **General anesthetic considerations**

The following sections discuss the anesthetic management of pediatric neurosurgical procedures. Topics common to most procedures are reviewed first, followed by discussion of specific considerations and surgical procedures.

# Preoperative assessment of the neurosurgical patient

In recent years, increased understanding of cerebral pathophysiology and improved diagnostic imaging techniques have improved the preoperative assessment of neurosurgical patients. However, the cornerstones of assessment of cerebral function are still the history and physical examination. The preoperative anesthetic work-up of the neurosurgical patient includes an assessment of ICP, assessment of the function of vital respiratory and cardiovascular centers that can be affected by neuropathological processes, either in the brainstem or in the spinal cord, and assessment of the specific disturbances in neurological function [85].

Of primary importance is the preoperative recognition of intracranial hypertension and major neurological deficits.

The history and physical findings of intracranial hypertension differ somewhat according to the age group. In general, the clinical presentation of patients with intracranial hypertension varies with the duration of increased ICP. Sudden massive increases in ICP often cause coma. In a less acute case, however, there may be a history of headache on awakening, suggestive of vasodilation caused by sleep-induced hypercapnia and reduced intracranial compliance. Vomiting is a common sign. Neonates and infants often present with a history of increased irritability, poor feeding or lethargy. A bulging anterior fontanelle, dilated scalp veins, cranial enlargement or deformity, and lower extremity motor deficits are also common signs of increased ICP in this age group [86]. Increased ICP in children is frequently caused by a tumor. As ICP reaches critical levels, vomiting, decreased level of consciousness, and evidence of herniation may develop.

Other symptoms include diplopia due to oculomotor or gaze palsies (sunset sign), dysphonia, dysphagia, and/or gait disturbances. Injury to the third cranial nerve may result in ptosis. Injury to the sixth cranial nerve produces a strabismus caused by loss of abduction. Nausea and vomiting usually occur, and older children complain of morning headache. Papilledema and absent venous pulsation of the retinal vessels may be seen on fundoscopy.

Neurogenic pulmonary edema is a syndrome that includes acute hypoxia, pulmonary congestion, pink, frothy, protein-rich pulmonary edema, and radiological evidence of pulmonary infiltrates [87]. It is associated with a variety of intracranial pathological occurrences, including hemorrhage [88], head trauma [89], and seizures [90]. The mechanisms responsible for activating the sympathetic nervous system and the vagal centers, which lead to pulmonary edema, are related to ischemia of the medulla and distortion of the brainstem [91]. Cranial nerve function and the patient's ability to protect the airway must be evaluated. During the preoperative assessment, the possibility of spinal cord dysfunction must be determined. Neurological dysfunction arising from cervical spinal cord injury may affect the respiratory and cardiovascular centers (see below).

Laboratory tests may yield evidence of the syndrome of inappropriate antidiuretic hormone (SIADH) and of electrolyte abnormalities or volume contraction from protracted vomiting. Diabetes insipidus may result in hypernatremia [92]. Disturbances in metabolism, such as hypo- or hyperglycemia, may be present. The preoperative history and chart review may reveal that the patient is receiving steroids to reduce tumor edema. If so, steroids will be required during surgery. Neurosurgical patients may be receiving anticonvulsant medication either to treat seizures or to prevent them. These drugs may have profound effects on the metabolism of other drugs (e.g. barbiturates, narcotics). Patients with suprasellar tumors, such as craniopharyngioma, frequently have pituitary dysfunction and should have a complete endocrine evaluation before surgery.

Skull radiographs, ultrasonography, computed tomography (CT) scan, and magnetic resonance imaging (MRI) aid in the assessment of intracranial hypertension. Skull radiographs may show the "beaten copper sign" and widening of the sagittal sutures in response to chronic increased ICP and universal suture stenosis. In infants and young children, the width of the cranial sutures should not exceed 2mm, and they should not have bridges or closures [93]. Ultrasonography of the brain is useful in premature infants and neonates because it is relatively inexpensive, does not require sedation, and can be performed at the bedside through the fontanelle. The real-time sector scanner can visualize virtually all parts of the brain [94]. The development of CT scan and MRI has revolutionized the investigation of brain disease.

## Premedication

The routine use of sedation in pediatric neurosurgical patients is best avoided. If sedatives and opioids are given, the patient must be closely monitored because the drugs may precipitate respiratory depression, hypercarbia, loss of airway integrity, and increased ICP. Exceptions to this rule include patients with intracranial vascular lesions (with no increase in ICP) who may benefit from sedation to reduce the likelihood of precipitating a preoperative hemorrhage. Sedation can be accomplished in small children with pentobarbital 4mg/kg or chloral hydrate 50 mg/kg administered orally or rectally 1h before surgery. Emotional preparation is essential and is accomplished by the anesthesiologist and the parents working together. In older children, a simple explanation of what to expect before induction of anesthesia will reduce the element of surprise and the incidence of hemodynamic responses in a threatening environment.

#### Patient positioning

Planning of a successful anesthetic includes the preparation of the operating table with proper equipment to protect the patient after positioning. The anesthesiologist's preoperative visit should provide information on patient positioning during surgery.

Although patient positioning varies according to the neurosurgical procedure, the general principles remain the same. The eyes must be securely taped closed and, if the patient is prone, the face and other vulnerable areas must be padded to prevent localized pressure. Since ventilation may be compromised by incorrect positioning, it is mandatory to ensure that chest excursion remains adequate, especially when the patient is prone. This can be achieved by using suitable bolsters or a frame that allows the abdomen to be pendulous and facilitates respiratory movement during intermittent positive pressure ventilation. The endotracheal tube (ETT) should be taped securely in place; in the prone position, secretions may loosen the tape. A 10° head-up position is usually advisable to improve cerebral venous return and reduce venous congestion. Rotation of the head to one side may kink the jugular veins and reduce venous return. This kinking can be avoided by rotating the trunk to maintain the axial position.

During any surgical procedure, it is important for the anesthesiologist to be able to inspect the ETT and circuit connection and to have access to the ETT for possible endotracheal suctioning. In addition, it is desirable to have a body part, such as a hand or foot, visible during surgery so that peripheral perfusion and color can be readily assessed.

#### Monitoring

Basic monitoring consists of a precordial/esophageal stethoscope, electrocardiography (ECG), a non-invasive blood pressure measuring device, a temperature probe, a pulse oximeter, and capnometry. In addition, a radial pulse Doppler allows continuous monitoring of peripheral perfusion on a beat-to-beat basis and provides a noninvasive measurement of blood pressure. The Doppler device is especially useful in neonatal anesthesia. A peripheral nerve stimulator for monitoring neuromuscular blockade is desirable. A urinary catheter is required for long surgical procedures and is mandatory if osmotic diuretics are administered.

#### Induction of anesthesia General principles

Anesthesia for pediatric neurosurgical procedures often presents a challenge to the anesthesiologist [17]. The anesthetic technique chosen and recognition of perioperative events may have profound effects on morbidity. Pediatric patients range from premature neonates to 18-year-old young adults. Knowledge of normal physiology in these differing age groups is essential. Neonatal anesthesia differs from that in the older child and adult, particularly with regard to the respiratory system, the cardiovascular system, and thermoregulation.

Anesthesia for patients with elevated ICP is fraught with danger. After induction of anesthesia, rapid tracheal intubation and hyperventilation will lower the ICP. The systemic hypertension associated with laryngoscopy may be avoided by giving IV lidocaine at induction of anesthesia. Rapid-sequence induction of anesthesia with thiopental, atropine, lidocaine, and succinylcholine, followed by carefully applied cricoid pressure and manual hyperventilation, is recommended [95]. An alternative is a modified rapid-sequence technique with large-dose rocuronium or vecuronium substituted for succinylcholine. With appropriate cricoid pressure, manual ventilation can be performed without distension of the stomach. Cricoid pressure reduces the likelihood of aspirating gastric contents; delayed gastric emptying is often associated with increased ICP. The rapid rate at which succinylcholine produces satisfactory intubation conditions outweighs the small increase in ICP that it causes. Consequently, succinylcholine is routinely used in pediatric neuroanesthesia. Rocuronium 1-1.2 mg/kg produces intubation conditions comparable to succinvlcholine [76]. In patients without ready IV access, anesthesia can be induced via a small butterfly needle, which can be inserted with minimal patient stress or hemodynamic fluctuation. Failing this, it is probably less injurious to children with raised ICP to perform a skillful inhalation induction of anesthesia than it is to subject them to a difficult IV

placement. Anesthesia is best maintained with nitrous oxide in oxygen, isoflurane, and a suitable muscle relaxant. Intermittent positive pressure mechanical ventilation is provided. Hypoventilation and hypercarbia are best avoided. An IV opioid can be used in children. Deep levels of anesthesia are not needed and are contraindicated.

# Fluid management and intracranial pressure control

#### Fluid management

Fluid administration to neurosurgical patients depends on the pathology or brain insult being treated. A frequent result of these insults is the development of brain edema, with a resultant increase in ICP. It is essential for the neuroanesthesiologist to understand the principles of fluid movement in the injured brain in order to administer the proper fluid regimen.

Edema formation occurs when there is inequality of net movement of fluid between the intra- and extracellular compartments. Edema is the result of pressure gradients between the hydrostatic, osmotic, and colloid oncotic pressures and the properties of the barrier that separates them. The blood-brain barrier is composed of capillary endothelial cells, which are connected in continuous fashion by tight junctions. This system forms a barrier that excludes polar hydrophilic molecules. The endothelium of the brain differs from that of the rest of the body. In most noncentral neural tissue, the tight junction between endothelial cells is 65 angstroms in diameter, whereas it is 7 angstroms in the CNS. In the brain, the size of these junctions is sufficiently small to prevent sodium from traversing them freely. Essential molecules, such as glucose and amino acids, cross the blood-brain barrier by energy-mediated transport systems. Only water freely communicates with both sides of the membrane. This passive movement of water is regulated by oncotic, osmotic, and hydrostatic pressure changes across the barrier. The colloid oncotic pressure is a relatively weak driving force. A reduction of 50% of the colloid oncotic pressure (normal 20 mmHg) results in a pressure gradient across the membrane, which is less than that caused by a transcapillary osmolarity difference of 1mOsm/L. A reduction in the colloid oncotic pressure of the brain does not have the same impact as that observed in the bowel. This is because the brain's extracellular space is poorly compliant, due to its network of glial cells, and discourages edema formation, even in the presence of a severe colloid oncotic pressure gradient. Administration of Ringer's lactate alone will lead eventually to hemodilution and reduced plasma osmolarity (osmolarity 273 mOsm/L), which would encourage cerebral edema [96].

The choice of fluid must be dictated by the neuropathological process involved. It should maintain an isovolemic, iso-osmolar, and relatively iso-oncotic intravascular volume. For example, a patient with increased ICP and/ or a brain mass requires a fluid regimen that balances adequate intravascular volume against efforts to dehydrate the brain mass. In a patient undergoing insertion of a ventricular shunt and/or repair of myelomeningocele, fluid management should replace third-space losses.

An osmolar gradient can be maintained only in areas where the blood-brain barrier is intact. Under normal circumstances, osmotic diuretics and plasma expanders, such as albumin, are excluded. Unfortunately, areas that might benefit the most from dehydration therapy, such as tumor edema, exhibit blood-brain barrier incompetence. Agents of high osmolality move into these tissues and increase the edema.

Efforts to dehydrate the brain are complicated by the need to maintain adequate circulating blood volume. In many neurosurgical procedures, a substantial portion of the blood loss is onto the drapes and is difficult to measure. Furthermore, the use of large amounts of irrigation solution makes it impossible to assess blood loss accurately. The initial phase of any neurosurgical procedure produces blood loss, especially scalp incisions. Infiltration of the scalp with bupivacaine 0.125% with 1:200,000 epinephrine reduces blood loss and reduces hemodynamic responses (increased heart rate and blood pressure) during incision [97]. In all cases, bupivacaine blood levels were within the therapeutic range. Resection of a vascular malformation may require massive volume replacement. Placing large-bore IV catheters and having available sufficient blood products are part of appropriate planning for anesthesia and surgery. Urine output in the face of aggressive diuresis is a misleading indicator of adequate volume replacement. In this instance, CVP monitoring is very useful.

There is no perfect protocol for fluid replacement in neurosurgical patients with increased ICP. However, maintenance of cerebral perfusion should represent the optimal goal of fluid therapy. Most anesthesiologists start osmotic diuretic therapy at the beginning of anesthesia and measure the resulting urine output. As surgery and blood loss progress, volume replacement usually consists of a mixture of crystalloid and colloid solutions to maintain an isovolemic, iso-osmolar, and iso-oncotic intravascular volume. After an initial 20mL/kg of crystalloid solution, a mixture of normal saline with albumin 5% in a ratio of 3:1 can be given. As described earlier, the brain that has sustained a recent insult (primary lesion) is vulnerable to so-called "secondary insult" (penumbra area) by a minor episode of hypotension, hypoxia or ischemia related to mechanical insult [98], (retraction) [99] or ischemia (hemodynamic instability) [100]. Although rapid administration of normal saline (10mL/kg) has little effect on cerebral blood volume and ICP, it may reinstitute hemodynamic stability. Blood products should

be administered only on the basis of hemodynamic instability and diminished oxygen-carrying capacity.

Solutions containing dextrose are associated with a poorer neurological outcome and are best avoided unless hypoglycemia has been confirmed [101]. Stressed neonates have reduced glycogen stores, and patients from the intensive care unit may have high glucose loads in their parenteral nutrition. Abrupt cessation of high-dextrose solutions can precipitate an insulin-induced hypoglycemia. In these patients, blood glucose levels should be sampled frequently and normoglycemia maintained.

# Osmotic and diuretic therapy to reduce intracranial pressure

# Hypertonic saline

Some investigators have suggested that extracellular volume dehydration can be accomplished by raising serum osmolality with hypertonic saline (3% saline) [102]. Hypertonic saline solution has been shown to be effective for volume resuscitation, while resulting in less cerebral edema and/or ICP elevation [103]. In children with severe traumatic brain injury, resuscitation with hypertonic saline (sodium 268mmol/L, 598mOsm/L) was superior to resuscitation with lactated Ringer's solution (sodium 131 mmol/L, 277 mOsm/L) [104]. Though children treated with the hypertonic saline solution had a shorter ICU stay and fewer ICP interventions, the overall survival rate and duration of hospitalization were no different between groups. In another study of children after traumatic brain injury, 3% hypertonic saline significantly reduced ICP when compared to normal saline resuscitation [105]. Based on these findings and others, there is no difference in recommendation between hypertonic saline or mannitol in the current pediatric brain trauma guidelines [106].

#### Mannitol

Mannitol (20% solution) remains the most popular diuretic for reducing ICP and providing brain relaxation. Small doses, such as 0.25–0.5 mg/kg, will raise osmolality by 10mOsm and reduce cerebral edema and ICP [107]. Mannitol's effects begin within 10-15 min of its administration and persist for at least 2h. Mannitolinduced vasodilation affects intracranial and extracranial vessels and transiently increases cerebral blood volume (CBV) and ICP while simultaneously reducing systemic blood pressure. In particular, some children may show transient hemodynamic instability (during the first 1-2min) after rapid administration of mannitol [108]. Therefore, the drug should be given at a rate not exceeding 0.5g/kg over 20-30min. The initial period of hypotension will be followed by increases in cardiac index, blood volume, and pulmonary capillary wedge pressure, all of which reach peak values 15 min after infusion [109]. The changes in intravascular volume last

for about 30 min and then return to normal levels. Administration of furosemide before administering mannitol may increase venous capacitance, reduce transient increases in intravascular volume, and provide more effective dehydration. There is, however, a danger of producing profound dehydration and severe electrolyte imbalance [110].

Larger doses of mannitol produce a longer duration of action, but there is no scientific evidence that they reduce ICP further. In animal studies, larger doses of mannitol have significantly decreased the rate of CSF formation [111]. In the presence of cerebral ischemia, larger doses of mannitol 2g/kg can be used with a presumed added benefit of free radical scavenging. In addition, higher mannitol dosages have been shown to increase CBF [112] and cardiac output [113], probably by reducing blood viscosity (rheology) [114] or by acutely increasing intravascular volume. Through the combination of these effects, it has been suggested that mannitol may cause cerebrovascular vasoconstriction and further reduce CBV. Regardless, the net effect is a multifactorial reduction in ICP from mannitol administration that most directly correlates with a reduction in CBV [115].

#### Loop diuretics

The loop diuretics, such as furosemide and ethacrynic acid, may reduce brain edema by inducing a systemic diuresis, decreasing CSF production [116] and improving cellular water transport [117]. Although furosemide can reduce ICP without increasing cerebral blood volume or blood osmolality, it is not as effective as mannitol [118]. The initial dose of furosemide should be 0.6-1 mg/kgif administered alone, or 0.3-0.4 mg/kg if administered with mannitol to children [119]. It has been suggested that ethacrynic acid reduces secondary brain injury by decreasing glial swelling [120]. Raising serum osmolality above 320 mOsm may precipitate acute renal failure and significant water retention, and create a clinical scenario where negative consequences occur when serum osmolality is decreased during recovery. Periods of aggressive dehydration may be followed by rebound intracranial hypertension during the recovery or normalization period.

#### Corticosteroids

Corticosteroids are an important part of the therapeutic regimen in neurosurgical patients with raised ICP. They reduce edema around brain tumors, but hours or days may be required to produce an effect. However, the administration of dexamethasone preoperatively or at the induction of anesthesia frequently improves the neurological status before the ICP decreases. It has been suggested that this is in response to a partial restoration of blood–brain barrier function [121].

#### **Temperature homeostasis**

In general, extremes of temperature should be avoided and situations of hypothermia and hyperthermia managed aggressively. Often, a normothermic temperature goal of 35.5–36.5°C should be used, with warming measures started below and cooling measures started above these temperature margins. Although hypothermia reduces the CMRO<sub>2</sub>, it frequently delays drug clearance, slows reversal of muscle relaxants, decreases cardiac output, causes conduction abnormalities, attenuates hypoxic pulmonary vasoconstriction, alters platelet function, causes electrolyte abnormalities, and can induce postoperative shivering [122]. In addition, the intraoperative vasoconstriction produced by hypothermia reverts to vasodilation and redistribution of body heat on rewarming, and the core temperature decreases [123].

Neonates and infants are at greatest risk of hypothermia because of their large surface area relative to body mass. Despite a warm operating room, body temperature falls immediately after induction of anesthesia owing to internal redistribution of body heat from the central compartment to the periphery [124]. As heat loss continues, pediatric patients trigger non-shivering thermogenesis in an attempt to rewarm themselves [125]. In the paralyzed and ventilated patient, body temperature and end-tidal carbon dioxide (PETCO<sub>2</sub>) concentration may increase at constant minute ventilation [126]. This phenomenon may not be readily apparent owing to cold fluid administration. Temperature monitoring is essential, but the actual site of the probe placement is less important than probe reliability. For this reason, we usually place the probe in the esophagus or rectum. During induction of anesthesia and during placement of IV lines and monitors, a large body surface area is exposed. During these procedures, premature infants and small infants should be placed under a servo-controlled radiant heat lamp. Extremities can be covered with plastic wrap or sheet wadding. Dry inspired gases should be warmed and moisturized with a heat exchanger [127,128]. Although the usefulness of warming blankets has been questioned, they appear to work well as long as they are positioned both above and below the patient. Blood warmers should always be used if substantial fluid replacement is required. Rewarming measures, such as a forced warm air system, can be used in the postoperative period.

Hyperthermia (>38.5°C) in the setting of pediatric traumatic brain injury has been associated with poor outcomes. Studies in both animal models and patients have shown that during and immediately after brain trauma or ischemia, temperature powerfully influences neurological recovery and increases CMRO<sub>2</sub> [129]. The association between the development of hyperthermia and increased morbidity and mortality has been described in adult and pediatric patients with ischemic stroke and closed head injury [130]. Based on these data, aggressive cooling strategies with forced air warmers, circulating cooling blankets, cold gastric lavage combined with anti pyretic therapy with acetominophen and non-steroidal anti-inflammatory agents (NSAIDs) may be required to treat and prevent hyperthermia [131].

#### Venous air embolism

Venous air embolism is one of the most serious complications of anesthesia and surgery. It may occur whenever the operative site is elevated above the heart, and the risk increases as the height difference increases. Classically, it is associated with posterior fossa surgery in the sitting position, but it is not confined to this procedure. It has been reported in infants and children during procedures involving the skull, such as morcellation of the cranial vault, craniectomy for craniosynostosis, and spinal cord procedures [132]. It has also occurred with the patient in the lateral position [133]. The incidence of venous air embolism has been reduced considerably by use of the prone position for posterior fossa surgery [134] and by use of mechanical ventilation.

Air entrainment occurs when a number of conditions are met, including (1) venous pressure at the operative site that is below atmospheric pressure, (2) a vein that is open to the atmosphere, and (3) a vein that is prevented from collapsing. It most commonly occurs during the first hour of surgery, and the most frequent sites of air entrainment are the cranial diploic veins, the emissary veins, and the intracranial venous sinuses, which are kept open by their dural attachment. Venous air embolism can also occur from veins in muscles and from the puncture site of the multipoint head-holder used in children over 3 years of age [135].

Detection of venous air embolism depends entirely on the sensitivity of the monitors used. The reported incidence of air emboli varies widely [136]. Using highly sensitive precordial Doppler, the reported incidence of air embolus is as high as 58% in adult patients undergoing posterior fossa surgery in a sitting position [137]. Less than half of the cases of detected emboli produce systemic hypotension [138]. In pediatric neurosurgery, the incidence of detectable air emboli is about 33% [139] but systemic complications occur in more than half of the cases. Although children are no more prone to air emboli than adults, they are more susceptible to them. For example, the incidence of air embolism during craniosynostosis repair in supine infants may be as high as 67% [140]. This may explain why, without any obvious reason, some patients experience periods of hypotension. In addition, the increased right-sided pressure may cause air to pass from the right side of the heart to the left via an atrial septal defect, causing paradoxical air embolus (PAE). Anatomically, some 27% of patients have a patent foramen

ovale and are potentially at risk for embolization to the left heart. Air also may reach the systemic circulation without the presence of an intracardiac septal defect [141] and may result in cerebral or myocardial infarction.

It is essential to take measures to avoid this potentially disastrous complication. Meticulous avoidance of a pressure gradient between the open tissue and the heart and the routine use of positive pressure ventilation are mandatory. On detecting air entrainment, the anesthesiologist must (1) advise the neurosurgeon to discontinue surgery, flood the surgical field with fluid, and compress the jugular veins and position the operative field lower than the heart to prevent further ingress of air; (2) ventilate the lungs with 100% oxygen; (3) attempt to withdraw air through the central venous catheter; (4) treat any hemodynamic consequences; and (5) if hemodynamic instability persists, turn the patient into a left-side-down position. When venous air is detected during craniotomy in children, air can be successfully aspirated from veins 38-60% of the time [139]. Intravenous fluids [142], appropriate antiarrhythmic and inotropic agents, or vasopressors may be necessary and should be administered as needed. Nitrous oxide must be discontinued because it increases the size of the embolus several-fold, causing further physiological compromise. Some authors have proposed that a positive end-expiratory pressure (PEEP) of 10 cmH<sub>2</sub>O might decrease the rate of air entry by increasing venous pressure, but less than 8 cmH<sub>2</sub>O pressure is not adequate to do so. It is possible that the use of PEEP may cause paradoxical air embolism [143]. However, 8 cmH<sub>2</sub>O PEEP did not raise the right atrial pressure above left atrial pressure [144].

# Specific anesthetic considerations

#### Neuroradiology

Children and infants, unlike adults, frequently require general anesthesia or sedation for neuroradiological diagnostic or interventional therapeutic procedures. Several special problems are related to the administration of anesthesia in this context. Among these is the delivery of care in a remote area away from skilled help, the limitations imposed by cumbersome equipment, the need to be at a distance from the patient during the procedure, and the occasional adverse effects of contrast agents. The principal indication for anesthesia in these circumstances is to provide total immobility for extended periods for young patients who cannot co-operate. The most common procedures are CT scanning, cerebral angiography, lumbar myelography, radiation therapy, and MRI. Specific anesthetic considerations for these procedures depend on the patient's condition and the radiological demands.

#### Skull abnormalities: craniosynostosis

This is the most common skull anomaly in pediatric anesthesia. Special considerations for patients with craniosynostosis include increased ICP and blood loss.

Children and infants undergoing craniectomy may have increased ICP, and induction of anesthesia should proceed as discussed before. The degree of blood loss is increased in patients with multiple suture synostoses and in those more than 6 months old with thicker bone tables. Most craniosynostosis surgery is performed between 2 and 6 months of age, a period that coincides with physiological anemia. Transfusion may therefore be required to maintain an acceptable hemoglobin level. Simple suture craniectomy in the young child with normal ICP seldom requires arterial line placement. However, adequate IV access for fluid and blood replacement is essential. Children with elevated ICP and those undergoing extensive multiple suture procedures usually require arterial line placement. See Chapter 32 for a more detailed discussion of these procedures.

#### **Hydrocephalus**

Hydrocephalus is a congenital or acquired pathological condition with many variations, but it is always characterized by an increase in the amount of CSF that is now or has been under increased pressure (Fig. 23.1). It can

**Figure 23.1** This 8-month-old boy was noted to have a recent and rapid head growth and a full anterior fontanelle. This axial CT scan reveals a communicating hydrocephalus. Note the enlarged subarachnoid space over the convexities in addition to the mildly dilated ventricles.

occur at any age. It is caused by one of four basic disease processes: congenital anomalies (e.g. Arnold–Chiari malformation), neoplasms, inflammatory conditions, and overproduction of CSF (choroid plexus papillomas).

#### Ventricular shunts

Three types of ventricular shunts are in current use: ventriculoperitoneal, ventriculoatrial, and ventriculopleural. Each has its indications and anesthetic implications. Often, as the pediatric patient grows, the shunt must be revised. It must be replaced if it malfunctions or becomes infected. Placement or revision of shunts is common in both severely neurologically impaired children and in otherwise healthy patients. These children may present to the operating room many times and may request a specific anesthesia induction technique. Patients who present for CSF shunting procedures may exhibit a broad spectrum of symptoms and clinical signs, ranging from an apparently healthy child with minimal disability to a seriously ill, comatose patient for whom surgery is urgent.

#### Considerations

Preanesthetic assessment must include the following.

- *Level of consciousness.* Patients presenting for primary shunting, shunt revision or malfunction may exhibit severe elevations in ICP that require aggressive treatment.
- *Full stomach.* Vomiting or delayed gastric emptying are indications to take precautions against aspiration of gastric contents (e.g. a rapid-sequence induction).
- *Co-existing pathology.* Does the child have evidence of other significant organ system compromise, such as the cerebral palsied child who frequently aspirates?
- *Age-related pathophysiology.* Is the patient likely to have apnea, poor pulmonary compliance or immature renal function?

#### Monitoring

Routine monitoring has been discussed earlier. Arterial line placement is usually reserved for the patient with uncontrolled ICP and hemodynamic instability.

#### Preinduction

A shunt scan helps to determine the site of malfunction. In some cases, the increased ICP caused by shunt malfunction can be reduced acutely by tapping the proximal reservoir. Infiltration of the skin with local anesthetic allows the tap to proceed with minimal trauma to the patient. The needle can be left in place to monitor ICP during induction. In the patient at risk for emesis during induction of anesthesia, placement of a nasogastric tube may precipitate coughing and bucking and increase ICP. Severely neurologically compromised children often have gastrostomy tubes, and opening these tubes before induction of anesthesia is recommended. However, this does not guarantee that the patient will not vomit and aspirate gastric contents.

#### Induction and intubation

Many patients with hydrocephalus have undergone multiple surgical procedures. If there is no clinical evidence of elevated ICP, anesthesia can be induced by mask or with IV drugs; we usually allow children their preference. On the other hand, children with increased ICP and delayed gastric emptying usually have anesthesia induced with thiopental, atropine, lidocaine, a narcotic, and a nondepolarizing muscle relaxant after preoxygenation. Cricoid pressure is applied and the patient is hyperventilated at low peak inspiratory pressures. Since laryngoscopy is a potent stimulus for increasing ICP, an oral tracheal tube is placed as smoothly as possible.

#### Maintenance

Patients are placed in a supine position with the head turned, or in a slightly lateral position. Patients with increased ICP should be placed in a 30° head-up position with minimal neck rotation or flexion to improve cerebral venous drainage. Patients whose shunt tubing is placed posteriorly and those who are placed in a lateral position should have an axillary roll placed and all extremities padded.

After the airway is secured, patients with increased ICP are hyperventilated to a  $PaCO_2$  of between 25 and 30 mmHg. Patients with normal ICP are maintained at normocapnia. Spontaneous ventilation should be avoided in patients with ventriculopleural shunts to reduce the risk of pneumothorax and in those with ventriculoatrial shunts to avoid air embolism. Also, spontaneous ventilation should be avoided when the cranium is opened. Patients with poor pulmonary compliance and those at risk for apnea should be mechanically ventilated during anesthesia.

Anesthesia is usually maintained with nitrous oxide in oxygen, low concentrations of isoflurane, and minimal narcotic supplementation. Although nitrous oxide increases cerebral blood flow in anesthetized pediatric patients, increases in cerebral blood flow and CMRO<sub>2</sub> are effectively blunted by hyperventilation and pretreatment with thiopental. Halogenated anesthetics increase cerebral blood flow, cerebral blood volume, and ICP in a dose-dependent manner, with isoflurane having a less adverse effect than halothane. These agents are therefore either used in low concentrations in patients with elevated ICP or avoided entirely until the CSF is drained. Muscle relaxation is usually maintained with vecuronium or atracurium if the procedure is expected to last a short time. Ventricular shunt procedures usually are not associated with significant blood loss or third-space losses, and fluid management centers around replacement of intravascular volume associated with emesis or drug-induced diuresis.

The body temperature may decrease during shunt procedures, despite their relatively short duration. Exposure of a large body surface area and cold preparation solution, particularly for ventriculoperitoneal shunting, may cause infants to cool rapidly.

#### **Emergence from anesthesia**

Enough time for elimination of the anesthetic agents and adequate reversal of neuromuscular blockade should be ensured before extubation of the trachea. Although it does not provide absolute insurance against regurgitation, the stomach should be suctioned before extubation of the trachea in patients suspected of having increased gastric contents. The patient should be fully awake and have an appropriate gag reflex to protect their airway against emesis. Many patients coming for shunt procedures are severely neurologically impaired and have poor airway control.

#### **Postoperative management**

As with any postsurgical patient, supplemental oxygen should be given and the respiratory pattern and adequacy assessed. Neurosurgical patients in general, and preterm infants who are less than 50 weeks' postconceptual age in particular, are likely to have abnormal respiratory patterns or apnea after surgery. Hypothermic patients should be rewarmed before extubation of the trachea.

Analgesics should be used judiciously in neurologically impaired patients. Infiltration of the skin with local anesthetic at the time of surgery substantially reduces the requirement for postoperative analgesia. Patients without preoperative neurological impairment can be given routine postoperative opioid narcotics.

#### **Intracranial tumors**

Neoplasms of the CNS account for a major proportion of all solid tumors in children younger than 15 years of age and constitute the second most common cancer in childhood after leukemia. Primary brain tumors are responsible for 20% of all cancers in children and for 20% of childhood cancer deaths. For the year 1991, the incidence for brain tumors in the United States was 3.1 per 100,000 children less than 15 years of age. Unfortunately, treatment of primary malignant brain tumors has not resulted in the same dramatic increase in survival seen with childhood leukemia. However, the survival of children with tumors of the CNS has improved significantly over the last several decades. Despite this improvement, much remains to be accomplished, especially in children less than 2–3 years of age at the time of diagnosis. From the anesthesiologist's point of view, intracranial brain tumors are divided according to the site of the tumor. The following section describes an anesthetic approach for supratentorial and posterior fossa craniotomies and for surgical excision of craniopharyngiomata.

#### Supratentorial craniotomy

Supratentorial lesions account for about half of all pediatric brain neoplasms. For reasons related to embryogenesis, pediatric brain tumors often arise from midline structures, including the hypothalamus, epithalamus, and thalamus, and the basal ganglia. These tumors tend to impinge on the ventricular system and cause obstructive hydrocephalus. Hemispheric masses are more common during the first year of life. Their frequency in infants is approximately twice as high as in older children (37% compared with 16–24%). The relative incidence of hemispheric tumors also increases after 8–10 years of age.

#### Anesthetic considerations

- *Increased intracranial pressure.* The ICP should be estimated. The CT scan and MRI film should be reviewed.
- *Full stomach.* Delayed gastric emptying occurs in the patient with raised ICP.
- *Electrolytes and fluid.* Hydration state and electrolyte balance may be altered in the child with intracranial pathology and SIADH.
- *Age-related pathophysiology.* Anesthetic considerations are identical to those discussed earlier.
- *Positioning*. The head should be elevated not more than 10° from level. It should be confirmed that venous return is not obstructed.

#### Monitoring

To the routine monitoring previously described, we add an arterial line for hemodynamic monitoring and blood sampling. In patients in whom we expect significant blood loss, hemodynamic instability or air embolism, we insert a central venous catheter. A urinary catheter is inserted because of the duration of the surgical procedure and the use of osmotic diuretics.

#### Preinduction

Detection of preoperative elevation of ICP in patients undergoing craniotomy is essential. Most patients with large mass lesions, significant tumor edema or obstruction to CSF outflow require an anesthetic approach that aims to reduce ICP. Some children undergo ventriculostomy placement before their definitive surgical procedure, as discussed earlier. Preoperative neurological deficits should be detected and documented. Many patients with intracranial pathology present with SIADH. Such children have evidence of hyponatremia, low serum osmolality, high urine osmolality, and oliguria. Peripheral edema is rarely present. Preoperative treatment of SIADH usually includes fluid restriction.

#### Induction of anesthesia and tracheal intubation

Unlike children with normal ICP, induction of anesthesia followed by rapid securing of the airway and hyperventilation are of paramount importance in patients with significantly elevated ICP. Induction of anesthesia generally proceeds as discussed in the section on hydrocephalus and includes IV thiopental, lidocaine, an opioid, and a non-depolarizing muscle relaxant. Cricoid pressure is applied and the patient hyperventilated with low peak inspiratory pressures to avoid inflation of the stomach. Laryngoscopy should proceed as smoothly as possible. Some anesthesiologists prefer nasotracheal intubation for patients in whom postoperative ventilation is expected or to better stabilize the ETTs of small infants.

#### Maintenance

Patients with increased ICP are generally ventilated to a PaCO<sub>2</sub> of 25–30 mmHg. Occasionally, lower levels of PaCO<sub>2</sub> are required if the brain is very "tight" and there is uncontrollable intracranial hypertension. Caution must be exercised because extreme hyperventilation may decrease CPP sufficiently to induce cerebral ischemia or to shift blood flow from brain with low flow to areas of brain with impaired autoregulation and high flow. PEEP is generally avoided to facilitate cerebral venous drainage. PEEP may also decrease MAP, which should be considered in patients with decreased CPP. In patients with impaired oxygenation, small amounts of PEEP may correct hypoxia without obstructing venous return.

Pediatric patients are usually placed supine for supratentorial procedures, with the head elevated slightly to facilitate venous drainage. Extremities should be well padded and the eyes protected from injury. Care must be taken to avoid undue flexion, extension or rotation of the neck.

Fluid management can be a problem. Patients with increased ICP are usually dehydrated after receiving mannitol. This increases the potential for hypovolemia and hypotension, especially when there is significant blood loss. CVP monitoring allows early detection of hypovolemia and volume expansion with colloid solutions such as 5% albumin. Simple craniotomy in patients without significantly increased ICP and in procedures with little blood loss frequently requires crystalloid replacement only.

#### Emergence

The decision to extubate the trachea at the end of the procedure is made on the basis of the success of the surgi-

cal intervention, smoothness of the intraoperative course, normalization of ICP, age of the patient, degree of residual neurological deficit, and the presence of factors that affect respiration and airway protection. Patients with inadequate respiratory efforts retain  $CO_2$  and their ICP may therefore be increased. Those without a gag reflex cannot protect their airway. Children who remain sedated and who hyperventilate during the postoperative period should be suspected of having increased ICP. Neonates with poor pulmonary compliance or an immature respiratory drive may require postoperative mechanical ventilation. Barring any of these complications, a child's trachea can be extubated after awakening and after reversal of the neuromuscular blockade and elimination of anesthetic agents.

#### Postoperative management

As with any postsurgical patient, supplemental oxygen should be administered and the adequacy of respiration assessed. Patients who require postoperative ventilation also require sedation and possibly muscle relaxation, to prevent agitation and increased ICP. Infiltration of local anesthetics into the wound intraoperatively or performance of a cervical superficial plexus block at the end of the procedure can reduce the requirement for postoperative analgesics. A balance between patient comfort and the ability to follow the patient's neurological status must be sought. An obtunded patient must be investigated for increased ICP or other surgically correctible pathology, such as intracranial bleeding. Body temperature should be maintained at a normal level.

The most common cause of increased ICP after surgery is uncontrolled systemic hypertension. When postoperative pain control has been achieved, blood pressure can be controlled with vasodilators.  $\beta$ -Blocking drugs have been used successfully, particularly labetolol, which normally does not cross the blood–brain barrier.

Seizures frequently occur during the immediate postoperative period. Therefore, many surgeons place their patients on anticonvulsants before surgery and continue these drugs postoperatively. Phenobarbital is the most commonly used drug, and phenytoin or other medications are added if the seizures are refractory to treatment.

#### Craniopharyngioma

Craniopharyngioma is a benign encapsulated tumor of the hypophysis cerebri (Fig. 23.2). Children with this tumor often present with symptoms of endocrine failure, visual disturbances or hydrocephalus, as the tumor grows beyond the sella turcica and compresses the optic chiasm or other midline structures. The trans-sphenoidal approach to this tumor is rarely used in pediatric patients, and most resections are therefore performed through a

**Figure 23.2** Sagittal gadolinium-enhanced T1-weighted MR of a 4-year-old boy with a large craniopharyngioma filing the sella turcica and elevating and distorting the third ventricle.

frontal craniotomy. Anesthesia for craniopharyngioma and hypothalamic tumor surgery is similar to that for supratentorial craniotomy.

Preoperative evaluation of the child with craniopharyngioma focuses on determining the presence of hydrocephalus and on the types of endocrine dysfunction that could affect anesthetic management. Children may present with symptoms of hypothyroidism, growth hormone deficiency, adrenocorticotropic hormone (ACTH) deficiency or diabetes insipidus (DI). Hormone replacement, including thyroid hormone and corticosteroids, may be necessary pre- and postoperatively.

Diabetes insipidus is a complication of pituitary surgery and head injury. It is caused by disruption of antidiuretic hormone (ADH)-secreting cells. It is rarely present preoperatively, but usually begins 4–6 h after surgery, although it occasionally becomes evident intraoperatively. Characteristically, patients produce a large quantity of dilute urine. Their serum osmolality increases and their urine osmolality is low (less than 200mOsm/L). The urine specific gravity is below 1.002. The patient becomes hypernatremic and hypovolemic. Treatment of DI requires careful determination of the patient's hourly urine output and administration of maintenance fluids plus 75% of the previous hour's urine output. The type of fluid to be administered is determined by the patient's serum electrolyte concentrations. Urine is low in sodium content and should be replaced with hypotonic solutions, such as D5W half-normal saline. Hyperglycemia and osmotic diuresis may occur if a large volume of D5W is used. Vasopressin or one of its analogs, such as DDAVP (1-deamino-8-D-arginine vasopressin), should be administered at an early stage of DI. When administered intraoperatively, aqueous DDAVP occasionally produces hypertension. Postoperatively, DDAVP is divided into two doses (5–30 $\mu$ g/day) and given transnasally. If DDAVP is given IV, the dose is one-tenth the intranasal dose, divided into two doses. DDAVP also can be administered by constant infusion at 0.5 milliUnits/kg/h. The rate must be adjusted to achieve the desired degree of antidiuresis.

Postoperative management should include administration of steroids, thyroid, mineralocorticoid, and sex hormone supplements. Insulin-dependent diabetics may have reduced insulin requirements after surgery. Therefore, the amount of glucose in their blood must be closely monitored and their insulin regimens altered as necessary.

Other problems that arise postoperatively include seizures and hyperthermia. Surgical exposure often requires significant retraction of the frontal lobes. Consequently, anticonvulsant prophylaxis may be necessary intraoperatively and should be continued postoperatively. Injury to the hypothalamic thermoregulatory mechanisms may result in hyperthermia. Efforts should be made to maintain normothermia and reduce the risk of hypermetabolic cell injury.

#### Posterior fossa tumor surgery

Posterior fossa tumors (Fig. 23.3) are more frequent in children than in adults and account for about half of all pediatric brain tumors. The four most common tumors are medulloblastoma (30%), cerebellar astrocytoma (30%), brainstem glioma (30%), and ependymoma (7%). The remaining 3% include acoustic neuroma, meningioma, ganglioglioma, and other much rarer tumors. Cerebellar astrocytomas have no gender predilection but medulloblastoma occurs more frequently in males. Hydrocephalus occurs in 90% of children with medulloblastoma and in virtually all children with cerebellar astrocytoma [145].

The most frequent surgical procedure, other than for tumors, is decompression for Arnold–Chiari malformation with obex occlusion. The Arnold–Chiari malformation is a complex developmental anomaly that characteristically presents with downward displacement of the inferior cerebellar vermis into the upper cervical spinal canal and elongation of the medulla oblongata and the fourth ventricle. Preoperatively, the anesthesiologist should pay particular attention to the neurological symptoms, such as cerebellar dysfunction, upper airway

**Figure 23.3** Sagittal unenhanced T1-weighted MR of a 4-year-old boy who presented with ataxia, headache and morning vomiting showing probable medulloblastoma with brainstem invasion.

obstruction (inspiratory stridor), cardiovascular instability, and increased intracranial pressure.

#### Anesthetic considerations

- Age-related pathophysiology.
- *Intracranial pressure*. Symptomatic hydrocephalus may require placement of an external ventricular drain (EVD) after induction of anesthesia. Maintenance of cerebral perfusion is essential. Mannitol, furosemide, and corticosteroids may be required.
- *Full stomach*. Pathology in the posterior fossa decreases gastric emptying in children and makes them prone to regurgitation and aspiration of gastric contents with induction of anesthesia.
- Associated pre-existing problems. Cardiovascular: some patients may be hypertensive in response to brainstem compression. Pulmonary: recurrent aspiration pneumonia is a common occurrence. Nervous system: central sleep apnea occurs and may persist postoperatively.
- *Air embolism*. See above.
- *Airway management*. Arnold–Chiari malformation or brainstem compression may cause upper airway dysfunction and inspiratory stridor.
- *Fluid and electrolytes.* Preoperative attempts to reduce ICP may cause electrolyte imbalance and contraction of the intravascular volume.
- Premedication.

# Preoperative evaluation and induction of anesthesia

Preoperative assessment of these patients is similar to that described previously. During the induction of anesthesia, attempts must be made to preserve CPP, to avoid ICP elevations, and to provide an appropriate depth of anesthesia. The choice of anesthetic is not as crucial as the manner in which it is administered. A combination of thiopental, atropine, and a non-depolarizing muscle relaxant associated with a narcotic opioid, such as fentanyl, is common. Succinylcholine can be used safely unless the patient shows signs of severe increased ICP with hemodynamic instability. To minimize the possibility of kinking and obstructing the ETT during positioning, a wire-reinforced armored orotracheal tube can be used. Many neuroanesthesiologists, however, prefer to use a nasotracheal tube for better stability and fixation. Use of an oral tracheal tube with a soft bite block reduces epistaxis and avoids possible nasal mucosal injury and infection.

#### Maintenance of anesthesia

As with induction of anesthesia, no single anesthetic technique has been shown to be superior, and the maintenance regimen must be tailored to the needs of the patient and the requirement of the surgical procedure. Muscle paralysis is provided with a non-depolarizing muscle relaxant [146], and the ICP is reduced with mannitol and furosemide. The intermittent positive pressure ventilation is adjusted to maintain the PaCO<sub>2</sub> between 25 and 28 mmHg.

#### **Patient positioning**

Three common patient positions are used for posterior fossa tumor operations. The older literature reported that the prone position is used in 55% of cases, the sitting position in 30%, and the lateral position in 15% [147–149]. In recent years the sitting position has rarely been used in pediatrics because of the increased risk of venous air embolism. It is the anesthesiologist's responsibility to ensure that during positioning the ETT is not advanced into or withdrawn from the trachea, that ventilation is adequate, that pressure points are well padded, and that the neck is not flexed enough to occlude jugular venous drainage. The method of head fixation depends on the age of the patient, the skull thickness, and the surgeon's needs. Horseshoe headrests are useful but the patient's face must be padded carefully and the eyes must be free of compression. After 3 years of age, the multi-pin head-holder is preferable. Infiltration of the pin sites with local anesthetic reduces nociceptive responses.

#### Monitoring

Monitoring for posterior fossa surgery is basically the same as for supratentorial craniotomy, with one important exception. The precordial Doppler should be used to detect air embolism (see above). Occasionally, sensoryevoked potentials should be obtained during resection of intramedullary or brainstem tumors.

#### Emergence and recovery from anesthesia

Prompt awakening is mandatory, but it is important to keep the patient hemodynamically stable and unstimulated during tracheal extubation. The pathological process often dictates the appropriate postoperative airway management (e.g. postoperative tracheal intubation is essential after resection of intramedullary tumor). When early tracheal extubation is appropriate, intraoperative administration of narcotics plus lidocaine 0.5-1 mg/kg to infants and children [150] will allow emergence from anesthesia without coughing and straining, which might otherwise lead to a hypertensive episode and intracerebral bleeding. Postoperative pain can usually be managed with morphine  $50 \mu \text{g/kg}$ , with or without acetaminophen. Avoidance of medications that affect the sensorium or the pupils is important.

#### Myelodysplasia

Hydrocephalus is accompanied by abnormalities in the spinal column and spinal cord in 70% of infants. Myelodysplasia is an abnormality in fusion of the embryological neural groove during the first month of gestation. Failure of neural tube closure results in a sac-like herniation of meninges (meningocele) or a herniation of neural elements (myelomeningocele). The spinal cord is often tethered caudally by the sacral roots, causing orthopedic or urological symptoms in later childhood if the tethered cord is not surgically corrected.

Myelomeningoceles most commonly occur in the lumbosacral region, but they can occur at any level in the neuraxis. Most children with meningomyelocele have an associated Arnold–Chiari type II malformation and hydrocephalus. An encephalocele is most frequently found in the occipital/suboccipital areas or nasally. Anencephaly results from a defect in anterior closure of the neural groove.

Myelodysplasia causes exposure of CNS tissue and places the patient at risk for infection and death. The incidence of infection increases the longer the lesion remains unrepaired but occurs in less than 7% of patients if the defect is repaired within 48h of birth. Furthermore, delay in closure of the defect increases the likelihood of progressive neural damage and decreased motor function. For these reasons, myelodysplasia is regarded as a surgical emergency, and most neonates present for surgery in the first 24h of life. In addition, patients with myelodysplasia have historically had an increased risk for the development of latex allergy. Because of this, routine care of these patients at many centers is to manage them presumptively as having "latex allergy" (see Chapter 40).

#### Anesthetic considerations

- *Co-existing disease*. Additional pathology may accompany myelodysplasia (Arnold–Chiari, hydrocephalus, congenital heart disease, prematurity).
- Age-related pathophysiology.
- *Airway management*. Encephaloceles may be associated with difficulty in control of the airway.
- *Positioning*. Protection of the neuroplaque.
- *Volume status*. High third-space losses from the skin defect.
- *Potential for hypothermia.* Exposure of large body surface area and loss of third-space fluid.

#### Monitoring

Routine monitoring is necessary. Blood loss can be insidious, especially if the sac is large and significant undermining of skin, relaxing incisions or skin grafting are required for closure of the defect. Blood transfusion may be necessary. Patients with encephaloceles who must undergo craniotomy for repair should have an arterial line placed for blood pressure and hemoglobin measurement. A central venous line may be indicated for repair of a nasal encephalocele when the repair is done in a semi-sitting position.

#### Preinduction of anesthesia

Infants presenting for repair of meningomyeloceles rarely exhibit increased ICP. The majority of myelodysplastic patients have an associated Arnold–Chiari malformation and most have hydrocephalus, which usually requires ventricular shunt placement. Preoperative assessment of these children reveals a variety of neurological deficits, depending on the level of the lesion. Seventy-five percent of all lesions occur in the lumbosacral region. Lesions above the level of T4 usually result in paraplegia, whereas lesions below S1 allow ambulation. The legs are severely affected by lesions between L4 and S1.

Before induction of anesthesia, the patient's volume status should be assessed. These patients have the potential for large third-space losses from the exposed myelomeningocele.

#### Induction of anesthesia and tracheal intubation

Anesthesia for patients with lumbosacral or thoracic myelomeningoceles can be induced either in the left lateral position or supine with the sac protected by a cushioned ring. Anesthesia can be induced in a majority of patients with propofol, atropine, and a muscle relaxant. Either a non-depolarizing muscle relaxant or succinylcholine can be used safely [151]. Patients with nasal encephalocele commonly have airway obstruction, and it may be difficult to obtain a good mask fit.

#### Maintenance of anesthesia

After tracheal intubation, the patient is turned to the prone position. Injury to the exposed neural tissue must be prevented. Chest and hip rolls are placed to ensure that the abdomen is free, to facilitate ventilation and to reduce intra-abdominal pressure and decrease bleeding from the epidural plexus. Since most of these children have an Arnold-Chiari malformation, excessive rotation of the neck should be avoided. The extremities should lie in a relaxed position and be well padded. The lungs are mechanically ventilated. Barotrauma in the immature lung must be prevented. Premature infants (especially those of less than 32 weeks' gestation) are at increased risk for retinopathy of prematurity [152] and lung injury from prolonged exposure to high oxygen concentrations. Anesthesia can be maintained with a variety of agents, but higher-dose opioids and ketamine may cause postoperative apnea. Muscle relaxants are contraindicated during maintenance of anesthesia because nerve stimulation is often required to identify neural structures. The large area of exposed tissue and the liberal use of cold surgical preparation solutions increase the risk of hypothermia in these patients. Care must be taken to prevent drying or thermal injury to the exposed neural tissue by radiant heat lamps.

Myelomeningocele repair is often accomplished with the aid of the surgical microscope, and some surgeons will request that neuromuscular blockade not be used during the repair so that motor response in the lower extremities can be detected.

#### Emergence

Neonates at risk for apnea after anesthesia, patients with severe central neurological deficits, and those undergoing craniotomy for encephalocele repair should be extubated fully awake. Patients with nasal encephalocele repairs may have residual airway obstruction or blood in the oropharynx, and may require postoperative tracheal intubation.

Basic anesthetic considerations for the postoperative period have been discussed above.

#### Spinal cord surgery

Common diseases of the spinal cord that require surgery include herniated disks, spondylosis, syringomyelia,

primary or metastatic tumors, hematomas or abscesses, and trauma (Fig. 23.4). In all cases, compression of the spinal cord may produce ischemia, interstitial edema and venous congestion, and may interfere with nerve transmission. Maintaining spinal cord perfusion pressure and reducing spinal cord compression are crucial. Despite apparently optimal surgical and anesthetic management, devastating neurological complications still occur with spinal surgery. Intraoperative monitoring of spinal cord function includes the wake-up test, somatosensoryevoked potentials (SSEPs), and motor-evoked potentials (MEPs). The wake-up test remains the traditional method for assessing spinal cord well-being during corrective procedures on the spinal column. Its main advantage is that it assesses anterior spinal cord (i.e. motor) function, but it does so only at one time. Evoked potential monitors (e.g. SSEP monitoring) generate an electrical potential by stimulation of peripheral nerves (e.g. the median nerve at the wrist or the posterior tibial nerve at the ankle). If nerve transmission is intact, a signal is recorded from the scalp

**Figure 23.4** This 8-year-old girl presented clinically with bent-over gait and severe back pain. A large extradural lesion was revealed during a sagittal T2-weighted MR. This mass is anterior to the thecal sac with severe compression of the thecal contents (*black arrow*) and scalloping of the posterior vertebral bodies (*white arrows*).

or at various sites along the neural pathway. The electrical signals arise from axonal action potentials and graded postsynaptic potentials as the impulse is propagated from the periphery to the brain. The technique measures only the response of the sensory nervous system. This limitation can be overcome by use of MEPs, in which the motor cortex is stimulated by a transcranial electric current or a pulsed magnetic field generated by a coil placed over the scalp. See Chapter 26 for a more detailed discussion of spinal cord monitoring, and scoliosis surgery.

## **Head injury**

Head trauma is a major cause of morbidity and mortality in the pediatric population. Skull fractures (Fig. 23.5) are found in more than 25% of all children who present at hospitals with head injuries and in more than 50% of fatal cases of childhood head trauma. The incidence of posttraumatic intracranial hematomas varies considerably, but some children with head injuries do require surgical treatment. Failure to recognize the presence of a hematoma may transform an otherwise mild head injury into a fatal or permanently disabling one. Head injury causes several different pathophysiological events, including intracranial hematomas (epidural, subdural, intracerebral, and brain contusion), brain edema, and systemic effects. Adults suffer more hematomas than children, and children have diffuse cerebral edema more frequently [153].

#### **Epidural hematoma**

This lesion is frequently caused by laceration of a middle meningeal artery during a deceleration injury. Children do not necessarily have an overlying skull fracture (Fig. 23.6). Epidural hematomas comprise 25% of all intracranial hematomas in pediatric patients and are a true neurosurgical emergency. In adults there is a lucid interval between the initial loss of consciousness and later neurological deterioration. Children often do not have the initial alteration in the state of consciousness observed in adults. The child who is old enough to talk complains of an increasing headache and then becomes confused or lethargic. Rapid development of hemiparesis, posturing, and pupillary dilation occurs frequently and may confuse

**Figure 23.5** Axial non-contrast CT showing no underlying contusion or hematoma in a 4-month-old boy. He suffered no neurological sequelae from this depressed "ping-pong" skull fracture.

**Figure 23.6** This non-enhanced axial CT reveals a typical lens-shaped epidural hematoma. Although the patient presented with a GCS of 14, he quickly became very lethargic.

the diagnosis. Rapid expansion of the hematoma causes herniation of the temporal lobe downward through the tentoria incisura. Anisocoria is an early sign. Herniation eventually leads to rostrocaudal deterioration and is associated with bradycardia, slowed and irregular breathing, and widened pulse pressure (Cushing triad). The relationship between the degree of brain shift and the level of consciousness has been confirmed; the role of uncal herniation in the syndrome has been questioned.

#### Subdural hematoma

Subdural hematomas are associated with parenchymal contusion, blood vessel laceration, and cortical damage (Fig. 23.7). The mass effect of the contused and edematous brain may prompt surgical removal of the hematoma if the brain region involved is not functionally important. Studies using positron emission tomography have demonstrated that cerebral metabolism and blood flow are reduced by 50% with brain contusion [154]. Severe edema and elevated ICP often lead to persistent neurological deficits.

#### Intracerebral hematoma

Intracerebral hematomas are rare but carry a poor prognosis. Surgery is usually avoided for fear of damaging viable brain tissue.

**Figure 23.7** A non-contrast axial CT in a 2-year-old comatose boy shows a large right acute subdural hematoma. It is important to notice the tremendous shift of the midline to the left.

#### Anesthetic considerations

- *Resuscitation and stabilization*. Airway, breathing, and circulation are essential components of the initial clinical assessment. Traumatized patients often have a variety of physiological disturbances, including acid-base and electrolyte imbalances and abnormalities of glucose homeostasis and body temperature control.
- *Neurological status*. The Glasgow Coma Scale provides a means of detecting changes in the patient's condition. Symptoms of raised ICP must be evaluated.
- Associated injuries. Pediatric trauma often occurs from high-velocity energy transfer, which leads to injuries to the neck, chest, and abdominal organs.
- *Full stomach*. Vomiting leads to pulmonary aspiration and respiratory complications.
- Age-related pathophysiology.

#### Monitoring

Arterial catheter and central venous line placement is indicated. A urinary catheter should be inserted unless contraindicated by an associated bladder neck injury. Central body temperature should be monitored at all times.

#### Preinduction of anesthesia

Computed tomography is the procedure of choice for evaluation of head injury during the first 72h after the accident. Management of an elevated ICP is essential to provide a safe anesthetic. Adequate hemodynamic resuscitation and stabilization must be achieved to maintain a normal CPP and brain tissue oxygenation.

#### Induction and intubation

Providing a patent airway is an essential part of the management of patients with head injury. Although the airway of an unconscious patient may not be compromised by the injury, tracheal intubation will protect the lungs against aspiration of stomach contents or secretions and allow ventilatory support of patients with increased ICP. The association of head injury and neck injury occurs so often in infants and children that tracheal intubation must be accomplished with minimal manipulation of the neck. The neck should be stabilized by an assistant who applies axial traction. Since a cervical spine fracture is always considered present until proven otherwise in patients with head injury, use of the Sellick maneuver is contraindicated. Patients should be hemodynamically stable before anesthesia is induced. After airway injury has been ruled out, anesthesia should be induced rapidly with atropine, thiopental, lidocaine, and either succinylcholine or a non-depolarizing muscle relaxant such as vecuronium. Ketamine is contraindicated. If the patient is suspected of having a difficult airway, a two-person

technique may be required for tracheal intubation. Depending on the age of the patient, the use of a volatile anesthetic and assisted ventilation or the use of neuroleptanesthesia with topicalization of the larynx is recommended.

#### Maintenance of anesthesia

Anesthetic considerations for maintenance of anesthesia are similar to those previously described for supratentorial surgery. Evacuation of an intracranial hematoma usually requires a craniotomy, which can commonly be done without opening the dura mater. Evacuation of a large hematoma may suddenly decrease ICP and allow upward movement of the brainstem through the tentoria incisura. This may result in transient hemodynamic instability and cardiac arrhythmias.

#### **Emergence and postoperative management**

Patients with severe head injury remain intubated after surgery to provide ventilatory support and to control elevated ICP. Transfer to an ICU is indicated for continued care.

#### **Cervical spinal cord injury**

Isolated cervical spine injury is uncommon in the pediatric population. However, all children with severe head injury should be treated as though they have a cervical spine injury, until proven otherwise. Injury to the high cervical cord is usually caused by high-velocity injuries to the cranium (Fig. 23.8). Children with cord injury or disruption of the cord often present without respiratory efforts, often in cardiac arrest or with profound hypotension. They frequently die from hypoxic/ischemic encephalopathy and may have serious traumatic brain injury. In one study, all patients with absent vital signs had high cervical cord luxation on a lateral view radiograph of the neck [155]. Physicians caring for such patients might think that the hypotension is related to blood loss from intra-abdominal, pelvic or thoracic injury, or even from devastating cerebral injury and loss of brainstem function.

#### Anesthetic considerations and management

Some cervical spine injury victims have signs of brain shift and elevated ICP. The anesthetic considerations for these patients include the following.

- Resuscitation and stabilization of cardiopulmonary function, i.e. spinal shock.
- Decreasing ICP and improving cerebral perfusion.
- Stabilization of the cervical spine.
- Correction of metabolic disturbances.
- Treatment of acute respiratory distress syndrome (ARDS).

**Figure 23.8** Lateral radiograph of the cervical spine of a 6-year-old boy showing a significant separation of the occipital condyles from the arch of C1 (*white arrows*). He presented with a GCS of 3 and no spontaneous respirations.

- Identification of the central rostrocaudal deterioration and uncal herniation.
- Meeting the fluid requirements for trauma victims with iso-osmolar solutions such as normal saline.
- Monitoring arterial pressure, CVP, and urine output.
- Correcting the coagulopathy often caused by brain tissue thromboplastin release.
- Treatment of DI (see craniopharyngioma).
- Treatment of SIADH.
- Controlling the hyperglycemia that frequently occurs in head-injured patients, which is thought to be a good indicator of the severity of the injury and a predictor of outcome. It is advisable to prevent the increase in glucose associated with head injury [156].

# Newer procedures in pediatric neurosurgery

There are several recent developments in the neurosurgical procedures performed in the pediatric patient population which require special attention to anesthetic details which affect the outcomes of these procedures.

**Figure 23.9** The first intraoperative MRI suite was installed at the Brigham and Women's Hospital, Boston, in 1994. Reproduced from Foroglou et al [187] with permission from Taylor & Francis.

#### Pre-, intra- and postoperative imaging

Computer-assisted navigation is a relatively new surgical tool, designed to improve both neurosurgical safety (through better navigation near critical anatomical structures) and effectiveness (through better localization of pathology). Tumor resection from the brain is made difficult when margins that were distinct on MRI are indistinct to visual inspection. The use of stereotaxy to locate the real-time position of surgical instruments relative to calibrated maps of patient anatomical and functional imaging is the most recent solution to this problem.

Clinical use of stereotaxy was first reported over 50 years ago, and was done by calibrating mechanical frames to atlas data of human anatomy [157]. The next development in neurosurgical stereotaxy was the use of CT scanning to calibrate stereotaxic frames to individual patient anatomy [158]. The technology continued to follow advancements in neuroradiology and engineering. In the last two decades, the technology has incorporated realtime spatial positioning of surgical activity to threedimensional maps of the patient's intracranial space, eliminating the need for the bulky and uncomfortable frame. These techniques use optical, ultrasonic or electromagnetic signals to track the position in space of surgical instruments relative to fiducial markers placed on the patient scalp at the time of preoperative imaging. The infrared optical devices have, in particular, become popular, and they use a system of cameras, light-emitting diodes, and/or reflective fiducials to track surgical instruments as they pass through the surgical field.

Thus, the science of neuronavigation has gone from frames calibrated to atlas data to real-time position determination in a patient-specific spatial map. The latest advancement in the field is predictable from this progression. The brain is not spatially fixed in time, and moves with position changes and surgical interventions. It has, therefore, become desirable to have not only real-time instrument tracking but also real-time updating of the topographical map of the surgical field. Immediate postoperative MRI of patients after tumor resection is one possible approach, but neurosurgical suites with in-room MRI are becoming a more common approach (Fig. 23.9) [159].

Specific anesthetic considerations for a surgical procedure involving perioperative imaging technologies include the potential for:

- awake patient
- analgesia
- airway maintenance.

Younger or anxious patients unable to co-operate will require general anesthesia, while older children and adults may be appropriate for awake craniotomy techniques.

Anesthetic management of these patients undergoing intraoperative MRI includes previously mentioned considerations inherent to the procedure, plus the added complexity of safely conducting the procedure in the operative environment. This issue involves not only the anesthesia machine and monitoring equipment, but includes all the ancillary equipment including the operating table, warming devices, and surgical equipment, including instrumentation and electrocautery. Thus, the vigilance of the staff for both patient and personnel safety is paramount – this includes limiting OR access and staff proximity to the MRI scanner [160,161].

#### Awake craniotomy for seizure treatment

Neurosurgical intervention for epilepsy is generally reserved for patients refractory to antiepileptic medications. Three types of surgery for epilepsy may be encountered: resection of a local epileptogenic lesion, such as a cavernous angioma or a focal cortical dysplasia; temporal lobe resection; and placement of a vagal nerve stimulator.

Focal epileptogenic regions of the brain are often delineated by invasive diagnostic mapping procedures. One such example is the placement of a subdural grid. The grids are placed over cortical areas suspected to be epileptogenic. Patients are kept in hospital and taken to an epilepsy observation unit while the grids are monitored for seizure activity. Functional mapping with stimulation of the electrodes is also helpful to define a plan for resection that optimizes seizure reduction and minimizes loss of function. Temporal lobe resection is one of the more common surgical procedures for epilepsy, and can involve varying degrees of resection to include the anterior region of the temporal lobe and underlying hippocampus.

Specific anesthetic considerations for a surgical procedure for treatment of epilepsy include:

- co-operative (awake) patient
- analgesia
- airway maintenance.

#### Preinduction

The preoperative evaluation must determine the degree of co-operation that can be achieved and if the patient can tolerate an anesthetic/analgesic without difficulty in airway management. Because of these issues, the ability to perform awake mapping is usually limited to older children and adults. Reports of "awake" or "asleepawake-asleep" (AAA) techniques have been applied in children as young as 4 years of age. However, the majority of children reported in the literature are greater than 11 years old. Anyone experienced in this technique will admit that success is dependent on preparing the parents and the child, establishing realistic expectations and determining if the child is psychologically mature and ready for an awake approach [162]. Patients (whether pediatric or adult) may not be good candidates if they have a movement disorder, poor co-operation with verbal commands or sleep disorders. Sleep apnea and a difficult airway are often considered absolute exclusions from this approach, as additional airway support is difficult given the patient's position during the procedure.

#### Anesthetic approach

Excision of a seizure focus requires a co-operative though sedated patient, permitting the precise mapping of the surgical site by cortical electroencephalography (ECG) (Fig. 23.10). Those most experienced with this procedure in children advocate a neuroleptic analgesic technique [163]. Historically, this was accomplished with intravenous administration of droperidol and fentanyl with or without a premedication, but newer agents such as dexmedetomidine and propofol are most frequently used. Most will supplement with nitrous oxide/O<sub>2</sub> by facemask to facilitate regional administration of local anesthetic and scalp block for placement of invasive monitoring lines (i.e. arterial and central venous catheters, if needed) and placement of the multi-pin head-holder [97]. Once the holder is in place, vascular access is adequate and patient is positioned, the MAC is provided using a total intravenous anesthetic (TIVA) technique.

Propofol sedation became the first widely used alternative to the classic neuroleptic technique. A variety of

Figure 23.10 Cortical electrode application on the surface of the brain to detect epileptic foci.

approaches have been reported using propofol with and without an opioid (such as fentanyl or remifentanil), and even having propofol dispensed in older children as patient-controlled sedation (PCS) [164,165]. Dexmedetomidine has been utilized in children and adults to facilitate awake craniotomy procedures. Studies evaluating the use of dexmedetomidine for this surgical approach have found successful sedation and reduced needs for supplemental medications for pain or nausea [166].

Electrical currents generated by seizure activity produce magnetic fields that can be measured by magnetoencephalography (MEG). This non-invasive technique is not affected by the soft tissues or bone, and can be integrated with EEG monitoring to improve the accuracy of cortical epileptic foci mapping. Since active seizure activity is required for this technique to be most effective, methohexital (1–1.5 mg/kg) is administered intravenously to increase epileptiform discharges. Note that this should only be done with the appropriate level of monitoring and presence of the anesthesiologist to manage the patient should they become postictal or oversedated.

### Hemispherectomy

Children with severe seizure disorders, unresponsive to medical management, may be candidates to undergo resection of the affected cerebral hemisphere, or hemispherectomy [167]. To meet criteria, children typically have a generalizable seizure that comes from a focus in a single hemisphere. This may require prior grid placement with mapping, functional MRI or other imaging prior to the grid removal and hemisphere resection.

### Deep brain stimulator placement

Patients with dystonia or refractory seizure acitivity may be candidates for a deep brain stimulator (DBS) [168]. Placement of these devices often requires preoperative imaging for stereotactic guidance followed by an intraoperative phase of the procedure that allows for conducting physiological tasks for improved mapping of the globus pallidus internus (GPI). Similar to an awake craniotomy, an AAA anesthetic can be utilized to facilitate the sometimes lengthy process of imaging followed by awake surgery. In centers that do not have an intraoperative MRI suite, this will require the patient to be imaged under anesthesia in a remote location and then typically transported under anesthesia/sedation and monitoring to the operating room. Once in the OR, the patient can then be emerged, extubated and maintained sedated with MAC using propofol or dexmedetomidine. Neurophysiological monitoring is incorporated to help establish microelectrode recordings to verify and adjust the position of the electrode/lead into the deep target of the brain. Because these procedures tend to be long (6-12h), a general anesthetic for the imaging proportions before the procedure is often required in children [169] while other groups have reported successful completion of the entire procedure in adults with little or no anesthesia (i.e. scalp block only) [170]. Regardless of the technique applied, the goal is to minimize interference with the introperative monitoring while facilitating communication during an often long and drawn-out procedural day, which will include a frame placement and burr-hole drilling [171,172].

## **Cerebrovascular anomalies**

Patients with intracranial vascular malformations such as arteriovenous malformations (AVMs) or cerebral aneurysms are commonly co-managed by the pediatric anesthesiologist in conjunction with neurologists, neurosurgeons and interventional neuroradiology [173]. This may require that one or more anesthetics be provided to facilitate the diagnosis and/or intervention for the lesion. Since congenital and acquired forms of AVMs can be one of the greatest anesthetic challenges throughout life, we will focus on their general management in infants and children.

Arteriovenous malformations and arterial aneurysms can be acquired, but the majority arise from abnormal development of the arteriolar-capillary network that connects the arterial and venous systems. These vascular malformations often consist of large arterial feeding vessels that lead to dilated connecting vessels and then to the venous system. Flow of blood through this lowresistance connection results in progressive distension of the venous structures and increased venous mixed oxygen content from the shunting of blood. Specific AVM scenarios that occur in infants and children involve the posterior cerebral artery and the great vein of Galen (Fig. 23.11). These anomalies often present in the neonatal period with congestive heart failure (CHF). Alternatively, patients can present with obstructive hydrocephalus from saccular enlargement or dilation of the vein of Galen that directly compresses the aqueduct and prevents drainage of the cerebrospinal fluid.

Outside the neonatal period, many AVMs go undetected until the fourth or fifth decade of life with only 18% reported to be in patients under 15 years of age. Though the incidence is low, when intracranial AVMs occur, neurological injury can result from one or more causes:

- hemorrhage with thrombosis or acute infarction
- compression of adjacent brain tissue or intracranial structures
- parenchymal ischemia created by "steal" of blood flow through the AVM
- congestive heart failure from the shunt
- surgical or interventional injury resulting in disruption or diversion of blood flow from viable brain tissue supplied by the AVM during treatment.

Therefore, families and physicians must balance these potential outcomes when deciding between surgical versus interventional treatment options. Regardless, patients with complex AVM lesions may undergo interventional or stereotactic radiosurgical procedures to control blood flow as definitive or adjunctive therapy. In

**Figure 23.11** Lateral view of an aneurysm of the great vein of Galen. The main arterial contribution is from the anterior cerebral artery. The dilated vein of Galen empties directly into an enlarged straight sinus.

addition, surgical clipping of feeding vessels or removal of aneurysmal tissue may need to be done as either a single or staged procedure, again necessitating clear communication between the anesthesiologist and the various treatment teams to facilitate optimal care.

## **Anesthetic considerations**

Considerations for patients undergoing AVM resection or embolization include the following.

- Assessment for pre-existing pathophysiology. Does the patient present with increased ICP or congestive heart failure? Does the patient have additional congenital defects?
- *Age-related pathophysiology.* Will organ system maturity affect the anesthetic technique?
- *Blood loss.* The possibility of massive blood loss is high, especially if pre-resection therapies for embolization were limited.
- *Ventilation pattern*. Hyperventilation to control cerebrovascular tone and reduce inflow is a therapeutic consideration for most AVM treatment.

#### Monitoring

Routine monitoring is as previously described. Patients undergoing AVM resection should have vascular access via two large-bore peripheral IV catheters that are capable of delivering blood products should hemorrhage occur. Intravenous solutions should be warmed throughout the procedure. Invasive hemodynamic monitoring with an arterial line is essential. CVP monitoring is useful for determining intravascular status, and to facilitate administration of medications. A urinary Foley catheter is essential and should be placed after induction of anesthesia.

### Preinduction

Symptoms can vary depending on the age of the patient and the magnitude and size of the AVM [148]. Older children often present with evidence of subarachnoid hemorrhage (SAH) or intraventricular hemorrhage (IVH). Up to 50% of children who present with spontaneous SAH have an AVM as the etiology [174]. In 24% of children, seizure is a common presenting feature. However, the neonatal presentation of AVM is often associated with congestive heart failure and deserves special attention.

The low-resistance pathway of the AVM creates a situation of volume overload and high-output heart failure. The symptoms of congestive heart failure rarely manifest *in utero* because the patency of the ductus arteriosus provides for increased systemic flow through the AVM and reduces the work of the ventricles. However, after birth, with closure of the ductus, the left ventricle alone is left to meet the demands of increased arterial to venous flow. The degree of the arterial to venous shunt will affect the demand on the left ventricle. In addition, in the presence of a low resistance cerebral AVM, a low systemic diastolic pressure results. The low intra-aortic pressure during diastole, combined with increased left end-diastolic pressure and heart rate from the ventricular failure, results in reduced coronary perfusion and worsening myocardial function from ischemia [175]. The cycle of ventricular failure and decreased oxygen delivery to the systemic tissues causes the cascade of adaptive mechanisms, which results in decreased urine output and increased fluid retention [148,149]. Physical examination of the infant shows signs such as tachypnea, pulmonary edema, tachycardia, hepatomegaly, and ECG changes. Echocardiography will often confirm the hyperdynamic nature of the congestive heart failure, and evidence of functional failure of one or both ventricles. Laboratory studies may provide evidence of electrolyte abnormalities from aggressive diuretic management. Some infants may require endotracheal intubation and mechanical ventilation support, and inotropic support, all of which may help reduce the workload of the failing myocardium.

# Induction of anesthesia and tracheal intubation

Prevention of hypertension during induction is desirable, given the possible association between AVM bleeding and hypertension. Inhalation or IV induction of anesthesia can be performed if there is no evidence of increased intracranial pressure. This can be accomplished with a variety of anesthetic agents. In the patient with AVM and elevated intracranial pressure, an IV induction is preferable with attention to avoiding hypotension and low cerebral perfusion pressure. In the neonate with AVM and congestive heart failure, special care should be taken to induce anesthesia and maintain cardiac output. Extreme caution should be maintained as many anesthetic agents are myocardial depressants, and could precipitate cardiac arrest. To this end, placement of IV and arterial lines is useful prior to induction. Either oral or nasotracheal intubation is reasonable after induction of anesthesia.

## Maintenance of anesthesia

Considerations for maintenance of anesthesia include the following:

- positioning
- ventilation
- anesthetic agents
- blood loss and fluid management
- temperature maintenance.

Positioning for the procedure will be dictated by the site of the AVM. Typically, AVMs receive blood supply from the middle cerebral artery and the majority are approached by a supratentorial craniotomy.

All patients should undergo mechanical ventilation with intended maintenance of normocapnia. Patients

with evidence of elevated ICP may require transient hyperventilation to control intracranial pressure, and consideration of ongoing ICP monitoring may be necessary. In general, normocarbia is preferable and hypocarbia should be avoided, as the resultant cerebrovascular vasoconstriction may result in more shunting of blood flow away from normal tissues and into the AVM – potentially contributing to increased cerebral ischemia and increased bleeding from the AVM.

Anesthetic agents used for maintenance are similar to those for any intracranial procedure. If congestive heart failure is absent, then permissive or controlled hypotension can be applied to facilitate control of bleeding from the AVM during ligation. This can be accomplished with infused antihypertensive agents, such as nicardipine, nitroprusside or fenoldepam. Neonates with congestive heart failure undergoing AVM ligation or treatment require inotropic support and are not candidates for permissive hypotensive strategies. In these infants, vasoactive drugs should be readily available and administered through a central venous catheter.

Fluid management in these patients is challenging. Neonates may not tolerated large volume shifts or decreases in hemoglobin concentration, especially if they have elements of cardiac dysfunction. Early efforts to maintain normal intravascular volume and stable hemoglobin content should be the goal. This may necessitate early blood replacement and judicious supplementation with inotropic support.

Maintaining a normal body temperature is important and can be difficult given the fluid losses and sometimes massive transfusion requirements. This usually requires the use of both fluid and convective warming devices that should be adjusted to avoid profound hypothermia and coagulopathy. Though the merits of hypothermia (temperature <35°C) for neuroprotection in neurosurgical procedures are debated, hyperthermia (temperature >38°C) should be avoided as this can worsen ischemic injury by increasing metabolic demands of the brain and the body.

## **Emergence from anesthesia**

Considerations for emergence from anesthesia after AVM treatment include the following.

- Elimination of anesthetic agents.
- Reversal of neuromuscular blockade.
- Assessment of respiration effort and airway patency.
- Assessment of neurological function.

Patients without a history of CHF can be extubated at the end of surgery if they are neurologically appropriate and hemodynamically stable. However, those patients with a history of significant CHF or who are at risk for significant neurological deficits (i.e. required brain resection, significant brain retraction or obvious cerebral edema) should remain sedated and be moved to the intensive care unit with an endotracheal tube in place.

#### **Postoperative management**

The basic anesthetic considerations for postoperative care of patients following AVM treatment include the following.

- Cerebral edema.
- Congestive heart failure.
- Hypertension.
- Vasospasm.

Cerebral edema can arise from either the AVM itself or from the therapeutic approach – be it surgical or interventional. Certainly, the interventional procedures for embolization or radiosurgery cause less injury to the tissues getting to the AVM but they can still result in significant edema [176]. In those situations where the edema is anticipated or recognized, leaving the trachea intubated and monitoring the patient in the ICU are indicated. Following resection of a large AVM, it may require several days for the cerebral edema to resolve and the patient's neurological exam and level of consciousness to become appropriate. During this period, supportive care and careful neurological monitoring are of greatest importance.

Despite removal or reduction of the extracardiac shunting of blood, patients with preoperative myocardial dysfunction remain critical in the days following recovery from the surgery and require ICU care. In addition to maintaining an adequate cerebral perfusion pressure, the care team must balance the needs of the myocardium to reduce afterload. Aggressive analgesic and antihypertensive management may be required to prevent sudden increases in arterial blood pressure, which not only stresses the heart but increases the risk of acute intracranial bleeding.

Vasospasm is not a common postoperative complication, but must be a consideration if the patient's neurological status deteriorates or if SAH was present in the perioperative period. The pathogenesis of vasospasm is not completely understood, but early diagnosis and intervention can be beneficial. Transcranial Doppler sonography has been used to guide therapy in adults, but its role in children remains limited. Certainly, these measurements can detect increased blood flow velocities and allow for diagnosis of the condition as well as providing a means of guiding therapy. Treatment is typically with adequate hydration, stable/generous blood pressure, and use of calcium channel blockers [177].

## Interventional neuroradiology

Over the past two decades, neuroradiological techniques and expertise in the diagnosis and treatment of diseases

of the CNS have undergone significant advances. Interventional neuroradiology (INR), or endovascular neurosurgery, has evolved as a hybrid of traditional neurosurgery and neuroradiology. Though practice varies between institutions, INR has developed a clear role in the management of a variety of neurosurgical conditions, particularly neurovascular diseases (see section on AVMs). INR, like interventional cardiology, can be broadly defined as treatment by endovascular access for the purpose of diagnosis and/or treatment by delivering therapeutic drugs and devices. The number, variety, and complexity of conditions treated using this route are increasing and this creates challenges for the pediatric anesthesiologist [178]. The pediatric anesthesiologist has a crucial role in facilitating neuroradiological procedures, and this requires an understanding of the indication and purpose for the procedures, their potential complications, and the management goals of the neurologists, neurosurgeons and neurointerventionalists, which will vary depending on the individual child.

Though most diagnostic neurological imaging can be accomplished with MRI and CT techniques, the power to both diagnose and intervene makes interventional techniques appealing, though they are often not the first choice for diagnosis [179]. INR procedures can be broadly classified on the basis of treatment goals.

- Closing or occluding procedures. Common examples include embolization of aneurysms, AVMs and fistulae of the brain and spine, preoperative embolization of vascular tumors such as meningiomas, temporary or permanent occlusion of intra- or extracranial arteries.
- *Opening procedures.* Common examples include treatment of vasospasm or stenosis by angioplasty and stenting, chemical and mechanical treatment of thrombolysis in stroke.

The most common INR procedures in children are endovascular treatment of aneurysms, AVMs, and preoperative embolization of tumors.

Though specific procedures will have different neurological complications, INR procedures are at higher risk for the following.

- Hemorrhage. This can result from vascular injury or dissection of an arterial vessel and/or aneurysmal perforation.
- Ischemia. This can result from malpositioning of a catheter or absence of collateral blood flow to a region, thromboembolic complication, displacement of a coil or stent that results in occlusion, and/or vasospasm of the vessel.

Non-neurological complications can also occur and are typical of other interventional procedures; they include contrast reactions, contrast nephropathy, and hematoma/bleeding/hemorrhage at the femoral puncture site.

## Anesthetic considerations

At many institutions, the interventional suites are situated remotely from the operating rooms. Because this not only involves multiple floors and distance but sometimes multiple anesthetic locations (i.e. CT angiography pre/ post in one location and the INR procedure in a different location), technical support must be co-ordinated for the anesthesia team, patient transport, and potentially remote patient recovery. Other potential problems typical of interventional radiological locations include working in reduced light, limited or poor access to the patient and equipment during the procedure, and concerns about ionizing radiation.

Anesthetic considerations when caring for patients undergoing INR procedures includes maintenance of patient immobility and physiological stability, manipulating systemic and regional blood flow, managing anticoagulation, and treating sudden unexpected complications during the procedure. The medical management of critically ill patients during transport to and from radiology suites and smooth and rapid recovery from anesthesia to facilitate neurological examination are equally important [180,181].

There are no studies demonstrating a clear benefit of one anesthetic management technique over another in the INR suite. Multiple approaches have been reported including general anesthesia, MAC and even sedation and/or awake techniques [179]. Because of the need for immobility in many of these procedures, we favor a general anesthetic with endotracheal intubation. Routine anesthetic monitoring is applied, and arterial blood pressure monitoring can often be obtained from the femoral arterial sheath. If postoperative ICU admission is anticipated with continued hemodynamic control (i.e. permissive hypotension) then a radial arterial catheter should be placed. Vascular access should include two good peripheral IV catheters for fluid and blood product administration. A Foley catheter should be placed to monitor urine output. If vasoactive drugs are to be administered as part of the procedure, a central venous catheter is desirable.

#### **Postoperative considerations**

Postanesthetic management of children following diagnostic or mapping neuroradiographic procedures is similar to other interventional cardiology and radiology procedures. Monitored transport to the postanesthetic care unit, with careful monitoring of bleeding complications from the femoral vein and arterial sheath sites, is necessary. In addition, careful neurological monitoring should be performed to assure return to the patient's baseline exam. Any new deficits or decline in neurological status should prompt aggressive assessment by the anesthesiologist and neuroradiologist, as bleeding complications may necessitate imaging, repeat intervention, and/or surgery.

Patients with anticipated swelling, neurological deficit or continued need for hemodynamic monitoring following the procedure should be transferred directly to an intensive care unit with or without tracheal extubation. Management goals should be discussed carefully between the neuroradiologist, neurosurgeons, anesthesiologist and intensivist, so that patient care can be optimized and the risk of ongoing neurological injury minimized. For patients with anticipated swelling and/ or deficits, we will often transport the patient to the intensive care unit sedated, intubated and monitored, and then facilitate extubation in the ICU where all concerned parties can examine and agree with the postprocedural neurological examination. This approach can also facilitate any additional neuroimaging, such as CT or MRI, that might be planned or unplanned, prior to admission to the ICU.

# Cerebral protection, resuscitation, and outcome

A comprehensive discussion of these topics is beyond the scope of this chapter. See Chapter 7 for a discussion of the physiology of the central nervous system. General principles are presented here for completeness [182].

### **Cerebral protection**

After ischemic injury, the CNS has limited regenerative ability. Brain protection has been defined as the "prevention or amelioration of neuronal damage evidenced by abnormalities in cerebral metabolism, histopathology, or neurologic function occurring after an hypoxic or ischemic event" (i.e. treatment that is instituted before and often sustained throughout the insult) [182]. Brain resuscitation refers to the treatment of the secondary brain injury or simply to therapy given after the primary insult. The secondary consequences of ischemia are those that occur after the cerebral circulation is restored and are usually termed postischemic injury or reperfusion injury. Cell vulnerability differs, depending on the type of neuron. For example, the limbic system, especially the pyramidal cells of the CA1 layer of the hippocampus, Purkinje cells of the cerebellum, and layers 3, 4, and 6 of the cortex, are extremely vulnerable to ischemia; spinal cord cells, on the other hand, seem to tolerate a longer period of oxygen deprivation before they are injured.

Cerebral protection increases oxygen delivery, reduces its demands or ameliorates the pathological process by free radical scavenging or by reducing the effects of excitatory amino acids (glutamate, aspartate) and ionic fluxes. The difficulty with cerebral protection is that these strategies must be instituted before the onset of ischemia. With complete global ischemia, the brain tolerates 4-6 min of oxygen deprivation. The goal of cerebral protection is to delay the onset of irreversible CNS damage. There are no proven methods of cerebral protection except for mild hypothermia in animal models of neurotrama [183-185]. However, recent human trials using hypothermia following neonatal birth asphyxia, cardiac arrest or trauma have demonstrated an unclear benefit to neurological outcome or survival. Whether this variable result relates to the differences in the method and degree of hypothermia administration, variability in clinical practice with the initiation and maintenance of a cooling method, variation in the patient population with co-morbid factors (i.e. renal failure or lung injury), or heterogeneity of the secondary brain injury remains unclear [186]. Therefore, maintaining adequate cerebral perfusion and oxygen delivery, avoiding hyperglycemia and aggressively managing hyperthermia are, at this time, the only means we have to reduce CNS injury.

## **Cerebral resuscitation**

Intracellular events that occur during ischemia or after restoration of circulation and oxygenation contribute to the ultimate neurological damage. Ischemia depolarizes neurons and allows ionic fluxes (Na<sup>+</sup> and Ca<sup>2+</sup>) into the cells, probably owing to release of glutamate and aspartate and activation of the NMDA receptors. Depletion of adenosine triphosphate (ATP) stores leads to the energy-dependent ion pump's failure to eject Na<sup>+</sup> and Ca<sup>2+</sup> from the cells. This leads to formation of prostaglandins and oxygen free radicals, to mitochondrial respiratory chain paralysis, acidosis, and finally membrane destruction.

#### **Cerebral outcome**

The future of cerebral well-being depends on our level of understanding of the pathophysiology of hypoxicischemic injury and our broad-based medical and pharmacological knowledge. Future therapy depends on development of a better understanding of the molecular and cellular processes that cause CNS injury and the development of specific treatments to salvage or protect injured tissue. Ultimately, the goal is to provide effective therapeutic measures that reverse the cascades of cellular events leading to injury.

## CASE STUDY

A 2-year-old girl chases a ladybug to her open second-story bedroom window. The window screen is unable to support her weight and she falls two flights, plus an additional half-flight into the basement stairwell, striking the side of her head on a concrete step. Paramedics transport the child from the scene to a prearranged Medivac flight waiting at a nearby school parking lot. She arrives at the trauma bay with generalized tonic-clonic seizure activity and cyanotic lips, with the pulse oximeter registering a heart rate of 80bpm, and 88% arterial saturation. Her left antecubital region is swollen around the insertion site of an IV that does not run freely, and her last blood pressure recorded on the transport monitor is "timed out."

The trauma team consists of a general pediatric surgeon, pediatric anesthesiologist, pediatric emergency room physician, and three nurses: one from the trauma service, one from the pediatric ICU and one from the pediatric emergency department. Prior to the arrival of the child, the anesthesiologist has chosen, from a shelf of prepackaged, age-dependent trauma supplies, a kit labeled "toddler: 1-3 years; 8-14kg." The package is unwrapped on the trauma table to reveal the following supplies: size 3 airway mask, laryngoscope handle with Miller 1 and Mac 2 blades and spare bulbs, uncuffed 3.5, 4.0 and 4.5 tracheal tubes and a cuffed 4.5 tracheal tube, sizes 6 and 14 French stylets, sizes 2 and 2.5 laryngeal mask airways, 8 French suction catheters, 60 mm oral airway, sizes 18 and 20 nasal trumpet with lidocaine jelly, tongue blades, an IV start kit with 20 and 22 gauge IV catheters and a 15 gauge interosseous needle.

A pediatric respiratory therapist and a pharmacist have also been paged to the room per rapid response protocol. The pharmacist has a tackle box filled with syringes predrawn and sealed in a sterile hood, including atropine 0.1 mg/mL, epinephrine  $100 \mu \text{g/mL}$ , lidocaine 20 mg/mL, phenylephrine  $100 \mu \text{g/mL}$ , rocuronium 10 mg/mL, succinylcholine 20 mg/mL, pancuronium 1 mg/mL, etomidate 2 mg/mL, fentanyl  $50 \mu \text{g/mL}$ , ketamine 100 mg/mL, midazolam 1 mg/mL, and thiopental 25 mg/mL. The cover of the tackle box is a table of weights and standard doses (in mL) for each of the predrawn medications included.

According to roles predetermined and practiced in a simulator setting, the pediatric anesthesiologist commences with the management and stabilization of the airway and hemodynamics of the patient while the surgeon and ER physician perform the trauma survey. Initial concerns for securing the airway are over-ridden by the more pressing concern for impending herniation, which might be hastened by an uncontrolled and unmedicated laryngoscopy. Bag-mask ventilation is applied to the child with 100% oxygen and jaw thrust while the respiratory therapist holds in-line traction, stabilizing the neck, and cricoid pressure is held while supporting the back of the neck to avoid posterior displacement in case of C-spine fracture. The anesthesiologist confirms that the lungs of the child are easily ventilated with a mask whereas the trauma surgeon reports a large, minimally responsive left pupil, and the ED physician reports a left hemotympanum. Neurosurgery is called. The ED nurse has transferred the patient monitoring to the overhead monitor, visible to all members of the team, with audible pulse oximeter tone and a blood pressure cuff cycling every minute. The child is still unresponsive with a Glascow Coma Score of 5, no eye opening, no verbal response, and abnormal flexor posturing with stimulation.

The immediate benefits of CO<sub>2</sub> reduction and restoration of normoxia are a reduction in cerebral blood volume and the heart rate rises to 120 bpm. The pulse oximeter reads 100% but the mean blood pressure reads only 45 mmHg. The PICU and trauma nurses are attempting IV placement, which is difficult because of the tonic-clonic seizure activity. The anesthesiologist requests the ED nurse to prepare the interosseous needle, estimates the patient weight at 12kg, and requests the intramuscular administration of 0.2 mg/kg midazolam to abort the seizure activity. Seizure activity stops within a minute of injection and two IVs are quickly placed. An intravenous bolus of 20 cc/kg of acetatebalanced 2% saline, which is part of the pharmacist tackle kit, is administered. After hypertonic saline administration, the arterial blood pressure is 105/45, mean 65mmHg, and the heart rate is 105 bpm. Both pupils are now responsive. The anesthesiologist requests drugs for laryngoscopy and intubation. Lidocaine 1mg/kg and atropine 0.15mg are given. After 1 min and an additional 20 cc/kg of normal saline, the arterial blood pressure is 100/45, mean 60 mmHg, and the heart rate is now 120bpm. Thiopental 2mg/kg (half of the usual induction dose) and rocuronium 1.2 mg/ kg are given. The trachea is easily intubated with in-line traction and cricoid pressure still in place. The 4.5 cuffed ETT is secured after confirming placement and ventilation is initiated and titrated to keep the ETCO<sub>2</sub> between 30 and 35 mmHg.

The arterial blood pressure after intubation is now 65/25 with a mean of 35 mmHg. Phenylephrine  $5 \mu g/kg$  is given and the repeat blood pressure is 90/45, mean 55 mmHg. The dose is repeated, along with an additional 10 cc/kg of 2% saline. Repeat blood pressure is 105/55, mean 65 mmHg. The trauma survey is completed and the child is taken to the CT scanner which reveals a large epidural hematoma with midline shift, effacement of cortical sulci and the ipsilateral ventricle, as well as imperceptible basal cisterns.

The child is taken immediately to the operating room for decompression. The anesthesiologists prepare for incision. *Continued* 

O-positive trauma release blood is requested to the room. An arterial line is started and a second IV is placed. Anesthesia is maintained with intravenous remifentanil and propofol. The child is ventilated without PEEP to an end-tidal  $CO_2$  of 30 mmHg and an arterial blood gas is sent, but the result is not available until the procedure is well under way. Blood pressure is stabilized with phenylephrine infusion titrated to keep systolic blood pressure greater than 90 mmHg and mean arterial blood pressure between 60 and 65 mmHg. Temperature is maintained between 36° and 36.5° without the need for a warming blanket. Mannitol 25 mg/kg is given and a Foley catheter is placed.

Incision is made 50 min after the initial trauma, and the hematoma is evacuated through a craniotomy within 5 min. After evacuation of the hematoma, the heart rate decreased to 65 pm and the arterial blood pressure decreased to 65/25. Phenylephrine and 10 cc/kg of trauma release blood are immediately given and the pressure responds. An additional 10 cc/kg of saline is required to replace the brisk urine output following mannitol administration.

A parenchymal fiber-optic intracranial pressure monitor is placed upon closure of the dura and skull, reading 12 mmHg with a normal waveform. The child is taken to the ICU with only the remifentanil infusion, as cerebral perfusion pressure is 55 mmHg without phenylephrine. In the ICU, the remifentanil is stopped hourly for neurological checks and within 6h of admission, the child is opening her eyes and reaching purposefully for the tracheal tube, which is removed. After a night without intracranial pressure elevations at a serum sodium of 145 mg/dL, she is interacting appropriately with her parents at the bedside and her intracranial pressure monitor is removed.

#### Conclusions

This case illustrates the main anesthetic considerations presented in this chapter in critically ill patients with neurotrauma and increased ICP undergoing emergency procedures, with choices for airway, drug, and hemodynamic management to facilitate successful outcomes.

Description of a novel use of this newer anesthetic agent for awake craniotomy in children.

## Introduction

Thoracic surgery and anesthesia for thoracic surgery have changed significantly in the pediatric population over the last 15 years with the advent of video-assisted thoracoscopic surgery (VATS) and robotic surgery. While VATS procedures have changed certain aspects of the perioperative and postoperative management of pediatric patients with thoracic disease, thoracotomy continues to be a relatively frequent surgical procedure, particularly in very small infants in whom thoracoscopic equipment is often too large and cumbersome to perform complex procedures. Hence, the pediatric anesthesiologist must have the capacity to manage both surgical approaches within the thoracic cavity.

Certain aspects of anesthetic practice remain common to both thoracoscopic and open procedures, particularly the need for one-lung ventilation (OLV). Indeed, the need to access the thoracic cavity by trocar in VATS (and the inability to pack off the lung) makes OLV even more necessary than during open thoracotomy, where surgeons can use both retraction and packing to facilitate surgical access and visualization without damaging the underlying lung parenchyma. The need for OLV in younger children has led to the development of many devices that allow lung isolation in children in whom the smallest size double-lumen tube (26 Fr) is too large.

Video-assisted thoracoscopic surgery has significantly decreased the requirement for neuroaxial blockade during the intraoperative and postoperative periods due to its less invasive and less painful nature. This has radically decreased the number of inpatient days following complex thoracic procedures [1]; however, due to the continuing need for thoracotomy within the pediatric population, the pediatric anesthesiologist must maintain the ability to provide adequate postoperative analgesia when necessary.

The relatively recent availability of rapid-onset and -offset anesthetic agents, specifically the highly insoluble desflurane and rapidly metabolized remifentanil [2], has allowed anesthesiologists to provide the rapid-onset and profoundly deep anesthesia necessary for thoracic surgery. The effects of these agents are so rapidly reversed at the end of surgery that rapid operating room turnover with alert, awake, compliant postoperative patients has become a reality rather than a pipe dream.

This chapter reviews the pathophysiology of OLV, discusses the anesthetic practice and tools necessary to facilitate the perioperative management of the pediatric thoracic surgery patient, covers analgesia for thoracic

surgery, and discusses in more detail some of the finer nuances of certain specific thoracic surgical challenges within the pediatric population, namely lobectomy, pneumonectomy, congenital cystic lung disease, anterior mediastinal mass, pectus excavatum, and empyema.

# Pathophysiology of one-lung ventilation

During thoracic surgery, several factors have profound effects on the matching of ventilation and perfusion (V/Q). General anesthesia, neuromuscular blockade, mechanical ventilation, the open hemithorax and surgical retraction all affect normal V/Q matching, primarily because of their effects on lung compliance [3]. OLV uncouples V/Q matching in the operative lung, which results in significant hypoxemia if not properly managed [3]. These factors apply equally to children and adults.

#### The lateral decubitus position

When awake, spontaneously breathing adults with unilateral lung disease are placed in the lateral decubitus position, oxygenation is optimal when the healthy lung is dependent ("down") and the diseased lung is nondependent ("up") [4,5]. Because of the hydrostatic pressure gradient between the two lungs, there is greater perfusion of the dependent, healthy lung than the nondependent, diseased lung, improving V/Q matching.

On the other hand, infants, both those breathing spontaneously and those receiving positive pressure ventilation, behave differently from adults. Oxygenation is improved with the healthy lung "up" and the diseased lung "down" [6,7], in part due to the fact that ventilation may be distributed differently in infants and adults because the soft, more compliant ribcage of infants does not fully support the underlying lung. This results in a functional residual capacity (FRC) that is closer to residual volume, making airway closure more likely in the dependent lung during tidal breathing [8]. In smaller children there is less cephalad displacement of the dependent hemidiaphragm by abdominal organs than in larger subjects. Thus, in accordance with Starling's Law, contraction is less forceful in the dependent hemidiaphragm than in the upper hemidiaphragm, which limits the dependent lung's efficiency of ventilation. Ventilation is therefore distributed preferentially to the non-dependent lung of infants.

The small size of the infant reduces the hydrostatic pressure gradient (present in adults) between the dependent and non-dependent lungs. Consequently, the favorable increase in perfusion of the dependent, ventilated lung, which occurs in adults, is attenuated in infants. It is not known at what age the adult pattern appears. It is suggested that during the postoperative period the child with unilateral lung disease should be nursed supine and in both lateral decubitus positions to determine which position provides optimal gas exchange.

## Pulmonary perfusion during one-lung ventilation

Current lung separation techniques have made it easier to deliver the entire tidal volume to the dependent lung. When OLV is initiated, residual oxygen is gradually absorbed from the unventilated alveoli until complete absorption atelectasis occurs. Continued perfusion of the unventilated lung, in addition to positional effects, increases V/Q mismatch or shunt fraction. This right-toleft shunt through the unventilated lung should produce an overall shunt fraction in excess of 50%. Fortunately, observed shunt fractions are much lower. Passive (mechanical) and active (biological) forces account for the lower than expected shunt fraction. Surgical manipulation, the effects of the open or artificial pneumothorax, and physical kinking of pulmonary vessels with lung deflation reduce blood flow to the operative lung. In addition, hypoxic pulmonary vasoconstriction (HPV) increases pulmonary vascular resistance in the unventilated lung, causing a gradual decrease in blood flow and shunt fraction. The true clinical importance of HPV has been questioned [9].

### Ventilation during one-lung ventilation

Ventilatory management of patients undergoing OLV has long focused on avoiding hypoxia. Hypoxia, however, is less frequent now because lung isolation is more complete, fiber-optic bronchoscopy permits confirmation of correct bronchial blocker or double-lumen tube position, and the anesthetic agents used have fewer or no detrimental effects on HPV. Recent publications have focused on prevention of acute lung injury (ALI) associated with OLV. ALI occurs after 2.5% of lung resections in adults, but occurs in 7.9% of patients after pneumonectomies. Around 40% of adults with ALI demonstrate morbidity or mortality [10]. Similar outcome data are not available in children. Recommendations for protective lung ventilation (PLV) during OLV include tidal volumes of 6 mL/ kg, limiting the plateau airway pressure to  $<20 \text{ cmH}_2\text{O}$ , and the use of 5–10 cmH<sub>2</sub>O positive end-expiratory pressure (PEEP) to preserve dependent lung unit aeration, prevent atelectasis and reduce injury from mechanical stress [11]. Continuous positive airway pressure (CPAP) or blow-by oxygen to the operative lung may be required to treat hypoxemia. Resumption of two-lung ventilation with 100% oxygen during surgery may be required if severe or refractory hypoxemia occurs. If this is not possible, the surgeon should consider placing a pulmonary artery clamp on the operative side during pneumonectomy or lung transplant.

# Anesthetic requirements for thoracic anesthesia

### **One-lung ventilation**

There are three principal indications for OLV [12].

- **1.** To control the distribution of ventilation: bronchopleural (cutaneous) fistulas, gigantic unilateral lung cysts or bullae, and differential lung ventilation.
- **2.** To avoid spillage of material or contamination: infection, hemorrhage, and unilateral pulmonary lavage.
- **3.** To provide a quiet operative field: thoracoscopy, thoracotomy, and thoracic non-pulmonary surgery.

To facilitate this, there are three basic techniques or devices that are currently widely used to isolate one lung from the other in the pediatric patient.

- **1.** Selective endobronchial intubation with a conventional single-lumen endotracheal tube.
- 2. A bronchial blocker.
- 3. A double-lumen tube (DLT).

In the modern era, with widespread availability of the fiber-optic bronchoscope (FOB), clinicians should strive to directly visualize and verify device placement where possible. The choice of device depends on patient age, size, and device availability (Table 24.1, Fig. 24.1).

### **Endobronchial intubation**

The simplest method of isolating one lung and the method most frequently used in the smallest of patients involves advancing a standard endotracheal tube (ETT) past the carina and into the non-operative main bronchus. When passed blindly, the ETT invariably enters the right main bronchus. To selectively intubate the left main bronchus, the ETT is rotated so that the bevel faces the right, the patient's head is rotated to the right and the ETT is advanced [13]. Placement should be confirmed with a FOB, which requires a good working knowledge of the anatomy of the bronchial tree distal to the carina.

An alternative is to place the ETT in the trachea and pass the FOB into the main bronchus before "railroading" the ETT over it. Unfortunately, the smallest size of FOB available is 2.2mm in diameter and this is not rigid enough to withstand "railroading" a rigid ETT without potentially causing significant damage to the FOB fibers.

#### **Bronchial blockers**

### Embolectomy catheter/blocker

Embolectomy catheters effectively achieve lung isolation in the smallest of patients [14]. The blocker can be inserted either through the ETT or alongside it. Fogarty catheters have a central stylet that can be bent to facilitate placing the catheter in either bronchus (Fig. 24.2) whilst being

Table 24.1 Device selection for OLV in children

Age	OLV airway device	
Less than 2 years	Selective endobronchial intubation Fogarty catheter (4Fr) as a bronchial blocker	
2–6 years	Fogarty catheter (4Fr or larger) as a bronchial blocker Wire-guided endobronchial blocker (5Fr)	
6–10 years	Wire-guided endobronchial blocker (5 Fr or larger) Univent tube (3.5 ID)	
Over 10 years	Wire-guided endobronchial blocker Univent tube DLT (26Fr or larger)	

Modified from Choudhry [15].

Figure 24.4 A standard 5.0 ETT with FOB and 5 Fr WEB in situ.

observed with a FOB through the ETT. The open tip of the catheter allows for lung collapse following isolation and for insufflation of oxygen if necessary.

## Wire-guided endobronchial blocker

Wire-guided endobronchial blockers (WEBs) are available in a "pediatric" size – 5 Fr. The blocker is placed through a standard ETT; a guidewire loop attached around the end of a FOB allows direct visualization and placement of the blocker. This device has the benefit of three ports that allow ventilation while the blocker is manipulated into place (Fig. 24.3). The smallest ETT that can be used with the smallest 5 Fr WEB is a 5.0 mm ETT, hence use of this device is limited to children between 2 and 4 years of age (Fig. 24.4).

Figure 24.3 The components of the wirequided endobronchial blocker (WEB).

Figure 24.5 A 5 Fr WEB placed alongside a standard 3.5 ETT with the FOB within the ETT.

The blocker can be placed alongside the ETT in smaller patients (Fig. 24.5) when there is insufficient room within the ETT for both blocker and FOB [15].

#### Univent tube and blocker

The Univent tube (Fuji Systems Corporation, Tokyo, Japan) has a second lumen containing a separate bronchial blocker that is styletted and can be bent to facilitate positioning of the tube (Fig. 24.6). The smallest size Univent tube is 3.5mm internal diameter; however, the total external diameter is 8mm, making it comparable in size to a 6.0mm internal diameter uncuffed ETT. This limits the use of this device to older children (approximately 8 years of age).

Figure 24.6 The smallest 3.5 ID Univent tube available next to a standard 5.0 ETT.

**Figure 24.7** Smallest DLTs available. Top to bottom: 28Fr (Mallinckrodt Medical, St Louis, MO) DLT, 26Fr (Rusch, Buluth, GA) DLT, 6.0 ETT (standard).

## **Double-lumen tube**

Double-lumen tubes (DLTs) are considered the gold standard for lung isolation in adults; however, the smallest size tubes available are 26 Fr (Rusch, Buluth, GA) and 28 Fr (Mallinckrodt Medical, St Louis, MO) (Fig. 24.7). These tubes can only be utilized in older children (8–10 years of age) and are positioned in the same manner as in adults. Due to the wide variation in the size of pediatric patients, there are no designated depth measurements for the placement of the DLT; hence its location in the bronchus should be confirmed with a FOB.

### Anesthetic techniques

Preoperative evaluation and preparation of patients are important and should be as thorough and complete as in all pediatric operative candidates. Some children will be otherwise completely fit and healthy; others may have significant concurrent and severe systemic illness. Premedication and the anesthesia induction technique are at the discretion of the anesthetic provider and need to be tailored to the individual [16].

Lung isolation, if required, and the postoperative analgesic technique should be planned well in advance. Arterial line placement is recommended for thoracotomy and should be seriously considered for VATS – particularly in small infants and babies in whom the potential for accidental overinflation of the pleural cavity and iatrogenic tension pneumothorax is significant. Lung isolation and deflation should be initiated early, particularly in VATS patients to allow adequate time for the lung to collapse (up to 20 min) and to minimize the need for lung retraction [15]. Once OLV is instituted, the lungs should be ventilated with enough oxygen to achieve oxygen saturations of 94% or above. Nitrous oxide is avoided because it may cause overinflation of tracheal and bronchial balloons and cause airway trauma [17].

There is a perception that isoflurane causes less V/Q mismatch during OLV because it is thought to have less impact on HPV than other volatile agents [18]. Isoflurane's slow offset time makes it less appealing as a primary anesthetic agent. The rapid offset of the more recently developed volatile agents, such as desflurane, particularly after a long case, makes them very appealing for thoracic anesthesia. To minimize inhibition of HPV, we advocate using a maximum of 1 minimum alveolar concentration (MAC) of the chosen volatile anesthetic and adding agents such as propofol and/or opiates that have little impact on HPV to prevent awareness during surgery [19].

When a short-acting volatile agent such as desflurane is combined with the profound  $\mu$  agonism of remifentanil, regional anesthesia or a non-steroidal anti-inflammatory drug (NSAID) (and where available, intravenous acetaminophen/paracetamol) at the end of the case facilitates rapid emergence from anesthesia and a coherent, relatively pain-free, and interactive patient.

## Analgesic requirements for thoracic surgery

Thoracic surgery, especially open thoracotomy and minimally invasive pectus excavatum repair, often results in significant postoperative pain. Thoracotomy is often associated with severe chest wall trauma that includes fractured ribs and peripheral nerve damage. The chest wall must remain in constant motion for effective gas transfer to take place and to clear secretions effectively. This increases the amount of pain. Shallow respirations and a poor cough predispose the child to atelectasis, sputum retention, and postoperative pneumonia. Sensitization of the child to painful stimuli following surgery can cause chronic pain and/or higher pain levels during subsequent surgical procedures. About a third of adult patients suffer from chronic pain after thoracic surgery [20] and the incidence of pain is similar whether the patient undergoes a thoracotomy or VATS [20–22].

Some surgical literature suggests that children should understand "that they are going to have to learn to be comfortable with being uncomfortable" [23]. The authors contest this statement and believe that it is the anesthesiologist's responsibility to their patients to do all they can to prevent/minimize the pain. Suresh asked the question: "If placing a thoracic epidural catheter in adults is considered the 'standard of care' in many institutions across the country, why is the child deprived of the same privilege?" [24]. We agree.

Various pain treatment modalities have been described for the treatment of post-thoracotomy pain, but when the factors influencing the generation of post-thoracotomy pain are considered, regional analgesia is the most logical approach [25]. This is because neurogenic pain, which results from intercostal nerve damage and chest wall trauma, and central nervous system hyperexcitability are poorly responsive to opioids [26,27]. Reliance on these drugs may detrimentally affect respiration and oxygenation [28,29]. To achieve optimal pain relief, it is logical to start the regional analgesic regimen preoperatively [30]. A multimodal analgesic approach that combines an effective afferent nerve block with a NSAID, acetaminophen/ paracetamol, and/or low doses of opioids usually achieves an optimal level of postoperative analgesia. Although regional anesthesia is the subject of another chapter (Chapter 18), several regional techniques deserve emphasis in a discussion of anesthesia for thoracic surgery.

#### **Epidural analgesia**

In contrast to older children and adults, epidural and subarachnoid blockade in infants and children under the age of about 6 years is characterized by hemodynamic stability, even when the level of the block reaches the upper thoracic dermatomes [31]. Although heart rate variability is lower, heart rate is preserved because the parasympathetic activity modulating heart rate is attenuated in infants [32]. This attenuated vagal tone allows the heart rate to compensate for peripheral vasodilation. Other factors that preserve hemodynamic stability are the relatively small venous capacitance in the lower extremities of infants and the relative lack of resting sympathetic peripheral vascular tone [33].

Thoracic epidural blockade of pain has been shown to improve several measures of respiratory function [34–36]. Evidence suggests that improved postoperative tidal volume and diaphragmatic shortening after thoracic epidural blockade may be due to changes of chest wall conformation and diaphragmatic resting length, and to a shift of the workload of breathing from the ribcage to the diaphragm following motor block of intercostal muscles [37].

In infants, thoracic catheter placement can be achieved via the caudal space with cephalad threading of a styletted catheter [38]. Although successful application of this technique has been described in children up to 10 years of age [39], in children over the age of 1 year the chance of the catheter exiting a dural sleeve or becoming knotted or tangled is increased [40,41]. Epidurograms [42], epidural electrocardiography [43], and electrical stimulation [44] have been used to confirm that the catheter tip is positioned at the desired level. With experience, ultrasound (US) has become the modality of choice for visualizing the epidural catheter tip [45-48]. Ultrasound localization is non-invasive, avoids exposure to radiation and contrast medium, and is not affected by the use of neuromuscular blocking drugs or epidural local anesthetics.

Epidural catheter tip placement near the dermatomal level of the surgical incision(s) allows the safest and most effective application of local anesthetics. Thoracic epidural catheters, which may be safely placed in anesthetized infants and children by experienced anesthesiologists [49], have less risk of contamination by stool and urine than caudally placed catheters. A prospective survey of the French-Language Society of Pediatric Anesthesiologists found no complications from thoracic epidurals, whereas there were 0.7 complications per 1000 caudal epidurals. The number of thoracic epidurals was much smaller than caudal epidurals, however (135 versus 15,013) [50].

## Paravertebral analgesia

The paravertebral space is wedge shaped. Its boundaries are the superior costotransverse ligament posteriorly; the posterior intercostal membrane laterally; the parietal pleura anteriorly; and the posterolateral aspect of the vertebrae, intervertebral disks, and intervertebral foramen anteriorly. The space contains spinal nerves and dorsal rami, rami communicantes, and the sympathetic chain anteriorly. Injection of local anesthetic into the paravertebral space avoids possible complications of central neuroaxial blockade.

Paravertebral block (PVB) has been employed in children since 1992, when two different techniques were described: Lönnqvist's modification of the original Eason–Wyatt percutaneous catheter technique [51] and Sabanathan's surgical catheter placement during thoracotomy [52]. The main indication for thoracic PVB is unilateral thoracic surgery. Continuous infusion is possible via a catheter placed transcutaneously or surgically via thoracotomy. A rate of 0.25 mL/kg/h is recommended [51,53–55]. The advantage of a PVB is that deposition of local anesthetic into the paravertebral space leads to a unilateral block of one or more adjacent dermatomes. Because all the effects of PVB are unilateral, hypotension, which limits the dose of local anesthetic used in epidural analgesia in children over the age of 6 years, is not a problem. Relatively large doses of drug can therefore be used with consequent improvement in efficacy of the unilateral blockade. The sympathetic chain that is known to be important in pain transmission is reliably blocked by PVB, whereas the central sympathetic blockade produced by epidural and spinal anesthesia leaves this pathway unaffected, thereby allowing central relaying of information (bypassing the blockade) [56]. Confirmation of the lack of provision of high-quality afferent blockade with epidural analgesia is shown by its failure to inhibit somatosensory-evoked potentials and the failure to produce stress inhibition for any surgery more rostral than gynecological or surgery that is more distal [57,58]. There are fewer PVB data for comparison, but PVB abolishes thoracic somatosensory-evoked potentials [59] and inhibits some parameters of the stress response [30,60].

#### Intercostal analgesia

Intercostal blocks after thoracotomy reduce opioid requirements and improve respiratory function in children with rib fractures [61–63]. The disadvantage of single-shot blocks is their limited duration of action. The development of degradable bupivacaine microspheres, which have a dramatically prolonged duration of action, may increase the usefulness of these blocks in the future [64,65]. Plasma concentrations of local anesthetics after intercostal blocks are greater than those after other regional blocks. Plasma concentrations of the local anesthetic rise faster in children than in adults [66,67].

A continuous infusion of local anesthetic through an extrapleural catheter placed by the surgeon during thoracotomy wound closure can prolong the analgesic effect [62]. The analgesic effect may result from delivering local anesthetic to the paravertebral space [68].

#### Summary

How can clinicians decide which regional analgesic technique to use in thoracic surgery in children? A metaanalysis of 10 trials that included 520 adult patients concluded that PVB and epidural analgesia provide comparable pain relief after thoracic surgery, but PVB has a better side-effect profile and is associated with a reduction in pulmonary complications [69].

For adult thoracic surgery, the Procedure-Specific Postoperative Pain Management (PROSPECT) Working Group evaluated the available literature comparing various regional analgesic techniques for the management of post-thoracotomy pain [70]. Seventy-four randomized studies in thoracotomy patients were identified that compared regional analgesic techniques with systemic opioid analgesia or with each other. The authors concluded that evidence supported the use of thoracic paravertebral block as an effective alternative to thoracic epidural local anesthetic (LA) alone, and showed that paravertebral block reduced the incidence of postoperative pulmonary complications compared with systemic analgesia. They suggested that further studies are required to determine whether thoracic paravertebral block provides equivalent pain relief and morbidity to thoracic epidurals when LA is combined with opioids. Apart from thoracic paravertebral block, all other regional analgesic techniques were inferior to thoracic epidural analgesia. In particular, interpleural techniques provide inadequate analgesia. However, if thoracic epidural or paravertebral techniques are not possible or are contraindicated, intercostal nerve block or preoperative intrathecal opioid is recommended.

## Thoracoscopy

The field of minimally invasive surgery (MIS) is the fastest growing area of surgical innovation. Each year, as new techniques and tools are developed, more patients benefit from these less invasive surgical procedures. Thoracoscopy has several potential advantages over thoracotomy for resection or repair of intrathoracic abnormalities in children. There is less postprocedure scoliosis, which develops in up to 30% of neonates after thoracotomy [71]. In addition, thoracoscopy is associated with less pain and better pulmonary mechanics postoperatively and with improved cosmesis compared to thoracotomy. Shorter hospital stays, a faster return to normal activity, and a shorter recovery period are just a few of the advantages that MIS offers to pediatric patients.

Originally, VATS was developed to provide biopsy specimens of intrathoracic structures in immunocompromised patients [72]. Although it continues to be used for this purpose in the pediatric population, increasing numbers of pediatric surgical conditions are also being addressed by VATS (Box 24.1).

With the advances in thoracoscopic equipment, including the availability of smaller scopes and improvements in both the fiber-optics and the quality of digital video signals and screen resolution, VATS is being applied to younger and younger children, even to neonates and infants.

Blood loss during thoracoscopic surgery is generally minimal; however, adequate venous access should be secured prior to the start of these procedures because there is the possibility that one of the trocars or an endoscopic instrument will inadvertently injury one of the intrathoracic vascular structures. Access to the Box 24.1 Thoracoscopic procedures in infants and children

- Diagnostic thoracoscopy
- Lung biopsy
- Pectus repair
- Empyema drainage

- Thoracic duct ligation
- Sympathectomy
- Mediastinal mass excision
- Anterior spinal fusion

extremities to obtain additional venous access during the procedure can be limited because these procedures are routinely performed in the lateral decubitus position. Standard perioperative monitoring includes pulse oximetry, electrocardiogram, end-tidal CO<sub>2</sub> and inhaled volatile agent concentration, non-invasive blood pressure measurement, and body temperature.

Routine central venous pressure monitoring offers little additional information that improves or influences anesthetic care of patients with normal cardiovascular function. Central venous access is generally reserved for cases in which adequate peripheral intravenous access is unavailable. Invasive monitoring of arterial blood pressure is not routinely used but its use is guided by the clinical status of the patient.

One-lung ventilation is highly desirable during thoracoscopy because lung deflation improves visualization of thoracic contents and may reduce the risk of retractorinduced lung injury. If OLV cannot be achieved, thoracoscopy can be performed during two-lung ventilation, using CO<sub>2</sub> insufflation and a retractor to displace lung tissue from the operative field [73]. This technique is also useful for improving the surgeon's view when there is inadequate separation of the two lungs and there is overflow ventilation into the operative side. During creation of the artificial pneumothorax, cardiopulmonary function should be monitored closely because displacement of intrathoracic contents and creation of an excessive pneumothorax (caused by either excessive volume or pressure) can decrease venous return or increase left ventricular afterload, which can significantly compromise the cardiovascular system. The effects of the artificial pneumothorax can be minimized by slowly adding the  $CO_2$  (flow rate 1 L/min), limiting the inflating pressure to 4–6 mmHg, and optimizing cardiovascular function, including optimization of myocardial contractility (if required) and restoration of the intravascular status [74].

Another significant risk during creation of an artificial pneumothorax is inadvertent  $CO_2$  embolism [75]. This occurs when the insufflating gas enters the circulation, either by direct injection into the vasculature during insufflation or when gas enters an internal vessel that was damaged during the procedure [76].

## **Robotic surgery**

The field of robotic surgery is progressing exponentially because newer robotic instruments articulate better, which increases the surgeon's dexterity and ability to work in small spaces. Articulated tools and a threedimensional optical stereoscopic view make the procedure more similar to open procedures for the surgeon. Good preoperative communication with the surgeon is essential to appropriately plan for positioning of the operating room table within the operating room, positioning of the operating robot so the anesthesia provider has good access to the child's airway, and positioning of the child on the operating table. It is of enormous benefit to perform robotic surgery in a dedicated operating room with staff who are experienced in the management of robotic surgery cases.

## Lung resection

In developed countries, the age of children undergoing pulmonary resections has steadily decreased over the last decades, reflecting a decline in the number of procedures performed for infectious etiologies. At the same time, there has been a rise in the number of resections performed for congenital malformations. An understanding of normal lung growth in the postnatal period is essential to predict pulmonary function after lung resection in children (see Chapter 6). Alveoli multiply after birth [77] from approximately  $20 \times 10^6$  at birth (in term infants) to approximately  $300 \times 10^6$  at 8 years of age. The most rapid increase occurs during the first 3 years of life. After 8 years of age, the alveolar number remains constant. The lung volume doubles between 8 and 25 years of age, which is accounted for by the increased volume of individual alveoli [78].

#### Lobectomy

While pulmonary resection in adults causes a proportional decrease in lung volume, infants who undergo lung resection have normal pulmonary function and develop normally, live normal lives, and have no physical impairment at rest. McBride et al [79] evaluated the pulmonary function of 15 patients who had undergone lobectomies for congenital lobar emphysema between 1 week and 3 years of age. They found that vital capacity and total lung capacities were within the normal range in the vast majority of these patients 8–30 years after surgery. There was an association between the resected anatomical portion of the lung and the extent of compensatory lung growth. The most vigorous compensatory growth occurred after upper lobectomies. The presence of normal residual volumes in their patients is further evidence that the compensatory growth was consistent with multiplication of alveoli.

### Pneumonectomy

Early studies described preserved pulmonary function after pneumonectomies performed during childhood. In 1947, Cournard [80] reported outcomes of four patients who had undergone left pneumonectomies for pulmonary infections between 6 and 16 years of age. The total lung capacity of the remaining lung was greater than would have been predicted for the right lung of an individual without a history of pulmonary resection. In three of the four patients, the vital capacity exceeded the predicted value for a right lung.

Laros and Westermann [81] stratified 130 pneumonectomy patients by age at the time of their operation. Preservation of total lung capacities decreased with increasing age at which the pneumonectomy occurred. The total lung capacity was 96% of the predicted value in patients who were younger than 5 years of age at the time of their pneumonectomy, 85% of predicted in patients between 6 and 20 years of age, but only 70% of predicted in patients between 31 and 40 years of age.

#### Postpneumonectomy syndrome

The postpneumonectomy syndrome is associated with progressive hyperinflation of the remaining lung and typically leads to progressive dyspnea. It can also lead to bronchomalacia and pulmonary infections. Postpneumonectomy syndrome is most commonly seen after a right pneumonectomy [82] due to counterclockwise rotation of the mediastinal structures and compression of the left mainstem bronchus or left lower lobe bronchus between the aorta and spine posteriorly and the pulmonary artery anteriorly. Postpneumonectomy syndrome can also be encountered after a left pneumonectomy in patients who have a right-sided aortic arch if the airway is compressed between ascending and descending aorta [83]. However, this complication has also been reported in patients after a left pneumonectomy who have a left-sided aortic arch [84]. In this case, the bronchus intermedius is thought to be compressed between the right pulmonary artery anteriorly and the thoracic spine posteriorly after clockwise rotation of the mediastinal structures into the right pleural cavity.

Early attempts to prevent mediastinal shifts after pneumonectomies in children included thoracoplasties, which were eventually abandoned secondary to the crippling deformities that developed. Other attempts to prevent mediastinal shifts in the past have included instillation of inert substances, such as oil, into the pleural cavity. The principles of treating this syndrome today include a combination of anterior pexy of mediastinal structures, such as the pericardium and pulmonary artery, and an intervention in the postresection pleural cavity to prevent future shifting [85]. For many years, rigid prostheses such as silastic testicular or breast prostheses were placed in the pleural cavities to stabilize the mediastinum [86], but the size of the prosthesis could not be adjusted in a growing child. In 1992, Kosloske and Williamson [87] reported the use of expandable tissue expander prostheses in an effort to address this problem. Finally, placement of endobronchial stents has been reported, mostly in adults.

## Thoracic surgical lesions

Thoracic surgery in neonates is done primarily to treat congenital pulmonary anomalies such as congenital cystic lesions, congenital diaphragmatic hernia (CDH), and tracheo-esophageal fistula (TEF). These anomalies often present *in utero* or in the newborn period. Other lesions, such as neoplasms, infectious diseases and musculoskeletal deformities, are found in later childhood. CDH and TEF are described elsewhere (see Chapter 21), but the remainder of these surgical lesions affecting infants and children are reviewed here, along with specific anesthetic considerations.

#### Congenital cystic lung disease

Of the many types of congenital cystic lesions, the overwhelming majority can be categorized into four groups: congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration (BPS), congenital lobar emphysema (CLE), and bronchogenic cyst (BC). These malformations have distinct features, yet they have significant overlap, suggesting there may be a single pathological mechanism for their development [88]. Of note, CCAM is more correctly termed CPAM (congenital pulmonary airway malformation) since many are neither cystic nor do they have adenoid tissue [89], but will be referred to as CCAM in this text, as is generally found in anesthesia and surgical literature.

Cystic lung lesions are often identified on routine fetal ultrasound at about 20 weeks' gestation [90]. Management in a fetus depends on the lesion itself and on the status of the fetus and mother. Large lesions may compress the esophagus, lung or vena cava and result in polyhydramnios, pulmonary hypoplasia or low-output cardiac failure and fetal hydrops, respectively. When there is evidence of fetal hydrops, intervention options include thoracocentesis, thoracoamniotic shunting, open fetal surgery and resection, ex utero intrapartum therapy and resection (EXIT procedure), or early delivery and postnatal resection. For a fetus greater than 32 weeks' gestation, resection during EXIT procedure is recommended. Those less than 32 weeks' gestation have the option of intrauterine surgery [91]. Anesthesia for fetal surgery and EXIT procedure is discussed in Chapter 19.

Small lesions may be asymptomatic or may cause respiratory distress in the newborn period. Initially asymptomatic lesions may develop into infection, pneumothorax or malignant degeneration later in life. Serial imaging has revealed, however, that many large lesions actually decrease in size [92,93]. Postnatal symptoms depend on the size, location and type of lesion, as well as any communication with the gastrointestinal tract or bronchopulmonary tree. Pulmonary hypoplasia can be associated with pulmonary hypertension or respiratory failure and may require extracorporeal membrane oxygenation (ECMO). Many lesions are asymptomatic and remain undiagnosed for years. Almost all patients eventually develop complications, most often as pneumonia unresponsive to medical management.

Patients with prenatally diagnosed lesions should have a computed tomography (CT) scan of the chest after birth. Children with lesions that were not identified prenatally and which cause respiratory distress after birth undergo chest radiography as the first diagnostic test and confirmatory studies, such as CT, afterwards (Figs 24.8, 24.9). Occasionally, magnetic resonance imaging (MRI) and bronchoscopy may be necessary. CCAM, CLE and extralobar BPS are occasionally associated with other congenital anomalies and may necessitate additional preoperative work-up, including echocardiography [88].

While there is consensus that all symptomatic lesions should be resected, there is debate whether asymptomatic lesions should be observed or resected. CCAMs and BPS sometimes resolve spontaneously on fetal ultrasound, but there is no evidence that this occurs after birth. Pulmonary lesions that become undetectable by fetal ultrasound and postnatal radiograph may be visible on CT. Ten percent of asymptomatic CCAMs that were followed conservatively required surgery later [92]. It is therefore still recommended that CCAM, intralobar BPS and BC be resected between 3 and 6 months of age. Extralobar BPS can remain asymptomatic for life but can also cause complica-

Figure 24.8 Chest radiograph of a newborn with a CCAM.

Figure 24.9 Chest CT of a newborn with a CCAM

tions. A period of observation has been advocated for this lesion [90] and for asymptomatic CLE, which may resolve spontaneously.

When neonates with congenital lung lesions require anesthesia, it must be determined if positive pressure ventilation (PPV) will be tolerated. PPV of the lungs of patients who have lesions with a bronchial connection to abnormal lung parenchyma could develop overdistension of the abnormal lobe and compression of normal lung tissue through a ball-valve effect. This can compromise ventilation, shift the mediastinum, compress the great vessels, and decrease cardiac output. If there is doubt whether there is a bronchial connection to the thoracic lesion, spontaneous ventilation should be maintained during induction and maintenance of anesthesia. Once the affected lung is isolated, PPV and neuromuscular blockade can be safely initiated. Postoperative analgesia can be by intravenous opioids or, preferably, by a thoracic epidural placed directly at the desired level or threaded from the caudal canal. Recently, more congenital lung lesions have been resected using VATS. When VATS is used in the infant population, it is challenging for the anesthetist and surgeon and often results in significantly longer operative times; however, it is safer for the patient and may reduce hospital stay [93,94].

#### Cystic adenomatoid malformation

A CCAM is a discrete intrapulmonary mass that is either solid or cyst containing, and is typically characterized by increased adenomatous respiratory bronchioles. The cysts can be of various sizes, from 1mm to over 10cm. Although the lesion is non-functional, it does communicate with the normal tracheobronchial tree, which can cause air trapping during positive pressure ventilation [91]. CCAM is usually present in only one lung lobe, and occurs in all lobes with equal frequency. When it involves more than one lobe, pneumonectomy may be required. Associated anomalies are uncommon.

Congenital cystic adenomatoid malformations are usually detected *in utero* by ultrasound. They rarely result in pulmonary hypoplasia, hydrops fetalis or fetal demise. Most CCAMs are asymptomatic and are resected electively in the neonatal period. Those that cause cardiac or respiratory distress may necessitate emergency resection, either in the immediate postnatal period or by EXIT procedure [91].

While there is a communication between the lesion and the tracheobronchial tree, CCAMs are usually solid or have small cysts, acting more like solid lesions. Thus it is usually safe to use PPV. Most lesions can be resected without lung isolation, but if necessary OLV is easily accomplished by mainstem intubation. Intraoperative and postoperative pain management is accomplished through an epidural catheter [95].

#### **Bronchopulmonary sequestration**

A BPS is a portion of non-functioning lung tissue without a bronchial connection. It typically has an anomalous blood supply, arising from bronchial or aortic vessels, and has systemic, bronchial or azygous venous drainage. BPS is usually found in the lower lobes. The majority of lesions are intralobar (inside lobe pleura) and the rest are extralobar (with their own pleura). BPS can be confused with CCAM and some lesions are considered "hybrid," having features of both BPS and CCAM.

Bronchopulmonary sequestration is frequently diagnosed *in utero*. Detection of a systemic artery from the aorta to fetal lung tissue that is identified by color flow Doppler is pathognomonic for BPS [91]. At birth, most BPSs are asymptomatic and present later in life as antibiotic-resistant pneumonia. Sometimes a large BPS will compress the lungs and cause respiratory distress. If the blood supply to the lesion is large, high-output cardiac failure may occur. BPS is diagnosed using CT, but a MRI is helpful for mapping the blood supply and drainage before surgical resection.

There are few unique anesthesia concerns for BPS. OLV is helpful for surgical resection, but because there is no connection between a BPS and the bronchial tree, it is safe to use PPV.

#### **Congenital lobar emphysema**

Congenital lobar emphysema is an abnormally emphysematous lobe of the lung that communicates with the bronchial tree. It occurs most commonly in the left upper lobe, then the right middle and then left lower lobes and can be distinguished from other cystic pulmonary lesions by ultrasound. It often enlarges before 28 weeks' gestation because fetal lung fluid is trapped within the lesion, similar to the air trapping that occurs postnatally. The lesion may regress and the lung tissue may appear normal at birth [91].

Even though CLE is usually asymptomatic, it is important that patients with CLE are carefully evaluated at birth because of the risk of air trapping in the emphysematous lobe. Overinflation of the lobe may lead to "tension emphysema" and compression of the contralateral lung [96]. At this stage CLE can be confused with a tension pneumothorax and a chest tube may be inappropriately inserted, leading to further respiratory distress. Large lesions may decrease cardiac output and eventually cause cardiac collapse. An emergency thoracotomy with rapid exteriorization of the lobe is required.

The primary concern for anesthetists is avoiding overdistension of the affected lung tissue. PPV may lead to rapid expansion of the lesion, due to a ball-valve effect; an effort should be made to maintain spontaneous ventilation. If PPV is necessary, low inflating pressures should be used. OLV is typically used to isolate the affected lung and once accomplished, it is also safe to use PPV. Nitrous oxide should be avoided throughout the case. At the end of the procedure, two-lung ventilation is instituted to check for gas leaks at the resection site. To reduce the incidence of air leaks, the trachea should be extubated early or, if the trachea remains intubated, the patient should be allowed to breathe spontaneously. The use of VATS is more challenging with CLE than it is with other cystic lung lesions [93]. As with other congenital cystic lesions, pain is well controlled by a thoracic epidural.

#### Bronchogenic cyst

Bronchogenic cysts are usually mediastinal, solitary unilocular cysts filled with gas, fluid or mucus. They do not communicate with the bronchopulmonary tree and therefore, like bronchopulmonary sequestrations, pose few additional anesthetic concerns. Positive pressure ventilation can be used and some authors have even reported that using nitrous oxide is safe [97].

#### Anterior mediastinal mass

Anesthetizing children who have anterior mediastinal masses may be associated with a high risk of morbidity and even mortality [98–101] that is caused by cardiovascular and/or respiratory collapse. Fortunately, over the past several decades, as anesthesiologists have become more aware of these risks and as perioperative management has improved, the morbidity and number of fatalities have decreased [102].

Mediastinal masses are located in the anterior, middle or posterior mediastinum, but this designation is somewhat arbitrary and there is overlap between them. Masses in the anterior mediastinum are the lesions that most often cause complications during general anesthesia [103]. Anterior mediastinal masses include several types of tumors, most commonly neuroblastoma in young children and lymphomas (Hodgkin and non-Hodgkin) in adolescents [104]. Other tumors include germ cell tumors, thymoma, bronchogenic cyst, carcinoma, granuloma and cystic hygroma [102]. A tissue biopsy (usually a CTguided biopsy) is required for diagnosis to guide chemotherapy, radiation therapy and/or surgical resection. Occasionally surgical biopsy through the mediastinum or thorax is necessary.

While most adults with anterior mediastinal masses are asymptomatic, 70% of children have symptoms related to the mass [105]. Typical symptoms include dyspnea, cough, and stridor. Children with these lesions often prefer to sleep in the lateral, semi-erect or even upright position. Symptoms that are associated with increased risk of anesthetic complications include orthopnea, upper body edema or compression of the trachea, bronchus or great vessels [101,104,106,107].

Imaging the mass is mandatory before elective anesthesia is undertaken. Chest radiographs may reveal a widened mediastinum, but CT is needed to demonstrate the size of the mass and the presence and severity of tracheal or great vessel compression (Figs 24.10–24.12). Angiography or echocardiography may be required to further evaluate vascular compression. Obstruction of breathing during induction of anesthesia is associated with 50% or greater compression of the trachea [106]. The tumor size, as defined by mediastinal mass ratios (the maximal width of the mass divided by the maximal width of the thorax), also correlates with tracheal compression and development of airway obstruction [100].

Pulmonary function tests (PFTs) are commonly ordered with the thought that a decreased peak expiratory flow rate (PEFR) or an increased mid-expiratory plateau with

Figure 24.10 Chest radiograph of a 7-month-old patient with an anterior mediastinal mass.

Figure 24.11 Chest CT of a 7-month-old patient with an anterior mediastinal mass, showing compression of the trachea.

changing from the upright to the supine position is indicative of variable intrathoracic airway obstruction and a risk for airway collapse during induction of anesthesia [102,108]. Most studies fail to show any correlation between PFTs and the degree of airway narrowing [106,108,109] or correlation between a decrease in any specific preoperative PFT and postoperative morbidity [110]. Flow-volume studies may, however, demonstrate dynamic compression of the airways that was not identified on CT.

The first consideration when developing an anesthetic plan is whether the proposed procedure is diagnostic or therapeutic. Diagnostic procedures, such as bone marrow biopsy or CT or ultrasound-guided biopsy of peripheral lymph nodes, can be done with local anesthesia or with

Figure 24.12 Chest CT of a 10-year-old patient with an anterior mediastinal mass. There is no visible compression of the trachea.

minimal sedation in most children. Ketamine (along with an antisialogog) has the advantage of maintaining hemodynamics in patients with cardiovascular compromise. Respiratory complications still occur, however, even when general anesthesia is avoided [104]. Elective procedures requiring general anesthesia should be delayed until chemotherapy and/or radiation therapy has reduced the size of the mediastinal mass. If a tissue diagnosis is necessary prior to chemo/radiation therapy, efforts should be made to obtain the tissue under local anesthesia [111]. Therapeutic procedures obviously necessitate general anesthesia.

Protocols developed for anesthetizing adults who have anterior mediastinal masses [112] use awake, fiber-optic intubations but this is not practical in pediatric patients [113,108] and is dependent on availability of resources, such as cardiopulmonary bypass and radiation therapy. There are, however, anesthetic strategies that can be generally applied in this situation (Fig. 24.13).

Before proceeding with general anesthesia, equipment and personnel should be immediately available to perform rigid bronchoscopy. Spontaneous ventilation should be maintained during induction of general anesthesia. This is usually accomplished by inhalation of a volatile anesthetic. The addition of CPAP may help maintain airway patency and prevent atelectasis. Some patients may require induction of anesthesia in the semireclined or upright position. Because loss of airway muscle tone can result in complete airway obstruction, negative thoracic airway pressure should be maintained, and neuromuscular blocking agents should be avoided. Tracheal intubation should be accomplished while maintaining spontaneous ventilation.

In the event of airway collapse, maneuvers which may help to alleviate the airway obstruction include:

- changing the patient's position to the lateral, recumbent or prone position
- intubating the trachea and advancing the endotracheal tube past the obstruction
- rigid bronchoscopy followed by endotracheal tube placement under direct vision or double-lumen tube placement into the most patent bronchus.

Some institutions advocate having cardiopulmonary bypass on standby. While there are several reports of patients being successfully placed on ECMO or cardiopulmonary bypass, bypass was initiated before the induction of anesthesia [114-118]. We found no published reports of patients successfully placed on bypass after the induction of anesthesia when cardiopulmonary bypass was available only on "standby." Even with a team ready and a pump primed, by the time the vessels are cannulated and circulation is restored, the patient will have likely suffered neurological injury [104]. Therefore cardiopulmonary bypass should not be considered a reasonable salvage plan. If the risk of cardiopulmonary collapse during the induction of anesthesia is high, the patient should be placed on cardiopulmonary bypass before the induction of anesthesia.

Patients presenting for thoracotomy for resection of a mediastinal mass or an open biopsy get excellent postoperative pain relief from a thoracic epidural or paravertebral block, both of which reduce the need for intravenous narcotics and allow the maintenance of spontaneous ventilation [119]. The patient's symptoms may be worse after surgery, particularly after a tumor biopsy in which the adverse effects of anesthesia are present without the benefit of tumor resection [103]. Potential surgical complications include phrenic or recurrent laryngeal nerve damage.

## **Pectus excavatum**

Pectus excavatum is the most common chest wall deformity. It is a congenital defect that results from excessive growth of the costochondral cartilages and inward depression of the sternum. It accounts for 90% of chest wall deformities and has an incidence of approximately 1 in 1000 with a male preponderance of 4:1. Pectus excavatum is sometimes associated with connective tissue disorders such as Ehlers–Danlos and Marfan syndromes. A family history of this deformity is present in as many as 50% of patients with a pectus excavatum [120]. Pectus carinatum (pigeon chest) comprises most of the remaining chest wall deformities.

## 582 Part 3 Practice of Pediatric Anesthesia

The severity of the lesion varies widely, from mild asymptomatic to severe deformities that distort the heart and great vessels (Figs 24.14, 24.15). Lesion-induced lung compression can lead to respiratory compromise, chronic airway obstruction, and the need for large negative inspiratory pressures. Compression of the stomach by the depressed chest can cause loss of appetite and impaired weight gain [121]. Most symptoms worsen during adolescence and more than half of adults with a pectus have some physical complaints [122]. Psychological complaints are also common [120]. Cardiorespiratory complaints are usually resolved with surgery [123].

Diagnosis of pectus excavatum is made by physical examination. Scoliosis is also present sometimes, particularly in female patients. Many patients have a murmur if the chest wall compresses the right ventricle. Characteristic

Lesion	Evaluation	Treatment	Anesthetic considerations
Tracheal stenosis			
Acquired	Laryngoscopy/bronchoscopy	Cricoid split	TIVA
Congenital	Laryngoscopy/bronchoscopy	Laryngotracheoplasty	TIVA, postoperative ventilation
Congenital cystic lung disease			
Cystic adenomatoid malformation	СТ	VATS versus thoracotomy	Minimize inflating pressure, avoid $N_{2} O$
Bronchopulmonary sequestration	CT, MRI	VATS versus thoracotomy	Minimize inflating pressure, avoid $\ensuremath{N_2O}$
Congenital lobar emphysema	СТ	VATS versus thoracotomy	Spontaneous ventilation, $N_2 O$ contraindicated
Bronchogenic cyst	СТ	VATS versus thoracotomy	Minimize inflating pressure, avoid $N_{\rm 2}O$
Congenital diaphragmatic hernia	CXR	Replace abdominal contents, Repair defect	Decrease PVR, minimize inflating pressure, avoid N2O, may need nitric oxide, HFOV, ECMO
Tracheo-esophageal fistula	CXR	Repair defect	Minimize inflating pressure, occlude fistula with ETT or blocker
Neoplasms			
Mediastinal	CT, MRI, PFTs	Needle or open biopsy, resection	Respiratory and/or cardiovascular collapse, possible OLV
Thoracic	CT, MRI	VATS versus thoracotomy	OLV, effects of chemotherapy and/or radiation therapy
Pectus excavatum	CXR, CT, PFTs, echocardiogram	Nuss versus Ravitch	Postoperative analgesia
Scoliosis	CXR, PFTs	Spinal fusion	Possible OLV with anterior fusion
Empyema	CXR, CT, pleurocentesis	Thoracostomy versus VATS or thoracotomy	Possible OLV

CT, computed tomography; CXR, chest x-ray; ETT, endotracheal tube; MRI, magnetic resonance imaging; OLV, one-lung ventilation; PFT, pulmonary function test; PVR, pulmonary vascular resistance; TIVA, total intravenous anesthesia; VATS, video-assisted thoracoscopic surgery. Modified from Hammer [16].

ECG findings include a negative P wave in V1, a negative T wave in V1 to V2 or V4, and an incomplete bundle branch block [122].

Surgical repair is typically delayed until late childhood to allow calcification of the sternum and ribs. Techniques for correcting a pectus excavatum include rib resection, external traction, cartilage resection, sternal osteotomy, and internal fixation [124]. The minimally invasive procedure of Nuss inserts a convex steel bar through bilateral thoracic incisions under the sternum and then turns the bar to elevate the sternum. This is the preferred method of repair today [125] because it is associated with shorter operative times, smaller incisions, less dissection, and less blood loss than the traditional Ravitch procedure. The Nuss procedure is successful 92% of the time compared to 70% success with the Ravitch procedure [124]. Pneumothorax is common, but resolves spontaneously in nearly all cases [124,125]. Less common complications of the Nuss procedure include cardiothoracic injuries, dys-rhythmias, pleural effusions, hemorrhage, subcutaneous emphysema, and infection of the bar [125,126].

Preoperative concerns include possible heart compression, right ventricular outflow tract obstruction, dysrhythmia, scoliosis and V/Q mismatching. Studies to help delineate the severity of disease include chest radiograph, CT, ECG and possibly echocardiography. Positioning of the patient during surgery can be a challenge. Placing the patient's arms in arthroscopy slings instead of over the head can reduce the incidence of brachial plexus injuries [127]. Continuous arterial blood

Figure 24.14 Chest radiograph of a 12-year-old patient with pectus excavatum.

**Figure 24.15** Chest CT of a 12-year-old patient with severe pectus excavatum showing cardiac compression.

pressure monitoring may be of benefit during surgery in patients with cardiac disease. Both the Ravitch and Nuss procedures are painful and postoperative pain control can be challenging. Epidural analgesia is both effective [128–130] and superior to patient-controlled analgesia [129,131]. Clonidine is an effective alternative to epidural opioids, and has fewer side-effects [130]. There may be a role for perioperative hypnosis [132].

### Empyema

Empyema or pleural space infection is a complication of bacterial pneumonia. Historically only 0.6% of admissions for pneumonia progressed to empyema [133], but the incidence is rising; more virulent strains of resistant organisms are the cause of this increase [134,135]. Empyema should be considered in any child who has pneumonia. There is neither consensus nor evidence for the best treatment of pleural infections, mostly because there are few prospective randomized controlled studies of the problem [135,136]. Options range from conservative therapy with antibiotics to thoracocentesis, chest tube drainage, fibrinolysis, and finally surgical intervention [135].

Empyema evolves over three stages [137].

- **1.** Exudative, in which fluid is thin with low cellular content and easily aspirated.
- **2.** Fibrinopurulent, in which there is accumulation of leukocytes, fibrin deposition and loculation.
- **3.** Organized, with the formation of a thick fibrous peel that causes lung entrapment.

During this last stage, drainage alone is ineffective in reexpanding the lung. Decortication may be necessary. The exudative stage can be as short as 24h and the fibrinopurulent stage 2–10 days, while the organizing stage generally lasts 2–4 weeks [138].

Pleural fluid analysis has long been used to stage empyema based on leukocytes, lactate dehydrogenase (LDH), glucose, and pH, but these criteria developed for adult patients have not been validated in the pediatric population [135]. Chest radiographs are not specific for diagnosing or staging of empyema. CT scanning is useful for both diagnosing and evaluating empyema with respect to consolidation, loculation, and pleural thickening (Figs 24.16, 24.17). Ultrasound can estimate the size of the effusion, show pleural thickening or loculi, and guide chest tube insertion. It has the advantage of being portable, which makes it useful for those unable to undergo CT.

Initial treatment for pleural infection is uncontroversial and consists of intravenous antibiotics, analgesics, and antipyretics. Effusions that are enlarging and/or compromising respiratory function should be treated with both antibiotics and drainage. The dilemma is which treatment option should occur next: thoracocentesis, thoracostomy tube drainage without or with fibrinolysis, or surgery. Tube drainage is recommended over repeated pleural taps for larger pleural infections, especially for younger children who seldom tolerate thoracocentesis under local anesthesia alone. Intrapleural fibrinolytics can lyse the fibrinous strands of a loculated empyema, improve pleural drainage, and produce successful outcomes

Figure 24.16 Chest CT of a 2-year-old patient with empyema, coronal view.

Figure 24.17 Chest CT of a 2-year-old patient with empyema, transverse view.

without surgery in up to 90% of cases [139]. Failure of chest tube drainage, fibrinolytics, and antibiotics should prompt surgical intervention.

Surgical management of empyema consists of VATS, mini-thoracotomy or open thoracotomy. Patients who undergo thoracotomy and debridement have earlier resolution of fever and shorter hospitalization than those treated by chest tube placement alone [135], but thoracotomy and debridement are associated with significant morbidity [140]. The use of VATS to treat empyema is less traumatic than open thoracotomy and has been advocated by many. VATS treatment is usually more effective when used early (within 1 week of diagnosis) in the course of empyema [138]. Only one prospective, randomized trial has compared VATS and thoracostomy drainage [141]. Although a small study (18 patients), it showed that hospital length of stay (LOS), number of days for which a chest tube was required, narcotic use, and the number of radiographic and interventional procedures were fewer in the VATS group. Several meta-analyses have shown that primary operative therapy is associated with shorter hospital stays [142–145] and a lower failure rate (by 11-fold) when compared to non-operative treatment [142]. Patients with necrotizing pneumococcal pneumonia or the need for ICU care before surgery are more likely to have complications and prolonged hospital admissions after thoracoscopy [146].

Patients who are treated conservatively (tube thoracostomy) for an extended period of time may progress to an empyema that, although initially treatable by VATS, becomes organized and only treatable by open thoracotomy. Treatment with VATS should be done early while empyema is still in the fibrinopurulent stage. For this reason many people advocate VATS as initial therapy before tube thoracostomy [147]. There is, however, no clear single therapy strategy for all patients. Each patient must be evaluated based on the stage of their disease and the therapeutic recourses available.

The anesthetic technique for patients with empyema depends on the procedure performed. Many patients tolerate pleurocentesis or tube thoracostomy with local anesthesia and/or minimal sedation. VATS or thoracotomy often necessitates one-lung ventilation. Good postoperative pain control is necessary for adequate lung re-expansion postoperatively. A paravertebral block or a thoracic epidural should be considered in non-septic patients who require a thoracotomy.

## Conclusion

This chapter has reviewed the pathophysiology of OLV and the anesthetic practice and equipment necessary to facilitate the perioperative management of the pediatric thoracic surgery patient (including analgesia for thoracic surgery). It has discussed in a little more detail some of the finer nuances of specific thoracic surgical challenges within the pediatric population, namely lobectomy, pneumonectomy, congenital cystic lung disease, anterior mediastinal mass, pectus excavatum, and empyema.

# CASE STUDY

A 14-year-old otherwise healthy girl presents for VATS for biopsy of a mediastinal mass.

• What additional information would you want to know at this point? *The additional information should include a detailed history, physical and review of radiological studies with specific emphasis on evaluation of airway and vascular compression.* 

The patient presented with a 6-week history of cough, increasing shortness of breath, and wheezing. After failed antibiotic treatment for suspected pneumonia, her symptoms progressed to dyspnea and then orthopnea. A chest radiograph showed an anterior mediastinal mass and CT showed a mass obstructing approximately a third of the distal trachea.

• Would you proceed to surgery? No. There are alternatives to proceeding with general anesthesia for thoracoscopy. A tissue diagnosis can often be obtained from a lymph node biopsy with local anesthesia. Alternatively, she can receive radiation therapy until the mass is no longer compressing the bronchus and she is asymptomatic. Then the mass can be removed if necessary.

Lymph node biopsy under local anesthesia was unsuccessful and the oncologist wanted a tissue diagnosis prior to initiating radiation therapy.

- How would you induce anesthesia in this patient? *First, the proper equipment and personnel must be available, including a difficult airway cart, rigid bronchoscope, and personnel trained in its use. We would perform an inhalation induction, maintain spontaneous ventilation, and then place an endotracheal tube under deep inhalational anesthesia while avoiding the use of muscle relaxation.*
- You are having difficulty ventilating the patient's lungs, what would you do next? The provider would first try to position the patient on her side. If this failed to relieve the obstruction, the endotracheal tube could be advanced in an attempt to stent past the obstruction, even to the point of endobronchial intubation. Finally, the available otolaryngologist could perform rigid bronchoscopy to stent the airway.
- The obstruction was relieved by advancing the endotracheal tube slightly. What other intraoperative and postoperative factors need to be considered? *Maintenance* of spontaneous ventilation for the remainder of the case with judicious use of narcotics would be prudent. The trachea should be extubated awake in the operating room and the patient should be admitted to the pediatric ICU for close postoperative monitoring and early intervention if needed.

# Introduction

Among the causes of infant mortality in the United States, congenital anomalies account for the largest diagnostic category [1]. Structural heart disease leads the list of congenital malformations. Over four million children are born each year in the United States and nearly 40,000 of these have some form of congenital heart disease (CHD). Approximately half of these children appear for therapeutic intervention within the first year of life, and the vast majority of them require care by an anesthesiologist. Initial reports of anesthetic mortality ranging from 3% to 10% in operations for CHD indicated a significant risk of anesthesia in this patient population [2,3]. However, the principles and techniques of pediatric anesthesia presented in this volume allow one to anesthetize CHD patients with minimal anesthetic mortality and morbidity [4–6]. This low anesthetic risk is predicated not only on adherence to these principles but also on an understanding of the pathophysiological circumstance of each patient and the nature of the planned surgical procedure. Implicit in all surgical procedures are potential complications that anesthesiologists, by virtue of their primary role in

*Gregory's Pediatric Anesthesia*, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos. © 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

monitoring and maintaining vital functions, are able to identify and treat. For cardiac surgery, knowledge of specific problems related to each type of cardiac repair helps to identify complications during the postbypass and postoperative periods, as well as later complications that affect subsequent anesthesia for non-cardiac procedures. The diagnostic information now available intraoperatively, in the form of intracardiac pressures and oxygen saturations as well as echocardiographic diagnoses, provides the pediatric cardiac anesthesiologist with the opportunity and responsibility to assess the adequacy of surgical intervention and its impact on hemodynamics.

This chapter describes general principles relevant to anesthesia for children with CHD; it does not present "recipes" for individual cardiac defects. The pathophysiology is presented as it relates to principles of management, patient assessment, selection and application of an anesthetic regimen, and specific cardiac lesions and procedures. Knowledge of these principles should permit safe administration of anesthesia to children with CHD undergoing both cardiac and non-cardiac operations. Optimal management will occur when the anesthesiologist regularly becomes involved in the care of these patients and has special insight and rapport with the entire cardiovascular staff, such that care is provided by a cohesive team in a smooth continuum from the preoperative preparation and diagnosis through the postoperative discharge.

# Pathophysiology of congenital heart disease

## **Principles of management**

The pathophysiological consequences of CHD are derived primarily from anatomical circumstances that produce abnormalities of flow: outflow obstruction, regurgitant lesions, shunt lesions, and common mixing lesions. Typically in more complex disease, shunts and obstructions may occur in combination. The pathophysiology of the most common purely obstructive lesions occurring outside the neonatal period is comparable to adult disease (e.g. aortic and mitral valve stenosis) and is not extensively reviewed here. Regurgitant lesions rarely exist as pure primary congenital defects except in Ebstein malformation of the tricuspid valve, in which a regurgitant volume flows back through the tricuspid valve and is directed across the patent foramen ovale to produce cyanosis and various degrees of heart failure. However, as a complicating feature of other CHDs, regurgitant lesions produce a volume-overload circulation with progressive ventricular dilation and failure. This is seen most commonly in regurgitation associated with atrioventricular canal defects, semi-lunar valve incompetence as seen in

tetralogy of Fallot with absent pulmonary valve syndrome, in truncal valve regurgitation in truncus arteriosus, or after interventions for aortic stenosis. Much of the remaining pathophysiology of congenital heart disease can be best understood by characterizing lesions with regard to the nature and magnitude of the shunt and the interaction of these shunts with obstructive lesions. Understanding the interactions of the various types of shunts and obstructions simplifies the bewildering variety of congenital heart lesions.

Many congenital heart lesions give rise to some degree of mixing of pulmonary and systemic venous blood, and they alter pulmonary blood flow. Varying degrees of hypoxemia may occur. These pathophysiological mechanisms alter the volume and pressure load of the heart, as well as cardiovascular development. Although such acquired developmental abnormalities may be adaptive, they can also further compound the effects of the original congenital heart defect. The resultant cardiac and pulmonary vascular structural abnormalities may become as important as the original heart defects when the pathophysiology is determined (e.g. severe left ventricular hypertrophy, seen with coarctation of the aorta, and right ventricular hypertrophy with progressive outflow obstruction, seen with tetralogy of Fallot). However, the intracardiac shunting and alterations in pulmonary blood flow comprise the major, unique problems encountered with CHD. These problems complicate the task of administering adequate anesthesia while maintaining normal cardiac output and oxygen transport.

## **Shunt lesions**

Cardiac shunting is the process whereby venous return into one circulatory system is recirculated through the arterial outflow of the same circulatory system. Flow of blood from the systemic venous (right) atrium (RA) to the aorta produces recirculation of systemic venous blood. Flow of blood from the pulmonary venous (left) atrium (LA) to the pulmonary artery (PA) produces recirculation of pulmonary venous blood. Recirculation of blood produces a physiological shunt. Recirculation of pulmonary venous blood produces a physiological left-to-right (L-R) shunt, whereas recirculation of systemic venous blood produces a physiological right-to-left (R-L) shunt. A physiological R-L or L-R shunt commonly is the result of an anatomical R-L or L-R shunt. In an anatomical shunt, blood moves from one circulatory system to the other via a communication (orifice) at the level of the cardiac chambers or great vessels. Physiological shunts can exist in the absence of an anatomical shunt. Transposition physiology is the primary example of this process.

Shunts may occur alone as simple shunts (e.g. a ventricular septal defect (VSD)) or with complicating obstructive lesions in complex shunts such as tetralogy of Fallot. The direction and magnitude of shunts are variable, both within each cardiac cycle and as a consequence of anesthesia and operative manipulation of the heart, great vessels and lungs, potentially destabilizing the circulation.

The hemodynamics in intracardiac shunts are complex and depend on many factors that determine shunt magnitude and direction (Fig. 25.1). Complete description of the dynamics of a particular shunt requires more data than are usually clinically available. The determinants of shunting may change considerably during anesthesia and operative manipulations without being readily measurable. Nevertheless, the concepts of control of shunting outlined below are useful during the perioperative period when it must be decided which shunts are hemodynamically significant and which are subject to intraoperative change.

Shunt orifice and outflow resistance are the most important determinants of shunting, particularly in ventricular and great vessel shunts. Ventricular compliance may also be important, but primarily as it relates to atrial level shunts. To simplify this discussion, ventricular compliance as a determinant of shunting is not further considered.

#### Simple shunts

With simple shunts (those without associated obstructive lesions), outflow resistance is equivalent to pulmonary vascular resistance (PVR) on the right and systemic vascular resistance (SVR) on the left (Fig. 25.2). The effects of shunt orifice and vascular resistances on simple shunts are outlined in Table 25.1. Although restrictive shunts are

relatively fixed in magnitude by the small shunt orifice, shunt direction and magnitude become more dependent on the ratio of outflow resistances (i.e. the relative resistances of the pulmonary and systemic vascular beds (PVR/SVR)), as the communication becomes larger and non-restrictive (equal to or exceeding the aortic valve area).

When the communication becomes large enough, the two structures effectively become a common chamber and complete mixing occurs. With complete mixing in a common chamber and no outflow obstruction, the amount of pulmonary and systemic blood flow depends on PVR/SVR. Because normal PVR is often much less than SVR (as little as 5% of SVR in older children and adults), pulmonary blood flows can become large with a non-restrictive simple shunt, even during the neonatal period.

Although a number of factors affect PVR/SVR, some are relatively fixed, whereas others are variable and dynamic. Simple shunting can change intraoperatively as dynamic factors change. Thus shunting may be manipulated to variable degrees depending on the size of the communication and the ability to manipulate the dynamic portions of the relative vascular resistance. When shunt orifices are large and non-restrictive, simple shunts are more subject to some manipulation.

#### **Complex shunt lesions**

With complex shunts (Fig. 25.3), a fixed outflow obstruction is present at the ventricular outflow, subvalvular, valvular or supravalvular level, or in major vessels such as the pulmonary artery or aorta. The fixed resistance

Figure 25.1 Effects of the many determinants on central cardiac shunting at various levels. PVR, pulmonary vascular resistance. Reproduced from Berman W. Cardiovascular Shunts: Phylogenetic, Ontogenetic and Clinical Aspects. New York: Raven Press, 1986, with permission from Lippincott, Williams & Wilkins.

Table 25.1 Simple shunts, no obstructive lesions

Restrictive shunts (small communications)	Nonrestrictive shunts (large communications)	Common chambers (complete mixing)
Large pressure gradient	Small pressure gradient	No pressure gradient
Direction and magnitude more <i>independent</i> of PVR/SVR	Direction and magnitude more dependent on PVR/SVR	Bidirectional shunting
Less subject to control	More subject to control	Net Qp/Qs totally depends on PVR/SVR
Examples: small VSD, small PDA, Blalock shunts, small ASD	Examples: large VSD, large PDA, large aortopulmonary shunts	Examples: single ventricle, truncus arteriosus, single atrium

PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; Qp, pulmonary blood flow; Qs, systemic blood flow; SVR, systemic vascular resistance; VSD, ventricular septal defect.

offered by the obstruction is added to the outflow resistance of the downstream vascular bed, which increases shunting to the opposite side of the circulation. When the fixed resistance is high, the resultant shunting away from the obstructed side is substantially fixed by the high resistance. Therefore, only a portion of a complex shunt is related to the relative resistances in the distal pulmonary and systemic vascular beds, and shunting through any communication is less dependent on PVR/SVR. As the outflow obstruction increases, changes in PVR or SVR become less important for determining flow. This is particularly true for the right side of the circulation, where normal PVR is low compared with the resistance offered by most right-sided obstructive lesions. For example, in tetralogy of Fallot with severe pulmonic stenosis, a component of the right-to-left shunting across the VSD is fixed by the pulmonary valve stenosis, but an additional, variable component of shunting may be due to variations in PVR or, more commonly, dynamic infundibular obstruction in the right ventricular outflow tract. Dynamic changes in variable portions of the total right-sided outflow obstruction may increase or decrease the total

**Figure 25.3** Determinants of complex shunting with (A) systemic or (B) pulmonary outflow obstruction. Orifice size limits the magnitude of the shunt. Outflow resistances are balanced by outlet obstruction on either side of the circulation and by the systemic vascular resistance (SVR) or pulmonary vascular resistance (PVR). Addition of outlet obstruction increases flow on the opposite side and decreases flow on the same side. Reproduced from Hickey PR, Wessel DL. Anesthesia for treatment of congenital heart disease. In: Kaplan JA (ed) Cardiac Anesthesia. Orlando, FL: Grune and Stratton, 1987 with permission from Elsevier.

amount of right-to-left shunting, thereby increasing or decreasing cyanosis. Right-to-left shunting in the baseline state, when the dynamic obstructive components are minimal, is determined largely by the fixed pulmonary stenosis. These statements presume a constant SVR and cardiac output; large changes in SVR, of course, change shunting by altering the other side of the balance (see Fig. 25.3). Characteristics and examples of complex shunts are listed in Table 25.2.

#### Complete obstruction and shunts

When obstruction to central outflow of blood becomes complete, as in tricuspid atresia, pulmonary atresia or aortic atresia, shunting across communications proximal to the obstruction becomes total and obligatory. This type of shunting must be associated with another downstream shunt, which provides flow to the obstructed side of the circulation. This associated shunt is exemplified by a patent ductus arteriosus, which provides pulmonary blood flow with pulmonary valvular atresia or provides systemic blood flow with aortic valvular atresia. The downstream shunting is variably dependent on PVR/ SVR, depending on the restrictive nature of the shunt orifice. Table 25.2 Complex shunts (shunt and obstructive lesion)

Partial outflow obstruction	Total outflow obstruction
Shunt magnitude and direction largely fixed by obstructions	Shunt magnitude and direction totally fixed
Shunt depends less on PVR/SVR	All flow goes through shunt
Orifice and obstruction determine pressure gradient	Pressure gradient depends on orifice
<i>Examples:</i> tetralogy of Fallot, VSD and pulmonic stenosis, VSD with coarctation	<i>Examples:</i> tricuspid atresia, mitral atresia, pulmonary atresia, aortic atresia

PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

# Manipulation of pulmonary and systemic resistance

Manipulation of PVR/SVR allows some measure of control over shunting, depending on the specific pathophysiology. PVR is particularly important because of the frequency of disturbances of pulmonary blood flow and right-sided defects in CHD. Usually PVR is decreased to improve pulmonary blood flow and right heart function but with some lesions, pulmonary flow may be excessively high at the expense of systemic blood flow and require increases in PVR. Some intraoperative manipulations may increase PVR, a common problem because of the increased reactivity and resistance of the abnormal pulmonary vasculature often found with CHD. These manipulations include sympathetic stimulation, encroachments on lung volumes that produce atelectasis (surgical retraction, pleural and peritoneal collections, abdominal packing), cardiopulmonary bypass (CPB), alveolar hypoxia, and hypoventilation. Ventilation is important because it is subject to control by the anesthesiologist and is crucial for determining PVR via airway pressure, lung volumes, PaCO<sub>2</sub>, pH, and FIO<sub>2</sub>.

## Ventilatory control of pulmonary vascular resistance

The PVR can be controlled independently of the SVR by manipulating various aspects of ventilation (Table 25.3), whereas specific or selective pharmacological control of PVR is difficult unless the pulmonary vascular bed is responsive to nitric oxide. Even with selective infusions of rapidly metabolized vasoactive drugs into the pulmonary circulation, systemic drug concentrations and systemic hemodynamic effects can be appreciable [7]. In contrast, high levels of inspired oxygen, especially 100%  $O_2$ , decrease elevated PVR in infants without changing (or slightly increasing) SVR, whereas inspired oxygen concentrations of 21% or less increase PVR [8,9]. The effective of the systemic of the systemic of the systemic of the systemic oxygen concentrations of 21% or less increase PVR [8,9].

Tab	le	25.3	Manipulations	altering	pulmonary	vascular	resistance
-----	----	------	---------------	----------	-----------	----------	------------

Increased PVR	Decreased PVR
Нурохіа	Oxygen
Hypercarbia	Hypocarbia
Acidosis	Alkalosis
Hyperinflation	Normal FRC
Atelectasis	Blocking sympathelic stimulation
High hematocrit	Low hematocrit
Surgical constriction	

PVR, pulmonary vascular resistance; FRC, functional residual capacity.

**Figure 25.4** Changes in PVR with changes to in  $PaO_2$  and arterial pH. Reproduced from Rudolph & Yuan. J Clin Invest 1966; 45: 399 with permission American Society for Clinical Investigation.

tiveness of oxygen (i.e. hyperoxia) as a pulmonary vasodilator after CPB, however, is unclear [10]. Hypoventilation, with associated acidosis and hypercapnia, also increases PVR [9] (Fig. 25.4). In contrast, hyperventilation to a pH of more than 7.5 reliably decreases PVR in infants with dynamically vasoconstricted small vessels [11,12]. This maneuver increases pulmonary blood flow and decreases right-to-left shunting in neonates, increasing the PaO<sub>2</sub> [13,14]. Some caution is required as prolonged hyperventilation to decrease PVR may in theory cause problems from decreased cerebral blood flow. Recent clinical observations support a link between the extent and duration of hypocapnia and development of white matter injury and subsequent neurobehavioral deficiencies in neonates [15]. The pattern of ventilation and use of positive endexpiratory pressure (PEEP) also can alter PVR. PVR is lowest at normal functional residual capacity (FRC). At low lung volumes (collapsed alveoli), PVR increases [16]. If atelectasis and pulmonary edema are corrected by PEEP, the PVR may in fact decrease. High levels of PEEP, however, may increase PVR, primarily by hyperinflating the alveoli. Different patterns of ventilation may further reduce PVR by stimulating production of prostacyclin in the pulmonary vasculature [17,18].

#### Anesthetics and pulmonary vascular resistance

The effect of anesthetic agents on PVR for the most part is minimal, although this depends to some extent on the underlying cause of the increase in PVR. Ketamine and nitrous oxide reportedly increase PVR in adults, particularly in patients with mitral stenosis, but do not affect the PVR of infants with normal or elevated PVR when ventilation and FIO<sub>2</sub> are held constant [19–21]. A rise in PVR with ketamine given to sedated children spontaneously breathing room air during cardiac catheterization has been noted [22]. However, in a cohort of patients with pulmonary hypertension spontaneously breathing 0.5% sevoflurane, no change in PVR was seen with ketamine administration [23]. Stress responses in the pulmonary circulation of patients with CHD are of primary concern in some patients during the perioperative period. Large doses of synthetic opioids (e.g. fentanyl) attenuate pulmonary vascular responses to noxious stimuli, such as endotracheal suctioning, in infants, but they do not change the baseline PVR [24,25]. Reactive hypertensive responses in the pulmonary bed are partially mediated by the sympathoadrenal axis and therefore are attenuated by an adequate depth of anesthesia, usually without changing the baseline PVR.

#### Manipulation of systemic vascular resistance

When deleterious intracardiac shunting cannot be controlled by manipulating PVR, it may be necessary to change SVR. In the presence of a complex shunt with *fixed* pulmonary outflow obstruction and right-to-left shunting (e.g. tetralogy of Fallot), an increase in SVR decreases the right-to-left shunting and increases arterial oxygen saturations [26]. Dynamic increases in infundibular outflow obstruction with tetralogy of Fallot that acutely increase baseline right-to-left shunting and hypercyanotic spells can be treated with IV pressor agents, which are shunted right to left directly into the systemic circulation, thus increasing SVR and decreasing right-to-left shunting. In the presence of a severely restrictive aortopulmonary shunt (e.g. Blalock-Taussig, Waterston) or when coronary perfusion is compromised, increases in systemic arterial pressure with pressor agents may increase pulmonary and coronary blood flow. Use of phenylephrine, norepinephrine or other  $\alpha$ -agonists to maintain high systemic perfusion pressure may be beneficial under these circumstances [26]. Alternatively, proximal aortic (or left ventricular) pressure can occasionally be increased by partially occluding the aorta with a clamp to increase SVR.

## **Pulmonary circulation**

Alterations in pulmonary blood flow caused by shunting in patients with CHD may produce several problems: pulmonary vascular obstructive disease, arterial desaturation or an increased volume load on the heart. These alterations are variable because of the changes in PVR that occur during development (Fig. 25.5). Because of these changes, associated problems may appear at different times during development. Dramatic alterations in pulmonary blood flow are seen during the neonatal period at the time of transition to adult-type circulation.

## **Transitional circulation**

The transitional circulation of normal neonates can be viewed as a transient form of CHD. Shunting occurs in either direction through the ductus arteriosus and the foramen ovale until these structures functionally, and later anatomically, close. Initially, high PVR promotes right-to-left shunting through the ductus arteriosus and foramen ovale, which causes hypoxemia (Fig. 25.6; see also Fig. 25.5). Later, as PVR falls, shunting through the ductus reverses and becomes left to right until the ductus closes anatomically (see Figs 25.5, 25.6). When undergoing major non-cardiac surgery, neonates may revert to this transitional circulation despite previous functional closure of the ductus arteriosus and foramen ovale. The anesthetic plan should anticipate this possibility, and all neonates should be considered to have potential for intracardiac shunting.

Intraoperatively, hypoxia, acidosis, hypercapnia, hypothermia, sepsis, and prolonged stress favor return to the transitional circulation pattern. This pattern occurs because the degree of hypoxic pulmonary vasoconstriction is much greater in normal newborns than in adults. The resulting high pulmonary artery pressures may exceed aortic pressures and produce intermittent or continuous right-to-left shunting through a patent ductus arteriosus or foramen ovale [27]. Once the period of perioperative stress is over, normal developmental changes modify and functionally eliminate the ductus arteriosus, foramen ovale, and high PVR.

In children with forms of CHD that are "ductus dependent," the transitional circulation serves a palliative role by providing either adequate pulmonary or systemic flow until intervention can establish more normal patterns of flow. In these patients the transitional circulation is actively supported with prostaglandin E1 (see below).

#### Pulmonary vascular obstructive disease

In the presence of a non-restricted simple shunt (e.g. a large VSD), blood flow into the lungs increases as PVR falls (see Fig. 25.5). However, the pulmonary artery pressure and volume overload resulting from such shunts may, over time, alter pulmonary vascular development and cause pulmonary vascular obstructive disease [28,29] (Fig. 25.7; see also Fig. 25.5) This occurs with large VSDs, atrioventricular canal, transposition of the great arteries, truncus arteriosus, and large patent ductus arteriosus. In lesions such as atrial septal defect (ASD), where only flow is increased and pulmonary artery pressures are initially normal, pulmonary vascular disease takes decades to develop [30]. In contrast, pulmonary vascular disease can occur even during the first year of life in patients with an atrioventricular canal or in the first weeks of life in those

**Figure 25.5** Normal and abnormal developmental changes in the pulmonary arterial tree during the first years of life. Pulmonary vascular resistance, arterial smooth muscle (%) and pressure normally decrease during the first year of life. A large, non-restrictive VSD with a large left-to-right shunt results in an immediate increase in flow and a later increase in vascular resistance. Reproduced from Rudolph AM. Congenital Diseases of the Heart. Chicago: Year Book Medical Publishers, 1974, p.79.

**Figure 25.6** Central shunting and blood saturations that occur normally in the transitional circulation during the first few hours and days after birth. (A) During the first few hours, the foramen ovale is widely patent and PVR is high, leading to right-to-left shunting. (B) A second, later stage of transitional circulation occurs when PVR decreases and the ductus arteriosus remains patent, resulting in left-to-right shunting. The foramen ovale is functionally closed. Reproduced from Hickey PR, Crone RK. Cardiovascular physiology and pharmacology in children. In: Ryan J, Todres, D, Cote C, Goudsouzian N (eds) A Practice of Anesthesia for Infants and Children. Orlando, FL: Grune and Stratton, 1986, p.175 with permission from Elsevier.

with transposition of the great arteries and VSD [31]. A progressive rise in PVR may lead to chronic right-to-left shunting and right ventricular failure.

Intraoperatively, the more muscular and less wellarborized pulmonary arterial tree of patients with pulmonary vascular obstructive disease is capable of additional increases in PVR in response to surgical stimuli and stress. Right-to-left shunting may appear or dramatically increase during this time. Minimizing the reactive component of PVR without lowering SVR is often critical in anesthetic management.

Decreased flow in the pulmonary circulation during development can also lead to early significant abnormalities in the pulmonary arterial tree, including hypoplasia in some areas and excessive flow producing vascular obstructive disease in other regions [32]. This is especially true in patients with tetralogy of Fallot and pulmonary atresia, in whom the pulmonary artery anatomy must be addressed early in life.

## **Arterial desaturation**

Systemic arterial desaturation in CHD frequently results from shunting of systemic venous blood into the systemic arterial circulation rather than from pulmonary parenchymal problems. If pulmonary parenchymal disease is also present, it is even more difficult to achieve adequate arterial oxygenation. Shunt-related arterial desaturation can occur whether pulmonary blood flow is greater than, equal to or less than systemic flow. The effects of alterations in pulmonary blood flow on arterial oxygenation in the presence of various shunts are listed in Table 25.4. It is important to realize that an FIO<sub>2</sub> of more than 0.21 has little effect on arterial oxygen tension in the presence of a large right-to-left shunt, but it has more effect as the shunt becomes smaller (Fig. 25.8). This statement presumes no pulmonary parenchymal disease and fully saturated pulmonary venous blood.

Hypoxemia also occurs in situations other than those with a pure right-to-left shunt with decreased pulmonary

**Figure 25.7** Developmental changes in the peripheral pulmonary arterial tree in normal infants and in those with a VSD and large left-to-right shunt. The alveolar/arteriolar (ALV/art) ratio decreases with age becasue of extensive arborization of the arterial tree as the arteriolar lumen increases and the muscle layer thins and spreads distally. Pulmonary hypertension and high flow of blood from a left-ro-right shunt in a patient with a VSD cause pulmonary vascular obstructive disease as evidenced by a decreased number of pulmonary arterioles (ALV/art of 25:1), a decrease in vessel lumen, an increase in muscle thickness and a more distal spread of muscle. Letters indicate arterioles from the level of the terminal bronchiolus (TB) to the alveolar wall (AW). RB, respiratory bonchiolus; AD, alveolar duct. Reproduced from Rabinovitch MB, Hawroth SG, Castaneda AR. Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease. Circulation 1978; 58: 1107 with permission from Lippincott, Williams & Wilkins.

 Table 25.4 Effects of central shunting and pulmonary blood flow on oxygenation

ḋp < ḋs	-	Hypoxemia (severe)	Hypoxemia (severe)

 $\dot{Q}p$ , pulmonary blood flow;  $\dot{Q}s$ , systemic blood flow; –, does not occur; \*Normoxemia when  $\dot{Q}p/\dot{Q}s$  ≥7–10.

**Figure 25.8** Isoshunt graph depicting the relation between inspired FIO<sub>2</sub> and arterial PaO<sub>2</sub>, with different amounts of right-to-left shunting. It assumes normal values of pH, PaCO<sub>2</sub>, pulmonary venous saturation, and mixed venous saturation. Adapted from Lawler P, Nunn J. A reassessment of the validity of the isoshunt graph. Br J Anaesth 1984; 56: 1325 with permission from Oxford University Press.

blood flow. If systemic and pulmonary venous blood mix in a vascular chamber, arterial desaturation occurs, even though pulmonary blood flow may be normal or increased (see Table 25.4). Mixing can occur at any anatomical level: right atrium (e.g. total anomalous pulmonary venous connection), left atrium (e.g. tricuspid atresia), ventricle (e.g. single ventricle) or great vessel (e.g. truncus arteriosus). When mixing is complete and pulmonary blood flow is normal or increased, hypoxemia is mild. When mixing is incomplete, hypoxemia may be severe, as occurs with the parallel circulation seen in patients with transposition of the great arteries.

Many poorly understood adaptations occur in patients with severe hypoxemia to allow reasonable levels of oxygen transport and consumption, including polycythemia, increases in 2,3-diphosphoglutarate (2,3-DPG) concentrations, vasodilation with increased blood volume, neovascularization, and alveolar hyperventilation with chronic respiratory alkalosis [33]. These and other poorly defined adaptive mechanisms maintain near-normal levels of mitochondrial oxygen utilization at rest without increase in lactate production. Elevated cardiac output and substantial shifts in the oxyhemoglobin dissociation curve are not essential adaptations in patients with severe hypoxemia [34]. The adaptations, however, may be associated with adverse physiological effects. Polycythemia increases blood viscosity, vascular resistance, and therefore ventricular afterload, especially in the pulmonary circulation [35]. As increasing viscosity elevates afterload, it decreases cardiac output, which opposes the benefit of polycythemia to oxygen-carrying capacity. The net reduction in oxygen *transport* is maladaptive and occurs when the hematocrit exceeds 60%. Such high hematocrits are associated with an appreciable incidence of cerebral and renal thrombosis, which increases with dehydration. This situation makes pre- and postoperative hydration crucial in these patients.

Cyanosis has been implicated in the genesis of coagulation and fibrinolytic defects particularly in patients in whom secondary erythrocytosis produces a hematocrit greater than 60%. The vast majority of studies investigating the effects of cyanosis on hemostasis have been conducted in chronically cyanotic adults and children >1 year old. Thrombocytopenia and qualitative platelet defects are common and are positively correlated with the level of erythrocytosis and arterial oxygen desaturation [36-43]. Defects in bleeding time, clot retraction and platelet aggregation to a variety of mediators have all been described [38,39,44,45]. The importance of erythrocytosis in the genesis of these quantitative and qualitative defects is underscored by the observation that multiple therapeutic phlebotomies using either plasma or isotonic saline to replace whole blood and reduce hematocrit to the 50-60% range result in improvement of platelet count and platelet aggregation [38,40]. In addition, shortened platelet survival time has been reported. Reduced survival time was weakly positively correlated with the level of erythrocytosis and arterial oxygen desaturation [41]. More recently, a baseline deficit in platelet GpIb receptors has been reported in cyanotic children [46]. These receptors play a pivotal role in inducing platelet aggregation and adhesion via von Willebrand factor (vWF). The platelets of cyanotic neonates and infants exhibit a hyporeactive response to thrombin receptor agonist peptides (TRAP) compared to non-cyanotic neonates and infants.

Prolonged prothrombin time (PT), partial thromboplastin time (PTT) and low levels of fibrinogen and factors II, VII, IX, X, XI, and XII have also been reported in association with cyanosis [36,37,39,43,47]. Therapeutic phlebotomies using isotonic saline to replace whole blood and reduce hematocrit to the 50–60% range result in an increase in factor II, VII and V levels [40]. Coagulation factor abnormalities appear to occur with lower frequency than platelet defects but the full extent of coagulation factor abnormalities is unknown because this issue has been incompletely studied.

Chronic disseminated intravascular coagulation (DIC) has been proposed as an additional mechanism leading

to a coagulopathic state in cyanotic heart disease [48]. While evidence of accelerated ongoing thrombin generation and fibrinolysis has been detected in cyanotic versus non-cyanotic patients, chronic DIC has not been substantiated [49,50].

Recent evidence documents the overproduction of platelet microparticles in erythrocytotic patients (hematocrit (Hct) >60%) with congenital heart disease [51]. Microparticles are cellular fragments that are the result of exocytotic budding and which contain both cytoplasmic and membrane components. These microparticles express FVa and FXa and are highly procoagulant. Microparticle formation occurs as a result of the high microvascular shear forces which accompany erthrocytosis and can be reduced via hematocrit reduction with therapeutic phelebotomy [51].

### Increased pulmonary blood flow

When pulmonary flow is greater than systemic flow (Qp/Qs more than 1), a volume load is imposed on the heart. With pure left-to-right shunts, the additional pulmonary flow does not increase arterial oxygen content. This increased load decreases not only cardiovascular reserve but also pulmonary reserve, because the work of breathing is increased owing to decreased pulmonary compliance and increased airway resistance [52]. These changes are due to increased lung water, compression of bronchi by distended pulmonary vessels at all levels, and general pulmonary vascular congestion. When left-to-right shunts are closed (e.g. ligation of a patent ductus arteriosus), lung compliance improves immediately [53].

## Preoperative assessment and preparation

Successful anesthetic management of patients with CHD is based on complete, accurate preoperative assessment and adequate preoperative patient preparation. The clinical and laboratory information routinely available preoperatively (Box 25.1) should be frequently reassessed and integrated with information from continuous monitoring during surgery and the immediate recovery phase. The anesthesiologist must be aware of the physical and laboratory findings that are of particular importance for CHD. Involvement of the anesthesiologist in the preoperative preparation and early postoperative management provides a perspective on the pathophysiology that improves perioperative care.

### Physical examination and laboratory data

A complete history and physical examination are required, and when such information is obtained attention should be directed to the extent of cardiopulmonary impairment, Box 25.1 Clinical and laboratory preoperative assessment

- History and physical examination

airway abnormalities, and associated extracardiac congenital anomalies. Upper and lower airway problems in patients with Down syndrome, calcium and immunological deficiencies in patients with aortic arch abnormalities, and renal abnormalities in patients with esophageal atresia and CHD are a few of the associated congenital abnormalities with which the anesthesiologist should be familiar. Intercurrent pulmonary infection is a common and significant finding in chronically overcirculated lungs. The presence, degree, and duration of hypoxemia are important details that, in the absence of iron deficiency, are reflected in the hematocrit. The nadir of physiological anemia during infancy may contribute to left-to-right shunting by decreasing the relative PVR [35].

Chest radiography shows heart size, pulmonary vascular congestion, airway compression, and areas of consolidation or atelectasis. The electrocardiogram (ECG) may reveal rhythm disturbances and demonstrate ventricular strain patterns (ST and T wave changes) characteristic of unphysiological pressure or volume burdens on the ventricles. Electrolyte abnormalities caused by congestive heart failure and forced diuresis must also be evaluated preoperatively. Severe hypochloremic metabolic alkalosis may occur in some patients. It is more important to discontinue digoxin preoperatively and to avoid hyperventilation and administration of calcium to these patients during induction of anesthesia. The alkalotic hypokalemic, hypercalcemic, hypotensive, dilated, digoxin-bound myocardium fibrillates with ease.

## **Echocardiographic and Doppler assessment**

Two-dimensional and, recently, real-time threedimensional echocardiography has revolutionized the field of pediatric cardiology over the last decade. Unlike adults, who may have a limited echocardiographic window, comprehensive cardiac assessment of the pediatric patient is routine. Doppler measurements add greatly to non-invasive diagnostic capabilities. Measurements of pressure gradients across semi-lunar valves and other obstructions are frequently accurate but may not always correlate with peak systolic ejection gradients measured at catheterization. Nonetheless, most neonates proceed to surgery without catheterization studies. In some instances, catheterization is necessary to clearly delineate coronary or aortopulmonary collateral anatomy or to clarify physiology when other clinical information is ambiguous or contradictory.

## **Cardiac catheterization**

Normal intracardiac pressure and saturation values in children are shown in Figure 25.9.

Shunt localization is usually accomplished using a combination of angiography and measurement of  $O_2$  saturations in the pulmonary veins, superior vena cava (SVC) and inferior vena cava (IVC), right heart chambers, left heart chambers, aorta, and pulmonary artery. Oxygen saturation sampling is used to detect an  $O_2$  saturation step-up in the right heart in the case of a left-to-right shunt or an  $O_2$  saturation step-down in the left heart in the case of a right-to-left shunt. A step-up is defined as >5% increase in the  $O_2$  saturation of blood in a particular location that exceeds the normal variability in that location, whereas a step-down is a >5% decrease in saturation for a given location.

Shunt quantification is based on comparison of systemic and pulmonary blood flows. Systemic (Qs) and pulmonary (Qp) blood flows are calculated by the Fick method.

$$Qp = VO_2 / (PVO_2 \text{ content} - PAO_2 \text{ content})$$

 $PAO_2$  content is the pulmonary arterial  $O_2$  content.  $PVO_2$ content is the pulmonary venous O2 content. Sampling blood from the left atrium (when the pulmonary veins return to the left atrium) will provide a weighted average of the four pulmonary veins' O<sub>2</sub> content. If a right-to-left atrial-level shunt is present, this sampling site will not provide an accurate assessment of pulmonary vein O<sub>2</sub> content. Each of the four pulmonary veins can be entered and sampled separately to assess for pulmonary sources of venous admixture (e.g. pneumonia, atelectasis or other pulmonary disease). When this is done, segmental areas of intrapulmonary shunt and V/Q mismatch can be detected. The PaO<sub>2</sub> or saturation of pulmonary venous blood from a lung segment with V/Q mismatch will improve with an increase in FIO<sub>2</sub> while there will be no improvement if an intrapulmonary shunt is present.

 $Qs = VO_2 / (SAO_2 \text{ content} - MVO_2 \text{ content})$ 

 $SAO_2$  content is systemic arterial  $O_2$  content.  $MVO_2$  content is mixed venous  $O_2$  content. True mixed venous blood is a mixture of desaturated blood from the IVC, SVC and coronary sinus. In a normal heart a mixed

**Figure 25.9** Cardiac catheterization findings in a normal child. Numbers in chambers are oxygen saturation (percent) and numbers in parentheses are oxygen content. Pressure in chambers are shown in circles. Note "probepatent" foramen ovale. M, mean pressure. Reproduced with permission from Nadas AS, Fyler DC. Pediatric Cardiology. Philadelphia: WB Saunders, 1972.

sample of venous blood from these three locations can be obtained from the pulmonary artery. In the presence of an intracardiac left-to-right shunt, PAO<sub>2</sub> saturation will overestimate true MVO<sub>2</sub> saturation because pulmonary arterial blood will be a mixture of mixed venous blood and oxygenated pulmonary venous blood from the left heart. In children, SVC O<sub>2</sub> content is commonly used as a surrogate for MVO<sub>2</sub> content.

After Qp and Qs have been calculated, shunts can be quantified. For an isolated left-to-right shunt, the magnitude of the shunt is Qp – Qs. For an isolated right-to-left shunt, the magnitude of the shunt is Qs - Qp. The ratio Qp/Qs is also useful. It can be calculated from content data alone because the  $VO_2$  terms cancel out:

$$Qp/Qs = \frac{(SAO_2 \text{ content} - MVO_2 \text{ content})}{(PVO_2 \text{ content} - PAO_2 \text{ content})}$$

Furthermore, if the blood is sampled using a low FIO<sub>2</sub>, the dissolved  $O_2$  portion of the content equation (PO<sub>2</sub> × 0.003) can be ignored. The hemoglobin × 1.34 term cancels out and the equation can be simplified to one using just saturation data from the four sites:

$$Qp/Qs = \frac{(SAO_2 \text{ saturation} - MVO_2 \text{ saturation})}{(PVO_2 \text{ saturation} - PAO_2 \text{ saturation})}$$

A Qp/Qs > 2.0 constitutes a large shunt, whereas a Qp/Qs < 1.25-1.5 constitutes a small shunt. Obviously, a Qp/Qs < 1.0 indicates a net right-to-left shunt.

For bidirectional shunts, it is necessary to calculate effective pulmonary blood flow ( $Qp_{eff}$ ) and effective systemic blood flow ( $Qs_{eff}$ ).  $Qp_{eff}$  is the quantity of desaturated systemic venous blood that traverses the pulmonary capillaries to be oxygenated.  $Qs_{eff}$  is the quantity of oxygenated pulmonary venous blood that traverses the systemic capillaries to deliver oxygen to tissue.  $Qs_{eff}$  and  $Qp_{eff}$  are always equal.

$$Qs_{eff} = Qp_{eff} = VO_2 / (PVO_2 \text{ content} - MVO_2 \text{ content})$$

The left-to-right shunt is defined as  $Qp - Qp_{eff}$  while the right-to-left shunt is defined as  $Qs - Qs_{eff}$ . The net shunt is the difference between these two calculated shunts.

In the presence of a left-to-right shunt and elevated PVR, pressure and saturation measurements are often repeated with the patient breathing 100% oxygen to assess both the reactivity of the pulmonary vascular bed and any contribution of ventilation/perfusion abnormalities to hypoxemia. If breathing 100% oxygen or nitric oxide increases pulmonary blood flow and dramatically increases Qp/Qs (with a fall in PVR), potentially reversible processes such as hypoxic pulmonary vasoconstriction are probably contributing to the elevated PVR. The patient with a high, unresponsive PVR and a small left-to-right shunt despite a large shunt orifice may have extensive pulmonary vascular damage from irreversible obstructive pulmonary vascular disease.

During cardiac catheterization, anatomical abnormalities are identified angiographically. Special angled views provide specific information about the location and extent of congenital defects. Ventricular function is assessed angiographically and physiologically (e.g. by pressure measurements). The calculated size of a cardiac chamber may have an important bearing on its ability to support the circulation of a child with hypoplastic ventricles.

## Magnetic resonance and computed tomographic imaging and angiography

Magnetic resonance imaging and angiography (MRI/A) has emerged as an important diagnostic modality in the evaluation of the cardiovascular system following the development of ECG-gated MRI. Image acquisition is triggered to the patient's ECG to counter motion artifacts and to acquire cine sequences that allow imaging of cardiac structures and visualization of blood flow throughout the cardiac cycle. In addition to providing excellent

anatomical and three-dimensional images, particularly of the pulmonary veins and thoracic aorta, it is also possible with magnetic resonance angiography (MRA) to qualitatively assess valve and ventricular function, and to quantify flow, ventricular volume, mass and ejection fraction [54,55]. While ferromagnetic implants near the region of interest might produce artifact, sternal wires and vascular clips produce relatively minor disturbances and therefore MRI can be performed in patients who have undergone previous cardiac surgery. Contraindications include patients with pacemakers, recently implanted endovascular or intracardiac implants and aneurysm clips on vessels that will be exposed directly to the magnetic field.

The claustrophobic small bore of the MRI machine and noise during imaging mean that sedation is necessary for most children undergoing cardiac MRI/A procedures. To allow three-dimensional MRA and gradient echo sequences for images of blood flow, breath-hold is necessary during image acquisition, and therefore general anesthesia is frequently required for neonates, infants and young children. As for procedures in the catheterization laboratory, the environment for MRI is often a difficult one in which to administer general anesthesia, and hemodynamic monitoring may be limited [56].

Computed tomographic (CT) imaging and angiography is particularly useful for visualizing extracardiac structures. Its advantages are brief imaging time (<5min), therefore minimal or no sedation is often required. Disadvantages are significant radiation exposure; risk: benefit of MRI vs CT are weighed carefully before selecting each modality.

## Assessment of patient status and predominant pathophysiology

Frequently, congenital heart defects are complex and can be difficult to categorize or conceptualize. Rather than trying to determine the management for each individual anatomical defect, a physiological approach can be taken. The following questions should be asked.

- How does the systemic venous return reach the systemic arterial circulation to maintain cardiac output? What intracardiac mixing, shunting or outflow obstruction exists?
- Is the circulation in series or parallel? Are the defects amenable to a two-ventricle or single-ventricle repair?
- Is pulmonary blood flow increased or decreased?
- Is there a volume-load or pressure-load on the ventricles?

Appropriate organization of preoperative patient data, preparation of the patient, and decisions about monitoring, anesthetic agents, and postoperative care are best accomplished by focusing on a few major pathophysiological problems, beginning with whether the patient is cyanotic or in congestive heart failure (CHF) (or both). Most pathophysiological mechanisms in the patient's disease that are pertinent to the anesthetic plan and to optimal preparation of the patient will focus on one of the following major problems: severe hypoxemia, excessive pulmonary blood flow, CHF, obstruction of blood flow from the left heart, and poor ventricular function. Although some patients with CHD present with only one problem, many have multiple inter-related problems.

## Severe hypoxemia

Many of the cyanotic forms of CHD present with severe hypoxemia (PaO<sub>2</sub> less than 50 mmHg) during the first few days of life, but without respiratory distress. Infusion of prostaglandin E1 (PGE1) in patients with decreased pulmonary blood flow maintains or re-establishes pulmonary flow through the ductus arteriosus. This may also improve mixing of venous and arterial blood at the atrial level in patients with transposition of the great arteries [57]. Consequently, neonates rarely require surgery while they are severely hypoxemic. During preoperative preparation with PGE1, neurological examination, as well as blood chemistry analysis of renal, hepatic, and hematological function, is necessary to assess the effects of severe hypoxemia on end-organ dysfunction during or after birth.

Cyanotic patients who present for surgery after infancy require adequate pre- and postoperative hydration to prevent the thrombotic problems caused by their high hematocrits. Adequate quantities of blood products for treatment of the coagulopathies are also needed, as outlined above. Premedication must be given cautiously to avoid causing hypoventilation in these patients.

Prostaglandin E1 dilates the ductus arteriosus of the neonate with life-threatening ductus-dependent cardiac lesions and improves the patient's condition before surgery. It can reopen a functionally closed ductus arteriosus for several days after birth, or it can maintain patency of the ductus arteriosus for several months postnatally [57,58]. The common side-effects of PGE1 infusion (apnea, hypotension, fever, central nervous system (CNS) excitation) are easily managed in the neonate when normal therapeutic doses of the drug  $(0.01-0.1 \mu g/kg/min)$  are used [59]. However, PGE1 is a potent vasodilator, so intravascular volume frequently requires augmentation. Patients with intermittent apnea resulting from administration of PGE1 may require mechanical ventilation preoperatively.

Prostaglandin E1 usually improves the arterial oxygenation of hypoxemic neonates who have poor pulmonary perfusion due to obstructed pulmonary flow (critical pulmonic stenosis or pulmonary atresia). By providing pulmonary blood flow from the aorta via the ductus arteriosus, an infusion of PGE1 improves oxygenation and stabilizes the condition of neonates with these lesions. The improved oxygenation reverses the lactic acidosis that may have developed during episodes of severe hypoxia. PGE1 administration for 24h usually markedly improves the condition of a severely hypoxemic neonate with restricted pulmonary blood flow [60].

### Excessive pulmonary blood flow

Excessive pulmonary blood flow is frequently the primary problem of patients with CHD. The anesthesiologist must carefully evaluate the hemodynamic and respiratory impact of left-to-right shunts (see above). Children with left-to-right shunts may have chronic low-grade pulmonary infection and congestion that cannot be eliminated despite optimal preoperative preparation. If so, surgery should not be postponed further. Respiratory syncytial virus infections are particularly prevalent in this population, but improvements in intensive care and palivizumab prophylaxis have markedly improved outcome with this and other viral pneumonias [61].

Aside from the respiratory impairment caused by increased pulmonary blood flow, the left heart must dilate to accept pulmonary venous return that is several times normal. If the body requires more systemic blood flow, the heart responds inefficiently. Most of the increment in cardiac output is recirculated to the lungs. Eventually symptoms of CHF appear.

Children with failing hearts increase endogenous catecholamine production and redistribute cardiac output to favored organs by their increased heart rate and decreased extremity perfusion. In the most severe cases, the evaluation reveals a child whose bodyweight is below the third percentile for age and who is tachypneic, tachycardic, and dusky in room air. The child may have intercostal and substernal retractions and skin that is cool to the touch. Capillary refill may be prolonged. Expiratory wheezes are usually audible (Box 25.2). Medical management with digoxin and diuretics may improve the patient's condition, but the diuretics may induce profound hypochloremic alkalosis and potassium depletion.

These clinical signs and symptoms suggest that profound pathophysiological alterations have occurred. This information, combined with the anatomical description from the two-dimensional echocardiogram and the physiological data from cardiac catheterization, permits accurate assessment of the severity of the illness and formulation of an anesthetic plan. For example, in the sickest patients with respiratory compromise and minimal cardiac reserve, it may be prudent to minimize premedication, begin an IV infusion while the patient is awake, induce anesthesia with an IV opioid while the patient breathes oxygen, and be prepared to support the circulation immediately with inotropic and pressor drugs when necessary. Alternatively, the physical examination may indicate that the patient is only mildly symptomatic and should tolerate a standard premedication

Box 25.2 Symptoms and signs of cardiac failure in a neonate and infant

#### Failure to thrive

- Poor feeding
- Diaphoresis

#### Increased respiratory work

and sevoflurane/nitrous oxide inhalation induction of anesthesia for an elective operation.

### **Obstruction of left heart outflow**

Patients who require surgery to relieve obstruction to outflow from the left heart are among the most critically ill children for whom the anesthesiologist must care. These lesions include interruption of the aortic arch, coarctation of the aorta, aortic stenosis, and mitral stenosis or atresia as part of the hypoplastic left heart syndrome. These neonates present with inadequate systemic perfusion and profound metabolic acidosis. The initial pH may be below 7.0 despite a  $PaCO_2$  of less than 20 mmHg. Systemic blood flow is largely or completely dependent on blood flow into the aorta from the ductus arteriosus.

Ductal closure in the neonate with these problems causes dramatic worsening of the patient's condition. The patient becomes critically ill or even moribund and requires PGE1 infusion (see above) for survival. PGE1 allows blood flow into the aorta from the pulmonary artery because it maintains the patency of the ductus arteriosus [60,62,63]. In neonates with acidosis, metabolic derangements, and renal failure due to inadequate systemic perfusion, PGE1 infusion improves perfusion and metabolism, and surgery can be deferred until the patient's condition improves. Ventilatory and inotropic support and correction of metabolic acidosis, along with calcium, glucose, and electrolyte abnormalities, are often indicated preoperatively. The stabilization period also allows assessment of the magnitude of end-organ dysfunction caused by the preceding period of inadequate systemic perfusion. Adequacy of resuscitation, rather than severity of illness at presentation, has an important influence on postoperative outcome [64].

## **Ventricular dysfunction**

Older patients with CHD and poor ventricular function due to chronic ventricular volume overload (aortic or mitral valve regurgitation or long-standing pulmonaryto-systemic arterial shunts) present a different problem. Although patients with large shunts may have complete mixing of systemic and venous blood and only mild-tomoderate hypoxemia as a result of their excessive pulmonary blood flow, the price paid for near-normal arterial oxygen saturation is chronic ventricular dilation and dysfunction as well as pulmonary vascular obstructive disease. Consequently, narrowing of the shunt or a staged approach to single-ventricle repair may be indicated before any other elective surgery can be undertaken.

Assessment should include an estimation of the patient's functional limitation as an indicator of myocardial performance and reserve, quantification of the degree of hypoxia and the amount of pulmonary blood flow, and evaluation of PVR. For patients with increased Qp/Qs, during induction of anesthesia systemic blood flow should be optimized without further augmenting pulmonary flow. However, during maintenance and emergence from anesthesia, retraction of the lung, positional changes, and abdominal distension may increase the hypoxemia and compromise the function of a dilated, poorly contractile ventricle. If this sequence occurs during surgery, the anesthetic management must be altered to improve pulmonary blood flow.

In addition, systolic function of the ventricle may be impaired by intrinsic myopathic abnormalities related to drug toxicity (e.g. adriamycin), inborn enzyme deficiencies or acquired inflammatory or infectious disease. Patients with such dilated cardiomyopathies require optimization of ventricular performance with emphasis on inotropic support and afterload reduction.

## Principles of anesthetic management

The diversity of CHD lesions and the variations of severity and pathophysiology of each lesion mandate individualized anesthetic management based on the known effects of anesthetics and other drugs in patients with CHD. Once the critical aspects of the patient's pathophysiology are understood, the anesthetic management plan is formulated, including plans for the surgery, plans for dealing with anticipated problems and complications, and plans for pre- and postoperative care.

## General care of patients with congenital heart disease

The patient's condition should be optimal within the limits set by the lesion. Cardiac medications such as antiarrhythmic drugs should be continued preoperatively and anesthetic plans adjusted accordingly. The general preparation for each major pathophysiological problem is outlined above.

Systemic air emboli are a constant threat in children with CHD, regardless of their usual shunting pattern, because of the dynamic nature of shunts during anesthesia and surgery. Air traps are advisable for all IV lines but are not a substitute for meticulous attention and constant vigilance concerning the purging of air bubbles. Direct shunting of micro- and macrobubbles of air into the systemic circulation from multiple IV lines is always possible. Even when shunting patterns are nominally left to right, transient right-to-left shunts may occur during some portions of the cardiac cycle or during straining or coughing in patients with open communications between the left and right sides of the heart when normal transatrial pressure gradients are transiently reversed [65]. Right-to-left shunting may occur even across functionally "closed" communications. A "probe-patent" foramen ovale is common in children, regardless of whether or not they have CHD, and transient right-to-left shunting through the foramen ovale has been documented in a normal child during emergence from anesthesia [66].

Prevention of bacterial endocarditis is an important consideration in patients with CHD undergoing noncardiac surgery [67]. Currently antibiotic prophylaxis is considered reasonable only for those patients deemed at highest risk (Box 25.3) undergoing the following procedures: dental procedures involving manipulation of of gingival tissues, periapical region of teeth, or perforation of oral mucosa; procedures on the respiratory tract; procedures on infected skin, skin structures or musculoskeletal tissue.

The immediate preoperative period is an anxious time for patients and parents. Many patients may have undergone prior surgery or investigational procedures and separation from parents may be difficult. Because many patients are now admitted on the day of surgery, adequate preparation for surgery in the preoperative clinic with a thorough explanation of the planned procedure and conduct of anesthesia, including a plan for induction, is essential. Clear fluids can be administered up to 2h preoperatively, and an extended period of fasting should be avoided where possible, particularly in cyanotic patients.

Given the many types of pathophysiology in CHD patients, no single premedication regimen is recommended. Ideally, one wants a sedated, quiet patient who has adequate ventilation and circulation. Oral midazolam **Box 25.3** Cardiac conditions associated with the highest risk of adverse outcome from endocarditis for which prophylaxis with dental procedures is recommended

- Prosthetic cardiac valve
- Previous IE
- Congenital heart disease (CHD)\*
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
     Completely repaired congenital heart defect with prosthetic
  - material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure<sup>†</sup>
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

\*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

<sup>†</sup>Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.

0.5-1.0 mg/kg is often an effective anxiolytic and, although it may not produce hypnosis, should enable separation from parents. This dose of midazolam in combination with oral ketamine 5-7 mg/kg is a very effective premedicant. An intramuscular premedication with ketamine 4-5 mg/kg, glycopyrrolate  $10-20 \mu \text{g/kg}$  and midazolam 0.1 mg/kg is effective for young children who will separate from their parents in the preoperative holding area, or who have limited hemodynamic reserve and are unsuited for an inhalation induction. However, the effects of premedication on the often fragile circulatory and ventilatory status of these patients must be appreciated, especially as cyanotic patients have decreased hypoxic drive [68].

### Induction of anesthesia

Because of the potential for rapid and dramatic hemodynamic changes in young patients with CHD, especially infants, complete preparation of anesthetic and monitoring equipment and required drugs is essential. Adequate assistance should be immediately available during the induction of anesthesia in case problems develop.

The choice of induction technique is influenced by the response to premedication, the parent–child–anesthesiologist relationship, and the anesthetic management plan. In older, non-hypoxemic patients who have minimal compromise of their cardiac reserve, the choice of induction techniques is large. Inhalation, intravenous or intramuscular induction of anesthesia can be accomplished with a variety of drugs with reasonable degrees of safety if individual pathophysiological limitations are understood. For younger, sicker, and less co-operative patients, the choices diminish.

In children with adequate peripheral veins, quick insertion of a small-bore IV needle for induction of anesthesia can be virtually painless. Preoperative use of a topical anesthetic preparation may facilitate IV placement. Cooperative children with an adequate cardiac reserve and difficult IV access or a morbid fear of needles can have anesthesia induced cautiously with inhaled anesthetics, even if they are cyanotic. An IV catheter can then be inserted to facilitate tracheal intubation and avoid the risk of deep levels of inhalational anesthesia for tracheal intubation in patients whose circulatory systems may have little reserve.

An intravenous induction should be used for all patients with severely limited hemodynamic reserve, particularly those with severe ventricular failure or pulmonary hypertension. In situations where hemodynamic instability during induction is likely, starting an inotrope agent such as dobutamine or dopamine prior to induction should be considered. While the stress of placing an IV may be considerable for some patients, particularly those with difficult IV access following previous procedures, this is preferable to the potential myocardial depression during an inhalation induction with sevoflurane.

Fentanyl 15–25 $\mu$ g/kg in combination with pancuronium 0.2 mg/kg provides hemodynamic stability and prompt airway control and attenuates the stress-induced increase in PVR associated with intubation. Ketamine 1–3 mg/kg IV is safe and reliable, providing hemodynamic stability and minimal increases in PVR. It is particularly useful in patients with severe CHF and ventricular outflow obstructions. Atropine 20 $\mu$ g/kg or glycopyrrolate 10 $\mu$ g/kg is traditionally given concurrently due to increased secretions. If IV access is difficult and stressful in infants, a combination of 4 mg/kg ketamine, glycopyrrolate 10 $\mu$ g/kg and succinylcholine 2mg/kg intramuscularly allows prompt induction and airway control.

Propofol can be used in patients with normal ventricular function. Titrated doses are suitable for short procedures such as cardioversion or transesophageal echocardiogram (TEE). Midazolam 0.1–0.2 mg/kg is also a useful adjunct during an opioid induction but may cause hypotension in patients dependent on a high sympathetic drive.

An inhalation induction with sevoflurane is suitable for most infants and children, provided they have stable ventricular function and adequate hemodynamic reserve. This emphasizes the importance of preoperative evaluation when planning the induction technique. Inhalational induction can be used safely in patients with cyanotic heart disease, although uptake may be slower due to the right-to-left shunt [69]. Saturations will generally increase, provided cardiac output is maintained and airway obstruction avoided.

For many younger children, the presence of a parent during inhalation induction may be preferable for both the patient and parent. This is a common technique for normal children undergoing induction of anesthesia for non-cardiac surgery, but careful preoperative preparation and explanation are necessary before this is undertaken in the cardiac operating room.

### **Maintenance of anesthesia**

Anesthesia maintenance techniques depend on the patient's preoperative cardiorespiratory status and pathophysiology of the underlying cardiac defect, the surgical procedure, the conduct of CPB, potential postoperative surgical problems and the anticipated postoperative management. Once induction of anesthesia and control of the airway are accomplished and monitoring is adequate, anesthesia can be maintained with inhaled anesthetics or additional intravenous drugs as dictated by the response of each patient, intraoperative events, and postoperative plans.

Stress responses to pain and other noxious stimuli are profound in even the youngest neonates, regardless of postconceptual age [70-72]. These hormonal and metabolic stress responses can be deleterious [73], particularly in patients with marginal hemodynamic reserve. Intraoperative deterioration in the patient's condition is not always clear, but changes in shunting, surgical manipulation of the heart, lungs or great vessels, and depression of the myocardium by anesthetics are common causes. Decreases in arterial oxygenation or in systemic blood flow and pressure frequently are due to alterations in intracardiac shunting. When circulating blood volume is adequate and anesthesia-related myocardial depression is unlikely, these problems are corrected by appropriately manipulating PVR and SVR. If PVR cannot be altered or is not part of the problem, vasopressor and inotropic drugs are used where indicated to increase SVR and cardiac function.

## Choice of anesthetic agents

Use of inhaled anesthetics in children with intracardiac shunting is complicated by differences in uptake and distribution of these agents. A complex computer model suggested that induction of anesthesia is slowed by the presence of central right-to-left shunts, slowed less by mixed shunts, and changed little by pure left-to-right shunts; the changes are proportional to the size of the

**Figure 25.10** Computer-modeled effect of solubility of anesthetic gases on delay of uptake (arterial/inspired gases concentration ratio) in children caused by a 50% right-to-left shunt. Ether is most soluble and thus least affected; nitrous oxide is least soluble. Reproduced from Tanner GE, Angers DG, Barash PG. Effect of left-to-right, mixed left-to-right, and right-to-left shunts on inhalational anesthetic induction in children. Anesth Anag 1985; 64: 101 with permission from Lippincott, Williams & Wilkins.

shunt [69]. These theoretical effects assume a constant cardiac output and are most marked for insoluble gases (e.g. nitrous oxide). Induction of anesthesia with more soluble gases, (e.g. halothane) is less affected (Fig. 25.10). Similar studies comparing the speed of induction with sevoflurane to other potent inhalation agents have not been performed; however, because it is less soluble than halothane, induction with sevoflurane should be expected to be slower in patients with a right-to-left shunt. In children with left-to-right shunts, the speed of inhalation induction is little altered clinically [74]. Data from animals with right-to-left shunts confirm that induction of anesthesia is slowed; data from children with right-to-left shunts are not available [75]. Inhalation induction often seems slower in children with pure right-to-left shunts but this effect is not marked, probably because multiple other variables are affecting uptake. The potentially slow induction of anesthesia in children with pure right-to-left shunts should be remembered when one must rapidly increase the concentration of potent inhaled anesthetics in these patients.

The direct effect of inhaled agents on Qp/Qs appears to be limited. Sevoflurane, halothane, isoflurane, and fentanyl/midazolam do not change Qp/Qs in children with atrial and ventricular septal defects when cautiously administered with 100% oxygen [76].

### **Potent inhaled anesthetics**

The volatile agents most commonly used during pediatric anesthesia are desflurane, isoflurane and sevoflurane.

Halothane is rarely used at present. All three can be used safely to maintain anesthesia in children with cardiac disease, although this depends to some extent on the child's cardiac anomaly and related pathophysiology. Cyanotic children with reasonable functional cardiac reserve can have anesthesia induced with sevoflurane or halothane and oxygen (even 70% nitrous oxide does not significantly decrease arterial oxygen saturation) [77–79]. Nevertheless, it is important that the anesthesiologist has an understanding of the potential effects of these anesthetics in young children with CHD.

Increased sensitivity of the immature cardiovascular system and decreased cardiovascular reserves are more serious problems with potent inhaled anesthetics. Use of these agents may considerably reduce the margin of safety in infants and younger children with severe CHD. Volatile anesthetics depress myocardial function primarily by limiting calcium availability within the myocyte, i.e. by reducing trans-sarcolemmal and sarcoplasmic reticulum calcium flux. The net result is depletion of intracellular calcium stores and, given the immaturity of the neonatal and infant myocardium, the potential for systolic dysfunction in these patients may be increased when volatile agents are used. In addition, diastolic ventricular function may also be impaired because of limited reuptake of calcium into the immature sarcoplasmic reticulum, and dependence upon trans-sarcolemmal sodiumcalcium exchange [80].

Therefore, it is not surprising that numerous studies have shown that the immature cardiovascular system of normal infants does not tolerate halothane and isoflurane well; up to 50% of infants with normal cardiovascular systems develop substantial hypotension and bradycardia during induction of anesthesia with these agents unless the cardiovascular system is supported [81,82]. The ventricular function of normal infants declines when anesthesia is induced with isoflurane; stroke volume and ejection fraction decrease by as much as 38% [82]. Somewhat less myocardial depression occurs with halothane in older children [83]. Halothane (1 and 1.5 MAC) depresses cardiac index and contractility in patients with CHD more than comparable levels of sevoflurane, isoflurane, and fentanyl/midazolam anesthesia [84]. In addition, halothane anesthesia may result in more severe hypotension and emergent drug use than sevoflurane anesthesia in infants and children with CHD [85]. Isoflurane causes less direct myocardial depression, is less soluble and therefore has a faster uptake and emergence, has no effect on intracardiac conduction and much less sensitization of the myocardium to catecholamines compared to halothane. As with isoflurane, sevoflurane causes less myocardial depression and has a low risk for arrhythmias in children compared to halothane [86-88]. Sevoflurane anesthesia is associated with prolongation of the QTc interval in infants [89]. Sevoflurane (1 MAC) and fentanyl/midazolam anesthesia have no significant effect on myocardial function in patients with a single ventricle [90].

### **Nitrous oxide**

The use of nitrous oxide in children with CHD and shunts is controversial because of its potential for enlarging systemic air emboli and for increasing PVR. Nitrous oxide may expand intravascular air emboli and exaggerate the effects of other anesthetics on the circulation, even without systemic air embolization [91]. However, neither has been demonstrated to be a clinical problem in patients with CHD.

Nitrous oxide has been reported to decrease cardiac output, systemic arterial pressure, and heart rate in adults, and it increased PVR, especially when the pre-existing PVR is elevated [92,93]. The latter would be detrimental to children with right-to-left shunts, pulmonary hypertension, and decreased pulmonary flow. However, increases in pulmonary artery pressure or PVR in infants given 50% nitrous oxide do not occur, regardless of preexisting PVR [19]. Mild but significant decreases in cardiac output, systemic arterial pressure, and heart rate were seen in these infants. Furthermore, inhalation induction of anesthesia with 70% nitrous oxide and halothane did not decrease the arterial oxygen saturation of cyanotic children, suggesting that pulmonary blood flow is not decreased and that PVR is not substantially increased by nitrous oxide [77,78]. Although the administration of nitrous oxide prevents the use of 100% oxygen, the arterial oxygen saturation of cyanotic children may not decrease because changes in FIO<sub>2</sub> have little effect on the arterial oxygenation of these patients [94] (see Fig. 25.8). Arterial desaturation that is caused by pulmonary disease is, however, probably a contraindication to the use of nitrous oxide.

#### Intravenous anesthetics

Some intravenous anesthetics provide a larger margin of safety for induction of anesthesia in the immature and compromised cardiovascular system of neonates and infants with severe cardiac disease. However, very high, transient arterial, cardiac, and brain concentrations of IV agents can occur when normal IV doses of drugs are given as a rapid infusion in children with known right-to-left shunts because mixing, uptake, and metabolism in the pulmonary circulation are bypassed. In dogs with right-to-left shunts, a 1 mg/kg bolus of IV lidocaine resulted in arterial drug concentrations above those reported to cause irreversible myocardial toxicity [95]. Routinely administered bolus doses of lidocaine used for dysrhythmias or intubation, or other drugs such as barbiturates,  $\beta$ -blockers or calcium channel blockers, may be

potentially toxic to children with substantial right-to-left shunts.

## Ketamine

When IV access or lack of patient co-operation is a problem, intramuscular ketamine (3-5mg/kg) is well tolerated in sick infants and children with cyanosis or congestive heart failure [96]. Because of the potential effects of ketamine on airways, ventilation, and secretions, it should be given in combination with an antisialagog (e.g. atropine or glycopyrrolate) while the airway and ventilation are carefully maintained, especially in children with decreased oxygen reserves. Ketamine can be mixed with atropine and succinvlcholine in the same syringe, the final volume being relatively small, and injection of this mixture allows rapid control of the airway. Small IV doses of ketamine (1-3mg/kg) are effective for supplemental sedation in unco-operative or apprehensive children who are unwilling to leave their parents. Excessive secretions, airway problems, and apnea do not occur with these doses as they occasionally do with larger IM doses and frequently do with IV doses of ketamine.

Although increased PVR is reported with ketamine in adults, 2mg/kg IV in premedicated infants and young children usually does not increase pulmonary artery pressure or PVR, even when the baseline PVR is elevated [20,21,23,97]. If hypoventilation or apnea occurs after an IV dose of ketamine, undesirable increases in PVR can occur because of the associated changes in PaO<sub>2</sub> and PaCO<sub>2</sub> [20]. Little change in cardiac output, heart rate or arterial pressure is seen after IV ketamine in infants and small children with CHD [20,21]. Despite reports of ketamine having a negative inotropic effect on isolated heart muscle in animal studies (at very high doses), the ejection fraction of children with CHD is well preserved after ketamine. Furthermore, arterial saturation, for the most part, is improved when ketamine is used to induce anesthesia in cyanotic patients. Clinical experience with ketamine as the induction agent has been excellent for sick infants and children with most forms of heart disease, including those with limited pulmonary blood flow and cyanosis. Ketamine alone or in combination with propofol or dexmedetomidine is also useful for sedation and for anesthesia for cardiac catheterization in children with CHD [98].

### **Opioid** anesthesia

High-dose opioid anesthesia provides excellent cardiovascular stability in children with CHD. Morphine (1 mg/ kg or more) given slowly over a prolonged period provides reasonable cardiovascular stability in children; however, as in adults, histamine release can occur and cause hypotension. The more potent synthetic opioids, fentanyl (25–75 $\mu$ g/kg) and sufentanil (5–15 $\mu$ g/kg), given

more slowly, provide better stability of the cardiovascular system on induction of anesthesia when used with pancuronium in very sick infants with CHD [99-103]. Because of its effect on the sympathetic nervous system and duration of action, pancuronium remains the muscle relaxant of choice to use with high-dose synthetic opioids. Shorter acting muscle relaxants such as *cis*-atracurium have a relatively benign hemodynamic profile, but should be administered as a continuous infusion during cardiac surgery because of their short duration of action. The doses of synthetic opioids required to blunt the systemic and pulmonary stress responses in younger and sicker children are generally well tolerated [24,25,71]. Changes in pulmonary and systemic hemodynamics are insignificant in infants with a bolus of fentanyl  $15-25\mu g/kg$ . Used with 100% oxygen, these high-dose narcotics are safe and result in increased arterial oxygenation in cyanotic children [100]. Fentanyl doses as low as 10µg/kg may be sufficient for effective baseline anesthesia in neonates, but larger doses are necessary for prolonged anesthesia [104-106]. A bolus dose of  $10-15\mu g/kg$  effectively ameliorates the hemodynamic response to intubation in neonates. For complete suppression of hemodynamic responses to intense stimulation of more vigorous children, supplementation of high-dose opioids with small amounts of inhaled anesthetic may be necessary. Although low doses of fentanyl 2-5µg/kg facilitate mechanical ventilation and decrease total lung compliance in an awake child, high-dose opioids produce chest wall rigidity and glottic closure in adults and neonates [107,108]. A muscle relaxant is required with rapid infusion of high-dose synthetic opioids.

The high-dose opioid technique is most suitable for sick infants and older children in whom postoperative mechanical ventilation is planned. This technique provides hemodynamic stability, although it does not guarantee suppression of the endocrine response to surgical stimulation. Neonates and infants undergoing deep hypothermic CPB surgery are able to generate a significant stress response [73]. A 17-fold increase in epinephrine and 10-fold increase in norepinephrine levels in infants were seen after 1h of circulatory arrest at 18°C [109]. Nevertheless, the reported magnitude of the stress response after cardiac surgery is variable, and influenced by patient age, type of anesthesia, level of hypothermia, and the duration of CPB and circulatory arrest [110].

Fentanyl doses of  $50\mu g/kg$  administered prior to CPB, a further  $25\mu g/kg$  at the onset of rewarming on CPB, and a further  $25\mu g/kg$  after bypass, depending upon hemodynamic stability, are commonly administered. These additional doses or a continuous infusion of potent opioids are necessary for surgery involving CPB, as opioid concentrations decrease markedly during CPB [111]. In a recent study of stress hormone

release during infant cardiac surgery and deep hypothermic cardiopulmonary bypass using this fentanyl dosing regimen, the endocrine response was not obtunded, yet there were no adverse outcomes. In addition, no specific relationship between opioid dose, plasma fentanyl level and hormone or metabolic stress response was established [112]. Considering the advances in surgical techniques, conduct of CPB and perioperative management over the past decade that have lead to a significant improvement in patient outcome, a strategy of high-dose opioid anesthesia to blunt the stress response may be less critical.

Remifentanil is a synthetic ultra-short acting opioid, rapidly metabolized by non-specific tissue esterases [113]. It is unique among the currently available opioids because of its extremely short context-sensitive half-time (3-5 min), which is largely independent of the duration of infusion. Remifentanil may cause significant respiratory depression and is usually administered to patients who are mechanically ventilated. It may be useful for patients with limited cardiorespiratory reserve undergoing procedures such as cardiac catheterization or pacemaker placement because intense analgesia is provided without significant hemodynamic complications. It may also be used to maintain anesthesia during mild hypothermic CPB for patients who are extubated immediately after surgery in the operating room, such as after atrial septal defect repair [114]. Patients usually emerge quickly once the infusion has been stopped, and opioid side-effects are reduced because of the short duration of action.

## Other intravenous agents

The benzodiazepine derivatives (e.g. midazolam) can be useful when titrated in small doses (0.05-0.1 mg/kg), especially in older patients with CHD. Lack of pain on injection and lack of vascular damage make water-soluble midazolam a more useful benzodiazepine than diazepam, particularly because it has a shorter duration of action. Benzodiazepines are commonly used to ensure adequate hypnosis during opioid-based anesthesia, but may also improve hemodynamic stability. In a study of children with acyanotic heart disease undergoing cardiac surgery, the addition of diazepam to fentanyl-based anesthesia  $(75 \mu g/kg)$  resulted in a more stable hemodynamic profile without an increase in epinephrine levels when compared to an isoflurane-based anesthetic technique [115]. In a study of younger children undergoing correction of tetralogy of Fallot, the combined use of sufentanil and flunitrazepam provided a more stable hemodynamic profile and catecholamine response compared to a sufentanil-based technique alone [116].

Propofol can be used judiciously in patients with CHD. The predominant hemodynamic effect of propofol 1–3 mg/kg is a reduction in SVR with no effect on PVR. In patients with right-to-left shunting this results in a decrease in pulmonary blood flow and arterial oxygenation saturation [117,118]. The venodilation associated with propofol administration also requires that it be used with caution in patients who have undergone a previous cavopulmonary connection. The resting venous tone is increased in this patient group, and the fall in preload could result in significant hypotension during induction.

Etomidate is an anesthetic induction agent with the advantage of minimal cardiovascular and respiratory depression. An intravenous dose of 0.3 mg/kg induces a rapid loss of consciousness with minimal respiratory depression for a duration of 3–5 min. At this dose it does not substantially alter hemodynamics or either right-to-left or left-to-right shunting in patients with congenital heart disease [119,120]. It may cause pain on injection and is associated with spontaneous movements, hiccoughing and myoclonus. Etomidate may be used as an alternative to the synthetic opioids for induction of patients with limited myocardial reserve. A single dose of etomidate can suppress adrenal steroidogenesis and as a result it is not approved for continuous infusion [121].

## Anesthesia for cardiac surgery

Communication between the anesthesia and surgical teams is of utmost importance during surgery for CHD. The manipulations of each team influence the other, and close co-ordination of activities is necessary for optimal patient care. Specific problems occurring with total repair or palliation of specific congenital cardiac lesions are covered later in the chapter. General problems that occur with various types of closed and open cardiac surgical procedures are considered here.

## Anesthetic management of closed cardiac procedures

Patent ductus arteriosus, coarctation of the aorta, and repair of vascular rings are the only congenital cardiac anomalies *corrected* with closed procedures. Closed palliative procedures, including systemic-to-pulmonary shunts, pulmonary artery banding, and procedures to improve interatrial mixing (Blalock–Hanlon atrial septectomy), are performed infrequently as the trend to definitively correct the CHD early continues. Anesthesia for closed palliative procedures is in some ways more demanding, because CPB is not available if the patient's hemodynamic status deteriorates. Therefore, monitoring requirements are stringent, and central venous and arterial access are usually mandatory. Pulse oximetry is invaluable in these cases to evaluate the infant's condition and to assess the effectiveness of the closed surgical procedure. Acid–base and electrolyte balance are meticulously maintained at normal levels throughout closed procedures. When these procedures are done via a thoracotomy, the operative field is rarely visible to the anesthesiologist, and marked deterioration of cardiopulmonary function may result from surgical manipulations. Any deterioration in the infant's condition should be immediately communicated to the surgeon, who has a view of the surgical field and knows what is being done there. Some compromise of ventilation and pulmonary blood flow inevitably occurs during these procedures, occasionally with severe decreases in arterial oxygen saturations.

## **Mechanical ventilation**

Altered lung mechanics and ventilation/perfusion abnormalities are common problems in the immediate postoperative period [122]. Besides preoperative problems secondary to increased Qp/Qs, additional considerations include the surgical incision and lung retraction, increased lung water following CPB, possible pulmonary reperfusion injury, surfactant depletion and restrictive defects from atelectasis and pleural effusions.

In general, neonates and infants with their limited physiological reserve should not be weaned from mechanical ventilation until hemodynamically stable, and factors contributing to an increase in intrapulmonary shunt and altered respiratory mechanics have improved.

## **Volume-limited ventilation**

A traditional approach to mechanical ventilation in children with congenital heart disease has been the use of a volume-limited, time-cycled mode, with large tidal volumes of 15–20 cc/kg and no PEEP. This approach was developed in the early years of congenital heart surgery when older generations of ventilators existed and the monitoring of ventilation was frequently less than ideal. While the peak inspiratory and mean airway pressure are usually increased using large tidal volumes in this mode, changes in compliance and resistance can be readily detected. If there is a sudden change in pulmonary mechanics from atelectasis, pneumothorax or endotracheal tube obstruction, the peak inspiratory pressure alarm limit is reached as the ventilator tries to deliver the preset tidal volume.

However, for neonates and infants, the compressible volume of the ventilator circuit  $(1-1.5 \text{ cc/cmH}_2\text{O} \text{ peak}$  inspiratory pressure) means that the delivered tidal volume is less than the preset volume. For older patients receiving larger tidal breaths, the volume lost by compression of gas in the circuit is minimal and rarely affects their tidal ventilation. But for neonates and infants, this compressible volume may be a considerable component of their tidal ventilation. Further, any leak around the

endotracheal tube means that a proportion of the delivered tidal volume may also be lost. Inspiratory and expiratory times also need to be closely observed to prevent excessive auto PEEP. Variable time constants, i.e. [compliance× resistance], within regions of the lung are common in children with defects associated with high pulmonary blood flow, as well as following CPB. Using a volumelimited, time-cycled mode, those areas of lung with an increased time constant may be preferentially ventilated and overdistended, contributing to ventilation/perfusion mismatch and potential lung injury.

### **Pressure-limited ventilation**

A pressure-limited, time-cycled mode of ventilation is often appropriate in children less than 10kg, particularly those with significant alteration in lung compliance and airway resistance. A decelerating flow pattern is used when a breath is delivered to the patient until a preset peak inspiratory pressure is achieved. The delivered tidal volume will vary according to the compliance and resistance of the lung, and therefore from breath to breath. Both the peak inspiratory pressure and the inspiratory time can be manipulated to increase or decrease the delivered tidal volume. A square wave pressure waveform is generated by changing the inspiratory time, which will also alter the mean airway pressure. In general, it is preferable to set a minute ventilation using the lowest possible mean airway pressure. In-line monitoring enabling breath-tobreath assessment of tidal volume and mean airway pressure is essential, with appropriate alarm limits set such that acute changes in compliance and resistance can be detected.

### **Cardiorespiratory interactions**

Cardiorespiratory interactions vary significantly between patients, and it is not possible to provide specific ventilation strategies or protocols that will cover all patients. Rather, the mode of ventilation must be matched to the hemodynamic status of each patient to achieve the appropriate cardiac output and gas exchange. Frequent modifications to the mode and pattern of ventilation may be necessary during recovery after surgery, with attention to changes in lung volume and airway pressure.

### Lung volume

Changes in lung volume have a major effect on PVR, which is lowest at FRC, while both hypo- and hyperinflation may result in a significant increase in PVR. At low tidal volumes, alveolar collapse occurs because of reduced interstitial traction on alveolar septae. In addition, radial traction on extra-alveolar vessels such as the branch pulmonary arteries is reduced, thus reducing the crosssectional diameter. Conversely, hyperinflation of the lung may cause stretching of the alveolar septae and compression of extra-alveolar vessels.

An increase in PVR increases the afterload or wall stress on the right ventricle (RV), potentially compromising RV function and contributing to decreased left ventricle (LV) compliance secondary to interventricular septal shift. In addition to low cardiac output, signs of RV dysfunction including tricuspid regurgitation, hepatomegaly, ascites, and pleural effusions may be observed.

### Intrathoracic pressure

An increase in mean intrathoracic pressure during positive pressure ventilation decreases preload to both pulmonary and systemic ventricles, but has opposite effects on afterload to each ventricle [123].

### **Right ventricle**

The reduction in RV preload that occurs with positive pressure ventilation may reduce cardiac output. Normally the RV diastolic compliance is extremely high and the pulmonary circulation is able to accommodate changes in flow without a large change in pressure. An increase in mean intrathoracic pressure increases the afterload on the RV from direct compression of extra-alveolar and alveolar pulmonary vessels.

Patients with normal RV compliance and without residual volume load or pressure load on the ventricle following surgery usually show little change in RV function from the alteration in preload and afterload that occurs with positive pressure ventilation. However, these effects can be magnified in patients with restrictive RV physiology, in particular neonates who have required a right ventriculotomy for repair of tetralogy of Fallot (TOF), pulmonary atresia or truncus arteriosus. While systolic RV function may be preserved, diastolic dysfunction is common with increased RV end-diastolic pressure and impaired RV filling.

The potential deleterious effects of mechanical ventilation on RV function are important to emphasize. The aim should be to ventilate with a mode that enables the lowest possible mean airway pressure, while maintaining lung volume. While the use of a low peak inspiratory pressure, short inspiratory time, increased intermittent mandatory (IMV) rate and low levels of PEEP has been recommended as one ventilation strategy in patients with restrictive RV physiology, the smaller tidal volumes, e.g. 6-8cc/kg, during this pattern of ventilation may reduce lung volume and FRC, thereby increasing PVR and afterload on the RV. An alternative strategy in a pressure-limited mode of ventilation is to use larger tidal volumes of 12–15 cc/kg, with a longer inspiratory time of 0.8-1.0 sec, increased peak inspiratory pressure of around 30 cmH<sub>2</sub>O and low PEEP (i.e. wide  $\Delta P$ ), and slow IMV rate of 12–15 breaths/ min. For the same mean airway pressure, RV filling is

maintained and RV output augmented by maintaining lung volume and reduced RV afterload.

## Left ventricle

Left ventricular preload is also affected by changes in lung volume. Pulmonary blood flow, and therefore preload to the systemic ventricle, may be reduced by an increase or decrease in lung volume secondary to alteration in radial traction on alveoli and extra-alveolar vessels.

The systemic arteries are under higher pressure and not exposed to radial traction effects during inflation or deflation of the lungs. Therefore, changes in lung volume will affect LV preload, but the effect on afterload is dependent upon changes in intrathoracic pressure alone rather than changes in lung volume.

In contrast to the RV, a major effect of positive pressure ventilation on the LV is a reduction in afterload. Using La Place's Law, wall stress is directly proportional to the transmural LV pressure and the radius of curvature of the LV. The transmural pressure across the LV is the difference between the intracavity LV pressure and surrounding intrathoracic pressure. Assuming a constant arterial pressure and ventricular dimension, an increase in intrathoracic pressure, as occurs during positive pressure ventilation, will reduce the transmural gradient and therefore wall stress on the LV [123]. Therefore, positive pressure ventilation and PEEP can have significant beneficial effects in patients with left ventricular failure.

Patients with LV dysfunction and increased enddiastolic volume and pressure can have impaired pulmonary mechanics secondary to increased lung water, decreased lung compliance and increased airway resistance. The work of breathing is increased and neonates can fatigue early because of limited respiratory reserve. A significant proportion of total body oxygen consumption is directed at the increased work of breathing in neonates and infants with LV dysfunction, contributing to poor feeding and failure to thrive. Therefore, positive pressure ventilation has an additional benefit in patients with significant volume overload and systemic ventricular dysfunction by reducing the work of breathing and oxygen demand.

## Lung injury

It is important to appreciate that mechanical ventilation may result in significant lung injury, particularly when high tidal volumes are used [124]. Large, rapid changes in tidal volumes may lead to shear stress on the alveolar septae and subsequent alveolar capillary disruption. The same mechanisms that result in air leak may also result in disruption of the microcirculation, causing an increase in total lung water with subsequent increase in airway resistance and reduction in lung compliance. Lung disease is usually not homogenous, with regions of the lung having different time constants, i.e. the concept of "fast" alveoli and "slow" alveoli. When using a volumelimited strategy, the more compliant alveoli will distend in preference to regions of lung that are collapsed or have slow time constants, thereby resulting in regional alveolar overdistension and trauma. This may be less evident with a pressure-limited strategy, as the more compliant or faster alveoli will distend to the preset pressure limit and then, depending on the inspiratory time, regions of lung with reduced time constants will gradually distend and be recruited.

While a relatively large tidal volume of 12–15 cc/kg is beneficial for many patients following congenital heart surgery for maintaining lung volume at lower PVR, lung injury may occur if a high-volume strategy is continued for a prolonged period (i.e. volutrauma). Using a pressurelimited mode of ventilation will enable a relatively constant tidal volume without a wide swing in peak inspiratory pressure or regional alveolar overdistension. It is essential to continually re-evaluate the mode of ventilation and modify it according to hemodynamic responses. Fortunately, most patients undergoing congenital cardiac surgery do not have parenchymal lung disease and changes in pulmonary mechanics, such as secondary to changes in lung water, are generally resolved following complete surgical repair and diuresis after CPB.

### Positive end-expiratory pressure

The use of PEEP in patients with congenital heart disease has been controversial. It was initially perceived not to have a significant effect in terms of improving gas exchange, and there was concern that the increased airway pressure could have a detrimental effect on hemodynamics and contribute to lung injury and air leak.

Nevertheless, PEEP increases FRC, enabling lung recruitment, and redistributes lung water from alveolar septal regions to the more compliant perihilar regions. Both of these effects will improve gas exchange and reduce PVR. However, excessive levels of PEEP may be detrimental by increasing afterload on the RV. Usually 3–5 cmH<sub>2</sub>O of PEEP will help maintain FRC and redistribute lung water without causing hemodynamic compromise.

### Management of cardiopulmonary bypass

Inasmuch as reparative procedures usually entail CPB techniques, the care of these patients must incorporate technical knowledge of CPB issues and take into account the effects of CPB on the function of multiple organ systems. An important component of the improvement in early outcome following congenital heart surgery has been the advances in cardiovascular support, especially cardiopulmonary bypass techniques, myocardial

**Figure 25.11** Cellular and humoral response to cardiopulmonary bypass.

protection, pharmacological support and mechanical support. It is well recognized that the exposure of blood elements to the non-epithelialized cardiopulmonary bypass circuit, along with ischemic-reperfusion injury, induces a systemic inflammatory response (Fig. 25.11). The effects of the interactions of blood components with the extracorporeal circuit are magnified in children due to the large bypass circuit surface area and priming volume relative to patient blood volume. Humoral responses include activation of complement, kallikrein, eicosanoid and fibrinolytic cascades; cellular responses include platelet activation and an inflammatory response with an adhesion molecule cascade stimulating neutrophil activation and release of proteolytic and vasoactive substances [125].

The clinical consequences include increased interstitial fluid and generalized capillary leak, and potential multiorgan dysfunction. Total lung water is increased with an associated decrease in lung compliance and increase in the alveolar-to-arterial O<sub>2</sub> (A-aO<sub>2</sub>) gradient. Myocardial edema results in impaired ventricular systolic and diastolic function. A secondary fall in cardiac output by 20-30% is common in neonates in the first 6-12h following surgery, contributing to decreased renal function and oliguria. Sternal closure may need to be delayed due to mediastinal edema and associated cardiorespiratory compromise when closure is attempted. Ascites, hepatic ingestion and bowel edema may affect mechanical ventilation, cause a prolonged ileus and delay feeding. A coagulopathy post CPB may contribute to delayed hemostasis.

Over recent years, numerous strategies have evolved to limit the effect of this endothelial injury resulting from the systemic inflammatory response. Of these, the most important strategy is limiting both the time spent on bypass and use of deep hypothermic circulatory arrest (DHCA). This is clearly dependent, however, upon surgical expertise and experience, and in certain situations DHCA is necessary to effect surgical repair. Hypothermia and steroids are important pre-bypass measures to limit activation of the inflammatory response. Attenuating the stress response, the use of antioxidants such as mannitol, altering prime composition to maintain oncotic pressure, and ultrafiltration are also used to limit the clinical consequences of the inflammatory response.

From a practical point of view, the amount of fluid that can be removed by ultrafiltration is limited by the level of blood in the venous reservoir. A number of different ultrafiltration techniques exist in children. Conventional ultrafiltration (CUF) refers to ultrafiltration occurring throughout CPB or during those intervals when venous reservoir volume is sufficient to allow it. This system would be expected to produce hemoconcentration. Modified ultrafiltration (MUF) allows ultrafiltration to continue after weaning from CPB. MUF may be performed utilizing either an arteriovenous or veno-venous system. Blood volume is kept constant as ultrafiltrate is lost by replacing it with blood from the CPB circuit, which passes through the ultrafiltrator before being delivered to the patient. In this way, the CPB circuit can remain primed and the patient's blood, as well as the CPB blood, can be hemoconcentrated. The endpoint for termination of MUF following CPB varies from institution to institution with institutions terminating MUF after a set time interval (15–20 min), a set hematocrit (40%) or a set volume removed (750 mL/m<sup>2</sup>). Heparin anticoagulation must be maintained during MUF with protamine reversal of heparin initiated after termination of MUF.

The major advantage of MUF over CUF is that it allows hemoconcentration to continue once CPB has been terminated. As a result, MUF normally allows a greater degree of hemoconcentration than can be obtained with CUF alone, particularly in small children. Some institutions utilize both CUF and MUF as the techniques are not mutually exclusive [126].

Dilutional (DUF) and zero-balance ultrafiltration (ZBUF) utilize the same system as CUF but involve high-volume ultrafiltration during CPB in which crystalloid solution is continuously used to replace the ultrafiltrate in order to maintain reservoir volume. ZBUF utilizes ultrafiltration rates of 200 mL/min/m<sup>2</sup> during rewarming. DUF is performed throughout CPB and utilizes rates of 40–80 mL/kg/h [127,128]. These methods do not result in hemoconcentration but may be beneficial in removing inflammatory mediators. MUF is usually used in conjunction with these techniques to obtain hemoconcentration.

In clinical application, MUF as compared to no ultrafiltration has been demonstrated to reduce total body water, attenuate dilutional anemia and coagulopathy, reduce homologous blood requirements, narrow the A-aO<sub>2</sub> gradient, improve LV compliance and systolic function as well as arterial blood pressure, and decrease inotropic requirements in the immediate postfiltration period [129-136]. In a non-randomized, retrospective analysis of cavopulmonary connection procedures (primarily hemi-Fontan and lateral tunnel Fontan), patients in whom MUF was used had a lower incidence of pleural and pericardial effusions and a shorter hospital stay than patients in whom MUF was not used [131]. MUF compared to no ultrafiltration may reduce postoperative ventilatory support times but this has not been a consistent finding despite short-term improvements in pulmonary compliance [129,133,137].

A number of studies have shown MUF to be effective in removing both anti-inflammatory (interleukin 10, interleukin 1 receptor antagonist) and proinflammatory (tumor necrosis factor  $\alpha$ , interleukin 1 $\beta$ , interleukin 6, interleukin 8, complement fragments C3a and C5a, and endotoxins) mediators generated during CPB while other studies have not confirmed this efficacy [133,138– 144]. In addition, MUF may offer no advantage over CUF in terms of inflammatory mediator removal [140]. The extent to which the beneficial effects of MUF are related to reduction of tissue edema, removal of inflammatory mediators, and hemoconcentration has not been clarified [126].

Zero-balance ultrafiltration in conjunction with MUF or DUF in conjunction with MUF may be a more effective strategy for removal of inflammatory mediators. ZBUF in conjunction with MUF has been shown to be more effective than MUF alone in reducing inflammatory mediator concentrations immediately following filtration [127]. Patients in the ZBUF group also had reduced blood loss, a shorter duration of postoperative ventilatory support and a narrower 24-h A-aO<sub>2</sub> gradient [127]. DUF in conjunction with MUF has been shown to be more effective than CUF alone in reducing plasma endothelin 1 and thromboxane B<sub>2</sub> levels following CPB and in attenuating postoperative pulmonary hypertension [128,132,145]. In addition, the duration of postoperative ventilatory support and transfusion requirements was reduced in a group of high-risk patients (neonates, patients with pulmonary hypertension, and patients with prolonged CPB times) [132,145]. A recent study demonstrated a modest reduction in interleukin 6, a narrowed A-aO<sub>2</sub> gradient, improved pulmonary compliance but no reduction in the length of postoperative ventilatory support with CUF in conjunction with MUF as compared to no ultrafiltration [146]. No advantage in terms of improved postoperative course was demonstrated when CUF combined with MUF was compared to CUF alone, despite the fact that a larger filtrate volume was obtained in the combined group [147,148]. In addition, MUF alone and CUF alone were indistinguishable in their effect on hematocrit, mean arterial pressure, heart rate, and LV shortening fraction when equal filtrate volumes were removed in another trial [149]. Finally, combining DUF and MUF offered no clinical advantage over DUF or MUF alone despite larger filtrate volumes in the combined group [150].

While these techniques are useful to hemoconcentrate and remove total body water immediately after bypass, they do not prevent the inflammatory response. And while it is perhaps modified, this response is nevertheless idiosyncratic; despite all the above maneuvers, some neonates and infants will still manifest significant clinical signs and delayed postoperative recovery. The development of drugs that will prevent the adhesion molecule– endothelial interaction, which is pivotal in the inflammatory response, continues to be pursued in both laboratory and clinical studies. To date, however, no one specific drug or treatment has proven beneficial. This highlights the multifactorial nature of the inflammatory response and that attenuation at multiple levels is important.

Special circumstances exist during management of CPB in patients with CHD that may not apply to adults undergoing correction of acquired heart disease. Venous cannulation in neonates and infants may be single or multiple, depending on the anatomy and bypass technique. Obstruction to venous return is more likely due to the small vessel size and will increase venous pressures, thereby decreasing perfusion pressure to the cerebral and splanchnic circulations. A fall in venous return to bypass circuit, abdominal distension and head suffusion all indicate problems with venous cannulation. Elevated SVC pressures will reduce cerebral blood flow, increase the risk of cerebral edema and reduce the rate of cerebral cooling. Systemic-to-pulmonary shunts and collateral vessels must be controlled when going onto bypass to prevent excessive pulmonary flow with resultant increased blood return to the heart, myocardial distension, systemic hypoperfusion and uneven cooling or rewarming. Most importantly, a high perfusion rate at the pump head does not ensure an equally high systemic flow unless all sources of potential aortopulmonary shunts (e.g. Blalock-Taussig), patent ductus arteriosus or native aortopulmonary collaterals are occluded. If these shunts are not occluded, other indices of the adequacy of the flow should be followed.

There are several bypass management strategies.

- Moderate hypothermia with normal or increased pump flow. Bicaval cannulation is generally used, and the risk of cerebral ischemia is reduced. However, CPB is prolonged and operative conditions may not be ideal. Pump flow rates are generally higher in neonates and infants, reflecting the increased metabolic rate. During bypass, there is no one measure of index that assures adequate perfusion. Generally flow rates of 100-150 mL/kg/min or indexed flows to 2.2-2.5 L/min/m<sup>2</sup> should provide adequate flow at normothermia. Pump perfusion in young patients is regulated primarily by flow rate, so that perfusion pressures of 30 mmHg or less are common in these patients when hemodilution has decreased SVR (low viscosity). A venous oxygen saturation of >75%, even differential temperature cooling, and low lactate levels suggest adequate perfusion [151]. However, these values may be misleading in patients with poor venous drainage, severe hemodilution, malposition of the aortic cannula or in the presence of a large left-to-right shunt. On-line continuous monitoring of blood gas and saturation of oxygen is important to identify trends in oxygen extraction. In addition, these only provide global indices of perfusion, and monitoring regional perfusion would be ideal. While cerebral perfusion can be monitored using transcranial sonography, near infrared spectroscopy and the electroencephalogram (EEG), to date there are no monitors available for routine clinical use to monitor perfusion of other vascular beds.
- Low-flow perfusion in conjuction with deep hypothermia(<18°C). Flow rates of 30–50 mL/kg/min</li>

are often referred to as "low flow" but the optimal flow rates during low-flow bypass are not firmly established.

- Deep hypothermic circulatory arrest (DHCA). This is a technique employed to improve exposure of intracardiac defects and to facilitate aortic arch reconstruction in infants and children. DHCA allows cessation of CPB, venous and arterial cannula removal, and exsanguination of the patient into the venous reservoir of the CPB circuit. There has been substantial refinement of the technique of DHCA since its successful inception in the 1970s. In the current era, DHCA is used selectively and for relatively short intervals (<60 min). It is utilized primarily for the aortic arch reconstruction component of the Norwood procedure, repair of interrupted aortic arch, neonatal repair of total anomalous pulmonary venous connection, and complicated intracardiac repairs in small (<2.5kg) neonates and infants [152]. Prolonged ischemia to the brain is a major disadvantage and is both time and temperature dependent. Interval durations <40 min are associated with a lower incidence of seizures and fewer neurobehavioral deficiencies than longer intervals [153–156].
- Regional low flow perfusion (RLFP) also known as antegrade cerebral perfusion (ACP). In an effort to prevent the potentially deleterious effects of DHCA on cerebral and somatic perfusion and oxygenation, technical innovations to avoid the use of DHCA for aortic arch reconstruction in children with hypoplastic left heart syndrome undergoing the Norwood procedure and in children with aortic hypoplasia or interruption undergoing biventricular repair have been developed.

A number of techniques to provide ACP via the right innominate artery have been described and are used in conjunction with deep hypothermia [157–160]. These techniques are felt to provide both cerebral and somatic (subdiaphragmatic viscera) perfusion. Somatic perfusion is felt to be the result of the extensive network of arterial collaterals in the neonate which link the supra- and subdiaphragmatic viscera such as the internal thoracic and intercostal arteries. The flow rates necessary to provide optimal cerebral and somatic perfusion during ACP have yet to be determined although rates of 30–70 mL/kg/min are common.

Because of the large body surface area to mass ratio in neonates and infants, a 2–3°C reduction in core temperature is common following induction of anesthesia and prior to bypass. The use of cooling/warming blankets, low ambient temperature and reduced overhead operating light intensity helps maintain a low temperature during bypass and minimizes radiant heating of the myocardium. Surface cooling is aided by placement of ice bags on and around the head and will assist with brain cooling.

Neurological injury is an inherent risk for any patient undergoing cardiac surgery and cardiopulmonary bypass. This has been particularly the case in neonates and infants where DHCA or low-flow techniques have been commonly used. While it is clear that brain maturity, congenital neurological abnormalities, and perinatal injury are important sources of long-term neurobehavioral deficiencies, efforts to improve modifiable sources of neuronal injury are essential [161]. Our current strategies to optimize cerebral protection during deep hypothermic bypass, with or without circulatory arrest, include a longer duration of cooling over 20min[162–164], the use of a pH-stat strategy of blood gas management during cooling (i.e. additional  $CO_2$  to the oxygenator) [165], a higher hematocrit (approximately 30%) [166], and DHCA intervals <40min [156].

### Weaning from cardiopulmonary bypass

During the rewarming phase, air is vented from the heart before blood is injected into the systemic circulation. Arterial blood gases, electrolytes, and levels of anticoagulation are checked periodically during bypass, but especially during rewarming. Electrolytes, especially ionized calcium, are normalized before separation from bypass is attempted. Adequacy of rewarming is judged by temperature recordings from multiple sites.

The need for vasopressor and inotropic support during weaning from bypass is determined by close observation of the heart during the rewarming phase. Rhythm problems, coronary perfusion problems, and the general state of myocardial contractility can be estimated by directly observing the heart during this period. Separation from bypass is accomplished in concert with the surgical team. Although monitoring of the appropriate intracardiac and intra-arterial pressures and waveforms may accurately indicate both left and right ventricular function, slavish adherence to the monitored values without visual confirmation of the adequacy of cardiac filling and performance can lead to many errors. The small size of the heart and the presence of unsuspected congenital defects sometimes make interpretation of pressures from monitoring lines difficult. When rewarming is complete and cardiac function is judged adequate, weaning from the extracorporeal circulation is accomplished by slowly allowing the heart to fill and eject while ventilation is re-established. Optimal ventricular filling pressures are estimated using filling pressures from preoperative catheterization data, the appearance of the heart, and infusion of small increments of volume while watching filling and systemic arterial pressures. The direct measurement of oxygen saturations from chambers of the heart enables calculations of a residual intracardiac shunt immediately following surgery, and direct pressure measurements across

systemic and pulmonary outflow tracts enable detection of residual significant obstruction. Transesophageal echocardiography has become an important diagnostic method to evaluate ventricular function, as well as assessing atrioventricular and semi-lunar valve competence, outflow obstruction and significant residual intracardiac shunting across the ventricular or atrial septums. If systemic arterial pressure or gas exchange is inadequate, CPB is reinstituted while the problem is analyzed and appropriate corrective measures are taken.

After discontinuing bypass, and despite full rewarming on bypass, mild hypothermia often develops in neonates and infants. Active measures to decrease radiant and evaporative losses are necessary because of the increased metabolic stress, pulmonary vasoreactivity, coagulopathy and potential for dysrhythmias associated with hypothermia. However, hyperthermia must also be actively avoided because of the associated increased metabolic rate and potential for ongoing neurological injury, particularly when myocardial function may be depressed and cerebral autoregulation impaired [167].

Hemostasis may be difficult to obtain if bypass has been prolonged and if there are extensive, high-pressure (often concealed) suture lines. Prompt management and meticulous control of surgical bleeding are essential to prevent the complications associated with a massive transfusion. Besides hemodilution of coagulation factors and platelets, complex surgery with long bypass times increases endothelial injury and exposure to the nonendothelialized surface of the pump circuit, thereby stimulating the intrinsic pathway, and platelet activation and aggregation. Preoperative factors including chronic cyanosis in older patients, and a low CO with tissue hypoperfusion and DIC, hepatic immaturity, and the use of platelet inhibitors such as PGE1 in neonates and infants also contribute to prolonged bleeding after bypass [168,169]. See Chapter 11 for more detailed discussion of the management of hemostasis and blood transfusion.

## Sternal closure and tamponade after cardiac operations

Chest closure is a time of particular instability after operations for CHD. The small infant's mediastinum makes compression of the heart and cardiac tamponade everpresent possibilities after chest closure, despite patent drainage tubes. The warning signs of tamponade are frequently not present in small children, even minutes before cardiovascular collapse from tamponade. Any significant deterioration in hemodynamics after chest closure should be first attributed to tamponade if ventilation and cardiac rhythm are adequate. Until the patient is safely transported to the intensive care unit and cardiovascular stability is ensured, continuous attention must be paid to the patient's hemodynamic status after chest closure.

## Anesthesia for non-cardiac surgery

The approach to anesthesia for children with CHD outlined above is the same whether the proposed operation is cardiac or non-cardiac. Because non-cardiac surgeons may have less appreciation of the delicate homeostatic balance of the child's cardiac pathophysiology, it is particularly important during non-cardiac surgery that the anesthesiologist understands the pathophysiology of the patient's problem(s). Furthermore, CPB is not immediately available for cardiovascular support if surgery and anesthesia overwhelm the patient's circulatory homeostasis. Because the anesthesiologist must understand and maintain the often fragile circulatory balance during surgery, surgical insults must be anticipated preoperatively and planned for. Familiarity with the child's pathophysiology and the planned non-cardiac procedure should avoid major problems in anesthetic management. Evaluation, preoperative preparation, choice of monitors, induction, maintenance, emergence from anesthesia, and plans for postoperative care are predicated on this familiarity.

An important aspect of the care of children with CHD who are undergoing non-cardiac surgery is a cardiology consultation to delineate the pathological lesion and provide objective assessment of the patient's current hemodynamic status. Most cardiologists have an incomplete appreciation of the physiological stresses that major non-cardiac surgical procedures impose on the cardiopulmonary system. When major blood loss is anticipated, when intrusion into the airway, peritoneal, thoracic or cranial cavity is necessary, or when a prolonged operative procedure is planned, a cardiology consult is often helpful *if* the cardiologist is informed about the anticipated perioperative stresses to homeostasis.

## Status of the disease

Children with CHD may present for non-cardiac operations before cardiac surgical treatment, after palliation, or after "repair" of their CHD. Palliated patients still have a distinctly abnormal circulation, and the consequences of CHD (e.g. CHF, hypoxemia, polycythemia, pulmonary vascular disease) may be a problem. It is important to note that even patients whose heart disease has been surgically "corrected" can have significant residual problems. Arrhythmias, ventricular dysfunction, shunts, valvular stenosis or regurgitation, and pulmonary hypertension may remain or develop after surgical "repair" of the CHD. Surgical "corrections" may be classified as Table 25.5 A classification for congenital cardiac surgical repairs

Type of repair	Outcome
Anatomic LV = systemic ventricle RV = pulmonary ventricle Circulation in series Cyanosis corrected	<ol> <li>Simple reconstruction: structurally normal after repair (e.g., ASD, VSD, PDA). Late complications unlikely</li> <li>Complex reconstruction: baffle, conduit, outflow reconstruction or AV valve repair; late complications likely</li> </ol>
<i>Physiologic</i> Circulation in series Cyanosis corrected	<ol> <li>Two ventricles: RV = systemic ventricle LV = systemic ventricle (e.g. Senning or Mustard procedure)         Single ventricle: Fontan procedure     </li> </ol>

RV, right ventricle; LV, left ventricle; ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; AV, atrioventricular valve.

"anatomical," whereby the circulation is in series and the left ventricle is connected to the aorta, or "physiological," where the circulation is also in series and the patient is no longer cyanosed. However, they may function with the RV as the systemic ventricle or have undergone a single ventricle repair (Table 25.5).

# Anesthesia for interventional procedures

## **Cardiac catheterization laboratory**

Adequate sedation and anesthesia during cardiac catheterization are essential to facilitate acquisition of meaningful hemodynamic data and to assist during interventional procedures. For the most part, hemodynamic or diagnostic catheterization procedures can be performed under sedation in all age groups. For many interventional procedures, sedation may be appropriate but for procedures that are associated with significant hemodynamic compromise, or are prolonged, general anesthesia is preferable. Whatever technique is used, it is essential that hemodynamic data be attained in conditions as close to normal as possible. When using sedation, full monitoring is essential to ensure that respiratory depression is avoided. During anesthesia, the effects of inspired oxygen concentration, mechanical ventilation and hemodynamic side-effects of various anesthesia agents must also be appreciated. Postprocedure monitoring in either a recovery room or intensive care unit is mandatory.

Cardiac catheterization laboratories are usually remote from the operating room, and rarely configured to accommodate anesthetic personnel. Relative to patient size, the lateral and anterior-posterior cameras used for imaging are in close proximity to the patient's head and neck, limiting access to the airway. An anesthetic machine and monitors around the patient will further confine the space in which the anesthesiologist may work and limit access to the patient. In addition, the environment is darkened to facilitate viewing of images, and monitoring with capnography and pulse oximetry is mandatory. The environment is also cooler because of computer and cine equipment, and children may become hypothermic from conductive and convective heat loss. In addition, frequent flushing of the catheters and sheaths to prevent clotting or air embolism may also contribute to hypothermia. Unnecessary exposure of the child must be avoided and convective warming blankets used where possible. Care must be taken when positioning a patient on the catheterization table because of the risk of pressure areas and nerve traction injury. In particular, brachial plexus injury may occur when patients have their arms positioned above their heads for a prolonged period of time to make room for the lateral cameras. To facilitate femoral vein and arterial access, the pelvis is commonly elevated from the catheterization table. This may displace abdominal contents cephalad, restricting diaphragm excursion and increasing the risk for respiratory depression in a sedated patient.

In addition to considerations related to the environment, there are a number of potential problems and complications that are inherent to any catheterization procedure, and some related to specific interventions (see below). The minimal monitoring available to all patients in the catheterization laboratory includes automated blood pressure, ECG, pulse oximetry, end-tidal carbon dioxide (PETCO<sub>2</sub>), and direct observation of the patient's airway and breathing.

### Interventional cardiology

Transcatheter treatment of CHD is replacing a number of conventional intraoperative surgical procedures. This experience has a significant impact on the severity and complexity of illness seen in the operating room and in the interventional laboratory. Procedures that are routinely performed in the catheterization laboratory now include balloon valvuloplasty of congenitally stenotic aortic, mitral, and pulmonary valves, angioplasty for pulmonary arterial stenoses and postoperative aortic recoarctation, or angioplasty combined with transcatheter placement of endovascular stents for sustained relief of obstruction in arterial or subarterial (intracardiac) locations, radiofrequency ablation of abnormal conduction pathways, and embolization or device occlusion procedures of systemic-to-pulmonary arterial communications, venous channels, fistulas, muscular VSDs, ASDs or patent ductus arteriosus (PDA). Many procedures (e.g. PDA closure) are performed on an outpatient basis with the full participation of the anesthesiologist [170].

Although many relatively uncomplicated procedures previously performed in the operating room are now performed in the catheterization laboratory, they have been replaced by surgical procedures for previously inoperable patients with more complex disease who have derived benefit from interventional catheterization techniques. These interventions have established an anatomical or physiological circumstance that lends itself to intraoperative repair. Among the best examples are patients with tetralogy of Fallot and pulmonary atresia with hypoplastic pulmonary arteries who are deemed inoperable after an early palliative shunt has failed to provide any meaningful growth of pulmonary arteries. By establishing antegrade flow to the pulmonary artery early in life with a surgically placed homograft from right ventricle to pulmonary artery, the child can undergo serial balloon dilations of the pulmonary arteries with subsequent growth that allows eventual surgical correction with VSD closure. Among patients with single ventricles who have undergone a modified Fontan procedure, high-risk candidates can be assisted during the postoperative period by leaving a communication at the atrial level that allows right-toleft shunting, and hence cardiac output, to be maintained during transient postoperative elevation in pulmonary vascular resistance. This fenestration can subsequently be test-occluded in the catheterization laboratory and permanently occluded with a device if indicated [171].

This collaborative approach to intervention and repair has offered improved results and new futures for patients with many types of serious congenital heart disease. Therefore, the cardiac anesthesiologist is faced with more complex, previously inoperable patients in the operating room, and with more demand for presence in the catheterization laboratory, where the environment is rapidly evolving into a hybrid operating room in need of the skills and balance of the anesthesiologist.

### **Risks and complications**

Placement of catheters in and through the heart increases the risk for dysrhythmias, perforation of the myocardium, damage to valve leaflets and cordae, cerebral vascular accidents and air embolism. The use of radiopaque contrast material may cause an acute allergic reaction (although this is rare in children with non-ionic contrast media), pulmonary hypertension and myocardial depression. Blood loss may be sudden and unexpected when large-bore catheters are used or vessels are ruptured. More insidious blood loss may occur over several hours in heparinized small children or neonates owing to

Figure 25.12 Algorithm for treating catheter-induced arrhythmias during cardiac catheterization.

bleeding around the catheter site or multiple aspirations and flushes of catheters. Transfusion requirements and appropriate vascular access should be continually assessed.

Arrhythmias, albeit transient, may be recurrent and fatal if not promptly treated. These include catheterinduced supraventricular tachyarrhythmias, ventricular tachycardia, ventricular fibrillation, and occasionally complete heart block requiring temporary transvenous pacing support. On most occasions, removal of the wire or catheter is sufficient for the arrhythmia to resolve, but when this does not happen, it is important that full resuscitation and cardioversion equipment be available. An algorithm for treating catheter-induced arrhythmias is shown in Figure 25.12.

Complications of various interventional procedures are related in part to the type of procedure, but all share the risks associated with percutaneous vascular access with large catheters that course through the heart and vessels. The specific problems that may occur during various interventional transcatheter procedures are listed in Table 25.6. While the underlying cardiac status or ASA classification of the patient may increase their risk for adverse events during catheterization, in many circumstances complications are sudden, occurring without warning, and reflect the inherent risk for that specific procedure. Many complications are potentially life threatening, and successful treatment of complications depends on prompt action by anesthesiologists co-operating closely with the interventional cardiologists who are manipulating the catheters.

Inadvertent release or detachment of embolic and closure devices results in systemic and pulmonary arterial embolization. Embolization usually occurs immediately after placement, and devices can often be retrieved by use of a variety of retrieval catheters, but in a small minority of cases surgical removal is required. If the device is lodged in the heart or a great vessel, CPB may be required for removal. Device embolization does not usually cause extreme hemodynamic instability or cardiovascular decompensation requiring emergency surgical removal, but an unscheduled surgical procedure is still required. Even after successful transcatheter retrieval, femoral artery and vein reconstruction during anesthesia is occasionally necessary when embolized devices or large dilation balloons are removed through these vessels. Deliberate embolization of aortopulmonary collaterals may decrease pulmonary blood flow excessively, causing severe hypoxemia; general anesthesia and muscle paralysis may be necessary to increase arterial oxygen saturation to acceptable levels by decreasing oxygen consumption while operating room preparations are made.

## Balloon dilation of pulmonary arteries

Pulmonary artery balloon dilation and stent placement to relieve stenosis is a common procedure performed in the catheterization laboratory, and complications that may occur during this procedure exemplify many of the potential problems that can occur during any catheterization. Pulmonary artery stenoses may be congenital or acquired lesions. They may be discrete, involving the main or branch pulmonary arteries, or multiple, involving distal

## Table 25.6 Complications in the cardiac catheterization laboratory

Procedure	Representative lesion	Complications
Diagnostic catheterization	Congenital heart disease	Blood loss requiring transfusion
		Air embolism
		Cerebral vascular accident
		Myocardial perforation and tamponade
		Femoral vessel occusion
		Arrhythmias; ventricular and supraventricular tachycardia, ventricular fibrillation, complete heart block
Coil embolization	Aortopulmonary collaterals	Fevers
	Blalock–Taussig shunts	Excessive hypoxemia
	Anomalous coronary arteries	Systemic embolization
	Hepatic hemangiomas	Hepatic necrosis
Transcatheter device closure	Patent ductus arteriosus	Air or device embolization
	Atrial septal defect	Blood loss
	Ventricular septal defect	Interference with atrioventricular value function, ventricular arrhythmias, complete heart block
	Baffle leak	
Balloon and stent dilations	Pulmonary artery stenosis	Pulmonary artery tear and bleeding
		Unilateral pulmonary edema
		False aneurysm
		Cardiac arrest (Williams syndrome)
	Blalock–Taussig shunt	Pulmonary artery tear and bleeding
		Thrombosis
		Pulmonary edema
	Pulmonary valve stenosis	Pulmonary insufficiency
	Aortic valve stenosis	Aortic regurgitation
		Ventricular fibrillation (neonate)
	Mitral valve stenosis	Mitral insufficiency
		Pulmonary hypertension
	Coarctation of the aorta	Aortic dissection
		Hypertension
	Right ventricular conduit	False aneurysms
		Stent embolization
Atrial septotomy	Transposition of the great arteries, mitral stenosis (atresia), and restrictive atrial septum	Perforation of the heart and tamponade
Radiofrequency mapping and ablation	Anomalous conduction pathways	Complete heart block
		Supraventricular tachycardia
		Thromboembolus from long sheath and prolonged procedure
Myocardial biopsy	Cardiomyopathy or transplantation	Myocardial perforation
		Complete heart block

segmental vessels. Some factors that determine whether dilation should be performed under sedation or general anesthesia include the extent of balloon dilation, anticipated complications, and the duration of the procedure.

Pulmonary artery disruption is signaled by hemoptysis of various degrees or the appearance of intravascular contrast medium in the pleural space or major lung fissures. In the presence of substantial hemoptysis, immediate endotracheal intubation is indicated for airway control and ventilation. Hypertension and further airway stimulation are avoided. Addition of PEEP may be useful. Heparinization is reversed and blood for transfusion is made immediately available. Intrapulmonary hemorrhage is often self-limited, but hemothorax can be severe and may lead to hypotension and death. Transient unilateral or unilobar pulmonary edema is also seen in the setting of pulmonary artery dilation. This is related to sudden large increases in pulmonary blood flow and distal pulmonary artery pressure after dilation in a previously underperfused pulmonary vascular bed. These two distinct entities, unilateral pulmonary edema and disruption of pulmonary artery integrity, can both occur abruptly, in isolation or together, during pulmonary artery dilation procedures, and both can cause the appearance in the airway of frank blood or blood-tinged edema fluid in substantial quantities. Treatment of both entities starts with endotracheal intubation unless symptoms are minimal.

The function of the right ventricle is critical. At the time of balloon dilation, cardiac output may decrease significantly, causing hypotension, bradycardia, arterial oxygen desaturation and a fall in end-tidal CO<sub>2</sub>. As the balloon is only inflated for a few seconds, and provided preload is maintained, the procedure is usually well tolerated and the circulation usually recovers spontaneously. Patients who have a hypertrophied, poorly compliant right ventricle with intraventricular pressures at systemic or suprasystemic levels may not tolerate the sudden increase in afterload associated with balloon dilation, even for a short period. In particular, myocardial ischemia and arrhythmias may occur, causing severe acute RV failure and loss of cardiac output. General anesthesia and controlled ventilation are recommended prior to the intervention in this at-risk group of patients.

Patients who have a dilated right ventricle secondary to a long-standing volume load, such as chronic pulmonary regurgitation, are also at risk for arrhythmias and low output during catheter manipulations and interventions. On most occasions the changes in rhythm are shortlived and settle once the catheters are withdrawn. Nevertheless, anesthesia and airway control are recommended if the circulation is compromised, and a defibrillator and transvenous pacing must be immediately available. Potential movement at the time of critical balloon dilation or stent placement must be avoided. The dilation of pulmonary arteries is painful and will often cause patients to waken from sedation and move. In addition, dilation of the pulmonary arteries may induce coughing. This is usually not a problem for isolated pulmonary artery dilation but if the patient moves during stent placement, it is possible that lobar or segmental branch pulmonary arteries can be inadvertently obstructed by the stent. Therefore, it is essential that the patient be immobile and additional sedation should be considered immediately prior to stent placement.

Balloon dilation of multiple peripheral pulmonary artery stenoses, such as seen in patients with Williams syndrome, is often a prolonged procedure and associated with significant hemodynamic changes; endotracheal general anesthesia is usually required from the outset. Besides right ventricular hypertension, an additional concern in this group of patients is the risk for pulmonary edema post dilation. This usually occurs immediately following balloon dilation, but can be delayed for up to 24h. Endotracheal intubation and controlled ventilation are usually necessary until the edema resolves.

## **Occlusion device insertion**

"Umbrella" or "clamshell" device closure of PDA, ASD and VSD is commonly performed in the catheterization laboratory. The placement of a PDA or ASD device is usually associated with minimal hemodynamic disturbance and can be performed in most patients using sedation techniques. General anesthesia may be necessary for airway protection if transesophageal echocardiography is used to guide device placement or if the procedure is prolonged and procedural complications such as device embolization occur.

In contrast to our experience with closure of PDAs or ASDs, transcatheter VSD device closures are prolonged procedures, and often associated with profound hemodynamic instability and blood loss [172]. Intensive care management is frequently required following placement. The indications for VSD device placement include closure of a residual or recurrent septal defect, preoperative closure of defects that may be difficult to reach surgically while on cardiopulmonary bypass and closure of acquired defects such as post myocardial infarction or trauma. While the clinical condition of patients undergoing VSD device placement may therefore vary considerably, the preoperative clinical condition or ASA status is not a predictor of hemodynamic disturbance during device placement. Rather, it is the technique necessary for deploying the occlusion device that results in significant hemodynamic compromise and all patients are therefore susceptible.

Factors contributing to hemodynamic instability include blood loss, arrhythmias from catheter manipulation in

the ventricles and across the septum, atrioventricular or aortic valve regurgitation from stenting open of valve leaflets by stiff-walled catheters, and device-related factors such as malposition of the umbrella with arms impinging on valve leaflets or dislodgment from the ventricular septum.

The procedures are often prolonged. Because of the large sheath required for the positioning of the delivery pod and folded umbrella device, and the need for frequent catheter changes through the sheath, considerable blood loss may occur (often concealed by drapes) and the risk for air embolism is also increased. In patients with intracardiac shunts, air embolization may be life threatening. When unoccupied by the device carrier system and collapsed device, the large delivery sheath represents a potential space for air accumulation and subsequent delivery into the heart. In addition, when the entry port of the large delivery sheath is open during removal and reinsertion of various catheters and devices, extreme inspiratory efforts may entrain intracardiac air. Air delivered into the right atrium may be shunted across the ASD even in the presence of nominal left-to-right shunting. Left atrial air embolization during these procedures can be seen with fluoroscopy; it produces ST segment elevation and often hemodynamic changes as it passes into the aorta. The resultant ST segment changes, hypotension, arterial desaturation, and bradycardia generally respond to aspirating and then sealing the entry port, along with administration of atropine, and inotropic and pressor support to maintain coronary perfusion. Meticulous purging of air from the catheter system and sealing of open ports should help to minimize the incidence of air embolism. Use of controlled positive pressure ventilation through an endotracheal tube in an anesthetized, paralyzed patient may also decrease the potential for transcatheter air entrainment during transcatheter closure of intracardiac defects.

### Transcatheter radiofrequency ablation

Pediatric patients undergoing radiofrequency ablation vary in age and diagnosis [173]. Ablation may be necessary in the newborn with persistent re-entrant tachycardia or ectopic atrial tachycardia and cardiac failure, as well as in older children with an ectopic focus and otherwise structurally normal heart. An increasing population of patients undergoing ablation are those who have undergone previous surgical repair of congenital heart defects. Patients with persistent volume or pressure load on the right atrium, and those who have required an extensive incision and suture lines within the right atrium, such as following a Mustard, Senning or Fontan procedure, may be at increased risk for supraventricular tachyarrhythmia (SVT) such as atrial flutter and fibrillation. Ventricular tachyarrhythmias may also develop late following repair of certain congenital heart defects, such as RV outflow tract reconstruction for tetralogy of Fallot.

Radiofrequency catheter ablations (RFCA) are usually prolonged procedures. It is difficult for children to lie still for some hours, and therefore endotracheal general anesthesia is preferred. In addition, it is important that patients remain immobile to avoid catheter movement at the time of ablation because sudden patient movement may result in a radiofrequency lesion being created at an incorrect site. For instance, if the focus is close to the AV node, inadvertent movement might displace the catheter and cause permanent AV conduction blockade. On occasion, holding the ventilation either in inspiration or expiration may be necessary to ensure adequate contact of the ablation catheter with the arrhythmic focus.

Although these procedures are prolonged, for the most part they are hemodynamically well tolerated and blood loss is minimal. During mapping, the focus is stimulated and the tachyarrhythmia induced. This may result in hypotension, but this is usually short-lived and can be readily converted via intracardiac pacing. If hypotension is prolonged and intracardiac conversion unsuccessful, transthoracic cardioversion may be necessary and a defibrillator should be immediately available.

Because anesthetic drugs have minimal effects on intrinsic conduction [88,174–177], a range of techniques can be used to maintain general anesthesia during RFCA. However, some tachyarrhythmias, such as ectopic atrial tachycardia, are catecholamine sensitive, and the focus may be difficult to localize after induction of anesthesia. For this reason, it is preferable in these patients to perform the procedure under light sedation or light general anesthesia if necessary.

## **Cardiac tamponade**

Acute myocardial perforation with tamponade occasionally occurs during interventional cardiac catheterization procedures. Prompt support of the circulation with volume infusions and pressor support, along with immediate catheter drainage of the pericardial space, are essential in the event of this complication. Hemopericardium after ventricular puncture is usually self-limited, as the muscular ventricle seals the perforation after the responsible wire or catheter is removed. However, laceration of the more thin-walled atrium may require suture repair under direct vision in the operating room.

Other causes of cardiac tamponade are seen in patients with CHD and treatment frequently requires the assistance of an anesthesiologist. Postoperative tamponade from bleeding immediately after operation, as discussed above, is best handled by facilitation of chest tube drainage or reopening the sternotomy. These patients are usually still anesthetized and mechanically ventilated so that new anesthetic considerations and choices are limited. However, some children develop pericardial effusions at other phases of their illness owing to hydrostatic influences (e.g. patients with modified Fontan operations) or postpericardiotomy syndrome. Fluid in the pericardial space may accumulate under considerable pressure and filling of the heart is impaired. If this problem is left unattended, the transmural pressure in the atria diminishes as the intra-atrial pressures rise and diastolic collapse of the atria can be observed echocardiographically. The patients become symptomatic with a narrow pulse pressure, pulsus paradoxus, tachycardia, respiratory distress, abdominal pain progressing to decreased urine output, hyperkalemia, metabolic acidosis, and hypotension with tremendous endogenous catecholamine response.

When hemodynamics are compromised, draining the fluid is imperative. A percutaneous approach to drainage is preferred when the fluid is accessible through a subxyphoid approach. This may be a formidable task in a frightened, combative child with impending shock. Anesthetic principles guiding sedation for pericardial drainage should focus on maintaining or improving intravascular volume, vascular tone, and the contractile state of the ventricle. Anesthetic agents used for sedation that excessively decrease preload or afterload and transiently impair myocardial function may have disastrous consequences, especially when they are combined with muscle paralysis and positive pressure ventilation, which further impairs ventricular filling. If a child demonstrates serious tamponade symptoms and a large circumferential, percutaneously accessible pericardial effusion is identified echocardiographically, drainage under sedation using a opioid, benzodiazepine or ketamine with local anesthesia is safer than an open surgical procedure with a rapid-sequence induction and positive pressure ventilation.

## Pathophysiology and anesthetic management of specific lesions and procedures

A unique feature of managing patients with congenital heart defects is the knowledge, expertise, and technical skills required to manage a heterogeneous population of patients with a wide variety of diagnoses and pathophysiology. The experience at Children's Hospital, Boston, over the past 5 years is shown in Figure 25.13. In addition, there has been a change in management philosophy over the past 20 years towards performing reparative operations on neonates and infants rather than initial palliation and later repair. With the emphasis on early surgical repair, the aim is to promote normal growth and development, and limit the pathophysiological consequences of congenital cardiac defects such as volume overload, pressure overload, and chronic hypoxemia. It is important to note, however, that older children and adults with congenital heart disease are an increasing group of patients

Figure 25.13 Spectrum of congenital cardiac surgical procedures performed at Children's Hospital, Boston, in a typical year. AICD, automated implantable cardioverterdefibrillator; ASD, atrial septal defect: CAVC, complete atrioventricular canal; PDA patent ductus arteriosus; PPM, permanent pacemaker; RVOT, right ventricular outflow tract; VSD, ventricular septal defect. presenting for cardiac and non-cardiac surgery. This includes patients undergoing a reparative operation, often some years following an initial palliative procedure, and patients who have had previous reparative surgery but subsequently require reintervention because of residual or progressive defects, such as conduit stenosis.

Virtually all congenital cardiac defects are now amenable to either an anatomical or functional repair, but while "corrected," they may not be "cured." However, palliative procedures are often necessary to control pulmonary blood flow prior to repair because of extreme lesion size, anatomical variations or need for maturation before repair. For example, a modified Fontan procedure is the definitive operation for many classes of complex CHD. However, the Fontan procedure requires low PVR and large pulmonary arteries, which are not characteristic of the neonate. Therefore, a shunt may be required to relieve hypoxemia and allow growth of the pulmonary arteries until the child is a few months older. Alternatively, if the pulmonary blood flow is excessive, a pulmonary band is required to minimize the possibility of CHF and to prevent any pulmonary vascular obstructive disease from developing until a Fontan repair can be done. Nevertheless, palliative procedures have immediate complications and may seriously compromise subsequent complete surgical repair of the lesion.

This section summarizes the basic pathophysiology of each lesion or procedure as a prelude to discussion of anesthetic management of the lesion. The discussion of anesthetic management before the repair applies equally well to non-cardiac procedures in unrepaired patients and to patients undergoing repair of the CHD but before CPD support is initiated. For some lesions, a separate discussion considers the anesthetic complications that occur after repair. This heading, where appropriate, outlines specific complications and problems that may be encountered months or years after repair of the anomaly. Otherwise, this information is found at the end of the section on anesthetic management.

### Surgical shunts: pathophysiology

When the anatomy or physiology includes severe obstruction of pulmonary blood flow and is unsuitable for immediate physiological repair, a shunt is required. This situation is seen most commonly in patients who have tricuspid atresia with restricted pulmonary blood flow, pulmonary atresia, or a single ventricle and severe obstruction to pulmonary blood flow. The surgically created shunt provides sufficient pulmonary blood flow to maintain acceptable arterial oxygen saturation in a circumstance where oxygenated pulmonary venous blood mixes with systemic venous blood. Optimally, the surgical shunt (a simple shunt) provides restrictive flow to the pulmonary circuit, allowing adequate, but not excessive, pulmonary blood flow.

## **Types of surgical shunts** Aortopulmonary artery shunts

Systemic-to-pulmonary artery shunts are palliative procedures that increase pulmonary blood flow, thereby relieving severe cyanosis, improving functional status and allowing for diffuse growth of small pulmonary arteries. The classic Blalock-Taussig (B-T) shunt redirects subclavian artery blood into the branch pulmonary artery on the side opposite the aortic arch [178]. This graft allows some growth during infancy but is unlikely to induce pulmonary vascular disease. Rather than compromise the subclavian artery and upper limb blood flow, a modified B−T shunt is now preferred using a Gore-tex<sup>TM</sup> synthetic tube graft interposed between the subclavian or innominate artery and the pulmonary artery. Performed either via a thoracotomy or median sternotomy, flow across the shunt is dependent upon the size of the Gore-tex tube (usually 3.5 or 4.0 mm diameter), the length of the tube, and site of take-off from the systemic artery. A shunt arising from the innominate artery is likely to have a higher flow because of a higher perfusion pressure than a more distally placed shunt arising from the subclavian artery. The B-T shunt is associated with low mortality and a low incidence of late postoperative complications. However, distortion of the pulmonary arteries may occur within a few months and seriously affect definitive repair.

The *Potts shunt* (descending aorta to left pulmonary artery) and the *Waterston shunt* (ascending aorta to the right pulmonary artery) are rarely used now because the size of the shunt orifice is difficult to control precisely, they may enlarge substantially with growth, becoming non-restrictive and resulting in excessive pulmonary flow and pulmonary vascular obstructive disease. They produce distortion and stenosis of the branch pulmonary arteries, and also are difficult to dissect and control prior to CPB during subsequent surgery. A *central shunt* between the ascending aorta and main pulmonary artery is occasionally used when branch pulmonary arteries are hypoplastic.

## Cavopulmonary artery shunt

The first cavopulmonary artery anastomosis (*Glenn shunt*) was a unidirectional shunt constructed as a palliative procedure for tricuspid atresia. A Glenn shunt provides systemic *venous* blood, instead of systemic arterial blood, to the lungs for gas exchange. The superior vena cava is disconnected from the right atrium and connected directly to the detached right pulmonary artery, i.e. superior vena cava blood perfuses the right lung and flow depends on the pressure gradient between the superior vena cava and left atrial pressures [179]. Therefore, the Glenn shunt is

limited to patients with low PVR, which precludes its use in neonates. This shunt is rarely performed today as the pulmonary arteries are not in continuity, and palliation is short-lived because of complications such as thrombosis or occlusion leading to SVC syndrome, and progressive cyanosis secondary to the development of pulmonary arteriovenous collaterals.

An important modification of the Glenn shunt that is now used during staged repair of single-ventricle defects involves the anastomosis of the cephalad portion of the superior vena cava to the right pulmonary artery, as in the original Glenn procedure, except pulmonary artery continuity is maintained and flow is therefore bidirectional through both right and left pulmonary arteries (hence the term bidirectional cavopulmonary anastomosis or bidirectional Glenn (BDG) procedure) [180-182]. It can be performed successfully in children as young as 3-4 months of age, after the PVR has decreased, and has the benefit that effective pulmonary blood flow is increased but with reduced pulmonary artery pressure [183,184]. It avoids imposing the volume load on the ventricle associated with aortopulmonary shunts and minimizes atrial distension and high right atrial pressures inherent in a full Fontantype operation in a high-risk patient (see below) [185].

## Anesthetic management before and during aortopulmonary shunts

Complications of surgical shunts can occur immediately after surgery or years later when another surgical intervention is contemplated. Severe hypoxemia may occur in the operating room during or after creation of the shunt, implying inadequate pulmonary blood flow. Intrapulmonary shunting must always be considered in lungs that are compressed by the surgeons, but mechanical obstruction of flow into the pulmonary artery caused by retraction during surgery or by shunt occlusion (kinking or thrombosis) is the usual cause. An increase in PVR may also reduce flow across the shunt, and inducing an alkalosis by hyperventilation and using a high inspired oxygen concentration may minimize PVR and optimize gas exchange until shunt flow can be improved. As a note of caution, however, an increase in mean intrathoracic pressure and overinflation of the lungs during vigorous mechanical ventilation may further restrict flow across the shunt.

Systemic-to-pulmonary artery shunts are inherently inefficient because they recirculate blood to the lungs without its having reached the systemic circulation. To substantially improve arterial oxygen content, pulmonary blood flow must be several times greater than the systemic flow (Fig. 25.14). However, if the surgically created shunt is not sufficiently restrictive, pulmonary flows become excessive and cause pulmonary edema, wide pulse pressures and, occasionally, inadequate sys-

**Figure 25.14** Changes in systemic arterial  $O_2$  saturation with mixing lesions as the Qp/Qs (pulmonary/systemic blood flow ratio) changes with different levels of mixed venous (mv)  $O_2$  saturation. It presumes a pulmonary (pv)  $O_2$  saturation of 100%. Reproduced from Rudolph AM. Congenital Diseases of the Heart. Chicago: Year Book Medical Publishers, 1974, p.79.

temic perfusion. Arterial oxygen saturation is relatively high despite complete mixing of systemic and pulmonary venous blood in the left heart. Maneuvers to increase pulmonary vascular resistance (see above) can compensate to a limited degree for excessive pulmonary flow, but shunt revision may be necessary.

## Anesthetic considerations after creation of an aortopulmonary shunt

In patients with systemic-to-pulmonary artery shunts, shunt flow is usually restricted by the shunt orifice and the balance between pulmonary and systemic vascular resistance. If the shunt is too large, excessive pulmonary blood flow will be evident by high arterial oxygen saturations, reduced systemic perfusion with increasing metabolic acidosis, low diastolic blood pressure and pulmonary edema. The work of breathing is increased and patients may have difficulty weaning from ventilation. If any shunt is large enough to allow excessive pressure and flow in the pulmonary vascular bed, pulmonary vascular obstructive disease may develop over time.

If the shunt is too small, arterial oxygen saturations will remain low, and pulmonary flow will be dependent on normal or increased systemic arterial pressures. Thus, hypotension seriously compromises arterial oxygenation, particularly as the shunt becomes more restrictive and must be treated aggressively. Other causes of a low oxygen saturation after shunt placement include a low mixed venous oxygen level secondary to a low cardiac output, and reduced oxygen-carrying capacity from relative anemia.

An appropriately sized shunt results in a balanced circulation (Qp/Qs approximately 1:1) with peripheral

saturations between 75% and 85% and a normal systolic pressure but a widened pulse pressure. Tachycardia is common initially once the shunt is open, and blood volume replacement is usually necessary. Inotrope support with dopamine may also be necessary as the increased pulmonary blood flow imposes a volume load on the systemic ventricle. The hematocrit should be maintained between 40% and 45%. Afterload reduction with a systemic vasodilator, such as sodium nitroprusside or a phosphodiesterase inhibitor, may be indicated if the patient has poor extremity perfusion, and to improve systemic perfusion if there is a relatively large shunt and excessive pulmonary blood flow. In general, most patients are mechanically ventilated postoperatively until flow is well balanced and adequate systemic perfusion maintained.

## **Pulmonary artery banding** Pathophysiology

When pulmonary blood flow is excessive and high pressure is communicated from the ventricle to the pulmonary vasculature, surgery may be required to prevent progressive pulmonary vascular obstructive disease or to lessen symptoms of CHF. If total correction of the lesion is not possible, pulmonary blood flow can be reduced by banding the pulmonary artery.

### Anesthetic management

With induction of anesthesia for banding of the pulmonary artery, pulmonary vascular resistance occasionally decreases enough to cause massive pulmonary flow and systemic hypotension ("pulmonary steal"). If so, partial occlusion of a branch pulmonary artery with a clamp or ligature reduces pulmonary blood flow and increases peripheral perfusion until the band is applied.

Banding of the pulmonary artery is imprecise, and the hemodynamics after banding are unpredictable. Adequacy of the band is assessed in the operating room by observing a 20-30% increase in systemic blood pressure and a decrease in systemic arterial oxygen saturation. Direct measurement of the pulmonary artery pressure beyond the band may be compared with the systemic arterial pressure. It should be about 50% of the systemic pressure or less. Continuous monitoring of oxygen saturation is helpful for quick assessment of the adequacy of pulmonary blood flow. Saturation by pulse oximeter should be about 80% in common mixing lesions [186]. As hemodynamic criteria are used to assess band tightness, anesthesia is best maintained with high-dose opioids and high concentrations of inhalation agents avoided. If the band is too tight, bradycardia, hypotension and cyanosis will develop, requiring urgent band removal.

The large resistance imposed by banding the pulmonary artery stimulates hypertrophy of the ventricle supplying the banded vessel. Consequently, depression of function of that ventricle quickly reduces pulmonary blood flow, particularly if a VSD or ASD is present, allowing shunting of blood into the systemic circulation. Longterm anatomical hazards of pulmonary artery bands relate to distortion of the anatomy and hypertrophy of the ventricle.

# Single ventricle and parallel circulation physiology

## Pathophysiology

In patients with a repaired two-ventricle heart, i.e. an "inseries" circulation whereby a separate ventricle ejects blood into the pulmonary artery and the pulmonary venous blood returns to a separate systemic ventricle, systemic oxygenation exclusively represents the efficiency of gas exchange in the lungs; lowering PVR and decreasing right ventricular afterload are important objectives when trying to increase pulmonary blood flow and correct hypoxemia in this situation. However, patients with single-ventricle anatomy represent a unique circumstance that requires physiological interpretation of oxygenation and hemodynamics in light of the "parallel" nature of the circulation. In this circumstance, a single ventricle supplies both pulmonary and systemic blood flow, and lowering pulmonary vascular resistance in these patients may improve oxygenation but adversely affect hemodynamics in some circumstances.

There are many anatomical variations of singleventricle or univentricular hearts. In general, both AV valves enter a single chamber. Most commonly, a small outflow chamber gives rise to one great artery, usually the aorta. Either AV valve may be atretic; subpulmonary stenosis or atresia is common. Occasionally subaortic stenosis is present at birth or develops subsequently. Therefore, in an infant with a single ventricle the anatomical variations may vary considerably, ranging from tricuspid atresia (a single left ventricle) through double-inlet left ventricle (two AV valves and one single ventricle) to mitral atresia (a single right ventricle, i.e. hypoplastic left heart). Despite the anatomical diagnosis, virtually all patients with effective single-ventricle hearts, as shown in Box 25.4, are amenable to a "physiological" repair, i.e. Fontan procedure.

It is important to note, however, that an effective "parallel" circulation or physiology can exist in patients with two ventricles (see Box 25.4). In these circumstances, the balance between pulmonary and systemic vascular resistance is the critical determinant of systemic perfusion and, therefore, a "balanced" circulation (Qp/Qs = 1). Much of the discussion below regarding maneuvers used to **Box 25.4** Anatomical diagnoses and surgical procedures that demonstrate parallel or balanced circulation physiology

## Defects amenable to a single ventricle repair (i.e., common mixing lesions)

- Atrioventricular valve atresia
  - Tricuspid atresia
  - Mitral atresia
- Ventricular hypoplasia
  - Hypoplastic left heart syndrome
- Double inlet left or right ventricle
- Unbalanced atrioventricular canal
- Outflow tract obstruction
- Aortic atresia
  - Shone's complex
- Pulmonary atresia and small right ventricle

#### Defects amenable to a two-ventricle repair

- Common ventricular outflow tract
- Truncus arteriosus
- PDA-dependent pulmonary blood flow
- Tetralogy of Fallot and pulmonary atresia
- PDA-dependent systemic blood flow

   Interrupted aortic arch

#### Postoperative single-ventricle palliation

- Norwood procedure for HLHS
- Modified Blalock-Taussig shunt

HLHS, hypoplastic left heart syndrome.

increase or decrease pulmonary blood flow applies in these patients as well prior to surgery. Examples include patients who have a large PDA (left-to-right shunt across the PDA from the aorta to pulmonary artery), common ventricular outflow tract (as in truncus arteriosus), or aortic arch interruption (right-to-left flow from the pulmonary artery to the distal aorta across the PDA to maintain systemic perfusion).

For patients with single ventricle anatomy, there is a common physiological principle, i.e. desaturated systemic venous blood returns to the heart and mixes completely with oxygenated blood returning to the same chamber from the lungs. Common mixing of systemic and pulmonary venous blood means that the aortic  $O_2$  saturation reflects the Qp/Qs. In the absence of lung disease (pulmonary venous desaturation), the pulmonary venous blood with oxygen saturations of 95–100% will drain to the ventricle and mix with systemic venous blood having saturations of 55–60% or less, depending on the amount of oxygen extraction in the periphery. If pulmonary and systemic blood flows are equal (i.e. Qp/

Qs = 1) then the resultant "mixed"  $O_2$  saturation that emerges from the ventricle and is measured in the systemic artery is 75-80%. As the pulmonary blood flow rises in proportion to systemic blood flow, so, too, rises the arterial oxygenation. Consequently, an arterial oxygen saturation of 90% is achieved at the expense of excessive pulmonary blood flow (Qp/Qs >3) and a substantial volume load to the single ventricle, which is required to supply all systemic and pulmonary (three times systemic) blood flow. CHF therefore ensues. If both the pulmonary artery and aorta are anatomically related to the ventricle and unobstructed, then flow to the pulmonary and systemic beds will be partitioned according to the relative resistances of each circuit (i.e. parallel circulations). As the pulmonary vascular resistance falls below SVR during the first few hours of life, pulmonary blood flow increases relative to systemic flow and systemic arterial oxygen saturation rises above 80%. Therefore, systemic oxygen saturation is a convenient marker of Qp/Qs. The effects of alterations of Qp/Qs on systemic arterial oxygen saturation for common mixing lesions are shown in Figure 25.14.

### Increased Qp/Qs

The deleterious effects of overcirculated lungs perfused at high pressure and flows, combined with the adverse effects of this volume load, particularly on the neonatal heart which is less capable of increasing stroke volume in response to increasing preload than the mature myocardium, will culminate in a picture of hyperdynamic CHF in which systemic perfusion is compromised and oxygen delivery is impaired despite the elevated arterial oxygen saturation (Fig. 25.15). The myocardium ultimately cannot provide adequate systemic flow as PVR falls and more and more of the stroke volume is inefficiently recirculated to the lungs. Treatment is therefore directed toward raising resistance to blood flow to the lungs, balancing pulmonary and systemic blood flow ratios, and maintaining adequate systemic blood flow (Table 25.7).

Pulmonary vascular resistance can be increased with controlled mechanical hypoventilation to induce a respiratory acidosis, and with a low FIO<sub>2</sub> to induce alveolar hypoxia. Ventilation in room air may suffice, but occasionally a hypoxic gas mixture is necessary. This is achieved by the addition of nitrogen to the inspired gas mixture, reducing the FIO<sub>2</sub> to 0.17–0.19. While these maneuvers are often successful in increasing PVR and reducing pulmonary blood flow, it is important to remember that these patients have limited oxygen reserve and may desaturate suddenly and precipitously. Controlled hypoventilation in effect reduces the functional residual capacity of the lung and therefore oxygen reserve, which is also compromised by the use of a hypoxic inspired gas mixture. Inotropic support is often necessary because of

**Figure 25.15** Effect of changes in PVR potentially contributing to circulatory collapse in patients with single-ventricle physiology. Qp, pulmonary blood flow; Qs, systemic blood flow; SaO<sub>2</sub>, arterial oxygen saturation; PBF, pulmonary blood flow; PVR, pulmonary vascular resistance.

ventricular dysfunction secondary to the increased volume load. Systemic afterload reduction with agents such as phosphodiesterase inhibitors may improve systemic perfusion, although they may also decrease PVR and thus not correct the imbalance of pulmonary and systemic flow. Patients who have continued pulmonary overcirculation with high SaO<sub>2</sub> and reduced systemic perfusion despite the above maneuvers require early surgical intervention to control pulmonary blood flow. At the time of surgery, a snare may be placed around either branch pulmonary artery to effectively limit pulmonary blood flow. Monitoring the SVC O<sub>2</sub> saturation, as a measure of mixed-venous O<sub>2</sub> saturation and therefore cardiac output, is often useful in patients with single-ventricle physiology. For instance, a patient with too much pulmonary blood flow may have an arterial O<sub>2</sub> saturation that is high (i.e. >85%), but a low SVC O<sub>2</sub> saturation (i.e. <50%) if systemic perfusion and cardiac output are reduced. Monitoring changes in the SVC O<sub>2</sub> saturation during treatment is a useful guide to the adequacy of management. In contrast, a patient who is hypoxic with a low arterial O<sub>2</sub> saturation (i.e. <75%) but has a normal arterial-SVC O<sub>2</sub> saturation difference of 25–30% can be assumed to have an adequate cardiac output and other causes for hypoxemia need to be evaluated.

### **Decreased Qp/Qs**

Decreased pulmonary blood flow, i.e. Qp/Qs <1, in patients with a single ventricle and parallel circulation is reflected by hypoxemia with an SaO<sub>2</sub> <80%. Preoperatively this may be due to restricted flow across a small ductus arteriosus, increased PVR secondary to parenchymal lung disease, or increased pulmonary venous pressure secondary to obstructed pulmonary venous drainage or a restrictive atrial septal defect. Initial resuscitation involves maintaining patency of the ductus arteriosus with a PGE1 infusion at a rate of 0.025-0.05 µg/kg/min. Most patients require tracheal intubation and mechanical ventilation either because of apnea secondary to PGE1 or for manipulation of gas exchange to assist balancing pulmonary and systemic flow. Systemic blood pressure, and therefore perfusion pressure across the ductus arteriosus, is maintained with the use of volume and vasopressor agents. Sedation, paralysis, and manipulation of mechanical ventilation to maintain an alkalosis may be effective if PVR is elevated. Nitric oxide as a specific pulmonary vasodilator may also be of use in this situation. Systemic oxygen delivery is maintained by improving cardiac output and red blood cell transfusions are performed to maintain a hematocrit >40%. Interventional cardiac catheterization with balloon septostomy or dilation of a restrictive atrial septal defect may be necessary; however, early surgical intervention and palliation with a systemic-to-pulmonary artery shunt are usually indicated.

### Anesthesia considerations

A thorough preoperative assessment is essential to assess the balance of pulmonary and systemic flow, presence of cardiac failure, and possible end-organ injury from reduced systemic perfusion. A spontaneously breathing patient who is well balanced prior to surgery may readily become unbalanced after induction of anesthesia and when mechanically ventilated. The arterial oxygen saturation usually rises once the patient is anesthetized and paralyzed, due to a rise in mixed-venous oxygen saturation from reduced peripheral O<sub>2</sub> extraction, and improved cardiac output secondary to reduced myocardial work and afterload on the ventricle. However, PVR may fall as well, leading to an increase in pulmonary blood flow at the expense of systemic perfusion. Hypotension and a fall in diastolic blood pressure may be evident. In this circumstance, it is important to maintain a low inspired O<sub>2</sub> concentration and ventilate with a low rate and tidal volume to maintain a mild respiratory acidosis. Close monitoring of the arterial blood gas is important, with the ideal being a pH 7.40, PaO<sub>2</sub> 40mmHg and PaCO<sub>2</sub> 40mmHg. If noninvasively monitored, an SaO<sub>2</sub> of 75-85% and end-tidal  $CO_2$  of 40–45 mmHg are usually appropriate.

It is very important that patients be deeply anesthetized to minimize hemodynamic changes, in particular

Table 25.7 Parallel circula	ion physiology:	management	considerations
-----------------------------	-----------------	------------	----------------

Clinical circumstance	Etiology	Management
Balanced flow SaO <sub>2</sub> 80–85% and normotensive	Qp = Qs ~ 1.0	No intervention

	<b>Clinical signs</b> Poor peripheral perfusion Oliguria/anuria Narrow pulse pressure	Minimize stress response Surgical revision Aortic arch and coronary anastomosis; transplantation Mechanical support of the circulation
	<b>Laboratory</b> Metabolic acidosis Low SvO <sub>2</sub> saturation Increased (SaO <sub>2</sub> –SvO <sub>2</sub> ) difference	

Qp , pulmonary blood flow; Qs , systemic blood flow; SaO<sub>2</sub>, arterial oxygen saturation; SvO<sub>2</sub>, SVC oxygen saturation; PVR, pulmonary vascular resistance; FiO<sub>2</sub>, inspired oxygen concentration; PDA, patent ductus arteriosus; B-T, Blalock-Taussig; SVC, superior vena cava.

tachycardia, in response to surgical stimulation. If the patient is overcirculated (i.e. Qp > Qs) and has a low diastolic blood pressure, coronary perfusion may not increase sufficiently to meet the increased demand of myocardial work in response to surgical stress. Myocardial ischemia may therefore occur, usually manifest as ST segment changes on the ECG or sudden onset of dysrhythmias, in particular ventricular fibrillation.

## Staged single ventricle repair/Fontan procedure

The "reparative" operation for infants with single ventricles is a modified Fontan procedure. Glenn [179] demonstrated in patients with tricuspid atresia that SVC blood could be directed into the lungs without passing through the heart, and Fontan and associates extended this concept to include blood returning from the inferior vena cava [187,188]. Since the original description, the Fontan procedure and subsequent modifications have been successfully used to treat a wide range of simple and complex single-ventricle congenital heart defects [189]. The repair is "physiological" in that the systemic and pulmonary circulations are separated, or in "series," after directing the systemic venous return directly to the pulmonary artery and patients are no longer cyanosed. However, based on longer-term outcome data, significant problems and complications may develop over time and the repair should perhaps be viewed as palliative rather than curative.

The Fontan procedure has undergone numerous modifications since the first description [189]. The original procedure was described by Fontan in a patient with tricuspid atresia, and involved disconnecting the pulmonary arteries from each other, creating a classic Glenn shunt, connecting the right atrium directly to the left pulmonary artery (PA) using a valved conduit and placing a valve at the IVC-RA junction [187]. It was believed the RA would function as a pumping chamber; however, following the development of echocardiography, it was apparent that the RA functioned primarily as a conduit with little pumping action contributing to pulmonary blood flow, and in the low-pressure venous system, the valves remained opened. Further, this procedure was complicated in the long term by a high risk of pleuro-pericardial effusions and atrial dysrhythmias secondary to the effects of RA hypertension and distension.

An early modification involved the direct anastomosis of the RA appendage to the PA, closing the ASD and patching over the tricuspid valve, if patent [190]. This procedure, however, continued to have a high risk of complications related to RA hypertension.

Over the past 15 years, the total cavopulmonary anastomoses have become the modified Fontan procedure of preference. The SVC is anastomosed directly to the PA and a lateral tunnel created in the RA, baffling IVC flow to the SVC [191]. This was associated with an improvement in mortality, although morbidity related to baffle hypertension persisted [192–194].

A significant advance was the creation of a fenestration or small hole in the intracardiac baffle, thereby creating an opportunity for a right-to-left atrial shunt. This fenestration is generally "fixed" in size at the time of surgery using a small 4 mm punch [171]. In the event of an increase in RA or PA pressure with reduced flow across the pulmonary vascular bed, and therefore less preload to the systemic ventricle, patients are able to shunt right to left across the fenestration. While patients develop increased cyanosis, cardiac output is maintained. This proved to be very successful and has enabled patients at relatively high risk to undergo a successful modified Fontan procedure [192,195]. While the early mortality has declined further since the introduction of fenestration techniques, the most significant improvement has been in patient morbidity. The incidence of early pleuro-pericardial effusions, ascites (Fig. 25.16) and atrial dysrhythmias has been significantly reduced. The fenestration can be test balloon occluded and easily closed in the cardiac catheterization laboratory with a clamshell device later in the postoperative period.

More recently, the use of an external conduit baffling the IVC to the pulmonary circulation has been reported [196]. A fenestration can be created between the external conduit and RA, if necessary. The major advantage in the immediate postoperative period is that the procedure can be completed on CPB without needing to arrest the heart. In the long term, the risk of atrial dysrhythmias may be reduced because of a lower RA pressure, absence of extensive atrial suture lines and anastomoses that are away from the sinoatrial node arterial supply.

**Figure 25.16** Incidence of pleural effusions and failure (i.e. take-down or mortality) during the early surgical evolution of the modified Fontan procedure at Children's Hospital, Boston. Modified from Castaneda AR. From Glenn to Fontan: a continuing evolution. Circulation 1992; 86: 1180 with permission from Lippincott, Williams & Wilkins.

### Selection crtieria

Fontan and others originally listed a number of selection criteria that were considered important determinants for a successful early outcome, including age between 4 and 15 years, low PVR (<4 Wood  $U/m^2$ ), mean pulmonary artery pressure <20mmHg, systemic ventricle ejection fraction >0.6, normal sinus rhythm, normal atrioventricular valve function, and normal systemic and pulmonary venous drainage [188]. Patients with a diagnosis of tricuspid atresia who meet these criteria had a mortality rate of less than 5% from this procedure [197]. Modifications to these criteria have subsequently been made over the years as experience and surgical techniques have evolved [198,199]. The modified Fontan procedure is now preferably performed in children under 2-4 years of age to enable earlier correction of chronic hypoxemia and to limit the potential longer-term complications associated with prior palliation. The Fontan procedure has also been successfully performed in selected patients greater than 15 years with CHD who have appropriate hemodynamics despite long-term palliation. Unobstructed flow across the pulmonary vascular bed is essential. A mean PA pressure <15 mmHg and a PVR <2 Wood U/m<sup>2</sup> are preferable, as they have been associated with a lower early mortality [200]. Diastolic dysfunction of the ventricle with an elevated end-diastolic pressure (e.g. >12mmHg) secondary to increased myocardial mass or outflow obstruction is an important consideration which could increase postoperative risk; a higher SVC and PA pressure will be necessary to maintain the transpulmonary gradient and therefore pulmonary blood flow in this situation.

#### Bidirectional Glenn or cavopulmonary connection

The benefits of a series circuit in patients with singleventricle physiology include improved systemic oxygenation and a reduction in the obligatory diastolic load borne by the ventricle that is simultaneously asked to fill systemic and pulmonary circuits (parallel circulation). The compensatory ventricular dilation that must occur in a parallel circuit places the ventricle at an unfavorable position on the Starling curve and over time will lead to progressive ventricular dysfunction. As previously noted, the increase in ventricular end-diastolic volume, and eventually end-diastolic pressure, may significantly compromise the Fontan physiology and effective pulmonary blood flow [201]. Therefore, early palliation and relief of any volume-load from the systemic ventricle is an important interim step in the staged management of patients with single-ventricle physiology. For most patients, this can be achieved by performing a bidirectional cavopulmonary connection or bidirectional Glenn (BDG) procedure during infancy, commonly around 3-6 months of age. The volume and pressure load is relieved from the systemic ventricle, but effective pulmonary blood flow is maintained and the chance of a successful conversion to a complete cavopulmonary anastomosis or modified Fontan procedure is improved.

After a bidirectional Glenn procedure, the Qp/Qs is reduced as the source of pulmonary blood flow is from the superior vena cava only. At the time of surgery, the azygous vein is usually ligated to prevent decompression of venous drainage from the SVC to veins below the diaphragm and the inferior vena cava, which could contribute to a lower arterial oxygen saturation. Following the BDG, the arterial oxygen saturation should be in the 80-85% range, and preload to the systemic ventricle maintained by mixing of pulmonary venous blood with systemic venous blood returning via the inferior vena cava to the common atrium. As the volume output of the ventricle must meet only the demands of the systemic circulation, the end-diastolic volume (EDV) is therefore substantially reduced. As the EDV decreases, an alteration in ventricular geometry takes place. In some children, the resulting small, hypertrophic ventricle exhibits diastolic dysfunction that was not present at higher EDV [201,202]. In other children, subaortic obstruction may appear across a bulboventricular foramen that was unobstructed in the preoperative state.

The BDG is usually performed on CPB using mild hypothermia with a beating heart. The complications related to CPB and aortic cross-clamping are therefore minimal, and patients can be weaned and extubated in the early postoperative period [183]. Systemic hypertension is common following the BDG procedure. The etiology remains to be determined, but possible factors include improved contractility and stroke volume after the volume load on the ventricle is removed, and brainstemmediated mechanisms secondary to the increased systemic and cerebral venous pressure. Treatment with vasodilators may be necessary.

## Ideal physiology immediately following the Fontan procedure

The maintenance of effective pulmonary blood flow and cardiac output following the Fontan procedure depends on the pressure gradient between the pulmonary artery and the pulmonary venous atrium. The factors contributing to a successful cavopulmonary connection are shown in Table 25.8. A systemic venous pressure of 10–15 mmHg and a left atrial pressure of 5–10 mmHg, i.e. a transpulmonary gradient of 5–10 mmHg, are ideal.

Intravascular volume must be maintained and hypovolemia treated promptly. Venous capacitance is increased and as patients rewarm and vasodilate following surgery, a significant volume requirement is not unusual. If the stated selection criteria are followed, patients undergoing a modified Fontan procedure will have a low PVR without labile pulmonary hypertension. Therefore,

	Aim	Management
Baffle pressure 10–15 mm Hg	Unobstructed venous return	$\rightarrow$ or $\uparrow$ Preload
		Low intrathoracic pressure
Pulmonary circulation	PVR < 2 Wood units/m <sup>2</sup> Mean PAp < 15 mmHg Unobstructed pulmonary vessels	Avoid increases in PVR, such as from acidosis, hypo- and hyperinflation of the lung, hypothermia, and excess sympathetic stimulation Early resumption of spontaneous respiration
Left atrium pressure 5–10mm Hg	Sinus rhythm	Maintain sinus rhythm,
	Competent AV valve	$\rightarrow$ or $\uparrow$ HR to increase CO
	Ventricle:	$\rightarrow$ or $\downarrow$ afterload
	Normal diastolic function	$\rightarrow$ or $\uparrow$ contractility
	Normal systolic function	
	No outflow obstruction	PDE inhibitors useful because of vasodilation, inotropic and lusitropic properties

Table 25.8 Management co	onsiderations	following a	modified Fo	ontan p	procedure
--------------------------	---------------	-------------	-------------	---------	-----------

PVR, pulmonary vuscular resistance; PAp, pulmonary artery pressure; AV, atrioventricular; HR, heart ratio; CO, Cardiac output; PDE, phosphodiesterase;  $\rightarrow$ , maintain/normal;  $\uparrow$ , increase;  $\downarrow$ , decrease.

vigorous hyperventilation and induction of a respiratory and/or metabolic alkalosis to further reduce PVR are often of little benefit in this group of patients; conversely, the increase in mechanical ventilation requirements to induce a respiratory alkalosis may have an adverse effect on pulmonary blood flow. A normal pH and PaCO<sub>2</sub> of 40 mmHg should be the goal and, depending on the amount of right-to-left shunt across the fenestration, the arterial oxygen saturation is usually in the 80–90% range. However, PVR may increase following surgery, particularly secondary to an acidosis, hypothermia, atelectasis, hypoventilation, vasoactive drug infusions, and stress response.

Any acidosis must be treated promptly. If the cause is respiratory, ventilation must be adjusted. A metabolic acidosis reflects poor cardiac output, and while correction with bicarbonate may be necessary in the short term to reduce the associated increase in PVR, treatment should be directed at the potential causes, including reduced preload to the systemic ventricle, poor contractility, increased afterload and loss of sinus rhythm.

The beneficial effect of spontaneous ventilation on the hemodynamics of Fontan patients has been largely overstated [203]. While large instantaneous increases in pulmonary blood flow are seen in Fontan patients with normal inspiration, the incremental improvement in flow associated with normal inspiration is quite modest when considered over the entire respiratory cycle. In fact, in adult total cavopulmonary connection (TCPC) patients approximately 30% of systemic venous flow to the pulmonary arteries is respiratory dependent as compared to 15% in normal two-ventricle patients. Furthermore, while inspiration augments pulmonary flow in TCPC patients, aortic blood flow (cardiac output) is actually higher during expiration. This is identical to the response seen in normal two-ventricle patients. In normal patients this is due to the fact that interventricular dependence results in the inspiratory increase in RV end-diastolic volume and stroke volume, simultaneously reducing LV enddiastolic volume and stroke volume. In TCPC patients in whom interventricular dependence is not a factor, it is due to the pulmonary vasculature serving as a largevolume reservoir.

Given the effects of negative intrathoracic pressure on pulmonary blood flow, the effects of positive pressure ventilation (PPV) on Fontan hemodynamics are of concern. Unfortunately, the effects on Fontan hemodynamics of PPV as compared to spontaneous ventilation have never been systematically evaluated. However, because pulmonary blood flow occurs throughout the respiratory cycle, employing a ventilation strategy that minimizes mean airway pressure is a more rational, physiologically based approach. Available evidence suggests that a near-linear inverse relationship exists between mean airway pressure and cardiac index. The use of PEEP continues to be debated. The beneficial effects of an increase in FRC, maintenance of lung volume and redistribution of lung water need to be balanced against the possible detrimental effect of an increase in mean intrathoracic pressure. A PEEP of 3–5 cmH<sub>2</sub>0, however, rarely has

hemodynamic consequences or substantial effects on effective pulmonary blood flow [204–208].

Non-specific pulmonary vasodilators such as sodium nitroprusside, nitroglycerine, PGE1 and prostacyclin have been used to dilate the pulmonary vasculature in an effort to improve pulmonary blood flow after a Fontan procedure. The results are variable, however. While PVR may fall, pulmonary blood flow could also increase as a result of reduced ventricular end-diastolic pressure and improved ventricular function secondary to the fall in systemic afterload. The response to inhaled NO is also variable and the improvement may relate to changes in ventilation/perfusion matching rather than a direct fall in PVR.

An elevated left atrial pressure may reflect systolic or diastolic ventricular dysfunction, atrioventricular valve regurgitation or stenosis, and loss of sinus rhythm with cannon "a" waves that raise left atrial pressure. Afterload stress is poorly tolerated after a modified Fontan procedure because of the increase in myocardial wall tension and end-diastolic pressure. Although pulmonary blood flow is phasic to a certain extent, a substantial proportion of flow occurs during diastole as well. The diastolic or relaxation characteristics of the ventricle play a significant role in the volume of pulmonary blood flow and, hence, the preload accepted by the ventricle. Therefore, low cardiac output accompanies diastolic dysfunction.

Therapeutic manipulations are not always successful in reversing this dysfunction once it is manifest. The rightsided filling pressure must be increased to maintain the transpulmonary gradient, and treatment with inotropes and vasodilators initiated. Despite the temptation to use them in low cardiac output states, the addition of inotropes may not improve hemodynamics and may actually worsen diastolic relaxation if large doses of drugs such as epinephrine are used. One should scrupulously maintain or augment circulating volume to avoid additional reductions in EDV. The phosphodiesterase inhibitor milrinone is particularly beneficial. Besides being a weak inotrope with pulmonary and systemic vasodilating properties, its lusitropic action will assist by improving diastolic relaxation and lowering ventricular end-diastolic pressure, thereby improving effective pulmonary blood flow and cardiac output. If a severe low output state with acidosis persists, take-down of the modified Fontan operation and conversion to a BDG anastomosis or other palliative procedure are life saving.

# Early postoperative complications after the Fontan procedure

Not all patients require a fenestration for a successful, uncomplicated Fontan operation. Those with ideal preoperative hemodynamics often maintain an adequate pulmonary blood flow and cardiac output without requiring a right-to-left shunt across the baffle. Similarly, not all Fontan patients who have received a fenestration will use it to shunt right to left in the immediate postoperative period. These patients are fully saturated following surgery, and may have an elevated right-sided filling pressure, but nevertheless maintain an adequate cardiac output. The problem is predicting which patients are at risk for low cardiac output after a Fontan procedure, and who will benefit from placement of a fenestration; even patients with ideal preoperative hemodynamics may manifest a significant low-output state after surgery. Because of this, essentially all patients have a fenestrated Fontan procedure at Children's Hospital, Boston. Premature closure of the fenestration may occur in the immediate postoperative period, leading to a low cardiac output state with progressive metabolic acidosis and large chest drain losses from high rightsided venous pressures. Patients may respond to volume replacement, inotrope support and vasodilation; however, if hypotension and acidosis persist, cardiac catheterization and removal of thrombus or dilation of the fenestration may need to be urgently undertaken [209] (Table 25.9).

Arterial  $O_2$  saturation levels may vary substantially following a modified Fontan procedure. Common causes of persistent arterial  $O_2$  desaturation <75% include a poor cardiac output with a low mixed-venous  $O_2$ , a large rightto-left shunt across the fenestration or additional "leak" in the baffle pathway producing more shunting. An intrapulmonary shunt, and venous admixture from decompressing vessels draining either from the PA to the systemic venous circulation or systemic vein to the pulmonary venous system are additional causes [210]. Re-evaluation with echocardiography and cardiac catheterization may be necessary.

The incidence of recurrent pleural effusions and ascites has decreased since introduction of the fenestrated baffle [211]. Nevertheless, for some patients this remains a major problem with associated respiratory compromise, hypovolemia and possible hypoproteinemia [212]. Usually secondary to persistent elevation of systemic venous pressure, re-evaluation with cardiac catheterization may be indicated.

Atrial flutter and/or fibrillation, heart block, and, less commonly, ventricular dysrhythmia may have a significant impact on immediate recovery, as well as long-term outcome. Sudden loss of sinus rhythm initially causes an increase in left atrial and ventricular end-diastolic pressure, and fall in cardiac output. The SVC or PA pressure must be increased, usually with volume replacement, to maintain the transpulmonary gradient. Prompt treatment with antiarrhythmic drugs, pacing or cardioversion is necessary.
Circumstance	Etiology	Treatment
Increased TPG:		
Baffle > 20 mm Hg	Inadequate pulmonary blood flow and preload	Volume replacement
LAp < 10 mm Hg	to left atrium:	Reduce PVR
TPG increased >> 10 mm Hg	Increased PVR	Correct acidosis
Clinical state:	Pulmonary artery stenosis	Inotrope support
High SaO <sub>2</sub> /low SvO <sub>2</sub>	Pulmonary vein stenosis	Systemic vasodilation
Hypotension/tachycardia	Premature fenestration closure	Catheter or surgical intervention
Poor peripheral perfusion		
SVC syndrome with pleural effusions and		
increased chest tube drainage		
Ascites/hepatomegaly		
Metabolic acidosis		
Normal TPG:		
Baffle > 20 mm Hg	Ventricular failure:	Maintain preload
LAp > 15 mm Hg	Systolic dysfunction	Inotrope support
TPG normal 5–10 mm Hg	Diastolic dysfunction	Systemic vasodilation
Clinical slate:	AV valve regurgitation and/or stenosis	Establish sinus rhythm or AV synchrony
Low SaO <sub>2</sub> /low SvO <sub>2</sub>	Loss of sinus rhythm	Correct acidosis
Hypotension/tachycardia	Afterload stress	Mechanical support
Poor peripheral perfusion		Surgical intervention, including takedown to
Metabolic acidosis		BDG and transplantation

Table 25.9 Circumstances, etiology and treatment strategies for patients with low cardiac output immediately following the Fontan procedure

LAp, left atrial pressure; TPG, transpulmonary gradient; SaO<sub>2</sub>, systemic arterial oxygen saturation; SvO<sub>2</sub>, SVC oxygen saturation; SVC, superior vena cava; PVR, pulmonary vascular resistance; AV, atrioventricular; BDG, bidirectional Glenn anastomosis.

## Anesthetic considerations for patients following a Fontan procedure

There are no prospective studies that have evaluated the effects of specific anesthetic techniques and drugs in patients with Fontan physiology. Anesthetic management will vary on a case-by-case basis according to the functional and clinical status of each patient, and the specific complications unique to the Fontan procedure. An increasing hazard function for failure or reintervention, a late decline in functional status and 15-year survival between 60% and 73% have been reported on intermediate-to-late follow-up [213–215]. However, these figures include patients operated upon in the earlier surgical years, and with improved surgical techniques and patient selection, subsequent survival figures have improved [216,217].

Arrhythmias, in particular atrial flutter, sick sinus syndrome and heart block, have been reported in 20% or more of survivors 10 years following the Fontan procedure. The probability of freedom from atrial flutter has been reported as about 40% at 15 years post Fontan procedure, although these data include patients from different surgical eras [218]. Predisposing factors include surgery involving the atrium with extensive suture lines, disrupted sinoatrial node blood supply, and chronic atrial distension. In addition, older age at Fontan operation, longer duration of follow-up, and type of surgical procedure are associated with an increased incidence of atrial flutter after Fontan operation. Patients with recurrent arrhythmias are often treated with long-term antiarrhythmic drugs, present for repeat cardioversions and may undergo radiofrequency ablation of re-entrant flutter pathways [173,219,220]. There are no recommendations at this time for prophylactic antiarrhythmic drugs, such as digoxin or amiodarone, prior to anesthesia for noncardiac surgery but it is important that facilities for immediate external cardiac pacing or cardioversion are readily available in the operating room for these patients.

There is an increased incidence of thromboembolism in patients who have undergone the Fontan procedure, but the routine use of long-term anticoagulation remains controversial. The actual incidence of thromboembolism is difficult to determine because of the heterogeneous patient population. A large retrospective review of 645 patients who underwent the Fontan procedure at Children's Hospital, Boston, over a 15-year period, between 1978 and 1993, described 17 patients (2.6%) who suffered a stroke following the Fontan procedure, presumed secondary to a thromboembolic event [221]. The nature of the Fontan circulation with increased venous pressure and stasis of flow through the right atrial baffle, atrial dysrhythmias, alterations in pro- and anticoagulant

factors and possible increased resting venous tone in this population of patients, are all contributing factors [222,223]. The role of prophylactic anticoagulant therapy in congenital heart disease in general, and the Fontan population in particular, is poorly defined. Antiplatelet therapy with aspirin is commonly used in the immediate and early postoperative period, although the benefit of long-term use has not been evaluated. In high-risk patients, and those who have had previous thrombus formation, coumadin therapy for an extended period is recommended. Patients with Fontan physiology may be at increased risk for deep venous thrombosis, or thrombus formation within the Fontan baffle or atrial appendage following non-cardiac surgery. Prophylactic subcutaneous heparin should be considered for older Fontan patients undergoing non-cardiac procedures, and patients should be kept well hydrated and mobilized early after surgery.

Protein-losing enteropathy (PLE) has been reported in 3–14% of Fontan patients on long-term follow-up [224]. Defined as persistent hypoalbuminemia (<3.0 mg/dL) in the absence of liver and renal disease, associated clinical features include abdominal pain, diarrhea, edema and ascites. Patients frequently have limited hemodynamic reserve with increased systemic venous pressure, decreased cardiac index and increased end-diastolic ventricular pressure.

Most patients with stable single-ventricle physiology subjectively report that they are able to lead relatively normal lives with moderate exercise tolerance. Nevertheless, deterioration in function according to New York Heart Association classification has been reported over longer follow-up [225,226]. Objective evaluation with exercise testing demonstrates the limited cardiorespiratory reserve of many Fontan patients [225,226]. The implications of these findings for subsequent anesthetics have not been studied, but the response to exercise testing may be useful for assessing a patient's ability to tolerate the stress of anesthesia and surgery. Compared to normal control subjects, those with Fontan physiology frequently demonstrate a reduced maximal exercise workload, less endurance, take longer to recover after stopping exercise and have a lower anaerobic threshold and maximal oxygen consumption. A fall in arterial oxygen saturation and an increase in arteriovenous oxygen saturation difference is common because of the suboptimal increase in cardiac index [227]. The inability to increase effective pulmonary blood flow and stroke volume during strenuous exercise underscores the importance of the pulmonary vascular bed in determining ventricular filling and the dependence upon heart rate to increase cardiac output.

Intraoperative monitoring during major surgery needs careful planning in patients with Fontan physiology.

Placement of a central venous line into the SVC will enable monitoring of systemic venous return, pulmonary artery pressure and mixed venous oxygen saturation. An important consideration, however, is the risk of thrombosis and obstruction to venous return. Cardiac catheterization may be indicated prior to surgery if there has been a change in symptoms or deterioration in function. In particular, prior to major surgery and if significant fluid shifts are anticipated, performing a hemodynamic study immediately prior to surgery is often beneficial. Besides being able to assess baseline hemodynamics, a balloontipped catheter can be wedged in a pulmonary capillary to measure the transpulmonary gradient. Positioning the catheter using pressure waveforms alone is difficult because there is no pulsatile arterial pressure waveform and the balloon may not readily float out to a lung segment. Placement under direct vision using fluoroscopy is preferable. Attempted measurement of cardiac output using thermodilution will also be inaccurate.

## **Tetralogy of Fallot** Pathophysiology

The four anatomical features of tetralogy of Fallot include a VSD, right ventricular outflow tract obstruction, overriding of the aorta, and right ventricular hypertrophy. In addition, there may also be VSDs of the muscular region of the septum and right-sided obstruction of the pulmonary valve and the main and branch pulmonary arteries.

The resistance to right ventricular outflow forces systemic venous return right to left across the ventricular septal defect (complex shunt) and into the aorta, producing arterial desaturation (Fig. 25.17). Pulmonary blood flow is less than systemic flow. The amount of blood that shunts right to left through the ventricular septal defect varies with the magnitude of the right ventricular outflow tract obstruction and with the SVR. Distal pulmonary vascular resistance is low and has minimal influence on shunting. Systemic vasodilation, in conjunction with increasing dynamic infundibular stenosis, intensifies right-to-left shunting and therefore hypoxemia, producing hypercyanotic "spells." Such spells can occur at any time before surgical correction of the anomalies and can be life threatening. Their treatment is outlined below. Because the morbidity associated with recurrent hypercyanotic spells is significant, many physicians consider recurrent episodes of hypercyanosis to be an indication for corrective surgery at any age.

## Anesthetic management

The surgical approach to TOF may involve either an early or delayed repair. The delayed repair in a symptomatic neonate requires early palliation with a systemic-to-pulmonary artery shunt to prevent hypercyanotic episodes,

followed by a transatrial and transpulmonary artery repair after 3 months of age [228]. Excellent outcome has been achieved with this approach and the need for a transpulmonary valve annulus outflow patch (transannular patch) at the time of surgery is reduced. More recently, aggressive efforts to preserve the RV outflow tract and pulmonary valve have been used, given the long-term consequences of pulmonary regurgitation and arrhythmogenic scar tissue in the right ventricular outflow tract (RVOT) in this population [229]. Some continue to argue that the risks of cyanosis and complications related to a systemic-to-pulmonary artery shunt argue for an early complete repair of TOF regardless of symptoms [230]. This may be performed in the neonate or young infant depending upon the degree of obstruction and arterial oxygen saturation level. Complete repair in neonates and young infants more often requires a transventricular approach to close the VSD, with pericardial augmentation of the RVOT. A ventriculotomy is performed in the RVOT and is frequently extended distally through the pulmonary valve annulus and beyond any associated pulmonary artery stenosis. The outflow tract is then enlarged with pericardium or synthetic material, and obstructing muscle bundles are resected to relieve the

outflow tract obstruction. Pulmonary regurgitation results after a transannular incision that may compromise ventricular function in the postoperative period. In approximately 8% of patients, abnormalities in the origin and distribution of the coronary arteries preclude placement of the right ventricular outflow patch [231,232], making it necessary to bypass the stenosis by placing an external conduit from the body of the right ventricle to the pulmonary artery.

Anesthetic management of these patients should maintain systemic vascular resistance, minimize pulmonary vascular resistance, and avoid myocardial depression. Hypercyanotic spells in non-anesthetized children are traditionally treated initially with 100% oxygen by facemask, a knee-chest position, and morphine sulfate. This regimen usually causes the dynamic infundibular stenosis to relax while maintaining systemic resistance. Deeply cyanotic and lethargic patients are given IV crystalloid infusions to augment circulating blood volume. Continued severe hypoxemia is treated with a vasopressor (e.g. phenylephrine  $1-2 \mu g/kg$ ) to increase SVR, and sometimes by judicious use of IV propranolol or esmolol to slow the heart rate; the latter allows more filling time and relaxes the infundibulum. If a hypercyanotic spell persists despite treatment, immediate surgical correction of the anomaly is indicated. The child can be anesthetized with IV opioids and an inhalation agent may be beneficial to reduce hyperdynamic outflow tract obstruction. Anesthetic agents that predominantly decrease SVR should be used with caution. The pattern of mechanical ventilation is critical as excessive inspiratory pressure or short expiratory times will increase the mean intrathoracic pressure and further reduce antegrade flow across the RV outflow.

When weaning patients from CPB following tetralogy repair, the aim of therapy is to support right ventricular function and minimize afterload on the RV. This is particularly important following repair in neonates or small infants. While systolic dysfunction of the RV may occur following neonatal ventriculotomy, more commonly the clinical picture is one of a "restrictive physiology" reflecting reduced RV compliance or diastolic function [233,234]. Factors contributing to diastolic dysfunction include ventriculotomy, lung and myocardial edema following CPB, inadequate myocardial protection of the hypertrophied ventricle during aortic cross-clamp, coronary artery injury, residual outflow tract obstruction, volume load on the ventricle from a residual VSD or pulmonary regurgitation and dysrhythmias.

Patients usually separate from CPB with a satisfactory blood pressure and atrial filling pressures <10 mmHg on inotrope support, such as dopamine  $5-10\mu g/kg/min$ . However, in neonates during the first 6-12 h after surgery, a low cardiac output state with increased right-sided

filling pressures from diastolic dysfunction is common following a right ventriculotomy, and continued sedation and paralysis are usually necessary for the first 24-48h to minimize the stress response and associated myocardial work. Preload must be maintained, despite elevation of the RA pressure. In addition to high right-sided filling pressures, pleural effusions and/or ascites may develop. Significant inotrope support is often required, and a phosphodiesterase inhibitor, such as amrinone or milrinone, is beneficial because of its lusitropic properties. Because of the restrictive defect, even a relatively small volume load from a residual VSD or pulmonary regurgitation is often poorly tolerated in the early postoperative period, and it may take 2-3 days before RV compliance improves following surgery and cardiac output increases. While the patent foramen ovale or any ASD is usually closed at the time of surgery in older patients, it is beneficial to leave a small atrial communication following neonatal repair. In the face of diastolic dysfunction and increased RV enddiastolic pressure, a right-to-left atrial shunt will maintain preload to the left ventricle and therefore cardiac output. Patients may be desaturated initially following surgery because of this shunting. As RV compliance and function improve, the amount of shunt decreases and both antegrade pulmonary blood flow and arterial oxygen saturation increase.

Arrhythmias following repair include heart block, ventricular ectopy and junctional ectopic tachycardia. It is important to maintain sinus rhythm to avoid additional diastolic dysfunction and an increase in end-diastolic pressure. Atrioventricular pacing may be necessary for heart block. Complete right bundle branch block is typical on the postoperative ECG.

Most patients recover systolic ventricular function postoperatively. However, there is a small group of patients, especially those repaired at older ages, in whom significant ventricular dysfunction remains. Pulmonary valve insufficiency may contribute to residual ventricular systolic dysfunction [235]. The most common cause of systolic dysfunction immediately after repair of CHD is a residual or unrecognized additional VSD [236,237] which causes a volume load on the left ventricle and pressure load on the hypertrophied right ventricle, leading to right ventricular failure and poor cardiac output. A residual VSD combined with a residual right ventricular outflow obstruction is particularly deleterious.

In some patients the distal pulmonary arteries may be so hypoplastic and stenotic that they cannot be satisfactorily corrected. Suprasystemic pressure develops in the right ventricle, which in some cases can be ameliorated by partially opening the VSD to allow an intracardiac right-to-left ventricular shunt. This shunt unloads the compromised right ventricle at the expense of decreased arterial oxygen saturation.

## Anesthetic considerations after right ventricle outflow reconstruction

Reconstruction of the RV outflow tract may lead to significant problems that affect RV function and risk for arrhythmias over time. While most of the long-term outcome data pertain to patients following tetralogy of Fallot repair, similar complications and risks are also likely for those who have undergone an extensive RV outflow reconstruction, such as placement of a conduit from the right ventricle to the pulmonary artery for correction of pulmonary atresia, truncus arteriosus and the Rastelli procedure for transposition of the great arteries with pulmonary stenosis.

Complete surgical repair of TOF has been successfully performed for over 40 years, with recent studies reporting a 30-35-year actuarial survival of about 85%. Many patients report leading relatively normal lives, but RV dysfunction may progress after repair and may only be evident on exercise stress testing or echocardiography. A spectrum of problems may develop, ranging from a dilated RV with systolic dysfunction to diastolic dysfunction from a poorly compliant RV, and these need to be thoroughly evaluated preoperatively (Table 25.10). In addition, continued evaluation is necessary because of the increased risk of ventricular dysrhythmias and late sudden death. Factors that may adversely affect longterm survival include older age at initial repair, initial palliative procedures and residual chronic pressure and/ or volume load such as from pulmonary insufficiency or stenosis [238,239].

 Table 25.10
 Long-term follow-up after tetralogy of Fallot repair: right ventricular function

Circumstance	Clinical
Systolic dysfunction: "nonrestrictive"	RV dilation: cardiomegaly Significant pulmonary regurgitation
	Volume overload: $\uparrow$ RVEDV, $\downarrow$ RV ejection fraction
	$\downarrow$ Maximal exercise capacity and endurance
	$\uparrow$ Risk for ventricular arrhythmias and possibly sudden death
Diastolic dysfunction: "restrictive"	$\downarrow$ RV compliance: cardiomegaly less likely Limited pulmonary regurgitation
	$\uparrow$ RVEDP, contractility maintained
	Improved exercise capacity
	Lower risk for ventricular dysrhythmias

RV, right ventricle; RVEDV, right ventricle end-diastolic volume; RVEDP, right ventricle end-diastolic pressure;  $\uparrow$ , increased;  $\downarrow$ , decreased.

Both RV and LV systolic dysfunction secondary to a residual volume load from pulmonary regurgitation (PR) after tetralogy repair are predictors of late morbidity [238,239]. There is also an association between RV dilation from PR and the risk of ventricular tachycardia (VT) and sudden death [240]. The consequences of chronic PR are reflected by cardiomegaly on chest x-ray, an increase in RV end-diastolic volume by echocardiography and on exercise testing as a reduction in anaerobic threshold, maximal exercise performance and endurance [241]. Patients who have significant pulmonary regurgitation and reduced RV function are at potential risk of a fall in cardiac output during anesthesia, particularly as positive pressure ventilation may increase the amount of regurgitation. Once again, it is difficult to predict those patients who are more likely to have instability during anesthesia for non-cardiac surgery; nor is it possible to formulate a "recipe" for anesthesia that will be suited to all patients. Nevertheless, preoperative exercise testing may provide some insight as to hemodynamic reserve.

An important group to distinguish are those patients who have restrictive physiology or diastolic dysfunction secondary to reduced ventricular compliance. They usually do not have cardiomegaly, demonstrate better exercise tolerance and the risk for ventricular dysrhythmias is possibly decreased. Although the RV is hypertrophied, function is generally well preserved on echocardiography with minimal pulmonary regurgitation [233].

The incidence of significant RV outflow obstruction developing over time is low. Residual obstruction contributes to early mortality within the first year after surgery, but is well tolerated in the long term. A gradient more than 40 mmHg across the RV outflow is uncommon and the pressure ratio between the RV and LV is usually less than 0.5. The gradient may become more significant with time, but as the progression is usually slow, RV dysfunction occurs late.

A wide variation in the incidence of ventricular ectopy has been reported in numerous follow-up studies, including up to 15% of patients on routine ECG and up to 75% of patients on Holter monitor. Multiple risk factors including an older age at repair, residual hemodynamic abnormalities, and duration of follow-up have all been considered important [173,220,240]. In common with these factors is probable myocardial injury and fibrosis from chronic pressure and volume overload, and cyanosis. While ventricular ectopy is common in asymptomatic patients during ambulatory ECG Holter monitoring and exercise stress testing, it is often low grade and has not identified those patients at risk for sudden death. Electrophysiological induction of sustained VT, especially when monomorphic, is suggestive of the presence of a re-entrant arrhythmic pathway. Although dependent on the stimulation protocol used to induce VT, the presence of monomorphic VT in a symptomatic patient with syncope and palpitations is significant and indicates treatment with radiofrequency ablation, surgical cryoablation, antiarrhythmic drugs or placement of an implantable cardioversion-defibrillator (ICD) [173,220,242]. The risk for ventricular dysrhythmias during anesthesia is unknown. While preoperative prophylaxis with antiarrhythmic drugs is not recommended, a means of external defibrillation and pacing must be readily available.

## Pulmonary atresia Pathophysiology

Atresia of the pulmonary valve or main pulmonary artery forms a spectrum of cardiac defects, the management of which depends on the extent of atresia, size of the RV and tricuspid valve (TV), presence of a VSD and collateral vessels, surface area of the pulmonary vascular bed and coronary artery anatomy. At birth, pulmonary blood flow is derived either from a PDA or from other aortopulmonary collateral blood vessels. These collaterals, which arise from the descending aorta and supply both lungs, may be extensive. The RV is usually hypertrophied, and a restrictive physiology is common during initial postoperative recovery.

At one end of the spectrum, critical pulmonary stenosis may exist with a variable degree of hypoplasia of the right ventricle, tricuspid valve, and pulmonary artery. There is no VSD. With critical pulmonic stenosis, only a pinhole orifice is present in the pulmonic valve, but the right ventricle is generally less hypoplastic than with pulmonary atresia. A fixed obligatory shunt of all systemic venous return occurs from the right to the left atrium, where blood mixes completely with pulmonary venous blood. Some blood may flow into the right ventricle, but because there is no outlet, blood regurgitates back across the tricuspid valve and eventually reaches the left atrium and left ventricle. Pulmonary blood flow is derived exclusively or predominantly from a PDA. These patients usually do not have extensive aortopulmonary collateral blood flow; consequently, they often become cyanotic when the PDA closes after birth. Critical pulmonary valve stenosis can be effectively treated by balloon dilation in the catheterization laboratory. Antegrade flow across the RV outflow may not improve immediately, but gradually increases over days as RV compliance improves.

Pulmonary valve atresia or short-segment main pulmonary artery atresia, with a VSD (PA/VSD) and normalsized TV, RV and branch pulmonary arteries, is completely repaired in the neonate, usually involving placement of a pericardial patch to reconstruct the outflow tract. If there is long-segment pulmonary artery atresia, a homograft "conduit" is necessary to reconstruct the RV outflow. Conduits may be extrinsically compressed or kinked at the time of sternal closure, causing partial RV outflow obstruction or direct compression of a coronary artery leading to ischemia.

The intracardiac anatomy of tetralogy of Fallot with pulmonary atresia (TOF/PA) is similar to that of simple tetralogy of Fallot, but the right ventricular outflow tract is atretic. Because of the atretic right ventricular outflow tract, all systemic venous return courses right to left through the VSD. Therefore, complete mixing of pulmonary and systemic venous return occurs in the left ventricle and aorta, producing arterial hypoxemia. Infants with tetralogy of Fallot and associated pulmonary atresia regularly exhibit significant systemic-to-pulmonary collateral flow. If antegrade flow is established from the right ventricle into the main pulmonary artery by a reparative procedure, the left-to-right shunt via collateral flow will impose a diastolic load on the left ventricle. Preoperative occlusion of these collateral vessels can be accomplished by interventional techniques in the cardiac catheterization laboratory but may leave the child precariously cyanotic in the hours before operation. The most effective temporizing therapy is to reduce oxygen consumption (e.g. anesthesia, mechanical ventilation) and to increase the systemic perfusion pressure across other systemic-topulmonary communications.

Patients with pulmonary atresia, a ventricular septal defect, but small RV and TV may not tolerate a complete initial repair. The RV may be unable to cope with the entire cardiac output, resulting in a low output state and RV failure (see below). Alternative management strategies therefore include initial palliation with a shunt and/ or RV outflow patch to improve pulmonary blood flow, or a repair of the outflow tract with fenestration of the VSD patch to enable a right-to-left shunt at that level. Two-ventricle repair may ultimately be limited by growth of the tricuspid valve. If the right ventricle subsequently grows, the shunt and the patent foramen ovale ASD and VSD can be closed surgically.

Patients with pulmonary atresia and an intact ventricular septum (PA/IVS) usually have a small RV and TV, which in general makes them unsuitable for a twoventricle repair in the long term. Initial palliation with an aortopulmonary shunt is necessary; reconstruction of the RV outflow with a pericardial patch or conduit may also be considered if the RV is a sufficient size such that a two-ventricle repair could be considered. Prior to surgery, the coronary anatomy should be determined, usually by cardiac catheterization. A large conal branch or aberrant left coronary artery across the RV outflow tract may restrict the size of a ventriculotomy and placement of a patch or conduit. Patients with pulmonary atresia, a hypoplastic RV and intact ventricular septum may have numerous fistulous connections between the small hypertensive RV cavity and the coronary circulation [243,244]. A significant proportion of the myocardium may therefore be dependent upon coronary perfusion directly from the RV. If, in addition, there are proximal coronary artery stenoses restricting coronary perfusion from the aortic root, then decompression of the RV following reconstruction of the RV outflow tract can lead to myocardial infarction.

At the worst end of the spectrum, severe pulmonary atresia may be associated with a hypoplastic RV and diminutive pulmonary arteries that are not suitable for primary repair [245]. A palliative procedure with a B–T or central shunt is usually necessary at first to improve pulmonary blood flow, followed by staged singleventricle repair (see Managing Fontan physiology).

Multiple aortopulmonary collateral arteries may be present, supplying some or all segments of the lung. They can be associated with a large left-to-right shunt, contributing to volume overload and pulmonary hypertension. Larger collateral vessels supplying significant portions of the lung can be anastomosed or "unifocalized" to the native pulmonary arteries, with the ultimate aim being to establish full antegrade pulmonary blood flow. Smaller vessels to some segments of lung can be coiled in the cardiac catheterization laboratory, provided there is antegrade flow from the native pulmonary arteries to those lung segments.

When the pulmonary arteries are very diminutive it is important to establish early antegrade flow from right ventricle to pulmonary artery, in an effort to promote growth and establish a pathway to the pulmonary arteries for subsequent balloon dilation. A B-T shunt may be necessary to provide sufficient pulmonary blood flow if the pulmonary arteries and right ventricle are small. Initially, the VSD can be left open, and postoperative management of cyanosis or CHF will be determined by the size of and the resistance offered by the pulmonary circuit. The course in these patients can be dynamic and demanding of the most experienced practitioners. When collaterals are occluded in the operating room and RV to diminutive pulmonary artery continuity is established, cyanosis may ensue and therapy is aimed at lowering PVR and/or (re)establishing adequate pulmonary blood flow. On the other hand, if the hemoglobin is fully saturated in the aorta with elevated pulmonary artery oxygen saturation and left atrial pressure, then a left-to-right shunt through the VSD may be developing, which will produce a volume load on the left ventricle and an unstable postoperative course, dictating VSD closure. When the patient is not fully saturated in the aorta but is suffering from a volume-loaded left ventricle with low cardiac output and high left atrial pressure postoperatively, excessive systemic-to-pulmonary collaterals may be the culprits, requiring catheterization laboratory investigation and occlusion or immediate reoperation.

## Anesthetic management

Anesthetic management of patients with pulmonary atresia is similar to that for tetralogy of Fallot, except that hypercyanotic spells do not occur in the same fashion. Maintaining the patency of the ductus for the perioperative treatment of neonates with pulmonary atresia and critical pulmonary stenosis is essential. If the right ventricle is sufficiently well developed and the main pulmonary artery is present, it may be possible to perform a pulmonary valvotomy and provide adequate pulmonary blood flow without a supplemental systemic-to-pulmonary artery shunt. The goal of therapy is to improve oxygenation and decrease right ventricular afterload. Because the underdeveloped non-compliant right ventricle requires high filling pressures, consequently, there may be substantial right-toleft shunting through the foramen ovale, making these infants hypoxemic during the immediate postoperative period. With growth and improved compliance of the right ventricle, the right-to-left shunting diminishes and the infant's oxygenation improves substantially. If hypoxemia persists, a PGE1 infusion should be started to increase pulmonary blood flow through the ductus arteriosus while arrangements are made to surgically create a pulmonary artery-systemic artery shunt.

In patients with long-segment pulmonary atresia, the need for a conduit to bridge the gap between the right ventricle and the pulmonary artery complicates the repair. Again, right ventricular failure may occur postoperatively, especially when there is a residual VSD or an outflow obstruction. The conduit may obstruct acutely during chest closure, further elevating pressure in the right ventricle.

After the VSD is closed and blood flow is from the right ventricle to the pulmonary arteries, there may be excessive pulmonary blood flow (Qp/Qs>1) owing to the combined flow into the pulmonary arteries from the right ventricle and from aortopulmonary collaterals described above. If this occurs, the patient develops CHF and requires intraoperative inotropic support of the heart and an extended period of postoperative mechanical ventilation. With large collateral flows, the pulse pressure is large and diastolic pressure low. The patients may require surgery to ligate the collateral vessels or may require embolization.

### Anesthetic considerations after repair

Patients with tetralogy of Fallot and pulmonary atresia are subject to the same late problems and complications as patients with tetralogy of Fallot alone. In addition, they may develop progressive conduit obstruction after surgery.

## Tricuspid atresia Pathology

In this condition an imperforate tricuspid valve and hypoplasia of the right ventricle are present, often accompanied by a VSD of variable size and by pulmonic stenosis. A fixed obligatory shunt of all systemic venous return occurs from the right atrium through the patent foramen ovale or ASD into the left atrium, where complete mixing takes place. The degree of hypoxemia depends on the amount of pulmonary blood flow, which is regulated by the severity of the pulmonic stenosis. The common presentation is characterized by significant hypoxemia caused by the decreased pulmonary blood flow induced by either a restrictive VSD or a severe pulmonic stenosis.

## Anesthetic management

The reparative operation of choice for tricuspid atresia is a modified Fontan procedure, but a palliative procedure may initially be required to improve pulmonary blood flow. A pulmonary artery band may be needed if the pulmonary blood flow is increased, or a shunt may have to be created for the severely hypoxemic child with decreased pulmonary blood flow. The anesthetic management and complications are those discussed in the sections on shunts, banding, and modified Fontan procedures (see above). Complications of chronic hypoxemia and cyanosis are also present.

## Transposition of the great arteries Pathophysiology

With transposition of the great arteries, the right ventricle gives rise to the aorta (Fig. 25.18). Almost 50% of patients with this anomaly have a VSD, and some of them have a variable degree of subpulmonic stenosis (see Fig. 25.18). Oxygenated pulmonary venous blood returns to the left atrium and is recirculated to the pulmonary artery without reaching the systemic circulation. Similarly, systemic venous blood returns to the right atrium and ventricle and is ejected into the aorta again. Obviously, this arrangement is compatible with life only for a few circulation times unless there is some mixing of pulmonary and systemic venous blood via a patent ductus arteriosus or an opening in the atrial or ventricular septum at birth. The physiological disturbance in these patients is one of inadequate mixing of pulmonary and systemic blood rather than one of inadequate pulmonary blood flow.

Mixing of blood at the atrial level can be improved by balloon atrial septostomy. If dangerous levels of hypoxemia persist after the septostomy and metabolic acidosis ensues, an infusion of PGE1 can maintain the patency of the ductus arteriosus, increase pulmonary blood flow (by increasing left-to-right shunting across the PDA), and thereby increase the volume of oxygenated blood entering the left atrium. The volume-overloaded left atrium is likely to shunt part of its contents into the right atrium and thereby improve the oxygen saturation of aortic blood. Unlike the kinetics with other lesions, increased shunting of blood during anesthesia improves arterial oxygen saturation before correction of the transposition.

Depending on the particular anatomy and the presence of a VSD or pulmonary stenosis, one of three corrective procedures is used. The intraoperative and postoperative problems encountered differ with each type of procedure.

## Atrial baffle procedure (Mustard and Senning)

An atrial-level partition is created with baffling to redirect pulmonary venous blood across the tricuspid valve to the right ventricle and thus to the aorta [246]. Systemic venous return is directed across the atrial septum to the mitral valve, into the left ventricle, and out the pulmonary artery. Although the pulmonary and systemic circuits are then connected serially instead of in parallel, this arrangement leaves the patient with a morphological right ventricle and tricupsid valve in continuity with the aorta. This ventricle must therefore work against systemic arterial pressure and resistance.

One problem with atrial baffles is that they can obstruct systemic and pulmonary venous return [247]. When this occurs, the patient manifests signs and symptoms of systemic venous obstruction, as evidenced by superior vena cava syndrome or other signs of systemic venous hypertension. When the pulmonary venous pathway is obstructed, pulmonary venous hypertension may be manifested by respiratory failure, poor gas exchange, and pulmonary edema (seen on chest radiograph). Severe pulmonary venous obstruction is manifested in the operating room by the presence of copious amounts of bloody fluid in the endotracheal tube, low cardiac output, and frequently poor oxygenation. Residual interatrial shunts also may cause intra- or postoperative hypoxemia. Long-term rhythm disturbances, along with limitations of ventricular and atrioventricualr valve function, have made this operation nearly obsolete.

## Arterial switch procedure

Because of the complications associated with atrial baffle procedures, Jatene and others explored whether anatomical correction of this lesion, by dividing both great arteries and reattaching them to the opposite, anatomically correct ventricle, would improve survival [248,249]. This procedure is now performed in virtually all patients with straightforward transposition of the great arteries. It requires excision and reimplantation of the coronary arteries to the neo-aorta (formerly the proximal main pulmonary artery).

**Figure 25.18** Catheterization findings in a patient with *d*-transposition of the great arteries and restricted pulmonary flow. Reproduced with permission from Nadas AS, Fyler DC. Pediatric Cardiology. Philadelphia: WB Saunders, 1972.

The success of the arterial switch procedure depends on adequate preparation of the left ventricle and technical proficiency with the coronary transfer. Anatomical correction of transposition of the great vessels is done during the neonatal period when PVR (left ventricular afterload) and left ventricular pressure have both been high. Left ventricular mass decreases progressively after birth in this lesion, and if the ability of the left ventricle to tolerate the work required is misjudged, the child may develop severe left ventricular failure postoperatively and require inotropic support and afterload reduction to provide normal cardiac output. Infants with transposition of the great arteries who are more than a few weeks of age and have an intact ventricular septum may have decreased left ventricular pressure and mass. In such cases, the left ventricle may not tolerate the work required to perfuse the systemic vessels. However, if the neonate has a non-restrictive VSD, the left ventricle is accustomed to high pressure and may tolerate the increase in workload at any age. In older patients with an intact ventricular septum, banding the pulmonary artery can prepare the left ventricle to function as a systemic ventricle by increasing its afterload and muscle mass. If the left ventricle is "prepared" by banding the pulmonary artery and augmenting pulmonary blood flow with a modified Blalock–Taussig shunt, then an arterial switch procedure can usually be accomplished 1 week later after hypertrophy and hyperplasia have occurred [250]. However, during this interval these patients are cyanotic, with a volume-loaded right ventricle and a pressure-loaded left ventricle, and they may require considerable pharmacological support [251].

In experienced centers, the incidence of mortality for neonatal repair of transposition of the great arteries is now less than 3% and may be less than 2% for most anatomical arrangements of coronary arteries if the aortic arch is normal [252–254]. Midterm follow-up of these patients shows excellent outcome. Alternative operations are reserved almost exclusively for patients with particularly difficult coronary anatomy or pulmonic (neo-aortic) stenosis.

Myocardial ischemia or infarction may occur after mobilization and reimplantation of the coronary arteries, especially if they are stretched or twisted. Inotropic support, maintenance of coronary perfusion pressures, control of heart rate, and treatment with vasodilators may be particularly useful, as in adult patients with myocardial ischemia. Postoperative bleeding and tamponade occur more commonly with this operation because there are multiple arterial anastomoses.

#### Ventricular switch (Rastelli procedure)

In patients with a large VSD and severe subpulmonic stenosis, the VSD can be closed obliquely to direct left ventricular flow to the aorta. The pulmonary valve is oversewn and the right ventricle connected to the pulmonary artery with a conduit [255]. Complications of the Rastelli procedure include obstruction of left ventricular outflow due to narrowing of the subaortic region by the VSD patch. The conduit also may obstruct during or after the immediate postoperative period [256,257]. There is a small but significant incidence of heart block in these patients, which can be a difficult postoperative problem.

#### Anesthetic considerations after repair

Patients who have a morphological right ventricle remaining as the systemic ventricle and the pulmonary ventricle can be regarded as having a physiological or functional two-ventricle repair. Actuarial survival figures at 20 years have been quoted up to 80%, but significant long-term functional deterioration is likely with increasing risk of right heart failure, sudden death and dysrhythmias [258– 261]. This situation is evidenced by systemic (right) ventricular dysfunction and tricuspid valve regurgitation long after the repair [262,263].

Unfortunately, late arrhythmias continue to be a problem. There is a progressive loss of sinus rhythm fol-

lowing both the Mustard and Senning operations. Actuarial analysis of several series reveals that by 10 years post operation, only about 60–70% of patients will be in sinus rhythm at rest and by 20 years, this will decrease to 40–50% [264–268]. In one series, only 7% of patients who underwent a Senning procedure for TGV with VSD were in sinus rhythm at 15 years [258]. The majority of patients not in sinus rhythm will be in a junctional rhythm without the necessity for a pacemaker. Atrial flutter is present in 8% of patients at 5 years and in 27% at 20 years [268]. Late development of atrial flutter/fibrillation may be a surrogate marker for ventricular dysfunction and as such may put the patient at risk for VT and sudden death [269].

The exercise response of patients who have undergone an atrial switch procedure is clearly abnormal, with RV dysfunction, chronotrophic impairment, failure to augment ventricular filling and stroke volume, deconditioning, and impaired lung function all playing a role [270–273]. Asymptomatic children have a normal increase in cardiac output in response to submaximal exercise. However, they clearly have a reduced maximal aerobic capacity and oxygen consumption [272,274–276].

The fact that there is poor direct correlation between RV ejection fraction and exercise capacity emphasizes the mutifactorial nature of this problem [271]. A recent investigation utilizing load-independent measures of RV systolic and diastolic function concluded that the primary limitation to exercise capacity in Mustard patients was not impaired systolic or diastolic function but a limited ability to maintain an increased stroke volume as heart rate increased during exercise [271].

One of the major advances in congenital heart surgery over the past 10–15 years has been the development of the arterial switch operation (ASO) to correct transportation of the great arteries. Long-term survival data are not available as the oldest survivors are only in their teenage years, but based on intermediate-term follow-up data, the risk for reoperation and complications after the arterial switch operation remains small.

Virtually all coronary artery patterns are amenable to the arterial switch operation. Early concerns existed regarding the long-term patency and growth potential of the reimplanted coronary arteries. Fortunately, these problems have not materialized on a large scale. The overwhelming majority (90–97%) of patients have normalsized, patent coronary arteries as assessed by coronary angiography [277–281]. A recent study of a large cohort demonstrated that survival without coronary events (death from myocardial infarction (MI), sudden death, and reoperation for coronary stenoses) is 92.7 % at 1 year and 88.2% at 15 years [280]. Patients with complex preoperative coronary anatomy are at increased risk of late occlusion [281]. After repair, the "native" pulmonary valve becomes the "neo-aortic" valve. Aortic insufficiency occurs in approximately 10–15% of patients at long-term follow-up with the majority (96%) graded as trivial or mild [252,282]. Time has shown aortic insufficiency to be a rare source of morbidity or indication for reoperation following the ASO [252,253].

In contrast to the atrial switch procedures, electrophysiological abnormalities are uncommon after the ASO. The most common abnormalities noted at midterm and long-term follow-up are rare asymptomatic atrial and ventricular premature beats [282–284].

Supravalvar pulmonary artery stenosis was an early complication, but is now less common with surgical techniques that extensively mobilize, augment and reconstruct the pulmonary arteries. The incidence of supravalvular stenosis severe enough to require reoperation (generally a gradient greater than 50–60 mmHg) is approximately 4–8% [252,253]. There continue to be refinements in surgical technique to further reduce the incidence of this complication [285].

Assessment of myocardial performance using echocardiography, cardiac catheterization and exercise testing following the ASO has demonstrated function identical to age-matched controls [286]. Based upon the currently available clinical, functional and hemodynamic data, a patient who has undergone a previous ASO with no evidence of subsequent problems should be treated as for any patient with a structurally normal heart when presenting for non-cardiac surgery.

Late complications of the Rastelli procedure include progressive conduit obstruction and right ventricular hypertension, residual VSDs and, occasionally, subaortic obstruction from diversion of left ventricular outflow across the VSD to the aorta.

## Total anomalous pulmonary venous connection

## Pathophysiology

Patients with total anomalous pulmonary venous connection are cyanotic because their pulmonary veins connect to a systemic vein and they have various degrees of pulmonary venous obstruction. The venous connection may be above the level of the heart (e.g. to the superior vena cava, innominate or azygos vein), directly to the right atrium or below the level of the heart and the diaphragm (e.g. to the hepatic veins). Patients with this anomaly must have a patent foramen ovale or an ASD that allows blood flow to the left side of the heart.

This anatomical arrangement provides complete mixing of all systemic and pulmonary venous blood in the right atrium. Unless there is significant stenosis of the pulmonary venous connection, most of this right atrial blood passes through the right ventricle into the pulmonary artery, which increases pulmonary blood flow. If pulmonary venous return is significantly inhibited, there is increased pulmonary venous congestion and decreased pulmonary blood flow.

#### Anesthetic management

These patients may be very ill, with hypoxemia, severe pulmonary edema, and pulmonary artery hypertension. Resuscitation, including mechanical ventilation, PEEP, and inotropic support of the myocardium, is followed by early surgical intervention to relieve the pulmonary venous obstruction. Although the patients are hypoxemic, their primary pathology is caused by obstructed venous return from the lungs. Therapy that increases pulmonary blood flow (e.g. PGE1) must be avoided. Surgical repair of total anomalous pulmonary venous connection requires attachment or redirection of the pulmonary venous confluence to the left atrium [287].

Intraoperative and postoperative problems are often related to residual or recurrent stenosis of the pulmonary veins. In patients who had severe stenosis and pulmonary venous hypertension preoperatively, the pulmonary vascular bed is highly reactive. This reactivity may produce high pulmonary artery pressures and poor right ventricular function after bypass and during the early postoperative period. Anesthetic management of these patients after completion of the repair should emphasize inotropic support of the right ventricle and avoidance of myocardial depressant drugs, and minimize pulmonary vascular resistance. Early extubation of the trachea is usually not feasible. Mechanical ventilation with hyperventilation and other postoperative therapy to decrease PVR are required. Use of inhaled nitric oxide has been particularly useful in this population.

## Anesthetic considerations after repair

Other than the potential for late development of recurrent pulmonary venous obstruction, these patients generally do well and have good cardiovascular reserve once recovery from the surgery is complete [288]. The size of the pulmonary veins at birth may be a predictor of late complications with recurrent pulmonary vein stenosis [289].

## Atrial septal defect Pathophysiology

There are three anatomical varieties of ASD. The most common, ASD secundum, is a deficit in the septum primum, which ordinarily covers the region of the foramen ovale. ASD primum is a deficit of the inferior portion of the atrial septum (endocardial cushion) and is usually accompanied by a cleft in the anterior leaflet of the mitral valve. Sinus venous defects are located near the junction of the right atrium and the superior or inferior vena cava; they are frequently associated with a partial anomalous pulmonary venous connection.

Left-to-right shunting (simple) occurs at the atrial level, causing a low-pressure volume load to the right ventricle. Pulmonary blood flow is increased, but not enough to make these patients symptomatic during early childhood. However, later in life, as the left ventricle becomes less compliant and the left atrial pressures increase, the leftto-right shunt and volume load increase and symptoms of CHF may occur. In rare patients the long-standing increase in pulmonary blood flows causes pulmonary vascular obstructive disease [30].

## Anesthetic management

The defect can be closed directly with sutures or, if it is sufficiently large, with a synthetic patch. Sinus venosus defects associated with partial anomalous pulmonary venous connection require a more extensive patch that also directs the partial anomalous pulmonary venous return into the left atrium.

These patients are among the healthiest encountered. Their anesthesia can be managed in many ways. Early tracheal extubation is usual. Atrial arrhythmias, including atrial flutter and atrial fibrillation, are rarely seen during the postoperative period. Mitral regurgitation may occur in patients who have undergone repair of an ASD primum. Although transient left ventricular failure has been reported, these patients rarely require inotropic support. Residual ASDs are uncommon, but occasionally failure to recognize partial anomalous pulmonary venous return results in a residual left-to-right shunt. Most patients can be extubated during the immediate postoperative period or in the operating room. With the exceptions mentioned above, these patients usually have nearly normal cardiovascular function and reserve after repair. As noted above, many of these defects can be closed in the catheterization laboratory with occlusion devices; only large defects with inadequate atrial borders, multiple defects or those associated with partial anomalous pulmonary venous return are closed surgically.

## Ventricular septal defect

## Pathophysiology

Defects in the ventricular septum occur at several locations in the muscular partition dividing the ventricles. Simple shunting occurs across the ventricular septum. The magnitude of pulmonary blood flow is determined by the size of the VSD and the PVR [290] (Fig. 25.19). With a non-restrictive defect, high left ventricular flows and pressures are transmitted to the pulmonary artery. Therefore, surgical repair is indicated within the first 2 years of life to prevent the progression of pulmonary vascular obstructive disease [28,32]. In patients with established pulmonary vascular disease, the pulmonary arteriolar changes may not recede when the defect is closed. In such cases, there may be progressive PVR elevation. The growth and development of the pulmonary vascular bed are significant factors in the patient's ability to normalize pulmonary vascular hemodynamics after surgery [291]. When PVR approaches or exceeds systemic vascular resistance, right-to-left shunting occurs through the VSD and the patients develop progressive hypoxemia (Eisenmenger syndrome) [292]. Closing the VSD in this circumstance adds the risk for acute right heart failure to that of progressive increases in PVR.

#### Anesthetic management

The defects are closed during CPB. The most common septal defect, the membranous defect, is frequently repaired through a right atriotomy and the tricuspid valve. However, lesions in the inferior apical muscular septum or those high in the ventricular outflow tract may require a left or right ventriculotomy. If so, the postoperative ventricular function may be impaired.

Before repair, measures that decrease PVR may appreciably increase left-to-right shunting in patients with a non-restrictive defect and may increase the degree of CHF. Postoperative right or left ventricular failure may be a manifestation of the preoperative status of the myocardium, a result of the ventriculotomy and CPB, or both. Small infants who fail to thrive, who are malnourished, and who have significant CHF preoperatively may have excessive lung water and may require prolonged mechanical ventilation postoperatively [293]. Such infants may have limited intraoperative tolerance for anesthetics that depress the myocardium or for maneuvers that increase pulmonary blood flow.

Persistent CHF and an audible murmur postoperatively, evidence of low cardiac output or the need for extensive inotropic support intraoperatively suggest that a residual or previously unrecognized VSD is continuing to place a volume and pressure load on the ventricles. When PVR is increased preoperatively, the increase in right ventricular afterload caused by closure of the VSD may be poorly tolerated, leading to the need for inotropic support of the heart and measures to decrease PVR. Occasionally ventricular outflow tract obstruction is caused by placement of the septal patch. Aortic regurgitation caused by prolapse of one of the aortic valve cusps can develop in subaortic or subpulmonic VSDs. In addition, heart block may occur after closure of VSDs with a patch. A pacemaker may be needed to maintain an adequate heart rate and cardiac output.

## Anesthetic considerations after repair

In the absence of residual VSDs, outflow obstruction, and heart block, most of these patients regain relatively normal myocardial function, especially if the VSD is

repaired early. However, a small percentage of patients, especially those who have had a large defect repaired late in childhood, continue to have some degree of ventricular dysfunction and also some pulmonary hypertension [294,295].

## Atrioventricular canal defects Pathophysiology

The endocardial cushion defect, complete common atrioventricular (AV) canal, consists of defects in the atrial and ventricular septa and the AV valvular tissue. All four chambers communicate and share a single common AV valve. The atrial and ventricular shunts communicate volume and systemic pressures to the right ventricle and pulmonary artery. The ventricular shunt orifice is usually non-restrictive (simple shunt); therefore, PVR governs the degree of excess pulmonary blood flow. Mitral regurgitation and direct left ventricular-to-right atrial shunting may further contribute to atrial hypertension and total left-to-right shunting.

## Anesthetic management

Surgical repair of this lesion consists of division of the common AV valve and closure of the atrial and ventricular septal defect with a single patch, modified single-patch or two-patch technique [296]. In addition, the mitral

valve (and sometimes the tricuspid valve) requires suture approximation and resuspension of the separated portions.

These patients have large left-to-right shunts. As a result of their high pulmonary blood flows, they have CHF and pulmonary hypertension. Myocardial depressants and therapy that decreases PVR while increasing shunt flow may be poorly tolerated before repair. Some patients, especially older children, may have obstructive pulmonary vascular disease. All of the potential complications of ASD and VSD closures are seen in these patients. In addition, the mitral valve may be regurgitant [297]. Inotropic support for the failing heart, afterload reduction for mitral regurgitation, and measures to decrease pulmonary vascular resistance may be required intra- and postoperatively after repair.

Patients with Down syndrome frequently have an associated complete AV canal. Measures to decrease PVR and the use of prolonged ventilatory support are often necessary because their airways and pulmonary vascular beds are hyper-reactive. The large tongues, upper airway obstruction, and difficult vascular access of these patients pose additional problems. The most frequent postoperative problems in Down syndrome patients are residual VSDs, mitral insufficiency, and pulmonary hypertension [298–300].

## Patent ductus arteriosus Pathophysiology

The ductus arteriosus is a fetal vascular communication between the main pulmonary artery at its bifurcation and the descending aorta below the origin of the left subclavian artery. When patent, it provides a simple shunt between the systemic and pulmonary arteries. The magnitude and direction of flow between the systemic and pulmonary vessels are determined by the relative resistances to flow in the two vascular beds and the diameter (resistance) of the ductus itself. With a large, nonrestrictive ductus and low pulmonary vascular resistance, the pulmonary blood flow is excessive and the volume load of the left heart is large. Systolic and diastolic flow away from the aorta may steal blood from vital organs (e.g. pulmonary steal) and compromise end-organ function at many sites. In addition, overcirculated lungs and elevated left atrial pressure increase the work of breathing.

## Anesthetic management

Although the patent ductus arteriosus of premature infants can often be closed medically with indomethacin or ibuprofen, contraindications to the use of these agents (e.g. intracranial hemorrhage, renal dysfunction, and hyperbilirubinemia) may require that the defect be closed surgically [301]. Whereas thoracotomy and surgical ligation of the ductus arteriosus are standard in older infants and children, some centers now occlude the ductus with a percutaneously inserted coil or occlusion device [302] or by using video-assisted thoracoscopic surgery (VATS) [303]. Advantages of VATS compared with open thoracotomy include decreased postoperative pain, shorter hospital stay and decreased incidence of chest wall deformity [304].

Healthy asymptomatic patients undergoing surgery can be extubated in the operating room, allowing many options for anesthetic management. However, the fragile premature infant with severe lung disease may require mechanical ventilation for protracted periods after ligation of the ductus arteriosus. Fentanyl, pancuronium, oxygen, and air constitute a common anesthetic regimen for this procedure. Anesthetic management of the premature infant in the operating room requires special considerations of gas exchange, hemodynamic performance, temperature regulation, metabolism, and drug and oxygen toxicity. Thoracotomy and lung retraction usually decrease lung compliance and increase oxygen and ventilatory requirements. A transient rise in systemic blood pressure with ligation of the ductus arteriosus may increase left ventricular afterload or elevate cerebral perfusion pressure to the detriment of a premature patient. Inadvertent ligation of the left pulmonary artery or descending aorta has occurred because the ductus arteriosus is often the same size as the descending aorta.

Ligation of an isolated ductus arteriosus generally results in normal cardiovascular function and reserve several months postoperatively [305].

## Truncus arteriosus

## Pathophysiology

With truncus arteriosus, the embryonic truncus fails to separate normally into the two great arteries. Indeed, a single great artery leaves the heart and gives rise to the coronary, pulmonary, and systemic circulations. The truncus straddles a large VSD and receives blood from both ventricles.

There is complete mixing of systemic and pulmonary venous blood in the single great artery, which causes mild hypoxemia. One or two pulmonary arteries may originate from the ascending truncus; the pulmonary artery orifice is seldom restrictive. The resulting shunt (simple) produces excessive pulmonary blood flow early in life as the pulmonary vascular resistance decreases. This "pulmonary steal" may elevate the arterial oxygen saturation and decrease the systemic blood flow. In such a case, net systemic oxygen transport decreases and lactic acidosis develops. Children with truncus arteriosus are at risk for developing early pulmonary vascular obstructive disease [306]. Regurgitation of blood through the truncal valve may place an additional volume load on the ventricles.

#### Anesthetic management

Complete repair of this lesion should be performed early, even in the neonate, before the development of irreversible pulmonary vascular changes [307,308]. The VSD is closed with a synthetic patch and the pulmonary arteries are detached from the truncus. Continuity is established between the right ventricle and the pulmonary arteries with a valved conduit. The truncal valve may require valvuloplasty if a significant amount of blood regurgitates through it.

Anesthetic management centers around control of pulmonary blood flow and ventricular support. Pulmonary blood flow may increase further with anesthetic agents, hyperventilation, alkalosis, and oxygen administration, resulting in hypotension and acute ventricular failure. If measures to *increase* PVR do not decrease pulmonary flow, occlusion of one branch of the pulmonary artery with a tourniquet limits pulmonary flow and restores systemic perfusion pressure until CPB can be instituted. Because these patients are frequently in highoutput CHF, myocardial depressants should be used with caution.

Immediately after repair, the combination of persistent pulmonary artery hypertension and right ventricular failure can be fatal. Hence, aggressive measures should be taken to provide normal myocardial function and lower the PVR. A residual VSD adds an additional volume and pressure load on the ventricles and may have a devastating impact on the patient's hemodynamics and oxygenation. A VSD should be suspected in patients who are not doing well postoperatively. Any residual VSD should be repaired if feasible. Truncal valve regurgitation or stenosis may induce left ventricular failure early during the postoperative period.

#### Anesthetic considerations after repair

Obstruction of the pulmonary conduit and the accompanying right ventricular hypertension may occur early or late during the postoperative course. Usually the conduit is unable to support flow in the growing child after several postoperative years. Late development of truncal (aortic) valve regurgitation is possible. For patients who underwent repair later in childhood, residual persistent pulmonary hypertension may be a problem.

## Coarctation of the aorta Pathophysiology

Patients with coarctation of the aorta have a narrowing of the descending aorta near the insertion of the ductus arteriosus into the aorta. Sometimes coarctation of the aorta is associated with hypoplasia of the aortic isthmus proximal to the coarctation. Aortic and mitral valve abnormalities, as well as VSDs, may also be present. With severe obstruction to blood flow in the descending aorta of neonates, systemic perfusion is inadequate, causing profound metabolic acidosis. The increase in left ventricular afterload is not well tolerated, and an elevated left ventricular end-diastolic pressure (LVEDP) reflexively causes pulmonary artery hypertension. Flow below the coarctation may then be provided primarily by rightto-left flow from the right ventricle and pulmonary artery through the ductus arteriosus. Maintaining or reestablishing duct flow can be accomplished with PGE1 infusion, which also reduces the left ventricular afterload.

With less severe forms of coarctation, the child may adapt to the obstruction by developing collateral circulation to the lower body and by increasing the left ventricular muscle mass. Upper extremity hypertension may be the only manifestation of the defect.

#### Anesthetic management

The optimal treatment for neonates, infants and children is currently felt to be complete excision of the area of coarctation and surrounding ductal tissue with endto-end anastomosis. Alternatively, a reverse subclavian patch repair can be undertaken. In this technique, the left subclavian artery is ligated and transected with the proximal portion of the artery used as a flap to augment the area of coarctation. Following this procedure, left arm pulses will be weak or absent. Dacron patch aortoplasty following resection of the posterior coarctation ridge has also been used, but this technique is associated with late development of hypertension and aneurysm formation as compared to end-to-end anastomosis [309]. All approaches require 10–25 min of aortic cross-clamping above and below the area of coarctation.

Acidosis, hypertension or spinal cord ischemia can occur during this period. Paraplegia is an extremely rare but tragic complication of the procedure. Extreme upper body hypertension may compromise left ventricular function and decrease cardiac output, especially to the lower body, and must be expectantly treated. If the elevated arterial pressure in the head is transmitted to the cerebrospinal fluid (CSF), the CSF pressure may be elevated. If these elevated pressures are transmitted to the CSF below the level of the coarctation, net spinal cord perfusion pressure is decreased [310]. Alternatively, if upper body hypertension is overtreated with vasodilators during cross-clamping of the aorta, the arterial pressure may be inadequate in the vasodilated lower half of the body, which is supplied by collaterals. If this occurs, spinal cord or renal ischemia may result [311].

These complications are not so much related to changes in proximal aortic pressure or distal CSF pressure as they are to distal perfusion pressures, adequacy of arterial collaterals, and duration of cross-clamping [312,313]. Monitoring of arterial pressures in the lower extremities may be helpful but impractical during the cross-clamp period. Hyperthermia to 38°C and 40°C during cross-clamping is associated with an increased incidence of paraplegia and transient renal failure [314]. Therefore, mild hypothermia (32–34°C) is used in some centers during aortic cross-clamping as a possible prophylaxis for these rare but tragic problems.

After the cross-clamp is removed and repair is complete, rebound hypertension may be a problem as the patient emerges from the anesthetic. The etiology of this persistent hypertension is multifactorial. The pulsatility of the postcoarctation descending aorta remains reduced following hemodynamically ideal repair [315]. The geometry of the aortic arch following coarctation and distal aortic arch repair is also a determinant of subsequent upper body vascular responses, pulse wave velocity, and left ventricular mass. Anatomy with a high arch height to width ratio (Gothic arch) is associated with impaired vascular response, increased pulse wave velocity, central aortic stiffness and increased LV mass as compared to anatomy with a lower arch height to width ratio (Crenel and normal Romanesque arch anatomy) [316,317]. Abnormalities in baroreceptor reflexes and in the reninangiotensin-aldosterone system have also been implicated as factors in persistent hypertension following successful coarctation repair [318]. Recent evidence suggests that abnormalities in cardiovascular reflexes are already present in neonates with coarctation prior to repair [319].

Development of abdominal pain and bowel ischemia during the postoperative period is related to insufficient flow in the mesenteric artery. Better control of postoperative hypertension has diminished the incidence of the severe form of this syndrome. Although propranolol and hydralazine may be useful for treating the moderate forms of postoperative hypertension, the more severe variety is best treated with sodium nitroprusside during the first few hours after surgery. Captopril may be a useful oral agent for treatment of persistent hypertension, and IV forms of enalapril are now available [320].

## Anesthetic considerations after repair

Persistent hypertension and left ventricular hypertrophy may be problems for anesthetic management in as many as one-third of patients after adequate repair of coarctation of the aorta [321]. If the left subclavian artery was used for the repair, the left arm cannot be used for accurate blood pressure measurements. Restenosis of the coarctation is routinely balloon dilated in the interventional catheterization laboratory.

## Interrupted aortic arch Pathophysiology

In some patients the aorta is completely interrupted at one or more points along the aortic arch. A patent ductus arteriosus and a VSD are nearly always present, and these supply systemic blood flow below the interrupted arch. In addition, left ventricular outflow obstruction may be present [322].

Flow beyond the interruption is supplied entirely by blood that is shunted right to left through the ductus arteriosus. Ductal closure eliminates blood flow to the lower body and leads to metabolic acidosis. Patency of the ductus arteriosus is re-established with PGE1 [323]. There is a left-to-right shunt through the VSD, which may cause excessive pulmonary blood flow and respiratory insufficiency.

#### Anesthetic management

Repair of this lesion in neonates consists of a patch closure of the VSD and a direct anastomosis of the descending aorta to the underside of the transverse arch. Alternatively, the pulmonary artery is banded after the graft insertion and the VSD closure is deferred, but this palliative approach is generally discouraged.

The introduction of PGE1 has substantially improved preoperative resuscitation and perioperative morbidity and has simplified anesthetic management. However, the residual effects of protracted poor perfusion may complicate the intra- and postoperative course of these patients. PGE1 infusion should be continued until the onset of CPB. Circulatory problems after CPB that require inotropic support may be caused by a significant residual VSD, by obstruction of blood flow in the aorta or by subaortic stenosis aggravated by the VSD closure and a narrow subaortic region [324].

Late problems are related to obstruction of the descending aorta with subsequent growth of the child. These problems are similar to those seen with coarctation of the aorta. Subaortic stenosis may also develop and presents considerable surgical challenges to adequate relief of obstruction.

## **Critical aortic stenosis** Pathophysiology

The aortic valves of these patients show thickening and rigidity. They have various degrees of fusion of the valvular commissures. In the newborn the valve appears amorphous. There also may be evidence of endocardial fibroelastosis of the left ventricle and functional or anatomical abnormalities of the mitral valve.

Left ventricular outflow tract obstruction is poorly tolerated in the neonate because it causes left ventricular failure, poor systemic perfusion, hypotension, and pulmonary congestion. Myocardial perfusion is often borderline because the coronary perfusion pressure is relatively low and intraventricular pressure is high. Ventricular fibrillation may occur with surgical manipulation of the heart. In extreme cases, systemic blood flow may be partly supported from the right ventricle by rightto-left flow through the ductus arteriosus, provided that there is atrial septal communication. Stabilization of the patient's condition can be aided by infusion of PGE1 to increase systemic perfusion.

### Anesthetic management

The treatment options for this isolated anomaly in the neonate are percutaneous balloon angioplasty and surgical valvotomy [325]. Myocardial depressants and rapid heart rates are poorly tolerated during either procedure. A defibrillator should be available for immediate use. Preoperative resuscitation of the left ventricle is imperative. Inadequate relief of the obstruction and persistence of left ventricular failure can complicate and prolong the postprocedure course. Residual stenosis or other added hemodynamic burdens further reduce myocardial performance. Mitral regurgitation may continue intraoperatively, and aortic regurgitation may occur after the valvotomy. Myocardial ischemia is not generally a problem after valvotomy. If the obstruction is adequately relieved, afterload reduction and inotropic agents may improve the poor myocardial function often evident postoperatively, especially when there is some degree of aortic regurgitation. In some patients, associated hypoplasia of the left ventricle or mitral valve may inhibit recovery and dictate a therapeutic approach to hypoplastic left heart.

## Hypoplastic left heart syndrome Pathophysiology

Few other congenital heart lesions have provoked as much controversy over management as hypoplastic left heart syndrome. It is a uniformly fatal disease if left untreated and debate continues over staged palliation versus neonatal transplantation versus comfort care [326,327]. The results of surgical management vary between institutions, and are clearly dependent upon expertise and experience, as well as the clinical condition of the neonate at presentation, and degree of hypoplasia of left heart structures [328].

This common example of single-ventricle physiology also represents the most severe form of obstructive left heart lesion. An anatomical spectrum of disease is implied for the lesion, but in its most severe and common presentation there is atresia or marked hypoplasia of the aortic and mitral valves with critical underdevelopment of the left atrium, left ventricle, and ascending aorta. A 1 or 2mm ascending aorta gives rise to the coronary circulation and the head vessels before converging with the ductus arteriosus, where the aorta becomes larger and supplies the circulation to the lower body. Pulmonary venous return arrives in the diminutive left atrium and cannot cross the atretic mitral valve; therefore, it is directed to the right atrium and right ventricle, where common mixing occurs with the systemic venous return and all blood is ejected into the pulmonary artery. Systemic blood flow is then supplied from the pulmonary artery, right to left, across the PDA. As the PDA constricts in the neonatal period, systemic blood flow decreases and all ventricular output is directed to the lungs. The Op/Os ratio approaches infinity as Qs nears zero. Therefore, one has the paradoxical presentation of high PO2 (70-150 mmHg) in the face of profound metabolic acidosis. When the ductus arteriosus is reopened with PGE1, systemic perfusion is re-established, the acidosis resolves and the PO<sub>2</sub> returns to the 40-60mmHg range, representative of a Qp/Qs ratio between 1 and 2.

#### Anesthetic management

Adequate preoperative resuscitation with PGE1 and correction of metabolic acidosis and end-organ dysfunction is crucial to the anesthetic preparation and management of patients with this lesion. Further facilitation of resuscitation can be enhanced by judicious use of inotropic agents, which can optimize cardiac output and blood flow to such organs as the kidneys. However, excessive delay in the timing of surgical intervention will result in a gradual reduction in pulmonary vascular resistance over days, with excessive pulmonary blood flow and inadequate systemic perfusion.

The surgical reconstructive approach to this lesion currently entails three operations, which ultimately aim to provide a 2- or 3-year-old child with a reconstructed aortic arch and a Fontan type of circulation for singleventricle physiology [329]. In the first stage of the reconstruction (Norwood operation), the pulmonary artery is transected at the bifurcation and an anastomosis is performed to the ascending aorta, which has been surgically incised so that the aortic and pulmonary arterial confluences arise together from the single right ventricle as the neo-aorta, which is extended into the remaining native aorta using homograft material. Pulmonary blood flow is established with either a 3.5 or 4mm modified Blalock-Taussig shunt or a 5 or 6mm unvalved RV-to-PA conduit (Sano shunt). The atrial septum is excised to ensure free flow of pulmonary venous return over to the tricuspid valve. In addition to HLHS, the Norwood operation is also used to repair other complex singleventricle defects with systemic outflow obstruction or hypoplasia [330].

The anesthetic considerations are the same as those outlined in detail for patients with single-ventricle physiology. The intraoperative and postoperative management requires careful manipulation of PVR and SVR to provide adequate but not excessive pulmonary blood flow and oxygen delivery while maintaining sufficient systemic and coronary artery perfusion. The precarious nature of the coronary os, which may be extremely small and closely approximated to the suture lines, means that even small variations in hemodynamics may compromise myocardial blood flow. Myocardial depressants are poorly tolerated, and ventricular failure and tricuspid (systemic) valve regurgitation can inhibit recovery.

The physiology of the modified Blalock-Taussig shunt and of the RV-to-PA conduit as a source of pulmonary blood flow differs in some important aspects. With a modified Blalock-Taussig shunt, blood is distributed to the pulmonary circulation in both systole and diastole after it has entered the systemic arterial tree (from the innominate artery to the pulmonary artery) while with a Sano conduit, blood is distributed to the pulmonary circulation in systole before it has entered the systemic arterial tree (from the RV to the pulmonary artery; much like a double-outlet RV). As a result, for a given cardiac output and Qp/Qs, the pulse pressure is wider and the aortic diastolic blood pressure lower in patients with a modified Blalock-Taussig shunt. The higher diastolic blood pressure obtained with the Sano shunt may provide better cerebral, coronary and splanchnic perfusion. The Sano shunt requires creation of a small right ventriculotomy. The RV is the systemic ventricle and the long-term functional consequences of this ventriculotomy are unknown. The Sano conduit is valveless, resulting in some pulmonary insufficiency. The volume load on the RV induced by this is small and probably offset by the fact that Sano shunt patients have a slightly lower Qp/ Qs and volume load than modified Blalock-Taussig shunt patients.

After CPB in the Norwood palliation procedure, the pulmonary vascular resistance may be transiently elevated and the modified Blalock–Taussig or Sano shunt barely adequate to sustain pulmonary blood flow and achieve adequate oxygenation. In this circumstance, hyperventilation with 100% oxygen and alkalosis may be required, with inotropic support of the systemic blood pressure. However, within hours, and sometimes within minutes, pulmonary vascular resistance falls, myocardial function is restored, and the Qp/Qs may become excessive. Hypoventilation with room air and the use of systemic vasodilators are not always effective at reversing the pulmonary steal phenomenon in this circumstance. More drastic measures, such as ventilation with hypoxic gas mixtures or ventilation with added CO<sub>2</sub>, have been advocated by some centers and have been intermittently embraced and abandoned by others over the years [331–333].

The Stage 1 hybrid procedure for HLHS is an alternative to the Norwood Stage 1 procedure with either a modified Blalock-Taussig shunt or a RV-to-PA conduit [334,335]. The hybrid procedure obviates the need for CPB and the associated use of either DHCA or ACP in the neonate. This procedure must be done in a location ("hybrid operating room") that provides full cardiac catheterization infrastructure, including biplane cardioangiography, in a sterile operating room environment. The procedure (Fig. 25.20) involves off-pump placement of a bare metallic stent in the ductus arteriosus, bilateral pulmonary artery banding, and dilation/stenting of the intra-atrial septum. The balloon atrial septostomy is generally performed prior to discharge from the hospital unless there is obstruction of pulmonary venous blood delivery to the right ventricle and pulmonary venous hypertension detected earlier. The physiological burden associated with CPB and DHCA or ACP avoided in the first stage is then incurred at the time of the comprehensive Stage 2 (bidirectional Glenn shunt, Stansel anastomosis, aortic arch reconstruction, and definitive atrial septectomy) performed at 3-6 months of age.

**Figure 25.20** Hybrid palliation in a neonate with hypoplastic left heart syndrome. Note stent in the patent ductus arteriosus and bilateral pulmonary artery banding.

## CASE STUDY

The patient is a term 3-month-old male weighting 4.0 kg s/p Stage repair on day 3 of life for HLHS with mitral and aortic atresia. He presents now for percutaneous endoscopic gastrostomy tube placement. The parents request that a circumcision be performed during the same anesthetic. The patient is poorly tolerant of oral feeds, has demonstrated poor weight gain and somatic growth (25th percentile for height and weight), and has medically managed gastroesophageal reflux. Oral medications are: 1/2 baby aspirin QD, furosemide 8 mg TID, digoxin 0.02 mg BID, captopril 1 mg TID, and ranitidine 8 mg BID.

Echocardiogram done 1 week ago reveals a patent Damis–Kaye–Stansel (DKS) anastomosis, non-restrictive atrial septum, a patent right modified Blalock–Taussig shunt without pulmonary stenoses, and a narrowed aorta at the junction of the isthmus and descending aorta with a peak Doppler-derived gradient of 30 mmHg without evidence of continuous flow in the abdominal aorta. There is mild-to-moderate tricuspid regurgitation and mild-tomoderate global right ventricular dysfunction.

Blood pressure is 70/30 mm Hg in the left arm, heart rate is 165 bpm in sinus rhythm, and the SaO<sub>2</sub> is 75% on room air. CXR reveals an enlarged cardiac silhouette with some increase in pulmonary vascular markings.

#### Questions

- 1. What is your assessment of this child's cardiovascular status? What is the significance of the tricuspid regurgitation and right ventricular dysfunction in the setting of residual arch obstruction? What is the likely mechanism of the tricuspid regurgitation (TR)? Are the increased pulmonary vascular markings due to ventricular dysfunction, a high Qp/Qs or both?
- **2.** Could better medical management of this child's heart failure obviate the need for a feeding tube?
- **3.** Should this infant undergo an arch dilation in the cardiac catheterization laboratory prior to the proposed surgery? Should this patient be considered for an early bidirectional Glenn as a means of decreasing the volume load on his RV and improving the TR?
- 4. Which A.M. medications will you have the parents give and which if any should be held? Is this infant an appropriate A.M. admission case or should he be admitted the night prior to surgery? Is the ICU necessary postoperatively?
- 5. What premedication will you administer? How will you induce and maintain anesthesia? What monitoring is necessary?

Induction of anesthesia proceeds smoothly and the anesthesia is maintained with remifertanil  $0.5 \mu g/kg/min$  and iso-

flurane 0.7% in 100%  $O_2$ . During introduction of the endoscope ST segment depression is noted in  $V_5$ . BP is 60/25 mmHg, HR is 170 bpm, ETCO<sub>2</sub> is 35 mmHg, and SaO<sub>2</sub> is 75%.

## Questions

- **6.** How will you adjust the ventilator (rate, tidal volume, PEEP, FIO<sub>2</sub>)?
- **7.** Is a fluid bolus warranted? Should inotropic support be initiated? Which inotrope?
- **8.** How will you assess the adequacy of systemic oxygen delivery?
- 9. What is the mechanism of myocardial ischemia?
- **10.** Once hemodynamics are stabilized and the ischemia resolves, should the case continue?

### Discussion

The primary goal in the management of patients with single-ventricle physiology is optimization of systemic oxygen delivery and perfusion pressure. This is necessary if end-organ (myocardial, renal, hepatic, splanchnic) dysfunction and failure are to be prevented. This goal is achieved by balancing the systemic and pulmonary circulations. The term "balanced circulation" is used because both laboratory and clinical investigations have demonstrated that maximal systemic oxygen delivery (the product of systemic oxygen content and systemic blood flow) is achieved for a given single-ventricle output when Qp/Qs is at or just below 1/1. This relationship is illustrated in the graphs (Figs 25.21–25.25). Increases in Qp/Qs in excess of 1/1 are associated with a progressive decrease in systemic oxygen delivery because the subsequent increase in systemic oxygen content is more than offset by the progressive decrease in systemic blood flow (Fig. 25.21). Decreases in Qp/Qs just below 1/1 are associated with a precipitous decrease in systemic oxygen delivery because the subsequent increase in systemic blood flow is more than offset by the dramatic decrease in systemic oxygen content.

Since Qp/Qs is not a readily measurable parameter in a clinical setting, pulse oximetry is commonly used as a surrogate method of assessing the extent to which a balanced circulation exists. An arterial saturation of 75–80% is felt to be indicative of a balanced circulation (Fig. 25.22). It is important to point out, however, that an arterial saturation of 75–80% is indicative of a Qp/Qs at or near 1/1 only if the pulmonary venous saturation is 95–100% and the mixed venous (SVC) saturation is 55–60% (Fig. 25.23). In fact, based on these assumptions, the equation used to calculate Qp/Qs in patients with univentricular physiology (SaO<sub>2</sub> –

Figure 25.21 Pulmonary/systemic blood flow ratio vs systemic oxygen delivery.

Figure 25.22 Systemic arterial oxygen saturation vs systemic oxygen delivery.

**Figure 25.23** Pulmonary/systemic blood flow ratio vs mixed venous oxygen saturation (Ssvc%).

Figure 25.24 Pulmonary/systemic blood flow ratio vs systemic arterial oxygen saturation.

Figure 25.25 Pulmonary/systemic blood flow ratio vs arteriovenous oxygen difference.

SsvcO<sub>2</sub>)/SpvO<sub>2</sub> – SaO<sub>2</sub>) can be simplified to:  $25/(95 - SaO_2)$ . In this simplified equation, SpvO<sub>2</sub> is assumed to be 95% and the AV O<sub>2</sub> saturation difference is assumed to 25%. Use of this simplified equation requires that the FIO<sub>2</sub> be at or near 21% in order that the dissolved O<sub>2</sub> content of the pulmonary venous blood can be ignored and an SpvO<sub>2</sub> of 95% used. Unfortunately, an arterial saturation of 75–80% can exist at the extremes of Qp/Qs depending on pulmonary and systemic venous saturation (Fig. 25.24). Specifically, in the presence of a high Qp/Qs it is possible for there to be inadequate systemic oxygen delivery (systemic venous desaturation, a wide AV O<sub>2</sub> difference, metabolic acidosis) in the presence of what is considered to be an adequate arterial saturation of 75–80%. In addition, clinically unrecognized episodes of pulmonary venous desaturation (SpvO\_2 <90%) further confound assessment of Qp/Qs based on SaO\_2.

Mathematical modeling of univentricular physiology reveals that systemic O<sub>2</sub> delivery is a complex function of cardiac output (CO), pulmonary venous O2 content, systemic O<sub>2</sub> consumption, and Qp/Qs. In fact, SaO<sub>2</sub> correlates poorly with Qp/Qs and the measurement of SpvO<sub>2</sub> and SsvcO<sub>2</sub> substantially improves estimation of Qp/Qs. Regression analysis demonstrates that SaO<sub>2</sub> accounts for 8% of the error in estimating Qp/Qs while  $SsvcO_2$  and SpvO<sub>2</sub> contribute 48% and 44% respectively. The figures illustrate the effect of CO (systemic blood flow 450 versus  $300 \,\mathrm{mL/min/kg}$ ) on O<sub>2</sub> delivery, SvO<sub>2</sub>, SaO<sub>2</sub>, and Sa-vO<sub>2</sub> as Qp/Qs varies with  $SpvO_2 = 95\%$  and  $O_2$  consumption = 9 mL/min/kg. It is clear that while SaO<sub>2</sub> remains satisfactory over a wide range of Qp/Qs, O<sub>2</sub> delivery and SsvcO<sub>2</sub> decrease precipitously outside a narrow range of Qp/Qs near 1.0. By the time a SaO<sub>2</sub> of 80% is reached, O<sub>2</sub> delivery is precipitously on the decline. Furthermore, Sa-vO<sub>2</sub> increases linearly with increasing Qp/Qs. Any combination of variables which produces a SsvcO<sub>2</sub> <30% is likely to result in the development of anaerobic metabolism. It is also clear that a higher CO allows maintenance of satisfactory O<sub>2</sub> delivery and SsvcO<sub>2</sub> over a wider range of Qp/Qs.

Debate continues as to the most efficacious method of manipulating the balance of SVR and PVR. Methods to elevate PVR include use of inspired  $N_2$  to reduce alveolar  $O_2$ , use of intentional alveolar hypoventilation to achieve mild hypercarbia and a slightly acidotic pH, or use of inspired  $CO_2$  to achieve mild hypercarbia and a slightly acidotic pH while maintaining normal minute ventilation.

Patients with congenital heart disease are more at risk for the development of subendocardial ischemia than is commonly appreciated. In some congenital lesions abnormalities in the coronary circulation predispose to the development of myocardial ischemia but in many others, ischemia occurs in the presence of normal coronary arteries secondary to myocardial oxygen supply/demand imbalance.

Subendocardial perfusion is largely determined by coronary perfusion pressure that is the mean aortic diastolic pressure minus the ventricular end-diastolic pressure. In addition, the time interval available for perfusion (predominantly diastole) is critical. As a result, the relationship between heart rate, diastolic blood pressure, and ventricular end-diastolic pressure will determine whether subendocardial ischemia occurs.

- Aortic diastolic pressure that is normally low in neonates and infants is further compromised in single-ventricle physiology lesions because these lesions promote diastolic run-off of aortic blood into the lower resistance pulmonary circuit.
- Subendocardial pressure is elevated and subendocardial perfusion is compromised in the presence of an elevated ventricular end-diastolic pressure. Elevated ventricular end-diastolic pressure occurs as the result of the ventricular volume overload, which accompanies single-ventricle lesions, lesions with a high Qp/Qs, and regurgitant atrioventricular and semi-lunar valve lesions.
- The duration of diastole diminishes geometrically as heart rate increases while the duration of systole remains relatively constant. As a direct consequence of this, the time available for diastolic coronary artery perfusion, or diastolic perfusion time, falls geometrically as heart rate increases. Consequently, a higher diastolic pressure is necessary to maintain subendocardial perfusion at higher heart rates. The obvious corollary is that subendocardial perfusion is more likely to be maintained in the presence of a low diastolic blood pressure if the heart rate is slower. In an infant with HLHS and an aortic diastolic pressure of 25mmHg, a heart rate of 130–140bpm may well be tolerated without evidence of subendocardial ischemia whereas it is unlikely that a heart rate of 170–180bpm will be tolerated at the same diastolic pressure.

## Introduction

Procedures involving the spinal column represent one of the most common of the major orthopedic surgeries in the pediatric-aged patient. Spinal deformities requiring orthopedic surgical intervention may be the result of congenital, acquired or traumatic conditions. They may be related to primary defects of the vertebral column (hemivertebrae), neuromuscular conditions (muscular dystrophy, cerebral palsy), neoplastic, infectious or therapy-related problems (radiation). Regardless of the cause, during surgical procedures to correct spinal deformities, there are several potential factors that may result in morbidity or even mortality, including co-morbid disease processes, patient positioning, blood loss, and neurological damage. In the most recent publication from the Perioperative Cardiac Arrest (POCA) registry, cardiovascular causes of cardiac arrest in the pediatric-aged patient were most common (41%), with hypovolemia from blood loss and hyperkalemia from transfusion being the most common causes of cardiovascular deterioration leading to cardiac arrest [1], the majority of these occurring during either craniofacial reconstruction or spinal surgery [1]. In an attempt to limit perioperative morbidity and mortality during spinal surgery in children, these patients should be approached in a standardized manner which includes a preoperative evaluation for the identification of co-morbid features, the intraoperative anesthetic plan with attention to monitoring, patient positioning, maintenance of normothermia, techniques to limit the need for homologous transfusion, control of coagulation function during large-volume transfusions, and the postoperative regimen with maintenance of hemodynamic and respiratory function as well as the provision of postoperative analgesia.

Surgical procedures on the pediatric spine may involve one or several vertebral levels with an incision at any level of the vertebral column (cervical, thoracic, lumbar, sacral). Further variations include an anterior approach, a posterior approach or, in the case of thoracic and lumbar spine procedures, a combined anterior–posterior (AP) procedure. The majority of the procedures performed in the pediatric-aged patient involve long segment surgery on the thoracic and lumbar spine related to either neuromuscular or idiopathic scoliosis.

This chapter reviews the developmental and gross anatomy of the spine, details the more common surgical procedures, outlines the preoperative assessment, discusses intraoperative anesthetic care, including methods to limit the need for homologous blood transfusion and spinal cord monitoring, and provides options for postoperative care, including pain management.

# Developmental and gross anatomy of the spine

## **Overview**

The spine can be divided into four regions corresponding to four natural spinal curves: cervical, thoracic, lumbar, and sacral. These naturally occurring spinal curves are either kyphotic or lordotic. The "normal" spine has thoracic and sacral kyphosis and cervical and lumbar lordosis. The lordosis curvature of the cervical neck and of the lumbar spine develops as a response to weight bearing. As an infant gains strength in the posterior neck muscles, the spine develops with a lordotic curve to support the heavy head. At about 12 months of age, the lumbar spine develops a lordotic curve as a result of walking. Cervical and lumbar lordoses are considered secondary curves due to their dependent development on weight bearing. Their purpose is to keep the spine balanced and to reduce workload on the posterior spinal musculature. The thoracic and sacral kyphosis are considered to be primary curves. Normal cervical lordosis ranges typically from 20° to 40° while lumbar lordosis ranges between 30° and 50°. Acceptable thoracic kyphosis curvature is 20–50°. Medically, there is a broad range of acceptable sacral curvature since S1–5 are fused in a kyphotic angle.

Abnormal curvatures of the spine that this chapter will address are scoliosis and kyphosis [2-4]. Scoliosis is a complex three-dimensional deformity which involves changes in the coronal, sagittal, and axial alignment of the spine. The structural changes include wedging of the vertebral body, rotation of the vertebral body to the convex side of the curve, and deformities of the posterior elements. These structural changes are greatest at the apex of the curve. At this point, the pedicle is shortened and thickened, the lamina heavier, and the spinous process deviated toward the concave aspect of the curve. The vertebral body becomes wedge shaped and thicker on the concave aspect of the curve as a result of the compression forces during spinal growth. On the convex side, the vertebral body becomes thinner since it is expanded. The transverse processes approach the sagittal plane on the convex side and are more towards the concave side in the frontal plane. Additionally, rib prominence is often noticed on the convex side of the curve. This is due to the rotation of the thoracic vertebra. These spinal structural and rib alterations result in an asymmetrical thoracic cavity and may compromise respiratory function, leading to restrictive lung disease.

There are several potential etiologies for scoliosis [2,3]. Congenital scoliosis describes a failure of formation or segmentation of the vertebrae. Neuromuscular scoliosis may be caused by cerebral palsy, muscular dystrophy, myelomeningocele, poliomyelitis, and other disease affecting the muscle or nervous system. Syndromes associated with development of a scoliotic spine include Marfan syndrome, neurofibromatosis, and bone dysphasia. Idiopathic scoliosis is by far the most common of all scoliosis and is classified according to age of development.

Abnormal kyphosis is a spinal deformity that is usually classified as either postural kyphosis, congenital kyphosis or Scheuermann kyphosis. Postural kyphosis, otherwise known as round-back deformity, is a flexible spinal deformity that generally responds to non-operative treatments. Less common but more serious is congenital kyphosis. Surgery is usually recommended with a congenital kyphosis diagnosis given its rapid rate of progression at 5–7° a year and the potential for neurological compromise. Congenital kyphosis, similar to congenital scoliosis, is known to be caused by either a failure of part or all of the vertebral body to form or a failure of segmentation of part or all of the vertebral body.

Scheuermann kyphosis may affect the thoracic, thoracolumbar, and/or lumbar spine. Although several possible etiologies, including hormonal, nutritional, traumatic, vascular, and genetic causes, have been suggested, no definitive etiology for thoracic and thoracolumbar Scheuermann disease has been defined. Trauma is the usual causative factor of lumbar Scheuermann kyphosis. All three Scheuermann kyphosis variations clinically result in rigidity of the affected area. Using a standard radiograph, the diagnostic criteria include  $\geq 5^{\circ}$  of wedging in at least three adjacent vertebrae. Additionally, the vertebral endplates are irregular and the disk plates are narrowed. Schmorl nodes, the result of a herniated disk protruding through the weakened endplate, are often visible radiographically. Depending on the symptoms and the degree of curve, treatment includes both nonoperative and operative modalities. A curve that is ≥75-80° generally warrants surgical intervention.

## Spinal nerves and cord

There are 31 pairs of spinal nerves: eight cervical, 12 thoracic, five lumbar, five sacral, and one coccygeal. The first cervical root exits between the skull and C1 while the eighth cervical nerve root exits between C7 and T1. Thereafter, all nerve roots exit at the same level as their corresponding vertebrae. However, one should note that the nerve roots branch off the spinal cord higher than their actual exit through the intervertebral foramen [4]. Specifically, the spinal nerve must usually travel caudad adjacent to the spinal cord prior to exiting through the vertebral foramen.

Development of these essential nerves is complex. The neural tube is crucial in embryonic development [5] as it becomes the central nervous system and the neural crest forms the majority of the peripheral nervous system. As the neural tube closes, the neural crest migrates between the neural tube and the somite. These neural crest cells form the peripheral nervous system, Schwann cells, and melanocytes. The neural tube becomes the spinal cord, brain, and peripheral afferent nerves and preganglionic fibers of the autonomic nervous system.

While the neural tube closes, the dorsal region separates into two halves, the alar and basal laminae, referred to as the roof and floor plates. The alar plate becomes the sensory pathways, or dorsal columns, whereas the basal plate develops into the motor pathways. The motor pathways or the ventral horn neurons develop axons that form the ventral roots. The axons of the ganglion cells form central processes, which become the dorsal roots and peripheral processes that end in sensory organelles. Motor neurons develop capabilities before sensory nerves, and autonomic nerve function is established last.

Upon gross dissection, one can identify that the motor fibers are located on the anterior side of the spinal cord with the sensory fibers on the posterior side. A group of motor fibers are referred to as ventral roots (anterior roots) while a collection of sensory fibers comprise the dorsal root (posterior root). The sensory nerves have an accumulation of cell bodies outside the spinal cord known as the dorsal root ganglia, which contain the nuclei of the sensory nerves. Directly lateral to the ganglia, the anterior and posterior (ventral and dorsal) nerve roots join to form a common spinal nerve surrounded by a dural sheath. This point is where the peripheral nerve begins. Immediately after formation, the nerve divides into a small dorsal (posterior) ramus and a much larger ventral (anterior) primary ramus. The posterior primary rami serve a column of muscles on either side of the vertebral canal and a narrow strip of overlying skin. All of the other muscle and skin are supplied by the anterior primary rami, which form the cervical, brachial, lumbar, and sacral plexuses and the intercostal nerves.

Additional gross dissection provides a view of the multiple layers of the spinal cord. Protection of the spinal cord is provided by three layers of meninges: dura mater, arachnoid layer, and pia mater. The dura mater, constructed of connective tissue, is the most external layer, gray in color, and is typically easily identified within the spinal canal. A thin subdural space separates the dura mater from the next layer, the arachnoid which provides much of the vascular supply. Between the arachnoid layer and the deepest layer, the pia mater, lies the subarachnoid space. This houses the cerebrospinal fluid, which protects the nerve pathways by providing a fluid as a shock absorber. The pia mater is closely adherent to the spinal cord and the individual nerve roots. Similar to the arachnoid layer, the pia layer is highly vascularized, providing the necessary blood supplies to the neurological structures.

The spinal cord extends from the foramen magnum to L1–4, depending on the age of the patient. With growth and development, the caudal end of the cord moves from its initial position of L3–4 in infancy to its adult level of L1. The end of the spinal cord terminates as the conus medularis and below this, the thick flexible dural sac contains the spinal nerves collectively known as the cauda equina. Within the cauda equina is the filum terminale, which extends from the conus medularis to the coccyx. The filum terminale acts as an anchor to keep the lower spinal cord in its normal shape.

## **Vascular components**

Circulation to the spinal cord requires multiple arteries and arteriolar branches [6,7]. The anterior arterial trunk and the two posterior lateral trunks are important suppliers of blood to the cervical, thoracic, and lumbar cord. All of these arteries arise from the vertebral arteries. Radicular arteries of the spinal cord assist these longitudinal arterial pathways. There are up to 17 radicular arteries anteriorly and as many as 25 posteriorly. The thoracic and lumbar radicular arteries are supplied by the aorta whereas the vertebral arteries supply the majority of the radicular arteries in the cervical spine. Additionally, the artery of Adamkiewicz feeds the lumbar section. It is usually on the left side, located at the level of T9–11. It is the largest of the radicular arteries which supply the spinal cord by anastomosing with the anterior (longitudinal) spinal artery. Injury to the artery of Adamkiewicz from trauma or during surgical procedures can result in devastating ischemia of the lower spinal cord and paraplegia. Additionally, the blood supply of the thoracic spine is more tenuous than the cervical or lumbar spine, especially at the T4-9 watershed area, which is more prone to ischemic injury.

A pair of segmental arteries, arising from the aorta, are present at every vertebral level providing blood flow to the extraspinal and intraspinal structures. The segmental arteries divide into many branches at the intervertebral foramen. A second network of segmental arteries lies within the spinal canal in the loose connective tissue of the extradural space. This second anastomotic network provides an alternative pathway for arterial blood flow, ensuring adequate spinal cord circulation after ligation of the segmental arteries during surgery.

### **Bony components**

The surrounding, outer layer of the vertebra consists of cortical bone, which is dense, solid bone tissue made of compact Haversian systems. Within the vertebra lies cancellous bone, a porous, loosely connected bone. Cancellous or trabecular bone is weaker and more susceptible to disease and loss of bone density than cortical bone. Together, these two types of bone (trabecular and cortical) form the vertebral body which is a thin ring with an hourglass shape. The outer cortical bone extends above and below the superior and inferior ends of the vertebrae to form rims. The pedicles, consisting of dense cortical bone surrounding a medullary canal, are two short, rounded processes that extend posteriorly from the lateral margin of the dorsal surface of the vertebral body. The anterior third of the pedicle and the vertebral body together are referred to as an anterior arch.

The posterior arch, which directly attaches laterally to the anterior arch, includes the laminae, the processes (spinous process, transverse process, superior particular process), and the posterior two-thirds of the pedicles. The laminae are two flat plates of bone extending medially from the pedicles to form the posterior wall of the vertebral foramen. The part of the lamina located between the superior and inferior articular processes is called the pars interarticularis. Spondylolysis is a term used to refer to a defect in the pars, most commonly at the L5 level.

The three spinal processes are projections of bony tissue that are the insertion sites for tendons and ligaments. Specifically, two inferior and two superior articular processes extend from the junction of the pedicles and laminae. The inferior articular processes meet with the superior articular processes to form facet joints. The facet joints are surrounded by a capsular membrane containing synovial fluid that, along with the intervertebral disk, provides mobility of the spine. Additionally, two transverse processes (one on each side of the pedicles) extend laterally and provide an attachment point for ligaments and tendons. A single spinous process arises posteriorly from the junction of the two laminae, again providing an attachment point for ligaments and tendons and serving as a lever for motion of the vertebrae.

Additional bony components include the endplate and apophyseal ring. Endplates are located superiorly and inferiorly within the rim of each vertebral body. Each endplate consists of a cartilaginous external layer and a bony internal layer and provides vascular nutrition to the avascular intervertebral disk. These endplates also serve as a growth ring, predominantly in height, for the vertebral body. The endplates are closed by 17-18 years of age. The apophyseal ring of cortical bone surrounds the vertebral body below portions of the endplate. Surgically, it is important to leave as much of the bony endplate intact as possible, thus preventing subsidence of the device into the soft cancellous bone. The endplate is well vascularized, offering an excellent site for a fusion graft. The apophyseal ring is an ideal site for interbody fusion devices.

# Surgical procedures on the pediatric spine

Scoliosis is a lateral and rotational deformity of the vertebral column. Its etiology is most commonly idiopathic (60-70%), neuromuscular or related to congenital bony deformities [8–10]. Other less common etiologies include post-traumatic injuries and therapy-related problems (previous surgical procedure or radiation for oncological diseases). Idiopathic scoliosis is more common in females with a female : male ratio of 3-4:1. The timing or need for surgery is based on the Cobb angle. The Cobb angle is calculated by identification of the most affected vertebra in the curve, also known as the apical vertebra (Fig. 26.1A,B). The apical vertebra is the vertebral body that has the greatest rotation and displacement from its ideal alignment. The top and bottom vertebrae of the curved or scoliotic segment are identified. These vertebrae have the most tilt, but the least amount of rotation and displacement. They are located above and below the apical vertebra, respectively.

On the radiograph, a line is drawn along the edge of these two vertebrae and extended out. On the top vertebrae, the line starts on the top, is drawn along the top edge, and slopes downward according to the angle of the vertebra. On the bottom vertebra, the line is drawn along the bottom edge in an upward direction. Perpendicular lines are then drawn from both lines so that they meet each other at the level of the apical vertebra. The Cobb angle is the angle formed by these two intersecting perpendicular lines.

Treatment modalities are based on the Cobb angle. If the angle is  $\leq 15^{\circ}$ , follow-up visits are scheduled to monitor the progression of the scoliosis. Bracing is generally indicated for a Cobb angle of 20–40° while surgical intervention is indicated when the Cobb angle is greater than 40° in the lumbar spine or greater than 50° in the thoracic spine. Although some correction of the curve may be feasible, the primary goal of surgical treatment is to stop progression of the curve. Without intervention, progression of the scoliosis will invariably lead to restrictive lung disease and respiratory insufficiency, resulting in severe morbidity (chronic hypoxemia and hypercarbia) and eventual death from cor pulmonale.

Options for surgical treatment include both anterior and posterior procedures. Surgical decision points regarding the approach and surgical therapy include the age of the patient, the underlying cause of the spinal deformity, and the severity of the curve. A patient with neuromuscular scoliosis may be surgically treated with a posterior procedure or may require an anterior spinal release followed by posterior fusion if the deformity is more severe to gain better correction. Although idiopathic scoliosis has been most commonly treated by a posterior approach

**Figure 26.1** Radiographs (A,B) showing the determination of the Cobb angle. The apical vertebra is identified by finding the verbetral body that has the greatest rotation and displacement from its ideal alignment. The top and bottom vertebrae of the curved or scoliotic segment are then identified. These vertebrae have the most tilt but the least amount of rotation and displacement. They are located above and below the apical vertebra, respectively. A line is drawn along the edge of these two vertebrae and extended out. On the top vertebrae, the line is drawn along the top edge and slopes downward according to the angle of the vertebra. On the bottom vertebra, the line is drawn along the bottom edge in an upward direction. Perpendicular lines are then drawn from both lines so that they meet each other at the level of the apical vertebra. The Cobb angle is the angle formed by these two intersecting perpendicular lines.

Figure 26.2 Standard long vertical posterior incision for instrumentation and correction of scoliosis.

**Figure 26.3** Anterior approach for surgical exposure and instrumentation in the treatment of idiopathic scoliosis. With the use of one-lung ventilation, the surgeon's access to the anterolateral aspect of the thoracic and lumbar vertebral bodies can be facilitated.

(Fig. 26.2), in some centers, an anterior approach with instrumentation is being used for idiopathic scoliosis (Fig. 26.3). The underlying diagnosis, the curve magnitude, and the patient's age are all important factors when determining the type of procedure.

One issue that affects the timing of surgery is that the fused segments will no longer grow. As such, complete surgical correction with fusion is undertaken only when spinal growth is nearly complete, generally at  $\geq 12-14$  years of age. When surgical treatment is necessary for

the juvenile idiopathic scoliosis patient, non-segmental posterior spinal instrumentation without fusion is used (i.e. growing rod). This approach allows correction of the scoliosis without decortications and fusion of numerous vertebral segments. Therefore, normal growth will continue. During the growing rod procedure, specific vertebral levels are decorticated and fused in an attempt to allow for correction of the curvature with normal growth of the remaining spine. In general, the convex sides are decorticated and fused so that the concave sides straighten out with the ensuing growth of the vertebral bodies. Patients undergoing growing rod procedures will require repeated operative intervention at 4-6-month intervals to adjust the growing rods. In most cases, definite posterior spinal fusion with instrumentation is performed once growth of the vertebral column has ceased. This approach is used most commonly in patients with bony congenital anomalies or muscular dystrophies that result in early onset (birth to 10 years of age) of scoliosis.

## Anterior surgery for scoliosis

Although idiopathic scoliosis has generally been treated via a posterior approach with posterior spinal fusion, anterior approaches have more recently been developed. Advocates of the anterior approach believe that successful correction of the curve can be achieved while limiting the extent of the fusion, thereby maintaining flexibility and mobility of the spine.

For the anterior approach, the patient is placed in the lateral decubitus position with the operating table flexed. The upper arm is moved forward and rotated away from the posterior portion of the spine. An axillary roll is placed to minimize pressure on the brachial plexus and the vascular structures. Depending on the level of scoliosis (thoracic versus lumbar), entry into the thoracic cavity may be required. When the thoracic cavity is entered, the use of one-lung ventilation may greatly facilitate the surgeon's access to the anterior spine. Following skin incision, access to the spine is achieved through the bed of the convex fifth rib for visualization of T5-12 or via the bed of the 10th rib for access to the thoracolumbar spine. The initial incision extends anteriorly to the lateral border of the rectus sheath with its length determined by the number of levels required to be exposed. The rib to be excised corresponds to the most superior vertebral body requiring exposure. For example, with a T6-12 anterior fusion, the fifth rib is excised. The costal cartilage is split anteriorly which can later serve as a landmark for closure.

Once the spine is exposed, retractors are positioned to protect the lung tissue and peritoneum. The surgeon can now access the vertebral disk or vertebral body with the caveat that segmental vertebral vessels (artery and vein) are present at each level. When necessary, these vessels can be ligated as vascular compromise of the spinal cord after ligation is uncommon even if several segmental vessels are ligated.

## Video-assisted thoracoscopic surgery

Video-assisted thoracoscopic surgical (VATS) techniques have also been incorporated into the surgical treatment of scoliosis. As with other types of VATS procedures, specialized surgical equipment is necessary, including the scope, light sources, cameras, flexible portals, monitors, and specific instrumentation. For the successful completion of such procedures, one-lung ventilation (OLV) is generally mandatory to allow for adequate visualization of the spine (see below). Contraindications to this approach include the inability to tolerate OLV, severe respiratory insufficiency, high airway pressures with positive pressure ventilation, and previous thoracotomy which may result in adhesions, thereby limiting surgical access and the ability to obtain lung deflation during OLV. Positioning and preparation are generally the same as for the open, anterior approach. The surgical landmarks for trocar and instrument placement include the scapular border, 12th rib, and iliac crest.

The first portal is placed at or near the T6–7 interspace in the posterior axillary line. After surgical incision, dissection continues with electrocautery through the intercostal muscle to enter the thoracic cavity. Once adequate lung deflation is ensured, flexible ports are inserted in the intercostal spaces with a trocar. A blunt-tipped needle is placed adjacent to the thoracic spine and a roentgenogram is obtained to confirm the disk spaces intraoperatively. The parietal pleura is completely resected without ligation of the segmental thoracic vessels. The disks and endplates are then removed. After the necessary diskectomies are completed, rib grafts are harvested through the portal sites. Prior to closure, a chest tube is placed through the most posterior inferior portal. The pleura may be closed or left open. The chest tube is connected to a water seal and the anesthesiologist tests for an air leak in the reinflated lung.

Potential perioperative issues include bleeding, damage to the lung tissue, dural tears, lymphatic injury, and sympathetic dysfunction on the operative side. If hemostasis cannot be obtained or visualization is not optimal, conversion to an open anterior approach may be required. Postoperatively, pulmonary problems may occur within the deflated lung, leading to recurrent atelectasis.

## Posterior surgery for scoliosis

Over the past 20 years, the surgical approach to scoliosis has changed with advances in segmental posterior spinal instrumentation. As such, correction of both sagittal and coronal plane spinal deformities has improved over older

**Figure 26.4** Jackson table used for prone positioning of patients during a posterior approach for spinal fusion.

systems such as the Harrington rods. The posterior surgical approach with instrumentation uses the spinous processes, the pedicles, the facets, and the laminae to control the alignment of the vertebral bodies with laminar hooks, pedicle hooks, pedicle screws, facet screws, and wires.

For the classic posterior approach, the patient is placed prone on an appropriate spinal frame with the abdomen hanging freely to avoid compression of the intraabdominal portion of the inferior vena cava and prevent interference with diaphragmatic movement. Traditionally, a Hall frame or, more recently, a Jackson table is used to support the patient in this position (Fig. 26.4). The patient's face should be well padded without pressure on the eyes (see below for an expanded discussion of postoperative visual compromise) (Fig. 26.5). The patient's back is completely draped with exposure to the entire spine and the iliac crest for harvesting of the bone graft. A midline incision over the spinous processes is made followed by splitting the apophysis and subperiosteal dissection to expose the spine laterally to the transverse processes. Placement of a blunt needle is followed by confirmation of the appropriate vertebral body using either fluoroscopy or plain radiograph. After a facetectomy and wide posterior release at each level, instrumentation is placed. The surgeon inserts pedicle hooks, pedical screws, laminar hooks, and sublaminar wires at the vertebral levels requiring surgical correction of the scoliosis. The first rod is placed on the concave side of the curve and rotated to correct the spinal deformity. This represents a key moment during the instrumentation procedure as alterations in spinal cord perfusion may occur during correction of the curvature. If changes are to be observed with neuromonitoring, it is usually during this portion of the surgery. Once correction is maintained with

**Figure 26.5** Specialized cushion or pillow used for positioning on the Jackson table. When applied appropriately, the pillow should eliminate pressure points on the face and eyes. The endotracheal tube can be brought out through the side hole of the pillow or through the bottom of the pillow and the supporting structure of the Jackson table.

the first rod, the second rod is placed. Cross-links are added, allowing an increase in torsional stiffness of the rod's construction. Decortication of the posterior elements prepares the spine for fusion. The placement of bone graft completes the procedure and is followed by a layered closure of the muscles, fascia and skin.

## **Preoperative and intraoperative care**

## **Preoperative evaluation**

The initial step in the perioperative care of pediatric patients presenting for spinal surgery is the preoperative evaluation to identify co-morbid features which may affect their perioperative care and to maximize the patient's preoperative state in the hope of preventing perioperative complications. Of primary importance when evaluating children and adolescents for spine surgery is the impact of the disease process on airway management and cervical spine stability. Cervical spine stability is the spine's ability to resist displacement under normal physiological loads. Patients presenting for cervical spine surgery, especially the trauma patient, should be assumed to have an unstable cervical spine or the potential for subluxation during flexion or extension of the neck which can result in spinal cord compromise [11]. Cervical spine issues and resultant instability may be related to a traumatic event or a congenital syndrome with associated cervical spine involvement such as trisomy 21, achondroplasia or other more uncommon craniofacial syndromes such as Pfeiffer, Apert or Crouzon syndrome [12-15]. Subluxation and upper cervical intervertebral fusions have been reported in 30% of

patients with Pfeiffer syndrome and odontoid hypoplasia with the risk of C1–2 subluxation has been reported in patients with Crouzon syndrome and the mucopolysaccharidoses [13,14]. Ligamentous laxity and the potential for cervical subluxation is also present in patients with trisomy 21 [15].

Patients with achondroplasia may have associated stenosis of the foramen magnum which may also affect airway management. Foramen magnum stenosis results from hypertrophy of the bony margins of the foramen magnum and can lead to narrowing of the cervical spinal canal with compression of the cervical spinal cord or medulla. In children with achondroplasia, who manifest neurological or respiratory symptoms related to foramen magnum stenosis, the diameter of the foramen magnum has been shown to be more than three standard deviations smaller than the mean for age-matched controls of normal stature.

Even in the absence of associated syndromes, cervical spine involvement from scoliosis or kyphosis may limit normal cervical spine movement, thereby leading to difficulties with endotracheal intubation. Given these issues, as time permits, an evaluation of the cervical spine for subluxation may be indicated as part of the preoperative work-up in such patients. Preoperative evaluation for cervical spine abnormalities includes a physical examination with an evaluation of neck movement supplemented with radiograph examination (flexion/extension films) or computed tomography scanning. If potential issues are identified during the evaluation process, various approaches to obtaining endotracheal intubation are available which can be performed in the anesthetized, sedated or awake state [11]. During anesthetic induction and airway manipulation, prevention of cervical spine movement can be accomplished by the use of manual in-line stabilization. In older, co-operative patients, awake airway techniques commonly used in the adult population (intravenous sedation with glossopharyngeal nerve and superior laryngeal nerve blockade) followed by direct laryngoscopy or fiber-optic bronchoscopy for endotracheal intubation may be feasible.

Patients with craniofacial syndromes may also have midface anatomical issues that affect airway management, including ease of bag-valve-mask ventilation and endotracheal intubation [12,13]. Common features of many of the craniofacial syndromes include micrognathia, microstoma, midface (maxillary) hypoplasia, and lip/palatal abnormalities. Glossal hypertrophy may be present in neuromuscular conditions or in association with trisomy 21. Although beyond the scope of this chapter, identification of potential difficulties with direct laryngoscopy and endotracheal intubation should prompt alternative approaches to the airway, including indirect video laryngoscopy or fiber-optic techniques. Additionally, there should be ready access to the equipment required for management of a difficult airway, including various sizes of laryngeal mask airway or a similar type of supraglottic device. See Chapter 14 for detailed discussion of management of the difficult airway.

Another situation faced by the anesthesia provider which affects perioperative airway management is the patient with an in situ tracheostomy requiring airway management and prone positioning for spinal surgery. Although there have been some suggestions regarding strategies to manage a tracheostomy in the perioperative period, including use of an existing tracheostomy, change to a cuffed tracheostomy, placement of an endotracheal tube (ETT) through the tracheostomy stoma or use of standard orotracheal intubation [16], there are no definitive consensus guidelines available. Although the presence of a tracheostomy initially may facilitate airway management, positioning and other intraoperative issues may affect airway patency. Most importantly, if a standard tracheostomy tube is used, given its rigidity, traction from the anesthesia circuit may cause posterior displacement of its lumen with occlusion against the tracheal wall [17]. Such problems can generally be avoided by exchanging the tracheostomy for an appropriately sized armored endotracheal tube. Use of the armored tube may avoid positional changes related to traction on the tube due to the weight of the anesthesia circuit. After exchange of the tracheostomy, the armored ETT can be secured in place using a suture to the neck or the anterior chest wall. Given that the tracheostomy site enters the trachea closer to the carina than standard endotracheal intubation techniques, careful placement and auscultation of bilateral breath sounds are necessary to avoid endobronchial intubation. Appropriate positioning of the endotracheal tube should be confirmed in the neutral position and with the neck flexed.

Following evaluation of the airway and cervical spine, the preoperative examination follows a sequential organ system approach. Co-morbidities of the central and peripheral nervous and muscular systems may be a frequent feature in the pediatric patient presenting for spine surgery. Pediatric patients with scoliosis presenting for spinal surgery may have associated cerebral palsy and static encephalopathy or associated neuromuscular conditions. The preoperative assessment and documentation of neurological and neuromuscular function will help in the identification of perioperative injuries related to the surgical procedure or positioning and aid in differentiating these from pre-existing conditions. Patients with cerebral palsy may have an associated seizure disorder with the need for one or more anticonvulsant medications. During the preoperative evaluation, therapeutic serum anticonvulsant concentrations should be documented and the parents instructed to give the usual anticonvulsant medications on the morning of surgery. Although many of the newer medications have long half-lives, perioperative dosing is recommended whenever feasible. Intraoperatively, appropriate conversion to intravenous administration is available for several anticonvulsant medications so that therapeutic levels are maintained perioperatively. Postoperatively, dosing can be converted to the oral route when the patient's status permits or alternative routes of delivery (intravenous or rectal) may be used.

Chronic anticonvulsant therapy leads to the induction of hepatic enzymes, thereby altering the pharmacokinetics and pharmacodynamics of several drugs, including neuromuscular blocking agents (NMBAs). Increasing the intraoperative doses of NMBAs and certain intravenous anesthetic induction agents may be necessary with concomitant anticonvulsant therapy [18–20]. Additionally, a secondary factor affecting dosing of NMBAs is the fact that many anticonvulsant agents have weak neuromuscular blocking properties, leading to the upregulation of acetylcholine receptors. Therefore, increased dosing requirements may be seen even for agents such as *cis*atracurium which are not dependent on hepatic metabolism for their elimination.

Mental retardation and associated visual and hearing disturbances may present a major challenge in the communication with and assessment of the patient. Some degree of intellectual impairment is noted in 30–50% of patients with Duchenne muscular dystrophy (DMD) and in a greater percentage of patients with cerebral palsy. In addition to limiting preoperative co-operation and understanding, these issues may be particularly problematic during the postoperative period when pain assessment may be difficult (see below).

Depending on the degree of scoliosis and the presence of co-morbid disease processes, there may be some degree of preoperative compromise of respiratory function from restrictive lung disease. Progressive scoliosis results in a restrictive defect with a decrease in the vital capacity, total lung capacity, and forced expiratory volume with no change in residual volume. The decrease is greater in patients with congenital or infantile scoliosis when compared to adolescent scoliosis [21,22]. The severity of respiratory impairment is related to the angle of the scoliosis, the number of vertebral levels involved, the cephalad level of the scoliosis, and the loss of the normal thoracic kyphosis. Respiratory compromise is worse in younger patients and those with infantile or congenital scoliosis. Muirhead and Conner noted that there was a moderate or severe ventilation defect (40-59% predicted for age) in 14 of 41 children with either infantile or congenital scoliosis compared to only four of the 51 adolescents with idiopathic scoliosis [21]. No child with a vital capacity ≥40% predicted for age required postoperative respiratory support. Other investigators have demonstrated that the effect of the surgical procedure on lung function is dependent on the surgical approach and the type of surgery. Surgical procedures involving the thorax (anterior spinal fusion) lead to a reduction in lung function at 3 months with a return to preoperative values by 2 years while the standard posterior approach leads to improved respiratory function at both 3 months and 2 years [22,23].

Of even greater concern when providing preoperative care for patients with neuromuscular disorders is the ability to determine the degree of respiratory compromise which is a contraindication to scoliosis surgery. Given its greater impact on respiratory function, this need is greater if an anterior approach is chosen when compared to a standard posterior approach. In the adult population, it has been suggested that prolonged postoperative mechanical ventilation is likely to be required in patients with a reduction of the forced vital capacity (FVC) or the forced expiratory volume in 1 second (FEV<sub>1</sub>) to less than 40% predicted. However, as there are generally fewer comorbid features in children, such as associated cardiac disease when compared with adults, it is likely that the same criteria used to predict postoperative respiratory function in adults should not necessarily be applied to pediatric patients.

The lack of predictive power of preoperative pulmonary function testing in children has been previously demonstrated by Tobias et al in a cohort of pediatric oncology patients requiring repeated thoracotomy for excision of metastatic disease [24]. After 32 thoracotomies in 19 pediatric oncology patients, there was a consistent decrease in pulmonary function test (PFT) values with a decrease in the FVC (% predicted for age) from  $68 \pm 3.6\%$ to  $60 \pm 2.4\%$  (p < 0.01) and the FEV<sub>1</sub> from  $69 \pm 4.2\%$  to  $60 \pm 3.8\%$  (p < 0.01). There was no permanent morbidity noted even in patients with decreased preoperative respiratory function. Five of the patients had severe preoperative decreases in pulmonary function (≤40% predicted for age). Although the incidence of morbidity, defined as postoperative mechanical ventilation, supplemental oxygen for more than 12h or persistent air leak, was three out of five in this group versus three of 20 in patients with mild or moderate lung disease (PFT 60-80% predicted for age), there was no postoperative mortality and no need for prolonged mechanical ventilation.

Similar data have more recently been reported by Harper et al in a cohort of adolescents with Duchenne muscular dystrophy and compromised respiratory function [25]. In their cohort of 45 patients, 20 had a preoperative FVC ≤30% predicted for age. The authors reported no statistically significant difference in several postoperative variables, including the duration of postoperative endotracheal intubation, duration of bi-level positive airway pressure (BiPAP) support, total time with ventilator assistance, and inpatient stay. However, there were significant cardiorespiratory complications in both groups, demonstrating that this is a high-risk population with the potential for perioperative complications. Five patients (25%) with an FVC  $\leq$ 30% had complications including acute respiratory distress syndrome (ARDS), respiratory tract infections, and the need for a tracheostomy while four (16%) with a preoperative FVC  $\geq$ 30% had complications. The one death in the cohort was in a patient with an FVC of 18% who initially had an uncomplicated postoperative course, but went on to develop ARDS.

Although the majority of patients presenting for spinal surgery without co-morbid conditions (idiopathic scoliosis) will not require postoperative mechanical ventilation, factors such as co-morbid conditions, intraoperative blood loss, and surgical duration may mandate providing a short period of postoperative mechanical ventilation to ensure patient safety. In addition to respiratory function, airway issues may necessitate postoperative mechanical ventilation. Prolonged procedures in the prone position may result in airway or lingual edema, thereby necessitating postoperative endotracheal intubation. Almenrader and Patel reviewed their 18-month experience in a cohort of 42 patients with non-idiopathic scoliosis [26]. In their series, 23.8% of patients required postoperative mechanical ventilation. Consistent with the data of Harper et al, they noted that patients with Duchenne muscular dystrophy and those with a preoperative FVC ≤30% were more likely to require postoperative respiratory support (40% in their series). They suggest the use of non-invasive ventilator techniques to ease the transition from mechanical to spontaneous ventilation.

In addition to respiratory issues in patients undergoing scoliosis surgery, perioperative morbidity and mortality may also be related to secondary cardiac involvement. Myocardial dysfunction in this group of patients may be related to the primary disease process such as muscular dystrophy or, less commonly, chronic hypoxemia from restrictive lung disease and associated cor pulmonale. The latter is uncommon as scoliosis is frequently addressed prior to the development of chronic cardiovascular effects. More commonly, various neuromuscular conditions such as the muscular dystrophies or myotonic dystrophies may lead to myocardial involvement with alterations in the contractile function or conduction abnormalities. Of these conditions, Duchenne muscular dystrophy is the most common disorder, with an incidence of 1 in 3300 male births. It is inherited as an X-linked disorder generally presenting as weakness during the first decade of life, usually between 4 and 8 years of age. The genetic defect results in a deficiency of the protein dystrophin in skeletal, cardiac, and smooth muscle. Although skeletal muscle involvement with weakness predominates as the major clinical feature of this disorder, as these patients enter the second and third decades of life, progressive myocardial involvement leads to impaired myocardial contractility, conduction disturbances, and arrhythmias.

The potential impact of this disorder on perioperative morbidity and even mortality cannot be ignored as the literature has demonstrated a significantly increased risk during anesthetic care in these patients [27]. Sethna et al reported intraoperative cardiac arrest and death in two of 25 patients requiring anesthetic care during various surgical procedures [27]. Given the potential for associated myocardial involvement in many patients, some type of preoperative screening to assess myocardial function and conduction disturbances may be indicated. In most cases, this will include transthoracic echocardiography and a 12-lead electrocardiogram (ECG). More recently, it has been suggested that the combination of a preoperative chest radiograph and ECG can be used to screen for the presence of myocardial dysfunction [28]. Although Clendenin et al noted that an abnormality on the chest radiograph (increased cardiac silhouette) and abnormal findings on the ECG were predictive in 81% of their 255 patients, echocardiography remains the gold standard [28].

A second group that tends to be increasing in the spinal surgery population is those with associated congenital heart disease. In this group of patients, especially those with residual lesions or single-ventricle physiology, preoperative assessment is of paramount importance to guide intraoperative care. In these patients or when myocardial dysfunction is identified, additional intraoperative monitoring (transesophageal echocardiography) with consultation from pediatric cardiology may be required. Furthermore, close observation during positioning is suggested as these patients may deteriorate rapidly with the institution of positive pressure ventilation or when turned prone due to changes in venous return or increased intrathoracic pressure.

The preoperative evaluation and preparation of the patient are essential to limit allogeneic blood product use. Simple measures to reduce the need for allogeneic blood products include identification and treatment of anemia prior to elective spinal surgery. In the adult population, age greater than 50 years, preoperative hemoglobin less than 12g/dL, fusion of more than two levels, and transpedicular osteotomy have been identified as independent risk factors for the need for perioperative transfusion [29]. Routine screening for the identification of preoperative anemia and its treatment are particularly important in patients with poor nutritional status or following menarche. Although treatment with oral iron is generally effective, a more rapid response within 2–3 weeks can be obtained with intravenous iron therapy [30].

More aggressive and more expensive preoperative blood avoidance techniques may include the administration of erythropoietin to augment preoperative autologous donation or the yield of intraoperative isovolemic hemodilution (see below). Issues with erythropoietin include varying reports of its efficacy, with some studies showing no benefit, variations in dosing regimens, and the need for weekly visits with laboratory measurement of hemoglobin and subcutaneous injections, as well as the potential to increase the incidence of postoperative deep vein thrombotic events. In a retrospective analysis of 178 pediatric patients undergoing spinal surgery, Vitale et al reported that homologous transfusions were administered to 30.6% of patients who did not receive erythropoietin versus only 17.5% of those who did (p < 0.05) [31]. In a subgroup analysis of patients with idiopathic scoliosis, the need for homologous transfusion was 3.9% in those receiving erythropoietin versus 23.5% of those who did not (p = 0.006). They also noted a shorter hospital stay in those patients who had received erythropoietin (6.7 versus 9.3 days, p = 0.02). Subsequent work from the same investigators demonstrated no benefit of preoperative erythropoietin in limiting the need for allogeneic transfusion in a cohort of 61 patients with neuromuscular scoliosis [32].

Other investigators have suggested the efficacy of erythropoietin when used in combination with an autologous blood donation strategy [33]. Although such techniques are feasible in the pediatric population, given the need for repeated phlebotomy and laboratory analysis with the inherent time, cost, and pain issues for the patient, there has been a significant decrease in the interest in and use of preoperative autologous blood donation. More recently, the safety of erythropoietin has been questioned. In the adult, population, Stowell et al reported a higher incidence of deep vein thrombosis of 4.7% versus 2.1% in a cohort of 680 adults [34].

Patients presenting for major orthopedic surgery may have chronic medical or nutritional conditions that affect coagulation function. The chronic administration of anticonvulsants including phenytoin and carbamazepime may adversely affect coagulation function. Nutritional issues and poor intake of vitamin K may result in a low levels of vitamin K-dependent coagulation factors, leading to preoperative coagulation dysfunction. Preoperative screening of coagulation function and simple measures such as the administration of vitamin K (oral or intramuscular) may alleviate such problems. Patients with chronic orthopedic problems and pain frequently use non-steroidal anti-inflammatory agents (NSAIDs). Although acetylsalicylic acid irreversibly inhibits cyclo-oxygenase and platelet function for the life of the platelet, NSAIDs cause reversible inhibition of platelet function that is dependent on the plasma concentration and hence the half-life of the NSAID. Discontinuation of most NSAIDs for 2–5 days prior to surgery will result in return of normal platelet function.

## Premedication, anesthetic induction, and positioning

Various agents or combinations may be required preoperatively in patients undergoing spinal surgery. Premedication regimens may include:

- high-flow nebulization of albuterol and an anticholinergic agent such as ipratropium in patients with airway reactivity or lidocaine if a fiber-optic intubation is planned due to a difficult airway scenario
- gastrointestinal prophylaxis in patients at risk for aspiration may include agents to increase gastric pH such as H<sub>2</sub>-antagonists (ranitidine), proton pump inhibitors or oral non-particulate antacids and motility agents such as metoclopramide
- dexamethasone for patients with airway reactivity and to decrease postoperative nausea and vomiting
- an anticholinergic agent such as glycopyrrolate or atropine to dry secretions, especially if a fiber-optic intubation technique is planned, to blunt cholinergicmediated airway reactivity and to prevent bradycardia during laryngoscopy and ET intubation
- hydrocortisone if patients are chronically receiving supplementation (chronic corticosteroid therapy is frequently used in patients with Duchenne muscular dystrophy given data suggesting its ability to slow progression of the disease [35])
- an anxiolytic which generally follows the standard practice in pediatric anesthesia including either oral midazolam in patients without intravenous access or intravenous midazolam in those with pre-existing IV access.

Following premedication, the patient is transported to the operating room and routine American Society of Anesthesiologists' monitors are placed. From the start of anesthetic care, attention should be paid to the maintenance of normothermia. Hypothermia is particularly common and may occur rapidly in patients with cerebral palsy and failure to thrive who may have limited body fat. Patients with static encephalopathy and related conditions may have abnormal central control of temperature, thereby placing them at further risk of hypothermia. In addition to other physiological effects, perioperative hypothermia has been shown to be a key factor in increasing intraoperative blood loss during major surgical procedures [36,37]. The maintenance of normothermia includes preoperative warming of the patient using forced air devices, keeping the operating room warmed until the patient is positioned and covered, warming intravenous fluids, blood and blood

Figure 26.6 Wire-reinforced endotracheal tube to prevent kinking during prone positioning with head flexion.

products, and the intraoperative use of forced air warming devices.

The technique and medications used for the induction of anesthesia are guided by the patient's co-morbid conditions, the assessment of the ease of tracheal intubation, and the patient's preference and/or demographics (age and cognitive function). For anterior or posterior spine surgery, a reinforced endotracheal tube may be used to prevent inadvertent airway occlusion during surgical dissection and/or neck flexion (Fig. 26.6). During prolonged cases with neck flexion, there may be a risk for nonreinforced ETTs to warm, bend, and obstruct if they are held in a flexed position over a protracted period of time. Although the time-honored practice has been to use uncuffed ETTs in patients less than 6-8 years of age, given limited access to the airway during the surgical procedure and the potential need for occlusion of the airway to provide adequate positive pressure ventilation, cuffed ETTs are being used more frequently to provide intraoperative anesthetic care. Once the ETT is secured in place and an esophageal stethoscope placed, a gauze roll is placed in the mouth to prevent biting during motorevoked potential stimulation (see below).

Several agents are available for the induction and maintenance of anesthesia in patients with stable cardiovascular function. In the absence of IV access, anesthetic induction can be carried out with sevoflurane in oxygen or oxygen and nitrous oxide. In patients with previously established IV access, several of the commonly used IV induction agents are suitable. If there is a plan for extubation in the operating room or immediately postoperatively, propofol may provide a more rapid awakening and a better recovery profile during the immediate postoperative period than induction with barbiturates such as thiopental. Although its effect on adrenal function has led to a re-evaluation of its use during endotracheal intubation in the critically ill ICU patient, etomidate may still be an appropriate choice for anesthetic induction in patients with diminished myocardial function.

Once adequate bag-mask ventilation has been demonstrated, inhalation or intravenous induction techniques can be followed by the administration of a nondepolarizing NMBA. Succinylcholine is contraindicated in patients with various neurological and myopathic conditions given the potential for rhabdomyolysis, hyperkalemia, and cardiac arrest. Similar problems with succinylcholine may occur in patients within 48-72 h following a spinal cord injury. In the absence of concerns about a difficult airway, endotracheal intubation can be facilitated with an intermediate-acting (vecuronium, rocuronium, cis-atracurium, atracurium) or short-acting (mivacurium) non-depolarizing NMBA [38]. The dosing of these agents should be titrated using train-of-four (TOF) monitoring, especially in patients with DMD and other myopathies as even a single dose for endotracheal intubation of an intermediate-acting NMBA may result in a prolonged duration of neuromuscular blockade. When motor-evoked potentials are being used to monitor spinal cord function, a single dose of a non-depolarizing NMBA can be used to facilitate endotracheal intubation with the understanding that repeated dosing will generally not be used once the patient is turned prone.

After the airway is secured, adequate intravenous access and invasive cardiovascular monitoring as indicated are obtained. Several factors may be responsible for hemodynamic changes during spinal surgery in pediatric patients, including co-morbid conditions, positioning on the operating room table, and blood loss. In general, for major spinal surgical procedures, two large-bore peripheral intravenous cannulas are placed for the rapid administration of fluids, blood, and blood products. Additional invasive hemodynamic monitoring with an arterial cannula and central venous access may be obtained, depending on the patient's condition and the surgical expertise. In experienced hands, blood loss is generally minimal in patients with idiopathic scoliosis (400-600 mL), thereby eliminating the need for central venous access. The accuracy of central venous pressure (CVP) monitoring in the prone position has been questioned [39]. In a cohort of 12 pediatric patients undergoing spinal fusion, hemodynamic assessment using CVP monitoring and echocardiography was assessed in the supine positioning and after positioning prone. CVP increased from a mean of 8.7 to 17.7 mmHg while left ventricular end-diastolic diameter decreased from 37.1 mm to 33.2 mm, thereby leading the authors to conclude that CVP may be a misleading monitor of cardiac volume in scoliosis patients in the prone position.

Once appropriate vascular access and monitoring have been established, the patient is then positioned on the operating room table. Patient positioning will be dependent on the specific type of surgery, with either prone positioning for posterior spinal fusion or lateral positioning if an anterior approach is chosen. If the cervical spine and upper thoracic vertebrae are included in the surgical field, neutral positioning of the head is required. Alternatively, for posterior spinal fusion that does not involve the lower cervical or high thoracic area or isolated lumbar surgery, the patient can be positioned prone and the head turned 90°, thereby limiting the potential for pressure points on the eyes and face. Regardless of the positioning, careful padding of pressure points is needed since many of these procedures can last up to 8h.

Positioning should also take into account techniques to minimize venous pressure at the surgical site to reduce bleeding. This is done by using rolls under the chest and pelvis to keep the abdomen free and by reverse Trendelenburg positioning. Mild reverse Trendelenburg positioning also helps to limit the development of dependent edema in the face, tongue and upper airway and may also limit the increase in intraocular pressure (IOP) which may occur with prone positioning. Alternatively, specialized frames (e.g. Wilson frame or Jackson table) can be used to position the patient and decrease venous pressure and therefore surgical bleeding (see Fig. 26.4). Use of the Jackson table with longitudinal bolsters has been shown to have the least effect on cardiovascular performance [39,40]. Keeping the abdomen free also facilitates mechanical ventilation by preventing compromise of diaphragmatic movement.

A major concern during surgical procedures in the prone position is the occurrence of postoperative visual impairment or blindness. Increased IOP with prone positioning has been postulated to be one of the contributing factors for this rare but devastating complication of blindness following prone surgical procedures [41-43]. In a cohort of 20 adults undergoing surgery in the prone position, IOP was  $19 \pm 1 \text{ mmHg}$  in the awake state, decreased to  $13 \pm 1 \,\text{mmHg}$  in the supine position after the induction of anesthesia, but then increased to  $40 \pm 2$  mmHg after  $320 \pm 107$  min in the prone position. Although various theories have been suggested to explain postoperative visual loss (POVL), no unifying theory (ischemic, thrombotic, oncotic, embolic) has been accepted. Given the devastating consequences and potential medicolegal implications of this phenomenon, the Postoperative Visual Loss Registry was established in 1999 in an attempt to determine factors associated with POVL [44]. In the registry, the authors reviewed 93 voluntarily reported cases of visual disturbances following spine surgery and noted that of the 83 cases of ischemic optic neuropathy, blood loss greater than 1000 mL and surgical duration of greater than 6h were present in 96% of the cases. Although other etiologies are feasible and appropriate positioning is mandatory to avoid ocular pressure, the current literature suggests that the majority of factors, including surgical duration and blood loss, are frequently outside the control of the anesthesia provider.

For anterior procedures, the patient will be positioned in the lateral position and a thoracotomy performed to gain access to the vertebral column. Alternatively, there is increasing experience with the use of thoracoscopic approaches for such procedures. Regardless of the approach (open thoracotomy or thoracoscopy), OLV can greatly enhance the surgeon's view of the surgical field.

## One-lung ventilation for anterior approaches

Options for OLV include a double-lumen endotracheal tube (DLT), a bronchial blocker or selective mainstem intubation [45-47]. The smallest commercially available DLT is 26 French, which can be used in patients who are 8-10 years of age. Advantages of a DLT include rapid placement, easy separation of the lungs, completion deflation of the operative lung, improved pulmonary toilet with access for suctioning of both lungs, the ability to rapidly switch to two-lung ventilation if needed, and the feasibility of administering continuous positive airway pressure (CPAP) or oxygen insufflation to the operative lung should this become necessary to improve oxygenation. In patients whose size precludes the use of a DLT, the bronchus on the operative side can be occluded with a balloon-tipped catheter that is placed using fiberoptic bronchoscopic guidance. Several different devices can be used as bronchial blockers including a Fogarty embolectomy catheter, atrio-septostomy catheter, pulmonary artery catheter, the Arndt endobronchial blocker (Cook Critical Care, Birmingham, IN), and the Univent endotracheal tube (Fuji Systems, Tokyo, Japan). Devices with a central channel have the advantage of allowing some degree of suctioning through the channel, not to clear the lung of secretions, as the channel is too small for that purpose, but rather to deflate the operative lung and improve surgical visualization or for the insufflation of oxygen and the application of CPAP. Without the central channel, air or gas cannot exit from the lung once the balloon is inflated; therefore the lung may not deflate totally and may obscure surgical visualization.

The final option for lung separation is selective endobronchial intubation. The major disadvantage of this is that it is not possible to quickly change from OLV to twolung ventilation as this requires repositioning the ETT from the mainstem bronchus into the trachea and vice versa. Additionally, with movement of the ETT, inadvertent extubation may occur which may be particularly problematic for the patient in the lateral decubitus position. Placement into the right mainstem bronchus can generally be accomplished blindly while left-sided placement requires guidance using a fiber-optic bronchoscope because of the different anatomical orientation of the left and right mainstem bronchi. See Chapter 24 for additional discussion of one lung ventilation techniques.

## Techniques to limit homologous transfusion

There is a growing body of evidence demonstrating the potential adverse effects of the administration of allogeneic blood products [48–52]. These adverse effects include the transmission of infectious diseases, immunosuppression, transfusion-related acute lung injury, transfusion reactions, and graft-versus-host disease. Of specific concern during the performance of major orthopedic surgical procedures is accumulating data demonstrating the association and potential causative role of allogeneic blood product use and postoperative infectious complications [49,50]. The primary focus on techniques to limit perioperative transfusions remains the appropriate preoperative preparation of the patient as well as attention to basic intraoperative tenets of pediatric anesthesiology such as patient positioning and maintenance of normothermia.

The general perioperative considerations which have a major impact on the perioperative need for allogeneic blood products include optimization of preoperative hemoglobin and coagulation function, including avoidance of NSAIDs preoperatively as well as attention to intraoperative anesthetic technique, including choice of fluid for intraoperative resuscitation and fluid therapy, proper patient positioning, and maintenance of normothermia (see above) [53,54]. As outlined above, the use of preoperative erythropoietin may be costly and timeconsuming and is therefore generally reserved for specific circumstances where avoidance of allogeneic transfusions is mandated, such as the Jehovah's Witness patient [55]. A more cost-effective approach is the identification and treatment of preoperative anemia, which may be especially prevalent in girls who have started their menstrual cycle. In most circumstances, treatment of anemia can be accomplished with nothing more than oral iron therapy.

The choice of intraoperative fluid administration may affect coagulation function, thereby affecting blood loss. During acute normovolemic hemodilution (ANH), intraoperative phlebotomy is performed and the blood removed is replaced with crystalloids and/or colloids. Due to the dilution of proteins with anticoagulatory effects, such as antithrombin III, hemodilution results in increased coagulation function [56]. Replacement with albumin or gelatinbased solutions has no effect or may actually improve coagulation function. Because of their effects on von Willebrand factor, either medium or high molecular weight hydroxyethyl starches may adversely affect coagulation function, in particular platelet function, when used in doses exceeding 10–15 mL/kg [57].

As important as the preoperative preparation of the patient is the recognition that there is no universal trigger for the administration of allogeneic blood products [58,59]. In the absence of co-morbid diseases which compromise end-organ oxygenation or limit the compensatory mechanisms for anemia, hemoglobin levels down to 7g/dL are generally well tolerated. Even in a recent prospective trial in the adult ICU population, with a restrictive strategy for the administration of blood (blood administered only for a hemoglobin less than 7 g/dL), no difference in outcome was noticed when compared to a liberal transfusion protocol (blood administered for a hemoglobin less than 10g/dL) [59]. In fact, in the less critically ill patients (APACHE score less than 20) and in those less than 55 years of age, there was a statistically significant improvement in 30-day mortality in the restrictive transfusion group.

Additional specialized techniques to limit perioperative allogeneic blood transfusions during spinal surgery may include:

- autologous transfusion therapy including preoperative donation with the use of erythropoietin and intraoperative collection using ANH
- intraoperative and postoperative blood salvage
- pharmacological manipulation of the coagulation cascade with antifibrinolytic agents (ε-aminocaproic acid (EACA), tranexamic acid (TXA), aprotinin) or procoagulant agents including desmopressin (DDAVP) and recombinant factor VIIa (rFVIIa) or
- controlled hypotension.

The goal of performing pediatric spine surgery without the use of allogeneic blood products is best accomplished by combining several of these techniques [60]. The use of these techniques will depend on the co-morbidities of the patient, the type of surgery, and likelihood of the need for allogeneic transfusions. During spinal surgery, factors which increase the likelihood of the need for allogeneic transfusions include the number of vertebral bodies fused and the presence of neuromuscular scoliosis [61,62]

### **Preoperative donation**

Although preoperative donation of autologous blood was first suggested by Fantus in 1937 when he founded the first blood bank in the United States, the technique did not become popular until much later, during the 1980s. Advantages of preoperative donation include reduction of exposure to allogeneic blood, the availability of blood for patients with rare phenotypes, reduction of blood shortages, avoidance of transfusion-induced immunosuppression, and the availability of blood for some patients who refuse transfusions based on religious beliefs [63].

There are no contraindications to the autologous donation based on the patient's weight or age. Patients who
weigh more than 50 kilograms can generally donate a standard unit of blood  $(450 \pm 50 \text{ mL})$  whereas patients weighing less than 50 kg will donate proportionately smaller volumes based on their weight and the presenting hemoglobin or hematocrit. Prior to donation, the hematocrit should be more than 33%. All patients enrolled in an autologous donation program should be on replacement iron therapy to augment erythropoiesis. Specific contraindications to autologous blood donation are similar to those for the donation of blood for allogeneic use. In general, patients with end-organ disease or limitations of the compensatory mechanisms which maintain tissue oxygen delivery during anemia are not candidates.

The efficacy of red blood cell production can be augmented by iron supplementation and the administration of erythropoietin [64]. Donations may be made every 3 days, but the usual practice is to donate one unit per week. The last unit should be donated at least 5-7 days prior to surgery to allow plasma proteins to normalize to restore intravascular volume and to allow for adequate erythropoiesis so that the patient does not present to the operating room with anemia. Although this technique has been endorsed by some as the easiest means of avoiding allogeneic transfusions [60], its use has decreased significantly over the past 5-10 years. Concerns regarding the use of autologous blood include the lack of standardized screening of these units for infectious diseases. As such, it is feasible to have an infected unit of blood sitting in the blood bank. Additionally, as the primary factor involved in major complications and death following the administration of allogeneic blood products is a clerical error with the transfusion of the wrong blood product, autologous units can be involved just as easily as allogeneic units. Many of the units of autologous blood are never used and therefore wasted if there is no standardized policy and procedure for their routine screening and subsequent move into the allogeneic pool. Additional limitations include the cost involved, time constraints as patients must return to the hospital several times before their operative procedure, and difficulties with vascular access in infants and children.

#### Acute normovolemic hemodilution

Perhaps a more cost-effective and safer means of obtaining autologous blood is ANH [65]. The technique involves the intraoperative removal of blood, generally after the induction of anesthesia and prior to the start of the surgical procedure. Blood is removed via a large-bore intravenous cannula, arterial cannula or central line and replaced with an equal volume of colloid or crystalloid in a ratio of 1:3 to maintain normovolemia. The blood is collected in standard CPD-A blood bank bags until they are full (approximately 450–500mL) or weighed to ensure that the appropriate amount of blood is removed. The amount of blood that can be safely removed is determined by the formula:

EBV × (initial hematocrit – target hematocrit)/ mean hematocrit

EBV is estimated blood volume, and the mean hematocrit is the average between the initial and the target hematocrit. The removed blood can kept at room temperature for up to 4h, thus maintaining the efficacy of platelets and clotting factors and providing a significant advantage over allogeneic blood and even predonated autologous blood. Intraoperatively, as needed, the blood is infused in the opposite order that it was withdrawn so that the units with the highest hematocrit are saved until the end of the procedure when there is the least amount of bleeding.

Compensatory physiological mechanisms to maintain oxygen delivery to the tissues despite a decrease in hematocrit include a decrease in blood viscosity resulting in increased venous return, peripheral vasodilation, increased cardiac output, and rightward shift of the oxyhemoglobin dissociation curve. Additionally, as oxygen delivery declines, oxygen extraction at the tissue level can increase to maintain adequate oxygen delivery to tissues. Although not recommended for routine clinical practice, the efficacy of the compensatory mechanisms was demonstrated by the study of Fontana et al which evaluated the effects of extreme ANH in eight adolescents undergoing posterior spinal fusion for idiopathic scoliosis [66]. During hemodilution, the hemoglobin decreased from  $10.0 \pm 1.6 \text{ g/dL}$  to  $3.0 \pm 0.8 \text{ g/dL}$ . Although oxygen delivery decreased from  $532.1 \pm 138.1$  to  $262 \pm 57.1 \text{ mL/min/}$  $M^2$ , the oxygen extraction ration increased from  $17.3 \pm 6.2\%$ to  $44.4 \pm 5.9\%$ . There was also an increase in cardiac output and maintenance of a stable heart rate. Although there was a decrease in the mixed venous oxygen saturation from 90.8  $\pm$  5.4% to 72.3  $\pm$  7.8% after ANH, the final value was still clinically acceptable and indicative of adequate tissue oxygenation.

#### Intraoperative blood salvage

The basic premise of intraoperative blood salvage is that shed blood is collected, anticoagulated, filtered for clots and debris, and then reinfused. There are three different techniques of intraoperative salvage. Semi-continuous flow devices were the first to be introduced and although they are the most complex to use, are still the type used most commonly for intraoperative blood collection and reinfusion. The commercially available equipment consists of an aspiration and anticoagulation assembly, a reservoir (various sizes are available depending on the size of the patient), a centrifuge bowl, a waste bag, and tubing. A double-line aspiration set includes an anticoagulation line that permits either heparin or citrate to combine with the aspirated blood at a controlled rate. The anticoagulated blood is collected into a disposable reservoir containing a filter. The filtered blood is then pumped into a bowl, centrifuged, washed with saline, and pumped into a reinfusion bag. Most of the white blood cells, platelets, clotting factors, free plasma hemoglobin, and anticoagulant are removed in the washing process and eliminated in the waste bag. The process takes approximately 5–10 min, resulting in a blood cell suspension with a hematocrit of 45–60%. Newer pediatric-specific devices are available which now allow the processing of smaller volumes of blood.

The second type of intraoperative salvage, otherwise known as the canister collection technique, uses a rigid canister with a sterile, disposable liner. Blood is aspirated from the wound and anticoagulant added in a manner similar to that of semi-continuous flow devices. The blood is collected in a rigid plastic reservoir containing a disposable liner. The blood can either be washed prior to infusion or reinfused without washing. Functioning platelets and coagulation factors are present if the blood is left unwashed; however, there is an increased risk of adverse effects due to cellular debris, free hemoglobin, and fragmented blood components. This type is rarely used in the perioperative setting.

The third type of collection is a single-use, selfcontained rigid plastic reservoir that collects the shed blood. The anticoagulant (citrate) is placed in the container prior to use. This apparatus is most commonly used for postoperative blood collection and reinfusion. The surgical drains are connected to the canister, and every 4h the canister is replaced and the blood reinfused. Coagulation factors and platelets are present in this blood as well. Adverse effects may occur as a result of cell fragmentation and the release of free hemoglobin.

Suggested indications for perioperative blood salvage include anticipated blood loss exceeding 20% of the patient's blood volume or a procedure during which more than 10% of patients require transfusion. Contraindications include situations in which there may be contamination of the collected blood with infectious or non-infectious agents (amniotic fluid, hemostatic agents such as topical thrombin or protamine). Potential complications include air and fat embolism, hemolysis, pulmonary dysfunction, renal dysfunction, coagulopathy, hypocalcemia, and sepsis [67]. Coagulopathy may occur related to the initiation of disseminated intravascular coagulation (DIC) due to incorrect technique and the infusion of blood cell fragments or the infusion of residual anticoagulant after washing [68]. Hemolysis may occur if the suction level is too high or if the aspiration method causes excessive mixing of air with blood. Free hemoglobin may be released during salvage and washing because of erythrocyte damage. Free hemoglobin levels exceeding 100–150 mg/dL may lead to hemoglobinuria and acute renal failure, as the binding capacity of haptoglobin is saturated and free hemoglobin is filtered in the renal tubules. Metabolic consequences of cell salvage may also be seen, including a metabolic acidosis and alterations in electrolytes such as magnesium, calcium, and potassium. Despite its potential complications and cost for the initial purchase of the machine and disposable items, it represents an effective means of limiting the need for allogeneic transfusion [69].

## Pharmacological manipulation of the coagulation cascade

Various agents have been used as prophylactic measures, even in patients with normal baseline coagulation function, to decrease intraoperative blood loss. Although these agents have been studied in well-designed, prospective trials, the outcomes of the studies are, at times, conflicting. Another issue to consider with the administration of any agent that alters coagulation function is the potential to invoke a prothrombotic state with venous or arterial thrombotic complications.

1-Deamino-8-D-arginine vasopressin (DDAVP) is a synthetic analog of vasopressin initially used in the treatment of diabetes insipidus. Its hemostatic effects result from the release of factor VIII and von Willebrand factor (vWF) from endothelial cells. Factor VIII, a glycoprotein, accelerates the activation of factor X by factor IX while vWF increases platelet adherence to vascular subendothelium, augments the formation of molecular bridges between platelets to increase aggregation, protects factor VIII in the plasma from proteolytic enzymes, and stimulates the synthesis of factor VIII. Although anecdotal reports have demonstrated its efficacy in augmenting coagulation function in various acquired and inherited forms of platelet dysfunction, prospective trials have failed to show an effect on blood loss during spinal surgery in pediatric patients [70].

 $\varepsilon$ -Aminocaproic acid (EACA) and tranexamic acid (TA) are  $\gamma$ -amino carboxylic acid analogs of lysine that inhibit fibrinolysis by preventing the conversion of plasminogen to plasmin. In the plasma, plasminogen is activated by tissue plasminogen activator to form plasmin which cleaves fibrin, thereby preventing the formation of the fibrin mesh. This fibrinolytic system is a basic defense mechanism that prevents the excessive deposition of fibrin following the activation of the coagulation cascade. Plasmin can also hydrolyze activated factors V and VIII. EACA and TA bind to the lysine group that binds plasminogen and plasmin to fibrinogen, thus displacing these molecules from the fibrinogen surface and inhibiting fibrinolysis.

One of the issues with the use of agents such as EACA and TXA is that various dosing regimens have been reported in the literature and there remains significant variation in current clinical practice [71]. In general, both drugs are administered as a loading dose followed by an infusion during the intraoperative period, with some studies continuing the infusion for a brief period of time into the postoperative course. Dosing regimens for EACA include an intravenous loading dose of 100-150 mg/kg (maximum 5g) followed by an infusion of 10-15mg/ kg/h (maximum 1g/h). Ninety percent of EACA is excreted in the urine within 4-6h of administration. Although TA is generally considered to be pharmacologically 7-10 times as potent as EACA, similar doses have been used clinically during spinal surgery. Adverse effects of EACA or TA may be related to the effect on coagulation function and the route of excretion. Since these agents are cleared by the kidneys, thrombosis of the kidneys, ureters or lower urinary tract may occur if urological bleeding is present. Both EACA and TA may be associated with hypotension during rapid intravenous administration. Given their limited adverse effect profile and general efficacy, these agents are commonly used as a means of limiting intraoperative blood loss during spinal surgery [71].

Florentino-Pineda et al evaluated the efficacy of EACA (100 mg/kg followed by 10 mg/kg/h) in 28 adolescents undergoing postoperative spinal fusion [72]. Patients who received EACA had decreased intraoperative blood loss (988 ± 411 mL versus 1405 ± 670 mL, p = 0.024) and decreased transfusion requirements ( $1.2 \pm 1.1$  units versus 2.2 ± 1.3 units, p = 0.003). TXA has been similarly effective in reducing blood loss during spinal fusion in pediatric patients with either idiopathic or neuromuscular scoliosis [73,74].

*Aprotinin* is a naturally occurring serine protease inhibitor first isolated from bovine lung in 1930. Its effects on coagulation function include both the inhibition of fibrinolysis by inactivating serine proteases including trypsin and plasma kallikrein, which convert plasminogen to plasmin, and the augmentation of platelet adhesion by protecting membrane-bound glycoprotein receptors (vWF receptor) from degradation by plasmin. As with the other antifibrinolytic agents, aprotinin has been shown to decrease blood loss and reduce requirements for allogeneic blood products during spinal surgery in children and adolescents [75].

Following intravenous administration, aprotinin undergoes rapid redistribution into the extracellular fluid, followed by accumulation in renal tubular epithelium with subsequent lysosomal degradation. The dose is expressed as kallikrein-inhibitory units (KIU). Potential adverse effects of aprotinin include allergic reactions and renal toxicity. Anaphylactoid reactions have been reported and are more frequent in patients previously exposed to aprotinin. However, even with previous exposure, the incidence of anaphylaxis is low, at less than 0.1%. The major concern with aprotinin, which led to its withdrawal from the market, is its effects on renal function. Although controversial, its use has been associated with renal failure in the high-risk adult population following cardiac surgery [76]. Renal toxicity is postulated to result from aprotinin's strong affinity for renal tissue and subsequent accumulation in proximal tubular epithelial cells or from its inhibition of serine proteases (kallikrein-kinin system). Histopathological examination of renal tissue reveals obstructed proximal convoluted tubules and swollen tubular epithelial cells. Given these effects, aprotinin has been withdrawn from the market.

#### **Controlled hypotension**

Controlled hypotension (deliberate or induced hypotension) may be defined as a deliberate reduction of systolic blood pressure to 80–90 mmHg, a reduction of mean arterial pressure (MAP) to 50–65 mmHg or a 30% reduction of baseline MAP, the latter being relevant for the pediatricaged patient whose baseline MAP may be within the 50–65 mmHg range to start with. Although the primary premise for the use of controlled hypotension is as a means of limiting intraoperative blood loss, an additional benefit may be improved visualization of the surgical field and thus shorter surgical times.

Advances in drug therapy have provided the clinician with several pharmacological options for controlled hypotension in the pediatric patient [77]. The agents available for controlled hypotension can be divided into those used by themselves (primary agents) and adjunctive or secondary agents which are used to limit the dose requirements and therefore the adverse effects of primary agents. Primary agents include regional anesthetic techniques (spinal and epidural anesthesia), the inhalational anesthetic agents (halothane, isoflurane, sevoflurane), the nitrovasodilators (sodium nitroprusside and nitroglycerin), trimethaphan, prostaglandin E1 (PGE1), and adenosine. The calcium channel blockers and  $\beta$ -adrenergic antagonists have been used as both primary agents and as adjuncts to other agents. The pharmacological agents used primarily as adjuncts or secondary agents include the angiotensin-converting enzyme inhibitors and  $\alpha$ adrenergic agonists such as clonidine. When neurological monitoring is used (see below), the potential impact of the agent used for controlled hypotension must be considered.

Sodium nitroprusside (SNP) is one of the agents most commonly used for controlled hypotension. It is a direct-acting, non-selective peripheral vasodilator that primarily dilates resistance vessels, leading to venous pooling and decreased systemic vascular resistance. It has a rapid onset of action (approximately 30 sec), a peak hypotensive effect within 2min with a return of blood pressure to baseline values within 3 min of its discontinuation. SNP releases nitric oxide (formerly endothelialderived relaxant factor), which activates guanylate cyclase, leading to an increase in the intracellular concentration of cyclic guanosine monophosphate (cGMP). cGMP decreases the availability of intracellular calcium through one of two mechanisms: decreased release from the sarcoplasmic reticulum into smooth muscle or increased uptake by the sarcoplasmic reticulum. The net result is decreased free cytosolic calcium and vascular smooth muscle relaxation. Adverse effects include rebound hypertension, coronary steal, increased intracranial pressure, increased intrapulmonary shunt with ablation of hypoxic pulmonary vasoconstriction, platelet dysfunction, and cyanide/thiocyanate toxicity. Direct peripheral vasodilation also results in baroreceptormediated sympathetic responses with tachycardia and increased myocardial contractility. The renin-angiotensin system and sympathetic nervous system are also activated. The result is increased cardiac output which may offset the initial drop in MAP. Plasma catecholamine and renin activity may remain elevated after discontinuation of SNP, resulting in rebound hypertension.

Nicardipine is a calcium channel antagonist of the dihyropyridine class that dilates the systemic, cerebral, and coronary vasculature with limited effects on myocardial contractility and stroke volume. Unlike SNP, nicardipine does have some intrinsic negative chronotropic effects which may limit the rebound tachycardia. Like other direct-acting vasodilators, nicardipine and the other calcium channel antagonists may increase intracranial pressure. Studies comparing SNP with nicardipine have demonstrated several potential advantages of nicardipine, including fewer episodes of excessive hypotension, less rebound tachycardia, less activation of the reninangiontensin and sympathetic nervous systems, and in some studies decreased blood loss [78]. One disadvantage of nicardipine is that its effect is somewhat prolonged (20-30 min) following discontinuation of the infusion. More recently, a new dihydropyridine, clevidipine, has been added to the list of agents which may be used for intraoperative blood pressure control [79]. Although its hemodynamic effects are similar to those of nicardipine, it is metabolized by plasma and tissue esterases, thereby resulting in a half-life of 2-3 min.

## Spinal cord monitoring

Without electrophysiological monitoring, the incidence of neurological deficits following surgical procedures on the vertebral column may be as high as 3.7–6.9%. This can be decreased to less than 1% with appropriate monitoring

[80]. The American Academy of Neurology, in their guidelines on intraoperative monitoring, concluded that the evidence favors the use of monitoring as a safe and efficacious tool in clinical situations where this is a significant nervous system risk, provided its limitations are appreciated [80]. One of the major limitations is that animal studies have demonstrated a window of opportunity of less than 10 min from the time when changes in monitoring are noted until permanent damage is done. Additionally, when various techniques are used, such as somatosensory or motor-evoked potentials, the anesthetic technique must be modified to facilitate processing of the technique (see below).

There are four techniques of intraoperative monitoring: the ankle clonus test, the wake-up test, somatosensoryevoked potentials (SSEPs), and motor-evoked potentials (MEPs). The ankle clonus test was the first to be used intraoperatively to assess spinal cord integrity [81]. During the normal awake state, descending inhibitory fibers prevent clonus in response to an ankle stretch. Likewise, the reflex is inhibited during deep levels of anesthesia. However, during emergence from anesthesia, inhibition of the central descending pathways allows ankle clonus to be elicited following dorsiflexion of the foot/ankle. If there has been damage to the spinal cord, flaccid paralysis will be present and therefore no spinal reflexes can be elicited. To elicit ankle clonus, neuromuscular blockade must be reversed or absent and the patient is allowed to emerge from general anesthesia as is done with a wake-up test (see below). In most circumstances, the ankle clonus test can be elicited prior to the patient regaining consciousness and therefore at a deeper level of anesthesia than a true wake-up test [81]. The test is both extremely sensitive and specific; however, it does not provide a continuous monitor of spinal cord function and is present only at a specific depth of anesthesia.

The wake-up test was originally reported in the 1970s as a means of monitoring spinal cord integrity. The technique should include a preoperative discussion with the patient regarding what the test entails, its purpose, timing during the procedure, and the fact that there may be some intraoperative recall during the period of time when the test is performed. At the appropriate intraoperative time, neuromuscular blockade is reversed and the depth of anesthesia decreased. The speed with which a patient will respond to verbal stimuli can be increased by the use of short-acting anesthetic agents (desflurane, propofol, and remifentanil). With the use of these agents, responsiveness and a successful wake-up test can generally be accomplished within 10min of the surgeon's request. The use of reversal agents for opioids and benzodiazepines, although available in clinical practice, is not recommended as they may have prolonged effects which will interfere with the resumption of anesthesia

after the wake-up test. The depth of anesthesia and the patient's awakening can also be judged by the use of neurophysiological or depth of anesthesia monitors such as the BIS (Bispectral Index®) monitor (Aspect Medical, Newton, MA). As the depth of anesthesia is decreased, one anesthesia provider stands at the head of the bed with one hand on the patient's head to limit the risk of sudden inadvertent movements. The other hand is used to feel the patient's response to a verbal command. When the patient reaches a light plane of anesthesia, a voluntary movement in the motor groups above the level of surgery (e.g. squeezing one's hand) is requested initially to ensure that the patient is awake enough to follow commands. This is then followed by a request to move the lower extremities to ensure that motor function is still intact. Once a positive response is achieved in the lower extremities, the depth of anesthesia is deepened by the bolus administration of propofol or thiopental. The wake-up test does entail certain risks, including having an awake patient in the prone position on the operating room table. Inadvertent or sudden movements may result in patient injury, dislodgment of venous or arterial cannulas, and hypertension with exacerbation of bleeding. Additionally, like the ankle clonus test, it provides only a single assessment of spinal cord integrity. In most centers, the wakeup test is used only when there are questionable findings on electrophysiological monitoring (see below).

Electophysiological monitors include both SSEPs and MEPs. SSEPs are monitored by stimulation of a distal nerve, generally in the leg (posterior tibial), and measuring the response at the cervical level and the central nervous system via standard EEG electrodes. The pathways involved include the peripheral nerve, the dorsomedial columns (fasciculus gracilis and fasciculus cuneatus) of the spinal cord, and the cerebral cortex. SSEPs do not monitor anterior cord (motor) function. Given the close proximity of the tracts (motor and sensory) in the spinal cord, damage to the motor tracts generally results in damage to the sensory tracts, making SSEPs a fairly reliable measure of motor function. However, given that the dorsomedial tracts and the anterior aspect of the spinal cord do not share the same arterial supply, isolated damage to the motor tract with intact SSEPs has been reported.

Since SSEPs can be affected by anesthetic agents, baseline recordings are performed after an appropriate level of anesthesia has been achieved [82]. The variables measured include both the height of the response (amplitude) and the time it takes the response to travel from the periphery to the central nervous system (latency). Significant changes include a reduction in the amplitude of  $\geq$ 50% or an increase in the latency of  $\geq$ 10%. The potent inhalational anesthetic agents and nitrous oxide cause a decrease in the amplitude and an increase in the latency of SSEPs. However, acceptable monitoring can be achieved with 0.5 MAC of isoflurane, sevoflurane or desflurane. Although practices vary from center to center, nitrous oxide is generally avoided. Intravenous anesthetic agents have been shown to have less of an effect on SSEPs, making a total intravenous anesthetic technique using propofol or midazolam combined with an opioid an effective option. In generally, either propofol or 0.5 MAC of an inhalational anesthetic agent is combined with a continuous infusion of a potent synthetic opioid, generally either sufentanil or remifentanil. Neuromuscular blocking agents have no effect on SSEPs, but will obviously eliminate the ability to obtain MEPs.

More recently, due to the concern that there can be isolated motor damage with intact SSEPs, many centers have moved to monitoring MEPs along with SSEPs. As with SSEPs, MEPs are affected by the type of anesthetic agent used. Various techniques have been recommended and there is variation from center to center, but the anesthetic technique is generally the same as for SSEP monitoring.

A recent addition to the anesthetic armamentarium is dexmedetomidine (Precedex<sup>®</sup>, Hospira Worldwide Inc, Lake Forest, IL), the pharmacologically active dextroisomer of medetomidine, which exerts its physiological effects via  $\alpha_2$ -adrenergic receptors. Its use in perioperative care continues to increase given its ability to decrease requirements for the inhalational anesthetic agents and propofol as well as its ability to decrease postoperative opioid requirements [83,84]. Of particular note during spinal surgery and neurophysiological monitoring is that provided the depth of anesthesia is maintained, no change in these parameters should be seen with the use of dexmedetomidine as part of the intraoperative anesthetic care [85,86]. With MEP monitoring, the level of neuromuscular blockade must be kept stable with maintenance of one or two twitches of the train-of-four. Alternatively, as is our preference, neuromuscular blockade with a short-acting agent is used only for endotracheal intubation and no neuromuscular blocking agents are used during the case.

## Intraoperative anesthetic care

Intraoperative anesthesia is generally best co-ordinated with the physicians and technicians providing intraoperative neurophysiological monitoring as significant variations in preference exist from center to center. The techniques generally combine either a propofol infusion or a low-dose inhalational anesthetic agent (0.5–1 MAC) with a potent synthetic opioid infusion (remifentanil or sufentanil). As mentioned previously, dexmedetomidine may be added to the intraoperative regimen to limit the requirements for either propofol or the inhalational anesthetic agent. We have also found that these agents can be effectively titrated to achieve an acceptable level of blood pressure control to provide controlled hypotension with a limited need for supplemental antihypertensive agents. In most cases when propofol, remifentanil, and dexmedetomidine infusions are used, controlled hypotension can be maintained with only an occasional need for intermittent doses of labetalol.

Although remifentanil is a frequent component of intraoperative care for spinal surgery, one issue that has been identified with its use is the development of acute opioid tolerance [87]. This may result in an increased opioid requirement during the postoperative period. Crawford et al investigated the effects of remifentanil on postoperative opioid requirements in a cohort of 30 adolescents undergoing posterior spinal fusion for the treatment of idiopathic scoliosis [87]. Thirty adolescents were randomized to receive a continuous infusion of remifentanil or intermittent doses of morphine as part of their intraoperative anesthetic regimen. Cumulative morphine use during the first 24 postoperative hours was 30% greater in the group receiving remifentanil. Despite such observations, the mechanisms responsible for the postoperative hyperalgesia remain undefined. Although it has been attributed to effects of remifentanil at the NMDA receptor, the hyperalgesia is not blocked by the administration of ketamine [88].

Another potential adjunct for the intraoperative anesthetic care of patients during spinal surgery is the inclusion of a magnesium sulfate infusion [89–91]. A magnesium sulfate infusion has been shown to decrease intraoperative anesthetic requirements for propofol, the inhalational anesthetic agents and neuromuscular blocking agents, be an effective agent for controlled hypotension, and even decreased postoperative opioid requirements. In a prospective trial of 61 children with cerebral palsy undergoing spinal fusion, patients were randomized to receive magnesium sulfate (50 mg/kg followed by an infusion of 15 mg/kg/h) or a saline placebo [91]. Postoperative analgesic requirements and pain scores were lower at 24 and 48h in the group that had received magnesium sulfate.

Additional intraoperative considerations include alterations in care which may affect postoperative surgical site infections (SSI) and the treatment of acute intraoperative events. Although various factors are involved in the genesis of a SSI, recent data have focused on the potential beneficial impact of the intraoperative FIO<sub>2</sub>. As oxygen is required for neutrophil killing of bacteria, it has been postulated that increasing the inspired FIO<sub>2</sub> may decrease the incidence of SSIs. In a case–control study, Maragakis et al compared the intraoperative course of 104 patients with SSIs to a randomly selected control group [92].

Given the complexity of the surgical procedure, various unique intraoperative complications may occur. As there is extensive removal of cortical bone and placement of screws, intrahemodynamic instability may occur related to either air, marrow or fat emboli [93]. Early recognition of such events is mandatory as cessation of surgical manipulation and flooding the surgical field with saline may limit the impact on hemodynamic status. In more extreme cases, resuscitation in the prone position may be necessary. Although flipping the patient may be an option, even rapid closure of the surgical wound and flipping can result in the loss of precious minutes of resuscitation. Several case reports and animal studies demonstrate that effective cardiopulmonary resuscitation can performed in the prone position [94]. The technique involves the placement of one hand over each scapula with compressions performed in a perpendicular motion toward the operating room table. If the patient is on a specialized frame, the thoracic supports will generally provide enough counter-pressure for effective changes in intrathoracic pressure.

# Postoperative care including pain management

One of the keys to the successful care of the pediatric spine patient is to provide a smooth transition from the operating room to the intensive care unit (ICU). This process begins with the preoperative preparation and education of the patient, preferably with a tour of the pediatric ICU. The patient should also be instructed regarding the correct use of incentive spirometry and patient-controlled analgesia if the use of these devices is planned. In some institutions, direct admission to the pediatric inpatient ward and not the pediatric ICU is feasible following spinal surgery. In such instances, a 2–4-h stay in the postanesthesia care unit is used to ensure cardiorespiratory stability.

At the completion of the procedures, it may be desirable to have an appropriate level of responsiveness so that a neurological examination can be performed to demonstrate adequate upper and lower extremity function. The decision to continue mechanical ventilation into the postoperative period is made on a individual basis. In all patients in whom there is any possibility of the need for postoperative mechanical ventilation, this should be discussed preoperatively with the parents and the patient. The need for mechanical ventilation may be related to either the patient (neuromuscular disorder, preoperative pulmonary dysfunction) or the surgical procedure (blood loss of more than one blood volume). In specific cases, the best option may be to provide 2-4h of postoperative mechanical ventilation to ensure cardiorespiratory stability, normal coagulation function, and correction of metabolic parameters. Once this is accomplished, the trachea can be extubated in the ICU setting. Given the prolonged prone positioning, lingual edema may be present and result in postoperative upper airway obstruction. Excessive lingual edema may mandate continuing

mechanical ventilation into the postoperative period. When the cuff is deflated, an adequate airway leak should be present before tracheal extubation.

Due to the significant length of the surgical incision and the degree of bony and soft tissue dissection required for such procedures, there may be significant postoperative pain. Accordingly, effective analgesia is a key in the provision of a stable postoperative course. Effective analgesia is generally best provided using a multi-modality approach, which includes analgesic agents, anxiolytic agents, and medications to control muscle spasms. Muscle spasms may be particularly problematic in patients with underlying cerebral palsy. Options for the provision of analgesia include the intravenous administration of medications and/or regional anesthetic techniques. For intravenous administration, we prefer the use of patientcontrolled analgesia (PCA). Although young patients or those with developmental disabilities may not be able to activate the device, nurse-controlled or parent-controlled analgesia may be provided. By using the device in this manner, the bedside nurse has ready access to a supply of opioid to provide an immediate dose to a patient who is in pain. Prior to instituting PCA, an appropriate level of analgesia must be achieved by the careful titration of opioid. This is generally done in the operating room on completion of the surgical procedure.

Once neurophysiological monitoring is completed, the remifentanil and propofol infusions are discontinued and desflurane or sevoflurane started to maintain the BIS at 50–60. Once spontaneous ventilation begins, incremental doses of either hydromorphone (2–3 $\mu$ g/kg) or morphine (20 $\mu$ g/kg) are titrated based on the patient's respiratory rate. Once tracheal extubation is completed, additional complaints of pain are treated with opioid. Once adequate analgesia is achieved, the PCA device is started to maintain analgesia. Given the significant interpatient variability that may occur, it is necessary to use age-appropriate pain scores and titrate the PCA doses up or down based on the patient's response.

To limit the total dose of opioid required and thus opioid-related adverse effects, adjunctive agents can be used. There is still significant controversy regarding the potential adverse effects of NSAIDs on bone formation. Given these concerns, many centers choose not to use these agents following spinal surgery in children. Our preference is to administer a fixed dose of acetaminophen (10 mg/kg either by mouth or per rectum) every 4–6h around the clock. Given the propensity of these patients to develop muscle spasms and the need, in some patients, to provide anxiolysis, benzodiazepines such as diazepam may be added to the postoperative regimen either on an as-needed basis or at fixed intervals. Alternatively, there may be a role for the  $\alpha_2$ -adrenergic agonists to provide anxiolysis as well as relief of muscle

spasms. Dexmedetomidine is a novel  $\alpha_2$ -adrenergic agent which currently has FDA approval for the sedation of adult patients in the ICU setting for 24h. Unlike clonidine, it has a half-life of 2–3h, thus allowing its titration by continuous infusion. Given its limited effects on respiratory function and its ability to potentiate opioidinduced analgesia, it may also have a role in the ICU setting to provide anxiolysis following major surgical procedures, including spine surgery. Although our experience is preliminary and anecdotal, a continuous infusion of dexmedetomidine (0.25-0.5µg/kg/h) may be efficacious in these patients. Despite the need to provide effective analgesia, adverse effects including respiratory depression may occur, especially in patients with comorbid features. In such patients, close monitoring of respiratory function with continuous pulse oximetry may be indicated.

The other class of agent that has gained popularity as an adjunct to opioid analgesia following spinal surgery is the  $\gamma$ -amino butyric acid analogs such as gabapentin and pregabalin [95-98]. In a prospective study of adult patients undergoing posterior lumbar spinal fusion, van Elstraete et al investigated the dose of gabapentin required to decreased morphine requirements by 30% [95]. Using an up-and-down sequential allocation model, they demonstrated that the median effective pre-emptive dose of gabapentin was 21.7 mg/kg. In a prospective study of 59 patients, 9-18 years of age, undergoing posterior spinal fusion, Rusy et al randomized patients to receive gabapentin (15 mg/kg preoperatively followed by 5 mg/kg by mouth three times a day for 5 days) or placebo [96]. Gabapentin significantly reduced total morphine consumption and pain scores in the PACU and on the first postoperative day. In addition to working during the acute postoperative period, the adult data suggest more prolonged effects of perioperative pregabalin with decreased pain scores and improved functional outcomes 3 months after surgery [97].

Given successes in other surgical procedures, there is also significant interest in the potential use of regional anesthetic techniques as a means of controlling pain following spine surgery in children. Reports in the literature regarding the use of regional anesthesia following spine surgery have included several variations:

- the dose of the medications used
- the route of delivery (intrathecal or epidural)
- the mode of delivery (single dose, intermittent bolus dosing or continuous infusion)
- the number of catheters used (one versus two)
- the medications infused (opioids or local anesthetics or both)
- the opioid used (morphine, fentanyl, hydromorphone)
- analgesic regimen of the control group, if present (intermittent "as-needed" morphine or PCA)

• the type of surgery (short-segment lumbar fusion, short-segment laminectomy for dorsal rhizotomy, posterior spinal fusion, and anterior spinal fusion)

• the surgical approach (open versus thoracoscopic). The reader is referred to a review of the reports regarding the use of regional anesthetic techniques following spine surgery in pediatric patients and a recent meta-analysis evaluating these techniques [99,100]. The evaluation of the efficacy of regional anesthetic techniques is clouded by the variation in the techniques which has been previously outlined. Future trials are needed to determine the optimal postoperative analgesic regimens for these procedures.

## Conclusion

There are many challenges facing the anesthesia provider during spine surgery in pediatric patients. As with any surgical procedure, the care of these patients begins with a thorough preoperative evaluation to identify co-morbid features which are present in many of these patients. Although idiopathic scoliosis is still a common disease, many of these patients will have associated neurological or myopathic conditions which affect anesthetic care. Intraoperative issues include techniques for airway management, vascular access, blood conservation techniques, patient positioning, intraoperative neurological monitoring, the administration of blood and blood products, and the maintenance of fluid and electrolyte homeostasis. There is also a need for a smooth transition to the postoperative period with an ongoing monitor to ensure stable cardiorespiratory function and an aggressive approach to the provision of effective postoperative analgesia.

## CASE STUDY

A 14-year-old, 72kg adolescent presented for posterior spinal fusion in the treatment of idiopathic scoliosis. His past medical history was unremarkable for co-morbid medical conditions or previous anesthetic care. Preoperative preparation included the administration of iron and two subcutaneous doses of erythropoietin. Preoperative coagulation function (PT, PTT and INR) was within normal limits and the hemoglobin was 14.6 g/dL. The patient was held nil per os for 6h and transported to the operating room where routine American Society of Anesthesiologists' monitors were placed. Following the inhalation of nitrous oxide for 3 min, a large-bore peripheral intravenous cannula was placed followed by intravenous induction with 3 mg/ kg of propofol and  $5\mu/kg$  of fentanyl. Tracheal intubation was facilitated by rocuronium (0.4 mg/kg). Core body temperature was monitored using an esophageal stethoscope. A rolled gauze pad was placed in the mouth to prevent lingual damage during neurophysiological monitoring.

Following anesthetic induction, maintenance anesthesia consisted of desflurane (expired concentration 4–5%). A second large-bore peripheral intravenous cannula and a radial arterial cannula were placed. Depth of anesthesia was monitored using a Bispectral Index (BIS). Intraoperative monitoring with both SSEP and MEP monitoring was planned and the appropriate electrodes were placed over the extremities and scalp. During placement of the monitoring electrodes, isovolemic hemodilution was accomplished by the withdrawal of blood from a peripheral intravenous cannula into a standard blood bank bag containing the anticoagulant solution CPD (citrate-phosphate-dextrose). A tetrastarch solution was administered in a ratio of 1:1 for the blood that was withdrawn. A total of

700 mL of whole blood was removed, resulting in a hemoglobin of 11.2 g/dL. The patient was turned prone onto a Jackson table and a pillow was placed to prevent pressure to the eyes and face.

To facilitate SSEP and MEP monitoring, total intravenous anesthesia was provided by a combination of propofol, remifentanil and dexmedetomidine. No additional doses of a neuromuscular blocking agent were administered. The dexmedetomidine was started at  $0.5 \mu g/kg/h$  without a loading dose. The propofol was started at  $120 \mu g/kg/min$  and titrated to maintain the BIS at 40–60. The remifentanil was started at  $0.1 \mu g/kg/min$  and increased as needed to maintain controlled hypotension with a MAP of 50–65 mmHg. Once positioned prone, a forced air heating device was used to maintain normothermia. The antifibrinolytic agent  $\epsilon$ -aminocaproic acid was administered as a bolus dose of 100 mg/kg followed by an infusion of 10 mg/kg/h until the wound was closed.

Intraoperatively, during surgical dissection to the vertebral column, the MAP increased to 75–80 mmHg despite a remifentanil infusion at  $0.3\mu g/kg/min$ . To provide controlled hypotension, the calcium channel antagonist clevidipine was started at  $1\mu g/kg/min$  and increased in increments of  $0.5-1\mu g/kg/min$  every 3min to achieve an MAP of 50–65 mmHg. With the clevidipine infusion at  $2.5\mu g/kg/min$ , the MAP was effectively decreased to the target range. The clevidipine infusion was continued until the surgical dissection had been completed. Intraoperatively, the propofol infusion was decreased to 70–80 $\mu g/kg/min$  based on the BIS number. Intraoperatively, blood salvage with a cell saver from the surgical suction devices was employed. With the total intravenous *Continued* 

anesthesia (TIVA) technique, effective monitoring of SSEPs and MEPs was achieved. The TIVA technique was titrated to allow for a wake-up test or ankle clonus test should there be changes in neurophysiological monitoring which did not respond to anesthetic manipulation of hemodynamic parameters.

Intraoperative arterial blood gas parameters and hemoglobin values were monitored. As the hemoglobin value decreased to less than 8g/dL, the 700 mL of blood that had been removed preoperatively by isovolemic hemodilution was administered. The surgical hardware was placed without incident and the wound was closed. During wound closure, 400 mL of intraoperatively salvaged blood was washed and returned to the patient.

Once monitoring of neurophysiological function was no longer indicated, the propofol and remifentanil infusions were discontinued and desflurane was started to maintain the BIS at 40–60. Once there was return of spontaneous ventilation, hydromorphone in incremental bolus doses of 0.1 mg was administered to achieve a respiratory rate of 8-12 breaths/min. The dexmedetomidine was continued at  $0.5 \mu g/kg/h$ . Ondansetron (4 mg) and dexamethasone (4 mg) were administered to prevent postoperative nausea and vomiting. At the completion of the surgical procedure, the desflurane was discontinued and the patient was turned supine.

Once there was eye opening and appropriate response to verbal commands, the patient's trachea was extubated. The patient was transported to the postanesthesia care unit and then to the pediatric ICU for overnight observation. Postoperative analgesia was provided by a hydromorphone PCA and the dexmedetomidine infusion for 24h. The hemoglobin value on postoperative day 1 was 13.6 g/dL. The remainder of the hospital course was unremarkable.

This case illustrates several of the basic tenets required for performance of anesthesia during spinal surgery. Of prime importance is tailoring of the anesthetic regimen to allow for effective monitoring of spinal cord function using SSEP and MEP modalities. This generally includes the use of a TIVA technique with propofol and a synthetic opioid such as remifentanil or sufentanil. During neurophysiological monitoring, if changes occur, immediate communication with the surgeon is necessary to allow for the reversal of any surgical intervention which may have resulted in these changes. This may include removal of recently placed hardware. If the neurophysiological changes do not respond to surgical intervention or simple manipulations of the hemodynamic parameters such as increasing the MAP or the hemoglobin, the anesthesia provider must be ready to allow for a wake-up test or ankle clonus test. Both require a rapid decrease in the depth of anesthesia which may be facilitated by the use of short-acting intravenous anesthetic agents. A second component of anesthetic care during spinal surgery is the use of techniques to limit intraoperative blood loss, including basic maneuvers such as effective patient positioning to avoid abdominal compression and distension of epidural veins as well as maintenance of normothermia. Additional techniques may include isovolemic hemodilution, administration of an antifibrinolytic agent, intraoperative blood salvage, and controlled hypotension. The final component is the provision of effective postoperative analgesia with the use of a regional anesthetic technique (epidural or intrathecal opioids) or opioid analgesia administered via PCA. A dexmedetomidine infusion may be added to decrease postoperative opioid requirements.

In this cohort of 45 patients, 20 patients had a preoperative FVC ≤30% predicted for age. There was no statistically significant difference in several postoperative variables, including the duration of postoperative endotracheal intubation, duration of BiPAP support, total time with ventilator assistance, and inpatient stay. However, there were significant cardiorespiratory complications in both groups, demonstrating that this is a high-risk population with the potential for perioperative complications. Five patients (25%) with an FVC ≤30% had complications including ARDS, respiratory tract infections, and the need for a tracheostomy while four (16%) with a preoperative FVC  $\geq$ 30% had complications. The one death in the cohort was in a patient with an FVC of 18% who initially had an uncomplicated postoperative course, but went on to develop ARDS.

## Introduction

Medical progress has made organ transplantation an accepted therapeutic modality for treating a variety of diseases affecting various organ systems in infants and children. Improvements in immunosuppressive therapy, surgical techniques, and organ preservation have permitted utilization of transplantation in a greater number of patients, and pediatric patients in particular have benefited from the growth of transplantation. The scope and magnitude of various transplant procedures in infants and children with underlying organ system disease will continue to challenge anesthesiologists caring for these patients. In addition, as more children undergo transplantation, anesthesiologists must be prepared to care for them following transplantation, including the management of post-transplant complications and procedures.

Anesthetic management of these procedures requires understanding the physiological implications of organ failure, as well as specific requirements of the transplant procedure [1]. To facilitate this discussion, issues related to the anesthetic care of children undergoing liver, renal, heart, heart-lung, lung, and multivisceral transplantation will be discussed separately. In addition,

other chapters describe anesthetic care of infants and children with specific organ dysfunction who require surgery.

Perioperative anesthetic management of solid organ transplant procedures has a number of similarities. Because of the logistic constraints involving donor organ procurement and admission of patients awaiting transplantation, there is limited time available to the anesthesia team for preparation. During this time, the patient must be admitted to the hospital and an updated history and physical examination and laboratory studies must be obtained. The short period of preparation usually limits the duration of nil per os (NPO) status for most children, which has implications for the anesthesiologist. Because several vascular anastomoses are required, there is significant potential for hemorrhage. Adequate vascular access, invasive monitoring, and availability of adequate quantities of blood product are required. Given the severity of underlying diseases, the physiological alterations they cause, and the frequency of intraoperative changes in the patient's condition, arterial blood gas and pH, blood chemistry profiles, and other hematological testing often are required during transplant procedures. When new transplantation programs are established, anesthesia departments should take an active role in defining the requirements and availability of these ancillary services to help in the care of these patients. Because of the urgent or emergency nature of most transplant cases, the resources must be available to the anesthesia team 24-h, 7 days a week basis.

# Care of organ donors after neurological death

Once brain death has been established in a donor, and suitability of the donor organs has been confirmed, the emphasis for patient care is directed toward organ preservation by maintaining cardiac output and oxygen delivery. After placement of the organs according to the United Network for Organ Sharing (UNOS) waiting list criteria in the US, co-ordination of the arrival of the harvesting teams is done by the local organ procurement agency, and an operating room time selected. The anesthesia team needs to ensure preservation of oxygen delivery to the harvested organs by maintaining adequate ventilation, cardiac output, hemoglobin, and blood pressure within target ranges. Diabetes insipidus is often present, requiring close attention to urine output and electrolytes, replacement of losses, and desmopressin (DDAVP) administration. Because of loss of sympathetic outflow from the central nervous system, hypotension and cardiovascular compromise are a constant possibility during the preparation for harvest. Close communication with the surgical team, or teams for multiple organ harvests, will assure optimal organ retrieval.

Brain-dead donors do not experience pain but they may experience hemodynamic changes from spinal cord reflexes with surgical incision and should be treated with inhalational anesthetics or opioids. After wide abdominal exposure, the retrieval team will ask for heparin (200–400 units/kg). Organs are generally removed according to their susceptibility to ischemia, with the heart first and the kidney last. After the heart, great vessels, and lungs are dissected out, the donor aorta is cross-clamped and the heart perfused with a preservation solution such as standard crystalloid cardioplegia or Celsior® to provide both cardioplegia and organ preservation. The organs are then placed in ice for transport at 4°C.

## **Donation after cardiac death**

Because of the ongoing shortage of donors for all organs, the concept of organ donation after cardiac death is advocated. Families may request organ donation after withdrawal of mechanical ventilatory support in patients who are otherwise suitable for donation, with an irreversible neurological injury, who do not have brainstem death.

This condition must be confirmed by the patient's physicians and agreed to by the patient's next of kin. In order to optimize organ retrieval, patients and families are typically taken to the operating room where ventilatory and circulatory support is withdrawn. A physician not involved with the organ procurement determines an irreversible cessation of cardiac and respiratory function, and the organ recovery takes place. As of 1 July 2007 in the US, transplant centers and organ procurement organizations are required to have policies and procedures in place for this process. Donation after cardiac death increased the number of donors by over 600 in 2006 [2].

# Immunosuppression for pediatric solid organ transplantation

Review of the history of solid organ transplantation demonstrates that successful outcomes are impossible without effective immunosuppression. The aim of immunotherapy is to minimize the risk of rejection and drug toxicity. Currently, pediatric solid organ transplantation protocols for induction, maintenance and desensitization vary widely between centers. Even single organ transplant groups are far from consensus on the ideal approach to immunosuppression [3]. A general strategy is depicted in Figure 27.1 [3]. Most transplant patients require indefinite maintenance therapy, although about 20% of pediatric

#### Transplantation

**Figure 27.1** Time line showing the different approaches for immunosuppression in relation to the time of transplant. Pretransplant protocols are reserved for patients with specific risk factors (e.g. HLA sensitization or ABO-incompatible transplantation). Depending on the transplanted organ and center, the use of induction may or may not be part of the protocol. Furthermore, low-dose steroids may remain part of the maintenance therapy, supporting a regimen of one or two drugs of different classes. Additional treatments are used for treatment of rejection. Reproduced from Urschel et al [3] with permission from Elsevier.

liver transplant recipients and some kidney recipients have been successfully weaned from immunosuppression late after transplantation [4]. Figure 27.2 illustrates the cellular targets of immunosuppressive drugs, and commonly used drugs are detailed in Table 27.1 [3]. Discussion of individual agents is beyond the scope of this chapter and has been addressed recently [3,5–10].

It is important to monitor drug levels because coexisting disease and drug interactions can result in subtherapeutic or toxic drug effects. Nephrotoxic agents should be avoided even if renal function is normal. Cystic fibrosis patients have unreliable gastric absorption and hepatic clearance and are at risk of developing acute toxicity from oral medications like cyclosporin. Hepatic enzymes such as cytochrome P450 metabolize commonly used immunosuppressant drugs. Perioperative drugs (e.g. metoclopramide, amiodarone, antibiotics, barbiturates, phenytoin) may induce or inhibit cytochrome P450 and alter drug levels of calcineurin and mammalian target of rapamycin (mTOR) inhibitors. Newer immunosuppressant medications often do not include liquid forms required for young children. Such liquid preparations must be compounded by local pharmacies and may have a short shelf-life, making them difficult to manage for patients not residing near a pediatric medical center. Moreover, absorption and pharmacokinetic data for infants and children often do not exist, making dosing decisions in drugs that may have narrow therapeutic windows challenging [11].

Drug name Mechanism Comments Induction therapy Polyclonal antibodies Rabbit ATG Antibodies against Aim for lymphocyte Equine ATG thymus-derived count of 0.1- $0.3 \times 10^{3}$ /ml epitopes Monoclonal antibodies Start before transplant Basiliximab IL-2 receptor Daclizumab (CD25) blocking Start before transplant antibodies Inhibit T-cell activation Induction and maintenance therapy Steroids Methylprednisolone Inhibition of activator Can be discontinued in Prednisone protein-1 and liver, heart and nuclear factor κ-B kidney. Usually continue in lung Maintenance therapy Calcineurin inhibitors Cyclosporin (CSA) Inhibit expansion and Choice and target level Tacrolimus (TAC) differentiation of of drug depend on T-cells type of organ, time after transplant and Inhibit expansion and differentiation of individual variables T-cells (e.g. renal dysfunction) Antiproliferative drugs Mycophenolate Inhibit de novo DNA Change from one to mofetil (MMF) synthesis other formulation may relieve Azathioprine gastrointestinal problems Avoid MMF/ecMPA use in pregnancy Limit sun exposure on azathioprine mTOR inhibitors Sirolimus Arrest in cell cycle May be protective Everolimus and differentiation against coronary allograft vasculopathy

Table 27.1	Immunosuppres	ssive options	in pediatric	transplantation

**Figure 27.2** T-cell activation and proliferation results from presentation of a peptide fragment of the donor antigen in the major histocompatibility complex class II (MHC II) of the antigen-presenting cell (APC) and a co-signal from interaction from CD80/CD86 and CD28. This mechanism results in activation of calcineurin, which leads to production of interleukin-2 (IL-2). Autocrine stimulation by IL-2 results in cell proliferation by a pathway involving target of rapamycin (mTOR) and cyclin/cyclin-dependent kinase (CDK). Immunosuppressive agents exert their effects at a number of different targets to prevent T-cell proliferation. The CD80/CD86 and CD28 interaction is targeted by specific antibodies (Co-stim-AB) abatacept and belatacept. Basiliximab and daclizumab (IL-2R antagonists) target the receptor for IL-2, required for cell activation via mTOR, which is targeted by sirolimus and everolimus. Tacrolimus and cyclosporin interfere in the signal transduction from the T-cell receptor by inhibiting calcineurin nuclear factor of activated T-cells (NFAT). Mycophenolic acid (MPA), mycophenolate mofetil (MMF) and azathioprine (AZA) interfere in the cell cycle, preventing the T-cell as well as the B-cell from proliferating. Steroids target multiple sites in the interaction. Alemtuzumab (ATM) and muronomab (OKT3) target specific lymphocytic surface structures to induce cytolysis; a similar principle is used for antithymocyte globulins (ATG) but with multiple targets on the surface. Reproduced from Urschel et al [3] with permission from Elsevier.

## Induction therapy

Induction immunotherapy is intense immunosuppression in the immediate perioperative phase of organ implantation to reduce the incidence of acute rejection in the early post-transplant phase [4,12,13]. Also, there are longer term benefits because chronic graft failure and decreased long-term survival correlate with the frequency of acute rejection. However, the side-effects of induction agents are significant (polyclonal antibodies, opportunistic infections, post-trasplant lymphoproliferative disorder (PTLD), anaphylaxis, monoclonal antibodies, hypersensitivity reactions). Induction therapy allows a delayed and gentle introduction of maintenance immunotherapy, thereby reducing the potential for harm (e.g. renal damage) from toxic drug concentrations [14,15].

## Maintenance therapy Steroids

Corticosteroids are used in most solid-organ transplant protocols for induction, maintenance and acute rejection. Their side-effects include hypertension, diabetes mellitus, osteopenia, poor wound healing, cataracts, emotional lability, hyperlipidemia, salt and water retention, Cushingoid habitus, weight gain, hirsutism, acne, and growth impairment. Steroid-free maintenance has been successfully achieved in liver, heart and kidney but not lung transplantation [16,17].

#### **Calcineurin inhibitors**

Adult data comparing the two calcineurin inhibitors (CNI) indicate that tacrolimus improved graft survival and prevented acute rejection more effectively than cyclosporin. Nephrotoxicity is an adverse side-effect common to both and is a major concern in pediatric solidorgan transplant patients. Acute toxicity is dose dependent and can lead to chronic renal damage and transplantation. Renal-sparing strategies include the use of mycophenolic acid (MPA) and mTOR inhibitors. The side-effect profiles of CNI drugs are similar; generally hirsutism, hypertrichosis, gingival hyperplasia, hypertension, and hyperlipidemia are more likely with cyclosporin and diabetes, tremor, peripheral neuropathy, alopecia, and gastrointestinal symptoms are more common with tacrolimus. The seizures associated with CNI agents seem dose related and are thought to be due to ischemia from cerebral vasoconstriction. Autoimmune hemolytic anemia and leukopenia have been reported with both drugs, but may improve by switching to the other CNI.

### Antiproliferative agents

The principal side-effect of azathioprine is bone marrow depression. Other concerns are UV-dependent increase in skin cancers, pancreatitis and hepatotoxicity. Azathioprine has largely been replaced by MPA-containing drugs such as mycophenolate mofetil (MMF) have similar mechanisms of action but are more potent and have better efficacy [18]. The two main side-effects of MPA are gastrointestinal problems and marrow depression.

#### Mammalian target of rapamycin inhibitors

Mammalian target of rapamycin inhibitors such as sirolimus and everolimus cause an arrest in cell cycle and cell differentiation. Sirolimus inhibits vascular smooth muscle proliferation and hence may have a protective effect against coronary artery vasculopathy in cardiac allografts [19]. Adverse side-effects of mTOR inhibitors include renal dysfunction, hyperlipidemia (typically responds to statins), delayed wound healing, bone marrow suppression, aphthous ulcers and systemic inflammatory response syndrome (e.g. pnuemonitis). The anti-CD20 monoclonal antibody rituximab may be added.

### Acute rejection therapy

Usual first-line therapy is steroids, with the addition of polyclonal lymphocyte-depleting antibodies (antithymocyte globulin, ATG) in more severe cases of rejection. Maintenance immunosuppression might be switched from cyclosporin to tacrolimus. Antibody-mediated rejection is treated with plasmapheresis and IV immunoglobulin.

#### **Newer agents**

Normal immune tolerance to self-antigens involves central and peripheral mechanisms that potentially may be manipulated to allow recipient tolerance to alloantigens [20]. Anti-CD52 antibodies cause profound lymphocyte depletion and were thought to hold promise as a tolerance-inducing agent. However, clinical studies to date are discouraging.

Abatacept and belatacept cause co-stimulation blockade of T-cell CD28 receptor binding to CD80/CD86 of the antigen-presenting cell and may allow less nephrotoxic maintenance regimens. Pediatric data are lacking.

## Liver transplantation

Thomas E. Starzl performed the first human liver transplant in a 3-year old child with biliary atresia in 1963. The attempt ended in failure from intraoperative hemorrhage, and Dr Starzl performed the first successful liver transplant in a child in 1967. One-year survival after liver transplant remained below 50% until the introduction of cyclosporin in 1979. By 1983, pediatric liver transplantation was deemed the standard of care for hepatic failure or end-stage liver disease [21] and in 2002, the pediatric end-stage liver disease (PELD) and model for end-stage liver disease (MELD) scores were implemented to prioritize organ allocation to the sickest patients, rather than to those with the longest wait time, as had been the case. In addition, the PELD system conferred special status and protection to pediatric organs and recipients. Today pediatric liver transplantation is one of the most successful solid-organ transplants. According to US Organ Procurement and Transplantation Network (OPTN)/ Scientific Registry of Transplant Recipients (SRTR) data, the 1-year patient survival rate is 83–91%, depending on the age at transplant [22]. The number of pediatric liver transplants per year has remained steady in the last 10 years, averaging approximately 600 annually. Currently, pediatric transplants account for about 10% of all liver transplants in the United States, and the majority of these transplants involve children less than 12 years of age. Liver transplantation is now performed on infants less than 3 months of age with graft survival and patient survival that are similar to older patients [23].

## Indications for hepatic transplantation

The indications for liver transplant are listed in Table 27.2. Life-threatening complications secondary to hepatic

 Table 27.2 Underlying diagnoses of children undergoing liver transplantation

Diagnosis	Frequency (%)
Cholestatic liver disease	48
Biliary atresia (15%)	
Other: Alagille syndrome, sclerosing cholangitis, progressive familial intrahepatic cholestasis	
Fulminant hepatic failure	11
Metabolic liver disease	13
Primary non-hepatic disease: ornithine transcarbamylase deficiency, primary hyperoxaluria type 1, organic acidemia	
Primary hepatic disease: Wilson disease, α1-antitrypsin deficiency, tyrosinemia, cystic fibrosis	
Liver tumors	4
Other	9

Reproduced from Ng et al [24] with permission from the American Academy of Pediatrics.

failure or chronic end-stage liver disease are the primary indications for transplantation. Another indication is progressive primary liver disease refractory to maximal medical management, before the development of lifethreatening complications. A smaller number of liver transplants are performed for metabolic disease, in which liver replacement is curative, and for unresectable primary liver tumors. Fulminant hepatic failure (FHF) is the indication for liver transplantation in approximately 11% of pediatric cases [24]. These children commonly present with rapidly developing life-threatening complications, and therefore establishment of the underlying diagnosis is not always feasible. Approximately 13% of children undergo liver transplantation because of metabolic diseases [25-28], and these patients generally have excellent outcomes [27,29]. Pediatric patients with liver tumors represent a growing group of transplant recipients. Hepatoblastoma is the most common pediatric primary liver tumor. Resection in combination with systemic chemotherapy is the preferred method of treatment. If the tumor is unresectable after appropriate chemotherapy, transplantation may be offered if there has been a demonstrated response to therapy, even in the face of pulmonary metastases [30-32]

## Pathophysiology of end-stage liver disease

Patients with end-stage liver disease that results from many causes manifest similar pathophysiology (Table 27.3). The clinical manifestations from end-stage liver Table 27.3 Pathophysiology in end-stage liver disease

Organ System	Common Findings
Cardiovascular	Hyperdynamic circulation; increased cardiac output, decreased systemic vascular resistance, increased stroke volume and ejection fraction Expanded plasma volume Arteriovenous shunting
Pulmonary	Restrictive pulmonary function secondary to ascites Hypoxemia secondary to ventilation/perfusion mismatch, impaired hypoxic pulmonary vasoconstriction, intrapulmonary shunting Pulmonary hypertension Hepatopulmonary syndrome
Central nervous system	Encephalopathy Cerebral edema with fulminant hepatic failure
Gastrointestinal	Hepatic dysfunction: synthetic, metabolic, excretory aspects Portal hypertension (esophageal varices, portal hypertensive gastropathy) Delayed gastric emptying
Renal	Renal dysfunction from prerenal azotemia (secondary in diuretics)
Hematologic	Elevated PT Thrombocytopenia Anemia Hypofibrinogenemia, dysfibrinogenemia Fibrinolysis Disseminated intravascular coagulation
Fluids, electrolytes, acid–base status	Intravascular volume depletion (secondary to diuretics) Hypokalemia, hyponatremia Metabolic alkalosis Metabolic acidosis (especially fulminant hepatic failure)

disease develop from the loss of hepatocytes and resulting fibrosis. The loss of hepatocytes results in the development of coagulopathy, hypocholesterolemia, hypoalbuminemia, and encephalopathy. Hepatocellular injury results in fibrosis and destruction of the portal triad with increased resistance to liver blood flow leading to portal hypertension manifest by varices (esophageal, bowel), hemorrhoids, ascites, spontaneous bacterial peritonitis, splenomegaly with thrombocytopenia, and hepatic encephalopathy.

The cardiovascular system undergoes marked changes as the child develops cirrhosis and end-stage liver disease. Patients frequently have a hyperdynamic circulation, decreased systemic vascular resistance, increased cardiac output, and a slightly decreased arterial blood pressure. The pathophysiology producing peripheral vasodilation remains obscure, and the "humoral factor" theory is the most widely accepted explanation [33]. In cirrhosis, increased intrahepatic resistance induces portosystemic collateral formation, allowing gut-derived humoral substances (endocannabinoids and nitric oxide (NO)) to enter the systemic circulation directly without detoxification by the liver. The hyperdynamic circulation of the patient has important implications for the anesthesiologist, including a decreased sensitivity to catecholamines and vasoconstrictors, an increase in mixed venous oxygen saturation, with a decreased arteriovenous oxygen difference. Because of the vasodilated state, anesthetics may cause severe hypotension in this patient population.

Patients with end-stage liver disease also manifest significant changes in the pulmonary system and are frequently hypoxemic. Many patients with chronic liver disease have abnormal pulmonary mechanics and some degree of alveolar hypoventilation. The presence of ascites and increased infra-abdominal pressure alters respiratory mechanics and often reduces functional residual capacity. Atelectasis produces ventilation/ perfusion mismatch and is common in patients with ascites, hepatosplenomegaly, and/or pleural effusions. Hepatopulmonary syndrome (HPS) is characterized by hypoxia from intrapulmonary arteriovenous shunting and intrapulmonary vascular dilation [34]. The diagnosis is predicated on either arterial hypoxia (PaO<sub>2</sub> <70 mmHg) or an alveolar-arterial gradient greater than 20mmHg in the setting of pulmonary vascular dilation. Intrapulmonary vascular dilation can best be demonstrated on echocardiography or by macroaggregated albumin perfusion scan [35]. Again, the most likely explanation for the development of HPS is systemic absorption of nitric oxide from the gut without detoxification in the liver. Supplemental oxygen therapy is the mainstay of supportive therapy and definitive treatment is liver transplantation. A case series of seven children with hepatopulmonary syndrome and severe hypoxemia were successfully transplanted and recovered from hepatopulmonary syndrome on average within 24 weeks of their liver transplant [36].

Portopulmonary hypertension (PPH) is defined as pulmonary artery hypertension (pulmonary systolic pressure  $\geq 25 \text{ mmHg}$ ) in the setting of normal pulmonary capillary wedge pressure and portal hypertension [37]. The incidence of PPH is 0.2–0.7% in adults with cirrhosis and is present in 3–9% of adults undergoing liver transplantation [38]. The incidence in children is probably lower, and occurrences are limited to case reports and one case series. The signs and symptoms of PPH on presentation include a new heart murmur, dyspnea, and syncope. Echocardiography can diagnose pulmonary hypertension and is one reason why routine screening of potential liver transplant candidates includes a baseline echocardiogram [39]. The largest retrospective review of 43 adult patients found mean pulmonary artery pressure (MPAP) to be predictive of outcome. Those patients with a MPAP <35 mmHg did not have increased mortality after orthotopic liver transplantation (OLT). In contrast, those with a MPAP = 35–45 mmHg had a mortality of 50%, and those with a MPAP >50 mmHg had 100% mortality [40].

Among children with PPH, early identification is essential. If PPH is suggested by screening echocardiography, a cardiac catheterization should be performed to confirm the diagnosis, measure the pulmonary pressures, and assess the response to NO and epoprostenol. Children who respond to medical management may be candidates for liver transplantation [41]. Severe PPH is generally a contraindication for liver transplantation because of the high mortality.

Hepatic encephalopathy is a significant neurological complication of liver disease that may be acute, as seen in fulminant hepatic failure, or chronic. Table 27.4 presents the staging of hepatic encephalopathy [42]. Cerebral edema is a feature of both acute and chronic encephalopathy; however, it is more severe and happens more rapidly in acute hepatic encephalopathy, commonly leading to increased intracranial pressure (ICP). The pathogenesis is thought to be due to hyperanmonemia that more readily crosses the blood–brain barrier and will cause astrocytes to swell, leading to low-grade cerebral edema [43]. Blood

Grade 0	Minimal hepatic encephalopathy, lack of detectable changes in personality or behavior; no asterixis
Grade 1	Trivial lack of awareness, shortened attention span, sleep disturbance, altered mood, and slowing the ability to perform mental tasks; asterixis may be present
Grade 2	Lethargy or apathy, disorientation to time, amnesia of recent events, impaired simple computations, inappropriate behavior, and slurred speech; asterixis is present
Grade 3	Somnolence, confusion, disorientation to place, bizarre behavior, clonus, nystagmus, and positive Babinski sign; asterixis usually absent
Grade 4	Coma, lack of verbal, eye, and oral response to stimuli

Reproduced from Zafirova & O'Connor [42] with permission from Lippincott Williams and Wilkins.

ammonia levels develop from catabolism of endogenous protein and gastrointestinal absorption. Ammonia is formed when bacteria in the gut break down nitrogencontaining products, which are then absorbed into the portal circulation. Therefore, blood ammonia levels will increase from increased catabolism due to infection, increased gut absorption from high protein diets, gastrointestinal bleeding, and renal failure. Arterial ammonia levels over  $200 \mu g/dL$  have been strongly correlated with cerebral herniation and death. Other factors that may contribute to cerebral edema include benzodiazepines, hyponatremia, and inflammatory cytokines. Management typically focuses on reducing gastrointestinal production and absorption of ammonia. Lactulose is often prescribed to create an osmotic diuresis and to acidify the lumen of the gut to trap ammonia and minimize absorption, yet has not been shown to improve survival [42]. Antibiotics (e.g. neomycin and metronidazole) are sometimes used to kill the gastrointestinal bacteria involved in metabolizing nitrogen products to ammonia.

As hepatic encephalopathy progresses, the child's ability to manage the airway should be carefully assessed. Children with grade 3 and 4 disease commonly require endotracheal intubation to protect their airway and to maintain oxygenation and ventilation. Increased ICP occurs in 38-81% of adult patients with fulminant hepatic failure [44] and brain computed tomography is recommended in those with grade 3-4 hepatic encephalopathy. Simple therapeutic measures, which can be performed on all patients, include elevation of the head of the bed to 30° and minimizing stimulation. Acute hyperventilation fails to reduce episodes of cerebral edema, and it does not delay onset of herniation [44]. Intracranial pressure monitors may help to diagnose intracranial hypertension and optimize management, although their use remains controversial [45,46]. Non-randomized trials have shown no survival advantage. Medical management to reduce ICP includes intravenous administration of sodium thiopental or propofol to minimize stimulation and to directly reduce ICP. Mannitol can be administered if ICP remains increased. Hypothermia has also been used to treat increased ICP. In a trial of 14 patients with fulminant hepatic failure, ICP was significantly reduced by mild hypothermia to 32-33°C [45]. Corticosteroids have no role in this setting [47] and OLT remains the definitive treatment.

The gastrointestinal system undergoes many changes when patients have end-stage liver disease, including abnormal synthetic, metabolic, and excretory functions of the liver and portal hypertension. Complications of portal hypertension include (1) altered hepatic and intestinal lymph flow and decreased plasma oncotic pressure, which facilitate the development of ascites, and (2) gastrointestinal bleeding from esophageal and gastric varices or from portal hypertensive gastropathy.

Renal failure commonly complicates acute and chronic liver disease in adults but the incidence in children is considerably lower [48]. Renal insufficiency is common and may be caused by prerenal azotemia, acute tubular necrosis or hepatorenal syndrome. Prerenal azotemia may develop from the use of diuretics, gastrointestinal bleeding, splanchnic pooling, and sepsis. Acute tubular necrosis develops when the kidney becomes ischemic from these same etiologies. Hepatorenal syndrome is characterized by renal insufficiency or failure in the setting of liver failure and portal hypertension.

The pathophysiology of hepatorenal syndrome is thought to be secondary to intense renal vasoconstriction from activation of the renin-angiotensin, arginine vasopressin, and sympathetic nervous systems [49]. Hepatorenal syndrome presents as prerenal azotemia (increased creatinine, decreased urine sodium) but a fluid challenge will not improve renal function. Rapid progression of renal failure from hepatorenal syndrome is classified as type 1, and is characterized by a rapid progression of renal failure with a 100% increase in creatinine in less than 2 weeks. This form usually occurs in acute liver failure. In type 2, renal failure progresses over weeks to months. Dopamine, diuretics, and octreotide have all been used to remove excess volume and optimize renal perfusion; however, OLT remains the definitive therapy because renal failure is reversible if the liver is replaced [50]. Combined liver-kidney transplantation is an option for children with both liver and renal disease.

Hematological abnormalities occur with liver disease because synthesis of fibrinogen and factors II, V, VII, IX, and X decreases [51]. Because of the decreased synthesis of these factors, the prothrombin time (PT) and the partial thromboplastin time (PTT) are increased. Thrombocytopenia is common when patients develop hypersplenism in response to portal hypertension. Also, anticoagulant factors (protein C and S, antithrombin III) are reduced in patients with end-stage liver disease. The altered hemostasis increases the risk of inserting vascular catheters and nasogastric tubes, and increases the potential for excessive bleeding from surgical wounds. Antifibrinolytics such as aprotinin and aminocaproic acid have been reported to reduce blood loss; however, there are insufficient data to recommend their use.

Electrolytes and acid–base balance often are altered in chronic liver disease by renal dysfunction and/or the use of diuretics. Acid–base changes may be due to renal dysfunction or to changes in ventilation. The intravascular volume status may be difficult to assess in patients with liver disease due to the presence of ascites, peripheral edema, and anasarca. The effective plasma volume is often inadequate. Consequently, intraoperative measurement of central filling pressures is required during transplantation.

## Anesthetic management Preoperative evaluation

Most transplant centers utilize a multidisciplinary approach for the evaluation of patients for liver transplantation. Typical laboratory studies include blood typing, blood chemistries, liver and renal function tests, coagulation profiles, and viral serologies. Cardiac and pulmonary systems are assessed through electrocardiogram (ECG), chest x-ray, and echocardiography. A careful neurological examination should be performed to detect any problems present in the preoperative period. Anatomical assessment of the native liver typically includes abdominal ultrasound and/or computed tomography or magnetic resonance imaging. A liver biopsy may be indicated to confirm the diagnosis or severity of the liver disease. Also, an assessment of the psychosocial and financial situation of the child's family is performed. Following the initial evaluation, the patient's history and data are presented to a selection committee, which decides if the patient is a candidate for transplantation. Patients approved for transplantation are then activated on the transplant center's recipient list. In situations of acute hepatic failure or rapid decompensation of chronic liver disease, the evaluation process can be condensed to a few hours.

Referral to the transplant center and acceptance of the child as a transplant candidate allow the transplant center physicians the opportunity to optimize the patient's medical condition while the child awaits transplantation. Medical therapy to control ascites, infection, and encephalopathy is initiated. Nutritional assessment and diet modification are frequently performed. Endoscopy and sclerotherapy may be performed to treat gastrointestinal bleeding. If the patient has cardiopulmonary disease, additional studies, including arterial blood gases, response to inhaled oxygen, and cardiac catheterization, may be indicated (see discussion above). Vitamin K may be administered to improve hemostatic function. Prophylactic dental work or dental extraction and tonsillectomy and adenoidectomy are performed if required prior to transplantation and initiation of immunosuppression.

### Perioperative period

In general, patients are admitted from home when a potential donor is identified. Because of the logistical complications associated with scheduling, performing donor surgery, and transporting the donor organ to the transplant center, 8–12h notice is often provided to the patient, family, and transplant team members.

Upon admission to the hospital, interval history and physical examination are performed to seek evidence of new changes and complications since the original pretransplant evaluation. Whenever possible, the child is made NPO prior to surgery. In addition to routine blood tests, multiple additional blood samples are obtained for serological studies, and specialized immunotesting. A peripheral intravenous (IV) line is usually started and maintenance fluids administered.

Following arrival of the donor organ at the hospital, final inspection and possible biopsy and frozen section of the liver are performed. Following notification from the transplant surgeon that the liver is appropriate for transplantation, the child is transported to a warm operating room. In some children, especially those who are older, premedication may be required with either intravenous or oral midazolam. Children with hepatic encephalopathy should not receive premedication because midazolam may produce significantly greater central nervous system (CNS) depression among these patients and may potentially increase intracranial pressure. Routine monitors (pulse oximetry, ECG, arterial blood pressure) are applied prior to induction of anesthesia. One hundred percent oxygen is administered by facemask. Because of concerns that these patients have a full stomach and may aspirate gastric contents, cricoid pressure is applied and a rapidsequence induction of anesthesia is performed for most patients. Those who present for elective transplant to correct a metabolic disease may undergo inhalational induction. Since patients with significant ascites are likely to have a reduced functional residual capacity (FRC), adequate preoxygenation is required. Once the airway is secure, mechanical ventilation with an increased inspired concentration of oxygen and positive end-expiratory pressure (PEEP) is initiated. Cuffed endotracheal tubes are favored because they will make a reliable seal between the tracheal tube and the tracheal mucosa and reduce the risk of inadequate ventilation and monitoring of ventilation from a leak around the endotracheal tube.

Following tracheal intubation, vascular access is obtained and monitoring catheters are inserted. Ideally, two large-bore intravenous lines are placed in the upper extremities (20–22 gauge for infants, 18–20 gauge for a young child, and larger for older children). Adequate venous access is critical during any liver transplant procedure because the anesthesia team must be able to respond rapidly to surgical hemorrhage. The fluid delivery system must allow for sufficient control over the volume and rate of fluid and blood product administration in small children to prevent overhydration. An arterial catheter is inserted, preferably in a radial artery, because the aorta may be cross-clamped during reconstruction of hepatic arterial inflow. A multi-lumen central venous catheter is inserted after induction. One lumen is used for central venous pressure monitoring and the other lumens for infusion of medications and/or volume. The surgical team may decide to insert a tunneled central line if long-term access is likely to be needed in the postoperative period. Measuring pulmonary artery pressures may facilitate the perioperative management of patients with cardiac disease or associated pulmonary hypertension. Except for these rare cases, central venous pressure monitoring is sufficient in infants and children for liver transplant. Many adult centers use transesophageal echocardiography to monitor cardiac function and filling during liver transplantation but this is much less common in the pediatric setting [52].

Particular attention is paid to maintaining normal body temperature during pediatric liver transplantation. Numerous factors facilitate development of unintentional hypothermia: exposure of the abdominal contents to air, duration of surgery, rapid administration of cool intravenous fluids and blood products, and implantation of the cold liver graft and wash-out of the cold storage solution during reperfusion of the organ. Rigorous attention is paid to warming the operating room and to the use of insulated wrapping of exposed extremities, forced-air warming blankets, humidified anesthesia circuit, and warming of all intravenous fluids.

No particular anesthetic regimen has proven superior in liver transplantation. A combination of potent inhaled anesthetic, bolus doses of opioids or an infusion provides a relatively stable intraoperative course during liver transplantation. Higher concentrations of inhaled anesthetics reduce splanchnic blood flow and should probably be avoided. Sevoflurane, isoflurane and desflurane are commonly used with success when added to a balanced anesthetic technique with opioids. Nitrous oxide should not be used in order to avoid bowel distension. A comparison of right ventricular function in adult patients undergoing liver transplantation found no difference between propofol and isoflurane [53]. Even though the primary metabolic pathway for propofol is hepatic, there appears to be extrahepatic metabolism in the lung, kidney, and intestine [54,55].

Intravenous opioids have been used extensively in the anesthetic management of adult and pediatric patients undergoing liver transplant. Although end-stage liver disease is likely to affect the distribution and plasma clearance of opioids, the functioning newly transplanted liver graft will improve opioid clearance. Opioid analgesics undergo hepatic biotransformation via mixed function oxidase (e.g. fentanyl) and glucuronosyltransferase (e.g. morphine). Because the hepatic extraction of morphine and fentanyl is high, plasma clearance is less affected by alterations in hepatic function than by alterations in hepatic blood flow. Morphine, fentanyl, and sufentanil appear to have unchanged plasma clearance and volumes of distribution in patients with end-stage liver disease, which may reflect the ability of the large volume of distribution to buffer any decrease in drug metabolism. In contrast, alfentanil, with its volume of distribution approximately 25% that of the other opioids, has a decreased plasma clearance and an increased free fraction of drug in patients with cirrhosis. The impact of large changes in and replacement of intravascular volume during the course of a lengthy liver transplant procedure is not known.

Liver disease affects the duration of action of nondepolarizing muscle relaxants. The action of pancuronium is prolonged in patients with liver disease. The duration of action of vecuronium depends on the extent of liver disease and on the dose of vecuronium. Vecuronium in a bolus of 0.1 mg/kg has the same pharmacokinetics in both patients with normal livers and those with liver disease [56]. In more advanced liver disease, a dose of 0.2 mg/kg of vecuronium may have a prolonged duration of action [57,58]. Similarly, rocuronium will have prolonged duration of action after repeated doses despite a normal onset of action for the first dose [59]. Redistribution of the drug within the body may be important for the termination of the drug's effect in patients with liver disease, but when larger doses of drug are administered, reduced hepatic clearance becomes more evident. Studies suggest that the liver graft with normal function rapidly resumes its role of drug metabolism [60,61]. Despite the overall uncertainty of anesthetic drug metabolism in the perioperative period following liver transplantation, delayed recovery from anesthetic drugs and neuromuscular blockade rarely poses a clinical problem.

The timing of extubation of the trachea varies among centers; however, immediate postoperative extubation has gained acceptance and is practiced more commonly. In the author's institutions, tracheal extubation in the OR is performed in over 50% of patients. Most commonly, the decision to extubate the patient early is based on the presence or absence of co-morbidities.

Because of the duration of the procedure and the potential for hypoperfusion of the skin and extremities, positioning is critical to prevent injuries. All extremities should be padded, and all cables and wires need to be wrapped and protected from the skin. The head should be turned and repositioned periodically to prevent pressure sores and alopecia.

#### Surgical procedure

Liver transplantation is usually divided into four stages: dissection, anhepatic, and reperfusion with biliary anastomosis. During the dissection period, the liver is mobilized via a large bilateral subcostal incision. All perihepatic adhesions are lysed, the suprahepatic vena cava, infrahepatic vena cava, and structures in the porta hepatis (portal vein, hepatic artery, and common bile duct) are identified and mobilized. Lysis of dense adhesions following a Kasai portoenterostomy or other previous surgery usually prolongs the dissection time and increases blood loss during this period. Adequate replacement of blood components during this time is essential.

Prior to implantation, the donor organ is stored in preservation solution, most commonly University of Wisconsin (UW) solution. Because of the high potassium content (120mEq/L), the donor organ is perfused with a cold crystalloid or colloid solution to remove the preservation solution before the liver is implanted. When the dissection phase is complete in the recipient, the preservation solution is flushed out of the donor liver and it is brought into the operative field. However, flushing the donor liver with large volumes of fluid does not always remove all of the potassium, air, and particulate matter. Consequently, when the donor organ is reperfused, the recipient will receive a bolus of hypothermic solution, and may be subjected to hyperkalemia, thrombotic and air emboli. Bradycardia and increases in pulmonary artery pressure are common, and occasionally, there is a hyperkalemic cardiac arrest at the time the donor organ is reperfused.

The anhepatic stage begins with cross-clamping the suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery. This surgical approach will significantly reduce preload from cross-clamping the inferior vena cava (IVC). However, patients with chronic cirrhosis develop collateral circulation, and inferior vena cross-clamp is generally well tolerated. Partial clamping of the IVC is used for reduced-size grafts or when IVC cross-clamping produces cardiovascular instability. Using the piggy-back technique [62], the liver is dissected away from the inferior vena cava, the short hepatic veins, portal vein, and left, right, and middle hepatic veins. The infrahepatic vena cava of the donor is oversewn, and the suprahepatic vena cava is anastomosed to the native hepatic veins. In addition, a portocaval shunt can be established for children who do not tolerate clamping of the portal vein. Typically, these recipients have not developed collateral flow secondary to portal hypertension (e.g. metabolic liver disease and acute fulminant hepatic failure). During the anhepatic period, the native liver is completely excised, bleeding is controlled in the retrohepatic area, and the donor liver is sutured in place. The liver is most commonly reperfused with venous inflow, which accounts for approximately 80% of liver blood flow. The anhepatic period ends with restoration of blood flow to the new liver.

Following restoration of blood flow into the new liver, the final stage of the operation, reperfusion, has started. The surgical goals during this time include completion or revision of the hepatic artery anastomoses and establishment of biliary drainage. In infants and children, reconstruction of the hepatic arterial inflow may be more difficult and frequently includes reconstruction via a patch graft from the recipient aorta or donor saphenous vein graft to celiac trunk, hepatic artery or aorta. Biliary drainage may occur via a direct choledochocholedochostomy or, more commonly in children, via a Roux-en-Y choledochojejunostomy. A major goal during the early reperfusion period is control of bleeding. This period requires close communication between surgeons and anesthesiologists to determine the presence of a coagulopathy (common in the early reperfusion period) as opposed to defined surgical bleeding (common following the total hepatectomy of the native liver and multiple vascular anastomoses and following previous abdominal surgery). The operating team uses a variety of clinical observations (color, texture, bile production) and laboratory measurements (PT, metabolic acidosis, ionized calcium, and glucose concentration) to document the status and quality of liver graft function.

Occasionally, infants who have cardiac anomalies and intracardiac shunts require liver transplantation. This is especially dangerous because when the graft is reperfused there is the likelihood of air, clot, and other debris entering the systemic circulation. If this occurs, there is the danger of coronary artery or cerebral artery embolism. One method used to reduce this risk is to leave the vena cava above the liver clamped and to open the vena cava below to allow the initial blood entering the liver from the portal vein to exit the vena cava into the abdomen. This often means that one-fourth to one-third of the blood volume is lost via this route. This period of phlebotomy requires rapid replacement of blood, but is effective in reducing the risk of systemic embolization.

## Intraoperative management issues Hemodynamics

Periods of hemodynamic instability are common during liver transplantation. In the earlier portions of the anesthetic (e.g. during line placement, preparing and draping the skin), the general debilitating effects of end-stage liver disease and the reduced blood volume induced by diuresis may limit the patient's ability to compensate for the hypotensive effects of anesthetics. In response to abdominal incision and dissection around the native liver, surgical stimulation may overcome light levels of anesthesia and produce hypertension and tachycardia.

A more common scenario is development of hypotension at various points during the operation. Massive blood loss must always be entertained in the differential diagnosis for hypotension. Given the site of surgery, the presence of extensive abdominal and retroperitoneal collateral vessels, and scar tissue from previous surgeries, bleeding may be significant during the dissection phase of surgery. It should always be kept in mind that splenic bleeding is a possibility. The changes in hemodynamics during the anhepatic period are frequently the most complicated to understand. With application of the venous clamps to the portal vein and to the infrahepatic and suprahepatic vena cava, there is an abrupt decrease in venous return to the right side of the heart and subsequently to the left side of the heart. Although there may be a brief period of hypotension in response to application of the clamp, infants and children appear to tolerate moderate hypovolemia and maintain normal systemic arterial pressures. Stimulation may produce hypertension and tachycardia if the anesthesia level is light. Reflex tachycardia, reduction in central venous pressure (CVP), dampening of the arterial waveform during positive pressure ventilation, and development of a metabolic acidosis are all consistent with significant hypovolemia. In addition, this same hemodynamic picture may develop from surgical manipulation, resulting in compression of the inferior vena cava or right ventricle.

In adult patients, cardiac index may decrease 30-50% when the venous clamps are applied, but systemic arterial pressure is only slightly decreased because there is a compensatory increase in systemic vascular resistance. Volume administration during the anhepatic period is guided by central venous pressure, systemic arterial pressure, and the arterial pressure waveform. While surgical attention is focused on the vascular anastomoses during the anhepatic period, significant bleeding may continue from areas behind the liver and at other sites of collateral flow. In rare situations, vasopressin (0.1-0.3 units/min IV) may be required to decrease splanchnic blood flow while the anastomoses are being completed. Fluid administration may include crystalloid, colloid or blood products, depending upon the hemoglobin, PT, and preference of the surgeon and anesthesiologist. Colloid solutions may have particular benefit during the anhepatic period and end of the dissection period. Care should be taken not to administer excessive fluid during the anhepatic phase because when the blood is returned to the central circulation with unclamping the inferior vena cava, a high CVP will impair hepatic venous drainage. Typically a CVP of 8-10 mmHg is adequate to maintain arterial pressure at the time of reperfusion with little need for vasopressors.

Because the portal vein is clamped during the anhepatic period, portal venous hypertension develops. Because of the increased venous pressure, there is a tendency toward fluid translocation and bowel edema during the anhepatic period. Administration of colloid solutions during the dissection and anhepatic period may reduce the amount of bowel edema that develops and facilitate closure of the abdomen at the end of the operation. In addition, the extent of bowel edema may influence the duration of impaired intestinal motility following the operation. Because large volumes of hydroxyethyl starch are associated with coagulopathy, albumin solutions are routinely utilized for colloid administration. Patients with persistent hypotension may require cardiovascular support with dopamine or epinephrine during this time.

Infants and children commonly have normal urine outputs during the anhepatic period, apparently because there are other pathways by which venous blood can return to the central circulation. However, low urine output during the anhepatic phase is not an indication for fluid administration because of the potential adverse effects of high CVP and the routine recovery of urine output after removal of the venous cross-clamp. The CVP is a better indicator of hydration status.

Completion of the anhepatic period restores venous return from the lower extremities and splanchnic bed. Despite adequate intravascular volume, hypotension is a common finding following graft reperfusion. Numerous factors are felt to contribute to the hemodynamic changes associated with reperfusion. Immediately upon reperfusion, a combination of hypotension, bradycardia, and supraventricular and ventricular dysrhythmias may develop. Prior to reperfusion, a small bolus of fluids may be administered to optimize ventricular filling. Acid-base status is checked approximately 5-10 min before reperfusion. Sodium bicarbonate and calcium are administered to achieve a high-normal pH and calcium levels prior to cross-clamp release. At the moment of reperfusion, attention must be divided between the cardiac monitor and the surgical field. Evidence of life-threatening hemorrhage requires the immediate infusion of blood products while the surgeons control the bleeding. Inspection of the cardiac monitor will detect ECG changes consistent with profound bradycardia and/or hyperkalemia. Bradycardia may result from the sudden atrial stretch occurring with restoration of normal venous return and/or influx of cold storage flush solution, with profound alterations in pH and electrolyte content. If the heart rate decreases by 30-40%, atropine should be administered, and warm solutions should be instilled into the abdominal cavity.

Electrocardiogram evidence of hyperkalemia includes development of peaked T waves (rare in babies), QRS widening, and sine-wave formation. Inspection of the arterial waveform trace will confirm the loss of mechanical activity. The occurrence of hyperkalemia at the time of reperfusion represents systemic toxicity of organ preservation solution that was not removed when the organ was flushed. Acute interventions for hyperkalemia include administration of calcium and bicarbonate, and circulatory support with closed chest cardiac massage and epinephrine. Because the surge in serum potassium is transient, treatment is directed towards decreasing the concentration of serum potassium and restoring the cardiac rhythm. The potassium concentration increases 0.5-1.5 mEq/L at the time of reperfusion in almost all patients. Because this increase in potassium is expected during reperfusion, care should be taken to prevent increases in potassium concentrations during the dissection and anhepatic periods. Forced diuresis (renal dose dopamine, diuretic administration) can help lower the potassium level. In addition, insulin and glucose administration effectively decreases the serum potassium concentration during the anhepatic period. Following the abrupt increase at reperfusion, potassium concentrations tend to decrease during the remainder of the operation. Urinary losses of potassium account for some of the decrease, while potassium uptake by muscle cells and allograft liver cells also contributes to the decrease in serum potassium. Potassium administration is indicated if the serum potassium concentration decreases and the urine output remains adequate in the postreperfusion period.

Other factors, including transient hypocalcemia, acidosis, and hypothermia, contribute to hypotension following graft reperfusion. Studies in adult transplant patients suggest that approximately 30-40% of patients develop a "post-reperfusion" syndrome consisting of decreased arterial blood pressure and profound vasodilation [63]. A study utilizing transesophageal echocardiography (TEE) found right ventricular dysfunction (paradoxical motion of interventricular septum, right atrial enlargement, right-to-left interatrial deviation) following reperfusion. In addition, the pulmonary circulation is known to be sensitive to acute alterations in temperature and pH. Perfusion of the lungs with ice-cold, hyperkalemic, acidic blood may increase pulmonary vascular resistance and cause right ventricular dysfunction. Embolization of air, clot, and cellular debris can occur at the time of graft reperfusion, as was shown by the TEE study mentioned above.

Perturbations of hemodynamics at reperfusion can affect other organs and systems. The liver graft is sensitive to increased levels of central venous and pulmonary artery pressure. Vascular engorgement of the liver is common following reperfusion of the liver, especially if the CVP was greater than 10 mmHg before the liver was reperfused. Because the arterial blood supply to the liver may still be compromised (e.g. during the hepatic arterial reconstruction), excessive passive engorgement of the liver may deprive some areas of the liver of oxygen and cause poor restoration of graft function. Anesthetic management must attempt to prevent liver graft engorgement. If the systemic arterial pressure is adequate, infusion of nitroglycerin may reduce elevated central blood volumes and graft swelling or engorgement. Specific treatment for pulmonary hypertension includes increased

ventilation, correction of acid-base status, and normalizing body temperature.

#### Hemostasis

Intraoperative hemostasis is a complex issue during orthotopic liver transplantation [51,61]. The hemostatic system is often impaired by intrinsic liver disease and as a result of the transplant procedure. Based upon preoperative diagnosis and coagulation testing, several groups have attempted to predict the risk of intraoperative bleeding during liver transplant [64]. However, a predictive score that indicates a low likelihood of bleeding is not a reason to decrease the level of preparedness. Blood products should be immediately available for transfusion. Low potassium units of blood should be used (less than 2 weeks since collection) or it is prudent to wash units of packed red blood cells to remove the excess potassium. Once the initial extent of dissection and coagulopathy is determined, the need for additional cross-matching of blood and/or preparation of fresh frozen plasma, cryoprecipitate, and platelets can be determined. In the event of significant hemorrhage, the blood bank must be notified of anticipated increased requirements for blood products.

The anesthesia team is responsible for maintaining adequate hemostasis during liver transplant procedures. Central to this role is the ability to rapidly monitor coagulation status intraoperatively. For the monitoring system to be effective, the anesthesiologist must have rapid access to the results of these tests so that the abnormalities can be corrected immediately. Routine coagulation testing should include measurement of PT, activated PTT, platelet count, hemoglobin concentration, and fibrinogen concentration. Thromboelastography (TEG), a specific type of whole-blood viscoelastic coagulation monitoring, has been used successfully by some clinicians during liver transplantation [65]. It is a test of clot strength and requires a 30-60-min recording of clot formation and lysis. The TEG gives an indication of clotting factor activity, platelet function, and fibrinolysis. Since significant fibrinolysis is less common in children, TEG monitoring is not routinely utilized in most centers [52].

Intraoperative management of coagulopathy during liver transplantation includes the administration of blood products and potential pharmacological interventions. The principal blood product administered is fresh frozen plasma (FFP), which will correct clotting factor deficiencies. Because hepatic artery thrombosis is one of the most common causes of graft failure in pediatric patients, FFP is administered to correct and maintain values for PT and PTT close to 1.5 times prolonged from normal, depending on the amount and severity of intraoperative bleeding. Cryoprecipitate is administered when infusing FFP does not correct a low fibrinogen concentration (<80– 100 mg/dL). In the postreperfusion period, intravascular filling pressures may be elevated. Consequently, the decreased volume of cryoprecipitate is better tolerated.

Thrombocytopenia is a common finding during liver transplantation. Many patients have decreased platelet counts because portal hypertension has induced hypersplenism. Intraoperative thrombocytopenia may develop or worsen due to replacement of blood loss during the dissection phase with solutions that do not contain platelets. Platelet counts decrease slightly during the anhepatic period and decrease significantly upon reperfusion of the graft. Platelet entrapment within the grafted liver has been demonstrated in a porcine model of liver transplantation; in addition, platelet activation and consumption increase following reperfusion of the graft. Platelet counts of 50,000-100,000 commonly develop and are not an indication for platelet transfusion in the absence of excess bleeding. Overtransfusion of platelets may also increase the risk of hepatic artery thrombosis. Platelet transfusion is indicated if thrombocytopenia is present and there is a clinical impression of abnormal hemostatic function.

Severe postreperfusion coagulopathy occurs in some patients who undergo liver transplantation, possibly because of the reperfusion-initiated disseminated intravascular coagulation. Studies indicate that primary fibrinolysis may develop during liver transplantation due to changes in the circulating concentration of tissue-type plasminogen activator (t-PA). Both ɛ-aminocaproic acid (EACA) and aprotinin have been utilized to pharmacologically reduce the severity of fibrinolysis during orthotopic liver transplantation. EACA improves the TEG findings of fibrinolysis during liver transplantation; however, prophylactic use of EACA has not been demonstrated to be of value. Administration of aprotinin, a protease inhibitor of kallikrein, decreases the laboratory abnormalities associated with fibrinolysis and reduces transfusion requirement during liver transplantation [66]. The worldwide marketing of this agent was suspended in 2008 due to complications in the adult cardiac surgery population, including thrombosis, stroke, and renal failure, and it is not available in the US. Children are hypercoagulable after liver transplantation because of a decrease in protein C and antithrombin III [67] and they may be more likely to develop hepatic artery thrombosis or emboli [68–70]. Therefore antifibrinolytics are not routinely used in most pediatric transplant centers.

Hepatic artery thrombosis may result from disorders of the coagulation system and/or technical factors in hepatic arterial reconstruction. Intraoperative and postoperative Doppler ultrasound examinations of the hepatic arterial and portal vein anastomoses are commonly used to assess patency of the anastomoses. Because of the potential for graft loss with vessel thrombosis, a slightly anticoagulated state is maintained in infants and small children following liver transplantation. This includes avoiding fully correcting the heparin effect in the operating room, maintaining a slightly higher prothrombin time, and early administration of aspirin. At Texas Children's Hospital, our practice is to start a heparin infusion in the operating room once hemostasis has been achieved after reperfusion and to continue this infusion for the first few days postoperatively. In addition, hyperviscosity from overtransfusion of red cells should be avoided. Maintaining the hemoglobin between 8 and 10 mg/dL provides adequate oxygen-carrying capacity.

## Metabolic control (K<sup>+</sup>, Ca<sup>2+</sup>, acid–base, glucose)

Acute changes in acid–base status, potassium concentration, ionized calcium, and glucose are common, both before and during liver transplantation. Concomitant renal dysfunction promotes acid–base changes and exacerbates electrolyte problems. Diuretic therapy can cause electrolyte imbalance (hyponatremia, hypokalemia, hypocalcemia) and prerenal azotemia. A common pattern of electrolyte changes develops in most patients. Consequently, an anticipated treatment plan can be developed. Routine intraoperative monitoring of arterial blood gases, electrolytes, and glucose concentrations will define the need for and further refine intraoperative electrolyte therapy. Because of the multiple factors contributing to hemodynamic instability in these patients, these parameters are more tightly controlled than in other operations.

Many patients who present for surgery have hyponatremia due to prerenal azotemia and the use of diuretics. Care should be taken to avoid a rapid rise in sodium concentrations during surgery from the use of salt-containing solutions, sodium bicarbonate and blood products. Also, both hypo- and hyperkalemia are frequently encountered during surgery (see discussion above).

Patients undergoing liver transplantation are particularly susceptible to the development of ionized hypocalcemia. Although total calcium concentrations are decreased in patients with chronic liver disease, ionized calcium concentrations are normal. Intraoperative administration of blood products decreases ionized calcium and magnesium concentrations because citrate-based anticoagulant solutions used in collection and storage of blood products bind these ions. Citrate usually is metabolized rapidly by the liver. In normal patients, low ionized calcium concentrations only occur following massive and rapid administration of blood products. Patients with end-stage liver disease are particularly sensitive to the administration of citrate-containing blood products, and administration of moderate amounts of FFP can significantly decrease ionized calcium concentrations.

Profoundly low ionized calcium concentrations, particularly during the anhepatic period, may cause myocardial depression and hypotension. Given the potential for dramatic changes in the ionized calcium concentration, direct measurement of ionized calcium is particularly useful during liver transplantation. Calcium replacement therapy during the dissection and anhepatic phases can be achieved with either bolus administration or constant infusion of calcium. Calcium chloride and calcium gluconate are equally effective in increasing the ionized calcium concentration during the anhepatic period [71]. Calcium requirements are expected to increase (often markedly) during the anhepatic period and to quickly decrease following reperfusion of the hepatic allograft. With restoration of blood flow to the liver graft, metabolism of citrate proceeds at a much greater rate than occurred with the native liver or during the anhepatic phases. Reduction in calcium requirement following reperfusion is consistent with adequate hepatic allograft function. As mentioned earlier, normal ionized calcium concentrations at the end of the anhepatic period may protect against the cardiovascular effect of abrupt increases in potassium from the reperfused liver. Measurement of ionized calcium 5 min before graft reperfusion and administration of calcium prior to reperfusion is suggested.

Metabolic acidosis is extremely common during orthotopic liver transplantation. Numerous factors contribute to its development, including tissue hypoperfusion, decreased or absent metabolism of lactate, citrate, and other metabolic acids by the liver, rapid administration of acidic blood products, associated renal impairment, and acidic effluent from the liver allograft. During the dissection period, development of acidosis most commonly reflects global tissue hypoperfusion. Administration of additional intravascular volume and restoration of adequate blood pressure and cardiac output often corrects the acidosis. The anhepatic period in particular is associated with rapid development of acidemia. The contribution of decreased tissue perfusion (caused by the abnormal hemodynamics associated with vena cava and portal vein occlusion) and the absence of hepatic function is unknown. Sodium bicarbonate is used to treat metabolic acidosis during the anhepatic period, and the amount of bicarbonate administered is based on the rapidity and severity of changes in acid-base balance. In general, with base deficits greater than 5-8 mEq/L or pH less than 7.35 (PaCO<sub>2</sub> <40 mmHg), bicarbonate should be administered to create a relatively normal pH immediately prior to reperfusion of the graft. Arterial blood gases and pH measurements obtained approximately 5min prior to reperfusion will determine the amount of bicarbonate required.

Following reperfusion of the liver graft, metabolic acidosis frequently recurs. Treatment of severe metabolic acidosis at this point is indicated when there is concomitant myocardial depression and/or there are signs of persistent hyperkalemia. Normally, the exacerbation of metabolic acidosis quickly abates during the postreperfusion period; this abatement is one of the early signs that the graft is functioning. The liver allograft usually resumes metabolic function rapidly, and hepatic metabolism of lactate and citrate frequently leads to the development of a metabolic alkalosis in the later portions of the operation and in the postoperative period. Resolution of metabolic acidosis (and development of alkalosis) is indicative of adequate allograft function, although the sensitivity and specificity of these findings are not known. The extent of the metabolic alkalosis is related to the amount of intraoperative transfusion, and not to the amount of bicarbonate administered.

Glucose balance is complicated by liver transplantation. Hypoglycemia may be present in patients with fulminant liver failure or severe chronic liver disease and may necessitate preoperative administration of dextrosecontaining fluids. It usually is necessary to administer glucose to these patients before the graft is reperfused. In theory, the anhepatic period should pose a greater risk of hypoglycemia because there is no liver in the circulation. Numerous factors are present that help maintain a relatively normal glucose concentration in the blood during the anhepatic period: stress response to surgery, steroid administration, dextrose-containing blood products, and reduced glucose utilization due to hypothermia. Since organ preservation solutions and flush solutions frequently contain dextrose, glucose concentrations commonly increase after reperfusion of the graft. Hyperglycemia in the reperfusion period also has been suggested as a marker for allograft function. Small infants may have markedly decreased glycogen stores when presenting for liver transplantation and are frequently at increased risk for developing hypoglycemia. Preoperative and frequent intraoperative glucose determinations are the best methods of detecting abnormal glucose levels. Dextrose should be administered if hypoglycemia is present. Persistent hyperglycemia, glucose greater than 250 mg/dL, is treated with insulin administration.

#### **Temperature maintenance**

Hypothermia is common during liver transplantation, despite utilization of multiple methods to conserve body heat. The long intra-abdominal operation, massive fluid and blood product administration, and implantation of a graft that has a temperature near zero all contribute to the development of hypothermia. There is usually a 1–2°C decrease in body temperature when the ice-cold donor liver is placed in the abdomen. There also may be an abrupt decrease in core temperature of 1–2°C with reperfusion when cold flush solution is infused into the systemic circulation. Profound hypothermia carries

significant theoretic risk, including cardiac depression, arrhythmias, abnormalities in clotting function, and decreased renal function. Because of these risks, specific efforts are directed at maintaining core temperature. Heating the operating room is imperative for infants and small children. A forced-air warming blanket is placed beneath the child and the exposed extremities are wrapped. Forced-air warming is useful over the legs and/or upper extremities in larger patients. Intravenous fluids and blood products are warmed prior to their administration. Lowering of fresh gas flows and using a humidifier will reduce the heat loss caused by use of cold dry inspired gases.

## **Special techniques** Reduced-size grafts (pare-down, split, live donor grafts)

Three advances in surgical technique have improved the number of available grafts for children: dividing the liver and using a reduced-size graft, or even two grafts for two recipients, and living donor transplantation. The surgical technique most commonly used to split the liver is performed while still in vivo (in the heart-beating donor) as compared with ex vivo (splitting performed after the graft is removed from the donor). This decreases cold ischemia time and facilitates hemostasis of the liver edge. This technique results in improved child and graft survivals [72,73]. The Studies in Pediatric Liver Transplantation (SPLIT) group is an excellent source of data regarding pediatric liver transplantation in North America. This group represents 46 pediatric liver transplant centers across America and Canada and reflects the results of programs with a strong pediatric emphasis. The most recent review of the SPLIT database reveals patient survival rates of 91.4% and 86.5%, at 1 and 5 years following liver transplantation, respectively [74].

Living related transplantation has greatly benefited the pediatric transplant population, particularly in countries in which there is limited availability of deceased donor grafts for cultural or even legal reasons [75]. In this procedure, a left lateral segmentectomy (segments 2 and 3) is performed in the donor and transplanted in a similar fashion to the whole organ. Approximately 300 living donor liver transplants are performed annually and 20% of these are in child recipients [22]. Despite the success of this technique for the recipients, there is considerable risk to the donor. Complications include exposure to blood products, peripheral nerve injuries, biliary leakage, abdominal wall defects, pleural effusions, pneumonia, pulmonary emboli, and death [76,77].

## Retransplantation

Hepatic retransplantation is performed to treat primary non-function of the allograft, allograft dysfunction resulting from thrombosis of the hepatic artery or portal vein, rejection unresponsive to aggressive medical therapy, or recurrent or primary disease in the transplanted liver. Retransplantation rates are 10-20%. Because of the dense adhesions around the transplanted liver, significant hemorrhage may occur during the dissection phase. In addition, if the liver has sustained an ischemic insult, disruption of the vascular anastomoses may occur and produce catastrophic hemorrhage. There must be adequate vascular access to allow massive volume resuscitation. Sufficient blood products must be available in the operating room to rapidly instill one blood volume in the patient. Most reports indicate that patient survival following retransplantation of the liver is worse than it is following the primary transplant. However, a recently published manuscript found graft and patient survival after retransplantation to be similar to primary liver transplantation [78].

## **Renal transplantation**

#### Indications

Renal transplantation is the optimal therapy for children with chronic renal insufficiency (CRI) and end-stage renal disease (ESRD). Despite the availability of dialysis for children, transplantation is the preferred long-term management for children with ESRD to allow the best chance for normal growth, activity, and development. Also, the risk for death is more than four times higher with dialysis than with renal transplantation [79]. The incidence of ESRD in children 0–19 years of age is between 5 and 12 per million. The incidence increases with age and males are more likely to develop ESRD than females secondary to the higher rate of congenital urological anomalies. The etiologies of ESRD, and therefore the disease processes leading to transplant, differ depending on the age of the patient. For children under 5 years of age, congenital lesions (renal dysplasia/aplasia, obstructive uropathy, complex urogenital malformations, and congenital nephrosis) are responsible for the majority of pediatric transplants. Over 5 years of age, glomerulonephritis (e.g. focal glomerulosclerosis, membranoproliferative glomerulonephritis) and recurrent pyelonephritis are major causes of ESRD. The North America Pediatric Renal Transplant Cooperative Study (NPRTCS) (https://web.emmes.com/ study/ped/registry) registry reported that from 1987 to 2008, in 9854 transplants, 47% were over 12 years of age, 33% were 6-12 years of age, 15% were 2-5 years, and only 5% were under 2 years of age.

The outcome of renal transplantation in children is encouraging. The North American Pediatric Renal Transplant Co-operative Study annually reports the overall graft survival rate (Table 27.5).

Table 27.5	Kidney transp	plant graft	survival rates	from the	North
American Pe	ediatric Renal	Transplant	Co-operative	e Study	

Graft survival rate							
Cohort	Living donor			Deceas	Deceased donor		
group	1 yr	3 yr	5 yr	1 yr	3 yr	5 yr	
1987– 1990	89.4	81.2	74.6	75.2	63.5	54.8	
1991– 1994	91.8	85.4	80.4	85.2	76.4	69.5	
1995– 1998	94.0	90.5	85.3	90.6	81.8	73.9	
1999– 2002	95.9	91.2	85.9	92.7	83.9	79.5	
2003– 2007	96.1	90.6	-	94.4	81.1	-	

Data from the North America Pediatric Renal Transplant Co-operative Study (NPRTCS).

#### Pathophysiology

A patient's fluid and electrolyte balance is dramatically altered by renal failure. Hypervolemia, hypovolemia (after dialysis), hyponatremia, hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis are common. Because the failing kidney may not excrete adequate free water, hypervolemia is frequent and is a cause of hypertension. Hypovolemia can occur after aggressive dialysis. Hyponatremia occurs when water retention exceeds sodium retention, or when there is salt wasting plus an inability to concentrate urine. Hyperkalemia may be a major problem due to its effects on the cardiac conduction system, and it may require treatment before general anesthesia can be safely induced. Hypocalcemia is secondary to the hyperphosphatemia that results from the kidney's inability to excrete phosphates. Metabolic acidosis develops because the failing kidney cannot excrete the body's daily production of metabolic acids.

Many organ systems are affected by ESRD. Hypertension, increased cardiac output, pericarditis, arrhythmias, and cardiomyopathy are manifestations of the altered cardiovascular system. Hypertension occurs secondary to fluid overload or to alterations in the renin-angiotensin-aldosterone system. Patients with anemia compensate for their decreased oxygen-carrying capacity by increasing their cardiac output. The use of recombinant erythropoietin has decreased the incidence of severe anemia in ESRD patients. Congestive heart failure due to hypertension and volume overload, a uremia-induced cardiomyopathy, and pericardial disease may complicate the management of children with ESRD. Pulmonary edema can develop as a result of fluid overload, hypoproteinemia, and altered pulmonary capillary permeability.

Anemia develops due to decreased erythropoietin production and decreased erythrocyte life span, despite normal reticulocyte counts. Uremic toxins decrease red blood cell (RBC) life span and suppress bone marrow function. The anemia is normocytic and normochromic, despite renal failure- induced deficiencies in folate and vitamin B12. There is an increased concentration of 2,3-diphosphoglycerate (2,3-DPG) which, in conjunction with the metabolic acidosis, shifts the oxygen-hemoglobin dissociation curve to the right. This shift and an increased cardiac output partially compensate for the decreased oxygen-carrying content caused by the anemia. Coagulation is often altered in uremic patients by residual heparinization following dialysis and by abnormal platelet function. Platelets are usually normal in number and life span but have a reversible functional defect secondary to accumulation of guanidinosuccinic acid, which inhibits adenosine diphosphate (ADP)-induced activation of platelet factor III, which is needed for normal platelet adhesion [80].

Renal failure induces numerous neurological effects. Uremic encephalopathy manifests as a global depression that is reversible with dialysis. Uncontrolled hypertension may lead to either focal neurological deficits or seizures; hypertension must be controlled. Seizures may also occur with rapid electrolyte changes (e.g. hyponatremia). Peripheral neuropathies are common in patients with renal failure and usually consist of axonal degeneration with segmental demyelination. The median and common peroneal nerves are frequently involved. Autonomic dysfunction develops in children with ESRD. Baroreceptor activity may be abnormal and lead to hypotension that is unresponsive to intraoperative volume administration.

Nutrition is generally poor in ESRD. Uremia causes anorexia, leading to poor caloric intake and growth retardation. Despite the need for protein and calories, protein intake must be carefully controlled to prevent worsening metabolic acidosis. Renal osteodystrophy, aluminum toxicity, altered somatomedin activity, and insulin and growth hormone resistance are all associated with the growth failure [81]. Delayed gastric emptying is common in children with renal failure. Therefore, patients undergoing a renal transplant may have an increased risk of aspiration of gastric contents regardless of the NPO interval.

#### Preoperative assessment and preparation

There are two sources of kidneys for transplantation into children: cadaver and living donors. Because living donor transplants are elective operations, there is adequate time to optimize the nutritional, hydration, and metabolic status of the patient.

Evaluation of the fluid and electrolyte status of the patient is of primary importance. If the patient has been recently dialysed, a review of the dialysis records is often helpful. Changes in weight, blood pressure, and electrolyte concentrations before and after dialysis should be noted. The patient's dry weight is the minimum weight not associated with hypotension or cardiovascular instability; the current weight compared to the dry weight will indicate the volume status of the patient. Because there are significant changes in electrolytes (e.g. Na+, K+) after dialysis, serum electrolytes should be determined after dialysis. Hypertension in patients with ESRD is common and frequently indicates hypervolemia. However, many patients also require antihypertensive medications, which should be continued until the time of surgery to avoid intraoperative rebound hypertension.

The physical examination should assess the airway and cardiopulmonary status of the patient and determine if a functioning arteriovenous shunt is present. If so, it must be protected during the operation. Patients with nephrotic syndrome or those who have been on steroids may be edematous, which could make tracheal intubation more challenging. Due to the delayed gastric emptying of patients with ESRD, the use of an antacid or anti-H<sub>2</sub> agent and metoclopramide may be helpful before anesthesia induction.

#### Surgical technique

Pediatric renal transplantation employs more than one surgical technique. In older children (weighing >20 kg), the standard surgical approach is similar to that of adults, that is, a lower abdominal incision with extraperitoneal placement of the donor kidney in the iliac fossa. Vascular anastomoses are usually to the iliac vein (end-to-side) and iliac or hypogastric arteries (end-to-side or end-to-end). For infants and small children (weighing <20 kg), a midline incision is made and the kidney placed intraabdominally. The vascular connections are made to the inferior vena cava and the lower abdominal aorta. The aorta and vena cava are cross-clamped while the anastomoses are being completed. In addition, the donor organs for most small children are from older children or adults, with obvious size implications.

#### Anesthetic management

Premedication with midazolam is usually safe and may allay anxiety if needed. Standard ASA monitors are used, and because of the potential for acute blood loss, largebore peripheral intravenous access and blood warmer are indicated. Because the patient's volume status is difficult to determine and may vary considerably during the operation, measurement of the CVP helps guide appropriate fluid management. The CVP catheter can also be used to obtain blood samples for laboratory tests and to administer vasoactive medications into the central circulation. However, preservation of sites for long-term vascular access in patients who may need hemodialysis in the future should be considered, and the subclavian veins are generally avoided for this reason. Larger, older children can usually be adequately managed with peripheral IV access alone. Also, an indwelling arterial catheter is not routinely used for adults or older children, but it may be quite helpful for smaller children, especially if the aorta is to be cross-clamped. One must be careful not to risk the patency of an existing arteriovenous shunt or to compromise future placement of such a shunt.

Anesthesia for renal transplantation is usually induced with intravenous drugs because the patients frequently have an IV catheter already in place. For patients without an IV catheter, inhaled induction of anesthesia is a viable alternative. The pharmacokinetics and pharmacodynamics of anesthetic drugs are altered in patients with ESRD, and this must be taken into account when administering drugs to induce anesthesia. Propofol will produce vasodilation and potentially hypotension in patients who are hypovolemic. Thiopental is normally extensively plasma protein bound. Children with ESRD have decreased plasma protein concentrations. Therefore, the effects of thiopental may be greater than expected, although the greater volume of distribution found in patients with renal failure may offset some of thiopental's increased availability. Ketamine can also be used as an IV induction agent for patients with ESRD, but its sympathomimetic effects may exacerbate pre-existing hypertension. To blunt the autonomic response to laryngoscopy and tracheal intubation, opioids or lidocaine can be given intravenously. As with all sick children, careful titration of anesthetic drugs to the desired effect is always the safest approach.

The choice of muscle relaxant for tracheal intubation continues to generate discussion. Because delayed gastric emptying is common in patients with renal failure, patients undergoing renal transplantation may be at increased risk for regurgitation and possible aspiration of gastric contents. This situation makes a rapid-sequence intravenous induction of anesthesia with an intravenous induction agent, cricoid pressure, and succinylcholine theoretically advantageous. However, the administration of succinylcholine may cause serum potassium concentrations to rise 0.5–0.75 mEq/L, in normal patients [82]. A number of conditions lead to an exaggerated rise of serum potassium and subsequent hyperkalemic arrest. Patients with ESRD are at risk for hyperkalemia if they have uremic neuropathy or if they have not been dialysed recently [83]. An alternative to succinylcholine

is to perform a modified rapid-sequence intravenous induction of anesthesia using an intravenous agent, a non-depolarizing muscle relaxant, cricoid pressure, and controlled ventilation. The non-depolarizing muscle relaxant used should not depend on renal pathways of elimination. Two categories that fit this requirement are the atracurium/*cis*-atracurium family, whose elimination is by Hoffman degradation and ester hydrolysis, and the steroid-based muscle relaxants that are predominantly metabolized by the liver. The steroid-based muscle relaxants vecuronium and rocuronium have some dependence on renal excretion, perhaps 10–25%, that will lead to some prolongation of onset and duration of action of the drugs when used in patients with ESRD.

Maintenance of general anesthesia during renal transplantation is usually provided by a combination of potent inhaled anesthetic agents and opioids. Nitrous oxide can be used, but it may distend the intestines and make it more difficult to close the abdomen at the end of the operation. Sevoflurane has the theoretical problem of producing a metabolite, compound A, that has been associated with renal concentrating defects, and although useful for inhaled induction of anesthesia, should probably not be the first choice for maintenance of anesthesia [84]. Fentanyl is the most widely used opioid for renal transplantation. No active metabolites are excreted by the kidneys, and there is extensive experience with its use in children without significant complication. The metabolites of morphine are excreted by the kidney so probably it should not be the first choice for intraoperative analgesia.

If the patient has an arteriovenous shunt, the extremity with the shunt must be positioned so that the shunt is protected and available to allow the anesthesiologist to periodically determine that the shunt is functional. A blood pressure cuff should not be used on that extremity. At the very least, the shunt should be checked both at the beginning and the end of the operation for a thrill or bruit and the presence of either or both should be documented on the anesthetic record.

Fluid management during renal transplantation is challenging owing to reduced preoperative renal function and to blood loss and third space fluid losses during the operation. Preoperative fluid status is discussed above. Interstitial fluid losses (third space) and blood losses are determined in the usual fashion (see Chapters 10, 11 and 17). Fluid administration should be based on estimates of need and clinical criteria, including vital signs and CVP when utilized. It should be recognized that hypovolemia should be avoided and fluid administered to produce normovolemia to hypervolemia with adequate blood pressure to the new organ. An isotonic crystalloid solution is a suitable choice of fluid. Theoretically, lactated Ringer's solution should be avoided due to the potassium (4mEq/L) that it contains. On the other hand, normal saline is hypernatremic (154mEq/L) and can lead to a hypernatremic metabolic acidosis if given in large quantities. Intermittent measurements of the serum electrolyte and glucose concentrations are always suitable to follow the metabolic status of the patient. If a blood transfusion is required, washed or fresh packed red blood cells are preferred due to the small volume and the minimal amount of potassium present after washing. The blood should also be irradiated to minimize graft-versus-host reactions in an immunocompromised host.

The surgeons may request a higher than normal mean arterial pressure (MAP) to ensure adequate perfusion of the new kidney. Whenever a new kidney is placed into a small recipient (<20 kg), it is possible that the aorta will be cross-clamped to perform the arterial anastomosis. When the aorta is subsequently unclamped, the blood pressure may decrease dramatically secondary to reduced afterload and the return of acidotic blood from the lower extremities. Furthermore, a large quantity of blood is diverted to the renal allograft, which will decrease the arterial blood pressure if the intravascular volume is inadequate. The anesthesiologist must be prepared to treat abrupt changes in arterial pressure with fluid and drugs. It must be remembered that these changes occur with patients who usually have baseline hypertension. Vascular thrombosis is a potential cause of graft failure in the smallest of recipients so the outcome may indeed depend on the reperfusion management.

The anesthesiologist will also be involved with the administration of immunosuppressant medications, antibiotics, diuretics, and other drugs during the operation. The surgeon or nephrologist should notify the anesthesiologist of the doses and timing of these medications. It is helpful to determine the common side-effects of these drugs that may affect anesthetic management. Antilymphocyte antibodies include muronab-CD3 (OKT3), alemtuzumab (Campath), antithymocyte globulin (equine - Atgam), and antithymocyte globulin (thymoglobulin). The infusion of these agents causes a cytokine response which can include fever, chills, rigors, and malaise that should be pretreated with acetaminophen, corticosteroids, and diphenhydramine [85,86]. Anti-interleukin-2 antibodies include basiliximab (Simulect) and daclizumab (Zenapax). These medications do not cause a cytokine response. Side-effects from antiinterleukin-2 antibodies are comparable to placebo except for an acute hypersensitivity reaction that can occur with basiliximab [85].

At the end of the operation, it should be determined whether the patient's trachea will be extubated. If so, residual neuromuscular blockade should be antagonized. Prolongation of the action of neuromuscular blockers is matched by prolongation of action of the reversal agents. The patient should be awake when the trachea is extubated. If there is evidence of pulmonary edema, or a relatively large kidney is placed into the abdomen of a small child, tracheal extubation can be delayed and the patient transported to a pediatric intensive care unit (ICU) and the patient's condition allowed to stabilize.

Postoperative pain control is most commonly achieved by the administration of intravenous opioids. Epidural analgesia can be used, but the association with possible hypotension has tended to limit its widespread use as well as the alterations in coagulation status of patients with ESRD.

## **Heart transplantation**

#### History

The first pediatric human heart transplant was performed in December 1967 in Brooklyn, New York, by Dr Adrian Kantrowitz and associates [87], only 3 days after the first human heart transplant by Christian Barnard. The recipient was a 17-day-old patient with Ebstein anomaly; the donor was an anencephalic infant. The recipient survived a few hours and died of apparent acute graft dysfunction [88]. Cyclosporin became available in 1978 and the first successful infant cardiac transplant was performed by Cooley and associates at Texas Children's Hospital in 1984 [88,89]. The number of pediatric heart transplants performed worldwide increased throughout the 1980s and early 1990s to the present number of approximately 400 transplants annually, and has remained relatively constant since 1991 [90,91].

## Indications for heart transplantation

The three major indications for pediatric heart transplantation are congenital heart disease, end-stage cardiomyopathy, and retransplantation for cardiac graft failure [90]. The relative proportion of each of these indications changes with age, with two-thirds of recipients less than 1 year receiving a transplant for congenital heart disease and approximately one-third for cardiomyopathy. Figure 27.3 shows the diagnosis distribution. In the 1–10-year age group, indications are almost evenly allocated to congenital heart disease and cardiomyopathy, and in patients 11–17 years of age, two-thirds have cardiomyopathy as the indication, with congenital heart disease less frequent and retransplant becoming the indication for 7% of transplants in this age group [90,91]. Figure 27.4 shows the frequency of transplant by age.

Figure 27.4 Age distribution of pediatric heart recipients for transplants reported to the International Heart and Lung Transplant Registry from January 1996 through June 2008. Reproduced from Kirk et al [91] with permission from Elsevier.

Precise indications vary by institution, but groups such as the American Heart Association have convened panels of experts to consider the evidence base for pediatric heart transplantation and develop recommendations for indications [92]. Because no randomized trials (level A evidence) exist, the recommendations are based on nonrandomized studies and registries (level B evidence) and consensus opinions of experts (level C evidence). Class I (general agreement of usefulness and efficacy) and Class IIA (weight of evidence and opinion is in favor of usefulness/efficacy) indications include cardiomyopathy or repaired/unrepaired congenital heart disease with severe systemic ventricular dysfunction despite maximal medical therapy, with associated severe limitation of exercise and activity or growth failure. Additional indications are life-threatening arrhythmias not amenable to drug or defibrillator treatment, restrictive or other cardiomyopathy with reactive pulmonary hypertension reducible to <6 Woods units/m<sup>2</sup>, with risk of developing irreversible pulmonary hypertension. In single-ventricle infants, indications for transplant as primary therapy include severe atrioventricular valve or semi-lunar valve insufficiency, stenosis or atresia in proximal coronary arteries, or severe ventricular dysfunction [92]. Other indications include severe cyanosis or protein-losing enteropathy not amenable to medical or surgical therapy. Indications for retransplantation include normal or depressed ventricular function associated with at least moderate coronary artery vasculopathy. Class IIB (no efficacy established) and Class III (contraindicated) contraindications include previous infection with hepatitis B or C virus, or HIV; history of substance abuse; history of significant behavioral, psychological or cognitive disorders, or history of noncompliance or poor family support structure. More absolute contraindications include irreversible multisystem disease, fixed severely elevated pulmonary vascular resistance, or severe hypoplasia of the central branch pulmonary arteries or veins. Contraindications for retransplantation include primary transplant less than 6 months previously, and ongoing acute allograft rejection.

## Cardiomyopathies: dilated, hypertrophic, restrictive

Causes of dilated cardiomyopathy include viral myocarditis from agents such as parvovirus or coxsackie virus, mitochondrial myopathies such as central core disease, extensive myocardial infarction from anomalous origin of the left coronary artery from the pulmonary artery, or cardiotoxic chemotherapy from anthracyclines [93]. These etiologies account for approximately 80% of transplants for cardiomyopathy [92]. Hypertrophic cardiomyopathies have a diverse spectrum of etiologies, including inborn errors of metabolism. They account for about 12% of cardiomyopathy transplants. Restrictive cardiomyopathies are more rare, and are characterized by diastolic dysfunction with normal ventricular size and wall thickness. These patients have a high incidence of pulmonary hypertension and sudden death, and are not amenable to other surgical or medical therapy, and so have a high rate of listing for transplantation when diagnosed. These patients account for approximately 5% of cardiomyopathy transplants [92].

#### **Congenital heart diseases**

In the modern era, virtually all patients with congenital heart disease are offered some form of corrective or palliative surgery; however, some patients will meet the criteria for transplant despite apparent successful surgery or from issues arising perioperatively, i.e. coronary artery or myocardial injury. Approximately a third of these patients are single-ventricle patients with residual poor ventricular function, severe valvar regurgitation or ongoing cyanosis [93] (Table 27.6). Other major causes include transposition of the great vessels, and left or right ventricular outflow tract obstructive lesions.

#### Retransplantation

Coronary artery vasculopathy, a chronic low-grade rejection phenomenon resulting in gradual vascular occlusion, is seen in 11% of recipients at 5 years, and 17% of recipients at 10 years after transplant [90] and results in listing for retransplantation if ventricular function deteriorates, or significant dysrhythmias or heart block ensue, because of the risk of sudden death. These patients often do not experience angina because of the denervated state of the transplanted heart.

#### Pretransplant work-up

The decision to list a patient for cardiac transplant is made by a multidisciplinary group led by the medical transplant team, the patient's primary cardiologist, and the surgical transplant team. They assess the patient's and family's capacity to comply with the complicated regimens necessary for ongoing care [94]; recent echocardiographic, cardiac catheterization, and other imaging information; cardiac rhythm; and evidence of pulmonary hypertension. In addition, other organ dysfunction such as neurological disease is reviewed and treatment optimized. Dental status should be assessed, and any caries or other decay treated.

Blood tests required before transplant include ABO/Rh typing, Epstein–Barr virus (EBV), cytomegalovirus (CMV), hepatitis B and C, and HIV status. A panel reactive antibody (PRA) screen is performed to determine the level of antibodies to red blood cell antigens from prior transfusions. High levels of antibodies to specific antigens may prevent transplant from a donor with those antigens, and a "virtual cross-match" is performed for donor and 
 Table 27.6 Diagnosis in pediatric cardiac transplant recipients with congenital heart disease

Diagnosis	n (N = 488)	%
Single ventricle	176	36%
D-transposition of the great arteries	58	12%
Right ventricular outflow tract lesions	49	10%
Ventricular/atrial septal defect	38	8%
Left ventricular outflow tract lesions	38	8%
L-transposition of the great arteries	39	8%
Complete AV canal	37	8%
Other	53	11%

AV indicates atrioventricular.

Diagnoses of patients >6 months of age with previously repaired or palliated congenital heart disease undergoing cardiac transplant. Data from Cardiac Transplant Research Database and Pediatric Heart Transplant Study Group [93].

recipient red cell antigens before accepting the organ. A strongly positive cross-match for specific antigens may prevent transplantation from a donor with those antigens. Other strategies for patients with high PRA titers include preoperative plasmapheresis, thymoglobulin, and cyclophosphamide treatment to reduce titers [95]. Human leukocyte antigen (HLA) matching is not routinely performed because of time constraints, and limited availability of donor organs.

Once listed for transplant, the patient is designated as status 1A (mechanical circulatory support, mechanical ventilation or high-dose/multiple inotropes, infant with severe reactive pulmonary hypertension, refractory arrhythmias with life expectancy <14 days), 1B (low-dose inotropes, growth failure) or 2 (does not meet status 1A or 1B criteria). Status 7 patients are patients who are temporarily unable to receive a transplant due to a reversible condition such as infection [96]. In the United States, organ donation and allocation are currently overseen by the United Network for Organ Sharing which operates the Organ Procurement and Transplantation Network under contract from the US Department of Health and Human Services, and the Health Resources and Services Administration. These organizations maintain the waiting lists for each type of transplant, and determine the rules for organ allocation, which depend on patient status and to some extent on proximity to the donor. Waiting times depend on age, with the median waiting time for pediatric patients being 60-80 days for those who receive transplants [97]. However, in infants <1 year, the number of donors is only about one-third the number of patients listed for transplantation [5] and the mortality rate while awaiting transplant is as high as 30-40% [98].

## Anesthesia for cardiac transplantation

The basic anesthetic considerations for transplantation do not differ from the normal preparation for congenital cardiac surgery. See Chapter 25 for a detailed discussion of pathophysiology. A thorough preoperative evalution and consultation with the patient and family and explanation of the anesthetic procedures are performed, within the time constraints imposed by the timing of organ harvest. The preoperative condition ranges from hospitalized status 1A patients maintained on extracorporeal membrane oxygenation (ECMO) or ventricular assist devices (VAD) to those called in from home. Some patients may have recent oral intake, and are at increased risk for pulmonary aspiration. The timing of entrance into the operating room must be planned and communicated with frequent updates due to difficulties in co-ordinating harvesting teams and donor hospital operating room time. It is preferable to err on the side of having the patient in the OR too early than too late; prolonged ischemic time will affect graft function and possibly long-term outcome. Time to place invasive vascular access lines and other anesthetic preparations must be considered when deciding an OR time.

#### **Prebypass period**

Intravenous or oral premedication, often with midazolam, is administered as necessary. Some patients will be maintained in the ICU on mechanical ventilation with inotropic support and some will receive mechanical circulatory support. A co-ordinated operating room transport is required to avoid a disruption of mechanical circulatory support. After arrival in the operating room, immunosuppressive drugs, for example azathioprine and corticosteroids, should be given prior to or soon after induction, as ordered by the transplant team. These critical medications may be easily overlooked in the busy OR environment. Standard non-invasive monitoring is most commonly used for induction, and invasive arterial access obtained after tracheal intubation in small children. However, older patients and those at very high risk of cardiovascular collapse may benefit from placing arterial access prior to induction.

Most pretransplant patients are at significant risk of developing dysrhythmias or cardiac collapse with the induction of anesthesia and positive pressure ventilation. Therefore, methods of resuscitation must be immediately at hand to support the patient. These include resuscitative medications, defibrillator, and the ability to rescue the patient with emergency cardiopulmonary bypass. Intravenous induction can often be accomplished with gradual titration of midazolam 0.05–0.1 mg/kg per dose, and fentanyl 1–5  $\mu$ g/kg per dose, followed by muscle relaxation. Assisted and then controlled mask ventilation is assumed, with frequent determination of non-invasive

blood pressure. Another option for intravenous induction includes etomidate 0.1-0.3 mg/kg, which has little or no hemodynamic effect or effect on cardiac contractility [99]. Ketamine 1-2 mg/kg IV should be used with caution in patients who are receiving infusions of  $\beta$ -adrenergic agonists, because the direct myocardial depressant effects of ketamine may be unmasked in patients whose endogenous catecholamines are depleted [100,101]. Propofol and thiopental should generally be avoided because of their venous and arterial vasodilating properties.

Tracheal intubation is accomplished after appropriate depth of anesthesia and muscle relaxation are achieved. Some centers prefer nasotracheal intubation in patients less than about 30 kg because of the perceived stability of the airway while transesophageal echocardiography is in use. A cuffed endotracheal tube is recommended for all patients except neonates, to minimize any air leak. And even in the neonatal population, the minimal risk of laryngeal injury from the use of a cuffed tube is greatly outweighed by the risk of an inability to effectively ventilate a patient with pulmonary hypertension. Cardiovascular compromise after induction must be anticipated and rapidly treated with volume expansion or vasopressors. Among patients with pulmonary hypertension, increases in pulmonary arterial pressure can be minimized by the use of larger doses of opioids, 100% oxygen, and mild hyperventilation prior to tracheal intubation. If a pulmonary hypertensive crisis develops, treatment with systemic vasopressors and pulmonary vasodilators, including inhaled nitric oxide, is immediately undertaken.

Invasive arterial access is necessary and is most commonly achieved after induction, being mindful to avoid arteries on the side of previous systemic to pulmonary shunts, thrombosed arteries or other abnormal or aberrant vessels. Normally, right or left radial or femoral arteries are preferred. Brachial or axillary arteries are not recommended for access because of the risk of ischemic complications, and pedal arteries are not reliable; a surgical cutdown is preferred if percutaneous access cannot be obtained in a reasonably short period of time. Double- or triple-lumen central venous access is essential, and may be obtained after induction in the internal jugular, femoral or subclavian veins. Strict sterile placement with full barrier precautions and ultrasound guidance will minimize complications and facilitate rapid insertion [102]. Antibiotic-impregnated catheters may prevent catheterassociated infections, and are important in immunosuppressed patients [102]. Some institutions avoid the right internal jugular vein as it is the access for future myocardial biopsies. Transthoracic intracardiac catheters can be placed for central venous access during rewarming on bypass, but adequate large-bore peripheral venous access must be assured before bypass, especially among repeat

sternotomy patients. Additional monitoring includes transesophageal echocardiography, which is useful to assess post-transplant cardiac function and status of cardiac and great vessel anastomoses. We routinely utilize near infrared spectroscopy (NIRS) measurement of cerebral oxygen saturation because of the high risk of cerebral oxygen desaturation from a low cardiac output state in these patients. Early detection and treatment of cerebral oxygen desaturation may lead to improved neurological outcomes. Although patients with poor cardiac function undergoing transplant are at higher risk for anesthesia awareness, processed EEG monitoring for depth of anesthesia will not reliably prevent this significant problem and is not recommended for use in this situation, particularly in young children [103].

Because many of these patients have undergone previous sternotomies and are at greater risk for intra- and postoperative hemorrhage, antifibrinolytic agents are often utilized. These include  $\varepsilon$ -aminocaproic acid, tranexamic acid or aprotinin, the latter only after a thorough assessment of the risk/benefit ratio of using the drug (aprotinin is not currently available in the US) [104]. Antibiotic prophylaxis, often cefazolin in uncomplicated transplants, is given 30–60min before incision, repeated after institution of bypass, and every 4h thereafter while in the operating room.

Patient positioning, preparation, draping, and sternotomy are accomplished as efficiently as possible. Mediastinal, heart, and great vessel dissection and preparation are also done quickly in order to minimize donor ischemic time. Prebypass anesthetic management is carried out according to the pathophysiology of the patient's underlying cardiac disease and response to surgical and anesthetic interventions. Maintenance of anesthesia is often achieved with large doses of opioids such as fentanyl, and amnestic agents such as midazolam. Low doses of volatile anesthetic agents are often employed. Although there are few data in children with cardiomyopathy or other causes of poor ventricular function, in congenital heart disease patients, isoflurane preserves cardiac output best of the studied volatile agents, with sevoflurane an acceptable choice due to its slight myocardial depressive effect [105,106].

#### Cardiopulmonary bypass period

Standard cardiopulmonary bypass (CPB) techniques are used for cardiac transplant, including heparin 300–400 units/kg for anticoagulation, and anticoagulation monitoring with celite activated clotting time (ACT), and heparin level assay or thromboelastography, according to institutional practice. Aorto-bicaval cannulation is utilized. General principles of bypass management used for congenital heart disease are practiced. See Chapter 25 for further details. Recent data suggest that pH stat blood gas management and maintaining higher hematocrits of 30-35% result in better long-term neurological outcomes [107]. Maintaining full flow cardiopulmonary bypass of 150 mL/kg/min for patients under 10 kg, and 2.4–2.8 L/  $min/m^2$  for those over 10kg may improve outcomes as well [108]. Moderate hypothermia to 25-28°C is commonly employed and deep hypothermic (<22°C) circulatory arrest (DHCA) is avoided; however, complex reconstruction of pulmonary venous or aortic anatomy may require DHCA. If possible, DHCA periods should be limited to less than 30 min; reperfusing for a short period and then re-instituting DHCA may be required, utilizing cerebral oximetry to guide bypass [109-112]. Ultrafiltration on CPB is very useful to achieve hematocrit goals and remove excess fluid and inflammatory mediators. Alternatively, modified ultrafiltration after CPB can be used to achieve the same goals.

In patients in whom high levels of PRA are measured or in ABO incompatible transplants (see below), an exchange transfusion is performed when CPB is initiated. A double CPB prime volume is prepared, with packed red blood cells and fresh frozen plasma. Upon institution of CPB, the patient's calculated blood volume is drained into a separate collection bag, bypassing the venous reservoir, and discarded. This process will reduce the red cell antibody concentration and limit possibility of acute rejection [113].

Surgical technique consists of orthotopic transplantation [114] where the donor heart is completely excised, except for a cuff of left atrial tissue containing all four pulmonary veins. Donor weight is ideally 80-160% of the recipient's weight. It is important for the surgical team to know the details of the donor's demise (appropriately preserving patient confidentiality), donor cardiac function (ejection fraction) and inotropic support and any donor structural abnormalities such as atrial septal defect (ASD) or patent foramen ovale (PFO). The entire right atrium is removed, leaving superior and inferior vena cavae for anastomosis. After arrival of the donor heart, the ABO and rH type of both the donor and recipient are checked and independently verified by two people, including the transplant surgeon. The donor heart is typically preserved with a solution such as crystalloid cardioplegia or Celsior® and stored on ice at 4°C. The heart is placed in the mediastinum and the left atrial anastomosis is performed first. Then the aortic anastomosis is performed. The aortic cross-clamp is usually removed at this point to minimize the donor heart ischemic time. Under normal circumstances, a limit of 5h of donor ischemic time is desired, meaning the time from donor heart cross-clamp at harvest until cross-clamp removal. This limits donor organ transport time to 3 <sup>1</sup>/<sub>2</sub>-4h. Although transplantation of hearts with longer ischemic times is reported, beyond 5h of ischemia graft function worsens and long-term graft function may be compromised [90].

After the aortic cross-clamp is removed, the donor heart commonly experiences ventricular fibrillation due to ischemia and/or electrolyte imbalance, and must be defibrillated (initial energy 2-10 joules) several times, until sinus rhythm is achieved. Lidocaine 2mg/kg into the CPB circuit is given 5min before aortic cross-clamp removal, and a repeat dose of 1mg/kg can be given if more than 1-2 defibrillations are required. Magnesium sulfate 25-50 mg/kg is often helpful, as is a lidocaine infusion at 20–40 µg/kg/min. Rarely, amiodarone 5 mg/ kg load, repeated up to two additional doses, may be required. With the cross-clamp removed and the heart beating, the bicaval anastomoses and the pulmonary artery anastomoses are completed. The surgeon must pay particular attention to the anatomy of congenital heart disease recipients. There may be a need for extensive aortic arch reconstruction, requiring a long length of donor aorta in patients with hypoplastic left heart syndrome, or for a long length of donor superior vena cava in single-ventricle patients with cavopulmonary anastomoses.

With establishment of sinus rhythm and completion of the anastomoses, rewarming is accomplished. Additional intravenous anesthetics and muscle relaxants are administered. During this period inotropic support is instituted, according to institutional preference, and taking into account ischemic time, systemic and pulmonary vascular resistance, and appearance of the myocardial function on visual inspection and transesophageal echocardiography. Low-dose epinephrine, 0.03-0.05 µg/kg/min, is a common choice in this setting. Milrinone 0.25–0.75  $\mu g/$ kg/min, with or without a loading dose of 25–75  $\mu$ g/kg over 15-30 min, is also useful in this situation for its inotropic, pulmonary and systemic vasodilator properties, as well as low propensity for arrhythmogenicity. Because the denervated heart has limited capacity to alter heart rate, and sinus node discharge of the donor heart often slows with edema, inflammation or hypothermia, an isoproterenol infusion in low doses of 0.01–0.03 µg/kg/min is often very useful to maintain adequate heart rate. Temporary atrial pacing can also be utilized. Recipients with pulmonary hypertension, and situations where the donor is smaller than the recipient (the donor right heart may have insufficient ability to overcome the recipient pulmonary vascular resistance (PVR)), the right heart can be supported with milrinone or inhaled nitric oxide, at 10-40 parts per million (PPM) [115]. In extreme cases a right VAD may be temporarily needed until the right heart is adequately conditioned.

Near the completion of surgery, additional transthoracic monitoring catheters, such as right and left atrial lines, and occasionally pulmonary artery lines, are placed by the surgeon, along with temporary atrial pacing wires, which may be needed to support the denervated heart. Ventilation is commenced with 100% oxygen, designed to produce mild hypocarbia of 32-35mmHg. Once heart rate and rhythm, hematocrit, ventilation, and electrolytes are optimized, CPB is weaned slowly with gradual volume loading of the heart, using TEE monitoring to assess for intracardiac air, as well as biventricular function. After separation from CPB, cardiac function is assessed with TEE, as is the status of the anastomoses of the aorta, pulmonary artery, vena cava, and left atrium, with particular attention paid to any pulmonary venous obstruction. After ensuring a period of adequate hemodynamics and cardiac function, protamine 1-1.3 mg per mg of heparin in the original dose is administered, to neutralize the anticoagulation. The TEE probe is removed if no longer needed, and surgical hemostasis is achieved. Platelets and cryoprecipitate (rich in fibrinogen) are often required to achieve hemostasis, particularly with repeat sternotomy and complicated great vessel reconstruction [116]. Patients who are supported with ventricular assist devices before heart transplant typically receive intensive anticoagulation to prevent thrombosis and embolization, and this group of patients more commonly develop uncontrollable hemorrhage after bypass. In this situation, recombinant factor VIIA, 90 µg/kg, repeated up to two additional times if bleeding persists, has been very useful to achieve hemostasis when administration of plasma, cryoprecipitate, and platelets has failed to achieve hemostasis [116].

## **Postbypass period**

In a few unstable patients, particularly small infants, the sternum may be left open for a period of 24–48 h to allow bleeding and myocardial performance to improve; these patients must have the sternum closed as soon as possible to reduce the risk of infection in the immunosuppressed patient.

After bypass, attention is directed to the need for additional antibiotic or corticosteroid/immunosuppressive medications. Extubation of pediatric cardiac transplant patients in the operating room is typically avoided, as many patients have an ongoing risk for myocardial dysfunction, arrhythmias, bleeding, and pulmonary hypertension. If the patient is stable, tracheal extubation can often be achieved in 12-24h after ICU admission. Upon transfer to the ICU, a thorough patient handoff report is given, including the surgical team discussing surgical issues and the anesthesia team giving a complete report to the attending ICU physician and bedside nurses. A standardized handoff note and verbal communication, along with an opportunity to answer any questions, are recommended practice for the effective transfer of care in these complicated patients.

## Post-transplant rejection surveillance

The mainstay of post-transplant surveillance for rejection is myocardial biopsy, with the first biopsy often performed 7–10 days after transplant to assess acute rejection. Biopsies are performed most frequently in the first year after transplant, often every 3 months for uncomplicated cases. Thereafter, biopsy every 6 months is often performed, along with thermodilution cardiac output. Coronary angiography is added to the yearly regimen after 1–2 years, to assess the development of coronary artery vasculopathy. Five to seven biopsies of the right ventricle are obtained, and rejection is usually assessed according to the International Society of Heart and Lung Transplantation (ISHLT) scale, 0–3 according to the degree of lymphocytic infiltration and myocyte damage in the specimen [117].

Rejection is classified as either cellular, primarily lymphocyte infiltration, or humoral, a predominance of antibody-antigen and complement complexes, which is often observed in patients with high PRA titers. Signs of acute rejection can range from low-grade fever and malaise, to poor myocardial function, to cardiovascular collapse. Treatment for acute rejection often begins with large doses of corticosteroids and higher doses of maintenance immune suppressants. Other agents such as antithymocyte globulin, antilymphocyte globulin or interleukin-2 receptor antagonists may also be added according to institutional practice. Plasmapheresis may be used for humoral rejection to reduce the antibody titers until immune suppressants have an effect. Rejecting patients may need additional therapy, including inotropic and ventilatory support, or even mechanical circulatory support with ventricular assist devices or ECMO. If all of these measures fail to reverse the rejection, retransplant is the only remaining treatment option.

## Morbidity and mortality after cardiac transplant

Survival after cardiac transplant is characterized by significant early mortality in all age groups followed by a slow attrition [90] (Fig. 27.5). Survival since 2000 has improved, primarily because of improved early survival in the first year, with no difference in the survival curves after 1 year [4] (Fig. 27.6). Early mortality is significantly increased for patients on ECMO, those having a congenital diagnosis, those undergoing retransplantation, and those requiring ventilatory support immediately prior to transplant [90] (Table 27.7). The leading causes of death in the first 30 days are graft failure in 35%, infection in 15%, and multi-organ failure and acute rejection 12% each. The leading cause of late mortality is coronary artery vasculopathy, responsible for 30-35% of deaths beyond 3 years after transplant [4]. Retransplantation is most commonly performed because of severe coronary

artery vasculopathy (CAV) or graft failure, and carries a higher risk of mortality, with a 5-year survival of about 60% in the modern era, versus 75–80% for primary transplantation [118].

Morbidities in cardiac transplant recipients at 5 years after transplant include hypertension in 63% (primarily associated with corticosteroid use), hyperlipidemia in 26%, coronary artery vasculopathy in 11%, and renal dysfunction in 9% [90]. Thus a substantial number of these patients will be taking antihypertensive medications, and some will be taking statins or other cholesterollowering drugs. Renal function requires assessment before anesthesia, to avoid or minimize use of agents with primary renal excretion, in appropriate patients. Infection and lymphoma are seen in a very small percentage of pediatric cardiac transplant recipients. Early coronary artery vasculopathy in the first 3 years after transplant is associated with a significantly higher risk of rejection.

# Anesthesia for the heart transplant recipient

## **Endomyocardial biopsy**

All cardiac transplant recipients require myocardial biopsy. Access is often gained via the right internal jugular vein, but femoral venous access is also often used and often simplifies the anesthetic and sedation management because the access site is remote from the airway. Some older teenage patients are mature and co-operative enough to receive intravenous sedation and local anesthesia to the access site, and an anesthesiologist is not commonly required. However, many older patients are

Table 27.7 Risk factors for mortality within 1 year for 3756 transplants performed January 1995 through June 2007

Variable	Number	Relative risk	95% Confidence interval	p-value

very anxious due to the lifelong nature of their medical interventions, and require higher doses of sedative medications and associated deeper sedation in order to perform the catherization. In stable outpatients without signs or symptoms of rejection or CAV, moderate or deep IV sedation with a variety of agents can be used, including benzodiazepines, opioids, and propofol. Patients with known or suspected rejection or CAV must be approached with great care. These patients may have significantly compromised cardiac function or very severe CAV with marginal myocardial perfusion. They have very limited reserve if the myocardial oxygen supply-demand balance is upset. Whatever technique is used, these patients should not be subjected to significant reductions in preload or to afterload as myocardial perfusion depends on blood pressure. Agents such as propofol or thiopental should be avoided, blood pressure monitored closely, and hypotension treated immediately. Tachycardia should also be avoided. If general anesthesia is chosen, positive pressure ventilation must be instituted carefully so as not to excessively decrease venous return. General endotracheal anesthesia is often preferred to definitively secure the airway.

#### Non-cardiac surgery

Cardiac transplant recipients may undergo surgical and diagnostic procedures unrelated to the transplant. In addition to the assessment of cardiac and non-cardiac problems, the anesthesiologist should determine the results of the most recent cardiac biopsy, cardiac output, signs of rejection, and whether there is a suspicion of CAV. Ideally, there should be a cardiology evaluation, including an echocardiogram, within 6 months. The hemodynamic goals noted above for endomyocardial biopsy are the same for non-cardiac surgery. The denervated heart does not respond to vagolytic agents, so bradycardia requires treatment with a direct-acting  $\beta$ 1agonist such as isoproterenol or epinephrine. Infective endocarditis prophylaxis guidelines have been significantly revised, and restrict the need for such prophylaxis to transplant recipients who develop valvulopathy, and only for dental and airway procedures where the respiratory mucosa is incised [119]. Prophylaxis is no longer recommended for gastrointestinal and genitourinary procedures unless there is active infection. Care should be taken with the reversal of non-depolarizing muscle relaxants using neostigmine. Variable parasympathetic reinnervation, along with humoral or cellular rejection, may produce unpredictable responses to neostigmine and glycopyrrolate, which have been reported to produce severe sinus bradycardia and asystole [120]. Stress-dose corticosteroids should be administered as appropriate for significant surgical procedures, where adrenal suppression is suspected.

# **ABO-incompatible transplantation**

As discussed earlier in this chapter, the number of infants listed for cardiac transplantation exceeds the number of donors by approximately 3:1, and there is significant mortality of infants waiting for transplant. Many infant heart transplant recipients who survive the first year after transplant are remarkably free of rejection. In 2001, West and colleagues described a series of infant cardiac transplants in patients up to age 14 months with ABOincompatible donors [113]. Anesthetic and surgical management of the transplant does not differ, except that an exchange transfusion, as described above, is performed upon institution of cardiopulmonary bypass. In addition, transfused blood products are selected to avoid antibodies to the donor heart. Midterm survival and rejection rates were not different from ABO-compatible transplants, and the waiting list mortality was reduced from 58% to 7% for infant transplants [113]. This technique has been adopted by more institutions, as evidence develops that overall survival of infants listed for transplant improves in the long term [121,122].

# Lung transplantation

#### History

The first human lung transplant was performed on an adult in 1963 by James Hardy at the University of Mississippi [123]. This was followed by adult lobar (Shinoi, 1966) and pediatric heart-lung transplantation (Cooley, 1968) but outcomes were uniformly dismal. Advances over the next decade included the introduction of cyclosporin, better surgical techniques and improved donor organ preservation, leading to the first long-term success with adult heart-lung transplant by Reitz at Stanford in 1981 [124]. Cooper and colleagues in Toronto demonstrated that bronchial omentopexy enhanced the vascularity and integrity of the bronchial anastomosis and subsequently reported the first long-term successful adult (1983) and pediatric (1987) lung transplants [88]. Living donor lobar transplantation was first performed at Stanford by Starnes in 1990.

Data about lung and heart-lung transplantation from many centers around the globe are updated regularly by the ISHLT and can be viewed at its website (www.ishlt.org/ registries). The ISHLT Registry 2009 report for the period 1984–2008 included 1278 pediatric lung transplant and 549 pediatric heart-lung transplant procedures [125]. Thirty-six centers reported pediatric lung transplant procedures. Of these, only one (3%) reported between 10 and 19 transplants per year, three centers (8%) reported 5–9 transplants per year, and the remainder (89%) reported <5 transplants per year (Fig. 27.7). Annually, fewer than 100 children received lung transplant surgery. Most

patients were adolescents and the number of infant transplants has remained low (Fig. 27.8).

In addition to the specific challenges inherent in caring for children, pediatric lung transplantation has many unique aspects, including a diverse spectrum of pulmonary and non-pulmonary diseases, donor/recipient matching and growth of the transplanted organs. Children receiving transplantation undergo many surgical and diagnostic interventions and frequently require sedation or general anesthesia. Provision of safe perioperative care requires familiarity with the relevant issues, including pulmonary pathophysiology and the conduct and consequences of lung transplantation.

# Indications, contraindications, and listing criteria in children

Generally, lung transplant surgery is considered for children with any end-stage lung disease for whom there is no medical treatment [126]. For all children less than 18 years of age, the common primary diagnoses leading to lung transplantation are cystic fibrosis (56%) and pulmonary hypertension, either idiopathic (10%) or related to congenital heart disease (5%) [125], whereas the common primary diagnoses in adults are chronic obstructive pulmonary disease or interstitial lung diseases. Indications for transplantation differ by age (Table 27.8), with cystic fibrosis the predominant indication for children aged 6 years or older. FEV<sub>1</sub>, elevated pCO<sub>2</sub> (>50 mmHg), falling pO<sub>2</sub> (<55 mmHg), deteriorating nutritional status, frequency of hospitalizations and the 6-minute walk test, are considered before listing the patient for lung transplant [127]. Perioperative management should address nonpulmonary manifestations of cystic fibrosis such as severe malnourishment, chronic infection, pancreatic insufficiency, diabetes mellitus, cholelithiasis, hepatic cirrhosis, distal intestinal obstruction syndrome, sinusitis, nasal polyps, osteoporosis and genitourinary problems [128,129]. Pretransplant mechanical ventilation was predictive of poor 1-year survival after lung transplantation [130]. There are reasonably compelling data documenting the beneficial impact of lung transplantation on functional status, hemodynamics, and quality of life but demonstration of a survival benefit for children remains controversial [131,132].

clinical evolution, histopathology, and response to therapy was proposed. A diagnosis of primary (or idiopathic) pulmonary arterial hypertension is made when no known risk factor is identified. Familial pulmonary arterial hypertension has been linked to mutations in receptors in the transforming growth factor (TGF)- $\beta$  superfamily, such as BMPR2 (bone morphogenetic protein receptor 2) and in ALK-1 (activin-like kinase 1), which affect vascular intimal proliferation. Pulmonary arterial hypertension associated with congenital heart disease constitutes a heterogenous group of conditions and has been classified based on circulatory pathophysiology [133].

Transplantation options for pulmonary hypertension include lung transplantation, heart-lung transplantation or lung transplantation in combination with repair of the underlying cardiac defect. Survival rates for these strategies have been reviewed (Table 27.9) [134]. In Eisenmenger syndrome secondary to ventricular septal defect, there was a survival benefit of heart-lung over lung transplantation [135]. Transplantation may improve the quality of life of patients with Eisenmenger syndrome but may not improve survival because most unrepaired Eisenmenger patients will survive beyond their 40th birthday [136]. Many children with pulmonary hypertension will be receiving agents such as endothelin receptor antagonists, phosphodiesterase inhibitors, prostacyclin analogs and nitric oxide.

#### Disorders of surfactant metabolism

Pediatric interstitial lung disease syndrome is an uncommon indication for lung transplantation and includes diseases of surfactant metabolism [137]. Surfactant proteins B, C and ABCA3 transporter are necessary for surfactant homeostasis and mutations in the genes encoding these proteins lead to surfactant dysfunction, giving rise to both lethal and chronic respiratory disease in infants. Patients may require lung transplantation in early infancy because of severe respiratory failure.

#### Miscellaneous disorders

Lung transplant surgery has been performed in children for a variety of other indications including bronchopulmonary dysplasia, congenital diaphragmatic hernia, hemosiderosis, bronchiolitis obliterans and emphysema.

# Criteria for listing and contraindications

The criteria for listing children for lung transplant surgery are based on the natural history of the disease, functional status, and expected improvement in the quality of life. Generally, a clear diagnosis with a life expectancy of less than 2 years is necessary for listing the child for the lung transplant. However, it is hard to develop survival models for relatively rare diseases.

Contraindications to lung transplantation are listed in Table 27.10 [126]. Mechanical ventilation is a risk factor for morbidity and mortality in older children but not infants. Children with cystic fibrosis who are colonized with multidrug-resistant organisms like *Burkholderia cenocepacia* and *B. gladioli* do poorly and most centers consider this a strong contraindication. Children with liver disease secondary to cystic fibrosis may be candidates for combined liver-lung transplant surgery and have good survival rates. Patient and parental psychosocial issues can be particularly challenging and may become a significant contraindication if child and family consistently fail to meet agreed-upon expectations for care and follow-up [11].

Perhaps the most difficult decision for pediatric lung transplant physicians is determining the appropriate time 
 Table 27.10
 Lung transplantation: most commonly agreed-upon contraindications

Absolute	Relative	
Active malignancy	Pleurodesis	
Sepsis	Renal insufficiency	
Active tuberculosis	Markedly abnormal Body Mass Index	
Severe neuromuscular disease	Mechanical ventilation	
Documented, refractory non-adherence	Scoliosis	
Multiple organ dysfunction	Poorly controlled diabetes mellitus	
Acquired immunodeficiency syndrome	Osteoporosis	
Hepatitis C with histological	Hepatitis B surface antigen positive	
liver disease	Fungal infection/colonization	
	Chronic airway infection with multiply resistant organisms

to accept organs because there is wide variation in the natural history of the primary diseases (Table 27.11) and the 5-year survival rate after lung transplantation is only about 50%. Most pediatric centers consider multiple factors, including waiting list survival estimates (when available), growth and nutrition status, frequency of hospitalizations, and potential for improvement in overall quality of life, before committing a child to lung transplant.

# Donor selection, availability, and the lungs allocation system

Like other organ transplant surgeries, donor availability has been a limiting factor. Only about 15% of the cadaveric donors have lungs that are considered acceptable for transplantation [138]. The Organ Procurement and Transplant Network (OPTN) implemented a new lungs allocation system in 2005 that used medical urgency as the primary determinant of organ allocation and discouraged the use of waiting time [139]. Under this system, a lung allocation score (LAS) is calculated for every patient >12 years of age using multiple variables including age, functional status, forced vital capacity and oxygen requirement. The new policy also mandated that the donor lungs from pediatric donors be preferentially given to pediatric patients. Recent data from adult and pediatric patients suggest that implementation of the LAS system has decreased waiting times and increased the annual number of lung transplant surgeries performed [139]. 
 Table 27.11
 Recommendations regarding timing of referral to lung transplant center

Specific disease	Timing of referral
Surfactant deficiencies	Patients with SP-B deficiency and ABCA3 deficiency with refractory respiratory failure should be referred immediately Patients with SP-C deficiency and less severe forms of ABCA3 deficiency may respond to medical therapy and should be referred when unrelenting progression of disease develops
Primary pulmonary hypertension	Patients who present in NYHA class III or IV or have evidence of right heart failure should be referred immediately Patients who fail to respond adequately to vasodilator therapy should also be referred
Eisenmenger syndrome	When the trajectory of pulmonary hypertension appears to be worsening with impaired exercise tolerance and worsening quality of life
Other pulmonary vascular disorders (pulmonary vein stenosis, alveolar capillary dysplasia)	These patients should be referred immediately since they typically do not respond to medical management and are at risk for sudden death
Cystic fibrosis	Patients with percent predicted FEV <sub>1</sub> values less than 30%, frequent hospitalizations, refractory hypoxemia or hypercapnia should be referred for transplant
Bronchopulmonary dysplasia	Patients with recurrent or severe episodes of respiratory failure or evidence for progressive pulmonary hypertension
Diffuse parenchymal lung disease	Patients without evidence for systemic disease that could affect outcome should be referred early

Reproduced from Sweet [11] with permission from the American Thoracic Society.

However, children younger than 12 years of age still received organs based on the waiting time accrued on the transplant list. Recognizing that infants carry the highest waiting list mortality rate among all transplant candidates, the OPTN recently approved proposals to preferentially direct organs from donors under 11 years old to younger children [140].

Donor lungs are selected after thorough medical screening and multiple laboratory tests. In younger children, comparable age and height (<20% discrepancy) are considered acceptable for matching lung volume. Selection criteria are relatively subjective. An ideal donor is younger

than 55 years, non-smoker and with no history of cardiopulmonary or significant neurological disease. The donor lungs should produce good gaseous exchange  $(PaO_2 > 350 \text{ mmHg with } FIO_2 \text{ of } 1.0)$  on moderate amount of ventilatory support. The chest radiography and bronchoscopy should rule out any significant infection, consolidation, and tumor. An expected ischemic time of <6h is preferred. Optimal donor lung management has been reviewed [141]. To increase the number of potential donors, some centers have advocated acceptance of longer ischemic times and "marginal" donors with reversible mild lung pathology [142]. Biochemical markers in the bronchoalveolar lavage fluid from the donor lungs (e.g. interleukin (IL)-8, IL-6 and IL-1b), are being evaluated as predictors of early and late graft dysfunction [143]. Additionally, using donation after cardiac death lungs is another option that has been considered to alleviate organ shortage [144].

The process of harvest includes systemic heparinization of the donor and infusion of prostaglandin E1 into the main pulmonary artery. A number of preservation solutions have been tried but currently Euro-Collins solution is used by most centers. Lungs are inflated with FIO<sub>2</sub> of less than 0.4 to an airway pressure less than 20 cmH<sub>2</sub>O. Lungs are removed *en bloc* with thoracic aorta, left atrial cuff, and main pulmonary artery [141].

# **Perioperative management** Preoperative considerations

Candidates for lung transplantation undergo an extensive medical and psychosocial evaluation. Imaging studies of major thoracic systemic and pulmonary vessels may be required for patients with congenital heart disease because abnormal vasculature can alter the conduct of organ harvest and transplantation surgery. Children with pulmonary hypertension undergo a diagnostic cardiac catheterization to quantify hemodynamics and test for reactivity to pulmonary vasodilator therapy. After listing, the child's clinical progress is monitored regularly and an anesthetic consultation obtained. Many children can be living at home with minimal oxygen supplementation while others, especially infants, are on chronic ventilatory or extracorporeal hemodynamic support. Recently, extracorporeal devices that facilitate respiratory exchange have been utilized as a bridge to lung transplant [145,146].

#### Anesthesia management

Like other solid organ transplants, timing of surgery is unpredictable. Most families are given a hospital pager and have been anticipating the surgery for a long time. Patients are often excited and frightened. Anxiolytics such as midazolam can be safely given to most children but discretion and monitoring are advised because of the potential for compromise to upper airway control, respiratory effort, and hemodynamic stability.

When relevant, the patient and family should be informed preoperatively that surgery may possibly not proceed to transplantation if the donor lungs are deemed unsuitable. Good communication between the donor and recipient teams is vital, with all parties having a clear understanding of the expected time of anesthesia induction and donor organ arrival. Anesthesia preparations are similar to those for pediatric hypothermic open heart surgery. Anesthesiologists often work under considerable time pressure because of concerns about extending the donor organ ischemic time.

Standard NPO guidelines are followed to minimize the risk of aspiration and contamination of the new lungs. The method of anesthesia induction and choice of agents will depend on the patient's clinical and NPO status. The hemodynamic goal is to preserve stability without increasing pulmonary vascular resistance. Both volatile and intravenous anesthetic agents are acceptable. Propofol is safe for hemodynamically stable children (e.g. many cystic fibrosis patients) but ketamine or etomidate may be the preferred drug for patients who have poor cardiac reserve and/or pulmonary hypertension. Anesthetic depth can be maintained with opioids and benzodiazepines and supplemented with inhalational or intravenous agents [147]. Nitrous oxide is best avoided because of concerns about myocardial depression, pulmonary hypertension, air embolism, and the requirement for high concentrations of inspired oxygen. The combination of anesthesia, right ventricular diastolic dysfunction and positive pressure ventilation may unmask a relative intravascular volume deficiency that can be corrected by IV fluid infusion.

Most often, pediatric lung transplants are performed with the assistance of CPB and the airway is secured with a single-lumen endotracheal tube because lung isolation is not required. Frequent toilet of the airway is advised, particularly in patients who have cystic fibrosis. Bronchodilator therapy should be available. Effective oxygenation and carbon dioxide elimination may be difficult during the pre-CPB period, and permissive hypercapnia is acceptable. Ventilation should be adjusted to minimize air trapping because lung hyperinflation can impede venous return to the heart. Strategies to limit airway pressure are advised for patients at increased risk of barotrauma, such as those with restrictive lung disease or chronic obstructive pulmonary disease. Occasionally, especially in infants, a sophisticated pediatric intensive care ventilator may be required in the operating room. Many patients who have end-stage lung disease have a chronic compensatory metabolic alkalosis. Enthusiastic hyperventilation to normal PaCO<sub>2</sub> values induces an iatrogenic alkalotic blood pH level that increases cerebral vasoconstriction and leads to relative cerebral ischemia.

Invasive monitoring appropriate for surgery with CPB is established. At many institutions, continuous monitoring of pulmonary pressure with pulmonary artery catheter is limited to adolescents with the pretransplant diagnosis of pulmonary hypertension [148]. The pulmonary artery catheter is introduced through a sheath in the internal jugular vein and advanced to the pulmonary artery after the patient has been weaned from CPB. For smaller children, a transthoracic catheter can be placed directly into the pulmonary artery by the surgeon. Intraoperative transesophageal echocardiography is useful for assessing cardiac anatomy and function, pulmonary hypertension, and to rule out pulmonary venous obstruction [149,150].

Anesthesiologists must ensure that the non-anesthetic drugs such as immunosuppressants and preoperative antibiotics are administered at appropriate times. For children with pulmonary hypertension, selective vasodilators such as nitric oxide and prostacylins must be maintained throughout the prebypass period to avoid rebound pulmonary hypertension.

Children undergoing lung transplantation are at increased risk for perioperative bleeding because of coagulopathies associated with CPB and cyanosis, and bleeding from chest wall adhesions (infections, previous surgery) or abnormal vessels (venovenous or arteriovenous collaterals). Antifibrinolytic prophylaxis with the lysine analogs may help reduce blood loss but there is insufficient information about their efficacy and safety in young children.

The function of the implanted lungs could be adversely affected by donor pathology, ischemia-reperfusion injury, CPB, blood product transfusions, denervation, lymphatic stasis, positive pressure ventilation, oxygen toxicity and hyperacute rejection.

Ischemia-reperfusion injury contributes to primary graft dysfunction (PGD) and can increase the risk of acute and perhaps chronic rejection. Oxygen is readily available to the metabolically active endothelium of lung allografts during the ischemic period and this allows production of free radicals, making lungs more susceptible to graft failure than other solid organs. Reperfusion injury appears to occur in two distinct phases. The first phase, seen immediately after the reperfusion, is initiated by donor macrophages and includes the release of superoxide anions and inflammatory cytokines, with mast cell degranulation and complement activation. These damage the vascular endothelium, causing movement of fluid to the interstitial and alveolar space [151]. The delayed phase of PGD starts a few hours later when the recipient's neutrophils are recruited by cytokines to the injured endothelium. These neutrophils produce reactive superoxide anions and greatly amplify the initial injury. Strategies to minimize reperfusion injury include improvements to the lung preservation solution, gentler reperfusion techniques, protective ventilation strategies and inhaled nitric oxide [152]. Ultrafiltration during and after CPB can ameliorate the inflammatory response. However, modified ultrafiltration increases right ventricular volume load and may precipitate right heart failure in the presence of pulmonary hypertension [153].

Before weaning from CPB, a bronchodilator may be administered by metered dose inhalation or nebulization, and the lungs are carefully re-expanded to check for bronchial air leaks and ventilation is resumed. Ventilator parameters are guided by the donor weight. Tidal volume and airway pressures are adjusted so that all atelectatic areas are expanded but not overdistended. Volutrauma caused by overdistension of the new lungs can increase endothelial permeability and potentiate primary graft dysfunction. Typically flexible bronchoscopy is performed to assess the bronchial anastomosis, and to remove blood and secretions from each lung under direct visualization. If possible, inspired oxygen concentrations should be lowered because of concern about oxygen toxicity and free radical damage [154]. Restriction of fluid infusions is advocated because the lung allograft is very sensitive to pulmonary edema but trials substantiating this practice are lacking.

Inhaled selective pulmonary vasodilator therapy (e.g. nitric oxide, epoprostenol) is initiated when pulmonary artery pressures are increased. Some centers routinely administer intravenous prostacyclin or PGE1 to reduce pulmonary artery pressures and preserve right heart function. Pulmonary hypertension must be anticipated and managed carefully [155,156]. Inhaled nitric oxide before and after transplantation may improve allograft function [157]. Right ventricular dysfunction can be supported by intravenous inotropes. Milrinone is a common choice because of its lusitropic and vasodilator effects.

#### Cardiopulmonary bypass

Although controversial, there is some evidence that CPB is an independent or contributing factor for primary graft dysfunction [158]. Therefore, most adult bilateral lung transplant centers perform lung transplantation using single-lung ventilation through dual-lumen endotracheal tubes. However, most children are physically too small to accommodate a double-lumen tube. Additionally, some children are too tenuous clinically to tolerate a prolonged period of single-lung ventilation. CPB allows the resection of both diseased lungs simultaneously, thus minimizing the risk of cross-contamination of the new lungs. Also, it provides stable hemodynamics during the extensive surgical dissection, greatly simplifies the anesthetic and

surgical management, and consequently reduces lung ischemic times. Therefore, most pediatric lung transplants are performed using cardiopulmonary bypass. A large single-center comparison of the incidence of primary graft dysfunction in pediatric and adult lung transplant found no difference, suggesting that CBP did not carry additional risk in children [159].

# **Surgical technique**

Most children undergo bilateral sequential lung transplantation through a trans-sternal, clamshell incision. Very few pediatric single-lung transplants are performed because the primary disease usually affects both lungs. Beating heart CPB with moderate hypothermia (28–32°C) is employed. Aortic cross-clamping and cardioplegia may be necessary if co-existing intracardiac defects require repair. Once CPB is established, both lungs are removed and the recipient's tracheal stump irrigated with an antibiotic solution. Meanwhile, a second surgical team prepares the donor lungs that are then implanted using end-to-end bronchial anastomoses. Since the surgery compromises the bronchial vasculature, peribronchial tissue is sutured loosely around the anastomoses to provide blood flow by new vessel ingrowth. The donor pulmonary artery is attached to the native main pulmonary artery. The pulmonary veins are reconnected to the recipient's left atrium en bloc, using the donor's atrial cuff. This method not only reduces the surgical time but also minimizes the risk of developing pulmonary vein stenosis.

Living donor lobar transplant (LDLT) involves two living donors, each providing a lower lobe to the recipient. LDLT has often been used to provide organs rapidly to children with cystic fibrosis who underwent an unexpected rapid progression of their disease. Although outcomes can be comparable to deceased donor transplant [160] and there is some evidence to suggest that the incidence of bronchiolitis obliterans is lower in LDLT recipients [161], the procedure is resource intensive and has ethical implications because 10–20% of donor lobectomy surgeries have serious complications [162,163]. The 2009 ISHLT report noted that the number of LDLT surgeries in pediatric recipients peaked in 1998–1999 and since then has decreased substantially to only three procedures during 2005–2007 [125].

When the recipient's chest is too small to accommodate the donor lungs, the donor lungs can be reduced in size. Options include lobectomy (typically, the right middle lobe or lingula), wedge resection using a linear stapler, single lobe transplant or split lung "bipartitioned" transplant (in which two smaller "lungs" are created from a single deceased donor lung. Reports suggest that outcomes in pediatric recipients of reduced-size organs can be comparable to recipients of full-sized grafts [164].

# Early postoperative management

Patients are sedated and on ventilator support when admitted postoperatively for intensive care. Duration of mechanical ventilation has to be individualized for each child but many can be extubated within 12h of the surgery. Infants often have complex clinical problems and are critically ill before surgery; they required ventilation for longer (average 24 days) than older patients with cystic fibrosis (average 3 days) [165].

Some programs elicit the help of pediatric pain service specialists for postoperative pain management. Many centers provide PCA and narcotic infusions. There are no pediatric studies of postoperative analgesia after lung transplantation comparing epidural and intravenous techniques. Regional anesthesia via an epidural catheter has been frequently used in adults and some older children when transplantation was performed without CPB. A recent report of 58 pediatric patients who underwent epidural insertion before surgery and CPB showed no apparent complications from this technique and a median time to extubation of 19h [166]. Epidural analgesia was less effective in adult patients undergoing unilateral and bilateral lung transplantation than in patients undergoing a thoracotomy for other indications, perhaps due to the extensive clamshell incision [167]. A survey of adults found the occurrence of moderate-to-severe persistent pain after lung transplantation was low (5-10%) [168].

# Physiological changes and growth of the transplanted lungs

The allograft lungs are denervated but this produces few clinically significant effects on airway reflexes, mucociliary movement and bronchial hyper-reactivity [169]. Lack of afferent stimuli to the respiratory center in transplanted patients results in poor co-ordination between thoracic and abdominal muscles and a subnormal increase in the minute ventilation with carbon dioxide challenge was noted in adult patients [170]. Loss of lymphatic drainage makes the transplanted lungs more susceptible to interstitial edema, increased water content and lower compliance [171].

It is uncertain whether transplanted lungs grow. Although spirometry measurements (i.e.  $FEV_1$  and FVC) after lung transplant may be in the normal range in infants [170] and older children [172], these measurements may indicate increased volume of each alveolar unit rather than alveolar tissue growth or increased surface area for gas exchange. Animal studies demonstrated lung tissue growth and serial imaging studies in humans showed airway growth [173]. The measurement of diffusing capacity for carbon monoxide (DLCO) provides an estimate of gas exchange surface area. A single-center study of the DLCO in pediatric recipients of

 Table 27.12
 Morbidity at 1 year and 5 years post pediatric lung transplant from April 1994 to June 2008

Outcome	Within 1 year	With 5 years
Hypertension	42.8%	69.2%
Renal dysfunction	10.5%	21.6%
Abnormal creatinine <2.5 mg/dL	7.5%	14.9%
Creatinine >2.5 mg/dL	2.1%	3.7%
Chronic dialysis	0.6%	2.2%
Renal transplant	0.4%	0.7%
Hyperlipidemia	4.8%	11.1%
Diabetes	27.1%	33.1%
Bronchiolitis obliterans syndrome	14.0%	36.6%

Reproduced from Aurora et al [125] with permission from Elsevier.

cadaveric and living donor transplants did not show an appreciable increase in DLCO, suggesting that the increase in lung volume seen after mature lobes is secondary to hyperinflation [174].

# **Complications of lung transplantation**

Common complications are summarized in Table 27.12 [125].

# **Airway complications**

A single-center study involving 470 bronchial anastomoses at risk reported 42 (9%) airway complications (stenosis, n = 36; dehiscence, n = 4; malacia, n = 2) requiring interventions. Most (90%) complications were diagnosed within the first 3 months after transplantation. Associated risk factors were preoperative Pseudomonas cepacia, postoperative fungal lung infection, and prolonged mechanical ventilation [175]. Infants are prone to developing tracheobronchomalacia and dynamic airway obstruction. Often the problem resolves without surgical intervention but the patients may need prolonged ventilatory support [176]. Airway stenosis is usually treated successfully with repeated mechanical balloon dilation through a rigid bronchoscope. Stents are generally avoided in children with potential for airway growth; the devices are difficult to remove and can cause problems with exuberant granulation tissue growing through the wire mesh.

# Vascular complications

A perfusion scan is typically performed early after surgery to quantify the distribution of pulmonary blood flow. Vascular complications are infrequent, with pulmonary vein obstruction being the most common problem. Cardiac catheterization is indicated if a vascular abnormality is suspected. Any significant obstruction to pulmonary blood flow requires urgent treatment by either surgery or interventional cardiac catheterization [177].

#### **Nerve injuries**

Early re-exploration of the chest was performed in 11% of cases in one series, most commonly for bleeding [177]. Phrenic nerve injury (typically the right) occurred in 22% of cases and previous thoracotomy was a risk factor. Hoarseness from left recurrent laryngeal nerve injury was noted in 10% of patients. Most of these nerve injuries resolved in the first several months after transplantation, but some patients required diaphragm plication because of poor respiratory function [177,178]. Injury to the vagus nerve frequently leads to gastropharyngeal reflux and gastric paresis. Gastroesophageal reflux disease and resulting recurrent silent aspiration has been implicated in deteriorating graft function and bronchiolitis obliterans syndrome [179]. The incidence of severe gastroesophageal reflux is high (50%), particularly in the young [180]. Patients with deteriorating pulmonary function have been shown to benefit from surgical treatment of gastro-esophageal reflux [181].

# Arrhythmias

Arrhythmias that require therapy include atrial flutter (11% of pediatric transplants), atrial fibrillation and supraventricular tachycardia [182]. Most can be controlled with drug therapy. The left atrial suture line is the presumed source.

# **Primary graft dysfunction**

Primary graft dysfunction (PGD) represents a severe form of acute injury to the allograft and is characterized by patchy pulmonary infiltrates, a low ratio of arterial oxygen to the fraction of inspired oxygen, diminished lung compliance, and pathological findings of diffuse alveolar damage [183,184]. There are many opportunities for lung damage during the processes of donor death, organ harvesting, allograft preservation and transplantation. PGD is the net product of these insults, with ischemic reperfusion injury being a major contributor [185]. Interestingly, primary pulmonary hypertension is a recipient risk factor independently associated with the development of PGD [186], presumably from right ventricle dysfunction. PGD may contribute to nearly half of the short-term mortality after lung transplantation [187]. Survivors of PGD even have increased risk of death extending beyond the first post-transplant year and PGD is associated with the subsequent development of bronchiolitis obliterans syndrome [187,188].

Once PGD develops, patients are managed with aggressive cardiopulmonary support involving mechanical ventilation or non-invasive ventilation in the prone position [189], inotropes and occasionally the use of ECMO. Early use of nitric oxide reduces the early mortality [190]. In most patients PGD resolves over several days. Children who need extracorporeal support have significantly higher mortality.

The preventive strategies used to reduce the incidence of PGD include minimizing reperfusion injury, reducing ischemic time, improving donor management and avoiding volu- and barotrauma. Surgeons routinely allow ejection of a small amount of blood into the pulmonary artery immediately after establishing vascular supply to the first lung. PGE1 and prostacyclin may reduce the incidence and severity of the reperfusion injury [191]. The value of prophylactic nitric oxide is questionable [192].

# Rejection

# Hyperacute rejection

This rare complication may lead to early graft failure and results from circulating preformed recipient serum antibodies binding to donor tissue antigens and causing complement-mediated graft injury. Endothelial cells lining the blood vessels of the new organ are the principal targets. Preformed antibodies directed at HLA or endothelial antigens are generally attributed to prior blood transfusions, a previous transplant or pregnancy. To evaluate the risk for this complication, testing for PRA is performed during the assessment process. PRAs include a mix of 60–100 different samples that express a wide range of antigens tested with the recipient serum. Sensitized patients with high PRA scores may qualify for specialized therapies such as intra- and postoperative plasmapheresis, thymoglobulin and intravenous immunoglobulins [152].

#### Acute rejection

Acute cellular rejection is T-cell mediated and is common in the first year after lung transplantation, especially during the first 3 months. Clinically, it may be difficult to differentiate from an acute respiratory infection and the histopathological findings are not always helpful. Often the diagnosis of acute rejection is made on clinical suspicion and confirmed by the response to therapy. Some patients are asymptomatic and the acute rejection is detected by airflow limitation (a 10% decrease from baseline in  $FEV_1$  is considered significant). Others present with dyspnea and hypoxia and have infiltrates on chest radiograph. Infants and toddlers have immature immune systems and a lower incidence of acute rejection compared with older children [193]. Also, patients who receive lung-liver transplants have less acute rejection and bronchiolitis obliterans [194]. A pathological diagnosis of acute cellular rejection is based on the presence of perivascular and interstitial mononuclear cell infiltrates in the lung biopsy samples. Histology is classified as follows: acute rejection (A0–A4); lymphocytic bronchitis (B0–B2R, Bx); obliterative bronchitis (C0-C1) [195]. Lymphocytic bronchiolitis represents airway-directed rejection. In adults, acute rejection and lymphocytic bronchitis have consistently been identified as strong risk factors for chronic rejection [196] but the evidence is less convincing for pediatric lung transplant recipients [197]. It is unclear to what extent humoral rejection, which is antibody mediated, occurs among lung transplant recipients [195].

Methylprednisolone pulse at 10 mg/kg/dose daily for 3 days followed by augmented oral prednisone is the treatment for acute cellular rejection. Overall, the response to this treatment is improvement of symptoms and pulmonary function test results within several days. Management of steroid-resistant acute rejection is currently controversial. Treatment options for humoral rejection include plasmapheresis for antibody removal and immunoglobulin infusion.

#### **Chronic rejection**

Chronic rejection is the primary obstacle to better longterm outcomes after lung transplantation (Fig. 27.9). It manifests as obliterative bronchiolitis which is characterized histologically by fibroproliferative tissue remodeling with extracellular matrix deposition and results in small airway occlusion with sparing of the alveoli. Because the pathology has a patchy distribution, diagnosis by transbronchial biopsy has low sensitivity and specificity. Therefore, a clinical surrogate - the bronchiolitis obliterans syndrome (BOS) - was created and is defined as a progressive deterioration in pulmonary function tests (Table 27.13) [195]. Measurement of lung function in young children can be challenging. Changes in lung function tests are likely late manifestations of obliterative bronchiolitis but other diagnostic modalities, including imaging and exhaled biomarkers, have not proven useful.

The etiology of BOS is unclear. Identified risk factors include late or recurrent refractory acute rejection, lymphocytic bronchiolitis, CMV infection, ischemia reperfusion injury (longer ischemia times), HLA mismatches, infection, and gastroesophageal reflux with aspiration.

**Figure 27.9** Pediatric lung recipients: freedom from bronchiolitis obliterans syndrome (follow-ups: April 1994–June 2008). Reproduced from Kirk et al [91] with permission from Elsevier.

Table 27.13	Classification	of bronchiolitis	obliterans :	syndrome
-------------	----------------	------------------	--------------	----------

Stage	Definition
BOS 0	$\text{FEV}_1 > 90\%$ of baseline and $\text{FEF}_{25-75\%} > 75\%$ of baseline
BOS 0-p	$FEV_1 = 81{-}90\%$ of baseline or $FEF_{25{-}75\%} \leq \!\!75\%$ of baseline
BOS 1	$FEV_1 = 66-80\%$ of baseline
BOS 2	$FEV_1 = 51-65\%$ of baseline
BOS 3	$FEV_1 \leq 50\%$ of baseline

BOS, bronchiolitis obliterans syndrome;  $FEF_{25-75\%}$ , forced expiratory flow between 25% and 75% of vital capacity;  $FEV_1$ , forced expiratory volume in 1 sec. Baseline: the average of the two highest measurements at least 3 weeks apart after transplantation.

Reproduced from Estenne et al [228] with permission from Elsevier.

Young children, LDLT recipients and liver-lung recipients have a lower risk of BOS.

To date, there is no effective treatment for BOS. Therapies attempted include pulse steroids, methotrexate, cyclophosphamide, cytolytic therapy, inhaled cyclosporin, total lymphoid irradiation, photophoresis and switching to a different immunosuppression protocol [198]. Azithromycin and other macrolides may be useful [199]. Antireflux surgery may reverse the decline in pulmonary function in some patients and statins have beneficial potential because they induce apoptosis in fibroblasts. Retransplantation is considered in relatively few patients; risk of postsurgical death within 1 year is nearly 50% [125].

#### Immunosuppression

Higher doses of immunosuppressant agents are administered for pediatric lung transplantation than for other solid organ transplantation. Induction immunosuppression is currently used in approximately half of recipients, with about 10% receiving polyclonal antilymphocyte globulin and 40% receiving IL-2 receptor antagonists [125]. Most patients are given triple drug therapy for maintenance immunosuppression. This consists of a calcineurin inhibitor (tacrolimus more commonly than cyclosporin), cell cycle inhibitors like azathioprine or mycophenolate mofetil and prednisone. Sirolimus (target of rapamycin inhibitor) is seldom administered during the first year post transplant, but is more common at 5-year follow-up. Virtually all patients receive long-term maintenance corticosteroids [125].

# Infection

Infections occur in 60–90% of recipients. The risk of infection is largely determined by the interaction of three factors: (i) technical/anatomical factors that involve the transplant procedure itself, and the perioperative aspects of care such as the management of vascular access, drains, and the endotracheal tube; (ii) environmental exposure to pathogens; and (iii) the patient's net state of immunosuppression [200]. Bacterial infections are most common but fungal and viral infections result in higher mortality. Hypogammaglobulinemia post transplant was associated with increased infections [201].

Respiratory viral infections are associated with decreased 1-year survival after transplantation [202]. Common pathogens included adenovirus, rhinovirus, respiratory syncytial virus, and parainfluenza virus. Fungal infections were independently associated with a decreased 1-year post-transplant survival [203,204] and most centers routinely administer antifungal prophylaxis. Lung transplant patients are also at increased risk for invasive mold infections [205].

Cytomegalovirus after lung transplantation is a serious infectious complication, especially in CMV-negative recipients receiving CMV-positive donor lungs (i.e. mismatch). Pediatric patients are at increased risk for mismatch because they are more likely to be CMV negative and their incidence of CMV disease was 30% [206]. CMV disease was associated with increased mortality after pediatric lung transplantation. Usually it presents as pneumonitis but can also involve the liver, small bowel, and retina. Antiviral prophylaxis (e.g. ganciclovir) is beneficial although the optimal duration of prophylaxis is uncertain. Surveillance blood testing to measure the viral load is recommended.

# Surveillance

Lung transplant recipients are closely monitored for rejection and other complications. Routine monitoring for rejection includes daily home spirometry, regular pulmonary function testing, chest radiographs, bronchopulmonary lavages and transbronchial lung biopsies (a typical biopsy schedule would be at 2 and 6 weeks, and 3, 6, 9 and 12 months after transplant) [152]. Transbronchial biopsies are the mainstay of rejection surveillance in young children because spirometry is not feasible [207]. Infant pulmonary tests (peak expiratory flow rate) using thoracoabdominal compressions can be done but require anesthesia and are not part of the BOS criteria. Sometimes it is difficult to obtain sufficient tissue via transbronchial biopsy in small children and an open lung biopsy may be necessary [11,172,208].

#### Outcome

### Lung transplant

Survival after lung transplantation is similar in children and adult recipients and has improved in recent years. Children transplanted between 2002 and 2007 had a 1-year survival of 83% and a 5-year survival of 50% [125]. These outcomes are inferior to those for other pediatric solid organ transplantation. Children in the 1–10-year age group have better long-term outcomes than infants or

**Figure 27.10** Pediatric lung transplantation: Kaplan–Meier survival by age group (transplants: January 1990–June 2007). Reproduced from Kirk et al [91] with permission from Elsevier.

**Figure 27.11** Pediatric lung recipients: relative incidence of leading causes of death (deaths: January 1992–June 2008). Reproduced from Kirk et al [91] with permission from Elsevier.

adolescents (Fig. 27.10). Infants have higher early mortality but have better long-term outcome than children above 11 years of age. This may be due in part to the observation that infants and toddlers appear to be more immunologically tolerant of the allograft [193]. Significant risk factors for mortality include preoperative ventilatory support, earlier era of transplant, center volume of <5 pediatric lung transplants per year and adolescent age group. The poor long-term outcome of adolescents is ascribed to the propensity for poor adherence to medical therapies [209]. Children with tetralogy of Fallot and pulmonary atresia had worse outcome after lung transplantation than patients with Eisenmenger syndrome or pulmonary vein stenosis [210]. Graft failure, technical issues, cardiovascular failure and infection are common causes of death in the early post-transplant period, whereas infection, graft failure and BOS are common causes of late death (Fig. 27.11). Children undergoing repeat lung transplant have slightly poorer outcome (41% 5-year survival).

# Heart-lung transplant

Fewer than 20 heart-lung transplants are reported per year to the ISHLT [125]. The majority of procedures are for congenital heart disease, primary pulmonary hypertension or cystic fibrosis. A higher proportion of younger children undergo heart-lung transplantation compared with lung transplantation but the majority of procedures are performed in adolescents. Survival after heart-lung transplantation is slowly improving, with 5-year survival of 45% in the most recent era. Infants appear to do worse than older children.

# Intestinal, multivisceral, and pancreatic transplantation

# Indications

Successful transplantation of liver, kidneys, hearts, and lungs has led transplant surgeons to attempt to treat other illnesses affecting infants and children. In children, the short-gut syndrome, which results from necrotizing enterocolitis, intestinal malrotation and volvulus, or congenital defects (intestinal atresia, abdominal wall defects), leads to dependence on total parenteral nutrition (TPN). The long-term sequelae of TPN include steatotic liver disease and eventual hepatic failure and the complications of long-term venous access. Isolated small bowel transplants, combined small bowel-liver transplants, and extensive multivisceral transplants (liver, pancreas, gastrointestinal tract from stomach to colon) have been performed in an attempt to manage short-gut syndrome. The results of intestinal transplantation have improved over the past decade. Transplantation of the intestine before liver failure improves early outcomes [211]. In 2005, the results of nearly 1000 intestinal transplant procedures (from 62 centers in 19 countries) were summarized in the report of the International Intestinal Transplant Registry (IITR) [212]. The most recent cohort (transplanted after 1998) demonstrated 65% overall 1-year patient survival and over 80% 1-year survival in those recipients who received induction therapy combined with tacrolimus. Recently, a single-center series reported 1- and 5-year patient and graft survival to be 78-85% and 56-61% respectively, despite divergent immunosuppression protocols [213]. More than 80% of transplant recipients who survive attain freedom from parenteral nutrition and resume normal daily activities.

Pancreas transplantation has been utilized most commonly as combined renal and pancreas transplantation for treatment of ESRD in diabetics with other end-organ dysfunction (retinopathy, neuropathy). Because of the interval between development of insulin-dependent diabetes in children and end-organ complications, few reports of pancreas transplantation have been reported in children, apart from the multivisceral procedures described above. The number of pancreas transplants peaked in 2004 and steadily declined through 2008. Even though pancreas transplantation of diabetic patients has stabilized or improved their nephropathy, retinopathy, and neuropathy, immunological failure of the transplant has led to abandonment of isolated pancreas transplant and only combined kidney and pancreas transplants are now performed in children [214].

# **Anesthetic management**

The exact form of intestinal transplantation (i.e. isolated, combined liver-small bowel or multivisceral transplantation) depends upon the cause of intestinal failure and associated extraintestinal organ involvement. Following identification of an appropriate donor, the recipient undergoes a regimen designed to purge and decontaminate the intestinal tract. Routine premedication is avoided, but may be required and administered under appropriate monitoring situations. Rapid-sequence induction of general anesthesia and tracheal intubation is planned. Despite normal or slightly impaired hepatic function, there is a potential for extensive blood loss and hemorrhage in most of these cases. Previous abdominal surgery and extensive dissection and evisceration of the native organs prolong the dissection period and increase blood loss. Venous access sites, particularly around the central circulation, may be limited because of previous TPN catheters. However, central venous access is essential for management. Arterial blood pressure and central venous pressure should be monitored directly. Intraoperative management is similar to liver transplantation: hemodynamic stability may require rapid infusion of crystalloid, colloids or blood products; maintaining metabolic homeostasis requires frequent arterial blood gases and electrolyte concentration determinations.

In multivisceral transplantation and combined pancreatic renal transplantation, particular attention is required to maintain normoglycemia. Tight intraoperative control of the glucose concentration may result in improved pancreatic allograft function. To achieve glucose concentrations of 80–150 mg/dL requires frequent intraoperative determinations of glucose concentration, and titration of a regular insulin infusion. A period of hyperglycemia is common following reperfusion of the pancreatic graft and requires additional insulin administration.

# **Complications following transplant**

# Rejection

A common complication associated with all forms of allograft transplantation is rejection of the transplanted tissue by the recipient. Rejection in the early post-transplant period may be a subtle process and difficult to assess by routine physical and laboratory examination. Clinical signs of rejection will vary by the transplanted organ, and are not likely to be specific. Therefore, there is need for early histological evaluation of the organ to diagnose acute rejection. Many transplant centers routinely biopsy the organ at weekly to monthly intervals to search for evidence of acute rejection. This generally requires an invasive procedure requiring anesthesia or sedation in children. Routine immunosuppression is altered in the face of acute rejection. Steroid administration is increased first, and then maintenance immunosuppressive therapy may be increased. See specific discussions of heart and lung rejection and surveillance above.

# Infection

Immunosuppression leads to an increased risk of infection. Various forms of infection are more common at different time periods [200,215,216]. In the *first month*, there are three major causes of infection: infection that was present in the recipient before transplant, infection conveyed with a contaminated allograft, and typical postoperative infections also observed in immunocompetent patients, such as surgical wound infections, pneumonia, infected lines or drains.

One to 6 months after transplantation is when more intense immune suppression produces the greatest effect on the risk of infection. During this period, two major classes of infection predominate: chronic viral infections and opportunistic infections. Viral pathogens such as CMV, EBV, human herpes virus 6 (HHV-6), and the hepatitis viruses (B and C) may be acquired from the donor, reactivated in the host, or the patient may become infected with a new strain of these viruses. During this 1–6-month post-transplant period, opportunistic infections are also observed and include organisms such as *Listeria monocytogenes, Aspergillus fumigatus*, and *Pneumocystis jiroveci*.

Once patients are more than 6 months post transplant, their infectious risk can be broken down into two categories of patients: those with a good result from transplant and a smaller group with a poor graft function. The majority of patients have good graft function, are on maintenance immunosuppression therapy, and are at greatest risk from typical community-acquired infections such as influenza, parainfluenza, and respiratory syncytial virus. The smaller group of patients with acute and chronic immunosuppression, poor allograft function and, often, chronic viral infection remain at high risk for recurrent infections related to mechanical problems from surgery as well as opportunistic infections attributable to organisms like Pneumocystis jiroveci, Listeria monocytogenes, Cryptococcus neoformans, and Nocardia asteroides. Infectious risk and outcomes related to lung transplant are discussed above.

# Malignancy

The risk of developing cancer after solid organ transplantation is about 5–10-fold more than that of the general population. Children receiving transplants are at high risk of developing a malignancy during their lifetime. The cumulative risk of cancer increases with age and is >50% at 20 years after transplantation.

Post-transplant lymphoproliferative disease (PTLD) is the most common cancer observed in children following solid organ transplantation, accounting for half of all such malignancies [217]. The incidence is about 5-10%. PTLD results from the uncontrolled proliferation of lymphocytes in the immunosuppressed transplant recipient and is a major contributor to long-term morbidity and mortality in this population. Among children, most cases are associated with EBV infection. PTLD is an early event (i.e. within the first 2 years after transplant) in most cases, likely because of more intense immunosuppression used for induction therapy or the exposure of the EBV-naive host to the virus, often from EBV-infected passenger lymphocytes in the allograft. PTLD commonly affects the lung allograft, lymphoid tissues, gastrointestinal tract and liver. Gastrointestinal involvement is associated with increased mortality [218]. Therapy for PTLD includes empiric reduction in immunosuppression, antiviral drugs, monoclonal antibodies specifically targeting the B-lymphocyte antigen CD20 (e.g. rituximab), or chemotherapy, when appropriate.

# **Renal dysfunction**

Renal dysfunction is one of the most common complications following solid organ transplantation. Ojo and colleagues found that the cumulative 5-year risk of chronic renal failure, defined as the need for either chronic dialysis or kidney transplantation, was 6.9–21.3%, depending on type of organ transplanted [219]. This study included more than 69,000 non-renal solid organ transplant recipients who were predominantly adults. The risk of death increased more than fourfold with the onset of chronic renal failure, and the cost of care was dramatically increased [219]. Table 27.14 shows the risk of renal failure related to the type of organ transplant.

There are multiple factors that produce renal dysfunction following solid organ transplantation; however, the calcineurin inhibitors (CNI) cyclosporin and tacrolimus are the major contributing factors. The CNI produce both acute and chronic nephrotoxicity. Acute nephrotoxicity involves afferent arteriolar vasoconstriction and reduced renal plasma flow, and is associated with high trough levels. In contrast, chronic CNI-induced nephrotoxicity is not predicted by individual trough levels, and is characterized by potentially irreversible structural changes including arteriolopathy, tubulointerstitial fibrosis and, eventually, glomerulosclerosis [220]. Strategies for man

agement of post-transplant renal dysfunction have largely focused on CNI minimization, replacement or avoidance.

# Growth and developmental delay

Organ failure frequently leads to a poor nutritional state and growth failure. After organ transplant, most patients demonstrate catch-up growth, yet a large percentage of patients do not reach their predicted adult height and weight. Immunosuppression regimens that limit the use of steroids seem to be well tolerated and allow for better growth; however, the long-term effect of CNI on growth is not well studied and may also contribute to growth failure [221]. Growth hormone can be used but there are theoretical concerns about the risk of triggering rejection [11].

Solid-organ transplant recipients display a wide range of developmental outcomes, from normal development to significant delays. Factors that lead to poor developmental outcome likely include long-term hospitalization, chronic malnutrition in the pretransplant period, and surgical complications. Children who receive heart transplantation may have better cognitive outcomes than expected considering the results of older studies of children with cyanotic congenital heart disease. The cognitive outcomes of liver and kidney transplant recipients may also be improving, but many still require special educational resources. Infants requiring intestine or liver and intestine transplant are probably at the highest risk for cognitive delay, but longitudinal studies that confirm these delays are lacking [221]. In all cases neurological co-morbidities increase the risk of delay. Despite recent

advances, a significant proportion of liver and heart recipients have serious developmental delay or neurological injury.

#### **Cardiovascular side-effects**

Immunosuppressive agents produce cardiovascular toxicity, causing an increased likelihood of hypertension, hyperlipidemia, hypercholesterolemia, and diabetes mellitus. Hypertension is found in 62–75% of pediatric patients (Table 27.15) [222]. Although both tacrolimus and cyclosporin can cause hypertension, cyclosporin appears to have a greater impact on blood pressure [223].

These side-effects are treated via an alteration of immunosuppressive regimen, or addition of specific medications to address each risk factor or complication. Since steroids and CNI provide the mainstay of immunosuppressive treatments, they generally cannot be eliminated. Steroid withdrawal or reduction as well as the use of tacolimus over cyclosporin may decrease the risk of hypertension, dyslipidemia or diabetes mellitus [220]. All classes of antihypertensive medications have been used and are ideally chosen based on the therapeutic profile. In addition to surveillance of tacrolimus levels, long-term monitoring of cardiac function may also be warranted in high-risk populations.

# **Post-transplant surgery**

Regardless of the transplant procedure, as transplant recipients age, they are likely to acquire diseases or conditions that require additional surgery. Prior to such procedures, the anesthesiologist must assess the function of the transplanted organ, review the status of the patient's immunosuppression, and perform a careful assessment of the other organ systems. Hypertension and chronic renal insufficiency are common findings in patients (see above). Most patients will demonstrate findings of chronic steroid administration.

# **Quality of life**

The functional status of most long-term survivors of solid organ transplantation is good, with greater than 80-90% of 5-year survivors from kidney, liver, heart and lung transplantation reporting no limitations in activity. Despite excellent function, children may experience psychological difficulties and an impaired quality of life [224]. Pediatric studies focusing on quality of life after transplantation remain scarce [223-225]. Research thus far shows improved overall quality of life after kidney, liver, heart and lung transplantation, although the debate continues for cystic fibrosis [132]. The quality of life after small bowel transplantation is probably equal to or better than quality of life on parenteral nutrition, and children report quality of life similar to normal schoolchildren. A study that used qualitative interviews to examine psychosocial issues after lung transplantation in adolescents with cystic fibrosis reported that patients were able to develop long-term goals and had a wish to reclaim control over their lives as much as possible and adjust to a new lifestyle, yet common emotional responses included fear and anxiety over rejection, uncertainty over the future, and frustration with parental overprotectiveness [226].

It has been proposed that quality of life should be included in the assessment of transplantation benefit [227]. Currently, timing of transplantation relies primarily on estimates of survival benefit because comprehensive objective measures of quality of life for pediatric lung transplantation are not available.

# **ABDOMINAL SURGICAL CONDITIONS**

# Intussusception

Intussusception is a common cause of intestinal obstruction and abdominal pain. The incidence of this lesion is 1 in 2000 infants and children and it is a true pediatric emergency. Intussusceptions occur when a segment of bowel (the intussusceptum) invaginates into the distal bowel (the intussuscipiens), usually in an antegrade direction. This results in venous congestion and bowel wall edema. If intussusception is not recognized and treated rapidly, bowel necrosis and perforation may result. Overall mortality from intussusception is less than 1%, and the outcome is excellent if the condition is diagnosed early and treated within 24h of onset.

# Epidemiology

Intussusception occurs primarily in infants and toddlers, and males are affected twice as often as females. The peak incidence of this abnormality occurs between 5 and 9 months of age; between 10% and 25% of cases occur after 2 years of age [1]. Intussusception rarely occurs in patients younger than 2 months of age, but rare instances have been reported in preterm infants.

Ninety percent of intussusceptions are idiopathic, but lymphoid hyperplasia has been suggested to be the "lead point" in the pathogenesis of some intussusceptions [2]. The incidence of this disease is higher during autumn and spring, suggesting that it might be a sequela of a previous viral infection [3]. Indeed, adenovirus, rotavirus, and human herpesvirus-6 infections have been associated with intussusceptions [4].

After introduction of the oral rotavirus vaccine in 1999, some >3-month-old infants developed intussusception, usually 3–14 days after the first dose of the vaccine was given [5]. This caused the vaccine to be withdrawn from the market [6]. Other common lead points are Meckel diverticulum, intestinal polyps, and lymphoma. Patients with systemic conditions, such as Henoch–Schönlein purpura, Peutz–Jeghers syndrome, familial polyposis, nephrotic syndrome, mesenteric nodes, and inverted appendical stumps, are also prone to developing intussusception [7–9]. Recurrent intussusception is uncommon but has been reported in 1–3% of infants and young

*Gregory's Pediatric Anesthesia*, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

 $\ensuremath{\mathbb C}$  2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

children after operative repair and in 10–15% after hydrostatic reductions of the lesion [10].

# Pathophysiology

Ileocolic intussusception accounts for more than 90% of the cases of intussusception, though it can occur in any segment of the bowel. The intussusceptum and its blood supply are propagated distally along the intestine. Venous congestion and bowel wall edema occur due to compression of the blood vessels by surrounding tissue. As the obstruction progresses, the arterial blood supply can be compromised and intestinal ischemia and bowel infarction may occur [1].

# **Clinical presentation**

Intussusception has both typical and atypical presentations, but many patients present with non-specific signs and symptoms. The classic presentation is a young child with a history of a recent viral illness, vomiting, and/or diarrhea. The classic clinical triad of intermittent abdominal pain, redcurrant jelly stool, and a palpable mass is found in 7.5–40% of affected children. Twenty percent of the children are pain free at initial presentation [11]. Infants younger than 4 months of age have a higher incidence of painless intussusception. Thirty percent of them present with diarrhea and are often misdiagnosed as having gastroenteritis [12].

Vomiting is the most common symptom and is frequently the only clinical finding in infants. Older children may present with colicky abdominal pain and bilious vomiting. Early in the course of the illness, stools are normal. Subsequently they become dark red and mucoid and resemble redcurrant jelly (indicating ischemia or mucosal sloughing).

A palpable right upper quadrant mass is often present on physical examination and is usually sausage shaped and ill defined. The mass may enlarge during episodes of pain. Some patients present with syncope, sepsis, and/or hypovolemic shock.

#### Diagnosis

No reliable clinical model accurately diagnoses all patients who present with intussusception. Plain abdominal films, ultrasound or a computed tomographic (CT) scan help to confirm the diagnosis.

#### Management

Management of an intussusception has changed significantly in recent years. Barium, aqueous or air enemas now are used to successfully reduce the intussusception (60–90% for air, and 60–80% for barium/aqueous contrast enemas). When non-operative reduction of the lesion is unsuccessful or is contraindicated, patients undergo surgery to reduce the lesion. Aggressive fluid resuscitation is often required before, during, and after surgery. Antibiotics are also required.

Preoxygenation and rapid-sequence intravenous induction of anesthesia with propofol and a muscle relaxant (succinylcholine or rocuronium) are used to facilitate tracheal intubation and reduce the risk of regurgitation and aspiration of gastric contents. Maintenance of anesthesia is accomplished with isoflurane, sevoflurane or an opioidbased anesthetic in critically ill patients.

# **Key points**

- Intussusception is a common cause of bowel obstruction in young children and has an incidence of 1 in 2000.
- The classic clinical triad of intussusception is intermittent abdominal pain, redcurrant jelly stools, and a palpable abdominal mass.
- A palpable sausage-shaped mass is often present in the right upper quadrant of the abdomen on physical examination.
- Barium, aqueous, and air enemas successfully reduce the intussusception in more than half of the patients; operative reduction is required if this fails.
- Aggressive fluid resuscitation may be required preoperatively to correct hypovolemia.

# **Biliary atresia**

Biliary atresia is defined as the absence of patent extrahepatic bile ducts and is a common cause of jaundice in neonates and infants. If untreated, biliary atresia leads to cirrhosis and liver failure within the first 2 years of life. The incidence of biliary atresia ranges from 1 in 10,000 to 1 in 16,700 livebirths, with a slight female preponderance [13,14]. There are three main types of biliary atresia: type I, atresia at the site of the common bile duct (11.9%); type II, atresia at the site of the hepatic duct (2.5%); type III, atresia at the porta hepatis (84.1%) [15]. Ten to 20% of patients with biliary atresia have other congenital malformations, the most common being poylsplenia [15]. Other anomalies include asplenia, anomalies of the inferior vena cava, bowel atresia, annular pancreas, and genitourinary anomalies [15,16].

#### Etiology

The exact cause of biliary atresia remains elusive, but there is some association between perinatal viral infections (reovirus type 3, rotavirus, cytomegalovirus, human papillomavirus, respiratory syncytial virus, and Epstein– Barr virus) and biliary atresia [17–21]. There may also be a genetic predisposition to its development. Defects in the immune response, autoimmune disorders, and defects in morphogenesis are other possible causes of biliary atresia.

# Pathophysiology

Whatever the cause, the end result is complete obstruction of the lumen of the extrahepatic bile ducts and progressive inflammation of the intrahepatic ducts. The degree of intrahepatic bile duct involvement is responsible for much of the morbidity encountered after hepatic portoenterostomy (Kasai procedure).

# **Clinical presentation**

Most patients present with jaundice, acholic stools, dark urine, and an enlarged, firm liver within several weeks after birth; eventually the child develops cirrhosis and splenomegaly. Coagulopathy and portal hypertension often follow. Malabsorption of fat-soluble vitamins leads to anemia, malnutrition, and failure to thrive. Karrer et al reported a less than 10% 3-year survival of children who do not undergo a definitive biliary drainage procedure [13].

#### Diagnosis

No single test reliably diagnoses biliary artesia. However, a combination of physical examination, serological evaluation of liver function, ultrasonography, and percutaneous liver biopsy is useful for making the diagnosis. An absolute, definitive diagnosis requires surgical exploration.

#### Management

Currently biliary atresia is managed in two phases [22].

- *Phase 1:* attempts are made to preserve the infant's liver by performing a Kasai procedure, which involves excising all of the extrahepatic biliary structures from the liver hilus. The denuded hilus is then anastomosed to the jejunal limb of a Roux-en-Y. It is hoped that microscopic biliary structures within the transected fibrous tissue will drain into the intestinal conduit. The Kasai procedure never works in about one-third of infants, it works for several years in another third, and it works for more than 10 years in the remaining third.
- *Phase 2:* if bile flow is not restored by the Kasai procedure or the cirrhosis worsens, the infant becomes a candidate for liver transplantation (see Chapter 27).

Anesthetic management for infants with biliary atresia can be challenging, since they are frequently malnourished and occasionally dehydrated. It is important to note and understand all of the laboratory and other diagnostic studies preoperatively. Blood products should be available because many of these patients are coagulopathic, and have significant potential for intraoperative blood loss during surgery done around major intra-abdominal vascular structures, e.g. the inferior vena cava (IVC) and the hepatic artery. Depending on the infant's condition and the type of surgery, the procedure may be scheduled as same-day surgery or after admission to hospital prior to surgery. Intravenous (IV) access may be difficult in these patients.

Anesthesia is usually induced with intravenous propofol and fentanyl; muscle paralysis is provided with rocuronium or pancuronium. Anesthesia is often maintained with either isoflurane or sevoflurane. It is preferable to have IV access in the upper extremity in case there is massive bleeding. Having a functioning arterial line during surgery is very helpful. Intraoperative hypotension is common with IVC compression by surgical instruments or with sudden blood loss. All replacement IV and irrigation fluids should be warmed. Plans are made before surgery for postoperative respiratory and pain management.

Some children develop cholangitis after a Kasai procedure and are very ill.

# **Key points**

- Biliary atresia is a common cause of cirrhosis and liver failure during the first 2 years of life.
- Complete obstruction of the lumen of extrahepatic bile ducts and progressive cellular inflammation of the intrahepatic ducts are common.
- These patients present with jaundice, acholic stools, dark urine, and an enlarged firm liver within weeks after birth.
- Biliary atresia is managed in two phases: phase 1 Kasai procedure, phase 2 liver transplantation.

# Malrotation of the bowel and intestinal atresia

Intestinal obstruction can occur at any age, but the etiology of obstruction varies according to the age of the patient. It is often embryological in origin, especially in children less than 1 year of age. The common congenital causes of bowel obstruction include bowel atresia/ stenosis, malrotation of the bowel, Hirschsprung disease, imperforate anus, and meconium ileus. Congenital or acquired small bowel obstructions are more common in children than are large bowel obstructions. Hernias, intramural and extramural intestinal lesions, tumors, inflammatory bowel disease, intestinal volvulus, and adhesions are some of the common causes of pediatric bowel obstruction. Adhesions account for about 60% of all small bowel obstructions [23]. Early diagnosis of intestinal obstruction depends on early recognition of the symptoms, e.g. bilious vomiting, abdominal distension and tenderness, and radiographic findings.

# **Intestinal atresia**

Jejunoileal atresia and stenosis are common causes of neonatal intestinal obstruction. Atresia is a congenital anomaly that completely occludes the intestinal lumen; this accounts for 95% of the cases of obstruction. Stenosis is defined as a partial intraluminal occlusion that incompletely obstructs the intestine. It is responsible for 5% of jejunoileal obstructions. Jejunoileal obstruction occurs in 1 in 330 (USA) to 1 in 400 (Denmark) to 1 in 1500 livebirths. Intrauterine mesenteric vascular compromise is thought to be the etiology of jejunoileal atresia. On the other hand, mucosal atresia is thought to cause duodenal atresia.

Prenatal ultrasound is useful for diagnosing intestinal atresia in babies whose mothers have polyhydramnios. A history of maternal polyhydramnios, neonatal bilious vomiting, abdominal distension, and failure to defecate meconium on the first day of life is the usual clinical presentation [24]. The diagnosis is confirmed by radiographic examination. Thumb-sized intestinal loops and air-fluid levels are highly suggestive of neonatal intestinal obstruction.

Management of intestinal atresia consists of surgical resection of the atretic/stenotic section of bowel. Common postoperative complications include obstruction at the anastomotic site and anastomotic leaks. Factors contributing to the morbidity and mortality of these patients include associated anomalies, respiratory distress, prematurity, and short bowel syndrome.

# Malrotation of the bowel

Intestinal malrotation refers to abnormal rotation of the midgut around the superior mesenteric artery and abnormal fixation of the gut within the peritoneal cavity. Several types of malrotation occur and are caused by errors in growth, rotation, and position of the duodenum and the ligament of Treitz. These abnormalities in rotation range from non-rotation to reversed rotation [25]. The most common form of gut malrotation in children is due to incomplete rotation and narrow attachment of the mesentery of the midgut to the posterior abdominal wall, which predisposes to midgut rotation and volvulus. Rotational abnormalities commonly occur with heterotaxia, which in this case refers to abnormal attachments of the body organs. Major, complex cardiac anomalies and other gastrointestinal anomalies (e.g. malposition of the stomach, liver and pancreas, asplenia or polysplenia) are associated with heterotaxia [24].

### Epidemiology

The exact incidence of malrotation of the gut is unknown, but it is thought to be about 1 in 500 livebirths [26]. The incidence is high in patients with heterotaxia (40–90%). There is no gender-specific preponderance for this lesion. Malrotation is also associated with other congenital or acquired lesions of the gastrointestinal tract (e.g. Hirschsprung disease, intussusceptions, and atresia of the jejunum, duodenum, and esophagus) [27]. These abnormal gut rotations and fixations can obstruct and strangulate the gut at any time between 10 weeks of intrauterine life and adulthood. Malrotation of the gut also occurs in patients with abdominal wall defects, e.g. omphalocele, gastroschisis, and diaphragmatic hernias.

# **Clinical presentation**

Sixty percent of patients presenting with malrotation of the gut do so during the first month of life. Twenty percent present between 1 month and 1 year of age and the remainder present later. Some patients are asymptomatic and their lesion is found accidentally. The usual presenting symptoms of neonates are bilious vomiting or signs of midgut volvulus. Beyond the neonatal period, the presenting symptoms vary from vomiting, intermittent colicky abdominal pain, failure to thrive, diarrhea, constipation, gastrointestinal hemorrhage (i.e. hematemesis or bloody stools), and acute intestinal obstruction [28]. Signs of abdominal distension and peritonitis are often found on physical examination.

### Diagnosis

Diagnosis of malrotation is radiological. Making the diagnosis may be difficult if there is heterotaxia because the location of the liver, spleen, and stomach is often ambiguous. Plain radiographs of the abdomen are frequently non-diagnostic. Occasionally, however, there is a "double bubble" sign (i.e. two air-filled structures in the upper abdomen – the stomach on the left and the duodenum on the right – with little or no air seen distally). This finding is usually indicative of acute duodenal obstruction. On an upper gastrointestinal series, if the duodenojejunal flexure and loops of jejunum are on the right side of the abdomen and the cecum is above its normal position on a delayed film, this is diagnostic of malrotation. Abdominal ultrasound and CT scans can fail to rule out the diagnosis of malrotation.

#### Management

Preoperative management of malrotation requires fluid resuscitation with a balanced salt solution to correct vomiting-induced hypovolemia and dehydration. Attaching a nasogastric tube to suction can increase volume loss. Antibiotics should be administered early. Some patients are severely acidotic from both hypovolemia and poor gut blood flow. If the acidosis is not corrected by fluid replacement, partial correction of pH with bicarbonate or tromethamine (THAM) should be considered. Once the patient is normovolemic, a Ladd procedure is done, which includes derotation of the midgut volvulus, division of bands and adhesions when present, and an appendectomy. The small bowel is then placed in the right side of the abdomen and the colon on the left side.

These patients must be considered to have a full stomach. Before inducing anesthesia, all laboratory and other diagnostic studies should be reviewed and the degree of acid–base imbalance and electrolyte abnormalities corrected. Adequate venous and intra-arterial access is required.

Just before the induction of anesthesia, the stomach is decompressed through an orogastric or nasogastric tube, and the lungs are preoxygenated. Rapid-sequence induction of anesthesia is accomplished with intravenous propofol 2-3mg/kg or etomidate 0.2-0.3mg/kg and a non-depolarizing mucscle relaxant, e.g. rocuronium 1-1.2 mg/kg or pancuronium 0.1-0.2 mg/kg, to facilitate rapid intubation. Intraoperatively, the patient's lungs are ventilated with a mixture of air and oxygen and low concentrations of sevoflurane or isoflurane. Intravenous narcotics, e.g. fentanyl, are titrated to effect. The key to a good outcome is fluid resuscitation and replacement of extracellular fluid losses in the perioperative period. Occasionally large volumes of colloids and blood are required. Circulatory support with vasopressors may be required, especially after derotation of the bowel.

These infants frequently require intensive care after surgery. Depending on the stability of the patient, the magnitude of the surgery, and associated co-morbid conditions, some patients require postoperative mechanical ventilation. Delayed return of intestinal function often makes parenteral nutrition necessary for a period of time.

# Intestinal pseudo-obstruction

If the surgeons find no cause for the bowel obstruction, the patient may have intestinal pseudo-obstruction, a condition in which the signs and symptoms of intestinal obstruction are present but no mechanical lesion is found. Pseudo-obstruction is myopathic or neuropathic in etiology and is not limited to the small intestine. Box 28.1 lists the causes of intestinal pseudo-obstruction. These patients have recurrent attacks of variable duration and frequency that include nausea, vomiting, abdominal distension, diarrhea, and constipation.

Treatment of intestinal pseudo-obstruction is difficult and is mainly medical. Erythromycin and octreotide have been used with some success to stimulate intestinal motility and contraction. New treatments that target intestinal serotonin receptors (alosetron) are in clinical trials. Surgery is only helpful for patients who have a short segment of intestinal dysmotility.

#### Box 28.1 Causes of intestinal pseudo-obstruction

#### Disorders of the nervous system

- Familial autonomic dysfunction
- Neurofibromatosis
- Autoimmune disease
- Paraneoplastic syndrome
- Hirschsprung disease
- Chagas disease

#### Disease affecting muscles and nerves

- Muscular dystrophy
- Systemic lupus erythematosus
- Amyloidosis
- Ehlers–Danlos syndrome
- Electrolyte disturbances
- Hypokalemia

#### Disorders of the endocrine system

- Diabetes mellitus
- Hypothyroidism
- Hyperparathyroidism

#### Medications

- Narcotics
- Laxatives
- Tricyclic antidepressants
- Phenothiazines

#### Key points

- Jejunoileal atresia and stenosis are major causes of neonatal intestinal obstruction.
- Abnormal intestinal rotation commonly occurs with heterotaxia, i.e. there are abnormal attachments of body organs.
- Neonates with intestinal malrotation present with bilious vomiting or with signs of midgut volvulus.
- Large volumes of crystalloids, colloids, and blood, as well as circulatory support with vasopressors, may be required. Acidosis is common and may necessitate blood volume expansion and alkali to correct it.

# Inflammatory bowel disease

Inflammatory bowel disease (IBD) includes two major forms of chronic intestinal inflammation: Crohn disease and ulcerative colitis. Both are associated with significant morbidity. Prompt and accurate diagnosis and appropriate treatment of IBD minimize its short-term and longterm physical and psychological effects.

# Epidemiology

The incidence of IBD is steadily increasing. Over 1 million Americans are afflicted with the disease, and 10–25% of them are children [29]. In pediatric patients, the incidence of Crohn disease is 11 per 100,000 per year compared to 2.3 per 100,000 per year for ulcerative colitis [30]. Males and females are equally afflicted. North America and northern Europe have the largest number of patients with IBD. Caucasians, especially in the Ashkenazi Jewish population, have the highest risk for the disease. However, the increased disease prevalence is occurring in diverse rural and urban populations alike and in people of different ethnic backgrounds.

# Etiology

The etiology of IBD is unknown, but a number of risk factors appear to play a role in its development. There appears to be a genetic predisposition because having a first-degree relative with IBD increases your risk for this disease by 5–25% [31]. Monozygotic twins are more likely to have IBD than dizygotic twins. Environmental factors, infections, immune system disorders, and psychological stress play a role in the development of IBD.

#### Pathophysiology

Ulcerative colitis is usually limited to the colon and rectum. However, the extent of the disease differs between children and adults. It is usually more extensive in children and may present as pancolitis. Microscopic changes of ulcerative colitis are limited to the mucosa and are continuous from the rectum upward [32]. Crohn disease, on the other hand, can affect any part of the gastrointestinal tract from the mouth to the anus. Children with Crohn disease usually have extensive lesions of the ileum and colon when first evaluated. The inflammatory lesions are focal, asymmetrical, and patchy in location and severity. In the colon, Crohn disease may be difficult to distinguish from ulcerative colitis. Patients with IBD also have extraintestinal manifestations and a higher than predicted risk of developing colorectal cancer.

#### **Clinical presentation**

The classic presentation of Crohn disease is abdominal pain, diarrhea, and weight loss. Bloody, mucoid diarrhea is classic for ulcerative colitis. Extraintestinal manifestations of IBD include anorexia, lethargy, pyrexia, arthralgia, arthritis, erythema nodosum, uveitis/iritis, and growth failure.

# Diagnosis

The gold standard for diagnosing IBD is upper endoscopy, colonoscopy, and tissue histology. However, there is no substitute for a complete history and physical examination. Laboratory screening tests include erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) [33], and examination of the stool for bacteria and parasites. Fecal inflammatory markers are also helpful for screening and monitoring patients with IBD. Fecal markers include proteins released from activated neutrophils in the bowel mucosa (e.g. lactoferrin, calprotectin, PMN-elastase, lysozyme) [34].

Serological biomarkers include anti-*Saccharomyces cerevisiae* (ASCA) IgA and IgG, anti-*E. coli* outer membrane porin C (OmpC), antiperinuclear antineutrophil (pANCA) IgG, anti-*Pseudomonas fluorescens* CD-related protein (I2) IgA, and antiflagellin (C Bir-1). It has been postulated that patients who have immune reactivity to antimicrobial antigens have a more severe form of disease [35]. Higher ASCA levels are associated with younger age at disease onset, structuring of the bowel, penetrating disease, and a need for surgery in both adults and children with Crohn disease.

Radiographic studies, CT scans, ultrasound, magnetic resonance imaging (MRI), and barium enemas are also used to detect disease and complications of the disease (e.g. abscess); however, use of these modalities is limited.

#### Management

Inflammatory bowel disease is quite debilitating. Therefore, the goals of management include induction and maintenance of disease remission to facilitate normal growth and development and improve the child's quality of life. Medical management consists of a combination of pharmacological agents, including administering corticosteroids for their anti-inflammatory properties to children who have moderate-to-severe active IBD. Sulfaxazine and 5-aminosalicylate are locally active medications that are useful for induction and maintenance of disease remission [36]. Immunomodulators, such as 6-mercaptopurine (6-MP) and azathioprine, are the most commonly prescribed agents for these children. These drugs act by incorporating 6-thioguanine nucleotide metabolites (6-TGNs) of 6-MP in leukocyte DNA [37]. Methotrexate is a second-line immunomodulator that has significant corticosteroid-sparing effects when injected weekly in children with IBD [37]. Cyclosporin and tacrolimus effectively control severe fulminant ulcerative colitis and fistula formation in Crohn disease by blocking production of the potent proinflammatory cytokine interleukin-2 [38,39].

Biological therapy with infliximab, a chimeric monoclonal antibody (IgG1), is directed against tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and is widely used in children with IBD [40]. Antibiotics/probiotics, especially ciprofloxacin (Cipro) and metronidazole (Flagyl), are used to prevent and treat infection, e.g. pouchitis [41]. Nutritional therapy with an elemental diet or total parenteral nutrition helps maintain nutrition and improve growth, which is important because poor nutrition is a major cause of growth failure in patients with IBD.

Psychological problems are common in children with IBD due to demanding treatment regimes, frequent relapses of their disease, pain, diarrhea, fecal incontinence, and altered physical appearance. These children frequently do not discuss their problem with peers. Multidisciplinary help is often needed for both the children and their families to help them cope with the practical and psychological implications of IBD [42].

Patients with IBD have an increased risk of developing cancer. It is estimated that the risk of cancer in patients with ulcerative colitis increases 1% per year after the first 10 years of the disease [43]. Patients with total colonic disease have the highest risk. After having the disease for 8–10 years, yearly surveillance of the bowel should be done in all patients, regardless of whether they are symptomatic or asymptomatic.

The incidence of surgery in these patients is declining due to better medical and nutritional management. Since surgery does not cure the disease, it is reserved for failures of medical management or for complications of the disease. Emergency surgery is indicated for fulminant disease that is refractory to medical management, including extensive rectal bleeding or toxic megacolon. In the past, proctocolectomy with ileostomy was standard treatment for ulcerative colitis. Since the 1970s restorative proctocolectomy with ileal-anal anastomosis has been practiced. Some patients develop strictures and require surgery to relieve them.

Anesthetic management of patients with IBD begins with a thorough history and physical examination. Particular attention is paid to the patient's fluid and electrolyte status. Optimizing the fluid and electrolyte status before elective surgery is crucial to a good outcome. Prophylactic steroid administration is recommended for patients who have been on long-term steroid therapy. Patients on total parenteral nutrition (TPN) require monitoring of their blood glucose and metabolic states during the perioperative period. Sudden discontinuation of a TPN solution that contains high glucose concentrations may lead to severe hypoglycemia. No one particular anesthetic technique is preferred.

Combined general and epidural anesthesia should be considered for abdominal surgery, since the epidural will provide significant postoperative pain relief. The extent of the surgery determines how much intraoperative monitoring is necessary. If the patient requires extensive colonic resection, arterial and central venous lines are appropriate. Attention to intraoperative fluid replacement, blood loss, and correction of fluid, electrolyte, glucose, and hematological derangements is important. Postoperative pain management can be challenging because many of these patients were receiving narcotics before surgery for their abdominal pain. Intravenous patient-controlled analgesia (PCA) and regional analgesia provide good pain relief and are used routinely.

Anastomotic leaks and abscess formation are the most frequent complications encountered after surgery. Abscess drainage by an interventional radiologist often requires general anesthesia.

# **Key points**

- Ulcerative colitis is usually limited to the colon and rectum.
- Crohn disease can affect the entire gastrointestinal tract from the mouth to the anus.
- Children with IBD and extraintestinal manifestations have a higher risk of developing colorectal cancer.
- The gold standard for diagnosing IBD is upper endoscopy, colonoscopy and tissue histology.
- Goals of IBD management are induction and maintenance of disease remission.
- Medical management combines pharmacological agents, corticosteroids, and anti-inflammatory agents.
- Emergency surgery is indicated for fulminant disease that is refractory to medical management or for extensive rectal bleeding or toxic megacolon.

# Abdominal masses: major abdominal and liver tumors, pheochromocytoma

Neuroblastomas, Wilms tumor, and hepatomas are the most common intraabdominal tumors in children. Neonates and infants with these tumors often present with an abdominal mass and abdominal distension. Box 28.2 lists the differential diagnosis of abdominal masses in children.

Laboratory, radiographic and imaging studies are common diagnostic measures used to determine the cause of the child's problem. Box 28.3 lists useful studies for the initial evaluation of patients with an abdominal mass.

# Neuroblastomas

Neuroblastomas arise from neural crest tissue. In the abdomen they arise from the adrenal glands and paraspinal sympathetic ganglia. Neuroblastoma is the most common neoplasm in infancy and the most common extracranial solid tumor during childhood. The behavior patterns of neuroblastomas are heterogeneous and range from complete regression to life-threatening progression despite treatment.

#### Epidemiology

Neuroblastomas account for more than 7% of malignancies in patients less than 15 years of age and around 15%

of all pediatric oncology deaths [44]. Approximately 40% of cases are diagnosed by 1 year, 75% by 7 years, and 98% by 10 years of age [45]. More than half of the patients are younger than 2 years old when diagnosed. The incidence of neuroblastoma is slightly more common in boys than girls (ratio of 1.2:1.0) [45]. A familial history of neuroblastoma, with an autosomal dominant pattern of inheritance, has been reported in 1–2% of patients. The median age at diagnosis of familial neuroblastoma is 9 months, com-

pared to 18 months for sporadic cases [44]. Maris et al found that 20% of patients with familial neuroblastomas have bilateral or multifocal tumors with evidence for a locus on chromosome 16p12–13 [46]. Approximately 75% of cases of abdominal neuroblastomas have metastasis at diagnosis, the most common sites being lymph nodes, bone marrow, liver, and skin.

#### **Clinical presentation**

The clinical presentation of neuroblastomas varies, depending on the site of the primary disease, the extent of metastasis, the size of the tumor, and any associated paraneoplastic syndromes. Patients in the early stage of the disease may have non-specific symptoms, such as pain and generalized malaise. Between 50% and 75% of patients present with an abdominal mass and may have abdominal pain and abdominal distension, weight loss, failure to thrive, fever, and anemia [45]. Tumors producing catecholamine cause hypertension in 25% of patients. Thoracic tumors may be discovered accidentally on a chest radiograph or when the patient shows signs of Horner syndrome (ptosis, miosis, enophthalmos, anhydrosis, and heterochromia of the iris) on the affected side. Patients with metastatic neuroblastomas can present with proptosis and periorbital ecchymosis, often referred to as "raccoon eyes." Infants with neuroblastomas can have hypokalemia and intractable diarrhea with watery, explosive stools. The diarrhea is thought to be the result of tumor-produced vasoactive intestinal polypeptide.

# Diagnosis

Neuroblastomas are diagnosed by serological and urine examinations and by radiological and isotope studies.

While there are no specific serum markers for neuroblastoma, high levels of ferritin, neuron-specific enolase, and lactate dehydrogenase are often present [47]; patients occasionally have high levels of serum and urinary catecholamines. Immunological analysis of serum and bone marrow is sensitive for detection of tumor cells. Radiographic examinations include plain x-rays of the abdomen, CT scan, helical (spiral) CT, MRI, and isotope bone scans. Once the diagnosis is made, the disease is staged according to the International Neuroblastoma Staging System (INSS). The INSS score is one of the main clinical variables used to predict outcomes of patients with neuroblastomas.

#### Management

Surgery, chemotherapy, radiation therapy, and immunotherapy are the main treatment modalities for neuroblastoma. Surgery is beneficial for patients who have localized tumors. However, more than half of children with neuroblastomas present with metastatic, unresectable tumors. When this occurs, they are initially treated with chemotherapy followed by tumor resection. Children with highrisk neuroblastomas undergo multimodal therapy, including induction of chemotherapy, surgical resection of the primary tumor, radiation therapy, and consolidation chemotherapy.

#### Surgical resection of the tumor

When children with neuroblastoma present for surgery, a complete history and physical examination and preoperative consultation with the patient's primary physician are important. Evaluation of the complete blood count, serum electrolyte concentrations, echocardiography, and radiological studies is also important. Knowledge of the chemotherapeutic drugs and steroids used is important as both therapies can cause complications.

Intraoperative anesthetic management consists of general anesthesia, tracheal intubation, standard monitoring plus intra-arterial and central venous monitoring. Occasionally neuroblastomas behave like pheochromocytomas.

#### Pheochromocytoma

Pheochromocytomas arise from catecholamine-producing chromaffin cells and are of neuroectodermal origin. These cells are found anywhere in the sympathoadrenal system but arise most commonly from the adrenal medulla. Tumors arising from extra-adrenal sympathetic and parasympathetic paraganglia are classified as extra-adrenal paragangliomas. Pheochromocytomas and *sympathetic* paragangliomas secrete catecholamines, but most *parasympathetic* paragangliomas are non-secretory. Pheochromocytomas secrete large amounts of adrenaline, noradrenaline, and dopamine, plus various peptides and ectopic hormones: enkephalin, somatostatin, calcitonin, oxytocin, vasopressin, insulin and adrenocorticotropic hormones [48]. Data on the etiology, diagnosis and management of pheochromocytoma in children are limited.

# Epidemiology

Pheochromocytomas are one-tenth as common in children as in adults (1 in 500,000 children compared to 1 in 50,000 in adults) [49]. Approximately 10% of tumors are bilateral, 10% are extra-adrenal, 10% are malignant, and 10% are familial. In children, 70% of the tumors are bilateral and extra-adrenal, the majority of them benign [50]. Advances in molecular genetics have allowed mutations in germline cells to be identified in 59% of patients presenting at 18 or fewer years of age and in 70% of patients presenting before age 10 years. The inherited predisposition is related to mutation(s) in the von Hippel-Lindau (VHL) gene, which encodes the subunits B and D of succinate dehydrogenase (SDHB and SDHD) and also the RET proto-oncogene that predisposes patients to the development of multiple endocrine neoplasia type 2 (MEN2) or neurofibromatosis type 1 (NF1). The VHL gene is the most commonly mutated gene in children who present with pheochromocytoma [51].

Though rare, pheochromocytomas may present in the neonatal period. However, they present more commonly in older, male children. There is a female preponderance for the disease during the reproductive years, suggesting a hormonal influence.

#### **Clinical presentation**

Patients with pheochromocytomas are thin, anorexic, and hypermetabolic. The most common symptoms include headaches, flushing, palpitations, hypertension, and sweating. Central nervous system manifestations include tremors, nervousness, anxiety, visual disturbances, and psychosis. Cardiovascular symptoms include hypertension, ventricular arrhythmias, cardiomyopathy, and cardiac failure. Some patients have symptoms of gastrointestinal disturbances.

#### Diagnosis

Pheochromocytoma is diagnosed by biochemical testing and imaging studies. Measurement of 24-h urinary vanillylmandelic acid, total metanephrine, and catecholamine concentrations is valuable [52]. Urinary metanephrine levels are increased in 95% of cases, and vanillylmandelic acid and catecholamine levels are increased in approximately 90% of patients [53]. Plasma catecholamine concentrations that exceed 2000 pg/mL during an hypertensive episode are diagnostic of pheochromocytoma. Normal levels are not. Plasma catecholamine levels between 500 and 1000 pg/mL are suggestive of pheochromocytoma, but further work-up is required [54]. Computed tomographic or MRI scans and <sup>123</sup>I-labeled metaiodobenzyl guanidine (MIBG) scintigraphy are all also helpful in making the diagnosis [55]. Abnormal neuroectodermal tissue takes up the isotope, which produces a focal area of increased uptake on the scan. These scans help localize extra-adrenal tumors. Positron emission tomography with 18F fluorodeoxyglucose or hydroxyephedrine is also useful for localizing tumors [56].

#### Management

Surgical excision of the tumor is the definitive treatment, but this requires optimization of the patient's condition medically before surgery. The goals of medical management include normalization of the arterial blood pressure and heart rate, restoration of blood volume, and prevention of a hypertensive crisis and its subsequent consequences.

Preoperative preparation of the patient should begin at least 10-14 days before surgery. Initial treatment includes a-adrenoreceptor blockade to reduce catecholamineinduced vasoconstriction and its sequelae [57]. Phenoxybenzamine is a non-selective  $\alpha_1$  and  $\alpha_2$  noncompetitive blocker that is administered orally in doses of 0.5–1 mg/kg twice a day. The dose is adjusted according to the patient's response to the drug. Phentolamine, a competitive non-selective  $\alpha$ -adrenergic blocker, is also used as an adjunct. Adequate  $\alpha$ -blockade is demonstrated by the presence of normotension or by the presence of side-effects to the drug, such as orthostatic hypotension tachycardia, nasal congestion, and dizziness [57]. The unopposed  $\beta$ -stimulation following  $\alpha$ -blockade causes tachycardia and arrhythmias, which are controlled by βadrenergic receptor-blocking agents, such as propranolol or labetalol. β-Receptor blockade should never be initiated until  $\alpha$ -blockade is fully accomplished because a severe hypertensive crisis can occur due to unopposed  $\alpha$ -stimulation. Occasionally,  $\alpha$ -methyl-para-tyrosine (metyrosine), which competitively inhibits tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis, is added [58] to reduce catecholamine stores in the tumor.

Patients with pheochromocytomas are generally intravascular volume depleted and have circulating plasma volumes of about 15% below normal. Once adequate pharmacological blockade is established, volume resuscitation is required.

Anesthetic management of patients with pheochromocytomas consists of providing stable anesthesia and avoiding surges in catecholamines. In spite of optimal medical management, patients can and do have sudden blood pressure fluctuations during induction of anesthesia and tracheal intubation, during surgical manipulation of the tumor, and after ligation of the tumor's venous drainage. Premedication with oral midazolam is often used to treat patient anxiety. General tracheal anesthesia or combined general and epidural anesthesia have been used successfully for intraoperative management of these patients.

Anesthesia is usually induced by mask with sevoflurane or with intravenous propofol or etomidate. Following induction of anesthesia, large-bore intravenous catheters and an arterial line are inserted. Muscle relaxation is achieved with a non-depolarizing muscle relaxant, such as rocuronium, vecuronium or *cis*-atracurium. A central venous catheter is inserted if one is not already in place. Fentanyl, sufentanil or a continuous infusion of remifentanil can be used. Intraoperative hypertension is managed by infusion of sodium nitroprusside, a potent arteriovenodilator. Esmolol is often used to control tachycardia and hypertension.

Hypotension may occur once the adrenal vein is ligated and the tumor is removed. The hypotension usually responds to fluid administration and discontinuation of vasodilators. Occasionally vasopressors, such as phenylephrine or norepinephrine, are required.

After surgery the patients are admitted to the ICU to monitor for and control hypertension, hypotension, and hypoglycemia. Once the tumor is excised, pancreatic  $\beta$ cell suppression is removed and insulin levels increase, which may cause hypoglycemia. Lipolysis and glycogenolysis cease after tumor removal and  $\alpha$ -blockade. Residual adrenergic blockade may mask the signs and symptoms of hypoglycemia. Consequently, blood glucose concentrations should be closely monitored.

If hypertension persists postoperatively, it is likely that there is a second pheochromocytoma. Normalization of catecholamine levels should be confirmed in all patients. Long-term follow-up is required to detect subsequent development of metachronous tumors and to detect tumors at other sites.

#### Wilms tumor

Wilms tumor (nephroblastoma) is the most common renal neoplasm affecting children. Diagnosis and treatment of Wilms tumor are discussed in Chapter 29.

#### Liver tumors

Liver tumors account for 1% of all pediatric tumors. Hepatoblastoma and hepatocellular carcinomas are responsible for most hepatic malignancies during childhood. Two-thirds of all liver tumors are hepatoblastomas. Benign liver tumors include vascular tumors, hamartomas, adenomas, and focal nodular hyperplasia. With advances in surgical technique, anesthesia, and chemotherapy, the 5-year survival of patients with hepatoblastoma has improved from 35% three decades ago to 75% at the present time [59]. However, the prognosis for patients with hepatocellular carcinoma remains poor.

# Epidemiology

Hepatoblastoma and hepatocellular carcinomas occur more commonly in males and are more common in 0.5–3-year-old children, the median age at diagnosis being 18 months. Only 5% of new hepatoblastomas are diagnosed in children beyond 4 years of age. Other conditions associated with hepatoblastoma include Beckwith– Wiedemann syndrome, familial adenomatous polyposis, hemihypertrophy, and low birthweight. Hepatocellular carcinomas are diagnosed after 10 years of age and commonly occur in patients with underlying liver disease, such as cirrhosis, tyrosinemia, and other inherited metabolic disorders [60]. Genetic aberrations in several chromosomes have been identified that predispose patients to the development of malignant liver tumors.

# **Clinical presentation**

Most children who have liver cancers present with a painless palpable abdominal mass. They may also have abdominal distension, anorexia, weight loss, and fatigue. Occasionally they present with abdominal pain, constipation, jaundice or sexual precocity.

#### Diagnosis

Laboratory and imaging studies are key to the diagnosis of liver tumors. Laboratory studies include complete blood count, chemistry panel, liver function tests, coagulation profile, and serum  $\alpha$ -fetoprotein (AFP) concentrations. AFP concentrations are the most sensitive laboratory test for hepatoblastoma and hepatocellular carcinomas, but this test is non-specific. On occasion, hepatoblastomas secrete  $\beta$ -human chorionic gonadotropin. Imaging studies, such as CT scan of the abdomen, ultrasonography, MRI, and magnetic resonance angiography, are also useful in diagnosing these tumors. The diagnosis is ultimately made, however, by liver biopsy.

# Management

Treatment of hepatoblastoma has improved markedly during the past several decades. Primary resection of benign liver tumors and stage I hepatoblastoma is curative. Unresectable tumors are initially treated with vincristine, cisplatin, and fluorouracil before the tumors are resected. If the tumor remains unresectable despite chemotherapy and is not metastatic, orthotopic liver transplantation is considered.

Preoperative assessment determines the extent of the tumor, whether it has metastasized, and if the patient has received chemotherapy. Careful attention should be paid to the patient's laboratory tests, liver function, blood count, coagulation status, and pulmonary, renal, and cardiac function, especially after chemotherapy. Patients should be typed and cross-matched for packed red blood cells and should have fresh frozen plasma and platelets available before and during surgery.

Anesthetic management of patients with liver tumors is challenging. Standard anesthesia induction agents are used. Tracheal intubation is facilitated with muscle relaxants, preferably cis-atracurium because its hepatic metabolism is minor. Standard monitors, plus intra-arterial and a central venous pressure monitoring, are usually used. Large-bore peripheral venous access is obtained, preferably in the upper extremities. In the event of major blood loss, perfusion, normothermia, and a normal pH should be aggressively maintained. It is occasionally necessary during surgery to quickly resuscitate patients who undergo acute, rapid hemorrhage. The main source of bleeding during liver resection is from the hepatic vein, which has no valves. High venous pressure increases bleeding. By keeping the CVP below 5 cmH<sub>2</sub>O during the dissection phase, blood loss can be reduced. Vasopressors (e.g. norepinephrine or vasopressin) may be required to maintain arterial blood pressure during some phases of surgery. Whether the trachea is extubabed in the operating room or the ICU depends on the extent of the liver resection, the amount of intraoperative blood loss, and the need for volume resuscitation. Postoperative pain is easily managed with a PCA.

#### **Key points**

- Neuroblastoma, Wilms tumor, and hepatomas are the most common intra-abdominal tumors in children.
- Neuroblastomas account for about 7% of malignancies in patients younger than 15 years of age and 15% of all pediatric oncology deaths.
- Diagnosis of neuroblastoma requires serological and urine examinations and both radiological and isotope studies.
- Measuring 24-h urinary concentrations of vanillylmandelic acid, total metanephrine, and catecholamines makes the diagnosis of pheochromocytoma.
- Preoperative preparation for pheochromocytoma surgery should begin with phenoxybenzamineinduced α-blockade prior to surgery.
- Hepatoblastoma and hepatocellular carcinomas are the most frequent hepatic malignancies of childhood.

# **Inguinal hernia**

An inguinal hernia is a protrusion of intestine through an open processus vaginalis (Fig. 28.1). An incarcerated hernia is an hernia that is irreducible and does not slide back into the abdominal cavity. When bowel entrapment interferes with the vascular supply of the bowel, the hernia is said to be strangulated.

Table 28.1 Characteristics of inguinal hernias

Figure 28.1 Laparoscopic view of a right inguinal hernia in a 2-monthold child.

# Epidemiology

Inguinal hernia repair is the most common elective procedure performed in pediatric patients. It occurs in 4.4% of all pediatric patients and is more common in males. Its incidence is 10–30% in premature infants versus 3–5% in full-term neonates [61,62]. Connective tissue disorders and cystic fibrosis also increase the incidence of inguinal hernia. Incarcerated hernias are more frequent in premature babies [63].

#### **Clinical presentation and diagnosis**

Inguinal hernias are diagnosed by physical examination when a bulge is felt at the internal or external inguinal ring. Most inguinal hernias are not painful, but large hernias may be. The bulge frequently disappears during sleep or rest. A Valsalva maneuver (e.g. crying) often provokes the bulge. The differential diagnosis of inguinal hernia includes hydrocele, retractable testis, lymphadenopathy, and a neoplastic process. Ultrasound helps diagnose a patent processus vaginalis. Patients with incarcerated hernias present with a tender firm mass in the groin. These children are often inconsolable and may have anorexia. The "silk glove sign" (thickened peritoneum of the patent process vaginalis that can be felt during palpation of the cord) is suggestive of an inguinal hernia [64].

### Management

Inguinal hernias do not heal spontaneously, but hydroceles often heal during the first year of life. These hernias require surgical repair to reduce the risk of developing an incarcerated hernia. Incarcerated hernias can usually be

	Simple	Incarcerated	Strangulated
Hernia sac	Herniates with Valsalva maneuver	Reducible	May or may not be reducible
Pain	No pain	Tender	Tender
Vascular supply	Intact	Intact	Compromised
Urgency	Elective	Within 24–72 h after reduction	Urgent

manually reduced. Once reduced, the hernia should be repaired during the next 24–48 h to prevent recurrence of the incarceration [65]. If the hernia cannot be reduced, it may progress to strangulation, necrosis, and gangrene of the bowel. Strangulated hernias require immediate surgical correction. General anesthesia and muscle relaxation often make a non-reducible hernia reducible. Some patients with strangulated hernias have necrotic bowel and require bowel resection during herniorrhaphy. Table 28.1 details the characteristics of inguinal hernias.

Children who are <6 months of age are at increased risk for developing strangulated or incarcerated hernias [66]. Consequently, their hernias are usually repaired soon after detection. Whether to operate on the contralateral side is debatable, but 28% of patients with a unilateral, clinically evident hernia early in life subsequently develop a symptomatic contralateral hernia [67]. Fifty percent of <2-year-old children have an open processus vaginalis, which should not be confused with an inguinal hernia. Laparoscopic visualization of the contralateral side is very helpful for determining if a second inguinal hernia exists on this side. This can be done even though the primary repair is done conventionally.

Premature babies often have bilateral inguinal hernias. Because of potential pulmonary complications and the fact that the surgical repair may be more difficult, there is controversy regarding when their hernias should be repaired. The reality is that most preterm neonates undergo hernia repair shortly before discharge home from the NICU for fear they will develop an incarcerated hernia.

Depending on co-morbidity and the surgical requirements, neuroaxial anesthesia, general tracheal, laryngeal mask or facemask anesthesia is appropriate. Laryngeal mask airways (LMAs) should be used with caution in preterm infants. A #1 LMA increases the dead space by approximately 100% and may increase the PaCO<sub>2</sub> significantly. Unless the depth of anesthesia is adequate, laryngospasm may develop during surgical manipulation of the hernia sac. Caudal blocks are often used as an adjunct to general anesthesia. In older patients, ileo-inguinal or ileohypogastric nerve blocks can be helpful.

Postoperative apnea occurs in 20–30% of otherwise healthy former preterm infants who undergo inguinal hernia repair [68]. The risk for postoperative apnea decreases with increasing post-conceptional age [69]. Spinal anesthesia is often used for these patients, although doing so does not decrease the incidence of apnea and bradycardia [70]. Ex-premature infants <60 weeks postconception and full term neonates <45 weeks post-conception are usually admitted to hospital overnight for apnea monitoring.

#### Long-term outcome

In one study 28% of patients with a unilateral, clinically evident hernia had a symptomatic contralateral hernia later in life. The recurrence rate of an inguinal hernia repaired early in infancy is under 5% [71].

# **Key points**

- Inguinal hernias are common in preterm infants.
- Determine if the hernia is non-incarcerated, incarcerated or strangulated.
- Spinal anesthesia for premature infants does not reduce the incidence of postoperative apnea.

# **Pyloric stenosis**

#### Epidemiology

The incidence of idiopathic hypertrophic pyloric stenosis (IHPS) is 2–4 per 1000 livebirths, with a female-to-male preponderance of 1:3. Recently, the incidence of IHPS has decreased in some countries. Premature infants develop IHPS later than full-term infants [72].

#### Etiology

The mechanism for hypertrophy of the pyloric muscle is unknown, but the hypertrophy causes the gastroenteral obstruction (Fig. 28.2). The increased frequency of the condition in males and in first-born infants who have a positive family history for IHPS suggests that the lesion has a genetic predisposition. Feeding-related, environmental factors, duodenal feeding of premature infants, and erythromycin exposure have all been suggested as causes of IHPS. The pyloric muscle fibers are hypertrophic (not increased in number) and are markedly thickened and edematous. After a pyloromyotomy, the pyloric muscle becomes completely normal over time.

**Figure 28.2** Pyloromyotomy. Note that the pyloric muscle has been partially transected and left open to heal. This increases the opening of the pylorus.

#### **Clinical presentation and diagnosis**

Between the second and 12th (classically between the third and eighth) weeks of life, most patients with IHPS present with non-bilious, projectile vomiting. The differential diagnosis includes overfeeding, pylorospasm, gastroparesis, gastroesophageal reflux, and duodenal bands. Patients with pyloric stenosis are usually hungry and alert. When dehydration develops, they become lethargic.

The diagnosis of IPHS is usually confirmed by ultrasound. A barium swallow may be indicated if the ultrasound study is inconclusive. The hypertrophic pylorus can often be palpated through the abdominal wall. Careful observation of the child after feeding often reveals a characteristic peristaltic wave moving across the epigastrium. Historically, patients presented at an advanced stage of the disease. Now widespread use of ultrasound and much better understanding of the disease by pediatricians allow the diagnosis to be made earlier. Consequently, fewer patients have severe electrolyte disturbances and dehydration at presentation.

If the diagnosis is made late, patients typically are dehydrated, hypochloremic, hypokalemic, and alkalotic at presentation. They may have lost weight and have gastritis with minor gastrointestinal bleeding. Initially these patients have an alkaline urine and loss of potassium and sodium as renal compensation for their vomiting. Later they secrete acidic urine, which further increases the metabolic alkalosis. This paradoxical aciduria occurs once potassium and sodium are depleted (Fig. 28.3).

Figure 28.3 Pathophysiology of pyloric stenosis.

Hypocalcemia often accompanies the hyponatremia. If this downward spiral is allowed to continue and additional fluid losses occur, prerenal azotemia, hypovolemic shock, and metabolic acidemia ensue.

#### Management

Idiopathic hypertrophic pyloric stenosis and concomitant hypovolemia represent a medical not a surgical emergency. The hypovolemia, acid-base abnormalities, and electrolyte abnormalities must be corrected prior to the induction of anesthesia. Surgery for IHPS is urgent but is not an emergency. These patients should be made nil per os (NPO) and their stomachs should be decompressed. Intravenous fluid therapy usually includes normal saline (NS), D5-1/2 NS or 1/4 NS at 1.5 times the maintenance fluid requirements. Care should be taken not to give excessive dilute solutions as they may cause seizures and death. Sufficient glucose should be provided to maintain normal blood glucose levels. Once satisfactory urine output is achieved, potassium can be added to the IV fluids. Homeostasis, as reflected by a serum chloride concentration >100 mEq/L and a serum bicarbonate concentration of <30mEq/L, should be achieved before surgery commences. Urine chloride concentrations >20 mEq/L suggest adequate restoration of intravascular volume, since the kidney retains chloride during volume contraction. An underlying deficiency in glucuronyltransferase is responsible for jaundice in 2% of patients.

Before tracheal intubation, atropine is often given to prevent bradycardia, and the stomach is suctioned while tilting the patient in four different directions to empty the stomach as thoroughly as possible [73]. It is occasionally necessary to lavage the stomach to remove barium or milk curds. The high risk for aspiration of gastric contents warrants intubating the trachea awake or after a rapidsequence induction or modified rapid-sequence induction of anesthesia and muscle paralysis with either succinylcholine or a non-depolarizing muscle relaxant. Intraoperatively, air is injected into the stomach through an orogastric catheter to verify the integrity of the duodenal mucosa. Preoperative cerebrospinal fluid alkalosis increases respiratory sensitivity to opioids. Consequently, these drugs are usually avoided because they can slow awakening from anesthesia and cause apnea. Acetaminophen per rectum and infiltration of the wound with local anesthetics are often sufficient for postoperative pain management. Pyloromyotomy can be done open or laparoscopically. The hospital length of stay and postoperative complications are similar with both techniques. Most patients have their trachea extubated at the conclusion of surgery. However, the presence of metabolic alkalosis increases their probability of postoperative apnea. Other common complications of a pyloromyotomy include perforation of the duodenal mucosa (1-2%), wound infection, incisional hernia, incomplete myotomy, and bowel injury [74]. Oral feeds are usually instituted several hours after surgery. Some patients have persistent postoperative vomiting from gastroesophageal reflux or an incomplete myotomy.

In developing countries where access to surgery is inadequate or totally lacking, medical management alone is provided. This consists of fluid and electrolyte replacement and administration of atropine to slow gastrointestinal peristalsis and decrease hypertrophy of the pylorus.

#### **Key points**

- Pyloric stenosis is a medical emergency, not a surgical emergency.
- Allow time for adequate preoperative rehydration and correction of electrolytes.
- Tracheal intubation is by rapid-sequence induction or awake.
- Opioids are avoided because they delay awakening from anesthesia and may increase apnea and the need for postoperative mechanical ventilation.

# Appendicitis

# Epidemiology

Acute appendicitis is the most common abdominal condition requiring surgical intervention. Four out of 1000 patients under 14 years of age will be diagnosed with appendicitis, and their lifetime risk for appendicitis is 7%. No single test, examination or symptom confirms the diagnosis in all cases. About 0.2–0.8% of patients with appendicitis die of complications of the disease. The rate of appendiceal perforation in <4-year-old children is 80– 100%, whereas it is 10–20% in children 10–17 years of age. The symptoms of appendicitis in younger children are

Figure 28.4 Pathophysiology of appendicitis.

often more diffuse [75], which makes the diagnosis more difficult to make. The atypical presentation increases the perforation rate in children [76].

# **Etiology and pathophysiology**

Appendicitis is caused by luminal obstruction of the appendix by edema, inflammation, and overgrowth of fecal bacteria (Fig. 28.4). Lymphoid hyperplasia, a foreign body or fecal matter causes the obstruction. If edema reduces the arterial blood supply, necrosis and perforation of the appendix may occur.

#### Clinical presentation and diagnosis

The diagnosis of appendicitis is often challenging because the position of the appendix within the abdomen varies. Only half of all patients have the classic symptoms of anorexia and periumbilical pain plus nausea, vomiting, and right lower quadrant pain. About one-third of patients present with atypical symptoms or are unable to describe their symptoms. In children, this leads to a falsenegative appendectomy rate of 5–25%. Examinations by CT scan with contrast or ultrasound reduce the falsenegative rate. The differential diagnoses include gastroenteritis, tubo-ovarian processes, mesenteric adenitis, cholecystitis, diverticulitis, pelvic inflammatory disease, ureterolithiasis and more. Appendicitis rarely occurs in neonates, and when it does occur the symptoms are virtually indistinguishable from necrotizing enterocolitis [77].

#### Management

Fluid resuscitation and administration of intravenous broad-spectrum antibiotics that cover enteric organisms are required. Patients with a ruptured appendix require antibiotics until their clinical condition improves. The clinical goal is to perform an appendectomy before the appendix ruptures and to prevent peritonitis, sepsis, and abscess formation. Immediate surgery is not necessary if the appendix is unruptured and the patient has been appropriately treated with antibiotics [78].

Most appendectomies are done laparoscopically because the incisions are smaller, there are fewer wound infections, and the incidence of ileus is lower. Initial experience with laparoscopic appendectomy suggested a higher incidence of intra-abdominal abscesses, but later studies have not confirmed this.

#### Anesthetic management

Anesthetic management of children undergoing appendectomy is usually straightforward and usually includes general endotracheal anesthesia. Rapid-sequence induction of anesthesia is used to avoid aspiration of gastric contents. If patients are septic and have a ruptured appendix, aggressive fluid resuscitation is often required. Surgical manipulation of an infected abdomen may induce acute hemodynamic deterioration. Ketorolac plus opioids are usually sufficient for postoperative analgesia after endoscopic surgery. Patient-controlled analgesia is seldom required if the appendix was not ruptured.

#### Key points

- Rapid-sequence induction of anesthesia is usually required to reduce aspiration of gastric contents.
- Beware of contrast material given as part of the evaluation for appendicitis.
- Patients with a ruptured appendix require additional fluid resuscitation.

# SPECIFIC INTERVENTIONAL AND SURGICAL PROCEDURES

# Gastrointestinal/endoscopic retrograde cholangiopancreatography/endoscopy procedures

Sedation is adequate for most endoscopic procedures in adults, but children usually require general anesthesia. Since many of the procedures are done in non-operating room locations, it is important that operating room standards be applied when anesthetizing patients in these locations. This includes preoperative evaluation, monitoring, postoperative care, and having help readily available in case a problem arises.

Anesthesiologists must understand the technical aspects of endoscopic procedures, some of which require multiple switching of endoscopes during the procedure for ultrasound examinations, banding varices, obtaining biopsies, and other interventions. Occasionally, the endoscope completely compresses the trachea and/or tracheal tube of an infant and obstructs the airway. Excessive insufflation of gas at high pressures and overdistension of the stomach and bowel may interfere with ventilation. Insufflation pressures should be kept at a minimum, usually  $12 \text{ cmH}_2\text{O}$ . At the end of the procedure, the stomach should be suctioned to remove as much gas and secretions as possible. Inserting a rectal tube may aid gas removal. Where multiple instruments are to be inserted through the esophagus or when contrast material or other fluids will be given into the esophagus or stomach during the procedure, it is advisable to intubate the trachea and secure the airway [79].

# Esophago-gastro-duodenoscopy

Indications for esophago-gastro-duodenoscopies include gastroesophageal reflux and sclerotherapy for esophageal varices. Most anesthesiologists use inhalational induction of anesthesia if the patient has mild-to-moderate gastroesophageal reflux disease (GERD). It is usually safer and easier to secure the airway of younger children with a tracheal tube, but some older children can be managed with intravenous anesthesia and a natural airway.

Insertion of the endoscope into the esophagus is the most stimulating part of the procedure and requires the deepest plane of anesthesia when procedures are done with natural airways. Antiflexion of the neck makes insertion of the endoscope easier. The oropharynx can be anesthetized with local anesthetics, but doing so may leave the child without protective airway reflexes after the procedure and increase the likelihood of coughing spells and/or aspiration of fluids.

Most esophago-gastro-duodenoscopies take only a few minutes. If general anesthesia and tracheal intubation are used, it is helpful to avoid the use of muscle relaxants and to administer short-acting opioids, such as remifentanil, for the induction and maintenance of anesthesia. Tracheal intubated patients are usually placed in the supine position for esophago-gastro-duodenoscopies. Patients with eosinophilic esophagitis must undergo repeated esophago-gastro-duodenoscopies. They frequently have multiple food allergies, including to soy and eggs, which contraindicate the use of propofol. They may also have asthma and atopic dermatitis so histamine-releasing drugs should be avoided [80].

# Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is used for patients with choledocholithiasis, for stent placement across malignant or benign strictures, and for tissue sampling [81]. Tracheal intubation is usually required when children undergo ERCP because the procedure can be long, patients are in the semi-prone position, and the use of multiple endoscopes may be required. These patients are often in acute distress from acute cholestasis and cholecystitis; they may also be dehydrated from prolonged anorexia, nausea, and vomiting. Injection of incremental doses of glucagon may be required during the procedure to increase bile duct motility.

# Percutaneous endoscopic gastrostomy

A percutaneous endoscopic gastrostomy (PEG) allows placement of a gastrostomy tube without the need for a laparotomy. PEGs are usually indicated for prolonged nutritional support or decompression of the stomach, although they may not effectively do the latter. Surgical access to the stomach is identical to that used during an esophago-gastro-duodenoscopy; some surgeons verify placement of the gastrostomy by doing a mini-laparoscopy to rule out having produced a gastrocolic fistula.

The underlying disease (cerebral palsy, metabolic disease, congenital malformations) dictates the anesthetic management. Patients who have a PEG in place should have their stomach decompressed prior to and during the induction of inhalational anesthesia. Venting the stomach requires the use of a specific venting tube; the tubes used for feeding do not effectively allow air to escape from the stomach.

# Colonoscopies

Colonoscopies are usually done in children who have inflammatory bowel disease or lower intestinal bleeding. Bowel preparation is required and may cause dehydration and electrolyte imbalances. In older children tracheal intubation is often not required for this procedure.

#### **Key points**

- Standards for monitoring and patient care in off-site areas should be the same as those used in the OR.
- Secure the airway in smaller children when the esophagus is being instrumented.
- Specific tubes (not feeding tubes) are required to vent gas through a PEG.

# Nissen fundoplication and gastrostomy

Gastroesophageal reflux is, to a certain extent, a physiological mechanism. The most common symptoms of this disorder in children are vomiting and regurgitation, pulmonary symptoms, dysphagia, abdominal pain, and hemorrhage [82]. In severe cases, life-threatening aspiration of gastric contents may have occurred.

Fundoplication is indicated for patients who have documented gastroesophageal reflux and fail medical treatment, have recurrent aspiration of gastric contents, intermittent apnea, failure to thrive, and Barrett esophagitis. Infants who have had life-threatening events and gastroesophageal reflux frequently present for a fundoplication after other causes for these problems have been ruled out. In one case series, the life-threatening events resolved in most patients after surgery [83]. Neurologically impaired children who require a gastrostomy tube for feeding may also require fundoplication to prevent aspiration of gastric contents [84].

During a Nissen fundoplication, the fundus of the stomach is plicated 360° around the inferior esophagus to restore lower esophageal sphincter function. Once this is done, the patient cannot vomit. The anterior or Thal fundoplication, on the other hand, uses only a 270° wrap, which maintains the patient's ability to vomit. Intestinal obstruction is common after the open approach [85]. Inability to vomit can cause progressive intestinal distension, bowel ischemia, and death if the bowel obstruction is not quickly relieved.

Typically patients requiring a fundoplication have other underlying diseases, such as cerebral palsy, inborn error of metabolism, trisomy 21 or other neurological impairments. The procedure is done either open or laparoscopically, and if needed, a gastrostomy is placed at same time. If a gastrostomy is placed without doing a fundoplication, the percutaneous approach is usually used.

#### Management

Symptoms of aspiration pneumonia or asthma may make it difficult to determine when to perform the procedure. One has to balance protecting the lungs from further aspirations with being able to improve the patient's pulmonary status. Rapid-sequence induction of anesthesia is usually warranted. The trachea of most patients can be extubated at the end of the procedure, depending on their preoperative status.

#### **Postoperative issues**

The reoperation rate following Nissen fundoplication for recurrent gastroesophageal reflux is high (6–12%) [86].

# **Key points**

- The primary disease often dictates the anesthetic management.
- There is a high risk for aspiration of gastric contents during the induction of anesthesia.
- Patients may present with a suboptimal pulmonary status due to aspiration pneumonia.
- Patients who require a gastrostomy frequently have a Nissen fundoplication to protect against aspiration of gastric contents.

# Laparoscopic surgery

Laparoscopic procedures are rapidly replacing many open pediatric surgical procedures (Box 28.4). Some

Box 28.4 Common pediatric laparoscopic procedures
Appendectomy
Cholecystectomy
Gastric banding
Gastric bypass
Colectomy
Inguinal hernia repair
Nephrectomy

- Pyloromyotomy
- Congenital diaphragmatic hernia
- Nissen fundoplication
- Orchidopexy
- Pyloplasty

Figure 28.5 Advantages and disadvantages of open and laparoscopic procedures.

advantages of the laparoscopic approach include minimizing the size of the incision and better visualization of the surgical area (Fig. 28.5). The pathophysiological changes associated with a pneumoperitoneum, the longer operating times, mechanical restrictions for the surgeon, and lack of haptic feedback and three-dimensional vision are the main drawbacks of laparoscopic surgery. A number of procedures are done laparoscopically without proof that the outcomes are better than those reported with open procedures.

Laparoscopic abdominal procedures require intraperitoneal access and insufflation of gas, often through the umbilicus. At least one additional incision is required for instrumentation. Various instruments are needed for ligation, stapling, suturing, and manipulation of viscera, but some are impractical for neonatal use because they are too large. Nissen fundoplication, pyloromyotomy, and repair of tracheo-esophageal fistulas are examples of laparoscopic procedures commonly performed in pediatric patients.

### Pathophysiology

The effect of increased intra-abdominal pressure and absorption of the insufflated gas are the two main pathophysiological changes associated with laparoscopic surgery.

### Hemodynamic changes

Changes in cardiac output (CO) differ, depending on the patient's position during the procedure.

Patients placed in the reverse Trendelenburg position, e.g. for laparoscopic cholecystectomy, often experience decreased arterial blood pressure, cardiac output, right atrial pressure, and wedge pressure. Pneumoperitoneum often raises the arterial, right atrial, and wedge pressures to their initial levels. Cardiac output also returns to baseline; systemic vascular resistance decreases mildly [87]. The reason why cardiac output normalizes is unclear, but it may be from reduced afterload or activation of the sympathetic nervous system by absorbed carbon dioxide.

In the Trendelenburg position, cardiac output is unchanged or mildly increased from baseline during pneumoperitoneum. The increased intra-abdominal pressure and gravity synergistically reduce cardiac filling.

Changes in arterial blood pressure and pulmonary vascular resistance are independent of the patient's position during laparoscopy. Systemic vascular resistance (SVR) and arterial blood pressure increase. The combination of tachycardia and an elevated SVR raises myocardial oxygen consumption. Insufflation pressures below 10 cmH<sub>2</sub>O have no significant effects on heart rate, arterial blood pressure, oxygen saturation or base excess in children [88].

Absorbed carbon dioxide partially alleviates the effects of the increased intra-abdominal pressure. However, increased intra-abdominal pressure may also produce transient oliguria of the splanchnic and renal vessels. Congestion and stasis of the lower extremities increase the risk for deep vein thrombosis. If there is a patent foramen ovale, the likelihood of paradoxical emboli and air embolism increases when the right atrial pressure rises. Peritoneal stretching may also produce vagally mediated hemodynamic changes.

#### Absorption of insufflated carbon dioxide

Carbon dioxide is absorbed from the abdominal cavity and causes respiratory acidosis and cardiac arrhythmias (in some patients). The rate of  $CO_2$  absorption is higher when artificial cavities are created (e.g. nephrectomy) [89]. The rate of  $CO_2$  absorption is very high when subcutaneous emphysema is present. Ventilation may increase as much as 400% in response to the  $CO_2$  [90]. Occasionally the increase in ventilation is insufficient to reduce the  $PaCO_2$  to acceptable levels. When this occurs, the procedure must be halted and time allowed for return of the  $PaCO_2$  to normal. It is rarely necessary to convert to an open procedure because of hypercarbia.

# Pulmonary pathophysiology

The usual anesthesia-induced decrease in functional residual capacity and the mismatch of ventilation and perfusion are aggravated by a further decrease in the functional residual capacity as the diaphragm is shifted more cephalad by the pneumoperitoneum. Due to the geometry of the infant's thorax (see Chapter 6), infants rely more on diaphragmatic excursion than on the intercostal muscles for ventilation. Positive end-expiratory pressure counteracts gas-induced pressure on the diaphragm and often improves ventilation and oxygenation. The tip of the tracheal tube can migrate towards the carina and enter a mainstem bronchus when a pneumoperitoneum is present [91].

Despite the negative intraoperative effects of the pneumoperitoneum, there are fewer postoperative pulmonary complications after laparoscopy than with conventional open procedures. On the other hand, the open approach for upper abdominal procedures decreases the vital capacity, FEV<sub>1</sub>, and functional residual capacity. These decreases, plus the incisional pain, inhibit coughing and sighing. Laparoscopic cholecystectomy is less often associated with postoperative pneumonia [92,93].

### Neuroendocrine effects

Surgical-induced inflammatory and immunosuppression responses are fewer with laparoscopic procedures. The concentrations of interleukin-1 and -6 and tumor necrosis factor  $\alpha$  are decreased compared with those found after open procedures. Dysfunction of mononuclear and polymorphonuclear cells, which are part of cell-mediated immunity, appears to be less deranged by laparoscopic procedures. The inflammatory effects are of concern with oncological procedures because tumor spread is a major concern.

#### Complications

Serious laparoscopy-related complications are rare.  $CO_2$  is the gas used most often because it is more rapidly absorbed if it is inadvertently given intravascularly. Massive  $CO_2$  embolism and venous air embolism produce the same sequelae [94]. Untreated pneumothoraces and pneumomediastina can be disastrous. Subcutaneous emphysema usually requires no treatment.  $CO_2$ -induced hypercarbia and acidosis occasionally cause cardiac

dysrhythmias. Insertion of a trocar occasionally causes hemorrhage and injures internal organs, especially in thinner infants with more elastic abdominal walls [95].

# **Key points**

- Intravenous access should be obtained above the diaphragm because a pneumoperitoneum can decrease blood flow through the inferior vena cava and delay drug and fluid administration.
- Filling pressures are higher during a pneumoperitoneum because the increased intra-abdominal pressure is transmitted in the thorax. Effective transmural pressures are low to normal.
- Changes in cardiac output in response to a pneumoperitoneum differ, depending on the patient's position.
- Urine output decreases transiently.
- Not all patients tolerate a pneumoperitoneum with high insufflation pressures.

# CASE STUDY

An 8-month-old, 10 kg child was brought to the emergency room with a history of loss of appetite, vomiting, irritability, and crying. His mother stated that he had had diarrhea for the last 2 days and that his stools were initially watery but were now mucoid and blood tinged at the last diaper change. Only a minimal amount of urine had been noted during the last 8–12h. The mother also stated that the child was no longer interactive and had become progressively lethargic during the last 2 days.

The emergency room physician saw the mother and child and obtained the following history. The boy was born at full term by normal vaginal delivery; there were no problems before or after birth. He went to the well baby nursery and was discharged home with the mother 24h later. At home, the baby was feeding well and received his normal immunizations. He was well until 2 days before admission when he became increasingly irritable and had vomiting and diarrhea.

At admission he was found to be lethargic and had a sunken anterior fontanelle, sunken eyes, and dry oral mucous membranes. His heart rate was 160 beats/min, his arterial blood pressure was 80/40 mmHg and his SaO<sub>2</sub> was 99% on room air. His abdomen was distended, and there was abdominal tenderness and guarding. An abdominal mass was palpated.

A peripheral intravenous catheter was inserted and 5% dextrose with 0.45% normal saline was infused at 60 mL/h. Blood was sent for complete blood count and chemistry. Plain radiographs of the abdomen showed a paucity of bowel gas and air-fluid levels.

The white cell count was 18,000 mm<sup>3</sup>, the hematocrit 40%, and the platelet count 400,000 mm<sup>3</sup>. The serum sodium was 138 mEq/L, serum potassium 4.5 meq/L, serum chloride 100 mEq/L, serum bicarbonate 20 mmol/L, and the blood urea nitrogen and creatinine 20 and 0.5 mg/dL respectively. A surgery consult was obtained and a nasogastric tube was inserted. The surgeon entertained a differential diagnosis of bowel obstruction or intussusception and scheduled the child for an emergency exploratory laparotomy.

The anesthesiologist reviewed the patient's history with the mother and examined the child. The child was lethargic. Fluids were infusing through a peripheral intravenous line. After obtaining informed consent, the child was taken to the operating room.

Rapid-sequence induction of general anesthesia and tracheal intubation were planned. Standard monitors were placed, and suction was applied to the nasogastric tube. After preoxygenation, anesthesia was induced with 2 mg/ kg of intravenous propofol and 1.2 mg/kg of intravenous rocuronium. Tracheal intubation was rapidly accomplished. A second peripheral intravenous line, an arterial line, and a Foley catheter were inserted. Anesthesia was maintained with sevoflurane and intravenous fentanyl.

The patient was found to have an ileocolic intussusception, which was easily reduced; however, part of the bowel was ischemic and required resection. Intraoperatively, the patient required additional fluid resuscitation with a crystalloid solution. Blood loss was minimal and no blood transfusion was required. At the end of the surgery, the trachea was extubated and the child was transferred to the intensive care unit. His postoperative pain was controlled with a continuous infusion of morphine and nurseadministered rescue boluses of the drug as needed.

This case illustrates the concepts that were explained in this chapter. Intussusception is a common cause of bowel obstruction in children less than 1 year of age, but the cause of intussusception is unknown in 90% of cases. Prompt diagnosis and treatment decrease the mortality and morbidity associated with intussusception.

Preoperative assessment should include signs of dehydration, such as dry mucosal membranes, sunken fontanelles, sunken eyes, and minimal urine output, which together indicate significant dehydration. Fluid resuscitation should be initiated immediately to replete the intravascular volume. When the volume is repleted, surgery can proceed.

Intraoperatively, the heart rate and arterial blood pressure may not truly reflect the patient's volume status. The urine output should exceed 0.5–1 mL/kg/h; urine output is a useful guide to circulating volume status.

Careful fluid management is essential. The volume of fluid administered equals the sum of hourly maintenance fluid, pre-existing fluid deficits, plus an additional 6–10 mL/kg/h to compensate for the evaporative losses caused by the open abdominal wound.

Hourly fluid maintenance is calculated from the patient's bodyweight (see Chapter 10). For the first 10 kg, it is 4 mL/kg. For 10-20 kg it is 40 mL + 2 mL/kg for every kilogram over 10 kg. If the weight is >20 kg, the requirement is 60 mL + 1 mL/kg for every kilogram above 20 kg.

Careful attention must be paid to blood loss. If significant blood loss is expected, the allowable blood loss should be calculated. Maximum allowable blood loss (MABL) is:

EBV×(Child's hematocrit – minimum acceptable hematocrit) Child's hematocrit

The estimated blood volume (EBV) is calculated by:

EBV = Weight in kg × average blood volume

Estimated blood volume is 95 mL/kg for premature neonates, 85 mL/kg for term neonates, and 65 mL/kg for older children and adults.

The volume of packed red blood cells to be transfused can be determined by the following formula:

EBV × (desired hematocrit – present hematocrit) Hematocrit of packed red blood cells

When blood products are used in neonates and infants, they must be filtered and irradiated to prevent emboli and graft-versus-host reactions.

Normothermia is maintained by warming the operating room and the intravenous fluids, using warm irrigation fluids and forced-air convention heating devices. Maintaining normothermia may be difficult during abdominal surgery because the bowels are exposed.

The postoperative decision to extubate the trachea depends on how awake the child is, whether he is breathing spontaneously after the reversal of muscle relaxants, and his core temperature.

Intravenous fluids are continued until oral intake is re-established.

# Introduction

Pediatric urological procedures are among the most common encountered by the pediatric anesthesiologist. A thorough understanding of the developmental pathogenesis and surgical procedures of the genitourinary system is important for the anesthesiologist to provide optimized care for these patients. This chapter will review the embryological development of common urogenital anomalies. Then the surgical approach, anesthetic considerations, and anesthetic management of these anomalies, including pain management, will be reviewed.

## **Development of urological anomalies**

Anomalies of the genitourinary system which require surgical procedures under anesthesia often arise from abnormal development *in utero*. A full description of the development of the genitourinary system is beyond the scope of this chapter. See Chapter 8 for further discussion of the development of the genitourinary system. It is helpful to have a brief overview recalling that the urinary and genital systems are closely associated. Normal development is influenced by genetic, hormonal and anatomical factors.

Both the urinary and genital systems develop from intermediate mesoderm at the level of the seventh through the 28th somite [1]. The nephrogenic mass (cord) arises from the dorsal side from a bulge into the coelom called the urogenital ridge, from which the urinary and genital structures are formed. The nephrogenic tissue from the seventh to the 14th somite levels breaks up into four segments: cervical, thoracic, lumbar, and sacral. The cervical nephrotomes eventually give rise to glomeruli. The excretory tubules arise from the thoracic, lumbar and sacral segments. Subsequent development leads to the primitive pronephros. By the fourth week of gestation, the mesonephros is present as an intermediate step in renal development. By around week 10, the mesonephros has receded in females, while evolving into the vas deferens in males. The permanent kidney or metanephros begins to develop early in the fifth week and is functional by the 11th week of development. The metanephric blastema gives rise to nephrons including the Bowman capsule, proximal convoluted tubules, loops of Henle, and distal tubules. The ureters are an outgrowth of the primitive mesonephric duct forming the major and minor calices and collecting ducts. The terminal end of each uereter becomes part of the bladder wall. Each eventually develops a distinct separate entrance into the bladder with time. Normal development of the ureteric bud and the mesonephric blastema is closely dependent on each other.

As the fetus grows, the kidneys migrate from the pelvis to the abdomen. Fetal urine production is critical to normal amniotic fluid circulation. Amniotic fluid is aspirated by the fetus, absorbed into the fetal bloodstream and subsequently excreted into the amniotic sac. Failure to produce adequate amounts of urine can lead to oligohydramnios and associated anomalies. One significant anomaly is pulmonary hypoplasia.

Development of the external genitourinary system occurs in parallel with internal development. The cloaca (Latin for sewer) forms from the caudal end of the hindgut. The allantois and mesonephric ducts open into the cloaca. During weeks 4–7 of development, the cloaca subdivides into the posterior portion, which becomes the anorectal canal, and the anterior portion, which gives rise to the primitive urogenital sinus. The bladder is formed from the upper part of the primitive urogenital sinus. Initially, the bladder is continuous with the allantois; subsequent obliteration of the allantois lumen forms the urachus, which connects the apex of the bladder with the umbilicus. The urachus eventually becomes the median umbilical ligament.

The reproductive system makes its appearance during the fifth and sixth weeks of development. The fetus goes through an indifferent stage in which sex cannot be determined. Eventually, gonads (testes and ovaries) develop from a thickening of the urogenital ridge to form the gonadal ridge and primordial germ cells. Primary sex cords form and grow into the underlying mesenchyme. If the SRY gene is present (normal genetic male), differentiation will proceed along the path leading to testes. Absence of the SRY gene expression (normal genetic female) will lead to development of ovaries. Development of external genitalia is determined by both genetic and hormonal factors. In the presence of normal testes, androgen production by the adrenal glands is required to stimulate development of mesonephric ducts and produce normal external male genitalia. In the absence of normal androgens, paramesonephric ducts develop and the fetus will develop female external genitalia. External genital development first goes through the indifferent stage with the genital tubercle forming at the upper end of the cloacal membrane. In the male, this tubercle then elongates to form the phallus. Labioscrotal swellings and urogenital folds appear around this time. The cloacal membrane divides to form urogenital and anal openings around the seventh week.

In the male, the phallus elongates to form the penis, pulling the urogenital folds together. When folds start to fuse, they enclose the urethra and the urethral opening moves progressively towards the end of the penis. The labioscrotal swellings fuse to form the scrotum. In the female, the phallus becomes the clitoris. The urogenital folds do not fuse and become the labia minora. The labioscrotal folds fuse only at the ends to form the labia majora.

Anomalies of gonadal development can be divided into anomalies of sex chromosomes, true hermaphrodites, and anomalies of receptors. Conditions that represent anomalies of sex chromosomes include Turner syndrome (45,X), Klinefelter syndrome (47,XXY), and other syndromes with multiple X polyploidy. True hermaphrodites are extremely rare and have both true testes and ovaries. Anomalies of receptors result in testicular feminization syndrome (XY females). Congenital anomalies of the reproductive system in females include ovarian dysgenesis, rudimentary uterus, bifid uterus, septate uterus, and imperforate hymen. Congenital anomalies in males include testicular agenesis, undescended testes, and hypospadias.

### **Bladder exstrophy**

Bladder exstrophy remains one of the most challenging conditions managed by pediatric urologists. It can be likened to the challenges the cardiovascular surgeon faces with repair of the single ventricle. Although rare, this disorder imposes significant physical, functional, social, sexual and psychological burdens on patients and families. For the healthcare system, the multiple, lengthy and complex operative procedures for exstrophy consume resources disproportionate to the small number of affected individuals [2]. The rarity of this condition (2.5 in 100,000 livebirths in the United States) makes it imperative that communication between the anesthesiologist and urologist occurs well before the start of surgery. The correction choices and timing for surgery are continually being modified. While it used to be standard practice to perform surgery in the first several days of life, in some institutions, surgeries are being delayed until the child is 4-6 weeks of age, with no change in the success rate [3].

The goals of reconstructive surgery for bladder exstrophy are to achieve closure of the bladder, obtain urinary continence, preserve renal function, and produce satisfactory appearance and function of the external genitalia. Wound dehiscence, bladder prolapse and multiple attempts at bladder closure have been identified as risk factors for lack of adequate bladder growth and inability to develop urine continence [4].

Classic bladder exstrophy can be conceptualized by visualizing that one blade of a pair of scissors is passing through the urethra into the bladder of a normal person; the other blade is used to cut the layers of the skin, abdominal wall, anterior wall of the bladder, urethra and symphysis pubis, and the cut edges are unfolded laterally as if opening a book (Fig. 29.1) [5].

Figure 29.1 Exstrophy of the bladder. Reproduced from Brock and DeMarco [5] with permission from Elsevier.

At birth, classic bladder exstrophy presents with an everted posterior bladder wall of varying size associated with separation of the symphysis pubis. This diastasis causes an outward rotation and eversion of the pubic rami at their junctions with the ischial and iliac bones [5]. Urine may be seen leaking from the inferior margin of the everted posterior bladder wall, but the ureteral orifices are not always obvious. The umbilicus is located on the immediate superior border of the bladder plate, and a small umbilical hernia or an omphalocele is ordinarily seen. The mucosa of the exposed bladder may look normal or thickened. In males, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half of that in unaffected boys. The scrotum is typically separated from the penis and is wide and shallow. Undescended testes and inguinal hernias are common. Females also have epispadias, with separation of the two halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse [5,6].

In patients with classic exstrophy of the bladder, anomalous development in other systems is unusual. However, bladder exstrophy can be considered a spectrum of anatomical variants referred to as the exstrophy complex. These variants include bladder exstrophy with imperforate anus and cloacal exstrophy. With extreme cases of classic bladder exstrophy and cloacal exstrophy, omphaloceles are also encountered above the level of the exposed bladder. In cloacal exstrophy, some form of spinal dysraphism, including tethered cord, myelomeningocele or

**Figure 29.2** Modified Buck traction. The child is positioned with weights maintaining the legs in an extended position parallel to the bed. This figure is available in color online at www.jpedhc.org. Reproduced from Kozlowski [13] with permission from Elsevier.

lipomyelomeningocele, is present in nearly all patients, with recent reports ranging from 64% to 100% [7].

Two options have been described for surgical reconstruction: primary single-staged closure of the bladder or a planned staged repair [8–12]. Regardless of the strategy chosen, failure of the initial repair decreases the potential for the later development of continence. Also, in each option pelvic osteotomies are often used to allow approximation of the pubic symphysis. Modified Buck traction is often required after surgery for 4–8 weeks (Fig. 29.2)[13].

Preoperative preparation involves an assessment of all organ systems to ensure that there are no associated anomalies of physiological significance. Preoperative complete blood count, type and cross-match are recommended, especially if pelvic osteotomies are necessary. Appropriate measures are taken to avoid trauma to the exposed bladder mucosa. Antibiotics are administered preoperatively and continued after surgery. The procedure involves long operating times (5–7h), unpredictable bleeding and fluid shifts after intravenous induction of anesthesia and endotracheal intubation [14]. Therefore, two intravenous catheters should be placed in the upper extremities if possible to avoid the sterile field. Central venous access may be necessary if peripheral venous access is difficult. An arterial line is also placed for both hemodynamic monitoring and measurement of blood gases, hemoglobin, coagulation studies, electrolytes and glucose.

Preoperative placement of an epidural catheter is helpful for intraoperative and postoperative pain management (Fig. 29.3) [4]. The sacrococcygeal ligament is punctured at position 1 (see Fig. 29.3) and an epidural catheter is threaded through the epidural insertion needle to reach a thoracic dermatome level of T10–12. The

**Figure 29.3** Placement of a tunneled caudal epidural catheter is depicted. (A) The sacrococcygeal ligament is punctured at position 1, and then an epidural catheter (approximately 6–10 cm) is threaded through the epidural insertion needle to reach a thoracic dermatomal level of T10–12. (B) The tunneling needle (a 17 or 18 gauge styletted Crawford or Tuohy needle) is inserted on the patient's side, near the posterior superior iliac crest, labeled as position 2. This is the final exit position and should be visible when the child is supine so that the site can be easily inpected. (C) The tunneling needle emerges at the epidural needle insertion (position 1). Note the epidural insertion needle is not removed and is left in place to protect the catheter. An 11 scalpel blade cuts the residual skin and subcutaneous tissue bridge between the two needles. (D) The epidural insertion needle is removed, leaving the catheter in place, depicted as a dashed line. (E) The stylet from the tunneling needle is removed and the distal end of the epidural catheter is threaded into the tunneling needle. (F) The tunneling needle is removed. The subcutaneous portion of the epidural catheter is depicted with a dashed line. (G) The primary insertion site and the final catheter exit site are secured with adhesive strips and covered with a transparent adhesive dressing. A loop is placed in the catheter to prevent accidental dislodgment. Reproduced from Kost-Byerly et al [4] with permission from Elsevier.

tunneling needle (a 17 or 18 gauge styletted Crawford or Tuohy needle) is inserted on the patient's side, near the posterior superior iliac crest, labeled as position 2. This is the final exit position and should be visible when the child is supine so that the site can be easily inspected in the postoperative period. The tunneling needle emerges at the epidural needle insertion (position 1). Note that the epidural insertion needle is not removed and is left in place to protect the catheter. An 11 scalpel blade cuts the residual skin and subcutaneous tissue bridge between the two needles. The epidural insertion needle is removed, leaving the catheter in place, depicted as a dashed line. The stylet from the tunneling needle is removed and the distal end of the epidural catheter is threaded into the tunneling needle. The tunneling needle is then removed. The subcutaneous portion of the epidural catheter is depicted with a dashed line. The primary insertion site and the final catheter exit site are secured with Steri-Strips and covered with transparent adhesive dressings. A loop is placed in the catheter to prevent accidental dislodgment [4].

At the time of surgery, the patient will have a wide surgical preparation, including the entire body anteriorly and posteriorly below the level of the nipples so that turning the child for surgical orientation does not lead to wound contamination [5]. Timing of the removal of the endotracheal tube after surgery depends on the infant's age, length and complexity of surgery, and amount of fluid and blood the patient received during surgery.

In the postoperative period it is imperative that the baby remain immobilized, sedated, and pain free to prevent movement that would cause distracting forces to compromise the repair. The tunneled epidural catheter is extremely useful in this situation. Epidural infusions through tunneled epidural catheters can provide safe analgesia for up to a month in neonates. Daily communication between pediatric urology, intensive care unit (ICU) staff, the pediatric pain service and experienced nursing staff is the prerequisite to providing analgesia and sedation without undue complications for a neonatal population [4,13].

#### **Posterior urethral valves**

The most common cause of severe obstructive uropathy in children is posterior urethral valves (PUV). The urethral valves are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. A slitlike opening usually separates the leaflets. Valves are of unclear embryological origin and cause varying degrees of obstruction. The renal changes range from mild hydronephrosis to severe renal dysplasia; their severity probably depends on the severity of the obstruction and its time of onset during fetal development. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia [15].

If the serum creatinine level remains normal or returns to normal after birth without intervention, treatment consists of transurethral ablation of the valve leaflets, which is performed endoscopically under general anesthesia. If the urethra is too small for transurethral ablation, temporary vesicostomy is preferred, in which the dome of the bladder is exteriorized on the lower abdominal wall. When the child is older, the valves may be ablated and the vesicostomy closed [16].

There are several classifications of this disorder, based on the type and severity of obstruction. The spectrum of abnormalities may represent the different degrees of obstruction, the timing of obstruction, and other genotypical risk factors. Mild obstruction may have a presentation delayed until adolescence. It appears that a partial outlet obstruction can be overcome with bladder wall hypertrophy that generates high voiding pressures [15,16].

An infant with severe PUV may present in the neonatal nursery with anuria and a palpable bladder. The clinical sequelae from PUV result in persistent bilateral hydronephrosis, either from vesicoureteric reflux (VUR) or elevated bladder pressures [16]. When the newborn's condition is especially severe, with associated lung hypoplasia, serial percutaneous needle bladder drainage may be undertaken to decompress the bladder until the newborn is optimized to have surgical repair.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (no. 5 or 8 French) is inserted through the urethra into the bladder for several days. Passing the feeding tube may be difficult, because the tube tip may coil in the prostatic urethra, causing urine to drain around the catheter rather than through it. A Foley (balloon) catheter should not be used, because the balloon may cause severe bladder spasm, which may produce severe ureteral obstruction [17].

Posterior urethral valves are now commonly diagnosed in the antenatal period. The ultrasound findings may include bilateral hydronephrosis, a distended thickwalled bladder, and oligohydramnios [16]. The incidence of PUV is 1/5000 livebirths. Of the 500 new cases of PUV each year, 150 will develop end-stage renal disease (ESRD) and require dialysis or transplantation in the first 18 years of life. Some institutions perform in utero interventions. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatal diagnosis of PUV, particularly when discovered in the second trimester, is associated with a poorer prognosis than those detected after birth [17]. While antenatal intervention improves pulmonary function and the restoration of amniotic fluid volume, it does not guarantee an improvement in the renal insufficiency [15,16].

The appropriate treatment of PUV is determined by examining all contributing factors. These include the overall condition of the infant, renal function, hydration status, and lung maturity [16]. Prophylactic antibiotics are started at birth and the bladder may need decompression. Valve ablation may be undertaken if the creatinine falls to less than 1 mg/dL. When the renal function does not continue to improve, usually a vesicostomy is performed as the initial step to decompress the kidneys. Most boys have a good prognosis if they complete a normal gestation and undergo neonatal valve incision.

These patients may present in the neonatal period for PUV incision and also for circumcision which may decrease the rate of urinary tract infections [16]. In the very small infant where the cystoscope will not pass through the urethra, a vesicostomy may be considered, with delayed valve incisions.

These infants may also have some degree of respiratory compromise, relating to the oliguria [17]. It is thought that the urinary obstruction and lack of urine production *in utero* limits the amount of fluid the fetus then aspirates, which helps to stent open the developing lungs. In turn,

this leads to pulmonary hypoplasia and respiratory distress syndrome [18]. An appropriate volume of amniotic fluid, which is produced by the kidneys and then excreted as urine, is necessary for the complete and proper branching of the bronchial tree and alveoli. Physical findings can include poor fetal breathing movements, small chest cavity, ascites, limb deformities from compression, and Potter facies [15]. Potter facies develops in utero secondary to the effects of oligohydramnios from any cause. Features include micrognathia, hypertelorism, pulmonary hypoplasia, and spade-like hands [19]. Neonates with pulmonary hypoplasia may require perioperative mechanical ventilation. These patients may require high peak pressures, and permissive hypercapnia must be tolerated. The severe patient may even require an oscillating ventilator, until the lungs mature further.

The preoperative evaluation of a neonate with PUV should include assessment of renal function, including the extent of urinary retention and fluid overload. Appropriate laboratory testing should search for evidence of renal failure. Hyponatremia, azotemia, hypertension, and hyperkalemia must be identified and treated prior to anesthetizing the patient. Patients in renal failure must be treated with appropriate fluid management and judicious use of anesthetic agents affected by renal metabolism.

When PUV cause mild obstruction, the associated complications are also mild or non-existent. The length of surgical intervention is generally less than 1h and the anesthetic approach includes general anesthesia with endotracheal intubation or laryngeal mask airway (LMA) for airway management. Postoperative pain is minor for cystoscopy and valve ablation.

### Circumcision

Circumcision is the most commonly performed surgical procedure in the world. There are very few absolute indications for circumcision, especially in the neonate. The American Academy of Pediatrics does not recommend routine circumcision in otherwise healthy boys. In this age group, if hydronephrosis is present, then a circumcision may help to decrease the likelihood of urinary tract infections [16]. In older children, persistent phimosis and recurrent balanitis are indications for circumcision [16].

Newborn circumcisions are most often done at the bedside or as outpatients with a Plastibell device or Gomco clamp. These procedures are usually performed by the pediatrician or obstetrician while the infant is still in the nursery. Circumcision in older children usually requires freehand sleeve resection performed under general anesthesia. Common surgical complications of circumcision include bleeding, infection, residual redundant skin, meatal stenosis, and skin bridges [20].

When infants and children require general anesthesia, it usually is induced via inhalational induction, a peripheral intravenous line is placed and the airway is secured with an LMA or endotracheal tube. A penile nerve block placed prior to incision is effective in providing intraoperative analgesia and postoperative pain relief [21]. Although caudal epidural anesthesia can be used for analgesia, penile block is usually preferred because less local anesthetic is given and less time is spent performing the block [22].

# **Hypospadias**

Hypospadias is the abnormal ventral opening of the urethral meatus which results from incomplete development of the urethra. This defect may be located anywhere from the corona of the glans to the perineum [22]. Therefore, the extent of surgical dissection and the staging of the repair depend on the complexity of the lesion [23]. Hypospadias is often discovered after a routine neonatal circumcision. Signs of hypospadias include abnormal prepuce, persistent ventral curvature (also known as chordee), and proximally displaced urethral orifice that is rarely obstructive but often stenotic [16]. The meatus is located on the glans or distal shaft in 70–80% of cases and in the middle of the shaft 20–30% of the time [16]. Rarely, the meatus is located in the scrotum or more proximally in the perineum.

Hypospadias can be associated with inguinal hernias, cryptorchidism, and low birthweight. The incidence of hypospadias is higher in patients with affected siblings [24].

Early repair of this defect is important for aesthetic considerations and toilet training, and also for long-term psychosexual adjustment [23]. Skilled pediatric urologists perform this repair in healthy term babies as early as 3 months of age. Delaying the repair past 15 months may increase cognitive, emotional, behavioral, and psychosexual issues. In addition, younger infants may develop less scar tissue and have better wound healing than older children [16].

The goals of repair are straightening the ventral curvature and extending the urethra distally. Historically, these operations were done as staged procedures. Currently, the majority are done as one procedure. Surgery may be staged if the penis has a curvature greater than 30°. A buccal graft may be needed for tubularization of the neourethra during the second stage, which occurs approximately 6 months later [16].

These patients are usually otherwise healthy. General anesthesia with LMA and supplemental caudal

anesthesia or a penile block is the most common approach. Postoperative urethral instrumentation must be avoided as catheterization of the newly formed urethra could cause disruption of the repair. These patients often have a urethral catheter left in place postoperatively, to allow passive urine drainage through the neo-urethra for approximately 1 week [16]. The penis is gently compressed with a Telfa<sup>®</sup> pad and bio-occlusive dressing following the procedure. Complications can include fistulas, meatal stenosis, urethral stricture, dehiscence, and recurrent curvature [16].

# Cryptorchidism

Cryptorchidism (undescended testes, UDT) is the most common disorder of sexual differentiation and occurs in approximately 2% of male births [25]. The consequences of cryptorchidism include degeneration of the testes, impaired fertility, and increased risk for germ cell testicular tumors [17]. Despite the significance of this problem, the etiology of UDT in the majority of patients is unknown. It is unclear whether the pathological changes in the cryptorchid testis occur as a result of a primary defect or from secondary changes produced by the higher temperatures imposed on the undescended testis [17].

Two-thirds of patients present with a unilateral abnormality, and the other third present with bilateral abnormalities [16]. When the undescended testicle is unilateral, the right side is more often affected. The incidence ranges from 3.4% to 5.8% in full-term males. The usual timing for testicular descent into the scrotum is during the seventh month of gestation. Spontaneous descent may occur up until the first 6 months of life. A number of risk factors have been implicated as a cause of undescended testicles. These include advanced maternal age, maternal obesity, breech presentation, low parity, preterm birth, low birthweight, and maternalconsumption of colacontaining drinks during pregnancy [16,26].

Cryptorchidism may occur as a single isolated abnormality in an otherwise healthy patient or be associated with other congenital anomalies such as prune belly syndrome, PUV, neural tube defects, gastroschisis, and microcephaly [27].

Treatment is focused on prevention of infertility, testicular malignancy, testicular torsion, and the psychological stigma associated with an empty scrotum. The rate of malignancy is approximately 1% in the cryptorchid patient. It is unknown whether this results from the abnormal position of the testis or an abnormality of the testis itself [16]. The rate of infertility is 38% in patients with bilateral cryptorchidism compared to 11% in unilateral cryptorchidism and 6% in normal males.

Treatment includes surgical exploration for the location of the testis. Sixty percent of the time, the testis is located in the inguinal canal or abdomen and 40% of the time, the testis is absent or composed of fibrous tissue. The current method of treatment is orchiopexy, or relocation of the testis into the scrotum. If the location of the testis is not easily determined, the vas deferens and testicular vessels are used to help locate it [22]. Vessel length is the determining factor in deciding whether to undertake the procedure in one or two stages. Small, short spermatic vessels lead to the risk of a non-viable testis if placed into the scrotum without staging. In the first stage, the vessels are dissected and the testicle is brought as close to the scrotum as possible. The second stage 1 or 2 years later moves the testicle the remaining distance into the scrotum. The waiting period allows the blood supply to enlarge and form collateral circulation to supply the testicle.

Hormonal treatments to stimulate testicular descent include human chorionic gonadotropin, gonadotropinreleasing hormone, and luteinizing hormone-releasing hormone. These hormones stimulate the Leydig cells to produce androgens, but the mechanism for testicular descent is unknown [16].

Children who present for orchiopexy are usually otherwise healthy. They require general anesthesia with either an endotracheal tube or LMA for airway management. Caudal epidural block is helpful to minimize postoperative pain. These procedures may be performed with conventional surgical incisions or, if abdominal position of the testes is suspected, laparoscopic surgery is often performed. If the anesthetic level is insufficient, laryngospasm may occur when the testis is manipulated. Otherwise, the postanesthetic course is generally unremarkable.

## **Testicular torsion**

Testicular torsion is a true surgical emergency. The diagnosis is usually made by history, physical examination, and diagnostic imaging studies. There are no definitive diagnostic imaging studies available, although color Doppler, isotope scans, and conventional ultrasound may be useful adjuncts [28]. Testicular torsion is best managed by early exploration, detorsion, and, when the testis is salvageable, fixation. When the testis is not salvageable, the surgeon will proceed with orchiectomy. In either scenario, a contralateral orchiopexy is usually performed [16].

Normally, the tunica vaginalis covers the anterior surface of the testis, epididymis, and spermatic cord, attaching with the gubernaculums and scrotal wall posteriorly, fixing the testis [16]. When these attachments are not secure, torsion may occur, leading to vascular compromise. There is a bimodal distribution in occurrence, with increased frequency during the neonatal period and puberty. During puberty, the rapidly increasing testicular mass increases the chances for rotation. In the neonatal period, the recently descended testis is very motile in the scrotum, increasing the risk of the spermatic cord rotating *en masse* [16].

The patient's history should focus on the age of the patient, association with pain, and history of trauma. The onset and severity of pain may help differentiate torsion from epididymitis. The pain in torsion is acute in onset, severe, and ipsilateral [16]. The patient may also have symptoms of abdominal pain, thigh pain, and nausea and vomiting. The orientation and location of the testis in the scrotum must also be evaluated.

Testicular infarction may occur within a few hours of the torsion. After 8h following the onset of pain, the testicular salvage rate declines precipitously [29]. In addition, studies in rats have confirmed that unilateral torsion can induce bilateral testicular damage and infertility [16]. This may result from reflex vasoconstriction, the formation of autoantibodies or other chemically mediated mechanism [16]. Therefore, surgery under general anesthesia with a rapid-sequence induction should proceed as soon as possible.

### **Vesicoureteral reflux procedures**

Vesicoureteral reflux (VUR) is the retrograde flow of urine across the ureterovesical junction (UVJ). There is a high rate of familial recurrence, suggesting a genetic component. Risk factors for developing this condition include anatomical and functional abnormalities of the UVJ, high intravesical pressures, and impaired ureteral function [16]. If the VUR is severe, renal dysfunction and hypertension may be present preoperatively, although the majority of the presenting patients are healthy.

The unidirectional flow of urine through the normal ureter depends on both active and passive components. It appears that the tunneling path that the ureter travels through the submucosal layers of the bladder wall is inversely related to the rate of VUR. When the submucosal course is short, and therefore perpendicular to the bladder wall, the flap-valve mechanism normally in place to prevent reflux is absent. Additionally, the intravesical pressure must be lower than that in the ureter for there to be flow in the antegrade direction. Common clinical scenarios in which this might occur are in patients with posterior valves, in patients with a neurogenic bladder or when ureteral peristalsis is abnormal [16].

Long-term antibiotic prophylaxis is recommended in these children, especially to the age of 8 years and in those with frequent recurrences [16]. This is continued until the reflux has resolved spontaneously or has been surgically corrected. This prophylaxis has been shown to decrease the amount of renal scarring and renal damage from repeated infections, helping to minimize the progression to chronic renal insufficiency and hypertension.

Management of vesicoureteral reflux may be surgical or medical. The main goal is to prevent pyelonephrosis, which can lead to the above complications. The treatment plan depends on gender, age, grade of reflux, concurrence of urinary tract infections, renal function, and likelihood of resolution [16]. If the reflux is sterile, with no associated urinary tract infection, it is not harmful to the kidneys and has no significant effect on kidney function and can probably be managed medically. Indications for surgical treatment include breakthrough urinary tract infections despite prophylactic antibiotics, VUR associated with congenital anomalies at the UVJ, renal growth retardation and the finding of worsening renal scarring. The endpoint of the surgical treatment is to restore the flap-valve mechanism, thereby preventing the VUR. The gold standard for this remains open surgical repair to establish an adequate submucosal tunnel for the ureter.

There are multiple techniques available for surgical repair, but the main components of each are freeing the ureter for mobilization, submucosal tunnel formation, transferring the ureter through the tunnel, and securing the ureter into the new position [16]. A minimally invasive technique for repair is also available. Using either an extravesical or intravesical approach, laparoscopic reimplantation can be undertaken. Endoscopic injection therapy, most frequently using polytetrafluoro-ethylene (PTFE) or silicone, is introduced submucosally at the 6 o'clock position of the UVJ [16]. By creating a mound at the opening of the UVJ, this narrows the ureteral orifice, thereby decreasing the amount of reflux allowed.

Anesthetic considerations for this case include duration and blood loss, which can be significant during open repair. An epidural catheter or caudal epidural (catheter or single shot) may be placed to supplement anesthesia intra- and postoperatively. Postoperatively, these patients may have significant bladder spasm. This may be effectively treated in a variety of ways, including with belladonna and opium (B and O) suppositories, oral or intravesicular oxybutynin, ketorolac or bupivacaine via epidural or in the bladder [21,20,30].

### Ureteropelvic junction obstruction

Ureteropelvic junction (UPJ) obstruction is the most common cause of obstructive uropathy in childhood and usually is caused by intrinsic stenosis. The typical appearance on ultrasonography is grade 3 or 4 hydronephrosis without a dilated ureter. UPJ obstruction most commonly presents on maternal ultrasonography revealing fetal hydronephrosis, as a palpable renal mass in a newborn or infant, as abdominal, flank or back pain, as a febrile urinary tract infection (UTI) or as hematuria after minimal trauma. Approximately 60% of cases occur on the left side, and the male: female ratio is 2:1. In 10% of cases UPJ obstruction is bilateral. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy, but approximately half of affected kidneys have relatively normal function [31].

Crossing vessels have been identified in 38–71% of patients with UPJ obstruction and in 19% of patients without UPJ obstruction [32]. Crossing vessels are believed to exacerbate rather than initiate the obstructive process [33]. If not recognized, crossing vessels can cause significant bleeding. These vessels are not excised as part of the repair, but the renal pelvis and ureter are rearranged by dismembered pyeloplasty [34].

The goal of surgery for UPJ obstruction is to preserve renal function by facilitating unobstructed drainage of urine. There are two common techniques: the more popular dismembered pyeloplasty and the flap technique. With the dismembered approach, there is complete severing of the ureter from the pelvis and then reanastomosis. With the flap approach, the renal pelvis is modified with the ureter intact.

The most common surgical approaches are the anterior subcostal, muscle-splitting approach and the dorsal lumbotomy approach. The anterior subcostal approach is performed in a modified supine position with the ipsilateral side at a 15–20° angle. The operating table is flexed at the level of the child's anterior superior iliac spine and a bump placed under the patient. The lumbotomy approach is performed with the child in the prone position.

Pyeloplasty can also be performed by the laparoscopic approach with and without robotics. Potential benefits of the laparoscopic approach include shorter hospital admission, decreased postoperative pain, less superficial scarring and earlier return to normal activity [35]. Because of the small incision used in the open procedure combined with the rapid convalescence of most children, controversy exists about which approach may be advantageous in this age group. The decision is likely left to surgeon preference and experience. Neither approach is responsible for prolonged extreme pain. The mean length of stay for an open procedure is 25h [36].

In most children, the general risk of anesthesia is relatively low. These children are usually healthy, but it is always prudent to search for co-existing diseases. Renal failure is not usually an issue, especially with unilateral disease. Because of positioning and length of surgery, and when a laparoscopic approach is planned, tracheal intubation is usually the safest route. Liberal fluid therapy allows free flow of urine. Regional block with local anesthetic via the caudal route with or without opioids and clonidine provides excellent postoperative pain relief. Because the mean length of hospitalization is about 25 h, epidural catheter placement usually is not necessary [20]. Ben-Meir et al demonstrated that a regimen of opioids and non-steroidal anti-inflammatory drugs in children after open pyeloplasty has efficacy similar to that of epidural analgesia [37].

#### Wilms tumor

Wilms tumor or nephroblastoma is the most common renal tumor of childhood and the seventh most common pediatric malignancy overall, accounting for about 5% of all childhood malignancies [38]. There are approximately 500 new cases of Wilms tumor each year. Most (75%) newly diagnosed patients are under 5 years of age, and usually between 2 and 3 years. Commonly, the tumor presents as a painless mass which is noticed by the parents as an abdominal bulge or a palpated mass. Some patients may exhibit signs and symptoms including malaise, fever, weight loss and frank hypertension. Classic associations with Wilms tumor include crytorchidism or hypospadias, aniridia and/or hemihypertrophy. Box 29.1 lists the characteristics associated with different types of Wilms tumor. The tumor usually involves one kidney but may affect both kidneys in about 5% of cases. As the tumor grows, it may spread by local invasion and in 12% may demonstrate hematogenous spread to the lungs and less commonly to the brain (0.5%) [39]. Children with tumors that are solitary, unilateral and have a low-risk genotype (see below) have an excellent prognosis. Bilateral masses and those with higher risk tumors (by genotype) are associated with significant morbidity and mortality. Common morbidities include recurrence of tumor, complications secondary to chemotherapy or radiation therapy and spread to other organs, particularly the lungs. Recent advances in molecular biology have improved understanding of factors which can affect the outcome of children with Wilms tumor. In particular, the loss of heterozygocity (LOH) of chromosome 1p and/or 16q is associated with anaplastic Wilms tumors, which have a worse prognosis than those without LOH. Older children also are more likely than younger ones to have LOH and therefore a worse prognosis. Patients who exhibit LOH at both the 1p and 16q loci have a significant chance of relapse after therapy and therefore a worse prognosis. Epidemiological and genetic factors have been used to stratify the risk associated with Wilms tumor. These are summarized in Table 29.1.

Children with Wilms tumor may require anesthesia for a variety of conditions, including primary tumor resection, radiological imaging (magnetic resonance imaging,

Subgroup	No. of patients	Percentage of patients in subgroups with

#### Box 29.1 Wilms tumor staging system

- Tumor limited to kidney and completely excised. The surface of the capsule is intact. Tumor was not ruptured before or during removal. There is no residual tumor apparent beyond the margins of excision.
- II. Tumor extends beyond the kidney, but is completely excised. There is regional extension of the tumor, i.e. penetration through the outer surface of the renal capsule into perirenal soft tissues. Vessels outside the kidney substance are infiltrated or contain tumor thrombus. The tumor may have been biopsied or there has been local spillage of tumor contained to the flank. There is no residual tumor apparent at or beyond the margins of excision.
- **III.** Residual non-hematogenous tumor confined to the abdomen. Any one or more of the following occur.
  - a. Lymph nodes on biopsy are found to be involved in the hilus, the peri-aortic chains or beyond.
  - b. There has been diffuse peritoneal contamination by tumor such as by spillage of tumor beyond the flank before or during surgery, or by tumor growth that has penetrated through the peritoneal surface.
  - c. Implants are found on the peritoneal surfaces.
  - d. The tumor extends beyond the surgical margins either microscopically or grossly.
  - The tumor is not completely resectable because of local infiltration into vital structures.
- **IV.** Hematogenous metastases. Deposits beyond stage III, i.e. lung. liver, bone, and brain.
- V. Bilateral renal involvement at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of extent of disease prior to biopsy.

MRI), diagnostic bone marrow biopsy and lumbar puncture, placement of central lines (percutaneously inserted central catheters, PICC) or radiation therapy. Usually the child will present to the operating room for surgical resection and staging. The main responsibility of the surgeon is to remove the primary tumor completely, without spillage, and to accurately assess the extent to which the tumor has spread, with particular attention to adequately assessing lymph node involvement. There is a difference in approach to the timing of initial surgery between the guidelines of the Children's Oncology Group (COG) in the US and those of the International Society of Pediatric Oncology (SIOP) in Europe. The American practice is to perform primary resection and staging before administering chemotherapy. The SIOP recommends preoperative chemotherapy because the tumor then is easier to resect and may be associated with a decreased incidence of tumor spill and a lower mortality and morbidity rate [39].

Commonly, anesthesia for primary tumor resection is similar to that for any major open laparotomy or radical nephrectomy. Proper preoperative assessment is crucial. The anesthesiologist should be aware of the extent of the tumor and whether it is adherent to surrounding organs. The tumor may involve a good portion of the kidney as well as the inferior vena cava, mesenteric arteries, a portion of the liver or right atrium. Patients with atrial involvement or atrial thrombus may need cardiopulmonary bypass support during the surgical procedure. Bilateral tumors or ones crossing the midline of the abdomen may affect the great vessels, adding a potential risk of significant blood loss. In addition, the anesthesiologist should be aware of any associated anomalies and the nature of any preoperative chemotherapy or radiation therapy. Chemotherapeutic agents such as actinomycin, doxorubicin and vincristine are used for preoperative and postoperative treatment. These drugs may be associated with myelosuppression, cardiotoxicity, pulmonary effects (pleural effusion, pneumonia, and interstitial pneumonitis), hepatotoxicity, and neurotoxicity in children [40]. The incidence varies and may depend on both dose and the patient's individual response to the agent [40–42].

The anesthetic plan depends on the preoperative condition of the patient and the surgical plan. These patients will require endotracheal intubation and general anesthesia with standard monitors. Two intravenous lines are useful, one to provide maintenance IV solutions and the second for rapid infusion of fluids or blood products. If there is intra-atrial involvement or if thoracotomy or cardiopulmonary bypass is required, an arterial line is useful to closely monitor the patient's blood pressure and obtain blood specimens for testing. Central venous access, if not present preoperatively, may be desirable to monitor central pressures and provide longer term venous access. For the abdominal approach, patients are positioned supine and commonly the surgical approach is through a transverse abdominal transperitoneal incision. Epidural analgesia for intraoperative and postoperative pain management may be quite useful. The level of the catheter is determined by the site of the incision. The tip of the catheter is best located at the mid or low thoracic level in order to provide adequate analgesia.

Despite proper planning and execution, up to 12% of cases may have a perioperative complication. Table 29.2 lists some of the possible surgical complications and reported incidence. In addition to these, the anesthesiologist should be mindful of possible injury related to patient positioning and take proper precautions to minimize the risk. Patients may have significant postoperative pain and discomfort depending on the location of the incision and extent of the surgical dissection. Postoperative use of patient- or nurse-controlled epidural analgesia may result in more comfort and rapid return to activity by avoiding the common side-effects of intravenous opioid analgesia. Without surgical complications, patients usually recover from surgery within 3-5 days. Postoperative therapy is determined by the stage of the tumor and risk stratification.

#### Chronic renal failure and dialysis

Children in acute or chronic renal failure may require peritoneal or hemodialysis. The insertion of the appropri

ate catheter in non-critically ill patients is usually performed in the operating room under general anesthesia. The critically ill child may require a procedure in the operating room while undergoing continuous renal replacement therapy (CRRT) in the ICU. This section will describe the types of renal replacement available, the mechanism by which dialysis is performed and finally a discussion of the types of dialysis catheters used for the pediatric patient. The perioperative care of children in renal failure requiring surgery will also be addressed.

Renal replacement therapy (RRT) defines dialysis therapies. However, some authors now refer to dialysis as renal support therapy because only fluid removal and filtering wastes are performed by dialysis and not the endocrine functions [43]. Dialysis employs only two physiologies for solute and fluid movement. Both methods necessitate blood being exposed to a semipermeable membrane against a dialysate solution of different concentration. Regardless of the modality employed, the goal of renal replacement therapy is to precisely control serum electrolytes, clear toxins and provide fluid removal for the patient in renal failure.

Dialysis employs a diffusive clearance while hemofiltration employs convective clearance. Hemodialysis and

peritoneal dialysis involve the diffusion of solutes across a concentration gradient from high to low concentration. Dialysate is passed across the semi-permeable membrane countercurrent to blood flow, allowing equilibration of the plasma and dialysate solute concentrations. This process may remove or add solute to the plasma water space, depending upon the composition of dialysate compared to the plasma. Water will also move along a gradient, in effect "following" the solute (ultrafiltration). Diffusive clearance is effective for removal of the small solute, including serum ions and urea, with subsequent fluid removal. In addition, other solutes such as antibiotics, narcotics and other medications will cross the membrane. Diffusion gradients change depending upon blood flow rates, dialysate flow rates and starting concentration gradients. CRRT employing countercurrent dialysate for solute clearance is considered as continuous venovenous hemodialysis (CVVHD) [44].

Hemofiltration uses a pressure gradient for fluid movement instead of solute concentration gradients. It is considered part of the CRRT modalities. A positive hydrostatic pressure drives water across the membrane from the blood side to the filter side and solutes follow water through the membrane. Due to the possibility of large shifts of volume during convective therapies, a filter replacement fluid (FRF) is often utilized to replace fluid lost by convection. In patients undergoing CRRT, bicarbonate is lost in the ultrafiltrate. Therefore, the replacement fluid is usually an isotonic, buffered electrolyte solution. The buffer used in the replacement fluid may be acetate, citrate, lactate or bicarbonate. The use of citrate is becoming more commonplace because it may be used as both a buffer and an anticoagulant to help prevent hemodiafilter clotting [45]. There are many names for the types of hemofiltration performed, including SLEF (slow extended hemofiltration), SCUF (slow continuous ultrafiltration), CVVH (continuous venovenous hemofiltration), and CVVHDF (continuous venovenous hemodiafiltration) [44].

Thresholds for the timing of dialysis in acute renal failure (ARF) are controversial and not well defined [43,46,47]. Indications for renal replacement therapy include volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy, persistent hyperkalemia, severe metabolic acidosis unresponsive to medical management, neurological symptoms (altered mental status, seizures), and the presence of progressive azotemia. The modulation of inflammatory mediators in ARF with sepsis or multiorgan system failure may be another indication [48]. An additional indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with ARF, dialysis support may be necessary for days or weeks [49].

In chronic renal failure, ESRD represents the state in which a patient's renal dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained with native kidney function and maximal medical management. Relative indications for renal replacement therapy include weight loss, malnutrition, persistent nausea and vomiting, refractory metabolic disturbances, refractory hypertension, fluid overload, school performance failure and chronic fatigue. Absolute indications include progressive uremic encephalopathy, bleeding diathesis related to uremia, pericarditis, pulmonary edema, and life-threatening hyperkalemia [43]. The ultimate goal for children with ESRD is successful kidney transplantation because it provides the most normal lifestyle and possibility for rehabilitation for the child and family.

Seventy-five percent of children with ESRD in the US require a period of dialysis before transplantation can be performed. It is recommended that plans for renal replacement therapy be initiated when a child reaches a glomerular filtration rate (GFR) between 29 and 50 (mL/  $min/1.73 m^2$ ) [49]. The optimal time to actually initiate dialysis, however, is based on a combination of the biochemical and clinical characteristics of the patient, including refractory fluid overload, electrolyte imbalance, acidosis, growth failure or uremic symptoms, fatigue, nausea, and impaired school performance [43]. In general, most nephrologists attempt to initiate dialysis early enough to prevent the development of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms. Pre-emptive transplantation before initiation of dialysis is increasingly observed [49]. Management of anesthesia for renal transplantation is discussed in Chapter 27.

The selection of dialysis modality must be individualized to fit the needs of each child. In the United States, two-thirds of children with ESRD are treated with peritoneal dialysis, whereas one-third are treated with hemodialysis. Age is a defining factor in dialysis modality selection; 88% of infants and children from birth to 5 years of age are treated with peritoneal dialysis, whereas 54% of children older than 12 years of age are treated with hemodialysis [50]. In acute renal failure each modality has its indications, contraindications, and challenges (Table 29.3) [46].

Peritoneal dialysis involves the transport of solutes and water across the peritoneum. The blood in the peritoneal capillaries is exposed to the dialysis solution in the peritoneal cavity, which typically contains sodium, chloride, and lactate or bicarbonate along with glucose to make the solution hyperosmolar. During the course of a peritoneal dialysis dwell, three transport processes occur simultaneously: diffusion, ultrafiltration, and absorption. The amount of dialysis achieved and the extent of fluid Table 29.3 Comparison of the advantages and disadvantages of continuous renal replacement therapies (CRRT), peritoneal dialysis (PD), and intermittent hemodialysis (IHD)

Variable	CRRT	PD	IHD
Continuous therapy	Yes	Yes	No
Hemodynamic stability	Yes	Yes	No
Fluid balance achieved	Yes, pump controlled	Yes/no, variable	Yes, intermittent
Easy to perform	No	Yes	No
Metabolic control	Yes	Yes	Yes, intermittent
Optimal nutrition	Yes	No	No
Continuous toxin removal	Yes	No/yes, depends on the nature of the toxin – larger molecules not well cleared	No
Anticoagulation	Yes, requires continuous anticoagulation	No, anticoagulation not required	Yes/no, intermittent anticoagulation
Rapid poison removal	Yes/no, depending on patient size and dose	No	Yes
Stable intracranial pressure	Yes	Yes/no, less predictable than CRRT	Yes/no, less predictable than CRRT
ICU nursing support	Yes, high level of support	Yes/no, moderate level of support (if frequent, manual cycling can be labor intensive)	No, low level of support
Dialysis nursing support	Yes/no, institution dependent	Yes/no, institution dependent	Yes
Patient mobility	No	Yes, if IPD used	No
Cost	High	Low/moderate. Increases with increased dialysis fluid used	High/moderate
Vascular access required	Yes	No	Yes
Recent abdominal surgery	Yes	No	Yes
VP shunt	Yes	Yes/no, relative contraindication	Yes
Prune belly syndrome	Yes	Yes/no, relative contraindication	Yes
Ultrafiltration control	Yes	Yes/no, variable	Yes, intermittent
PD catheter leakage	No	Yes	No
Infection potential	Yes	Yes	Yes
Use in AKI-associated inborn errors of metabolism	Yes	No	Yes
Use in AKI-associated ingestions	Yes	No	Yes

removal depend on the volume of dialysis solution infused (called the dwell), how often this dialysis solution is exchanged, and the concentration of osmotic agent present [51].

Peritoneal dialysis requires less clinical expertise, fewer equipment resources, and decreased cost. It can be used in all pediatric patients including neonates and stable postoperative heart surgery patients. It can be performed in patients with a ventriculoperitoneal shunt and also in patients with prune belly syndrome. Peritoneal dialysis provides gradual solute clearance and ultrafiltration, thus causing less hemodynamic instability. Slow solute clearance and ultrafiltration is an obvious disadvantage for patients with severe fluid overload or severe lactic acidosis requiring precise fluid balance and controlled ultrafiltration that can only be attained with intermittent hemodialysis or continuous renal replacement therapy [46].

Peritoneal dialysis can worsen respiratory distress by limiting diaphragmatic movement. Diaphragm defects are a contraindication to peritoneal dialysis. Because peritoneal dialysis can result in the loss of immunoglobulins, peritonitis is a risk. Catheter malfunction is common, resulting in leaks, hernias, and catheter obstruction.

Intermittent hemodialysis has the clear advantage of rapid ultrafiltration and solute removal when compared to peritoneal dialysis or CRRT. The hemodialysis circuit is composed of the patient's blood compartment access in the form of a surgically placed arteriovenous fistula (AVF) or arteriovenous graft (AVG), or a venous catheter connected to polyethylene tubing through which the patient's blood travels to and from the dialyzer. The dialysate consists of highly purified water into which sodium, potassium, calcium, magnesium, chloride, bicarbonate, and dextrose have been introduced. The low molecular weight waste products that accumulate in uremic blood are absent from the dialysis solution. For this reason, when uremic blood is exposed to dialysis solution, the flux rate of these solutes from blood to dialysate is initially much greater than the back-flux from dialysate to blood. During dialysis, concentration equilibrium is prevented, and the concentration gradient between blood and dialysate is maximized, by continuously refilling the dialysate compartment with fresh dialysis solution and by replacing dialyzed blood with undialyzed blood. Normally, the direction of dialysis solution flow is opposite to the direction of blood flow. The purpose of "countercurrent" flow is to maximize the concentration difference of waste products between blood and dialysate in all parts of the dialyzer [52].

Like peritoneal dialysis, intermittent hemodialysis can be performed outside the ICU. This modality is useful in children with toxic ingestions, tumor lysis syndrome, and inborn errors of metabolism [53,54]. Rapid solute and fluid removal afforded by intermittent hemodialysis can lead to disequilibrium syndrome. Careful dosing and selection of dialysate solution, with judicious use of mannitol are required to prevent dramatic osmolar fluctuation [55,56].

Continual renal replacement therapy refers to any continuous mode of extracorporeal solute or fluid removal. The common denominator to all forms of CRRT is an extracorporeal circuit connected to the patient via an arterial or venous access catheter. A variety of alternative CRRTs have been developed to address many of the problems associated with intermittent hemodialyisis and peritoneal dialyisis discussed above. CRRT provides better metabolic control of azotemia and fluid removal without compromising intravascular volume and facilitates fluid and electrolyte management and nutritional support in critically ill patients. CRRT is an invaluable means of supporting critically ill children with a variety of illnesses, including acute renal failure, drug intoxication, inborn errors of metabolism, liver failure and multiorgan failure. However, the ideal method of applying the technique is unknown [57,58]. On the basis of the successful use of CRRT in patients with ARF, it is now occasionally used to facilitate fluid removal in patients without renal failure but for whom diuretic therapy alone has been unsuccessful or is contraindicated [59].

# Dialysis catheter placement in the operating room

For children who do not undergo pre-emptive renal transplantation or who initially present with ESRD, establishment of adequate dialysis access is of paramount importance because it is directly linked to the quality of life and health of the patient. With respect to hemodialysis, all attempts should be made to create a primary arterial venous fistula. For patients without adequate veins, a PTFE graft is required. A native fistula is clearly preferred because of superior patency rates, although this option does require the presence of suitable veins, which excludes infants and small children under 20kg [52]. Vascular catheters are the predominant vascular access in children. In children with ESRD, renal transplant is the first line of therapy. As an AV graft is recommended for long-term dialysis, such grafts are inappropriate for children who will undergo renal transplantation within a year [60,61].

The National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines recommend that the order of vascular access be sequential: the right internal jugular vein, right external jugular vein, the left internal and external jugular veins, subclavian veins, femoral veins, or translumbar access to the inferior vena cava. This order is based on complication rates from lowest to highest [62]. Additionally, these catheters can lead to central venous stenosis and thrombosis, which can make future permanent upper extremity vascular access more difficult to achieve.

Peritoneal dialysis is performed after placement of a Tenckhoff catheter. A double-cuffed peritoneal dialysis catheter is inserted via an open or laparoscopic surgical procedure under general anesthesia. The loop of the catheter is placed in the pelvis. During the procedure, it is important to ascertain that fluid can run freely through the catheter into the abdomen and drain freely as well. The laparoscopic technique appears to afford no advantage for successful catheter function in the early postoperative period [63]. In addition, other factors that did not influence catheter function include previous peritoneal dialysis (PD) catheter placement, previous abdominal surgery, type of catheter, or location of catheter exit site. However, Argo et al showed that use of the laparoscopic technique was helpful in children with an *in situ* ventriculoperitoneal shunt [64].

The most common cause of catheter failure is occlusion, either from an internal fibrin plug or obstruction by omentum, bowel or other structures. The single controllable factor that was associated with a decreased risk of occlusion was the performance of simultaneous omentectomy. Overall, children weighing less than 10kg have a higher risk of PD catheter failure than children weighing over 10kg.

The annualized infection rate decreases with age. Tenckhoff straight and Tenckhoff curled catheters have similar times to first peritonitis infection. Overall, first time peritonitis infection took longer for catheters with two cuffs compared to one, for swan neck tunnels compared to straight tunnels, and for down exit sites compared to up and lateral [50,65].

Children who are scheduled for PD catheter insertion are usually in stable condition with chronic renal failure and are receiving a catheter for RRT in anticipation of renal transplantation. Occasionally, a child in acute renal failure will require surgical insertion of a dialysis catheter, such as the patient with new-onset hemolytic uremic syndrome.

The preoperative evaluation includes a physical exam and review of the patient's metabolic status. The timing of the patient's most recent dialysis session, if any, is very important. Of particular importance are serum potassium concentration, fluid status, and dosing of drugs which undergo predominantly renal clearance. The patient requiring a PD catheter or hemodialysis catheter will require standard ASA monitoring but usually not invasive monitoring. Arterial catheters are normally avoided in these patients, as are blood pressure cuffs on the extremity of an existing AV fistula or graft. Of critical importance is a preoperative discussion with the patient's nephrologist or surgeon about vascular access sites to be avoided. Long-term patency of major veins and arteries is critical to maintain in these patients, who may undergo a number of vascular access procedures over a lifetime. It is also important, when anesthetizing a patient with an existing dialysis fistula, to monitor blood flow during the anesthetic, and maintain blood pressure and intravascular volume status to ensure AV fistula or graft patency. Tracheal intubation is prudent since many children in acute and chronic renal failure have delayed gastric emptying and thus have a pulmonary aspiration

risk. The need for rapid-sequence induction or modified rapid sequence must be determined on an individual patient basis. While succinylcholine may be used for rapid-sequence induction if the serum potassium is at normal levels, rocuronium may be a better choice. Neuromuscular blockade with rocuronium is of similar duration or only slightly prolonged in patients with chronic renal failure (CRF) as compared to patients with normal renal function [66]. Fentanyl and hydromorphone are not metabolized by the kidney and are reasonable choices for perioperative analgesia [67].

# Continuous renal replacement therapy in the operating room

Most patients receiving CRRT are critically ill, may be on mechanical ventilator support, and are often receiving myriad vasoactive agents. These patients are challenging because they may have underlying coagulopathies, yet CRRT requires anticoagulation for filter patency. If these children need surgical procedures, in most instances, CRRT treatment can be discontinued while in the operating room. However, in some procedures, for example liver transplantation, CRRT may be used during surgery to optimize fluid and electrolyte management [68].

Most anesthesiologists and OR personnel are not familiar with CRRT or the equipment needed to provide the therapy. It is imperative that a meaningful discussion occur among the intensivists, nephrologists, and surgeons involved in the procedure, in order to outline the operative care of the patient. In our institution, a technician familiar with the CRRT device manages the apparatus in the operating room. Careful monitoring of arterial blood gases and electrolytes is essential to ensure normal acid–base balance [59].

## Priapism

Ischemic (veno-occlusive, low-flow) priapism is a nonsexual, persistent erection causing a compartmental syndrome that is a medical, and sometimes surgical, emergency in any episode lasting greater than 4 h. Patients typically report associated pain. In children, the etiologies include sickle cell disease, oncological disease, and neuroleptic drugs. Unlike normal erections which involve engorgement of the corpora cavernosa and the corporus spongiosum, priapism only involves engorgement of the corpora cavernosa.

Trazodone is a triazolopyridine derivative that holds considerable appeal for treatment of depressive illness and adjunct for chronic pain because it has little anticholinergic activity and few cardiovascular side-effects. However, it possesses significant  $\alpha$ -blocking activity, which appears to be a likely explanation for the pathogenesis of priapism in our patient in the Case Study (see below). Trazodone-induced priapism resembles priapism due to sickle cell hemoglobinopathy [69].

In general, since ischemic priapism of more than 4h in duration irrespective of etiology implies a compartment syndrome, decompression of the corpora cavernosa is recommended for counteracting and preventing ischemic injury. Definitive first-line treatment consists of evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injection of an  $\alpha$ -adrenergic sympathomimetic agent. A dorsal nerve block or local penile shaft block is generally performed prior to penile maneuvers. Priapism resolution employing aspiration with or without irrigation is approximately 30%.

Sympathomimetic agents can be expected to exert contractile effects on the cavernous tissue and thus facilitate detumescence. Among these, phenylephrine, as an  $\alpha_1$ selective adrenergic agonist, is the preferred drug for this application since it minimizes the risk of cardiovascular side-effects compared with other sympathomimetic agents having  $\beta$ -adrenergic effects as well. Evacuation of stagnant intracorporal blood may be required for the medication to be most effective [70,71].

In patients with an underlying etiological disorder, intracavernous treatment of ischemic priapism should be provided concurrent with appropriate systemic treatment. This recommendation applies to priapism associated with sickle cell disease as well as that associated with other hematological diseases, metastatic neoplasia or other causes having standard treatments. Support for this recommendation is provided by a literature review showing that ischemic priapism resolved in 37% or less of patients with sickle cell disease managed with systemic medical treatments, whereas much better resolution rates were achieved with therapies directed at the penis [70]. Thus, for priapism related to sickle cell disease, conventionally recommended medical therapies such as analgesia, hydration, oxygenation, alkalinization, and even transfusion may be performed, but these interventions should not lead to delays in intracavernous treatment if prolonged periods of ischemia have occurred [71].

The surgeon may proceed with surgical intervention once it is apparent that intracavernous treatment has failed [70]. A surgical shunt has the objective of facilitating blood drainage from the corpora cavernosa, bypassing the veno-occlusive mechanism of these structures [71]. Surgical correction involves connecting the engorged cavernosal tissue with the glans, corpus spongiosum or dorsal or saphenous vein. This surgically created fistula will allow blood to drain from the corpora cavernosa until the pathological process has resolved. Ideally, the surgically created fistula will spontaneously close after the factors causing the priapism have resolved [72].

# CASE STUDY

The patient is an 11-year-old male who has a history of Asperger syndrome and epilepsy. Chronic insomnia had been treated with trazodone for approximately 1 month. On the morning of surgery, he awoke at 9 a.m. with a rigid and painful erection which persisted throughout the day. There was no history of pelvic trauma or sickle cell disease. That evening, he was instructed to proceed immediately to the emergency department. After initial evaluation, the pediatric urologist aspirated his corporal bodies and attempted to irrigate with saline. This did not result in detumescence. Diluted phenylephrine was then injected as per protocol (Fig. 29.4) for the next 1 h [70]. The treatment was unsuccessful and the child was taken to the operating room for a distal shunt after his 15th hour of experiencing priapism.

The patient underwent a modified rapid-sequence induction with rocuronium and propofol. The trachea was

intubated and general anesthesia was maintained with an inhalational agent. A caudal epidural block was performed with an appropriate dose of 0.25% bupivacaine for postoperative analgesia and the child was placed in the supine position. A 14 French Foley catheter was placed in the bladder to allow for continuous urine flow. At this point, his erection still remained very rigid. An incision was made approximately 4mm distal to the coronal collar on the glans and dissected down to the corporal bodies. The corporal bodies were exposed bilaterally and they appeared very dusky; an ellipse of tissue was excised from the tunica albuginea from just above the tips of the corporal bodies bilaterally, resulting in immediate tumescence. Four weeks later, on follow-up outpatient visit, the patient was doing well and able to have spontaneous erections without problems. He is no longer treated with trazodone.

# Clubfoot

Clubfeet or congenital talipes equinovarus are classified as being positional or rigid (Fig. 30.1). Rigid abnormalities are either flexible or resistant. The incidence of clubfoot (CF) is 1/1000 livebirths in the United States but may be higher in certain ethnicities (i.e. Polynesian islanders). Males are twice as affected as females. There is bilateral involvement in 30-50% of cases. Parents of a child with clubfoot have a 10% chance of having another child with clubfoot [1]. The etiology of CF is unknown. Most infants have no identifiable genetic syndrome or extrinsic cause. Extrinsic causes include oligohydramnios, congenital concentric rings, and teratogenic agents. Pathophysiological theories include arrest of fetal development, defective cartilage production, changes in innervation leading to paresis, increased fibrous tissue in muscles and ligaments, abnormal tendon insertion, and possible prenatal polio-like condition; the latter is based on changes in the motor neuron of the anterior horn in the spinal cord [2].

On physical examination, the foot is supinated in the varus position and adducted. Dorsiflexion is limited. The navicular, cuboid, and anterior aspects of the calcaneus are displaced medially [3]. There are contractures of the medial plantar soft tissues. The heel is small and empty. The medial malleolus is difficult to palpate and is often

in contact with the navicular bone. The tibia is often internally rotated. The leg muscles are frequently atrophied, especially the peroneal muscle group. Although the number of muscle fibers is normal, they are smaller in size. The calf is often small and remains small even after successful correction of the lesion [4].

The goal of therapy is to correct the deformity early and maintain alignment of the foot until growth ceases [5]. The Pirani scoring system is used to identify the severity of the clubfoot and is based on the curvature of the lateral border, medial crease, uncovering of the lateral head of the talus, posterior crease, emptiness of the heel and degree of dorsiflexion [6]. Non-operative treatment (splinting and casting) begins 2-3 days after birth with forefoot adduction, followed by forefoot supination, and then correction of the equinus [7]. Gentle manipulation of the foot is needed to avoid producing a rocker-bottom foot. If splinting and casting are unsuccessful, surgery is indicated, usually at 6 months of age when the anatomy is more identifiable. In children younger than 5 years of age, soft tissue procedures are indicated. In children older than 5 years, bony reshaping or osteotomy of the calcaneum may be needed. Lateral wedge tarsectomy or triple fusion is required in children older than 10 years [8]. Complications of surgical correction are wound breakdown, infection, avascular necrosis, stiffness, and residual deformity.

Preoperatively, one looks for co-morbid conditions (e.g. arthrogryposis, myelomeningocele) that include cardiovascular, respiratory, hematological and neurological problems that have their own anesthetic implications. Although both general and regional anesthesia may be performed for clubfoot surgery, peripheral nerve blocks like posterior sciatic and femoral nerve blocks are generally avoided because the surgeons must examine the patient for postoperative neurological changes and for possible compartment syndrome with casting. While spinal and epidural anesthesia have been used for clubfoot surgery, there was no significant decrease in postoperative opiate use [9]. Tourniquets must be used cautiously in patients who have fragile bones. Postoperatively, pain is minimal and amenable to standard doses of narcotics and acetaminophen.

#### **Hip dysplasias/dislocations**

Hip dysplasia refers to a hip that can be dislocated from or relocated into the acetabulum. Hip dislocation describes a non-reducible hip that is associated with shortening, decreased abduction, and asymmetry of skinfolds. The normal hip joint consists of a femoral head and the acetabulum which develop from the same primitive mesenchymal cells. In the 11th week of fetal life, the hip joint is fully formed and may begin to dislocate if predisposed to do so [10]. Subluxation of the hip occurs in 1% of newborn infants. Patients with dysplasia or dislocation of the hip do not have the normal tight fit between the femoral head and the acetabulum. The majority of abnormalities in developmental hip dysplasia or dislocation are on the acetabular side. Acetabular shape is determined by 8 years of age in most children. Growth of the acetabulum is affected by abnormal acetabular cartilage which is influenced by several factors, including the presence of a spherical femoral head, interstitial growth within the acetabular head, appositional growth under the perichondrium, and growth of adjacent bones (ileum, ischium and pubis). The dysplastic hip has a ridge (the limbus) in the superior, posterior, and inferior aspects of the acetabulum that is made of cellular hyaline cartilage. The limbus is a hypertrophied labrum [11].

Increased risk for abnormalities of the hips is indicated by female gender, first born, breech delivery, oligohydramnios, a positive family history for hip dysplasia, persistent hip asymmetry, torticollis, and lower limb deformity. All newborns are now screened for hip dyslplasia and dislocation with the Ortolani and Barlow signs [12]. The Ortolani sign is positive when the hip is abducted, the trochanter is elevated, and the femoral head glides back into the acetabulum with a characteristic click. The Barlow sign is positive when the femoral head exits the acetabulum with the hip flexed and adducted. Ultrasonography helps to confirm the diagnosis and identify more subtle forms of dysplasia or dislocation. This should be performed in suspected cases at 4-6 weeks of age. If the diagnosis is missed at birth, there are four possible outcomes. The hip may become normal, subluxate or develop partial contact, completely dislocate or remain located in the hip with dysplastic features. Physical findings of late diagnosis include shortened limb, asymmetry of gluteal, thigh or labial skinfolds, and limited hip abduction. Patients with bilateral involvement have a waddling gait and hyperlordosis.

The Pavlik harness is the treatment of choice for infants and neonates with developmental hip dysplasia or dislocation. This device consists of a chest strap, shoulder straps, and anterior and posterior stirrup straps that maintain the hips in flexion and abduction while restricting extension and adduction [13] (Figs 30.2, 30.3).

Figure 30.2 Pavlik harness: posterior.

Figure 30.3 Pavlik harness: anterior.

Contraindications to the Pavlik harness include major muscle imbalance (e.g. myelomeningocele), major stiffness (e.g. arthrogryposis), ligamentous laxity (e.g. Ehlers– Danlos), patients older than 10 months of age, and lack of family support and care. The harness is worn until there are no positive findings on clinical, ultrasonographic or radiographic examinations. If the hip remains unstable with use of a Pavlik harness, a hip abduction brace is recommended. Complications of the harness include inferior dislocation, femoral nerve palsy, and avascular necrosis of the hip from excessive hip flexion [14]. An abduction orthotic is an alternative for infants who are more than 9 months of age. This maintains abduction while allowing the child to walk. Skin traction is recommended for older infants who have a dislocated hip and have failed to improve with a Pavlik harness or for children greater than 9 months old. Skin traction is followed by adductor tenotomy, closed reduction of the abnormality, and spica cast application (see below) [15]. Children greater than 2 years old are treated with primary femoral shortening, open reduction of the hip, capsulorrhaphy (suture of capsule tear in order to prevent dislocation) and pelvic osteotomy [16,17]. The decision to perform open reduction of the hip is made in the operating room after arthrography and failed closed hip reduction [18].

Preoperatively, it is important to identify co-morbid conditions or underlying bone pathology that may affect the overall anesthetic. Baseline laboratory studies, such as complete blood count, chemistry, and coagulation studies, are not necessary for healthy children but will help identify abnormalities if co-morbidity exists. Both general and regional anesthesia can be used during correction of hip pathology, if no contraindications exist. Spinal or epidural anesthesia may help with postoperative pain control in inpatients. If an epidural catheter is placed, care must be taken to cut a hole in the spica cast so that the catheter can be removed from the patient. While the child is being placed in a spica cast under anesthesia, care must be taken during cast application to insure that the arms are supported and head and neck are in alignment to prevent injury to major nerves. Postoperatively, oral pain medication can include acetaminophen, opioids, and short-term non-steroidal antiinflammatory drugs.

# **Spica cast**

Spica casts create stability and immobilize femoral fractures or hip abnormalities (Figs 30.4, 30.5). Contraindications to these devices include unacceptable shortening or angulation of the lower extremities, open fractures, thoracic or intra-abdominal trauma, and large or obese children [19]. Anesthesia is usually required to apply a spica cast. Fluoroscopy is used to determine optimal position, i.e. the affected limb or hip is placed in mild abduction. Too much abduction results in lateral bowing of the femur due to pull of adductors. The degree of hip flexion, hip adduction, and external rotation depends on the location of the femoral fracture or hip abnormality [20]. A folded towel is placed on the anterior thorax and abdomen and padding and casting material are placed over the towel. This creates space between the cast and the thorax/abdomen, allowing for free breathing after the towel is removed. Two layers of stockinette are

Figure 30.4 Spica cast table.

Figure 30.5 Spica cast: child on table.

placed to ensure that the cast padding can be pulled over the edges of the cast. Gore-tex<sup>™</sup> soft wrap is often applied prior to applying a thick felt belt across chest, sacrum, posterior superior iliac spine, and anterior superior iliac spine. The casting material is often placed over the nonaffected side for stability. A wooden stick is placed between both legs and covered in cast material. This reinforces the cast and prevents breakdown of the cast at the hip joint. In small children, spica casts are applied while the child is on a portable elevated narrow table that provides very little head support.

The goals of anesthesia during cast placement include hemodynamic stability, appropriate amnesia and analgesia, and safe positioning of the patient. The choice of anesthetic technique is dictated by the patient's health status and by any co-existing disease. With elevation of the patient off the operating room table, vigilance is required to assure that the upper extremities and neck are in alignment with the long axis of the body to prevent further nerve injury and paralysis.

#### **Blount disease**

Blount disease is a growth disorder of the medial aspect of the tibia in children. It causes the legs to bow outwards below the knees [21]. Normal infants have a small amount of physiological bowing that usually resolves by 2 years of age. In Blount disease the legs remain bowed, and the inner surface of the legs bulge outward just below the knee. A metaphyseal-diaphyseal angle greater than 11° is more indicative of Blount disease [21]. The toes also begin to point inwards as internal tibial rotation and asymmetrical leg shortening develop. Most patients are healthy, without congenital abnormalities, and may not experience much pain. If pain is present, it is usually related to the knee joints.

Blount disease usually affects children younger than 4 years old, in which case it is called infantile tibia vara. Adolescent tibia vara occurs after 4 years of age. Blount disease is more common in Africa, West Indies, and Finland. Sixty to 70% of cases are bilateral and symmetrical [22]. Risk factors for Blount disease include female sex, African-American race, obesity, early age at walking, and a positive family history for this problem. The cause of Blount disease is unknown but may be related to a combination of genetic, environmental, and mechanical factors [23]. The medial aspect of the growth plate fails to develop properly, while the lateral aspect grows normally. This results in deviated growth of the tibia. If untreated, the disease results in the onset of osteo-arthritis in the third decade of life. In the US, estimated prevalence of infantile Blount disease is less than 1% and adolescent disease is 2.5%. The disease is non-existent in nonambulatory people. Adolescent tibia varus differs from Blount disease in that patients with varus complain more about knee pain, have unilateral involvement in 80% of cases, have shortened leg length, and may be obese [24-26].

Under 2 years of age, observation of the patient and follow-up with an orthopedic surgeon are recommended to distinguish physiological bowing from abnormal bowing. If bowing persists during ages 2–4, orthotic braces from the top of the thigh to the tips of the toes are recommended [27]. In children with severe bowing or who are more than 4 years of age, osteotomies of the tibia and occasionally the fibulae are most commonly performed to correct the misalignment [28]. Other operative treatments include removing the epiphysis to stop abnormal growth or an osteotomy followed by external fixation [29,30]. If treated early, patients develop fully functioning lower limbs and have no limitations of movement. Complications of treatment include loss of alignment of lower extremities, vascular impairment, pathological fractures, and wound infection.

Preoperatively, the anesthetic implications of existing co-morbidities must be considered. Concurrent obesity may lead to airway difficulties, respiratory problems, obstructive sleep apnea, increased risk of aspiration, and difficulty inserting an intravenous catheter. A detailed history and directed physical examination are needed to identify any major organ or airway dysfunction. Intraoperatively, both general and regional anesthesia can be utilized if they are not contraindicated. Fat or venous air embolism must always be suspected if acute decompensation in the patient's condition occurs during surgery. Presenting symptoms of fat embolism under general anesthesia may include hypoxia, petechial rash, and hypotension. Presenting symptoms of venous air embolism under general anesthesia may include decreased end-tidal carbon dioxide and hypotension. Surgical blood loss is usually minimal. Postoperatively, it is important to perform a neurovascular examination to make sure that no important vascular or neural structures were damaged during corrective repair. Pain control is managed easily with intravenous patient-controlled analgesia (PCA) or oral medications, such as acetaminophen and narcotics.

## Slipped capital femoral epiphysis

Slipped capital femoral epiphysis (SCFE) consists of a defect of the proximal femoral growth plate, which causes instability of the femoral head. The femoral head is displaced posteriorly and inferiorly from the femoral neck. SCFE presents with hip, medial thigh, and knee pain. The range of motion of the hip is limited and causes a limp. The incidence of SCFE is 10.8/100,000 children. Higher rates of prevalence exist in males, African-Americans, Hispanics, and people who live in the west and north-east of the United States [31]. The average age of occurrence of SCFE is between 10 and 16 years. Twenty percent of patients have bilateral involvement. High-risk patients include those with obesity, hypothyroidism, low concentrations of growth hormone, pituitary tumors, craniopharyngioma, Down syndrome, renal osteodystrophy and adiposogenital syndrome [32-34]. The left hip is affected more commonly than the right. Familial involvement is present in 5-7% of patients with SCFE. In patients younger than 10 years of age, SCFE is associated with metabolic endocrine disorders. Unstable SCFE produces a non-ambulatory patient and has a higher risk of avascular necrosis [35]. On physical examination, internal rotation of the affected leg is very painful.

Emergency treatment is necessary. If surgical correction is performed within 24h of onset, the risk of avascular necrosis decreases. Immediate internal fixation with a screw is the treatment of choice [36]. Repair of SCFE permits early stabilization of slippage, prevention of further slippage, increased physeal closure and improvement of symptoms [37]. The fixation may require revision if the child outgrows the screw. Prophylactic fixation of unaffected hips should only occur if patients have endocrinological or metabolic conditions and are outside the usual age group of 10-16 years [38,39]. Osteotomy of the proximal femur may be required to reposition the femoral head and improve functional range of motion. Bone graft epiphysiodesis and internal fixation can be performed but may result in avascular necrosis, chondrolysis, poor initial fixation, prolonged operative time, increased intraoperative blood loss and loss of epiphyseal position [40].

Preoperatively, a thorough history and physical examination elucidate significant co-morbidities that may affect anesthetic technique. Given that obesity has a high association with SCFE, one must evaluate and prepare for an obstructed airway, restrictive lung disease, and a difficult airway. Some obese patients also have type 2 diabetes. In rare cases hypothyroidism and renal osteodystrophy may also be present. Preoperative studies should include baseline hematocrit, serum electrolytes, and a type and screen for blood.

Intraoperatively, the patient may be placed supine or in lateral position. During positioning of the patient, care must be taken to avoid nerve compression or injury, especially in obese patients. The Chick fracture table (Fig. 30.6) is often used and requires careful

Figure 30.6 Chick table.

padding and securing of the patient to the table. Access to the airway during surgery can be limited. Tracheal intubation is usually done prior to transfer to the fracture table.

The choice of anesthetic technique is influenced by the patient's baseline health status and co-morbidities. General anesthesia, in conjunction with regional anesthesia, may be performed if there are no contraindications to regional anesthesia. A one-time caudal injection of local anesthetic can be helpful; inserting caudal catheters is usually unnecessary. If the patient is obese or has a difficult airway, a modified rapid-sequence induction (RSI) may be considered. Third space fluid losses are usually 3–6mL/kg/h. Blood loss is typically minimal. Postoperative pain is usually controlled with opioids and acetaminophen. Short-term non-steroidal anti-inflammatory drugs may also be helpful and have not been shown to significantly affect epiphyseal growth.

#### Hand surgery

Many different types of disorders that require hand surgery exist in childhood (Box 30.1). These include, but are not limited to, extra fingers (polydactyly), webbed fingers (syndactyly), missing fingers (symbrachydactyly – hand or arm deficiency), abnormal thumbs, stiff joints, nerve and skeletal injuries [41,42]. The abnormalities range from mild to severe in their presentations. Given

Box 30.1 Hand malformations

- Cerebral palsy contractures
- Arthrogryposis contractures
- Juvenile arthritis
- Madelung's deformity malformed wrist bones
- Ulnar longitudinal deficiency
- Bite wounds
- Retained foreign objects
- Ganglion cysts
- Hemangiomas
- Lipomas
- Vascular malformations
- Amputations
- Crush injury
- Nailbed injury
- Mallet finger damage to extensor tendon
- Rugger jersey finger damage to flexor tendon
- Burn wound and scar management
- Polydactyly
- Symbrachydactyly
- Syndactyly

the complexity and variation of each deformity, only a few of them will be described in detail in this text. Although most hand malformations cause little functional deficit, surgery is usually performed within the first 2 years of life to improve growth and scarring, and reduce psychological trauma. Early surgery also improves adaptation to the use of the newly formed part [43].

Syndactyly surgery is performed after a child is 2 years old and growth of the hand has slowed [44]. Syndactyly is twice as common in boys as in girls and occurs in 1/2000 livebirths. It commonly affects the long and ring fingers [45]. Skin grafts may be required to close the defects caused by separation of the digits. About half of treated children return for surgery during adolescence for further cosmesis once the hand reaches full size [46]. Symbrachydactyly is a condition in which a child is born with small or missing fingers, a short forearm or a missing hand. It is the most common form of hand or arm deficiency [47]. The cause is unknown and is not attributed to genetic inheritance. It is usually unilateral; muscular abnormalities may be present on the ipsilateral side. Although surgery is often not required, it can help to deepen the webs between the fingers and to stabilize the fingers when bone grafts are used. Thumb polydactyly has varying forms, ranging from a broad fingernail to complete double thumbs [48]. Reconstructive surgery sometimes combines parts of the two different thumbs to create one functional thumb. Surgery is usually delayed until the thumb is large enough to allow the surgeon to reconstruct the nerves, ligaments, and bone.

Trigger thumb occurs when a nodule on the tendon causes the thumb to jump or lock into a bent position with movement. This condition develops after birth and is present at 1 year in 3.3/1000 livebirths. Hand surgeons must evaluate and treat this condition promptly to prevent contracture, but 30% of these lesions resolve spontaneously. Treatment involves surgery to enlarge the tendon sheath and allow the tendon to move more smoothly. This is performed usually between the ages of 1 and 3 years.

Radial club hand (RCH) is a deficiency of the radius in the forearm. It occurs 1/30,000–100,000 livebirths and includes absent or an incomplete radius, absent or incomplete thumb, deviation of wrist toward the radial side, and some degree of neuromuscular deficiency. The cause of RCH is unknown, but it has been suggested that irradiation or environmental and nutritional factors may be involved. Radial club hand may be associated with other genetic syndromes such as VACTER (V vertebrae, A anus, C cardiovascular, TE tracheo-esophageal fistula, R renal system), Holt–Oram syndrome (heart and hand syndrome), TAR (thrombocytopenia with absent radius) syndrome and Fanconi anemia [49]. Therefore a thorough investigation of other possible organ abnormalities must be undertaken. Treatment of radial club hand starts with splinting, casting, and non-surgical manipulation of the hand. If needed, surgery is typically performed between 6 months and 1 year of age. The procedure is called centralization/radialization of carpus on ulnar epiphysis, which relocates the hand over the ulna [50]. The affected limb is usually shorter than the contralateral limb after this repair. If too severe, a procedure can be done between 6 and 8 years of age to lengthen the extremity. If the thumb is absent or underdeveloped, the hand surgeon can also make the index finger into a thumb ("pollicization") to allow grasping.

Preoperative evaluation consists of gathering information about other possible co-morbidities and evaluating the child's maturity and social environment. All may affect the type of anesthesia chosen. For example, it must be determined if children with congenital hand deformities have associated heart, lung, kidney or airway problems that must be addressed. If there are vascular malformations of the hand, one must be suspicious that there are other vascular malformations (e.g. oropharyngeal) and that the child may have a high output state and heart failure. In trauma, full stomach aspiration risks need to be addressed. The child's maturity will also dictate whether a procedure should be performed with sedation or local anesthesia, with or without general anesthesia. If the surgery is elective or semi-urgent, laboratory tests should determine if anemia or coagulopathy is present. If other co-morbidities exist, an electrocardiogram and chest x-ray should be considered if indicated. A baseline neurovascular examination should be performed to evaluate sensation and perfusion to the affected hand. The findings of the examination should be documented in the anesthetic record.

Combined regional and general anesthesia has been shown to improve postoperative recovery and decrease the need for postoperative analgesics. Most children who undergo surgery require general anesthesia. Small cases, such as distal fingertip amputation, can be performed with local anesthesia and sedation if the child is co-operative. More extensive cases are amenable to using a combined regional and general anesthetic if there are no contraindications. Contraindications to peripheral blocks include hand infection, generalized sepsis, coagulopathy, predisposition to compartment syndrome, parental/child dissent, or the surgeon's need to perform an immediate postoperative examination of the extremity [51].

The nerve supply to the hand includes three major branches of the brachial plexus. The median nerve originates from the lateral and medial cords of the brachial plexus (C5–T1). It innervates the muscles involved in pinching and grasping (i.e. flexor carpi radialis, palmaris longus, flexor digitorum superficialis, flexor pollicis longus, flexor digitorum profundus, and pronator quadratus). It provides sensation to the lateral aspect of the palm, including the thenar eminence and the distal ends of the first three and a half fingers dorsally. The ulnar nerve originates from the medial cord of the brachial plexus (C8–T1). Motor branches innervate the flexor carpi ulnaris, flexor digitorum profundus, and the hypothenar muscles. This nerve provides sensation to the medial dorsal aspect of the hand and to the last one and a half fingers. The radial nerve originates from the posterior cord of the brachial plexus (C6–8) and innervates the wrist extensors and provides sensation to the lateral dorsal aspect of the hand and proximal portion of the first three and a half fingers.

Regional anesthetic techniques appropriate for hand surgery include Bier block (intravenous local anesthetic), axillary block (Fig. 30.7), infraclavicular block, wrist block, elbow block and digital block [51]. Of these, the infraclavicular block is best suited to catheter placement because the area is generally cleaner, and it is easier to secure the catheter. Intravenous regional anesthesia is useful in trauma patients who have a full stomach if the patient can be safely sedated. Regional anesthesia is relatively contraindicated in children less than 1 year old due to systemic local anesthetic toxicity. It may also be contraindicated in children susceptible to tourniquet injury (i.e. osteogenesis imperfecta). Most hand surgery requires use of a tourniquet, which is associated with hyper/ hypotension and respiratory and lactic acidosis from repeated inflation and deflation of the tourniquet. If not properly applied, tourniquets can lead to paralysis, sensory loss, excessive edema, skin problems and muscle damage.

Figure 30.7 This patient with thumb polydactyly is undergoing an axillary nerve block.

Postoperatively, it is important to determine if there are new or worse neurovascular deficits. Pain can be controlled with residual regional anesthetic, intravenous PCA and oral medication. Although not much is known regarding the long-term use of tramadol in children, some studies in healthy children suggest that it can be used safely for 7–30 days and provides good pain control. There was no significant increase in the incidence of sideeffects [52,53].

### Supracondylar femur fractures

A supracondylar fracture represents 12% of femoral fractures in children and is the most common cause of femur fracture in infants less than 1 year old, often due to child abuse [54]. Although the incidence is slightly less, it is still very common at ages 1–4 years. The American Academy of Orthopedic Surgeons recommends screening children younger than 36 months of age with femoral shaft fracture for child abuse. In adolescents, motor vehicle accidents (cars, bicycles) are the leading cause of femoral shaft fractures. Other causes of femoral shaft fracture include falling hard on the playground and contact sports. Fractures are described by location, shape of fractured ends, and number of fractured parts [55].

Non-surgical treatment of some femoral fractures includes closed reduction, a Pavlik harness or spica casting (see above) [56]. Pathological bone is often treated with closed methods, due to abnormal bone fragility. Closed reductions are often done under sedation, but the child may require general anesthesia if they are uncooperative or the defect is extreme. Pavlik harnesses are soft restraints that go around the patient's shoulders and body and hold the hips in a flexed position. Spica casts typically begin at or below the nipple line of the chest and extend to slightly beyond the fracture or defect [57]. They hold the broken bone in alignment while it heals. The broken bones should not overlap by more than 2 cm when in the cast. Increased growth of the damaged femur will overcome the initial shortening caused by the overlap [58]. If casting causes greater than 3 cm shortening or misalignment of the bones, traction may help to align the bones properly. Children who are older, large or obese and have multiple trauma, head injury, and/or soft tissue damage usually require operative fixation of the bones.

Recently, there has been a trend towards more surgical stabilization than in previous years, due to earlier mobilization, faster rehabilitation, and less time spent in hospital [59]. Flexible intramedullary nails are used in 6–10-year-old children [60]. If the bone is broken into many pieces (comminuted), other options include a plate

with screws to bridge the fracture, an external fixator, or prolonged traction with a temporary pin in the femur [61]. Once skeletal maturity is achieved (about 11 years of age), there is less risk of vascular compromise to the growth plate. Treatment options at this point include flexible or rigid locked intramedullary nails. Rigid locked intramedullary nails allow walking immediately. Most children with femoral shaft fractures will heal, regain normal function, and have legs of equal length. The intramedullary nails may need to be removed after healing if skin or tissue irritation occurs [62]. If there is significant leg length discrepancy, angulation or rotation of the leg, or if infection or non-union persist, further surgical intervention will be required [63].

Preoperatively, it is important to note the mechanism of injury, as this may provide clues to other associated injuries (i.e. neck or skull injury). Conditions associated with bone fragility require care in positioning the patient, care in the use of non-invasive versus invasive blood pressure monitoring, and care in the use of a tourniquet. In addition to thorough airway, respiratory, and cardiovascular examinations, it is important to perform and document a neurovascular examination that will provide the baseline for evaluating postoperative changes. A preoperative hematocrit and a type and cross-match of blood should be obtained because hemorrhage can occur into the thigh with femur fractures.

Intraoperatively, either general or regional anesthesia may be used to provide anesthesia. Spinal anesthesia works well in older, co-operative children if there are concerns for a full stomach or a difficult airway. Peripheral nerve blocks plus general anesthesia work well, but a thorough discussion with the surgeon should take place beforehand, as there is a high risk of compartment syndrome (which can be masked by a nerve block) and coagulopathy. Adequate intravenous access must be present for infusing fluid and blood products. Depending on the location of the fracture and the size of the patient, a tourniquet may be used to limit the amount of blood loss. The anesthesiologist must be prepared for the hemodynamic changes that are sometimes associated with using a tourniquet. Fat and venous air embolism from bone manipulation may also cause adverse hemodynamic effects. Postoperatively, patients are typically placed into casts to stabilize the fracture site. Narcotics and acetaminophen are usually adequate for pain control.

## Septic arthritis

Septic arthritis usually occurs in the first 3 years of life or during teenage years (gonoccocal infections). Septic arthritis is a true clinical emergency because it can have serious implications for future joint mobility and organ dysfunction [64]. Pain with passive motion is the most common finding on physical examination. Prior to the introduction of antibiotics, septic arthritis was often severely incapacitating and/or fatal [65]. Haemophilus influenzae type b (Hib) was previously the most common causative organism associated with septic arthritis but since the institution of Hib vaccination in the 1970s, Staphylococcus aureus is now the foremost culprit [66,67]. Other less common pathogens include Streptococcus species, Pseudomonas aeruginosa, pneumococci, Neisseria meningitidis, Escherichia coli, Klebsiella species, and Enterobacter. Newborns can acquire Neisseria gonorrhoeae from an infected birth canal. Kingella kingae, a fastidious aerobic gram-negative micro-organism, has rapidly become a formidable pathogen that is difficult to grow in culture but must be suspected and treated, if present, in children aged 3 and younger [68].

Septic arthritis may develop after a penetrating wound or from trauma, surgery or adjacent cellulitis. However, the most common cause is hematogenous spread from transient bacteremia. Usually in healthy individuals, the bacteremia is quickly eliminated by intrinsic immune defense mechanisms. In immunocompromised and extremely young patients (neonates), the defense mechanisms are too overwhelmed or immature to eliminate the infection. Developing pediatric bone has vascular loops that provide nutrients to the metaphyseal side of the growth plate. The blood supply to this area is relatively slow, and the growth plate is not well covered by the reticuloendothelial system. This leaves the area vulnerable to infection. From 0 to 18 months of age, an abscess in the metaphyseal area may spread into the epiphysis through blood vessels that cross the cartilaginous physis and enter the joint. Those blood vessels disappear after 18 months of age. An abscess in the metaphyseal area will only cause septic arthritis in the areas where the joint capsule is attached to the metaphyses, such as the hip, shoulder, ankle, and elbow joints [65].

Once in the joint, the pathogens and the counteracting leukocytes release proteolytic enzymes that degrade the articular cartilage. Damage can occur in as little as 8h. The synovial membrane becomes edematous and hypertrophied and produces increased amounts of exudative fluid and pus. Increased pressure within the joint can interrupt the blood supply to the epiphysis. This causes bone destruction, loss of adjacent growth plate, dislocated joints, and injury to the capsule ligament. Rupture of the synovium can lead to extracapsular infections, such as myositis, soft tissue abscesses and bacteremia.

Presenting symptoms that should make one suspicious of septic arthritis include fever, malaise, erythema, swelling, and tenderness of the joint. Pain with passive motion of the joint is the most common finding. As in the hip, the child will hold flexion, abduction, and external rotation to diminish pain and increase intracapsular volume. Refusal to move the affected joint is called pseudoparalysis, which can be mistaken for a neurological problem. Differential diagnosis of septic arthritis includes, but is not limited to, juvenile rheumatoid arthritis (more gradual onset), Legg-Calvé-Perthes disease (avascular necrosis of the proximal femoral head), Lyme disease, mycobacterial or fungal infections, abscess of the psoas muscle (presents with bladder irritability or a femoral nerve neuropraxia [69]), or transient synovitis from a selflimiting viral infection, mostly involving the hip [70]. A high index of suspicion must be present for neonates and immunocompromised patients, as they can have multiple sites affected without fever and without an elevated white blood cell count [71].

Septic arthritis is a true surgical and/or procedural emergency. Aspiration of the joint in the emergency room, interventional radiology suite or operating room must be accomplished quickly to insure prompt diagnosis and appropriate therapy. Typically these cases are completed within several hours of being scheduled. Frequently it is necessary to keep the child anesthetized while a gram stain and initial pathological evaluation of the aspirated fluid are performed. Treatment includes appropriate antibiotic therapy and drainage of the affected joint to prevent degradation of joint and bone. Open drainage of the joint is more effective than percutaneous aspiration and is indicated if the hip, shoulder, and peripheral joints fail to respond to percutaneous aspiration. Open drainage is also indicated for patients with systemic illness, Staphylococcus aureus and gram-negative bacteria that produce cartilage-destroying enzymes. Patients with pus in fascial layers have a high mortality rate as these pockets of infection can lead to venous thrombosis.

During the preoperative assessment it is important to find out if any co-morbidities exist. Hematogenous spread of bacteria can cause lung involvement that manifests as pleural effusion, pneumatoceles (lung abscesses), pneumothorax, wheezing, inflammation and edema-induced stridor. If respiratory symptoms present, a chest x-ray may help to identify the problem. Cardiac involvement includes pericardial effusion, myocarditis, endocarditis, and pericarditis, which can all limit cardiac function. An echocardiogram is recommended for patients with congenital defects, unresolved fever or prolonged bacteremia without a known source. Renal function may be affected through hematogenous spread of infection, decreased intravascular volume or medication-induced injury. Baseline laboratory studies and a coagulation profile are helpful as they can be adversely affected by infection. Chronically ill anemic patients may require blood transfusions. Platelets and coagulation factors may

be decreased. Disseminated intravascular coagulation is a major complication of dispersed infection so blood products should be available prior to surgery and administered if needed. Adequate venous access must be available for giving volume support, blood products, and inotropes if necessary.

Shoulder or neck septic arthritis may cause cervical ligamentous laxity that can cause C1-2 subluxation during tracheal intubation. Intravascular volume must be repleted prior to induction of anesthesia to avoid hypotension. Chronic illness-induced decreased concentrations of intrinsic catecholamines may also cause acute decompensation of vital signs with induction of anesthesia. Intraoperative manipulation of the infected joint during surgery may release pathogens and their toxins into the bloodstream and produce acute hemodynamic changes. General anesthesia is typically required for these types of surgeries because regional anesthesia may obscure a possible compartment syndrome or lead to a new infectious point of entry/spread or a hematoma if coagulation abnormalities exist. Although positive pressure ventilation may predispose to pneumothorax and decreased venous return, it is still preferred over spontaneous ventilation, which may be associated with breath holding, laryngospasm, and bronchospasm.

Choice of anesthetic drugs can vary. Ketamine should be avoided for induction of anesthesia if catecholamine stores are depleted or are suspected to be depleted, as this can cause hypotension after induction of anesthesia. Succinylcholine should also be avoided if renal dysfunction and chronic illness exist because hyperkalemia can lead to significant injury and/or death.

Postoperatively most patients improve quickly after drainage and removal of infectious material. Fluid, blood products and inotropes should be continued if needed. Pain is controlled with narcotics and acetaminophen. NSAIDS are avoided when renal dysfunction or abnormal coagulation status is present. Although chronic NSAID use has been suggested to inhibit osteogenesis, new evidence indicates that perioperative use of these drugs for 48h use may not significantly affect osteoblasts and bone formation. This should be addressed with the surgeon on a case-by-case basis.

### Osteogenesis imperfecta

Osteogenesis imperfecta (OI), also called brittle bone disease, blue sclera syndrome, fragile bone disease, and Lobstein disease, is a relatively common skeletal dysplasia (Fig. 30.8). It has long been documented in human history and was found in a partially mummified infant's skeleton from Egypt. Oral historians believe that a Viking

chieftain named Ivan the Boneless (865 AD) may also have had the disease.

Osteogenesis imperfecta is most commonly identified by three characteristics: blue sclerae, bone fragility, and hearing loss. Less common symptoms include triangular facies, macrocephaly, defective dentition, barrel chest, scoliosis, joint laxity, growth retardation, constipation, and sweating. Type 1 collagen is an important component of bone, ligament, dentin, and sclera. In OI, there is a decrease in either quality or quantity of type 1 collagen. Most cases of OI are autosomal dominant mutations of the genes encoding type 1 collagen [72]. Quantitative defects typically cause mild clinical disease, while qualitative defects cause severe clinical disease.

Osteogenesis imperfecta (types 1–4) occurs in 1/20,000 births. There is no predilection for OI by race, gender or age. More severe forms present at a younger age [73]. Types I and IV have milder clinical presentations, while types II and III are more severe.

- Type I presents with blue sclera, normal birthweight, moderate bone deformity, and variable degrees of bone fragility. Fractures occur when the child begins to walk and diminish after puberty. Twenty percent have scoliosis, and some may have dentinogenesis imperfecta.
- Type II presents with dwarfism, blue sclera, and bowed limbs at birth. Multiple fractures exist at birth, and the disease is usually fatal during or shortly after birth.

Figure 30.8 Child with osteogenesis imperfecta. Note abnormal chest and extremities.

- Type III presents with severe fragility and bone fractures at birth and frequently requires orthopedic surgery. Blue sclerae become white in adulthood. Dentinogenesis imperfecta is common. The chest and rib cage are spared from involvement in this type of OI. Children usually have bowed limbs and are wheelchair bound and non-ambulatory. They are often of short stature and have a mild pectus carinatum.
- Type IV presents with white sclerae. Patients have moderate bone fragility. Kyphoscoliosis is common.

Recently bisphosphonates have been used to increase bone mass and strength. Intravenous pamidronate, a synthetic analog of pyrophosphate, inhibits osteoclastmediated bone resorption on the endosteal surface of bone by binding to hydroxyapatite. This allows unopposed osteoblastic new bone formation on the periosteal surface and increases cortical bone thickness. Bisphosphonates decrease the number of fractures by increasing bone mineral density [74]. This decreases bone pain and increases height. Physiotherapy, in conjunction with bisphosphonate therapy, promotes gross motor development and maximizes function. Adverse effects of bisphosphonate therapy include acute febrile reaction, leukopenia, a transient increase in bone pain, mild hypocalcemia, and scleritis. Other medical therapies under investigation include growth hormone, a recombinant human form of parathyroid hormone, bone marrow transplantation, and gene therapy.

Orthopedic goals for osteogenesis imperfecta include improving strength and preventing fractures. The aim of surgical intervention is to improve function [75]. Release of lower limb contractures improves mobility. Bony deformities and fractures are treated with intramedullary stabilization with or without corrective osteotomies [76]. Rods, pins, and wires are preferable to nails, plates, and screws as the former are less frequently associated with bone fractures. Complications of rods include breakage, rotational deformities, and migration. With the use of bisphosphonates, non-extendable rods are being used more often than extendable rods [77]. Posterior spinal arthrodesis is preferable to ineffective bracing for scoliosis. Arthrodesis is done in mild OI patients with greater than 45° curvature or in severe OI with greater than 35° curvature.

Preoperatively, it is important to identify the type of OI and the severity of clinical symptoms. Often the patient has required previous medical care. Lung function may be restricted due to chest wall deformities. A chest x-ray and pulmonary function tests, although not required, may help predict postoperative respiratory failure. Airway examination includes neck mobility, dentition, and mouth opening, as there may be a high likelihood of difficult tracheal intubation due to a short neck, macrocephaly, macroglossia, and fragile dentition. Ventral brainstem compression by an invaginating clivusodontoid complex may further make tracheal intubation difficult. Therefore, evaluation of the patient for symptoms of upper cervical cord compression and x-rays of the craniovertebral junction may help prevent injury. Cardiovascular abnormalities, although not significantly increased in comparison to healthy individuals, are usually related (when present) to aortic insufficiency caused by aortic root dilation. If a murmur is present or suspicion of aortic insufficiency is high, echocardiography is indicated. Patients with OI do have an increased risk for bleeding diathesis. The abnormal collagen on platelet-endothelial cell interaction results in increased capillary fragility, defective contraction of small blood vessels, and defective platelet aggregation. Typical coagulation studies (prothrombin time (PT) and partial thromboplastin time (PTT)) will be normal but platelet function will be abnormal. Patients at risk should avoid nonsteroidal anti-inflammatory drugs for at least 7 days preoperatively.

Intraoperatively, care must be taken to position and pad the patient so no further fractures occur. Non-invasive blood pressure monitoring may cause fractures [78] so less frequent monitoring or invasive arterial blood pressure monitoring is preferred. Tourniquets may produce fractures and should be placed on top of a soft material such as Kerlex or Coban. Facemasks may damage fragile mandibles and maxillae. Laryngeal mask airways have been used successfully in lieu of facemasks to prevent facial fractures. Tooth guards are used when patients have fragile dentition. The increased incidence of difficult tracheal intubation warrants having a wide variety of airway equipment immediately available, including multiple sizes of tracheal tubes, multiple laryngoscope blades, gum elastic bougies, laryngeal mask airways, video laryngoscopy, and fiber-optic laryngoscopes.

Hyperthermia and lactic acidosis have occurred in patients with OI, possibly from an increased metabolic rate or associated hyperthyroidism, but not from malignant hyperthermia. There is no respiratory acidosis or muscular rigidity with OI. Hyperthermia is more often associated with the administration of anticholinergic drugs and with inhaled anesthetics. A cooling blanket should be used to treat hyperthermia. Succinylcholine is avoided due to the theoretical risk of fasciculationinduced fractures.

Postoperatively, patients may also have febrile responses from the increased metabolic rate or hyperthyroidism. Because these patients suffer from chronic pain, they should be treated with their baseline narcotic plus adjuvant pain medications, as needed. The patient's respiratory status should be carefully evaluated postoperatively to detect obstruction that is caused by residual anesthesia or by decreased hypercapneic-hypoxic respiratory drive from restrictive lung disease. Caution must be exercised during transfer from one bed to another to prevent additional fractures occurring.

### Arthrogryposis

Arthrogryposis multiplex congenita presents at birth with multiple contractures throughout the body. It is present in 1/3000 livebirths and is more common in isolated populations such as Finland and the Bedouin community in Israel [79]. Males and females are affected equally. Thirty percent of cases have a genetic abnormality [80].

The major cause of arthrogryposis is fetal akinesia (decreased fetal movement in utero) [81]. The etiologies of arthrogryposis are many and include neurogenic, muscular, connective tissue abnormalities, mechanical limitations or maternal factors such as infection, drugs, trauma, and other illnesses. Malformations of the central and peripheral nervous systems are the most common cause of arthrogryposis [82]. Decreased fetal movement can also cause polyhydramnios, pulmonary hypoplasia, micrognathia, ocular hypertelorism and short umbilical cord. Lack of fetal movement results in the development of extra connective tissue around the joints, which limits joint movement and fixes it in a contracted state [83]. Half of patients with associated CNS abnormalities die within the first year. Infants born to mothers with myotonic dystrophy, myasthenia gravis or multiple sclerosis are at high risk for developing resistant contractures. Exposure of mothers to hyperthermia, such as hot tubs or prolonged hot baths, can cause abnormal nerve growth and decreased fetal movement.

Patients with arthrogryposis have cylindrical extremities, decreased subcutaneous tissue, and absent skin creases. Defects are symmetrical and are more severe distally in the hands and feet. Joint dislocation may occur in the hips and knees [84]. Sensation is present but deep tendon reflexes may be decreased or absent. Limb malformations include deletion anomalies, radio-ulnar synostosis, syndactyly and short digits. Deformities associated with fetal akinesia include intrauterine growth retardation, pulmonary hypoplasia, short gut syndrome, scoliosis, genital deformities, and hernias (both inguinal and umbilical). Congenital cardiac anomalies and cardiomyopathy may be present. The genitourinary system may have structural abnormalities. Musculoskeletal abnormalities include decreased muscle mass, soft muscle texture, fibrous bands, and abnormal tendon attachments. The skin is often soft, doughy and thick with webs and dimples over affected joints.

Goals of treatment for arthrogryposis are lower limb alignment, stability for ambulation, and upper limb function for self-care [85]. Early gentle manipulation of the contractures after birth helps passive and active range of motion [86]. Physical therapy is indicated for most forms of arthrogryposis but recurrence of the contractures can be high following stretching, necessitating surgery. Soft tissue surgery should be undertaken early and osteotomies performed when growth plates have fused. The most common deformity in the foot is a rigid talipes equinovarus deformity. The goal is to make the foot plantigrade and braceable. Casting often fails early on and typically the patient has to undergo an extensive medial and lateral release of ankle tendons with postoperative bracing. Recurrence of talipes equinovarus is common and other procedures, such as lateral column shortening (distal calcaneal resection), may be required. In an older child in whom the bone is skeletally mature, a triple arthrodesis (fusion of talocalcaneal and talonavicular and calcaneocuboid joints) is performed. In the knees, flexion deformities are more common than fixed knee deformities and are more resistant to treatment. Moderate contractures of between 20 and 60° require soft tissue release with posterior capsulotomies. Severe contractures of greater than 60° may require femoral shortening in addition to soft tissue release. Older children with severe deformity may require a knee disarticulation. Extension deformities, if unresponsive to physical therapy, will need quadricepsplasty if the child is younger than 6 months of age.

Hip deformities should be addressed after foot and knee deformities have been corrected [87]. Intervention to improve the hip should take place before 1 year of age to make ambulation easier. Hip flexion greater than 35° requires soft tissue release. Bilateral hip dislocations that exceed 35° and the presence of a flexion contracture should be treated with soft tissue release but no reduction [88]. Unilateral hip dislocation requires reduction to avoid the development of scoliosis and pelvic deformity. Upper extremity surgery should be done when the patient is older than 5-6 years. With elbow contractures, the goal is to make possible arm flexion for feeding and extension for hygiene needs. Extension is corrected with either a capsulotomy or capsulotomy plus triceps or pectoralis major transfer. Wrist deformities are usually flexed with ulnar deviation [89]. A severe deformity requires proximal row carpectomy with or without fusion. For severe finger deformities, soft tissue releases and proximal interphalangeal fusions are done. In scoliotic spines, curvatures greater than 35° are treated with spinal fusion.

Preoperatively, any co-morbid conditions that would affect an anesthetic must be identified.

 Cardiac function must be evaluated because congenital abnormalities and cardiomyopathy may be present.

- Respiratory function must also be evaluated as scoliosis may restrict lung function. A weak or hypoplastic diaphragm will also decrease lung function.
- Craniofacial deformities include limited jaw motion, flat nasal bridge, hemangioma, micrognathia, small eyes, corneal opacities, craniosynostosis, and high cleft palate.
- Laryngeal and tracheal clefts/stenoses, as well as hemangiomas, must be detected beforehand because they may cause difficulty with tracheal intubation. A thorough airway examination is required because some patients have limited jaw opening and micrognathia.
- Skin can be doughy and thick, making IV access difficult. Cold and blue distal limbs can be evidence of abnormal skin vasculature.
- There may be vertebral instability secondary to decreased muscle mass and high cervical hypoplasia.
- Renal abnormalities may affect anesthetic drugs that are metabolized or excreted by the kidneys. Structural abnormalities of the genitourinary system may be present.
- Neuromuscular junctions will have upregulation due to decreased muscle mass and increased sensitivity to non-depolarizing medications and a hyperkalemic response to succinylcholine.

Intraoperatively, care with positioning and tourniquet use is needed, as these children have osseous hypoplasia and are prone to fractures. Intraoperative hyperthermia is usually caused by hypermetabolism, not malignant hyperthermia unless there is an underlying predisposing neuromuscular disorder like King–Denborough. Hyperthermia occurs regardless of the type of anesthetic used. A cooling blanket should always be available. A wide array of laryngosopes, tracheal tubes, laryngeal mask airways, video laryngoscopy, and fiber-optic scopes should readily available, given the high likelihood of difficult intubation.

Choice of anesthetic agent depends on co-morbid conditions. Ventilation may be affected by scoliosis-induced restrictive lung disease. Pneumothorax, either spontaneous or mechanical ventilation induced, may be the result of pulmonary hypoplasia. Postoperatively, there is an increased risk of aspiration when the cause of arthrogryposis is neurogenic or muscular. Therefore, full return of baseline neuromuscular function and ability to protect the airway before emergence from anesthesia and tracheal extubation is required. Patients will be in casts postoperatively for approximately 6 weeks. Preoperative pain medication should be continued into the postoperative period and enough pain medication added to treat surgical pain. This helps prevent narcotic withdrawal and a wind-up phenomenon.

## **Cerebral palsy**

Cerebral palsy (CP) describes the movement and posture disorder that is the result of a motor deficit caused by brain injury *in utero*, at birth or postnatally. It is present in approximately 2 per 1000 births [90]. The clinical features of CP are classified by the number of extremities with motor deficits (mono-, di-, tri- or quadri-). Involvement of one side of the body is hemiparesis. Spastic quadriparesis is the most common form of CP, requiring multiple surgeries. The causes of CP are many, but the exact etiology is often difficult to define in any given infant. The functional limitations from paresis include hypotonia or hypertonia and occasionally extrapyramidal symptoms. Function can frequently be improved by multiple surgical procedures that address the extremities. Surgeries to straighten the spine help maintain posture and lung volumes. Anesthesia is often required to inject medications to treat spasticity and contractures (e.g. botulinium toxin-A or baclofen) [91].

Preoperative assessment and medical optimization should occur ahead of the surgery, since the majority of surgeries are elective.

Anesthetic challenges include appropriate communication with children who can have either normal cognitive abilities or severe developmental delay. A particularly challenging group of CP patients are cognitively intact, non-verbal patients. Patients with hypotonic CP often have the most severe developmental delay. Preoperative discussions with the family should include estimation of the child's developmental level and the best means of communicating with them. Ideally a pain scale is identified that will be used postoperatively so the child and family can become familiar with its use.

Patients with CP may also have epilepsy. Their scheduled antiepileptic drugs are administered, despite preoperative fasting. A history of recent seizure patterns and frequency is obtained. Many of the antiseizure medications affect P450 degradation pathways. Drugs utilizing these pathways for elimination (e.g. non-depolarizing neuromuscular relaxants) will benefit from train-of-four monitoring and more frequent dosing to achieve the desired effects [92].

Pulmonary pathology includes the usual incidence of childhood diseases (e.g. reactive airway disease), and they may be exacerbated by anatomically scoliosisinduced restricted airways. Feeding discoordination increases the risk of aspiration and recurrent respiratory infections. Gastroesophageal reflux is common, difficult to control medically, and often requires fundoplication. Respiratory muscle strength may also be compromised.

Poor oropharyngeal function often causes excessive drooling. This is controlled with antisialogogs or salivary gland surgery. Premedication with glycopyrrolate facilitates tracheal intubation and decreases pooling of secretions intraoperatively.

Patients with severe CP may be chronically underhydrated, since most of them are tube fed and empirically hydrated. Preoperative rehydration may be required. Complete blood count (CBC) and coagulation studies are indicated for potentially bloody procedures because there is an increased incidence of prolonged PT/PTT in this patient group.

Scoliosis surgery is covered in Chapter 26. Other orthopedic procedures often required include extremity surgeries to address contractures and gait abnormalities. Historically these have been done serially as the child grows and movement is evaluated. Some centers are now undertaking elaborate gait and movement studies preoperatively to plan and perform a single operation that addresses multiple extremities simultaneously. The advantage of doing this is that the child can be mobilized more quickly and there is one recovery process instead of several. An important component of this approach is close co-ordination with a pediatric acute pain service to optimize pain management postoperatively, often with regional analgesia.

Clubfoot and hip dislocations are common acquired deformities in CP and often require surgery. They are described in detail above. Heel cord lengthening, adductor myotomy, and hamstring lengthening are the most common surgeries needed.

For clubfoot, the foot is rotated inward, the back of the heel is moved up, and the forefoot deviates medially. During the newborn period the heel cord is cut under local anesthesia and is serially casted. For surgical correction of clubfoot, general anesthesia, with or without caudal block, is usually used. Acquired clubfoot is the result of the paralysis associated with CP.

Contracture releases are performed to facilitate patient comfort, positioning, and mobility. Ober fasciotomy is done for flexion at the hip that is abducted and externally rotated (frog leg in appearance). Incision is anterolateral and just distal to the iliac crest. The fascial attachments are loosened to obtain neutral extension.

The iliotibial (IT) band may be tight, causing flexion of the knee. In the Yount procedure, a distal midlateral longitudinal incision is made above the knee, and a segment of the IT band and lateral intermuscular septum is removed and not repaired.

Tendon lengthening/transfer is done to release contractures. Tendon transfers are done to change the direction of muscle force to compensate for paralysis or paresis of muscle groups.

Intraoperative considerations for CP include maintaining warmth, since these patients tend to be hypothermic. Using warm blankets and forced-air warming devices in the preoperative area facilitates venous cannulation. Non-depolarizing neuromuscular relaxants are less potent in patients with CP, with or without the presence of chronic anticonvulsants. Contractures present positioning problems and make vessel cannulation difficult.

The use of succinvlcholine is controversial and best avoided in CP patients. There are anecdotal reports of succinylcholine-induced cardiac arrest in CP patients [93]. Moreover, Theroux et al reported increased sensitivity of CP patients to succinvlcholine due to CP patients having a lower effective dose (ED50) [94]. The relative immobility of CP patients may also upregulate their acetylcholine receptors [95]. However, Dierdorf did report normal plasma potassium concentrations before and after succinvlcholine administration in CP patients as well as normal controls [93]. Muscle biopsies demonstrate variable neuromuscular junctions in CP patients undergoing spinal fusion, with about 30% of them having abnormal apposition of the acetylcholine receptor compared to normal control patients undergoing spinal fusion [96]. When the risk for aspiration is increased, sufficient rocuronium can be used to safely allow a modified RSI of anesthesia and tracheal intubation considering the potential risk of hyperkalemia.

Postoperative concerns include resumption of all preoperative medications, with close attention paid to the dosing of antiseizure medication and to spasticity regimens. Serum drug levels may be indicated if medications were discontinued for a prolonged period. Postoperative spasms can be painful and may require acute and chronic pharmacological therapy. Current oral regimens include diazepam, baclofen, tizanidine, and dantrolene. Intrathecal pumps are used to deliver baclofen for chronic spasticity. Baclofen overdosing or underdosing can be life threatening, particularly with abrupt withdrawal of the drug. Regional anesthesia supplementation decreases spasms in some instances.

### Neuromuscular diseases

Perhaps one of the most common dilemmas in pediatric anesthesia is the anesthetic choice for a patient with neuromuscular disease, including those with hypotonia of unknown etiology [97]. The potential for anesthethic complications, based on choice of anesthetic technique, is present and yet the recommendations are still varied and controversial. Each technique carries its own risk profile. Furthermore, regardless of anesthetic technique, these patients have a higher incidence of cardiomyopathy and arrhythmias from disease effects on the heart muscle. Respiratory function can also be compromised, due to both decreased respiratory muscle strength and to restrictive function associated with advanced spine and rib cage deformity induced by the diseases. Neuromuscular diseases can be divided into muscular dystrophy (progressive and congenital), developmental myopathy, and metabolic myopathy.

# Progressive muscular dystrophies (Duchenne and Becker)

Progressive muscular dystrophies include the dystrophinopathies (absent or deficient dystrophin such as Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD)), limb girdle muscular dystrophies, fascio-scapulo-humeral muscular dystrophy, and oculopharyngeal muscular dystrophy. Most expert opinions now agree that there is not an increased risk of malignant hyperthermia (MH), but life-threatening rhabdomyolysis (RHA) can occur. Frail muscle membranes break down with exposure to halogenated volatile agents. Thus, in clinical practice many providers still choose to deliver a trigger-free anesthetic (i.e. avoidance of succinylcholine and volatile anesthetics). The risk of RHA is highest in young children with more muscle mass. As the child ages and the disease progresses, muscle mass decreases and is replaced with fibrosis. An elevated creatine kinase (CK) is common in this group of patients.

Duchenne muscular dystrophy (DMD) usually presents as a toddler or early school-age boy with delayed walking or global motor delay. The incidence is approximately 30 per 100,000 births [98]. They have progressive lower extremity weakness, pseudohypertrophy of the calves, and markedly elevated CK levels. A waddling gait and proximal muscle weakness are hallmark signs. Gower sign is common and describes the process of using the arms to rise from the floor. Approximately one-third will develop cardiomyopathy and or arrhythmias by 14–18 years of age, and cardiac disease does not necessarily follow the severity of skeletal muscle disease. Patients typically die in mid-adulthood from either cardiomyopathy or ventilatory failure.

Becker muscular dystrophy (BMD) is similar to DMD in its clinical presentation but presents in the adolescent years and progresses more slowly, due to a partial loss of dystrophin. It is less common, with an incidence of 3–6 per 100,000 births. Cardiomyopathy generally presents about age 30 with most patients surviving to 30–60 years of age.

Anesthetic risks for progressive muscular dystrophy, in addition to succinylcholine-induced hyperkalemia and RHA, are related to the degree of cardiac and respiratory compromise. Preoperative preparation includes an annual cardiac assessment for cardiomyopathy and/or arrhythmias and pulmonary function tests. Cardiac condition should be medically optimized prior to anesthesia and surgery. Postoperative planning should include longer observation times after surgery and the possible need for ventilatory assistance in an intensive care setting.

#### **Congenital muscular dystrophies**

These are characterized by early infancy presentation and slow progression that are sometimes associated with CNS anomalies. The incidence is only about 4 per 100,000 births; thus much less is known and/or written about preferred anesthesia techniques for patients with congenital muscular dystrophy. Creatine kinase levels are usually elevated. There is a case report of an undiagnosed hypermetabolic response with volatile agent use and a report of rhabdomyolysis.

# Congenital myopathies (central core disease and core-rod myopathies)

These infants primarily have contractures with decreased muscle strength; diagnosis is based on the histology of a muscle biopsy. The CK level is normal or only mildly increased, and the disease progresses slowly. Central core disease and core-rod myopathy patients are at high risk for MH. Other congenital myopathy patients have milder or no association with MH. However, given the difficulty for the anesthesiologist to track down and interpret specific genetic testing, a trigger-free anesthetic is prudent in the known or suspected congenital myopathy patient.

#### **Myotonias**

There are several variants, both autosomal dominant and recessive, and they are divided into dystrophic and non-dystrophic forms. Myotonia congenita is a nondystrophic form. The primary symptom for all myotonia patients is impaired muscle relaxation following sudden contraction. Succinylcholine can result in total-body sustained contraction and/or masseter muscle rigidity and should be avoided. Anticholinesterase drugs have also been reported to cause sustained contraction so careful titration of short-acting non-depolarizing muscle relaxant is advised only when clinically necessary. Halogenated agents have been used safely in these patients, but there are also some case reports of hypermetabolic reactions.

### **King–Denborough syndrome**

This rare autosomal dominant disease has a high association with MH, so succinylcholine and halogenated agents are avoided. Muscle disease is non-specific and mild. These patients are characterized by short stature, pectus carinatum, kyphosis, cleft palate, low-set ears, ptosis, down-slanting palpebral fissures, and delayed motor development.

# Metabolic myopathy (mitochondrial and carnitine disorders)

Mitochondrial diseases interact either with the energy supply to the muscle (ATP synthesis) or with ion channels involved in the process of contraction and relaxation. These patients develop progressive dysfunction in organs with high-energy requirements such as brain and muscle. All anesthetic agents interfere with mitochondrial function so there is no ideal anesthetic for these patients. However, many anesthetics have been conducted safely with all anesthetic agents. There is increasing evidence that propofol infusion syndrome (PRIS) results from mitochondrial dysfunction and thus propofol should be avoided or used cautiously [99] in patients with mitochondrial disease. These patients do not have a clear genetic or clinical association with MH, though there are two case reports of possible MH [100,101]. One suggested anesthetic technique is to use ketamine and a low-dose volatile agent and avoid using propofol. Dexmedetomidine can also be added as another adjuvant agent when titrated carefully with prolonged postoperative observation. Ketamine, midazolam and dexmedetomidine used together for muscle biopsies can be titrated to a depth sufficient to allow muscle biopsy without volatile agent.

Carnitine deficiency or any problem with its transport makes patients dependent on glucose for energy needs. The most common of these rare disorders is carnitinepalmitoyl transferase II deficiency that also has been associated with RHA following stress, exercise or anesthesia. There is one case report of MH.

Other forms of metabolic myopathy include potassiumrelated periodic paralysis, glycogenoses, and lipid myopathies.

#### Undiagnosed hypotonia

Clinical experience and a recent retrospective study suggest that a cerebral cause for hypotonia is far more frequent than a peripheral neuromuscular cause in a neonate or infant with undiagnosed hypotonia who is presenting for muscle biopsy [102,103]. Since many infants/small children who present for muscle biopsy are not diagnosed, the best anesthetic choice is difficult to determine [104,105]. Taking a careful family history and reviewing genetic or neurological consultations, as well as lab results, are critical. An elevated CK may represent the presence of an undiagnosed progressive muscular dystrophy, such as DMD or BMD. A recent review article recommends that all children with motor delay and who are not walking at 18 months of age should undergo neurological evaluation and/or genetic evaluation prior to elective general anesthesia or sedation [106]. An elevated serum lactate concentration may be indicative of metabolic myopathies such as mitochondrial diseases. Discussion with the infant or child's pediatrician or neurologist, in addition to obtaining CK and lactate levels, may help elucidate a more exact clinical suspicion or diagnosis to help guide anesthetic planning for diagnostic examinations and elective surgeries.

# Anesthetic complications associated with neuromuscular diseases (Box 30.2)

- Succinylcholine-induced hyperkalemic cardiac arrest following succinylcholine administration to patients who have neuromuscular disease still occurs despite the FDA black box warning initiated in 1992. The hyperkalemic response is proportional to the upregulation of the nicotinic acetylcholine receptors (AChRs). Pretreatment with a non-depolarizing neuromuscular relaxant does not prevent succinylcholine-induced hyperkalemia. Thus succinylcholine is avoided for any patient with a known condition associated with upregulation and patients who have weakness and/or hypotonia without a diagnosis.
- Acute RHA occurs due to the breakdown of the muscle surface membrane and causes the release of myoglobin, potassium, and CK. This can be life threatening and difficult to differentiate from malignant hyperthermia.
- Hypermetabolic response with unexplained fever can mimic MH but is distinguished by the absence of acidosis and the presence of a normal CK. This condition has been described during anesthesia in both primary

**Box 30.2** Severe anesthetic complications associated with neuromuscular and orthopedic diseases

#### Succinylcholine-induced hyperkalemic cardiac arrest (upregulation of nAChR)

- muscular dystrophy
- acute burn patients
- denervation
- muscle atrophy

#### Neuromuscular conditions associated with rhabdomyolysis

- Duchenne and Becker muscular dystrophies
- dystrophinopathies (absent or deficient)

# Hypermetabolic response with unexplained fever but no acidosis or increase in CK

- Duchenne muscular dystrophy
- osteogenesis imperfecta
- arthrogryposis

#### Neuromuscular diseases highly associated with MH

- central core disease (and core-rod myopathies)
- King–Denborough

neuromuscular conditions and orthopedic syndromes such as osteogenesis imperfecta and arthrogryposis.

• Malignant hyperthermia (see Chapter 40) has been associated with most neuromuscular diseases but most experts now classify only central core disease and King–Denborough as being high risk for MH.

### Juvenile rheumatoid arthritis

Juvenile rheumatoid arthritis (JRA) (also known as Still disease) is diagnosed approximately three times per 100,000 children under the age of 15, and approximately 70% of these patients are female [107]. In addition to the usual childhood surgeries, JRA patients require general anesthesia for surgery on multiple affected joints as well as diagnostic examinations. Intra-articular corticosteroid injection in very young children may also require general anesthesia.

The usual age for presentation of JRA is 2–4 years of age. It is a systemic condition that is characterized by fever, rash, joint redness, leukocytosis, and increased erythrocyte sedimentation rate. It affects collagen and the connective tissues of joints and organs. About 36% of JRA patients have cardiac involvement, with pericarditis being the most common cardiovascular presentation. Severe disease may also include splenomegaly, lymphadenitis, and polyarthritis. JRA is an autoimmune disease that causes deposition of autoantibodies (antinuclear antibodies (ANA) and rheumatoid factor (RF)) in the affected joints. Reactive lysosomal enzymes are released and ultimately damage the joints.

Preoperative preparation includes careful assessment of the airway with regard to neck and jaw mobility because temporomandibular ankylosis, mandibular hypoplasia, and cricoarytenoid arthritis can be present. Fiber-optic intubation of the trachea may be indicated. JRA patients may have atlantoaxial or low cervical subluxation, so extension of the neck should be limited or avoided. Anemia is also common. Children may be on multiple medical therapies, including steroids, nonsteroidal anti-inflammatory drugs, and methotrexate.

Postoperative analgesia can be challenging due to the pre-existing chronic pain. Continuous regional anesthesia has been used to provide acute pain relief for larger surgeries, such as hip arthroplasty.

# Genetic syndromes and orthopedic surgery

There are many syndromes with accompanying orthopedic problems. Table 30.1 contains a listing of these syndromes. The reader is referred to Chapter 38 for a discussion of the anesthetic approach to patients with these conditions.

(Continued)

Table 30.1 Orthopedic syndromes with potential anesthetic implications

Syndrome	Potential anesthetic implications
Achondroplasia	Chronic respiratory infection, hydrocephalus, long narrow mouth with high arched palate, limited head extension, prominent mandible and forehead, constrictive thoracic cage, cyanotic and apneic episodes, dwarfism
Apert	Facial, limb and cardiac anomalies, hydrocephalus, choanal atresia, craniosynostosis
Arnold–Chiari	Vocal cord paralysis, stridor, respiratory distress, apnea, abnormal swallowing, recurrent aspiration pneumonia, possible $\uparrow$ intracranial pressure, unstable blood pressure, weakness $\rightarrow$ paralysis
Cri du chat	Microcephaly, micrognathia, facial asymmetry, high vaulted palate, cleft lip/palate, feeding and swallowing difficulties with chronic aspiration, congenital heart defects, seizures, severe retardation
Crouzon	Facial and ocular anomalies, upper airway obstruction, choanal atresia, seizures, craniosynostosis, mental retardation
Cornelia de Lange	Facial and cardiac anomalies, micrognathia, seizures, choanal atresia, contractures, hypertonia
Ehlers–Danlos	Joint laxity, fragile blood vessels, cardiac valvular prolapse, glaucoma
Ellis-van Creveld	Facial and cardiac anomalies, small thorax
Freeman–Sheldon	"Whistling facies" with microstomia, $\uparrow$ muscle tone, vertebral anomalies, myotonia
Goldenhar	Laryngeal, ocular, cardiac and renal anomalies, cervical spine fusion, hemifacial micrognathia, glaucoma, encephalocele

#### Table 30.1 (Continued)

Syndrome	Potential anesthetic implications
Holt–Oram	Cardiac, vertebral and upper limb and shoulder girdle anomalies, hypoplasia of distal blood vessels
Hurler	Facial anomalies, macroglossia, chronic respiratory infections, growth and mental deficiencies, joint stiffness, cardiac failure, hydrocephalus
Lesch–Nyhan	Self-mutilation, airway distortion 2 degrees to scarification, mental retardation, spasticity, choreo-athetosis, seizures, contractures, hypertension, aspiration pneumonia
Marfan	Joint laxity, vertebral and ocular anomalies, mitral valve prolapse, dilatation or dissection of ascending aorta with aortic valve insufficiency
Möbius	Microstomia, micrognathia, limb and brain anomalies, cranial nerve palsies
Morquio	Odontoid hypoplasia, vertebral anomalies, growth deficiency, aortic value insufficiency, joint contractures
Neurofibromatosis	Brain, vertebral, dermal and cardiac anomalies, subcutaneous tumor with tendency to malignancy, mental deficiency, kyphoscoliosis
Noonan	Facial, vertebral and cardiac anomalies, micrognathia, mental deficiency, pectus evacatium
Radial aplasia-thrombocytopenia (Tar)	Facial, vertebral, cardiac and renal anomalies, micrognathia, severe thrombocytopenia, anemia, intracranial hemorrhage
Robin (Pierre–Robin)	Severe micrognathia, cleft palate, laryngeal anomalies, mandibular growth improves with age during infancy
Treacher Collins	Severe micrognathia (not improving during infancy), facial, auricular and cardiac anomalies, choanal atresia, microstomia, airway hypoplasia
Trisomy 21 (Down)	Odontoid hypoplasia, macroglossia, cardiac defects, joint laxity, mild mental deficiency
Turner (XO)	Micrognathia, short neck, growth retardation, cardiac anomalies
VATER association	Vertebral, cardia, renal and limb anomalies, TE fistula, esophageal atresia, congenital scoliosis, imperforate anus

## CASE STUDY

An 8-year-old boy with a history of osteogenesis imperfecta and mild asthma is admitted to the hospital for a mechanical breakage of one of the non-extendable rods in his left femur. He was playing on his crutches at school after lunch with other children when he felt a distinct pop and a sharp pain in his left thigh. In the emergency room, he is crying and slightly wheezing. His vital signs remain stable, his weight is 30 kg, and his height is 50 inches (127 cm). Mother states that he has osteogenesis imperfecta type III with mild deafness. His weight was normal at birth, and he had three fractures. During two previous procedures he had rods placed in both femurs. There is no history of mandibular or maxillary bone fragility. Mother denies any complications with anesthesia but does state that he had a high temperature after his last surgery. The fever dissipated with cooling blankets. A flow murmur was diagnosed at age 2, but no further work-up was done to evaluate this, and the patient has been asymptomatic. He currently requires crutches to ambulate and has not had fainting spells or decreased appetite. His wheezing notably increases with cold air, exercise, and stress. He uses his inhaler approximately three times a month. He has never been hospitalized for his asthma and has never had formal pulmonary function testing done. He was previously on bisphosphonate therapy for 4 years but had some leukopenia and stopped the drug at age 6. Currently his medications include a fentanyl patch and ibuprofen for breakthrough pain.

On physical examination the patient appears well nourished with adequate capillary refill and moist mucous membranes. He has varus deformities on both ankles and slight bowing of both legs with greater deformity on the left. His temperature is 36.9°C. His blood pressure is 109/64, heart rate 117/min, and his respirations are 18 breaths per minute. He has triangular facies, with blue-white sclerae bilaterally; his mouth opening is adequate. He has some limited range of motion of his neck secondary to the occurrence of tingling in the fingers bilaterally when he moves his head. There is macroglossia. His neck is short and his thyromental distance is adequate. There are several small filed-down teeth. Two teeth are missing from the upper jaw. There is mild expiratory wheezing throughout all lung fields as well as mild scoliosis and a pectus carinatum. Cardiovascular examination reveals a mild systolic murmur that is best heard at the left sternal border. The murmur diminishes with inspiration. The left leg is swollen with macular purpura on its lateral aspect. Laboratory data demonstrate a normal hemoglobin concentration and platelet count and a normal chemistry panel. Standard coagulation studies are normal. Chest x-ray shows mild hyperinflation bilaterally and mild scoliosis but normal size cardiac silhouette. Electrocardiogram shows mild left atrial enlargement and occasional premature ventricular contractions. An echocardiogram is not performed due to lack of symptoms and the innocent quality of the murmur (i.e. systolic in nature, diminishes with respiration, non-radiating).

Review of his previous anesthetic records indicates that his airway was abnormally anterior, he had fragile dentition, and two attempts were required to intubate the trachea. The estimated blood loss during the last intramedullary stabilization was 10 mL/kg. No blood products were given at that time. Currently the patient is calm in his mother's arms and allows an intravenous catheter to be placed. It has been 4h since the injury and the last ingestion of solids. He is given 0.1 mg/kg of midazolam intravenously prior to transfer to the operating room. His fentanyl patch is identified and maintained in place. In the operating room, a cooling/warming blanket is placed on the operating table. Careful transfer of the patient results in atraumatic placement on the operating table. All pressure points are padded. A variety of airway equipment is readily available in the operating room. The patient prefers to hold the facemask to his face. All standard ASA monitors are placed, including a non-invasive blood pressure cuff that is set to cycle every 5 min.

Given that the patient has a full stomach and a possibly difficult airway, a modified RSI is planned. The patient is given nebulized albuterol and tooth guards are placed prior to induction of anesthesia. After two full minutes of preoxygenation, remifentanil 1  $\mu$ g/kg is administered prior to propofol 2mg/kg. Use of these two agents decreases the sympathetic response and produces a relatively immobile patient for a short period of time without affecting neuromuscular junctions. This provides optimal intubating conditions. If unsuccessful, succinylcholine can still be used

with caution, since there is a risk for a fasciculation-induced fracture. The risk of a lost airway and aspiration of gastric contents must be weighed against the risk of iatrogenic fractures. The head and neck are stabilized with in-line stabilization, and video laryngoscopy is used to visualize the airway. Although there is an anterior, grade 3 view with external pressure, a 5.0 cuffed tracheal tube is placed under direct visualization. General anesthesia is maintained with a total intravenous technique using both propofol and fentanyl infusions with intermittent doses of vecuronium. The intravenous anesthetic technique is chosen to decrease the likelihood of hyperthermia. After establishing hemodynamic stability post induction of anesthesia, the noninvasive arterial blood pressure cuff continues to cycle every 5 min and is changed to a different extremity to avoid iatrogenic fractures. The surgeons then remove the broken non-extendable rod and replace it with a new one. This particular surgery is not amenable to a tourniquet, so none is used. The patient's temperature slowly increases from 36.9°C to 37.4°C. The cooling blanket is used to keep his temperature between 36.5°C and 37.0°C. Bleeding is a little greater than 15 mL/kg, therefore an invasive arterial line is placed to allow blood draws to evaluate for anemia and lactic acidosis, and to provide arterial blood pressure monitoring. The non-invasive blood pressure cuff is stopped.

With evidence of bleeding, relative hypotension and hemoglobin of 7 g, the patient is given 20 mL/kg of packed red blood cells with a good increase in arterial blood pressure and hemoglobin concentration. Despite the transfusion, the surgeon states that there is still oozing in the surgical field. Due to the capillary fragility and qualitative platelet dysfunction present in osteogenesis imperfecta, desmopressin is discussed as a possible treatment. Desmospressin works by increasing plasma concentrations of factor VIII, von Willebrand factor, and tissue plasminogen activator and by increasing platelet adhesiveness. The adverse effects of desmopressin include facial flushing, headache, hypotension, tachycardia, and thrombosis. There also have been a few rare case reports of hyponatremia and seizures in children. The use of desmopressin in patients with osteogenesis imperfecta has not been fully evaluated as an effective method to stop perioperative oozing [108]. Therefore in this instance, given that the bleeding has slowed over time and the risk of causing the aforementioned side-effects, desmopressin is not given.

At the end of surgery, the patient's pH is 7.25 and there is evidence of mild respiratory acidosis, which is attributed to the patient's asthma and pectus carinatum. He is given 10 puffs of albuterol from a metered-dose inhaler and improves. It is deemed appropriate, given his recent PO status, evidence of macroglossia, and a history of difficult tracheal intubation, to extubate his trachea when the patient is fully awake. This assures his airway reflexes will *Continued*
be intact. Upon tracheal extubation, the patient has mild wheezing and inspiratory stridor. This resolves with nebulized racemic epinephrine. Postoperatively, he is watched closely in the recovery room for signs of respiratory failure. His temperature remains between 37.0°C and 37.4°C. The cooling blanket is turned off but kept nearby in case his temperature increases. His baseline fentanyl patch is continued, and a morphine PCA is used for breakthrough pain.

## Introduction

Ear, nose, throat, airway, eye, and dental surgery are among the most frequent procedures requiring anesthesia in children. These cases range from very simple brief anesthetics in healthy children to very complex airway procedures in patients with multisystem disease, requiring a significant amount of preoperative planning and communication with the surgeon. This chapter will begin with a discussion of an approach to the child with an upper respiratory tract infection. Then, we will consider the anesthetic management of specific ear, nose, throat, and airway surgery, followed by a discussion of eye surgery. Finally, anesthesia for dental surgery in children will be presented.

## Approach to the child with an upper respiratory tract infection

Many children scheduled for surgery including procedures involving the eyes, ears, nose and throat areas present with nasal discharge that may represent either allergic rhinitis or an upper respiratory infection (URI). It is important to differentiate between the two conditions, as URI predisposes to respiratory complications such as breath-holding episodes, laryngospasm, bronchospasm and occasionally stridor [1,2]. Tait et al described a point system to help differentiate between the two conditions, but others have noted that parental reports are just as accurate [3,4].

The anesthesiologist is faced with a dilemma about proceeding or postponing the procedure in a child with URI. The increased risk for laryngospasm, bronchospasm, oxygen desaturation, and postintubation croup with anesthesia during URI should be balanced with the fact that these risks will not be significantly reduced without waiting 4–6 weeks or longer, by which time the child will frequently have another URI [5]. Emergency procedures should be performed even in the presence of significant medical problems. However, elective procedures should be undertaken cautiously in the presence of a URI. Most anesthesiologists would postpone elective surgery in a child presenting with purulent secretions and fever. A number of risk factors for adverse respiratory events in children with URI undergoing surgery have been

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

described, including the age of the child, exposure to second-hand smoke [6], prior history of respiratory disorders such as asthma, cystic fibrosis, bronchopulmonary dysplasia, presence of copious secretions, nasal congestion and surgery involving the airway, along with the choice of anesthetic agents and devices to maintain airway patency. Tait and Malviya have described a reasonable algorithm for managing children with URI, where the decision to proceed or postpone the procedure is based on the urgency, site of the operation (with higher risk for airway surgery), clinical severity of URI symptoms, presence of co-morbid conditions and whether tracheal intubation is planned [7].

Although the term "URI" implies an upper airway infection, the lower airway may also be affected with peripheral airway abnormalities and airway hyperreactivity. Decreased diffusion capacity, increased closing volumes, abnormal frequency dependence of compliance and increased airway resistance have been reported in patients with URI [8–11]. This may explain why anesthetized children with a URI demonstrated a more rapid decrease in their oxygen saturation to 95% during apnea [12]. Decreased functional residual capacity (FRC) and closing volumes have been noted during spirometry in awake children with URI [13].

Bronchospasm is a major and potentially life-threatening intraoperative event that occurs more frequently in children with URI, including those without a prior history of asthma. Increased airway reactivity may represent immunological and inflammatory mediator release responses to viral infection. Epithelial damage from viral infections may result in airway receptor sensitization and abnormal neural responses to tachykinins such as substance P. The contractile effects of both substance P and capsaicin were enhanced in bronchial ring segments taken from guinea pigs infected with parainfluenza 3. Pretreatment with histamine-1 and -2 (H1, H2), muscarinic, serotonergic, and  $\alpha$ -adrenergic blockers did not obliterate the effect of substance P [14]. This non-cholinergic bronchospasm may explain why albuterol pretreatment did not decrease bronchospasm in children with URI [15]. Acetylcholinerelated bronchospasm from increased vagal reactivity can be inhibited by atropine [16] which blocks the effect of acetylcholine on the smooth muscle, but also increases the release of acetylcholine from the vagus nerve endings [17]. A better strategy would be to use a more selective drug to block the muscarinic-3 (M3) receptor (stimulation of which causes bronchoconstriction) but not the muscarinic-2 (M2) receptor (which inhibits acetylcholine release at nerve terminals).

Viruses can produce other substances that result in hyper-reactivity of the airway during a URI. Parainfluenza and influenza viruses contain an enzyme, neuraminidase, which cleaves sialic acid residues present on the M2 muscarinic receptor agonist binding sites. Inhibition of the M2 inhibitory site increases acetylcholine release. Studies in guinea pigs have demonstrated alteration of high-affinity agonist binding (carbachol) in lung membrane preparations in response to either neuraminidase or parainfluenza virus. In addition, a neuraminidase blocking agent inhibited viral-induced changes [18].

In children with URI, more respiratory events occur in those who received general anesthesia with endotracheal intubation [1,19,20]. Tracheal intubation elicits a potent airway reflex that enhances the decrease in FRC following induction of general anesthesia [21].

The intense physical and pharmacological stimulation of the airway that occurs during endotracheal intubation results in significant airway hyper-reactivity, particularly in patients with asthma. However, even patients without underlying bronchospastic disease may develop a temporary increase in airway reactivity during viral infections.

Children with URI presenting for minor surgery which does not require instrumentation of the airway are not at increased risk of complications following general anesthesia [3,22]. In contrast, there is a twofold increase in the incidence of laryngospasm in patients with URI symptoms undergoing airway surgery [23]. Rolf & Cote also reported a higher frequency of minor desaturation episodes and an increased risk of bronchospasm following tracheal intubation in children with URIs [19]. The use of a laryngeal mask airway (LMA) in preference to an endotracheal tube when providing anesthesia for children with recent or active URI may cause less tracheal stimulation and respiratory complications from increased airway reactivity [20]. Nevertheless, some studies have shown an association between LMA use and respiratory complications, especially in children with recent (within past 2 weeks) or active URIs [24,25]. Randomized controlled trials are required to determine a true cause-and-effect relationship between the use of LMA and the incidence of respiratory complications [26].

Increased airway reactivity associated with a URI has been stated to last approximately 4-6 weeks. Empey demonstrated a 200% increase in airway resistance after inhaled histamine in adults who had a URI, compared with a 30% increase in controls [27]. The increased airway reactivity persisted as long as 6 weeks after the URI ended. Nandwani studied the upper airway reflex sensitivity of non-smoking, healthy adult patients who inhaled ammonia vapor [28]. Airway reactivity was 2-2.5 times higher than normal, but had returned to baseline 2 weeks after the URI ended. However, many children have at least 6-10 URIs per year, making it difficult to time the procedure for a period when airway reactivity has returned to normal. In addition, it has not been consistently shown that waiting for 6 weeks reliably decreases the incidence of respiratory complications with general

anesthesia [5]. In these circumstances, surgery may have to be performed and the anesthesiologist should be prepared to treat bronchospasm aggressively, deliver supplemental oxygen to patients during transport from the operating room to the recovery room, and carefully monitor breathing patterns and oxygen saturation in the recovery room to ensure adequate ventilation and oxygenation before discharge home or to the ward. The anesthesiologist should also consider the preferential use of drugs known to be associated with decreased airway irritability, e.g. sevoflurane rather than desflurane, propofol rather than thiopental.

Although "URI" is considered a single disease process, often with a common set of presenting symptoms, there may be enormous variability in the pathophysiological effects and clinical manifestations of a particular virus, depending on the stage of the illness (e.g. initial symptoms, height of symptoms, recovery phase). Therefore, there will always be a need for subjective interpretation of a particular patient's clinical signs, symptoms, and past history when surgery is proposed.

## Anesthesia for specific surgical procedures

Surgery around the head and neck involves sharing of the workspace and airway between the surgeon and anesthesiologist, making close communication between the two imperative for good patient management. A preoperative discussion is useful in determining the factors necessary for optimal operative conditions, and should include a focus on the steps involved in the procedure, patient positioning, intraoperative movement of the tracheal tube, the potential effect of neuromuscular blockade on nerve integrity monitoring, and a need for additional precautions to avoid airway fires. The most common pediatric conditions requiring surgical intervention in the head and neck region include:

- myringotomy and pressure equalization tube insertion for treatment of chronic otitis media infection
- middle ear surgery
- tonsillectomy and adenoidectomy for relief of obstructive sleep apnea or for the management of recurrent streptococcal pharyngitis
- airway surgery for evaluation of subglottic stenosis and resection of laryngeal papillomas
- removal of foreign bodies.

### Myringotomy and insertion of pressure equalization (ventilation) tympanostomy tubes (grommets)

Otitis media is one of the most frequent diagnoses made in pediatric patients. It is an inflammation of the middle ear that often accompanies viral or bacterial upper respiratory tract infections. It may be accompanied by a collection of fluid in the middle ear which becomes thick and glue-like and results in conductive hearing loss if left untreated. Failure of antibiotic therapy to resolve these symptoms warrants surgical drainage of the middle ear fluid. A simple myringotomy will create an opening in the tympanic membrane for drainage of accumulated fluid but the drainage path created eventually heals, leading to a recurrence of symptoms. Placement of a ventilating tube in the ear drum provides stenting of the middle ear and allows for drainage of fluid till the tubes are naturally extruded in 6–12 months.

The procedure of myringotomy and/or placement of ventilating tubes can be completed in 5-10min in most cases, usually requiring only inhalation anesthesia delivered via facemask However, the procedure may be more surgically challenging in children with narrow ear canals as seen in some syndromes (e.g. Down, Apert syndrome). In this situation, the use of an LMA may be considered during maintenance of anesthesia, as it is associated with fewer hypoxemic episodes and better perioperative working conditions for the surgeons during myringotomy tube placement when compared to the use of a facemask and oral airway [29]. Children with cleft palates frequently develop otitis media due to abnormalities in the cartilage and muscles surrounding the eustachian tubes and procedures in these children may last longer than a routine myringotomy tube insertion, but can usually be managed with a facemask.

Anesthetic management for myringotomy tube placement involves a brief inhalation of potent inhalation agents (commonly sevoflurane) and nitrous oxide in oxygen. However, maintenance of airway patency and adequate ventilation is essential, and an oral airway is often placed to alleviate airway obstruction under anesthesia. Assisted ventilation may be required if the depth of anesthesia exceeds the apneic threshold. Most practitioners do not establish vascular access in healthy patients undergoing these short procedures, but do so in children with significant underlying medical conditions. Nevertheless, an intravenous fluid set-up should be readily available in the operating room in case it is required for urgent drug treatment of laryngospasm (see below).

A variety of management strategies exist for the mild postoperative pain associated with myringotomy tube placement, with the predominant therapy based on institutional or anesthesia practitioner preference. Preoperative oral acetaminophen (15–20mg/kg) or intraoperative acetaminophen suppositories (40–45 mg/kg) are often used, but acetaminophen (10mg/kg) with codeine (20mg/kg) has been found to be superior to oral acetaminophen [30]. The intraoperative administration of ketorolac, intranasal butorphanol or fentanyl  $(2\mu g/kg)$ reduces rescue analgesic requirements [31–33]. This patient population is at high risk for emergence agitation following sevoflurane anesthesia and the administration of intranasal fentanyl has been found to reduce the incidence [34]. Patients receiving an intraoperative nerve block of the auricular branch of the vagus nerve had similar pain scores in the postoperative period to patients who received intranasal fentanyl with less postoperative emesis [35]. Intramuscular morphine at a dose of 0.1 mg/ kg has also been administered for analgesia in these patients.

#### Middle ear and mastoid surgery

Myringotomy tubes are usually extruded spontaneously, but on occasion need to be removed. While the procedure can be performed in an office, small children may not co-operate and removal under general anesthesia may be required in a few cases. The myringotomy opening in the ear drum usually heals spontaneously, but occasionally the insertion of a paper patch or a fat graft may be required for persistent tympanic membrane perforation.

Anesthetic management for insertion of a fat graft differs slightly from a routine myringotomy as the administration of nitrous oxide should be discontinued or limited to 50% maximum prior to the insertion of the tympanic membrane graft in order to prevent pressurerelated displacement of the graft. Nitrous oxide diffuses along a concentration gradient into air-filled middle ear spaces more than nitrogen moves out because nitrous oxide has increased solubility in blood (34 times that of nitrogen). While normal passive venting of the eustachian tube occurs at 20–30 cmH<sub>2</sub>0, nitrous oxide increases pressure such that the ability of the eustachian tube to vent the middle ear within 5 min is exceeded, thereby resulting in pressure build-up, pain and potential graft displacement [36]. Repeated middle ear infections can result in extension to the mastoid area and large perforations in the tympanic membrane which may not be amenable to transcanal repair only and require posterior auricular exposure. The skin over the outer surface of the ear drum can start to grow through the perforation and into the middle ear, forming a destructive and expanding growth called a cholesteatoma. These problems require surgery.

Routine anesthetic management usually requires inhalational agents with opioid administration. Endotracheal intubation is facilitated by intravenous propofol and/or laryngotracheal application of lidocaine. Following endotracheal intubation, the operating table is usually turned 90° or 180° away from the anesthesia machine with the patient's head positioned on a soft headrest below the height of the operating table. In addition, the surgeons may request extreme lateral rotation of the operating room table to view the ear structures. The anesthesiologist and surgeon must be vigilant to ensure that nerves, muscles and bony structures are properly padded and not injured during positioning, and to prevent accidental dislodgment of the endotracheal tube. The use of extra-long anesthesia circuits could also be considered if the head of the patient is positioned some distance from the anesthetic machine. The surgical drapes should be placed to allow easy access to the patient and endotracheal tube. Careful head positioning is particularly important in children with Down syndrome as well as in achondroplasia as 15-31% of these children are prone to develop atlantoaxial (C1-2) subluxation [37,38]. The facial nerve is in close proximity to the surgical field during middle ear and mastoid surgery and monitoring of nerve integrity will require the avoidance of neuromuscular blockade or demonstration of a return of the neuromuscular response to 70% of baseline.

Bleeding during middle ear surgery should be minimal as the operative site is visualized through a microscope. Concentrated epinephrine is injected around the area of the tympanic vessels to produce vasoconstriction. Close attention should be paid to the concentration and amount of epinephrine injected in order to avoid arrhythmias and wide variations in blood pressure. Relative hypotension (mean arterial pressure  $\leq 25\%$  from baseline) may decrease the degree of bleeding intraoperatively.

The use of nitrous oxide during these cases can result in an increased volume of gas in the air-filled cavities of the middle ear and sinuses. Subsequent discontinuation of nitrous oxide results in immediate absorption and negative pressure in the middle ear with displacement of any patch placed on the tympanum. Disarticulation of the stapes, one of the ossicles in the middle ear, can occur, with a hearing impairment, which may last for up to 6 weeks postoperatively. In addition, nitrous oxide contributes to the high incidence of postoperative nausea and vomiting in children following middle ear surgery. The negative pressure caused by reabsorption of nitrous oxide stimulates the vestibular system by producing traction on the round window. The relatively compliant walls of the eustachian tubes then collapse and prevent re-equilibration with atmospheric pressure [39]. Older children (greater than 8 years of age) appear to have less compliant eustachian tubes and therefore do not suffer effects of negative middle ear pressure contributing to postoperative nausea and vomiting. While all children are predisposed to developing postoperative nausea and vomiting, children under 8 years of age seem to be most affected. Prophylactic administration of antiemetics like dexamethasone and ondansetron is helpful in this patient population. Postoperative opioid requirements and postoperative nausea and vomiting (PONV) were reduced by approximately 66% following great auricular nerve blockade.

However, analgesic requirements were similar in those receiving the nerve block prior to skin incision or 1 hour before the end of surgery [40,41].

A smooth emergence from anesthesia is preferred in these children. Extubation of the trachea while deeply anesthetized can be easily performed if the children are allowed to breathe spontaneously toward the end of surgery and opioids are gradually titrated as tolerated so the patients can emerge with minimal pain. Administration of intravenous lidocaine (1–1.5 mg/kg) in children older than 1 year of age and gentle suctioning of the oropharynx when the patient is awake can minimize or prevent coughing following extubation.

#### **Cochlear implants**

Early insertion of cochlear implants is rapidly gaining acceptance as a method of rehabilitation of profoundly hearing impaired children, as this allows an opportunity for better auditory, speech and language skills. These children are more easily mainstreamed with their peers when they receive cochlear implants early in life. Children as young as 6 months can receive cochlear implants as long as special attention is paid to the physiological and anatomical differences in this age group. Surgical placement of cochlear implants involves meticulous soft tissue dissection, hemostasis and bone drilling as bleeding from the bone marrow may be very difficult to control. The cochlear implant stimulates the auditory nerve to enable hearing and intraoperative limits of implant stimulation are set by evoked stapedius reflex thresholds (ESRT) as well as evoked compound action potentials. The latter measurement has not been found to be affected by anesthetics; however, volatile anesthetics abolish the stapedius reflex in more than 50% of children [42] and cause a dose-dependent increase in the ESRT. This results in ESRT levels that overestimate a child's comfort level and can lead to difficulty adjusting to the implant postoperatively. Propofol does not affect the ESRT; therefore the use of volatile anesthetics during this phase of the surgery is discouraged. Other anesthetic considerations are similar to those for middle ear surgery. Appropriate communication with the surgeon ensures the successful outcome of these procedures.

#### Adenoidectomy and tonsillectomy

Adenoidectomy can be performed alone although it is commonly performed in conjunction with tonsillectomy and/or myringotomy and tube insertion. The indications for adenoidectomy alone include chronic otitis media with effusion secondary to adenoid hyperplasia, chronic sinusitis and chronic or recurrent purulent adenoiditis. Severe adenoid hyperplasia results in nasopharyngeal obstruction, obligate mouth breathing, failure to thrive, and speech disorders. Long-standing nasal obstruction due to adenoid hyperplasia may result in orofacial abnormalities including narrowing of the upper airway and dental abnormalities ("adenoidal facies").

Tonsillectomy with or without adenoidectomy is one of the most common ambulatory pediatric surgery procedures performed in the United States [43]. The most common indications include recurrent or chronic tonsillitis refractory to medical therapy and obstructive adenotonsillar hyperplasia. The association of tonsillitis with peritonsillar abscess or airway obstruction is also an indication for surgical removal of the tonsils. Hypertrophic tonsils may result in chronic airway obstruction, failure to thrive, dysphagia and speech abnormalities, halitosis, cervical pharyngitis and persistent pharyngitis. Children with cardiac valvular disease are predisposed to developing endocarditis due to recurrent streptococcal bacteremia as a result of infected tonsils. Severe airway obstruction can result in carbon dioxide retention, cor pulmonale, and cardiac failure.

#### Preoperative assessment

Children less than 3 years of age presenting for this surgery require special attention as this age group has the highest respiratory morbidity following adenotonsillectomy [44,45]. The indication for adenotonsillectomy in this age group is obstructive sleep apnea, which has different features in children compared to adults, with a peak age of 2-6 years, equal male/female distribution and an excellent response to adenotonsillectomy. Obstructive sleep apnea (OSA) is at the end of a spectrum of sleep-disordered breathing which starts from normal respiration and includes snoring, upper airway resistance syndrome, obstructive hypopnea and obstructive sleep apnea. Obstructive sleep apnea occurs during rapid eye movement (REM) sleep and is characterized by snoring with continuous partial upper airway obstruction during sleep, resulting in paradoxical respiratory effort, ineffective ventilation, hypercarbia, and hypoxemia [46]. In severe cases, the patient can develop respiratory acidosis and vasoconstriction of the pulmonary vasculature with accompanying right ventricular hypertrophy. Children with severe obstructive sleep apnea are occasionally admitted to the hospital preoperatively for oxygen treatment via non-invasive nasal continuous positive pressure which stents the airway open, prevents airway collapse and improves functional residual capacity. Bilevel positive airway pressure ventilation (BiPAP) may also be instituted; this provides airway pressure that decreases during exhalation and has been found to improve pulmonary hypertension, decrease the postoperative complication rate and may be beneficial in some pediatric patients [47,48].

While snoring, breath-holding or apneic spells, failure to thrive and repeated respiratory infections are

Table 31.1	Respiratory	events that	may occur	during	polysomnography

Event	Definition
Central apnea	Pause in airflow with absent respiratory effort, scored when >20 sec or two missed breaths and >3% decrease in oxygen saturation
Obstructive apnea	>90% reduction in air flow despite continuing respiratory effort, scored when event lasts at least 2 missed breaths in children
Obstructive hypopnea	>50% reduction in airflow despite continuing respiratory effort, scored when event lasts at least 2 missed breaths in children and >3% decrease in oxygen saturation or arousal
Mixed apnea	≥90% reduction in air flow, lasting at least 2 missed breaths, and containing absent respiratory effort initially (central apneic pause), followed by resumption of respiratory effort without resumption of airflow (obstructive apnea)
Obstructive hypoventilation	End-tidal $CO_2 >50$ mmHg for >25% of total sleep time with paradoxical respirations, snoring and no baseline lung disease

Adapted from Schwengel et al [49] with permission from Lippincott Williams and Wilkins.

suggestive of obstructive sleep apnea, the gold standard of diagnosis is overnight sleep polysomnography. Table 31.1 lists the respiratory events that may occur during polysomnography.

The number of hypopnea-obstructive episodes that occur during a sleep study is usually combined to give an apnea-hypopnea index (AHI) which is defined as the number of discrete obstructive events per hour that occur. However, this number usually includes central apnea which is a normal occurrence in children and is not associated with any impaired respiration. True documentation of obstructive sleep apnea in children should be based only on obstructive episodes associated with respiratory impairment as normal children tend to have more central apnea episodes and this feature cannot be used to diagnose OSA in children [50,51]. Many sleep laboratories will report an AHI or a respiratory disturbance index (RDI) that includes the total number of respiratory events, including central apnea, that occur per hour. OSA is considered to be severe if the AHI  $\geq 10/h$  and the oxygen saturation nadir is ≤80% (Table 31.2). The severity of obstructive sleep apnea is usually based on a number of factors: the patient's total clinical picture, frequency and severity of oxygen desaturation during the apneic episodes, duration of elevated carbon dioxide, and the number of obstructive events per hour [52-55].

Table 31.2 Severity ranking system based on polysomnography [56]

	Apnea–hypopnea index	Oxygen saturation nadir
Normal	0–1	>92%
Mild OSA	2–4	
Moderate OSA	5–9	
Severe OSA	>10	<80%

OSA, obstructive sleep apnea.

Peak end-tidal  $CO_2$  (EtCO<sub>2</sub>) and duration of time spent with EtCO<sub>2</sub> >50 mmHg should be considered when assessing severity of OSA.

#### **Special problems**

A number of special problems may be encountered in some children who present for adenotonsillectomy. These include patients with craniofacial disorders, Down syndrome, sickle cell disease, and known bleeding disorders. The risks of general anesthesia in these patient populations are discussed in Chapters 11, 14, 32, and 38.

The anesthesiologist should be prepared for potential difficulties in establishing airway patency and tracheal intubation and maintaining ventilation, particularly in patients with craniofacial disorders who present for adenotonsillectomy. For example, patients with mucopolysaccharidosis I (Hurler syndrome) and II (Hunter syndrome) have diffuse infiltration of the upper airway and larynx with abnormal mucopolysaccharidoses which predisposes them to upper airway obstruction and difficult endotracheal intubation. In addition, patients with Hurler syndrome may have cardiac involvement, resulting in valvular, myocardial involvement as well as coronary artery disease which may occur at an early age. Patients with Hunter syndrome may also have severe kyphoscoliosis which may affect positioning for endotracheal intubation.

Patients with trisomy 21 (Down syndrome) also have craniofacial anomalies which may affect intraoperative management during adenotonsillectomy. These patients have a baseline midface hypoplasia characterized by narrow oral and nasal passages and glossoptosis. In addition, these children have hypopharyngeal hypotonia leading to hypopharyngeal collapse during induction of anesthesia. Mask ventilation may be difficult, requiring oral and/or nasal airway. Some of these patients also develop hypertrophy of lingual tonsils, which are located posterior to the tongue and are not easily appreciated on oral examination [57] (Fig. 31.1). Lingual tonsil hypertrophy can be responsible for persistent obstructive sleep apnea following adenotonsillectomy in this group of

**Figure 31.1** Hypertrophied lingual tonsil, difficult to appreciate on oral examination. Reproduced from Olutoye et al [57] with permission from Lippincott Williams and Wilkins.

patients [58]. While these tonsils are not appreciated on oral examination even in their hypertrophied state, the anesthesiologist should be alerted to this condition as it may result in a "cannot ventilate-cannot intubate" clinical scenario [57,59,60].

Patients with sickle cell disease who have recurrent tonsillitis are predisposed to developing sepsis. In addition, hypoxemia in sickle cell patients with OSA may precipitate a sickling crisis. Therefore frequent episodes of tonsillitis (>6 episodes per year) or adenoid hypertrophy resulting in upper airway obstruction are treated very aggressively in this subset of patients. Sickle cell patients undergo special perioperative evaluation and management, depending on the preference of the hematologist at each individual institution. The main goals of these regimens include prevention of perioperative hypoxemia, adequate hydration to decrease blood viscosity and subsequent concentration of sickle cells, increase in hemoglobin level to 10g/dL via simple blood transfusion and decrease in hemoglobin S concentration by aggressive blood transfusion. There are differences in opinion regarding the trigger hemoglobin value for preoperative blood transfusion in sickle cell patients undergoing minor surgical procedures. Many centers have firm policies for management of sickle cell patients undergoing routine surgery, including temperature maintenance, hydration, oxygen therapy and pain management. The evidence that these measures are useful has not been well established for minor surgical procedures [61–66]. Patients with sickle cell disease may require an increased amount of analgesia postoperatively [67] and this may pose a challenge as moderate amounts of opioid administration may result in shallow respirations and ultimately hypoxemia, which is avoided in these patients.Preoperative consultation with the hematology service is essential before these surgeries (see Chapter 11).

#### **Coagulation status**

The adenotonsillectomy procedure differs from other operations in that a large raw surface (tonsillar bed) is left open and the edges are not apposed for hemostasis. It is therefore very important to obtain a history suggestive of bleeding tendencies, and discontinue medications which interfere with coagulation such as aspirin, nonsteroidal anti-inflammatory drugs and valproic acid prior to surgery. However, discontinuing such medications perioperatively may be problematic as in the case of children with congenital heart disease taking aspirin in order to maintain patency of a Blalock-Taussig shunt. The risks of bleeding need to be balanced against the risks of a clot developing in the shunt. Preoperative consultation with the patient's cardiologist should be obtained. In children with a history suggestive of bleeding disorders, preoperative consultation with a hematologist may be indicated as well. Appropriate laboratory tests include prothrombin time to test the extrinsic and common coagulation pathway, activated partial thromboplastin time (aPTT) to test the intrinsic and common pathway, as well as bleeding times and studies of platelet function.

Von Willebrand disease is a hereditary disorder characterized by a deficiency of von Willebrand factor and prolonged bleeding time while hemophilia A or B is characterized by deficiency of clotting factors VIII and IX respectively. Adequate consultation with the hematology service to determine the dose and time of administration of specific factors to correct the coagulation defect is indicated prior to surgery (see Chapter 11).

#### Intraoperative management

The duration for adenotonsillectomy is usually 15–30 min and surgery is performed in a variety of ways, including guillotine and snare, cold and hot dissection, ultrasound coblation and electrocautery. Many combinations of inhaled and intravenous agents have been used to provide satisfactory anesthesia for the procedure, but anesthesia usually involves mask induction, establishment of vascular access and tracheal intubation with a preformed curved Ring–Adair–Elwyn (RAE) tube. The use of a preformed oral RAE tube allows for easy positioning of the

**Figure 31.2** Child positioned for tonsillectomy and/or adenoidectomy. The endotracheal tube is secured along the mandible away from the operative field. It is imperative to ensure that the endotracheal tube is not kinked or occluded by the retractor.

self-retaining mouth gag used by the surgeons. In addition, the preformed bend allows the anesthesia circuit to be connected at a location away from the site of surgery (Fig. 31.2). However, many practitioners have been successful with regular oral endotracheal tubes and in some institutions the LMA is routinely used for adenotonsillectomy. A non-depolarizing muscle relaxant may be used to facilitate tracheal intubation but many anesthesiologists will intubate the trachea without muscle relaxants, after an inhalation induction and deepening the anesthetic with propofol 1–2 mg/kg IV, assuming no contraindications. This technique has the advantage of avoiding the need to reverse the muscle relaxant in the case of a very fast surgery, and allows easier resumption of spontaneous ventilation if the plan is to extubate the trachea with deep anesthesia.

Some anesthesiologists recommend the routine use of a cuffed endotracheal tube based on the premise of a reduced leak of anesthetic gases, thereby permitting reduced inspired oxygen concentrations and decreasing the risk of airway fires. Adenotonsillectomy is considered a high-risk procedure in which an ignition source (electrocautery) is in close proximity to an oxidizerenriched environment (the presence of oxygen in a concentration above that of room air, and/or the presence of nitrous oxide) and combustible tissue, thus completing the triad necessary for the development of an operating room fire [68]. After securing the airway, FIO<sub>2</sub> should be reduced to the lowest practical level, i.e. 0.21-0.30, to minimize the risk of airway fire. The use of cuffed endotracheal tubes limits the number of repeated laryngoscopy attempts, allows for the use of low-flow anesthesia and also decreases the amount of detectable anesthetic gas concentration in the operating room, as well as limiting the oxygen concentration in the oropharynx, reducing the risk of airway fires [69]. There is no existing randomized, controlled trial to determine which method of securing the airway for this procedure is safest.

The trachea can be extubated with the patient awake or deeply anesthetized provided the patient is breathing comfortably without episodes of breath holding. There is no evidence that any one method is associated with increased risks of adverse respiratory events; most randomized trials on this subject have not been sufficiently powered to demonstrate any benefit of one technique versus the other. Some anesthesiologists are reluctant to extubate the trachea under deep anesthesia when a child with OSA has undergone adenotonsillectomy because of the risks of adverse respiratory events when intraoperative opioids have been administered. If the decision is made to extubate the trachea under deep anesthesia, personnel and systems must be in place to detect and treat airway complications (airway obstruction, apnea, laryngospasm) as the patient emerges from anesthesia in the postanesthetic care unit (PACU) after the anesthesiologist has turned over patient care. The anesthetic setting is important in this regard. Extubation decisions may differ in an outpatient surgery setting with no anesthesiologist available for back-up and recovery nurses with limited pediatric experience versus a large children's hospital operating room with readily available personnel and highly experienced pediatric recovery nurses who can respond rapidly and skillfully to airway problems. See below for a discussion of airway emergencies.

Intraoperative pain management resulting in a comfortable patient postoperatively, without episodes of respiratory obstruction, continues to be a challenge for the anesthesiologist. Opioids are the mainstay of analgesic treatment in this patient population. However, children with a history of obstructive sleep apnea may be more sensitive to the effect of opioids and reduced doses may be required to prevent postoperative respiratory depression [70]. In patients with severe OSA, small doses of opioids are titrated to effect in the PACU only after the patient is awake.

Non-steroidal agents (NSAIDs) are not associated with postoperative respiratory depression but concern for their effects on hemostasis has limited their use [71]. A recent Cochrane systematic review of studies failed to show increased bleeding in tonsillectomy patients who received NSAIDs [72]. Different combinations involving opioid and non-steroidal agents have been used in the search for the optimal analgesic regimen [73,74]. This has included the use of acetaminophen administered orally, rectally and more recently in an intravenous form. Rectal doses should be higher (40–45 mg/kg) compared to the oral route (15–20 mg/kg) to achieve satisfactory blood levels.

Intraoperative infiltration of local anesthetics has also been utilized by some surgeons in an attempt to decrease postoperative morbidity in this patient population following surgery [75–77].

The introduction of the  $\alpha$ 2-agonist dexmedetomidine, with effects of mild analgesia without respiratory depression, has provided a plausible agent for analgesia in adenotonsillectomy patients. It reduces postoperative opioid consumption in adults undergoing major inpatient surgery [78]. In children undergoing adenotonsillectomy, doses of 1µg/kg and 0.75µg/kg of dexmedetomidine increased the time to requirement of postoperative opioid medication but the total amount of postoperative morphine consumed by the patients was the same when compared to those who received morphine intraoperatively [79].

Different surgical techniques have also been explored to try to determine which provides the least postoperative morbidity due to pain [80–83].

Intraoperative dexamethasone has been used in these patients to reduce postoperative pain and edema and to prevent nausea and vomiting. The minimum dose for reducing opioid consumption was 0.5 mg/kg, but parents reported reduced pain scores with 1 mg/kg of dexamethasone [84]. More recently, there has been considerable discussion about a report of increased bleeding in this patient population when dexamethasone was used [85]. However, this study has been criticized for the high incidence of primary hemorrhage and need to return to the operating room on the day of operation. Dexamethasone is useful as an antiemetic and its combination with an antiserotonin drug such as ondansetron is recommended for this procedure.

#### **Postoperative complications**

Postoperative or secondary hemorrhage and respiratory impairment are the most frequently observed complications following adenotonsillectomy; the incidences of these are significantly dependent on age. Postoperative hemorrhage is more common in children older than 10 years of age [86] while respiratory complications such as supraglottic obstruction, breath holding and need for airway rescue maneuvers are more common in children younger than 3 years of age [52,87,88]. In many institutions, children less than 3 years of age are observed at least overnight in the hospital following adenotonsillectomy, particularly if they have co-morbid conditions (e.g. Down syndrome, developmental delay, OSA). Other complications following adenotonsillectomy which are rare in incidence include uvular edema, uvula amputation, velopharyngeal insufficiency and nasopharyngeal stenosis. Throat pain, otalgia and poor oral intake are also common complications following discharge.

#### Post-tonsillectomy hemorrhage

This is the most common complication that results in children presenting to the operating room for reexploration, within the first hour after surgery or more commonly within 2 weeks after the initial surgery. Dislodging of the eschar on the surgical site with exposure of raw mucosal surfaces is usually responsible for hemorrhage that occurs a few days after surgery. This condition requires surgical exploration and cauterization of the bleeding surface. The incidence of post-tonsillectomy hemorrhage is higher in older children. Usually children have been swallowing the blood and therefore should be treated as having a full stomach when they present to the operating room. The degree of bleeding can be assessed clinically by the degree of dehydration observed on clinical examination. Severe dehydration is characterized by dry mucous membranes, sunken orbits, and decreased skin turgor.

Intravenous access may be difficult to obtain in severe cases and the use of an intraosseous catheter may be necessary. Alternatively, large-bore intravenous access should be secured as crystalloid and colloid replacement will be required. Preparation for induction of these children should include having two available suction catheters, preferably firm suction catheters (Yankauer) and drugs for a rapid-sequence induction. Preoxygenation should be followed with rapid sequence induction with the surgeon holding one suction catheter and the other within easy reach of the anesthesiologist. In cases of severe bleeding, the vocal cords may not be visible; in this case the anesthesiologist should direct the endotracheal tube (ETT) at the site where air bubbles are seen escaping from the glottic opening when an assistant presses on the chest wall to produce a forced exhalation. Careful laryngoscopy is recommended as the process of laryngoscopy itself may scrape the tonsillar bed and also precipitate bleeding. Cuffed endotracheal tubes are recommended in the presence of a full stomach. Significant anemia may be present from blood loss so a perioperative hemoglobin level should be obtained and adequate preparation should be made for blood transfusion. Prompt identification of the bleeding sites usually occurs so surgery for cauterization of the tonsillectomy bed lasts only about 20 min. Blood may be transfused intraoperatively or in the recovery room as time permits.

#### **Endoscopic sinus surgery**

Chronic sinusitis is characterized by inflammation and occlusion of the sinus ostia which allow drainage from the sinuses into the nose. In some patients adenoidectomy can relieve symptoms, but endoscopic sinus surgery (ESS) has become the mainstay of surgical treatment for chronic sinusitis refractory to antibiotics and adenoidectomy. The operation involves direct telescopic visualization of the nasal mucus membranes with the aid of sharp, biting instruments or the use of a microdebrider to relieve areas of obstruction and improve ventilation through the sinuses, while leaving the mucous membranes intact.

Cystic fibrosis is a common underlying disease in children presenting for this surgery as the associated impaired mucociliary function predisposes them to infection. The anesthesiologist should ensure that these patients are medically optimized prior to surgery.

Bleeding can make surgical visualization difficult, and therefore the nasal cavity is packed with pledgets soaked in one of a number of different vasoconstricting solutions. The most common vasoconstricting solutions which may be used include oxymetazoline 0.025% to 0.05%, phenylephrine 0.25 to 1%, cocaine 4% to 10% and 2% lidocaine with epinephrine 1:100,000 or epinephrine 1:200,000. The anesthesiologist should be aware of the type and dose of vasoconstrictive agent being used and ensure that the maximum allowable concentration/amount has not been exceeded as rapid absorption occurs from raw mucosal surfaces, leading to changes in heart rate (tachycardia or bradycardia) or hypertensive episodes [89,90]. This may occur especially if intraoperative anticholinergics have been administered. Intraoperative hypertension usually is transient and resolves spontaneously without aggressive treatment. In children, the recommended dose of phenylephrine should not exceed 20µg/kg. Cocaine has been reported to result in myocardial infarction in otherwise healthy individuals [91]. The spread of anesthetic effects of cocaine may also cause blockade of the nasociliary ganglion, resulting in transient anisocoria postoperatively [92].

Intraoperative management for ESS involves endotracheal intubation with the use of an oral RAE tube which is securely fixed along the mandible, allowing easy surgical access to the maxilla and sinuses. The use of cuffed endotracheal tubes prevents fogging of the endoscopic equipment and also prevents excessive gas leak around the tube. Throat packs are almost always utilized during this surgery to prevent escape of gas into the environment from around the endotracheal tube. The anesthesiologist must confirm removal of the throat pack at the conclusion of surgery prior to extubation of the patient as this may be a cause of airway obstruction or emergence agitation postoperatively. Intravenous corticosteroids are warranted during this surgery in order to prevent postoperative swelling.

Frequently, at the end of this surgery, some stenting material is left in the sinuses by the surgeon. This may cause discomfort or a perception of difficult breathing by the patient upon emergence. Therefore, an anesthetic technique that provides adequate analgesia and quick emergence is desired. A second endoscopic procedure is usually required approximately 6 weeks following the initial surgery in order to remove the existing packs (if non-absorbable packs were used) and to examine the surgical site. This procedure is usually quick and the use of a laryngeal mask airway may be considered.

### Airway complications and pathology

#### Laryngospasm

Laryngospasm is a life-threatening event in which either the true vocal cords or both the true and false vocal cords appose in the midline, resulting in an involuntary closure of the glottis by the intrinsic laryngeal muscles and inability to exchange gas [93]. The primary muscles involved in laryngospasm are the lateral cricoarytenoid, the thyroarytenoid muscles (adductors of the glottis) as well as the cricothyroid muscles which are tensors of the vocal cords. Laryngospasm is the most frequently reported respiratory complication associated with upper respiratory tract infections, particularly in younger children undergoing airway surgery and in those cared for by less experienced anesthesiologists [23]. While most patients who develop laryngospasm have otherwise normal airway anatomy, airway anomalies have been found to have an increased association with laryngospasm [25].

Laryngospasm is most commonly associated with airway manipulation (e.g. intubation or extubation of the trachea), foreign material in the larynx (e.g. secretions) or with light anesthesia in a non-intubated patient. The clinical scenario of laryngospasm may be preceded by an irregular breathing pattern or noisy airway sounds that vary in intensity and tone but usually resemble a highpitched squeak indicating partial airway obstruction. Airway obstruction as a result of laryngospasm may be partial or total, resulting in an absence of spontaneous ventilation or inability to manually ventilate the patient. In the mildest form, this scenario is usually relieved by airway manipulation such as a jaw thrust or application of continuous positive airway pressure (CPAP) of 10-20 cmH<sub>2</sub>O for 30-45 sec. If the scenario of partial airway obstruction without arterial desaturation persists, small subhypnotic doses of propofol, 0.5-1 mg/kg, may alleviate symptoms [94,95]. If the condition does not resolve following these interventions, marked oxygen desaturation typically ensues and the administration of a muscle relaxant may become necessary in order to break the laryngospasm and allow ventilation with 100% oxygen. A small dose of intravenous succinylcholine, 0.1–0.3 mg/ kg is effective. However, if the child is hypoxemic, administering succinylcholine may precipitate profound bradycardia and further worsen oxygen delivery. If succinylcholine is to be given to a hypoxemic child or if

the initial dose is not effective, atropine 20µg/kg should also be administered prior to the next dose. In situations where laryngospasm occurs prior to placement of an intravenous line, succinycholine may be administered via a number of alternative routes: intramuscular (4mg/kg), intralingual (1.1mg/kg), submental or via the intraosseous route [96]. Intravenous lidocaine (2mg/kg) has been found to control or prevent laryngospasm in both children and adults [97,98]. Aerosolized lidocaine also alleviates symptoms of postextubation laryngospasm [99]. Topical lidocaine is thought to effectively decrease the incidence of laryngospasm by suppressing laryngeal mucosal neuroreceptors without affecting central neural reflex.

In piglets, topical lidocaine decreased both the laryngeal chemoreflex and mechanoreflex without decreasing the superior laryngeal nerve adductor reflex [100]. However, intravenous lidocaine had no effect on laryngeal mucosal reflexes [97]. The increased depth of anesthesia provided by lidocaine appears to decrease the occurrence of laryngospasm.

Whatever the final treatment strategy, early recognition of laryngospasm is essential, particularly in infants and young children in whom oxygen consumption is high and arterial desaturation is very rapid. There is no substitute for well-developed airway management skills.

The LMA provides an alternative to endotracheal intubation for a variety of procedures. Some authors have proposed that this device may reduce airway complications in patients who have a URI as instrumentation of an irritable airway (due to a URI) is avoided. However, in one study, LMAs were associated with a similar incidence of cough, breath holding, excessive secretions, and laryngospasm as occurred with endotracheal tubes [20]. Patients whose airways were managed with an LMA had a lower incidence of mild bronchospasm and a lower incidence of oxygen desaturation during placement of the airway than those treated with an endotracheal tube. Treatment of bronchospasm and laryngospasm that developed during use of an LMA was not addressed in this study. Both may be more difficult to treat because high peak airway pressures cannot be delivered through an LMA.

The lower blood:gas partition coefficient of desflurane of 0.45 allows for rapid emergence from anesthesia. Despite the theoretical advantages, children receiving desflurane have a higher incidence of laryngospasm, breath holding and coughing following either endotracheal extubation or removal of the laryngeal mask airway [101,102]. In general, laryngospasm is unlikely if the anesthetic depth is sufficiently deep to permit tracheal stimulation during intubation and extubation. However, careful vigilance of the anesthesia care provider is essential for rapid management of laryngospasm.

Total airway obstruction following laryngspasm may result in acute pulmonary edema [103,104]. The pathogenesis of this edema is akin to that which occurs following acute obstruction due to trauma, masses [105], croup and epiglottitis [106]. An attempt at ventilation against a closed glottis generates an intrapleural pressure of approximately 30-60 cmH<sub>2</sub>O. In concert with the catecholamine surge, the intrapleural pressure causes acute pulmonary capillary hypertension and permeability exacerbated by acute hypoxemia. This process, followed by an immediate decrease in airway pressure that occurs with the relief or treatment of laryngospasm, induces pulmonary edema [106]. The increased negative intrapleural pressure and increased venous return (i.e. increased preload) may both result in injury to the microvasculature (i.e. increased permeability). The combination of the preload and the increased vascular permeability allows fluid movement out of the vasculature and produces interstitial edema and pulmonary edema. In addition, negative intrathoracic pressure increases left ventricular transmural pressure (i.e. afterload) [107] and affects cardiac performance. A third process, mechanical stress at the alveolar-capillary membrane, is thought to be responsible for both pulmonary edema as well as frank alveolar hemorrhage. While pulmonary hemorrhage may occur in children as a result of acute airway obstruction [108], other etiologies of pulmonary hemorrhage should be initially ruled out when this complication develops in association with laryngospasm [109].

Laryngospasm-induced pulmonary edema is most effectively managed by prompt tracheal intubation and application of continuous positive airway pressure or positive end-expiratory pressure with positive pressure ventilation. Diuretics, morphine, and sedatives are also effective adjuncts. If the patient has no underlying cardiorespiratory problems, the pulmonary edema resolves quickly, allowing the trachea to be extubated within several hours.

#### Stridor

Stridor is noisy breathing caused by turbulent flow through the narrowed lumen of an airway. It may be appreciated on inspiration or expiration, depending on the location of the obstruction. Inspiratory stridor occurs as a result of anomalies that narrow the airway above the thoracic inlet (e.g. cysts or masses, laryngomalacia, vocal cord paralysis, hemangiomas, laryngoceles, papillomas), adenotonsillar hypertrophy, midfacial hypoplasia, and croup. Expiratory stridor is most commonly associated with airway obstruction below the thoracic inlet (e.g. cysts, hemangiomas, vascular rings, foreign bodies) [107,110]. Biphasic stridor is common and is characteristic of midtracheal abnormalities secondary to tracheomalacia and tracheal stenosis. Diagnostic laryngoscopy and fiber-optic and/or rigid bronchoscopy and a variety of imaging procedures are often required to determine the etiology of stridor. To accomplish these procedures, deep sedation or general anesthesia usually is required. Therefore, the anesthesiologist should understand the physiology and clinical implications of stridor.

Inspiration through a partially obstructed extrathoracic airway reduces the intraluminal pressure of the extrathoracic airway below atmospheric pressure. The transluminal pressure gradient narrows the lumen further, increasing the stridor. During expiration, the extrathoracic intraluminal pressure is positive and greater than atmospheric, dilating the lumen and decreasing stridor. In contrast, inspiration through a partially obstructed intrathoracic airway reduces extraluminal pressure below intraluminal pressure and dilates the airway. During expiration, the reverse occurs and the expiratory noise (wheezing) worsens [107,110].

A careful medical history covering the severity and duration of symptoms, age and acuteness of onset, as well as a history of previous tracheal intubation, is important. For example, the newborn with severe stridor is likely to have a congenital anomaly of the airway as the etiology. A 3 year old with sudden onset of severe stridor is more likely to have a foreign body or an infectious etiology as the cause. The child in the recovery room or intensive care unit who develops stridor following tracheal extubation is likely to have airway edema as the cause. The severity and rapidity of progression of the symptoms define the diagnostic and treatment plan.

Approximately 45–60% of stridor (except postextubation stridor) in the young infant is due to laryngomalacia [110,111]. Symptoms of laryngomalacia generally are present from birth and must be differentiated from other congenital anomalies that cause stridor. Babies with laryngomalacia usually do not have feeding difficulties, but children with glottic or oropharyngeal lesions or a tracheo-esophageal fistula commonly do have these symptoms. The noise is usually worse in these babies when they are agitated or positioned supine. An occasional improvement in symptoms may occur when these babies are placed in the prone position. Although many of these infants do well and improve as they grow, their stridor often persists for 4–5 years [111].

Although infants and children with laryngomalacia do not have a higher incidence of upper or lower respiratory tract infections, their upper airway obstruction often worsens in the presence of an upper respiratory infection [111]. A child with laryngomalacia and an upper respiratory tract infection presenting for anything but emergency surgery should be carefully evaluated and surgery should proceed cautiously, especially if it will involve general anesthesia with endotracheal intubation. If the surgery is emergency, an endotracheal tube that allows an audible air leak when a positive pressure of  $20-25 \text{ cmH}_2\text{O}$  is generated should be used. In addition, the patient should be monitored postoperatively in a pediatric intensive care unit (PICU), where prompt ventilatory support can be provided.

Although uncommon, neurological abnormalities in an infant may present with stridor. Laryngeal nerve paralysis may be caused by birth trauma, cardiac malformations that affect the left recurrent laryngeal nerve or as a postoperative complication following ligation of a patent ductus arteriosus. Frequently, the etiology of the injury is unclear. Unilateral vocal cord paralysis commonly is the result of a peripheral nerve lesion and often improves with growth. Infants with unilateral cord paralysis commonly have stridor or hoarseness and feeding difficulties. Infants with bilateral vocal cord paralysis often have central nervous system disease (e.g. hydrocephalus, Arnold-Chiari malformation, Dandy-Walker cyst, encephalocele, posterior fossa hematomas or child abuse) [112–116]. Some authors relate the stridor to vocal cord paralysis that is caused by stretching the vagus nerve over the jugular foramen. However, it is often unclear why stridor occurs and why it persists after the increased intracranial pressure is normalized. Children who have bilateral vocal cord paralysis and serious respiratory obstruction or recurrent aspiration pneumonia often require a tracheostomy.

Anesthetic considerations for children who are stridorous are similar, regardless of the etiology of the obstruction. Maintaining continuous positive airway pressure during spontaneous ventilation via a facemask can reverse the upper airway pressure gradient and decrease or eliminate the obstruction. It is vital to have a wide range of endotracheal tubes available for intubation as some lesions, such as cricoid ring stenosis, webs, cysts, hemangiomas, epiglottitis and croup, will usually necessitate the use of a smaller than normal endotracheal tube. Lesions such as vocal cord paralysis which may also cause stridor do not narrow the airway. It is important to ensure that the endotracheal tube used for intubation has a leak at approximately 20–25 cmH<sub>2</sub>O airway pressure in order to prevent further injury to the trachea.

Postextubation stridor is a significant problem in children receiving mechanical ventilation for prolonged periods of time, resulting in laryngeal/tracheal edema, airway narrowing, and stridor. It may also occur in children who have undergone airway surgery or even those who have been intubated for surgery. The use of cuffed endotracheal tubes for general anesthesia in children, previously thought to contribute to the occurrence of postextubation croup, has been found not to result in the development of this condition [117]. The mucosa of the subglottic area in children is vascular and consists of loose areolar tissue and the cricoid cartilage is the narrowest area in the airway of a child less than 5 years of age. Therefore swelling caused by a tight-fitting endotracheal tube, burns or other trauma results in inflammation and narrowing of the internal diameter of the airway, because the cartilage of the trachea prevents edema from being displaced outward. Consequently, this area of the trachea is prone to edema.

Inhaled racemic epinephrine, heliox (79%, 70% or 60% helium in 21%, 30% or 40% oxygen) and occasionally steroids have been utilized to treat stridor. Racemic epinephrine (0.5 mL of 2.25% solution nebulized in 2.5 mL of normal saline) can be administered repeatedly at 5-min intervals to decrease edema if the heart rate is less than 200 beats/minute. Oxygen saturation should be monitored during treatment and if multiple treatments are required, an arterial blood gas should be obtained to ensure that ventilation is adequate. This is important particularly if increased work of breathing is observed in the child.

Heliox may also be used to facilitate ventilation in patients with stridor. The decreased density of heliox compared to oxygen and air provides more laminar flow in obstructed airways and decreases the work of breathing. In order to avoid hypoxia, however, heliox should not be used in children with a high oxygen requirement.

Steroids may be used in the management algorithm for stridor. However, the possible effect of delayed wound healing should be balanced against the possible benefit of steroids on the airway. In instances of failure to wean a patient from mechanical ventilation, without other obvious reasons, a 48-h trial of steroid therapy may lessen airway edema and allow successful extubation.

#### **Supraglottitis**

Acute supraglottitis (previously known as epiglottitis) (Fig. 31.3) is a life-threatening infection characterized by

Figure 31.3 Edematous epiglottis in a case of acute epiglottitis. Courtesy of Deidre Larrier MD.

severe edema of the supraglottic structures with a potential risk for upper airway obstruction. Children usually present with complaints of upper respiratory infection (rhinorrhea, cough) followed by severe sore throat and fever. As symptoms progress, the child constantly drools and may prefer to lean forward to improve their breathing pattern. Prior to the routine immunization of children with the Haemophilus influenzae type B (Hib) polysaccharide vaccine, many of the invasive cases of acute supraglottitis in children between the ages of 2 and 6 years occurred due to infection with Haemophilus influenzae type B. The frequency of this infection and disease process has since diminished in children [118,119] and other causative agents have been implicated, namely group A streptococcus infection [120], Neisseria meningitides [121] and Candida albicans [122]. Supraglottitis has a fulminant onset and therefore has a characteristic history and presentation; nevertheless, the differential diagnosis for this disease includes laryngotracheobronchitis (croup) and tracheitis (Table 31.3). Tracheitis can present with symptoms similar to those of supraglottitis.

The patient with suspected supraglottitis is at risk for sudden and complete airway obstruction so a multidisciplinary team is generally involved in managing these patients from the time of initial presentation to an emergency room or clinic. It is essential to have this co-ordinated approach established and all services available immediately. When the diagnosis of supraglottitis is made or strongly suspected, the goal is to secure the airway in a controlled, calm manner as soon as possible. Endotracheal intubation is the preferred method of supportive airway care as it is a safe and efficacious alternative to tracheostomy. The following approach is consistent with that reported in other centers [123].

A pediatrician, an anesthesiologist skilled in pediatric airway problems, and a surgeon skilled in placing a tracheostomy in an infant or child should be notified and be present when, or shortly after, the child arrives in the emergency room. A thorough, rapid cardiopulmonary history and assessment are made. Examination of the airway is limited to noting respiratory rate, observing the pattern of breathing, and assessing the work of breathing and level of respiratory distress. At most, the heart and lungs should be examined. Any maneuver that may result in the child becoming agitated should be reserved for the operating room setting; this includes manipulation or examination of the mouth or oropharynx, intravenous catheter placement, venepuncture or arterial blood gas sampling. Instead, the child should remain sitting up on a parent's (or other familiar caretaker's) lap and receive supplemental oxygen. Oxygen saturation is monitored with a pulse oximeter, while the child is observed closely by the medical personnel.

Characteristic	Supraglottitis	Laryngotracheobronchitis	Tracheitis
Age	2–6 years	2 months – 3 years	2–6 years
Onset	Fulminant	Gradual	Gradual
Etiology	Bacterial	Viral	Bacterial
Presentation			
Voice	Muffled	Bark	Bark
Secretions	Drooling	Drooling	None
Fever	>38.5°C	37–38°C	>38.5°C
Distress	Anxious, sitting up	Normal	Toxic appearing, sitting up

Table 31.3	Supraglottitis,	laryngotracheobronchitis,	tracheitis
------------	-----------------	---------------------------	------------

In the absence of respiratory distress, obtaining a single lateral radiograph of the neck to confirm the diagnosis may be considered. In this case, the child must receive supplemental oxygen while being transported sitting up to the radiography suite. They must be accompanied by someone who can intubate the trachea instantly if necessary although the ideal place for this to occur is the operating room. If the child is in significant respiratory distress or the diagnosis is made clinically, the child should be promptly transported, sitting up, to the operating room while receiving oxygen and being monitored. Radiological confirmation will be omitted in this urgent scenario. The patient must be accompanied by personnel skilled in pediatric airway management and cardiopulmonary resuscitation (CPR).

The tracheostomy tray should be open with the surgeon present when the patient arrives in the operating room. A smooth induction of anesthesia with sevoflurane in 100% oxygen, with the child sitting on the caretaker's lap, will allow for minimal airway irritation [124]. Halothane was previously used and traditionally allowed for a smooth inhalation induction in this situation. The appropriateness of parental or other caregiver presence during induction of anesthesia needs to be assessed for each patient.

With the onset of anesthesia, the patient is placed in the supine or semi-sitting position, often while continuous positive pressure is applied via facemask to overcome upper airway obstruction. Intravenous catheter placement may commence once an adequate depth of anesthesia has been achieved. Carefully evaluating the depth of anesthesia is vital to avoid precipitating laryngospasm during laryngoscopy and endotracheal intubation. The endotracheal tube should be approximately 0.5–1.0 mm smaller in diameter than is appropriate for the age and size of the patient. An initial orotracheal intubation may subsequently be changed to a nasotracheal tube by some anesthesiologists as the child often remains intubated for a number of days afterwards and a nasotracheal tube is more secure and better tolerated by the patient.

Blood and laryngeal cultures should be obtained during anesthesia, and appropriate antibiotics should be administered intravenously. The selection and dose of antibiotic will vary depending on the organisms seen in a specific geographic area and in a specific patient (e.g. immunocompromised, HIV infection). If the diagnosis of supraglottitis is ruled out when the upper airway is examined, and if the diagnosis is thought to be bacterial tracheitis, the antibiotic of preference may differ from that chosen to treat supraglottitis. Consulting with the pediatric infectious disease specialist is appropriate. The morbidity from 24-48h of tracheal intubation is minimal with excellent nursing care. Most otolaryngologists prefer the use of an endotracheal tube over performing a tracheostomy to treat airway obstruction. The patient can return to the operating room (OR) for an endoscopic examination of the airway once a leak (indicating resolution of the airway edema) has developed around the tube.

Although supraglottitis is rare in the modern era, the above general approach can be used for any form of acute severe upper airway obstruction.

# Endoscopy of the larynx, trachea, and bronchial tree

The major challenge of endoscopy of the respiratory tract is that the anesthesiologist must share the airway with the endoscopist and maintain adequate alveolar ventilation, oxygenation, a quiet surgical field and also provide a clear view in a patient with some degree of upper or lower airway compromise. Communication is essential and best achieved in the preoperative period by a discussion between the entire OR team so that all members are aware of the aims and steps in the procedure, equipment required and any special precautions, e.g. need for spontaneous respiration, potential fire hazards and method of ventilation during the procedure.

Lesions commonly diagnosed endoscopically include laryngomalacia or tracheomalacia, vascular anomalies causing tracheobronchial compression, congenital or acquired subglottic stenosis, vocal cord palsies, papillomas, hemangiomas, cysts, granulomas, and foreign bodies [110,125]. Therapeutic bronchoscopy is performed for extraction of foreign bodies or to selectively aspirate thick, tenacious plugs from the bronchi in order to resolve atelectasis, as occurs in cystic fibrosis [126].

Preoperative evaluation of the airway requires a careful history of the degree of airway obstruction that occurs during sleeping, crying or feeding. It is also important to determine the degree of accompanying respiratory distress (use of accessory muscles of respiration, tachypnea) and which positions or manuevers aggravate or alleviate the symptoms. The anesthesiologist should examine any available chest radiographs, head and neck computed tomographic scans, magnetic resonance imaging scans, pulmonary function tests or arterial blood gas determinations to obtain a complete view of the clinical situation [127,128].

### Fiber-optic direct laryngoscopy and bronchoscopy

In rare situations, this procedure can be accomplished with only topical anesthesia and mild sedation in infants or older children. More commonly, general anesthesia is required for an adequate endoscopic examination of the tracheobronchial tree. Preoperative sedatives and opiates should be administered with caution in any child with accompanying airway compromise, and then only with appropriate monitoring and by a person who is skilled in advanced airway management. Some experts recommend an anti-sialogogue to minimize secretions [129-131]. Sedation/anesthesia can be induced with midazolam, propofol or inhaled anesthetics, usually sevoflurane which is less irritating to the airway than desflurane, in an inspired oxygen concentration (FIO<sub>2</sub>) of 1.0. The larynx and trachea may also be anesthetized with local anesthetics (2-4% lidocaine, 3-5mg/kg (total dose)) typically sprayed onto the vocal cords by the endoscopist. This allows for the use of lower concentrations of inhalation agents so spontaneous ventilation can be maintained during observation of vocal cord movement, while providing adequate jaw relaxation and satisfactory conditions for initial airway endoscopy [132]. Propofol infusions, at rates of 150-200µg/kg/min, along with inhalation agents, also provide adequate conditions for laryngoscopy. Spontaneous ventilation may be maintained throughout the whole procedure. In rare cases, intermittent doses of non-depolarizing neuromuscular blocking agents, such as rocuronium or vecuronium, may be used after the status of the airway is known. Few pediatric anesthesiologists will use succinylcholine in this setting, particularly in light of the recent black box warning (severe contraindication warning by the US Food and Drug Administration) for succinylcholine [133]. The goal at the end of the procedure is to have a patient with spontaneous ventilation through a natural airway so muscle relaxants must be utilized judiciously, if at all.

## Jet ventilation, without an endotracheal tube

Since the late 1960s, jet ventilation through the side-arm of a bronchoscope or directly into the trachea via a specially adapted laryngoscope has been used to ventilate the lungs of patients during endoscopy when the surgeon requires a totally unobstructed view of the upper airway. The Sanders device delivers oxygen through a 14-16 gauge cannula at 50 psi down an open bronchoscope. The Venturi effect created entrains sufficient gas during delivery of the jet of oxygen at high pressure to provide ventilation. The system depends on gas escaping through an open glottis during an unobstructed expiratory phase of respiration. If expiration is obstructed, gas trapping and barotrauma can occur. Dangerously high inflation pressures may be present when the 3 and 4mm bronchoscopes are used. Pediatric patients are less likely to have a significant gas leak around the bronchoscope, particularly very small patients, and higher inflation pressures may develop [130]. A variety of modifications of the Sanders device have been introduced, which attempt to reduce the incidence of barotrauma during endoscopy procedures while maintaining adequate ventilation. Other complications that may occur include tumor, such as papillomas, other tissue or blood being forced into the airway.

Jet ventilation does not allow precise control of  $FIO_2$ nor does it allow measurement of end-tidal carbon dioxide, or peak or end-expiratory airway pressure.  $FIO_2$ of 1.0 is usually administered, since entrainment of air by the Venturi jet dilutes the oxygen. The volume of air entrained may be 10–20 times that delivered by the jet itself. In order to be effective, the jet ventilation laryngoscope must be aligned carefully with the glottic opening. If this does not occur, poor ventilation, inadequate oxygenation, and/or gastric dilation may result. The use of pulse oximetry does not obviate the need for clinical vigilance, and the anesthesiologist must have a clear view of the patient's chest at all times to ensure that appropriate chest wall movement occurs with each breath.

Miyasaka et al [129] reported that in 6-month to 3-yearold children, maximal inflation pressures and the volume of ventilation are vulnerable to small alterations in variables such as the size of the jet and the bronchoscope, length and angle of the jet, shape of the bronchoscope (tapered or straight), and the introduction of a suction cannula. Tidal volumes in excess of 10 mL/kg were achieved with driving pressures of 24–45 psi. However, the results of this study are applicable only when the Sanders No. 19 adapter is used. Any modifications should be carefully assessed [129].

Patients with underlying pulmonary disease and poor lung or chest wall compliance are not ideal candidates for jet ventilation as they are particularly susceptible to barotrauma.

Total intravenous anesthesia is commonly administered for jet ventilation via a laryngoscope or bronchoscope and opioids such as fentanyl or remifentanil in combination with propofol or thiopental may be administered to blunt airway reflexes. Muscle relaxants are also frequently administered in order to prevent coughing during the procedure which may lead to severe complications. However, jet ventilation is rarely, if ever, used in small children.

#### **Rigid bronchoscope**

The rigid pediatric ventilating bronchoscope is equipped with an optical telescope and a fiber-optic light source. An optical telescope, when used with the Storz® pediatric bronchoscope (Karl Storz-Endoskope, Tuttlingen, Germany), gives superior resolution and magnification, and a wide-angle view [126]. Miniaturized grasping or biopsy forceps can be manipulated through the instrument channel. An advantage of this system is that a closed system is maintained, permitting ventilation while the viewing telescope is in place [126,131]. A forceps may be placed through the main channel of the scope for retrieval of foreign bodies, if the telescope magnification is removed. A side-arm port also makes it possible to attach the ventilating bronchoscope to any anesthetic system to maintain anesthesia and oxygenation, and to assist or control manual ventilation (Fig. 31.4).

The optical telescope used with these systems occupies nearly the entire internal lumen of the smaller bronchoscopes. This reduces the area for gas flow, markedly increases airflow resistance, and retards passive expiration, potentially resulting in hyperinflation and hypoventilation [134]. A persistent increase in intrathoracic

Figure 31.4 Ventilating bronchoscope, optical telescope and foreign body forceps

pressure increases the risk of barotrauma and cardiac output can be impaired [134]. Maintaining adequate expiratory time is essential to allow complete expiration. A 2.8mm telescope in a 3.5mm bronchoscope allows adequate exhalation and prevents hyperinflation of the lungs, even during positive pressure ventilation [131]. When smaller scopes are used intermittently, the endoscopist can remove the telescope and occlude the orifice of the scope, thereby allowing the anesthesiologist to deliver brief periods of unobstructed manual hyperventilation [134]. For bronchoscopic examinations of longer duration, intermittent determinations of PaCO<sub>2</sub> can confirm the adequacy of ventilation. When evaluating the airway of small infants using a 2.5 mm bronchoscope, the surgeons must remove the telescope more frequently to permit adequate ventilation and complete passive exhalation.

Any rapid deterioration of cardiac function during bronchoscopy should make one highly suspicious of the possible development of a tension pneumothorax [135]. Clinical findings of a pneumothorax alone justify thoracostomy before obtaining a chest radiograph. Vocal cord movement may be evaluated by laryngoscopy as the patient awakens from anesthesia. Care must be taken to avoid inducing laryngospasm during this time.

### **Airway foreign bodies**

#### Foreign body aspiration

Aspiration of foreign bodies, including organic food items, toy parts, batteries, pin caps, etc. (Fig. 31.5), is a major source of morbidity and mortality in children below 5 years, with a peak incidence between the ages of 1 and 2 years [136–140]. Depending on the nature and location of the aspirated object, removal can be life saving. A detailed discussion with the anesthesia and nursing team to co-ordinate the procedure is mandatory for a smooth procedure and this should occur before the child is brought into the operating room.

A thorough history is pertinent to the diagnosis of foreign body aspiration. Some parents may report witnessing a choking episode which may have been short-lived such that they did not consider it significant at the time. This results in delayed presentation and diagnosis. The presenting symptoms of foreign body aspiration vary depending on the location, size, and duration of aspiration of the object. Acutely, a child may present with hoarseness, stridor, dyspnea, and unilateral decreased air entry or wheezing on auscultation [141–144]. Acute airway distress occurs especially if the object is lodged at or near the glottic inlet. However, normal auscultation or physical examination cannot eliminate the possibility of an aspirated foreign body as 14–45% of patients with an

Figure 31.5 A variety of foreign bodies retrieved from the airway, clockwise from top left: plastic tube, toy flag, safety pin and bubble gum. Courtesy of Ellen Friedman MD.

abnormal bronchoscopic finding including foreign bodies have a normal physical examination preoperatively [145-147]. Objects located in the larynx or trachea can be associated with mortality as high as 45% [148]. According to one study, the diagnosis of laryngotracheal foreign body was made within the first 24 h of aspiration in only slightly more than one half the patients. The remaining patients were diagnosed following failure of medical management for croup or reactive airway disease, usually within 1 week of aspiration. Children diagnosed late either did not respond to therapy or their condition deteriorated despite appropriate medical therapy [143,149]. Partial obstruction by smaller objects may go unrecognized for weeks [148] and such children may present with recurrent or chronic pneumonias or bronchiectasis [150]. Some episodes of choking are not witnessed but a high index of suspicion should be raised when a toddler/child presents with respiratory distress in the absence of a prior history of infection or trauma. Chronic abnormalities on chest radiography should be suspicious for pneumonia due to an aspirated foreign object.

A variety of objects can be aspirated (see Fig. 31.5). Radiopaque objects are more easily appreciated on chest radiograph and some plastic toys contain radiopaque markers for easy detection on chest x-ray. Unfortunately, the most frequently aspirated items (food) are radiolucent and are unlikely to be detected by radiography. In such instances, lateral decubitus views can confirm the presence of lower airway obstruction due to the presence of

Figure 31.6 Patterns of foreign body-induced airway obstruction. Courtesy of Ellen Friedman MD.

an aspirated foreign body. Four major patterns of airway obstruction have been described [151,152]: bypass valve obstruction, check valve obstruction, ball valve obstruction and stop valve obstruction.

- Bypass valve obstruction involves both phases of respiration and the chest radiograph is usually normal because aeration occurs beyond the point of obstruction although it is somewhat diminished (Fig.31.6A).
- Check valve obstruction is characterized by normal inhalation of air and impedance of exhalation resulting in hyperinflation of the ipsilateral affected lung field.

To appreciate this effect, inspiratory and expiratory radiographic films are required. As expiratory films may be difficult to obtain in children, lateral decubitus films are obtained. When a foreign body has been aspirated, a mediastinal shift should occur toward the normal side if the difference in volume is significant. On a left lateral decubitus film, the mediastinum/heart structures should shift to the left, while on a right lateral decubitus film, the mediastinum should shift to the right. If there is an obstructing foreign body on the right main bronchus, the ipsilateral lung field (right) will remain aerated and inflated on a right lateral decubitus film (Fig. 31.6B, C).

- Ball valve obstruction is characterized by a partial obstruction which intermittently prolapses and obstructs the affected bronchus. A chest radiograph in this instance will notably have a mediastinal shift toward the involved side with decreased air entry leading to early atelectasis and collapse.
- Stop valve obstruction denotes a complete bronchial obstruction with impedance to air flow during both inspiration and expiration. A consolidation of the involved bronchopulmonary segment occurs with subsequent collapse (Fig. 31.6D).

The urgency to proceed with anesthesia and bronchoscopic removal of a foreign body is dictated by the severity of respiratory distress, and the location and nature of the aspirated material. Foreign bodies can move from one part of the airway to another and cause sudden complete airway occlusion. Ideally, the foreign body is removed very shortly after aspiration to minimize the occurrence of pneumonia or other complications. When possible, removal of the object should be done as an urgent, not emergency, procedure in a well-prepared patient [141,153,154]. Bronchoscopic removal of a foreign object is successful 95-98% of the time, but a small number of patients may need repeated bronchoscopies because the foreign body either was not found or it was removed incompletely [141,154]. Rarely, thoracotomy may be necessary [154,155].

A variety of methods have been successfully utilized to anesthetize children for bronchoscopy and retrieval of a foreign body [156,157]. The exact anesthetic technique, however, depends on a number of factors, namely the condition of the patient, suspected location of the foreign body and personal preference of the anesthesiologist or surgeon. The presence of an intravenous catheter before proceeding with surgery allows for administration of an anticholinergic to dry up secretions, prevent a vagal response from insertion of the bronchoscope and attenuate cholinergic-mediated bronchoconstriction during airway manipulation as well as permitting steroid administration to decrease airway swelling. Administration of preoperative sedatives may be controversial as sedation may exacerbate upper airway obstruction.

Inhalation induction allows the anesthesiologist to avoid positive pressure ventilation and the possibility of moving the foreign body distally in the airway and making it more difficult to extract. However, if the child has a "full stomach," spontaneous ventilation will not offer any protection from aspiration of gastric contents. Few anesthesiologists would advocate a rapid-sequence induction of anesthesia in an infant if there is respiratory distress and no absolute delineation of the current location of a foreign body. Routine fasting guidelines should apply if the patient's ventilatory status is stable.

Once anesthesia has been induced, the head of the table should be rotated 90° away from the anesthesiologist with the patient's head to the anesthesiologist's right, and the airway is managed from the patient's left side by the anesthesiologist or by the surgeon who is positioned at the head of the bed. The gums (in an edentulous infant) or teeth are protected from injury with the use of moist gauze or with a plastic guard. A laryngoscope is inserted, topical local anesthetic sprayed on the glottis with an atomizer, and the laryngoscope is reinserted and suspended in the vallecula to expose the epiglottis, arytenoids and vocal folds which are then inspected for any mucosal abrasion or presence of foreign body. A bronchoscope is then inserted to visualize the distal airway. Once the ventilating scope is inserted in the subglottic area, the anesthesia circuit is connected to allow oxygen delivery and positive pressure ventilation if necessary.

For maintenance of anesthesia, most anesthesiologists would follow a "middle course," allowing a child to breathe oxygen and a potent inhalation anesthetic until it can be established that gentle positive pressure ventilation adequately expands the chest. At this point, a decision can be made about muscle relaxation. If the decision is made to avoid muscle relaxants, a deep level of anesthesia is required to permit bronchoscopy without coughing. The addition of topical anesthesia is also helpful in attenuating airway reflexes. Regardless of the method of ventilation chosen, the child's airway is exposed to the atmosphere multiple times during the procedure (when the surgeon removes the bronchoscope or optical eyepiece). For this reason, total intravenous anesthesia is preferred to decrease airway pollution from inhalational agents and also to provide an uninterrupted source of general anesthesia to the patient.

Ideally, spontaneous ventilation should be preserved at least until the nature and location of the foreign body have been identified by bronchoscopy, especially if the object could not be localized radiographically. Even if the position of the foreign body was detected by radiographic studies, the anesthesiologist must always be aware that its position may change intraoperatively. The use of nitrous oxide during this procedure is contraindicated in most cases because it reduces the inspired concentration of oxygen. Also, if significant air trapping is present, nitrous oxide could increase the gas volume and pressure in the affected lung. Rapid bronchoscopy usually allows rapid removal of the foreign body. On occasion, the bronchoscope may dislodge a tracheal foreign body and push it peripherally into a mainstem bronchus with improvement in ventilation and relief of the immediate crisis.

Occasionally, the size of the foreign body exceeds the internal diameter (ID) of the bronchoscope. When this occurs, the foreign body, the forceps, and bronchoscope must be removed together through immobile vocal cords [153]. Administering a small dose of a short-acting nondepolarizing muscle relaxant allows adequate, brief relaxation to permit removal of the bronchoscope and foreign body. If the foreign body is lost during its attempted removal, the pharynx should be immediately inspected. If the object is not found, the bronchoscope should be reintroduced, and the larynx or trachea reexamined. If tracheal obstruction occurs and the object cannot be immediately removed, it may be necessary to push the object back to its original location to allow ventilation of the lungs. If possible, the foreign body should be returned to the affected lung and not to the unaffected lung because placing it in the unaffected lung could result in unreliable ventilation of either lung. Following removal of the foreign body, the endoscopist must re-examine the airway to look for additional multiple or fragmented foreign bodies and to remove secretions that are distal to the obstruction.

The bronchoscope often must be reinserted several times before the foreign body and secretions are successfully removed. This may produce mucosal edema and respiratory distress after bronchoscopy. Administration of steroids, humidified oxygen, nebulized racemic epinephrine and, rarely, tracheal reintubation for 1 or 2 days may be required until the edema subsides [158]. Initial doses of 0.5-1.5 mg/kg dexamethasone (and smaller doses for 2–3 days) may minimize the subglottic swelling caused by repeated insertion of the bronchoscope. Racemic epinephrine (2.25%) may be given in a 1:6 to 1:10 dilution through a nebulizer and clear plastic facemask for 10-min periods while monitoring the electrocardiogram (ECG). Treatment is repeated as necessary every 2h [158]. Some patients treated with racemic epinephrine develop "rebound" edema so patients who respond to racemic epinephrine should be monitored carefully for at least 3-4h after each dose of the drug to determine if "rebound" edema occurs.

Aspirated vegetable matter like peanuts occasionally become fragmented during removal and pose a significant challenge during bronchoscopy. Larger aspirated material may acutely occlude both mainstem bronchi and a thoracotomy by a surgeon skilled in pediatric thoracic surgery would be required for retrieval of the material. A Fogarty No. 3 embolectomy balloon catheter may also help dislodge impacted foreign bodies [126,153].

Although prompt removal of a foreign body through an open rigid bronchoscope is the mainstay of treatment of a tracheal foreign body, diagnostic flexible bronchoscopy also may have a role [159–161]. When foreign body aspiration is not clearly evident by history, physical examinations, and radiography, some surgeons may perform diagnostic flexible bronchoscopy under local anesthesia and sedation instead of a rigid bronchoscopy as this is less traumatic to the patient and their airway [160]. If a foreign body is subsequently identified, the patient then undergoes rigid bronchoscopy. Flexible bronchoscopy is not recommended when respiratory distress is present. The decision to utilize fiber-optic bronchoscopy for diagnostic evaluation for foreign body aspiration depends on the skills and services available at each medical center. The risks of possibly having to undergo two procedures should also be carefully considered.

## **Esophageal foreign bodies**

Endotracheal intubation and airway protection should precede foreign body extraction from the esophagus. Inadvertently dropping an esophageal foreign body into an unprotected larynx can cause a disaster [149]. Endoscopic removal of foreign bodies from the upper gastrointestinal inlet is successful in greater than 98% of cases [161]. It is necessary to perform an immediate second look after removal of the foreign body to ensure there has been no trauma from the attempt and to rule out the presence of more than one foreign body, or a congenital defect (e.g. pouch, esophageal stenosis) that can increase the risk of subsequent impaction of food or other foreign bodies. Frequently, foreign bodies that have passed through the gastric outlet into the small and large intestines pass through the gastrointestinal tract spontaneously and surgical intervention is rarely needed [162]. As with chronic airway foreign bodies, retained esophageal foreign bodies can be treacherous. Complications include bronchoesophageal fistula, aortoesophageal fistula, mediastinitis, esophageal diverticulum, and lobar atelectasis. These retained foreign bodies may require a thoracotomy to remove them [163].

### Laser microlaryngeal surgery

The most common indication for laser microlaryngeal surgery is recurrent laryngeal papillomas or juvenile

Figure 31.7 Papillomas on the vocal cord. Courtesy of Deidre Larrier MD.

laryngeal papillomatosis which is the most common airway tumor found in children. It is a chronic, debilitating and frequently life-threatening condition. Laryngeal tumors occur as a result of human papillomavirus (HPV) infection which is transmitted from the mother to the child during pregnancy. These tumors are typically located on the vocal cords, epiglottis, and in the larynx or trachea (Fig. 31.7). They are usually symptomatic and result in aphonia, hoarseness, stridor and respiratory distress. When a large number of these tumors are present on a chronic basis, symptoms of right ventricular hypertrophy or cor pulmonale may develop.

Surgical excision and ablation of these lesions, the current mode of management, is possible using carbon dioxide (CO<sub>2</sub>) laser through an operating microscope. The CO<sub>2</sub> laser's light waves are absorbed by all biological tissues and rapidly vaporize intracellular water present in tissue, leading to a rapid increase in temperature and denaturation of protein in the targeted tissue. Minimal bleeding occurs as the thermal energy of the laser beam cauterizes capillaries as it vaporizes tissues and very little postoperative edema occurs. The benefit of CO<sub>2</sub> laser treatment is that the surrounding tissues are unaffected. The CO<sub>2</sub> laser has been used with excellent results for treating such lesions as papillomas of the nose, oral cavity or larynx, subglottic stenosis, subglottic hemangioma, glottic webs, choanal atresia, postintubation granuloma, vocal cord nodules, and lymphangiomas [154,164]. It has the advantage of providing excellent hemostasis, with minimal postoperative edema and scarring, rapid healing and preservation of the quality of voice [165,166]. It is the preferred mode of surgical treatment of laryngeal papillomas, even though laser resection does not cure this condition.

In a recent survey of the practices of pediatric otolaryngologists, about 50% of practitioners now use the laryngeal microdebrider rather than  $CO_2$  laser removal for laryngeal papillomas [167]. The microdebrider device uses suction and rotating cold blade excision for more precise removal of papillomas. It has a slightly angulated tip that sucks mobile papilloma tissue into the cutting blade and leaves firmer underlying native tissue intact. A prospective comparison of the microdebrider and the CO<sub>2</sub> laser revealed that the microdebrider resulted in equivalent postoperative pain with greater improvements in voice quality, shorter procedure times and overall lower cost [168].

Adjuvant medical therapy for laryngeal papillomas is also on the rise with the use of cidofovir and interferon which have been beneficial in some children. Cidofovir is, however, reserved for severe cases (requiring four or more surgical treatments per year) due to its carcinogenic potential and lack of supportive data for its use [169]. The newly available HPV vaccine may have an effect on the incidence and severity of laryngeal papillomatosis but to date this has not been studied.

Surgical requirements for suspension laryngoscopy using the  $CO_2$  laser include hyperextension of the neck and a motionless surgical field (i.e. relaxed vocal cords) so that the lesion may be ablated without injury to the surrounding healthy tissue. Prompt recovery of consciousness and protective airway reflexes must be present at the conclusion of surgery.

### Anesthesia for laser microlaryngeal surgery

Children with recurrent laryngeal papillomas present frequently for therapy due to the recurrent nature of the tumors. The mainstay of an effective treatment program to keep the airway free is by repeated endoscopic and laser excision of the papillomas until puberty, when they tend to regress [170].

Perioperative anxiety is therefore fairly common in children requiring repeated surgeries. The judicious use of sedatives and, most importantly, a reassuring preoperative visit by the anesthesiologist help to allay fears. A child with significant airway obstruction should only receive preoperative sedation while being monitored and when oxygen, positive pressure ventilation, and suction are available. An anesthesiologist or surgeon skilled in advanced airway intervention must be present at all times. The perioperative care of children with laryngeal papillomas can be very challenging, depending on the location of the lesions. Pedunculated papillomas may obstruct the airway, causing a ball valve obstruction in certain positions. It is prudent therefore to avoid initial administration of muscle relaxants and maintain spontaneous respiration till the surgeon has adequately examined the airway and determined the location of the lesions. These children should be approached in a similar manner to those with anticipated severe airway obstruction, with a slow inhalation induction with sevoflurane in 100% oxygen without stimulation in order to avoid agitation and potential obstruction during induction. It is often helpful to maintain 5–10 cm of positive endexpiratory pressure in the anesthetic system to distend the hypopharynx and to facilitate mask ventilation. Muscle relaxants should be used only after positive- pressure ventilation by mask can be demonstrated.

Laser surgery may be performed during anesthesia with spontaneous, apneic or jet ventilation or with the use of laser-safe endotracheal tubes. However, the use of such tubes is declining, with only 10% of otolaryngologists stating this as their preferred mode of anesthesia in a recent survey [167].

Spontaneous ventilation without intubation allows the surgeon to work without interruption (of intermittent placement of the endotracheal tube to deliver positive pressure ventilation). A deep anesthetic plane achieved with total intravenous anesthesia (TIVA) using propofol (200–300 $\mu$ g/kg/min) plus intermittent opioid administration (morphine 0.05 mg/kg, fentanyl 2–3 $\mu$ g/kg or remifentanil infusion 0.1–0.25 $\mu$ g/kg/min). Aerosolized lidocaine helps decrease airway irritability and intravenous dexamethasone administration helps prevent postoperative swelling. Intermittent mask ventilation may be required to treat periods of hypoxemia; alternatively the patient may be briefly intubated by the surgeon for brief periods of manual ventilation to increase the patient's saturations.

Jet ventilation with intermittent apnea technique is also utilized in some institutions. The operating laryngoscope may be fitted with a catheter through which air is entrained and the lungs are intermittently ventilated by the jet. Jet ventilation also offers a quiet surgical field as there is no movement from large excursions of the diaphragm and it also offers uninterrupted surgery. However, there is some concern about the use of jet ventilation and the possibility of papillomas being forced into the tracheobronchial tree. In addition, this technique may not provide effective ventilation in children with small airway disease. The inability to measure expired carbon dioxide and the possibility of barotrauma are also possible complications. (See Jet ventilation above.)

In an effort to improve existing Venturi jet techniques, Brooker et al developed a subglottic ventilation anesthesia system [171]. The Hunsaker Mon-Jet tube is a lasersafe subglottic jet tube that allows monitoring of tracheal pressure and end-tidal CO<sub>2</sub>. The device aligns the jet away from the tracheal mucosa to prevent injecting gas into the submucosa. The device also uses an automatic jet ventilator with an adjustable rate, inspiratory to expiratory (I:E) ratio, and flow rate. Peak inspiratory and peak end-expiratory airway pressures are monitored and the device shuts off if the limits are exceeded.

When there is significant obstruction or depending on the surgeon's or anesthesiologist's preference, the trachea may be intubated after induction of anesthesia with sevoflurane in oxygen. Suspicion has been cast on the possibility of distal tracheal papillomas being spread with intermittent instrumentation of the airway during surgery [167]. Difficulty ventilating the lungs after intubating the trachea may occur if a papilloma is released into the trachea or obstructs the endotracheal tube. An endotracheal tube several sizes smaller than the one appropriate for the child's age is chosen as there usually is scarring from repeated laser therapies and it is important to maintain an adequate view for the surgeon to visualize lesions that need to be treated. The use of an endotracheal tube during laser surgery increases the risk of this surgery as regular polyvinyl chloride (PVC) endotracheal tubes are flammable and can be ignited and vaporized by a laser beam. Red rubber endotracheal tubes wrapped with metallic tape deflect the laser beam but the segment of the tube beyond the vocal cords cannot be covered with metallic tape and is still vulnerable to the laser beam and vaporization. Some non-latex endotracheal tubes have been manufactured specifically for laser surgery but they tend to be more expensive and also have larger outer diameters than their regular PVC endotracheal tube counterparts, especially in the small sizes. There are therefore not adequate for use in small children or children with an airway markedly narrowed by papillomas.

At the conclusion of surgery, an endotracheal tube may be inserted and secured till the child is completely awake or if spontaneous ventilation was maintained during surgery, inhalation agents can be discontinued and the patient transported to the recovery room with blow-by oxygen until the patient finally awakens in the recovery room. Racemic epinephrine for stridor may be required postoperatively.

## Safety precautions during laser airway surgery

Laser radiation increases the temperature of absorbent material so flammable material such as surgical drapes must not be in the path of the laser beam. Minimal surgical drapes should be used during laser surgery. Burning of surgical drapes can result in burns to the patient and also produces significant smoke which may result in smoke inhalation injury to the patient and operating room staff [172]. The face, neck and shoulder surfaces should be covered with wet towels which absorb laser energy and prevent burns from deflection of the laser beams during surgery.

In contrast to the argon laser and the neodymium:yttrium-aluminum garnet (Nd:YAG) laser, the CO<sub>2</sub> laser does not penetrate the cornea. Nevertheless, to prevent thermal injury to the cornea or retina from the laser beam, operating room personnel must wear protective eyewear (regular eyewear will suffice for individuals with prescription eye glasses) and the patient's eyes must be protected with moist gauze pads or protective goggles. Argon and Nd: YAG lasers are used primarily in ophthalmological surgery and to treat gastrointestinal bleeding or for excision of endobronchial lesions, respectively. These devices can penetrate the cornea and damage the retina. They also penetrate glass so glass windows in the OR should be covered with appropriate material.

Vital structures some distance from the operative site can be injured by overshoot of the laser beam or by reflection of the beam off a polished instrument. This has caused tracheal laceration in a child undergoing resection of recurrent laryngeal papillomas. The tracheal tear became evident in the recovery room with the development of bilateral pneumothoraces and subcutaneous emphysema. Constant vigilance by recovery room nurses is important to observe and detect laser-induced pneumothorax [173].

In institutions where foil-wrapped endotracheal tubes are used for laser surgery, the foil can be covered with a moist sponge layer to absorb any heat generated. This outside sponge layer also provides a smooth surface that minimizes trauma to the airway. While the shaft of the endotracheal tube can be covered with protective material, the endotracheal tube cuff is vulnerable to the effects of laser radiation and filling the cuff with saline rather than air is recommended. Placement of saline-soaked pledgets above the endotracheal tube cuff during laser surgery has also been recommended.

In addition to the risk of combustion, foil-wrapped tubes may kink, irritate the tracheal mucosa, obstruct the airway if the foil separates from the tube and, on occasion, permit the laser beam to penetrate and ignite unprotected portions of the tube [164,166,174,175].

The mixture of gases delivered into the endotracheal tube may affect the risk of combustion during general anesthesia and laser surgery of the airway. Although helium impedes combustion during carbon dioxide laser surgery, the differences between nitrogen and helium effects on combustibility are not clinically significant [176]. In a previous study, nitrous oxide and oxygen were shown to be additive in their ability to sustain combustion [177]. FIO<sub>2</sub> should be reduced to as low as possible, i.e. 0.21–0.30, with an air-oxygen mixture; N<sub>2</sub>O must not be used during laser surgery.

The different methods of airway management during laser surgery have the common goal of preventing airway fires but each method has its own set of problems. If, despite all precautions, ignition of the endotracheal tube should occur, the flow of oxygen should be discontinued immediately and the endotracheal tube should be disconnected from the gas source and immediately removed. Most materials do not readily burn in air [166]. The anesthesiologist must have direct access to the tube at all times and ensure that the entire tube has been removed from the airway. A chest radiograph should be obtained and bronchoscopy should be performed to reveal the extent of the injury to the lung and trachea caused by direct burn, smoke inhalation or retention of a foreign body. Complications are treated according to the severity of the injury and may include steroids, humidification of inspired gases, tracheostomy, and assisted ventilation. Tracheal stenosis can be a late complication [166].

## **Other tracheal surgery**

Recent studies show that the use of early continuous positive airway pressure (CPAP) in early preterm infants results in shorter periods of intubation and a decrease in the incidence of bronchopulmonary dysplasia [178]. However, with the improved capability of ventilatory support for preterm infants, prolonged periods of tracheal intubation have occurred, resulting in increased survival but accompanied by laryngotracheal injury in as many as 2.5% of neonatal patients [179]. Glottic or subglottic compromise ensues, with the latter being more frequent and serious than the former [180]. The exact location of injury is detected by careful endoscopic evaluation of the airway [179]. Subglottic stenosis may also occur in older children following laryngeal injury. In these instances symptoms such as progressive hoarseness, dyspnea, stridor or feeding difficulties may occur approximately 2-4 weeks following injury. In addition, these children may present with repeated upper respiratory tract infections.

Congenital anomalies of the larynx or trachea may also occur in neonates. For example, some children are born with laryngeal atresia or congenital high airway obstruction in which a large portion of the larynx is absent at term. In these children, an initial life-saving tracheostomy is placed during delivery while the baby is still on placental bypass during *ex utero* intrapartum therapy (EXIT procedure) [181] (see Chapter 19).

Treatment options for subglottic stenosis include tracheostomy or tracheal reconstruction, including the anterior cricoid split and laryngeal reconstruction. The extent or severity of the stenosis determines the nature of surgical repair. The degree of stenosis may be assessed by soft tissue radiographic images of neck and computed tomography with three-dimensional image reconstruction, in which the length of the stenotic segment can be appreciated and precisely measured. In addition, direct inspection of the airway under general anesthesia in the operating room provides valuable information. Depending on the degree of stenosis, a rigid or flexible bronchoscope is utilized to visualize the larynx and trachea beyond the stenotic area. The trachea is usually intubated intraoperatively in order to "size" the trachea. The size of endotracheal tube that can be easily inserted with an audible leak provides information on the degree of stenosis. The most mild instances of subglottic stenosis can be managed by endoscopic dilation or CO<sub>2</sub> laser endoscopic scar excision with or without application of mitomycin, an antimitotic agent designed to prevent reapposition of the raw submucosal edges [182]. A tracheostomy is required for about 50% of patients with congenital subglottic stenosis and for an even higher percentage of patients with severe acquired subglottic stenosis [183] (see Chapter 14). The advent of procedures such as anterior cricoid split may prevent some infants from developing severe subglottic stenosis or may reduce the number of patients requiring a tracheostomy.

Tracheostomy significantly changes the quality of life and although often life-saving, it can be associated with a significant risk of morbidity and mortality. This has led to the development of reconstructive operative therapy such as the anterior cricoid split procedure and external laryngeal reconstruction to allow early decannulation of the trachea at the youngest age possible so speech and language development are not impaired [184].

#### Anterior cricoid split procedure

The goal is to decompress the area of the subglottic space enclosed by the cricoid ring, the only complete cartilaginous ring of the airway. This procedure is performed over the largest endotracheal tube that can be inserted into the trachea via the nose. A midline vertical cartilaginous incision is made 2mm from the thyroid notch inferiorly through the second tracheal ring (Fig. 31.8) [185]. Stay

**Figure 31.8** Anterior cricoid split. Reproduced from Zalzal and Cotton [185] with permission from Elsevier: www.Expertconsultbook.com.

sutures are placed through the cricoid ring as in a tracheostomy, and the skin incision is closed. The endotracheal tube often is left in place for approximately 1–2 weeks to temporarily stent the incision open as it allows fibrous ingrowth and prevents airway obliteration with granulation tissue. It also allows the mucosal swelling to subside and provides time for the split cricoid to heal. After this period, tracheal extubation is attempted after treatment with steroids.

#### Laryngeal reconstruction

Positioning for this procedure involves placement of a shoulder roll and hyperextension of the head. Either inhalation or intravenous anesthesia may be used for induction and maintenance during surgery. The existing tracheostomy is replaced with an endotracheal tube; initially an oral RAE tube is inserted through the stoma as this can be easily anchored. The tip of the oral RAE tube may need to be cut in order to prevent endobronchial intubation. Laryngotracheoplasty is performed through a horizontal skin incision with midline dissection from the cartilage of the thyroid notch superiorly to the third or fourth tracheal rings inferiorly (Fig. 31.9) [183]. A vertical median anterior incision is made into the stenotic lumen. Posterior subglottic or posterior commissure stenoses may require a midline posterior cartilaginous incision to increase the posterior lumen. Sculpted segments of harvested costal cartilage are then sutured into the midline incisions, thereby increasing the airway lumen. A solid stent may be necessary to provide support during the postoperative period. This stent may be wired to the tracheostomy tube.

After allowing an appropriate period for stable healing of the grafts, the stents may be removed and the intraluminal granulation tissue excised. Further operative procedures may be required to remove granulation tissue and to allow the epithelium to cover the grafts and operative sites. Decannulation occurs when an adequate airway lumen has been obtained.

Partial cricoid resection with primary thyrotracheal anastomosis was initially performed in adults with significant subglottic stenosis. Previous concerns about performing the procedure when the larynx is still growing have not been confirmed and there are now several reports of a high success rate of approximately 97% in children with subsequent normal laryngotracheal growth following this procedure [186–189]. Since this surgery seems to have no significant effect on the laryngeal growth of young children, this mode of treatment of subglottic stenosis may provide earlier and less traumatic decannulation from tracheostomy.

The anesthetic challenges of these procedures include sharing the airway with the surgeon and repeated removal of the existing airway during the procedure to allow for

**Figure 31.9** Laryngotracheoplasty. Horizontal skin incision incorporating the superior aspect of the tracheostomy stoma. (A) A vertical incision is made in the thyroid cartilage from a point immediately below the anterior commissure through the upper tracheal rings, with care to remain in the midline. (B) The intraluminal scar and lining mucosa are incised along the length of the stenotic segment. (C) The costal cartilage graft is then shaped into an ellipse and placed in position with the lining perichondrium facing internally. surgical access and stent placement. A quiet surgical field is also essential and postoperatively, adequate sedation and relaxation are mandatory during transport to the intensive care unit.

#### Eye surgery

Unlike in adults, most pediatric ophthalmological procedures are extraocular rather than intraocular. Extraocular conditions that require operations include the management of nasolacrimal duct obstruction and strabismus. Intraocular conditions that may require a surgical approach in children include glaucoma, cataracts, retinoblastoma and retinopathy of prematurity. Several medical problems are associated with congenital and acquired eye anomalies and pathology. The anesthesiologist must have a good understanding of the associated medical entities as well as the many anesthetic drugs and procedures that profoundly affect ocular physiology (Table 31.4). A basic understanding of intraocular pressure and its control, along with the pharmacology of drugs used by the ophthalmologist and the potential for drug interactions with anesthetics, is necessary to provide adequate anesthesia care for pediatric patients during eye surgery.

#### **Extraocular procedures** Nasolacrimal duct obstruction

Up to 6% of healthy neonates have congenital nasolacrimal duct obstruction, presenting with epiphora or continuous tearing. In the absence of infection, a conservative approach is appropriate for a few months to see if the tear duct opens with time. However, if nasolacrimal duct stenosis persists, a series of procedures with increasing invasiveness are performed. These start with probing and irrigation of the nasolacrimal duct. With the increased safety of general anesthetics, this brief procedure is performed in an operating room. A standard mask induction and maintenance of anesthesia with inhalation agents can provide satisfactory operative conditions. Some anesthesiologists would place an LMA to secure the airway. Instillation of fluorescein dye to test patency of the duct and the possibility of some bleeding potentially increase the risk of laryngospasm with mask or LMA. If simple probing and irrigation are not enough to resolve the condition, the child is brought back for balloon dilation and/or silastic stent placement. The anesthetic management should be the same as for tear duct probing. In a very small percentage of patients the obstruction persists for a while and may result in infections of the tear sac.

Drug	mg/drop	Ophthalmological effect	Anesthetic implications
Atropine (1%)	0.5	Mydriasis, cycloplegia	Tachycardia, flushing
Cocaine (1%)	0.5	Vasoconstriction	Hypertension, dysrhythmia,
Cyclopentolate (1%)	0.5	Mydriasis, cycloplegia	Hyperthermia
			Convulsions – not common
Echothiophate (0.25%)	0.1	Antiglaucoma	Anticholinesterase, long acting
Epinephrine (0.25%)	0.1	Antiglaucoma	Hypertension, dysrhythmias
Phenylephrine (2.5%)	1.2	Mydriasis, vasoconstriction, decongestion	Hypertension
Scopolamine (0.5%)	0.25	Mydriasis, cycloplegia	CNS excitement
Timolol (0.25%)	0.1	Antiglaucoma	$\beta$ -Blockade, non-selective

 Table 31.4
 Anesthetic effects of commonly used ophthalmological drugs

CNS, central nervous system.

This may require a more invasive and longer procedure such as dacryocystorhinostomy. The anesthetic management should include securing the airway with tracheal intubation as access to the airway will be unavailable during the operation. Analgesic drugs should also be used. These procedures are performed on an outpatient basis unless the child has some other concomitant medical condition.

#### Anesthesia for strabismus surgery

Strabismus, a misalignment of the visual axes, can be congenital or acquired and it occurs in 2–7% of children. Strabismus correction is one of the most common surgical procedures in ophthalmology. The congenital form may occur as a result of abnormal innervation while the acquired form may occur following traumatic nerve palsies. Strabismus can also occur in association with congenital myopathies as well as meningomyelocele. The outcome of this surgery is excellent when performed early in life.

The primary considerations for anesthesiologists caring for children having strabismus surgery are cardiovascular effects of medications placed in the eye, the oculocardiac reflex and and postoperative nausea and vomiting. In the past, patients with strabismus were thought to be susceptible to malignant hyperthermia (MH) as most patients with MH had associated musculoskeletal disorders, including strabismus and ptosis. A subsequent review of 2500 patients tested for MH susceptibility did not show any association with strabismus surgery. Malignant hyperthermia is no longer considered to be a risk for children with strabismus and these children are now routinely anesthetized with inhalational anesthetics without an observed increase in the incidence of MH [190,191].

Masseter muscle spasm (MMS) has also been associated with strabismus surgery, particularly in patients who received halothane and succinylcholine [192] although another study contradicted this finding [193]. The increase in jaw tension initially observed following succinycholine adminstration in addition to an inability to displace the mandible from the maxilla to facilitate insertion of an oral airway is now thought to represent a normal clinical state following succinylcholine administration [190,191].

In summary, it seems the association between strabismus and MH is no longer an issue [194] but if masseter muscle spasm is suspected, it is important to recognize that this patient may be susceptible to developing MH [190,195]. The importance of a detailed anesthetic family history also cannot be overemphasized.

Phenylephrine is placed in the eye(s) to produce mydriasis and hemostasis. However, absorption of the phenylephrine can cause profound systemic vasoconstriction and hypertension. To prevent systemic hypertension, only 1.0–2.5% (not 10%) phenylephrine should be used and only one drop should be instilled into each eye [196,197]. Other agents (0.5% cyclopentolate, 0.5% tropicamide) may be used to induce mydriasis without causing hypertension.

Surgery for strabismus often requires traction on the extraocular muscles, which produces vagal stimulation via the trigemino-vagal reflex (oculocardiac reflex); this reflex can usually be prevented by a delicate surgical technique. A retrobulbar block may trigger the oculocardiac reflex if moderate pressure is applied to the eye but when the block takes effect, it can prevent the oculocardiac reflex by blocking the afferent limb of the trigeminovagal reflex. This reflex is common during strabismus surgery or any surgery in which there is traction on the rectus muscles or eyelid. It may also be elicited by pressure on the eyeball or empty globe. The afferent pathway of this reflex involves the trigeminal nerve and the efferent limb is the vagus nerve. This trigemino-vagal reflex (or oculocardiac reflex) may result in a variety of dysrhythmias including sinus or junctional bradycardia, atrioventricular block, bigeminy, multifocal premature ventricular contractions, ventricular tachycardia or sinoatrial arrest [192]. The oculocardiac reflex may also occur following a retrobulbar block, enucleation and endoscopic sinus surgery if pressure is applied to ocular muscles and the reflex is not abolished by the administration of local anesthetics. Alerting the surgeons and subsequent alleviation of traction on the rectus muscles or pressure on the eye usually dissipates symptoms. The changes in rhythm may decrease during the surgery, since the reflex may fatigue or diminish with continued intermittent traction. Medical therapy may be required which includes the administration of anticholinergic agents. Administration of glycopyrrolate or atropine  $10-20 \mu g/$ kg shortly after intubation for eye surgery helps decrease the frequency, intensity, and duration of this reflex.

The LMA provides an effective alternative to endotracheal intubation in normal children scheduled for elective strabismus surgery [198]. In the absence of gastroesophageal reflux, the LMA provides an excellent airway for patients who can sustain spontaneous ventilation for the duration of eye muscle surgery. Hypercarbia may exacerbate the oculocardiac reflex [199] so in order to treat or prevent hypercarbia during anesthesia with an LMA, the anesthesiologist may consider mechanical ventilation with positive inspiratory pressure not exceeding 20–25 mmHg.

## Strabismus and postoperative nausea and vomiting

Nausea and vomiting occur in 50-80% of patients following strabismus surgery and may delay discharge from the hospital following surgery. A recent review revealed postoperative nausea and vomiting as the reason for 50% of unplanned overnight hospital admissions following strabismus surgery [200]. The exact mechanism of increased predisposition to nausea and vomiting following strabismus surgery is not known but may be related to altered visual perception and a different afferent input postoperatively or it may be secondary to an oculoemetic reflex, which is analogous to the oculocardiac reflex. Prevention of the oculocardiac reflex during strabismus surgery by prophylactic treatment with anticholinergic agents (atropine or glycopyrrolate) did not reduce the incidence of nausea and/or vomiting [201]. A large number of studies have examined the management of postoperative nausea and vomiting (PONV) in general. Prophylactic antiemetics are clearly indicated with more than one drug according to the consensus statement of the Society for Ambulatory Anesthesia [202]. However, no single agent, combination of agents or anesthetic technique has completely eliminated this problem.

Propofol has contributed to the decline in the incidence of PONV [203] and studies have shown that it offers some protective qualities against developing PONV following strabismus surgery [204–207]. Droperidol and metoclopramide, both antidopaminergic drugs, reduce nausea and vomiting by their action on dopaminergic sites [208,209]. Droperidol was favored in the past as an antiemetic as it was cheaper than its counterpart serotonin antagonist agents. However, it was associated with occasionally prolonged periods of sedation. Furthermore, the recent FDA black box warning against the use of droperidol, citing serious cardiac arrhythmias due to prolongation of the QTc interval and recommendations of 12-lead ECG monitoring 1h before and 2–3h postoperatively, has resulted in a drastic decline in the use of this agent [210,211]. In addition, cost considerations are no longer a concern with the availability of generic versions of ondansetron.

Metoclopramide has also been used for many years to treat PONV. However, when compared to ondansetron, a serotonin antagonist, metoclopramide decreased nausea and vomiting to a much lesser degree in patients following strabismus surgery [212,213]. Strategies to decrease PONV in strabismus patients currently revolve around serotonin antagonists. These drugs are frequently administered in conjunction with dexamethasone  $50 \mu g/kg$ , which was found to be just as effective as doses as high as  $250 \mu g/kg$  [214]. Nitrous oxide and the use of opioids have been implicated in the development of PONV. Therefore avoidance of nitrous oxide as a maintenance agent and administration of non-steroidal agents such as ketorolac will help decrease the incidence of PONV following strabismus surgery. High-risk patients such as those undergoing strabismus correction surgery will benefit from combination antiemetic therapy [215,216].

### Intraocular procedures Intraocular pressure and its control

Aqueous humor is present in both the anterior and posterior chambers of the eye. The majority of the aqueous humor is produced in the posterior chamber by active secretion, filtration, and diffusion from the blood supply to the ciliary body (Fig. 31.10). Aqueous humor passes from the posterior chamber through the ciliary body behind the iris to the front of the lens, then through the pupil into the anterior chamber. The most lateral portion of the anterior chamber, called the angle, contains a meshwork of tissue that filters the aqueous humor before it reaches the canal of Schlemm and eventually drains into the episcleral veins (Fig. 31.11). This fluid contains no blood cells and only 1% of the concentration of protein found in plasma. Thus, the aqueous humor is clear and allows transmission of light to the retina [217].

Normal intraocular pressure (IOP) is maintained between 10 and 21 mmHg by a balance between the production and drainage of aqueous humor, choroidal blood volume, extraocular muscle pressure, and vitreous humor volume [218]. Sudden increase in IOP may result in acute glaucoma. If this occurs in the presence of an open globe, prolapse of the iris or lens and/or hemorrhage from blood vessels may occur. Therefore it is imperative that the anesthesiologist maintains normal IOP during eye surgery.

Laryngoscopy and intubation of the trachea, coughing, vomiting or straining during induction or emergence from anesthesia can dramatically increase intraocular pressure to values as high as 40 mmHg [219]. Although the effect of laryngoscopy is transient and is of no serious consequence in the patient with normal intraocular physiology, this increase in pressure may be very significant for patients with glaucoma or other eye pathology. Administration of intravenous lidocaine prior to intuba-

Figure 31.10 Magnified view of ciliary body showing aqueous humor production and flow pattern.

tion has been found to prevent an increase in IOP [220,221]. Intraocular pressure changes with LMA insertion are less than those following tracheal intubation [222]. Coughing causes venous hypertension which increases the intraocular blood volume and has a dramatic effect on intraocular pressure. Several metabolic or acid–base derangements may occur during general anesthesia which can affect IOP. Hypoxia and hypercarbia cause retinal venodilation and can increase IOP [223]. Mild hypo- or hypercarbia produces clinically insignificant effects [224]. Hypothermia decreases IOP by decreasing the rate of aqueous humor production. Arterial pressure changes have little effect on IOP [218].

#### Intraocular pressure and anesthetics

In general, hypnotic agents, inhalation agents, and opioids tend to decrease IOP, with the exception of ketamine [218]. Earlier reports on the use of ketamine and IOP determined by Schiotz tonometry, which measures corneal compressibility, indicated that it resulted in an elevation of IOP [225], IOP is now routinely measured with applanation tonometry, a method believed to be more accurate. While ketamine does not lower IOP, the IOP measured following ketamine administration may be more reflective of the awake measurement. The use of ketamine may actually be preferable to other agents when an accurate measurement of IOP is necessary as is the case of children with suspected glaucoma in which accurate measurements of the IOP can only be obtained under anesthesia [226,227]. Nystagmus and blepharospasm associated with ketamine may, however, contraindicate its use in children with an open globe injury.

Non-depolarizing muscle relaxants decrease pressure on the globe and may decrease IOP [218]. Succinylcholine, a depolarizing muscle relaxant, increases IOP by inducing tonic extraocular muscle contracture, choroidal

Figure 31.11 Anatomy of the anterior chamber of the eye.

vascular dilation and relaxation of orbital smooth muscle. In normal eyes, an increase in IOP of about 7mmHg has been observed [228]. This modest increase is transient and of little consequence in a patient with normal IOP. However, if a patient has high IOP, the increase following succinylcholine may be greater and any rise may be significant. In the case of an open globe, an increase in pressure could result in loss of vitreous humor. Despite reports to the contrary, no one method has been shown to prevent the intraocular hypertension observed with the administration of intravenous succinylcholine [229,230]. While some reports state that there are no adverse events following the use of succinycholine for anesthesia in a child with an open globe injury [231], caution should be exercised when using this drug in the presence of an open globe injury. High-dose rocuronium provides a viable option for rapid-sequence induction in this subset of children who present for emergency surgery.

#### Glaucoma

If outflow of aqueous humor is obstructed for any reason, IOP increases and causes glaucoma. As with cataracts, glaucoma can be an isolated primary congenital disorder or it can be part of a syndrome (e.g. Sturge–Weber syndrome, mesodermal dysgenesis). A late or juvenile form of congenital glaucoma presents after 6 years of age, often in families with a strong history of open-angle glaucoma.

Successful surgical treatment of infantile glaucoma requires early recognition of the problem. Confirming the diagnosis in infants who present with a history of excessive tearing, photophobia, irritability, and buphthalmos usually requires measuring the IOP during a general anesthetic. The eye examination and pressure measurement can be followed by surgery if the diagnosis is confirmed. The initial surgery usually consists of goniotomy or trabeculotomy to create a route for the exit of aqueous humor via Schlemm's canal. If unsuccessful, cryotherapy is sometimes used to destroy the ciliary body and decrease aqueous humor production.

Anesthetic considerations for patients during glaucoma surgery include awareness of associated medical problems, especially if a syndrome has been diagnosed, as well as knowledge of how to manage IOP (see section on Intraocular pressure and its control, above).

## Anesthesia for open globe injuries in a patient with a "full stomach"

Traumatic eye injuries are common in children. The best chance of salvaging the eye requires that the wound be surgically explored to remove foreign material and the laceration closed within several hours of the injury. After penetrating trauma, the pressure inside the eye is atmospheric. External pressure on the eye or an increase in internal pressure can prolapse the lens, iris or vitreous and markedly reduce the chance of recovery of vision. The goal preoperatively and during the induction of anesthesia is to prevent coughing, crying, and vomiting because these activities increase intraocular venous blood volume. Increasing intraocular venous blood volume and IOP may cause the ocular contents to extrude.

Preventing an increase in IOP is important but difficult to accomplish. Preoperatively, the child should remain flat and quiet, and the eyes should be patched to minimize eye movements (which can be frightening and confusing to young children). Sedating the child before patching the eyes is essential if the child is too young to co-operate and cannot understand a careful, gentle explanation of the procedure. Giving a young child oral midazolam (0.5-0.75 mg/kg) or diazepam (0.2 mg/ kg) may provide sufficient sedation to allow insertion of an IV catheter. After a sedative has been administered, EMLA (eutectic mixture of local anesthetics) cream should be applied to several sites where veins are visible (or likely to be present) and covered with a clear occlusive dressing. Forty-five to 60 min later, the skin should be numb enough to allow painless insertion of an IV catheter. Once vascular access has been achieved, subsequent doses of sedatives can be titrated to effect, and a rapid-sequence induction of anesthesia can be easily accomplished.

The anesthesiologist should assume that all children who present with a penetrating eye injury have a full stomach. After trauma, stomach emptying is so erratic and unpredictable that delaying surgery for 6–8h does not reliably decrease the risk of aspirating gastric contents. Tracheal intubation should not be attempted until paralysis is complete. This prevents coughing and its potentially catastrophic effect on IOP.

In the presence of an open eye injury, the anesthesiologist must carefully preoxygenate the patient, being careful not to allow the mask to press on the injured eye. Preoxygenation is followed by injection of an anesthetic and a non-depolarizing muscle relaxant into a rapidly flowing IV catheter, preferably directly into an injection port at the site of the catheter. Some anesthesiologists give a dose of lidocaine (2mg/kg), fentanyl  $(2-3\mu g/kg)$ or morphine sulfate (0.05-0.1 mg/kg) before administering propofol (2mg/kg) or thiopental (4-6mg/kg), to minimize the effects of laryngoscopy and intubation on IOP. Administration of the anesthetic is immediately followed by a dose of a non-depolarizing muscle relaxant (rocuronium 0.8–1.5 mg/kg, vecuronium 0.15–0.2 mg/kg, pancuronium  $0.1 \,\mathrm{mg/kg}$ ). These doses of muscle relaxants allow tracheal intubation to be accomplished within 45-60 sec. Rocuronium (0.8-1.5 mg/kg) offers advantages over atracurium, vecuronium, pancuronium and succinylcholine because it provides rapid onset of neuromuscular blockade and a decrease in IOP without side-effects.

Neuromuscular blockade should be monitored during the induction of anesthesia to ensure that paralysis is complete before laryngoscopy is attempted. Sufficient cricoid pressure should be applied to occlude the esophagus and prevent passive regurgitation of stomach contents into the lungs; this pressure should be maintained until the airway is secured. The application of cricoid pressure also may decrease the likelihood of stomach dilation if gentle positive pressure ventilation is required before the trachea is intubated.

For the normal, chubby toddler who has no visible veins, the risk of crying, struggling, and raising IOP while an IV catheter is being inserted may be greater than that of aspiration during induction of anesthesia with inhaled anesthetics and cricoid pressure. Such a toddler could benefit from oral premedication with midazolam. The  $\alpha$ 2-agonist dexmedetomidine also shows promise as an effective oral premedication [232]. It also is effective as a premedication when administered intranasally [233,234]. Dexmedetomidine is not painful when administered nasally, in contrast to intranasal midazolam which may cause crying and agitation and should therefore be avoided in this setting. Administration of dexmedetomidine has also been found to attenuate the increase in IOP associated with succinylcholine administration [235].

#### Cataracts

Cataracts in children may be congenital or acquired. Congenital cataracts are of two types: idiopathic and those associated with syndromes. Several syndromes (e.g. Stickle, Hallermann–Steiff, Laurence–Moon–Biedl, Lowe, Conrad cerebrotendinous xanthomatosis, Marfan) are associated with a high incidence of cataracts (see Chapter 38). Metabolic disease states such as galactosemia and chromosomal abnormalities such as trisomy 21 are also associated with the presence of cataracts. Cataracts may be acquired as a complication of radiation therapy for retinoblastoma.

Cataract surgery in otherwise healthy children or in those with minimal associated medical co-morbidities is performed on an outpatient basis. General anesthesia is routinely administered for cataract surgery. One study showed that general anesthesia supplemented with a regional block (subtenon block) resulted in less postoperative pain and fewer requirements for postoperative rescue medication [236]. As with all general anesthetics, associated co-morbidities or medical conditions must be taken into account when administering anesthesia for cataract surgery. A deep plane of anesthesia is required for all patients to minimize the chance of coughing or straining and loss of vitreous humor or other intraocular contents after the globe is incised. If a patient's cardiovascular system cannot tolerate a deep plane of anesthesia, neuromuscular blockade should be established. Succinylcholine should not be administered after the globe is incised, because contraction of the extraocular muscles for 15–20 min can potentially increase IOP sufficiently to extrude the ocular contents through the surgical incision.

Ideally, the patient who has had cataract surgery should not cry excessively or struggle postoperatively. Extubation of the trachea or LMA removal while the patient is still deeply anesthetized will help achieve this goal.

#### Retinoblastoma

Radiation is the primary treatment for retinoblastoma, a congenital malignancy that usually is diagnosed and treated during the first 3 years of life. Radiation therapy is administered over a 4–6-week period, often 4–5 times per week. During each session, the head must remain absolutely motionless for 45–90 sec. Patients are unattended during the treatment to avoid exposing medical personnel to excessive radiation. Postanesthesia sedation should be minimal to avoid disrupting the infant's feeding and sleeping schedules, so that he or she continues to grow and develop normally during these 4–6 weeks. Propofol bolus (1–2mg/kg), followed by an infusion usually accomplishes satisfactory anesthesia for these procedures.

These children frequently return to the operating room for examination under anesthesia to monitor tumor growth or resolution. This examination is usually very brief. Smooth inhalation induction of anesthesia with insertion of an LMA and anticholinergic prophylaxis for oculocardiac reflex with or without acetaminophen (oral or rectal) suffices for anesthetic management.

#### **Retinopathy of prematurity**

Retinopathy of prematurity (ROP), formerly known as retrolental fibroplasia, is a vasoproliferative disorder of premature infants that may result in blindness. The first stage of this disease is characterized by suppression of vascular endothelial growth factor by hyperoxia, resulting in an arrest of normal retinal vascularization. The second phase is characterized by vascular proliferation induced by hypoxia-triggered stimulation of vascular endothelial growth factor. Hence both hyperoxia and hypoxia play a role in the pathogenesis of ROP [237]. The practice of decreasing the concentration of supplemental oxygen with a corresponding reduction in acceptable baseline oxygen saturations levels to 95% in neonates has reduced the incidence of ROP. This has led to an advocacy of maintaining oxygen saturations at or around 95% in premature infants having surgery. Nevertheless, with the increased survival of low-birthweight infants, more premature babies develop ROP.

Rapidly progressing ROP can lead to blindness and retinal detachment within 1–2 weeks. Hence early intervention with laser photocoagulation or cryotherapy is advocated and these cases are often scheduled as urgent cases in the late afternoon, after ROP is diagnosed upon routine followup eye exam. Laser therapy has been found to result in better visual acuity compared to cryotherapy and is the most widely used treatment for ROP [238,239]. For late-stage retinopathy in which retinal detachment has already occurred, buckling or vitrectomy is performed but these procedures usually fail to provide useful vision [240].

The anesthetic management of these children is challenging as multiple medical co-morbidities exist in this patient population, including apnea of prematurity, bronchopulmonary dysplasia, which may be associated with oxygen requirements, and congenital cardiac anomalies. While general anesthesia with mechanical ventilation is commonly administered for these procedures, the laryngeal mask airway is a viable alternative in the occasional premature infant with mild-to-moderate lung disease who did not require tracheal intubation in the past. Intravenous sedatives, analgesics and topical anesthesia have also been utilized in neonates who are ventilated mechanically or spontaneously breathing [241–243].

The goal is to provide a comfortable patient with minimal cardiorespiratory compromise and a quiet surgical field. While the procedure is not very stimulating, manipulation of the globe may be painful [244]. Opioids must be cautiously administered if pain is suspected during the procedure. Co-existing apnea may be exacerbated by the general anesthetic, and extubation of the trachea should occur only when a regular respiratory pattern without apnea is achieved; caffeine citrate 10 mg/kg IV may be effective in ameliorating significant apnea. These infants may need mechanical ventilation for 12–24h after the procedure, especially if any opioid is required for pain management.

There is some institutional variation in the location where these procedures occur. Laser surgery may be performed in the operating room if the neonate's pulmonary status will allow for transportation. In some institutions, operations are undertaken in the intensive care unit which allows for seamless postintervention monitoring [245]. Patients with ROP are at increased susceptibility to develop strabismus, cataracts and glaucoma and should have yearly examinations to help prevent and treat these conditions.

### Dental procedures

Dental procedures in children are routinely performed in the dentist's office with local anesthesia with or without sedation. General anesthesia may be required to facilitate dental work in children with behavioral disturbances such as severe autism and severe developmental delay, or in children with multiple medical problems, and those requiring extensive dental restoration. General anesthesia allows the dentist to complete the restoration in a timely fashion without the use of excessive amounts of local anesthetic or without approaching the limits of sedation they are comfortable with in the dental office.

#### Sedation versus anesthesia

The use of sedation is occasionally complicated with serious morbidity and mortality in children, with the most serious adverse events relating to respiratory complications [246]. Adverse events usually occur when combinations of drugs include opioids [247,248] or when relatively higher than usual doses of local anesthetics, sedatives or analgesics, including opioids, are administered with inadequate monitoring or insufficiently skilled personnel available [249]. The increase in prevalence of childhood obesity also poses a challenge for the pediatric dentist with regard to administration of sedatives. Administration of sedatives based on the total bodyweight may result in oversedation, which in an obese patient can easily result in airway obstruction. In contrast, administration of sedatives based on the lean body mass may result in undersedation and decreased duration of sedative effects [250]. An increase in adverse events following sedation [251,252] and an observed increase in mortality in office-based procedures [253] strengthen the case for improved monitoring during sedation for outpatient procedures in general [254]. A revised recommendation by the Committee on Drugs (COD), Section on Anesthesiology, of the American Academy of Pediatrics, [255] states specifically that:

- **1.** the patient must undergo a documented presedation medical evaluation including a focused airway examination
- **2.** there should be an appropriate interval of fasting before sedation
- **3.** children should not receive sedative or anxiolytic medications without supervision by skilled medical personnel (i.e. medication should not be administered at home or by a technician without medical supervision)
- **4.** sedative and anxiolytic medications should only be administered by or in the presence of individuals skilled in airway management and cardiopulmonary resuscitation
- **5.** age- and size-appropriate equipment and appropriate medications to sustain life should be checked before and be immediately available
- **6.** all patients sedated for a procedure must be continuously monitored with pulse oximetry
- an individual must be specifically assigned to monitor the patient's cardiorespiratory status during and after the procedure: for deeply sedated patients, that

individual should have no other responsibilities and should record vital signs at least every 5 min

8. specific discharge criteria must be used.

An area of controversy that exists is the exact definition of conscious sedation provided in outpatient settings. Conscious sedation is defined as a state of sedation that "permits appropriate response by the patient to physical stimulation or verbal command, e.g. 'open your eyes'." This implies that the patient retains the capability to interact with the medical care team. Purely reflexive activity, such as the gag reflex, simple withdrawal from pain or making inarticulate noises, does not constitute an appropriate response for the purpose of this definition. A sedated child who displays only reflex activity of this sort is in a state of deep sedation, not a state of conscious sedation. The Committee on Drugs recommends that it is more appropriate to recognize the most current terminology of the American Society of Anesthesiologists [256] and replace the term "conscious sedation" with "moderate sedation."

#### **Considerations for dental surgery**

Existing co-morbidities should be considered when planning the anesthetic management for this group of children. Many of them have underlying cardiac anomalies and may require systemic bacterial endocarditis (SBE) prophylaxis (see Chapter 25). The facial and airway structure of some patients may make direct laryngoscopy challenging and may require the use of special equipment to intubate the trachea. Patients with developmental delay or serious behavioral disturbances can pose difficulties because of poor motor control and involuntary movements, spasticity, and aggressive behavior (screaming, biting, kicking), particularly when they are frightened by a strange environment. This behavior may result in difficulty placing and securing an intravenous catheter or in performing an inhalational induction of anesthesia. Intramuscular ketamine 3–5 mg/kg mixed with atropine  $(10-20\mu g/kg)$  has been useful for the induction of anesthesia in some of these patients [257,258]. After injection of this mixture of drugs, sedation or a "catatonic state" will develop, and the patient can be moved, intravenous access obtained, general anesthesia induced, the patient's trachea intubated, and anesthesia maintained with a technique of choice. Many patients in this category have seizure disorders and should receive their anticonvulsant medications on the day of the procedure. Ketamine can be employed in patients with seizure disorders without precipitating seizures.

#### **Dental anesthesia**

Extensive dental restoration is best managed with endotracheal intubation. Most anesthesiologists and dental surgeons prefer nasotracheal rather than orotracheal intubation for dental procedures. The tube can be secured around the patient's head with a fabric tube holder; it should not be taped to the skin. In some patients, however, nasotracheal intubation is not practical. In patients with previous cleft palate repair or epidermolysis bullosa, for example, inserting an endotracheal tube through the nose may cause significant damage. A nasotracheal tube may damage previous repair lines in patients who have undergone palate repair and it may induce blister formation in response to pressure, friction or minor trauma of the mucosa in patients with epidermolysis bullosa. In these cases, an oral RAE tube may be placed instead. The stability of an oral tube is potentially a problem and requires constant attention to prevent the tube from being accidentally removed. Securing and maintaining an orotracheal tube during dental anesthesia requires uncompromising vigilance. Oral tubes are usually secured to one side of the mouth and then carefully secured on the other side when necessary during the procedure.

Following inhalation induction, oxymetazoline drops are applied to both nares to provide mucosal vasoconstriction which helps decrease bleeding during insertion of the endotracheal tube. Graduated sizes of lubricated nasopharyngeal airways may also be placed, to assist in dilation of the nares in preparation for nasotracheal intubation. Placement of the nasotracheal tube in warm water prior to its use helps to decrease the stiffness of the polyvinylchloride tube, and consequently decreases the incidence of epistaxis following nasotracheal intubation. A cuffed endotracheal tube should be inserted when possible. Limiting the number of attempts at nasotracheal intubation may decrease the incidence of epistaxis. Epistaxis can make nasotracheal intubation more difficult because it severely limits visualization of the larynx.

In most children, the endotracheal tube can be inserted under direct vision without difficulty following inhalation induction and propofol 2–3mg/kg, without muscle relaxant. The vocal cords usually can be visualized easily and the endotracheal tube can be directed through the vocal cords, with or without the use of Magill forceps. The nasal RAE tube is commonly used for dental surgery as it allows the surgeon to use a rubber dam if preferred [259]. The preformed, fixed bend helps stabilize the endotracheal tube, decreases the likelihood of kinking of the tube, and allows a low profile for maximum surgical convenience when the bend is situated at the opening of the nares. The preformed bend also offers some challenges as the distance from the bend to the distal end of the tube is fixed. This may result in endobronchial intubation in children who are shorter than expected for age, while in others the tip of the tube barely extends below the vocal cords. In addition, the presence of the bend makes suctioning difficult.

A gauze throat pack is usually inserted prior to the beginning of surgery to prevent aspiration of blood or extracted teeth. Patients may remain spontaneously ventilating or may be mechanically ventilated during surgery. Because multiple teeth are normally restored, local anesthetic is used infrequently in young children by the dentist because of concerns of a toxic drug dose. Therefore, intraoperative analgesia with fentanyl  $1-2\mu g/kg$ , morphine 0.05–0.1 mg/kg, and rectal or IV acetaminophen is often effective for postoperative analgesia. If there is pain

CASE STUDY

A 13-year-old obese male, a resident of a home for children with special needs who has a history of severe developmental delay and occasional violent behavior, is scheduled for bilateral strabismus surgery. Other pertinent medical history includes obstructive sleep apnea for which the patient's pediatrician has prescribed a CPAP machine but the patient has been non-compliant with its utilization.

#### Preoperative considerations

If possible, it will be helpful to obtain information about the severity of the patient's OSA (see Table 31.2) as this will be helpful in planning the anesthetic (may influence administration of intraoperative opioids). The immediate challenge with the care of this patient is how to easily separate the child from his parents or caretaker in order to proceed into the operating room. The patient is unlikely to go back to the operating room with the anesthesia care provider. If he is accompanied by one of the staff of the resident home and has a special rapport with this person, or is accompanied by a parent, the presence of this individual during induction could be encouraged, depending on the institutional practice. An alternative which would eliminate concerns for respiratory difficulty would be administration of intramuscular (IM) ketamine together with IM midazolam and glycopyrrolate to counteract hallucinations and excessive drooling respectively, both due to ketamine administration. Another alternative is the administration of an oral premedication of midazolam 0.5-1 mg/kg. A lower dose would be preferable in this obese child with a history of OSA. Some practitioners would even administer a much lower dose of 0.25 mg/kg PO.

#### Intraoperative considerations

Administration of IM ketamine (which results in dissociative anesthesia) with a small amount of propofol supplementation may suffice for the insertion of an LMA. Strabismus surgery is typically of short duration (approximately 45 min), especially if only one muscle per eye will be operated on. The patient's obesity and history of sleep in the PACU, morphine 0.05 mg/kg IV, repeated once if needed 20 min after the first dose, is usually sufficient. NSAIDs, i.e. ketorolac, are normally not recommended because inhibition of platelet function may increase gum and mucosal bleeding.

The postoperative period may be characterized by emergence delirium and postoperative nausea and vomiting. Most patients have the procedure performed on an outpatient basis.

apnea, however, may preclude the use of an LMA as relaxation of the hypopharyngeal soft tissue may result in ineffective spontaneous ventilation under anesthesia. The patient may be placed on pressure control ventilation with the pressure not exceeding 20–25 mmHg in order to avoid gastric distension and possible aspiration of gastric contents.

Considering the co-morbid conditions of obesity and sleep apnea, the best option for securing the airway may be endotracheal intubation which provides a protected airway. This child may receive a muscle relaxant of short duration. Desflurane with its low blood:gas solubility would be the ideal inhalation agent for maintenance of anesthesia in this obese patient. Gentle titration of intraoperative opioids of the anesthesia practitioner's choice should be administered, preferably when the patient develops spontaneous ventilation under anesthesia, in which case, the opioids can be titrated to a respiratory rate of 16–20 breaths per minute. For patients with severe OSA, intraoperative opioid administration should be minimized and the gentle titration of opioids following extubation, when the patient is awake, is recommended.

Intraoperatively, the heart rate is observed to decrease to 60 from 110. There is concern that the oculocardiac reflex is being triggered.

This reflex is most commonly elicited by traction on the medial rectus muscle. Administration of IV glycopyrrolate (0.01 mg/kg) and informing the surgeons to gently release traction on the eye muscles during surgery can result in resolution of bradycardia.

At the conclusion of surgery, neuromuscular blockade should be fully reversed and the trachea should be extubated with the patient awake in a semi-sitting or lateral/ non-supine position.

#### **Postoperative considerations**

This patient should remain in the semi-upright, lateral or other non-supine position throughout recovery in order to decrease the incidence of airway obstruction. Strabismus surgery alone is an outpatient procedure. For this patient with associated co-morbidities, however, the course in the PACU will determine whether or not he should be discharged to the resident home. The degree of care available in the resident home should also be considered (i.e. availability of a nurse on site and the degree of supervision/ care the patient will have). Some hospitals have policies regarding the duration of PACU stay for patients with a history of OSA and in fact recommendations by the American Society of Anesthesiology regarding the postoperative management of these patients include postoperative observation in the recovery room for 2-3h longer than those who do not have OSA [49,260]. The recovery of these children from anesthesia occasionally depends on the amount of opioids they have received. If necessary, the administration of oral acetaminophen with codeine or other non-steroidal analgesics should be considered to alleviate additional pain symptoms in the recovery room. Familiar caretakers should be readily allowed into the recovery room to prevent or decrease postanesthetic emergence anxiety.

Despite awake tracheal extubation, the patient cannot be weaned off oxygen, with oxygen saturations intermittently decreasing to (85–88%) for approximately 10 sec. The use of a shoulder roll and oral airway is also required to prevent airway obstruction.

The patient appears to have an oxygen requirement and is experiencing airway obstruction despite normal maneuvers to alleviate the problem, i.e. placement of oral airway and shoulder roll to prevent flexion of the head and obstruction of the airway. A respiratory therapist should be called to fit the patient for a CPAP mask. Hopefully, the patient will be receptive to this while still recovering from anesthesia. Depending on the institution's practice, a consultation with the intensive care unit or stepdown unit physician will be warranted to accommodate the use of the CPAP machine and to monitor the patient postoperatively. There is no consensus regarding postoperative disposition of patients with OSA within the hospital setting, i.e. observation postoperatively in the intensive care unit or step-down unit. There is agreement, however, that these patients be observed in a monitored postoperative setting which includes pulse oximetry monitoring [260].

## Introduction

General anesthesia has allowed surgeons to correct disfiguring lesions in infants and children since the introduction of anesthesia in the middle of the 19th century. Cleft lip and palate reconstruction was among the earliest surgical procedures for which general anesthesia was used for pediatric patients [1]. John Snow published the first report of giving an ether anesthetic to a 7-year-old boy for cleft lip reconstruction in The Lancet in 1847. He subsequently administered chloroform for lip reconstruction 147 times between 1847 and 1858, mostly to infants between 3 and 6 weeks of age. Cleft lip and palate repairs have also been an impetus for other innovations in anesthesia care for infants. This includes Ivan Magill's first use of endotracheal anesthesia for an infant in 1924 and Philip Ayre's introduction of the T-piece circuit in 1937 [2]. Modern developments in anesthesia and plastic surgery have permitted increasingly complex reconstruction of disfigured infants and children. The past decade has seen major advances in the understanding of anomalous development and the evolution of diagnostic and therapeutic technology. This chapter focuses on the anesthetic challenges encountered in major craniofacial reconstruction, including cleft lip and palate repair.

## **Craniofacial embryology**

#### Normal development

The basic structures of the fetus are formed during the embryonic period of gestation, i.e. between postconceptual weeks 2 and 8. The skeleton of the head is composed of the neurocranium (calvaria or cranial vault), the viscerocranium (facial skeleton), and the cranial base. These structures are highly integrated, and their formation and

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

<sup>© 2012</sup> Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

development are closely interwoven. The cranial base is the foundation of the skull, and its formation and development greatly influence the morphology of the other components. Embryologically, the cranial base and facial complex are derived from neural crest tissues; the neurocranium arises from mesoderm [3,4].

The neural tube closes by the third week of gestation. Its dorsal crests are composed of multipotent tissue that migrates widely into adjacent mesenchyme between the diencephalon and the cardiac swelling. Translocated neural crest cells undergo differentiation into a wide variety of cell types and form cartilage, bone, ligaments, muscles, and arteries of the cranial base and facial regions.

#### **Cranial base**

The cranial base extends from the foramen magnum to the frontonasal junction and consists of the sphenoid, petrous portion of the temporal bone, and cranial surfaces of the ethmoid bones. The pars basilaris of the clivus and the occipital bone are also part of the base. Phylogenetically, it is the oldest portion of the skull, and its development appears to be genetically determined. The bony structure is preceded by a cartilaginous structure, the chondrocranium, which first appears in the 6th week of gestation. Before chondrification, blood vessels, cranial nerves, and the spinal cord are established between the brain and extracranial sites. Centers of ossification appear during the 8th week of gestation. In contrast to the largely intramembranous bone of the cranial vault, which originates by direct ossification of mesenchyme, the osteogenic membrane, the cranial base is endochondral bone and formed from a cartilaginous prototype. Its sutures are cartilaginous joints (synchondroses), which grow by chondrocyte mitosis. The spheno-occipital synchondrosis is the principal site of growth in the cranial base during childhood.

The cranial base is an important shared junction between the cranial vault and face. Its inner surface relates to the brain and its outer surface relates to the nasopharynx and facial complex. Its shape and size strongly influence final calvarial morphology. The primary stimulus for growth of the cranial base is growth of the brain. The ventral parts of the frontal and temporal lobes determine the size and alignment of the floor of the cranial base, namely the anterior and middle cranial fossae [5]. The cranial base is, in turn, the template on which the upper face develops. Various junctures between the cranial base and facial bones, especially in the nasomaxillary complex, determine the influence of the cranial base on facial growth. The anterior cranial fossa is spatially related to the nasomaxillary complex. The middle cranial fossa is also related to the pharyngeal space and airway. The interposition of three sets of space-occupying sense organs complicates the attachment of these two skull components to each other and influences the growth of the facial skeleton in particular. These interactions become obvious in most craniofacial pathologies, e.g. in hyper- or hypotelorism, are associated with cranial vault or cranial base malformations or plagiocephaly with unilateral coronal synostosis with facial scoliosis.

#### **Cranial vault**

The cranial vault consists of the frontal, parietal, temporal, and occipital bones. The mesenchyme that precedes the cranial vault or neurocranium is derived from paraxial mesoderm and is at first arranged as a capsular membrane around the developing brain. Ossification of intramembranous calvarial bones requires the presence of the brain. According to the functional matrix concept, bone growth occurs in response to functional demands. The sutures of the calvaria can be considered interosseous ligaments that connect opposing bone surfaces. The bones of the calvaria are displaced outward by the expanding brain and deposit new bone at the contact edges of the sutures [5]. The ultimate size and shape of the cranial vault are therefore determined by internal hydrostatic pressures that the expanding brain and cerebrospinal fluid (CSF) pulsation waves exert on the cranial sutures. This stimulates compensatory sutural bone growth.

#### Face

Development of the head and face occurs between the 4th and 10th weeks of gestation by fusion of five facial swellings: the single frontal prominence and paired maxillary and mandibular prominences (Fig. 32.1). This depends upon the inductive activities of the prosencephalic and rhombencepahlic organizing centers, which are regulated by the expression of the sonic hedgehog gene as a signaling protein in the neural floor plate cells [6,7]. The rostral prosencephalic center induces the visual and inner ear apparatus, the upper third of the face, and the neurocranium. The caudal rhombencephalic center is responsible for the viscerofacial skeleton (i.e. middle and lower thirds of the face). Gradients of chemical and physical properties emanating from the organizing centers regulate the process of craniofacial formation [8]. The five facial swellings surround a central depression, which is the stomodeum or future mouth.

The frontal prominence encloses the forebrain from which pairs of thickened ectodermal surface placodes (nasal and optic) are derived. The nasal placodes invaginate to form the nasal passages. The surface ridges or nasomedial and nasolateral processes give rise to the nose, the philtrum of the upper lip, and the primary palate. The nasal complex is formed when the frontal prominence merges with the nasal capsule, which is part of the cranial base. The nasal capsule surrounds the olfactory organs and forms the cartilages of the nostrils and the nasal septum. Septal cartilage intervenes between the

**Figure 32.1** Stages in the embryonic development of the face. The median and paramedian structures from upper lip to forehead derive from the frontal prominence. The maxillary and mandibular regions, the ear, and the pharyngeal and laryngeal structures, derive from the branchial arches. Reproduced from Patten BM. Human Embryology, 3rd edn. New York: McGraw-Hill, 1968, p.346 with permission of the McGraw-Hill Companies.

cranial base above and the palate below and plays a major role in subsequent growth of the midface. The optic placodes, which ultimately develop into eyes, are induced by lateral optic diverticula from the forebrain. Expansion of the cerebral hemispheres produces medial migration to a frontal position.

The maxillary and mandibular prominences are derived from the first branchial arch. The branchial arches are five segmented bilateral swellings of the pharyngeal foregut, consisting of a mesodermal core surrounded by neural crest tissue. The arches are separated by branchial grooves externally and pharyngeal pouches internally. The cartilaginous skeleton of the first arch, Meckel's cartilage, provides a template for development of the mandible. The ear and auditory apparatus are derived from the first and second arches and from the first groove and pouch. The external ear components migrate from an initial cervical location. The internal ear components arise from the otic placode, which is induced by the vestibulocochlear nerve. The rest of the branchial arches, grooves, and pouches form various parts of the pharynx and laryngeal apparatus.

The facial prominences and their skeletal cartilage, mesenchyme, and neurovascular bundles undergo cell proliferation, swelling, migration, and fusion in a critically timed series of events. Fusion of the paired mandibular prominences in the midline provides continuity of the lower jaw and lip. Fusion of the maxillary and mandible prominences laterally creates the commissures of the mouth. Fusion of the nasomedial processes and maxillary prominences provides continuity of the upper jaw and lip and separation of the stomodeal chamber into separate oral and nasal cavities. Fusion of the nasomedial processes in the midline forms the central upper lip, the tip of the nose, and the primary palate (see Fig. 32.1).

During the 6th week of development, the secondary palate is formed from palatine shelves that initially grow inferiorly from the maxillary prominences downward into the stomodeum and lateral to the tongue. Initially, these palatal shelves are widely separated from the primary palate owing to their vertical orientation on either side of the tongue. During the 7th-8th week of gestation, coincident with longitudinal growth and straightening of the embryo and withdrawal of the tongue from between the shelves, the lateral palatal shelves rotate to a horizontal position and fuse with each other. The palatal mesenchyme then differentiates into bony and muscular elements that correlate with the position of the hard and soft palate, respectively. In addition to fusing in the midline, the secondary palate fuses with the primary palate and the nasal septum. These fusion processes are complete by the 10th week of embryogenesis; development of the mammalian secondary palate thereby divides the oronasal space into separate oral and nasal cavities, allowing mastication and respiration to take place simultaneously [9]. The nature of the "intrinsic shelf force" responsible for this reorientation is unknown, although mouth-opening reflexes, which involve withdrawal of the face from against the heart prominence, have been implicated in the withdrawal of the tongue from between the vertical palatal shelves.

The neural crest tissue gives rise to the facial skeleton, and the mesoderm will form the facial muscles. Current studies demonstrate the influence of the cranial base as it adjusts to its broader structural context and provides added support for the developmental and structural integration of the cranial base with both the cranial vault and face [10]. During facial development, cells are monitored by genetically determined pathways and adjust their rates of accumulation, apoptosis, and hyperplasia to produce organs of predetermined size [11]. Forward growth of the mandible relocates the tongue more anteriorly. Successful fusion of the components of the palate by the 12th week requires a complicated synchronization of shelf movements with withdrawal of the tongue and growth of the mandible. By this time the face takes on a human appearance.

#### **Anomalous development**

Various genetic and environmental factors cause anomalous craniofacial development [12]. The etiology of craniofacial syndromes and craniosynostosis is heterogeneous and multifactorial. Genetically based malformations may be caused by single-gene deficiencies or by chromosomal aberrations. Genes for several autosomal dominant craniofacial malformations have recently been defined: mutations in genes regulating fibrous growth factor receptors (FGFR-1, FGFR-2, FGFR-3, FGFR-4) and transforming growth factors (TGF-1, TGF-2, TGF-3) as well as *MSX2* and *TWIST* genes [13–15].

The identified gene loci associated with cleft lip and palate include regions on chromosomes 1, 2, 4, 6, 14, 17, 19 and X chromosome (*MHFR*, *TGFA*, *D4S175*, *F13A1*, *TGFB3*, *D17S250*) with gene products, e.g. TGFA, TGF $\beta$ 3, MSX1, IRF6, TBX22, GSTM1 [16,17]. Currently, there are no specific tests available for genetic susceptibility to orofacial clefts. Environmental factors include congenital infections, irradiation, and exposure to chemical teratogens, such as phenytoin, vitamin A analogs, and alcohol. For many malformations, the etiology is unknown.

Maldevelopment can occur through several mechanisms. Malformations that develop during the embryonic period are distinct from deformations that occur later in the fetal period and may be self-correcting with postnatal catch-up growth [6]. Fetal or postnatal head restraint can also cause premature fusion of cranial sutures [15]. Malformations can originate in anomalies of neural crest cells that may be deficient in number, may not complete

migration, or may fail to cytodifferentiate. Neural crest tissues also form much of the cardiac conotruncal septum, and there is an association between craniofacial and cardiovascular malformations in syndromes in which neural crest defects play a role [18,19]. Examples include retinoic acid syndrome, DiGeorge syndrome, the CHARGE association, and some variants of hemifacial microsomia. Malformations can also be caused by intrauterine compression of the embryo early in gestation. For example, in the amnion rupture sequence, early rupture of the amnion leads to defective morphogenesis secondary to compression of the embryo. In addition, adherence of amniotic bands to developing embryonic structures may interfere with normal development and result in simple to bizarre malformations that are not associated with embryological lines of fusion.

Malformations may result from intrauterine vascular accidents. For example, a shift in the blood supply of the face from the internal to the external carotid artery occurs during the 7th week of gestation when the normal stapedial artery atrophies. This shift occurs at a critical time of midface and palate development and has the potential to cause deficient blood supply and defects of the midface, upper lip, and palate. Malformations can also be secondary to defects in brain development because all components of the skull depend on the brain development [12–15,20,21]. Several syndromes are described below.

#### Craniosynostosis

Precocious brain development is reflected by rapid head enlargement, beginning in early gestation and continuing through the first postnatal year. Craniosynostosis, or premature closure of the cranial sutures, arrests skull growth in the related region. Isolated synostosis produces characteristic skull distortions as growth is redirected toward patent sutures (Table 32.1). The degree of skull deformity depends on the number of sutures involved and the time at which premature fusion begins. The earlier the synostosis, the greater the deformity and this may result in reduced intracranial volume. Due to the expanding cerebral structures and reduced intracranial volume, intracranial hypertension can develop later on.

Several different mechanisms are responsible for craniosynostosis [12–15]. Intrauterine constraint of the fetal head, e.g. in multiple pregnancies, can cause isolated nonfamilial craniosynostosis. A genetic defect is responsible for familial simple craniosynostosis and for most craniosynostosis syndromes with known genesis. Ninety different disorders with craniosynostosis have been described. Several specific genetic defects have recently been identified (Table 32.2). Crouzon, Apert, Pfeiffer, and Jackson– Weiss syndromes, once thought to be separate but overlapping entities, are now known to result from different mutations of the same genes [23]. In syndromic Table 32.1 Nomenclature of craniosynostosis

Affected suture	Traditional name	Literal translation
Sagittal Metopic Unilateral coronal	Scaphocephaly Trigonocephaly Plagiocephaly*	Boat skull Triangle skull Oblique skull
Bicoronal Multiple sutures	Acrocephaly <sup>†</sup> Turricephaly <sup>†</sup> Oxycephaly Kleeblattschadel	Topmost skull Tower skull Sharp skull Cloverleaf skull

\* Plagiocephaly is not necessarily synonymous with unilateral coronal synostosis.

<sup>+</sup>Some authors use acrocephaly and/or turricephaly synonymously with brachycephaly to indicate bicoronal synostosis.

families, some members have normal phenotypes but different sutures can be affected in different individuals. Syndromes with Mendelian genetic patterns are also described with no molecular genetic evidence so far. Craniosynostosis can also be caused by metabolic and hematological disorders and by microcephaly that is caused by defective brain growth (Box 32.1). Known teratogens that cause craniosynostosis are diphenylhydantoin, aminopterin and methotrexate, retinoic acid, oxymetazoline, and valproic acid.

Craniosynostosis may be an isolated deformation or part of a malformation syndrome. Isolated non-syndromic craniosynostosis occurs in six in every 10,000 births [12]. Sagittal synostosis is most common (57%), coronal synostosis is less frequent (18–29%), and metopic and lambdoidal synostoses are the least frequent, although recently

**Figure32.2** Single-suture craniosynostosis results in specific cranial deformities. (A) Trigonocephaly is the result of premature closure of the metopic suture and typical features are a frontal keel ( $\uparrow$ ), anterior displacement of the coronal sutures ( $\uparrow\uparrow$ ), and compensatory bulging of the parietal squamae ( $\uparrow\uparrow\uparrow$ ). (B) Scaphocephaly is characterized by bitemporal or biparietal narrowing ( $\uparrow$ ), frontal ( $\uparrow\uparrow$ ) and occipital ( $\uparrow\uparrow\uparrow$ ) compensatory bossing. The shape of the skull resembles the keel of a boat or a saddle. (C) Brachycephaly means short skull and is the result of bicoronal craniosynostosis. The frontal region is flattened ( $\uparrow$ ) and some cases show early compensatory oxycephalic deformity ( $\uparrow\uparrow$ ). (D) Anterior plagiocephaly results from unilateral coronal synostosis and causes asymmetrical and rotational deformity of the fronto-orbital region with additional midface and skull deformities.

there has been a marked rise in the incidence of trigonocephaly in non-syndromic cases [24]. Calvarial synostosis may also be part of a widespread craniofacial malformation that involves the cranial base and face.

#### Single suture craniosynostosis

The typical skull deformities following single suture craniosynostosis result from compensatory growth (Fig. 32.2). The cephalic index (maximum biparietal diameter multiplied with 100 divided by maximum anteroposterior diameter) was introduced by the Swedish anatomist

Anders Retzius and is used to measure the extent of deformity as well as for follow-up of later head development. Not all premature craniosynostoses lead to an obvious skull deformity. Typical anthropomorphic skull types are dolichocephalic (long headed), brachycephalic (broad headed) and mesocephalic (moderate head form).

#### Sagittal craniosynostosis

This is the most frequent form of craniosynostosis and presents the typical scaphocephalic form of skull with an elongated anteroposterior diameter and a narrowed biparietal diameter. The fused sagittal suture often forms a bony ridge and resembles the keel of a boat. The biparietal region is particularly narrow and sometimes lowered (Fig. 32.3). Frontal and/or occipital bossing can be very prominent and result from compensatory skull growth. The head circumference is generally increased, and the head is dolichocephalic. In 11% of cases, additional morphological brain changes were found on MRI studies.

#### Unicoronal craniosynostosis

The unilateral supraorbital ridge is retruded and the contralateral side sometimes compensates for the lack of growth and protrudes. In most cases, there is facial scoliosis that is caused by unilateral midface involvement. The deformity is described as anterior plagiocephaly. Patients may squint and have a compensatory head tilt (Fig. 32.4).

Figure 32.3 Scaphocephalic child with typical biparietal narrowing and resulting flattened head.

Figure 32.4 Facial scoliosis in a child with anterior plagiocephaly.

Figure 32.6 (A) Hypotelorism in metopic synostosis. (B) Frontal keel.

Figure 32.5 Brachycephalic head caused by bicoronal craniosynostosis.

#### **Bicoronal craniosynostosis**

This entity can be syndromic and a genetic work-up is indicated. The head circumference is decreasing, due mainly to a marked flattening of the forehead (Fig. 32.5). The orbits and both temporal squamae protrude. Additional turricephalic compensation can occur. This is the typical picture of a brachycephalic head. Early surgery is sometimes necessary to treat elevated intracranial pressure. The midface is often also involved.

#### Metopic craniosynostosis

The skull deformity with metopic craniosynostosis varies from a frontal ridge to severe trigonocephaly with narrowing of the frontal region and a keel-shaped forehead with hypotelorism and epicanthal folds (Fig. 32.6). It can be associated with genetic syndromes such as Opitz C syndrome or trisomy 11. The head circumference is usually decreased.

#### Lambdoidal craniosynostosis

Isolated lambdoidal craniosynostis is rare and accounts for only 3% of all premature synostoses. Most of the clinical forms of posterior plagiocephaly are positional deformities and do not require surgical correction. In true lambdoidal craniosynostosis, the contralateral forehead bulges forward. In cases that are caused by position, there is ipsilateral bossing.

#### Syndromic craniosynostosis Acrocephalosyndactylies

Craniosynostosis syndromes that are also associated with hand and feet abnormalities are described as acrocephalosyndactylies.

#### Apert syndrome

Apert syndrome is the most severe of several craniosynostosis syndromes that involves all the craniofacial structures: calvaria, cranial base, and face. Apert syndrome occurs in approximately 1 per 55,000 births due to mutations in the FGFR-2 gene on chromosome 10 [22]. Although the mode of transmission can be autosomal dominant, most cases are sporadic. Apert syndrome is characterized by craniosynostosis, midface hypoplasia and retrusion plus symmetrical syndactyly of the hands and feet (Fig. 32.7A,B). The dysmorphic features are listed in Box 32.2.

In Apert syndrome the craniosynostosis involves multiple cranial sutures, but most commonly involves the

**Figure 32.7** Six-year-old boy with typical features of Apert syndrome. (A) Downslanting palpebral fissures, depressed nasal bridge, dental malocclusion. (B) Flat facies due to midface hypoplasia.

coronal sutures and causes brachycephaly. The occiput is usually flattened. The cranial base has a broad, flat, short contour with premature synostosis. The anterior cranial fossa is markedly shortened, which constrains development of the nasomaxillary complex. The nasal cavity, palate, and maxilla are shortened, narrowed, and retropositioned. The midface hypoplasia and brachycephaly result in proptosis because the orbits are too shallow to house the globe. The middle cranial fossa is rotated to a more vertical position than normal, which secondarily diminishes the dimensions of the pharynx. The interorbital space is always large, and the orbits may be misaligned. The shortened cranial base results in a vaulted cranium and a deep forehead. Platybasia, Chiari malformation, and hydrocephalus are relatively common. Severe dental malocclusion is typical. Lateral skull base deformities are responsible for a high rate of hearing disorders. A significant number of patients are mentally retarded; most of the children have IQs below 80.

#### Saethre-Chotzen syndrome

Phenotypically variable, the relatively common Saethre– Chotzen syndrome is often misdiagnosed. Because mild forms may not be recognized, the true incidence is unclear.

Typical features are brachy- and acrocephalic deformities, mostly due to bicoronal abnormalities and plagiocephaly (Fig. 32.8). The hairline is low and the facial appearance broad, flat, and asymmetrical. The nose is beaked, and there may be ptosis of the eyelids. The inheritance pattern is autosomal dominant.

#### Pfeiffer syndrome

The clinical phenotype of Pfeiffer syndrome is variable. Patients typically show a turribrachycephalic deformity that is mostly due to abnormal bicoronal sutures. Cloverleaf heads have also been reported. hypoplasia, Hypertelorism, proptosis, maxillary mandibular prognathism and malocclusion occur as well. Ankylotic joints are typical skeletal findings. Severe skull base anomalies are associated with platybasia and Chiari malformation and also with spinal malformations and vertebral fusion. The incidence of this syndrome is about one in 210,000; its inheritance is autosomal dominant. Early surgical correction of the constraining skull structures can lead to normal neurocognitive development if brain growth is not impaired.

#### Crouzon syndrome

The phenotype of this syndrome is characterized by brachycephaly caused by bicoronal synostosis,

#### Box 32.2 Features of Apert syndrome

#### Craniofacial dysmorphology

- Craniosynostosis
- Coronal synostosis most common
- Steep full forehead (frontal bossing)
- Flat occiput
- ± Hydrocephalus
- Maxillary retrusion (midface hypoplasia) – Flat facies
- Shallow orbits
- Exorbitism or proptosis
- Relative mandibular prognathism
- Variable facial asymmetry
- Supraorbital horizontal groove
- Hypertelorism
- Down-slanting palpebral fissures
- Strabismus
- Parrot-beaked nose
- Depressed nasal bridge
- Cleft palate or bifid uvula
- Trapeziodal-shaped (cupid's) lips
- High arched palate
- V-shaped maxillary dental arch
- Severe tooth crowding
- Dental malocclusion
- Reduced nasopharyneal dimensions

#### Limb dysmorphology

- Syndactyly
  - Osseous and/or cutaneous
  - Fingers and toes

- Digits 2, 3, 4 always
- Symmetric
- Thumb and great toe malformations

- Cardiovascular
- Atrial septal defect
- Overriding aorta
- Ventricular septal defect
- Pulmonic stenosis
- Coarctation of aorta
- Endocardial fibroelastosis
- Pulmonary artery atrophy
- Skeletal
  - Aplasia or ankylosis of joints
  - Synostosis of radius and humerus
  - Short humerus
  - Cervical spine fusion
- Pulmonary
  - Pulmonary aplasia
  - Cartilaginous anomalies
  - Tracheoesophageal fistula
- Gastrointestinal
  - Pyloric stenosis
  - Ectopic anus
- Renal
  - Polycystic kidney Hydronephrosis
- CNS
- Mental retardation
- Hearing deficit

Figure 32.8 Infant with Saethre-Chotzen syndrome. (A) Brachycephaly. (B) Metopic ridge due to premature synostosis and turricephaly.

maxillary hypoplasia, and shallow orbits that lead to ocular proptosis and a beaked nose. Besides coronal synostosis, scaphocephaly, trigonocephaly, and cloverleaf skull may also exist. Skull base abnormalities with platybasia and Chiari malformations are also found. Due to the midfacial deformities, nasopharyngeal airway obstruction is common and may lead to sleep apnea and impaired nose breathing.

The prevalence of Crouzon syndrome is one per 25,000 livebirths, with about two-thirds of cases being familial

#### **Occasional abnormalities**

(autosomal dominant) and one-third sporadic. Neuro-cognitive development is rarely affected.

#### Cloverleaf skull (Kleeblattschädel)

The cloverleaf skull deformity is the most severe form of craniostenosis and is most often associated with Pfeiffer syndrome. All major sutures and the skull base are involved which produces marked constriction of intracranial structures, including the rapidly developing brain and its vessels, especially important venous structures. Early surgery is mandatory to protect the brain. Chiari malformation and hydrocephalus are common accompaniments of this lesion and need to be treated early as well. Other deformities are hypertelorism, orbital proptosis with visual impairment, and a hypoplastic skull base and midface structures that produce upper airway problems.

Other relatively common craniofacial syndromes are Jackson–Weiss and Carpenter or Antler–Bixler syndrome.

#### **Facial anomalies**

#### **Branchial arch malformations**

Branchial arch anomalies are symptom complexes caused by deficient development of the branchial arches. They are etiologically and pathogenetically heterogeneous [12] with wide variability in expression. External ear deficiencies, auricular tags, and persistent branchial clefts or cysts are common branchial arch anomalies. Micro- or macrostomia results from abnormal merging of the maxillary and mandibular prominences. These abnormalities are examples of severe first arch anomalies. Micrognathia, also a first arch anomaly, is the result of retarded mandibular development by any mechanism; it may be an intrinsic malformation or a deformation by the chin being compressed against the chest late in gestation.

#### Treacher Collins syndrome (mandibulofacial dysostosis)

Treacher Collins syndrome (TCS) occurs with an incidence of one in 50,000 livebirths and involves structures derived from the first and second branchial arches [12]. The major facial features include midface hypoplasia, micrognathia, microtia, conductive hearing loss, and a cleft palate that is caused by deficiencies of maxillary and branchial arch mesenchyme. The syndrome can be an autosomal dominant disorder with variable expressivity, but over 50% of cases are new mutations. The gene responsible for this syndrome has been mapped to chromosome 5q31.3–32. The mutation causes aberrant expression of a nucleolar protein named treacle. The abnormalities are bilateral, usually symmetrical, and con-

#### Box 32.3 Features of Treacher Collins syndrome

#### Facial dysmorphia

- Skeletal hypoplasia/aplasia
  - Malar and zygomatic bones
  - Supraorbital ridges
  - Mandible
- Facial muscle hypoplasia/hypotonia
- Eye
  - Lower lid coloboma or notching
  - Partial absence of lower eyelashes
  - Antimongoloid slant to palpebral fissures
- Ears
  - Auricle malformation, misplacement
  - Ear canal defects, conductive deafness
  - Inner ear malformations
- Nonpneumatized mastoid
- Pharyngeal hypoplasia
- Dental malocclusion
- High arched palate
- Projection of scalp hair onto lateral cheek
- Bind fistulas, dimples, or tags between the ears and angle of the mouth

#### **Occasional abnormalities**

- Macrostomia
- Microstomia
- Cleft palate
- Velopharyngeal incompetence
- Upper eyelid coloboma
- Choanal atresia
- Microphthalmia
- Absence of parotid gland
- Congenital heart disease
- Mental deficiency not common

fined to the craniofacial complex (Box 32.3; Fig. 32.9). Besides the facial features, the patients often have choanal atresia, microphthalmia, absence of the parotid gland(s), and congenital heart disease. Mental deficiency is not common.

The characteristic facial appearance is the product of an abnormal cranial base and a dysmorphic mandible and maxillary-malar complex [26]. The face is narrow, with down-sloping palpebral fissures, depressed cheekbones, and a large down-turned mouth. The cranial base angle (nasion-sella-basion angle) is reduced, which positions the posterior pharynx forward. The pharyngeal dimensions are reduced in all dimensions by several hypoplastic skeletal elements [26–28]. Some patients also exhibit a discrete area of constriction near the base of the tongue, such as occurred in an 11-year-old patient whose pharyngeal lumen was 5mm wide [27]. Little correlation exists between the degree of pharyngeal hypoplasia and the

Figure 32.9 Fifteen-year-old girl with mandibulofacial dysostosis. She has no mental but has malar deficiencies, auricle malformation, microtia and retrognathic mandible.

severity of the facial deformity. The malar (cheek) bone is hypoplastic and the orbital wall is deficient. The mandible is disfigured in all dimensions.

Nager and Miller syndromes are characterized by facial features that are similar to those of Treacher Collins plus limb deformities.

#### Robin sequence

The Pierre Robin sequence (PRS - MIM 261800) is a welldefined subgroup of the CL/P (cleft lip and/or palate) population with an unknown etiology of the branchial arch. PRS is characterized by cleft palate, micrognathia and respiratory difficulties (due to glossoptosis) in the early neonatal period, and is often observed as a part of other mendelian syndromes such as Stickler syndrome, velocardiofacial syndrome and Marshall syndrome or fetal alcohol syndromes [29,30]. PRS is also a part of campomelic dysplasia (CD - MIM 114290), consisting of bowing of the long bones, malformation of the pelvis and spine, rib anomalies, club feet, hypoplastic scapulae, micrognathia, and cleft palate [31]. In a "sequence," some anomalies are secondary to a primary anomaly, whereas in a syndrome, multiple anomalies have a single pathogenesis. The PRS may be the result of deregulation of SOX9 and KCNJ2 [32]. The pathogenesis of the Robin sequence is diverse, but the common feature is failure of mandibular development and secondary failure of the tongue to descend from between the palatal shelves. When this is an isolated finding, the deformity may be due to intrauterine mandibular constraint. The mandible is intrinsically normal and will undergo catch-up growth postnatally [6]. If the Robin sequence is associated with a syndrome that includes intrinsic mandibular hypoplasia, the mandible remains small.

## Oculo-auriculovertebral spectrum: Goldenhar syndrome and hemifacial microsomia

The oculo-auriculovertebral spectrum (OAVS) is also known as the first and second branchial arch syndrome, hemifacial microsomia, Goldenhar syndrome or facioauriculovertebral syndrome. This condition is caused by maldevelopment of the first and second branchial arches and is complex and heterogeneous. There is defective facial development involving the ear, eye, zygomatic bone, mandible, parotid gland, tongue, and facial muscles. Maldevelopment is not limited to facial structures: cardiac (tetralogy of Fallot, ventricular septal defect), pulmonary (hypoplasia or aplasia of lung), renal, skeletal (vertebral anomalies, commonly cervical), central structures (cranial nerve anomalies) and other anomalies, including laryngeal anomalies, also occur. The abnormalities present in various combinations, tend to be asymmetrical and are unilateral in 70% of cases [20]. Malformations of the external ear or microtia are mandatory features of the OAVS and occur as an isolated malformation (population frequency of 0.03%), or in association with other anomalies such as mandible hypoplasia, epibulbar dermoids, and spinal vertebral defects. The constellation of anomalies

suggests that they originate at approximately 30–45 days of gestation.

It has been suggested that disturbances in the branchial arches or in neural crest cells impede development of adjacent tissues. A vascular pathogenesis caused by hematoma formation at the time the stapedial artery system develops has been demonstrated in animals [33]. In this model, focal hemorrhage and an expanding hematoma destroy tissues in the ear and jaw areas. Three unrelated children have been reported with similar unilateral craniofacial defects and other structural abnormalities that had a known disruptive vascular pathogenesis [34]. The frequency of occurrence is estimated to be one in 3000-5000 births. The condition is usually sporadic, although familial instances have been reported. Several chromosomal anomalies have been associated with this condition, and it has occurred in infants born to mothers who had taken thalidomide, primidone or retinoic acid. It is usually discordant in monozygotic twins.

Maxillary, mandibular, and auricular hypoplasia is the primary feature of this syndrome. Macrostomia is the result of a lateral facial cleft from the commissure of the mouth. Mandibular condyle deformities, present in all patients, range from slight hypoplasia to complete absence of the condyle with agenesis of the ascending ramus. When accompanied by epibulbar dermoid and vertebral anomalies, it is called the Goldenhar syndrome, and when it occurs predominantly unilaterally it is called hemifacial microsomia. Most of these patients have normal intelligence.

#### Hypertelorism and orbital malposition

Orbital malposition may occur in any direction and may involve different directions in each orbit. The bones and sutures making up the walls of the orbits may be primarily involved. The malposition may also be the result of craniosynostosis or craniofacial clefting. It may be associated with encephalocele, tumor, or other cranioorbital malformations. Other cranio-orbital malformations include encephaloceles that involve craniofacial structures; frontoethmoidal or sincipital and basal subtypes (nasofrontal, nasoethmoidal, naso-orbital and transethmoidal) [35]. These malformations lead to significant naso-orbital deformities (Figs 32.10, 32.11). One of the most disfiguring tumors of the orbital region is the plexiform neurofibroma that is associated with neurofibromatosis type 1. Isolated orbital hypertelorism is a skeletal deformity that consists of lateralization of the bony orbit and enlarged ethmoid sinuses. The nose may be slightly involved or severely distorted, and the nasal deformity may be difficult to correct. Dysfunction of the upper eyelid, extraocular muscles, and lacrimal system frequently occurs. Orbital hypotelorism is uncommon

Figure 32.10 Twelve-year-old boy with frontoethmoidal encephalocele with maxillary involvement and hypertelorism.

Figure 32.11 Infant with frontonasal cleft and related encephaloceles and hypertelorism.

and is seldom present as an isolated anomaly. It is often seen in metopic craniosynostosis.

#### **Facial clefts**

Facial clefting occurs when the skeleton or soft tissues are interrupted. Clefts develop when the facial prominences fail to merge. Clefts that cannot be explained embryologically may be caused by disruptive factors [12]. The causes of most clefts are unknown, and the majority occur sporadically. Skeletal and soft tissue hypo- or aplasia are the anatomical defects of craniofacial clefts. Any part of the cranium or face may be involved. Various combinations of eye, ear, and central nervous system (CNS) deformities are associated with clefts.

Tessier devised an anatomical and descriptive classification that correlates clinical appearance with surgical anatomical findings [36]. This system designates 15 locations (numbered 0 through 14) for clefts and describes their respective courses through bone and soft tissue (Fig. 32.12). Many syndromes that include hypoplastic facial dysmorphology are categorized as clefts. Treacher Collins syndrome includes clefts 6, 7, and 8 in its complete form (see Fig. 32.9) and cleft 6 in its incomplete form. Cleft 6 accounts for the eyelid coloboma, cleft 7 the absence of the zygomatic arch, anterior displacement of the scalp hair, and mandible deformities, and cleft 8 the defects in the lateral orbital rim. The oculoauriculovertebral spectrum (hemifacial microsomia, Goldenhar) is cleft 7.

#### Cleft lip and palate

Cleft lip and/or palate are the most frequent congenital craniofacial malformations. They occur in one in 700 births in the United States, and there is a marked racial predilection. The highest incidence is found in parts of Latin America and Asia (China, Japan), the lowest in Israel, South Africa, and southern Europe. Rates of isolated cleft palate are high in Canada and parts of northern Europe and low in parts of Latin America and South Africa [9]. Clefts may be isolated, familial or part of a syndrome. More than 400 syndromes are associated with facial clefts [12]. Cleft lip, cleft palate or both can be part of a syndrome, but more syndromes are associated with cleft palate than with cleft lip. They constitute a heterogeneous group of malformations with great variability in the degree of cleft formation (Fig. 32.13). A cleft lip may be complete, incomplete or only a microform with a small vermillion notch. Osseous defects in the alveolus and the palate of patients with complete labial clefts contribute to instability of the dental arch; sometimes there is collapse of the lateral segments of the arch. For cleft classification, Kriens proposed the LAHSHAL code to represent clefts of the left and right (L)ip, (A)lveolus, as well as (H)ard

Figure 32.12 Tessier's classification of facial clefts. (*Left*) Locations of clefts on the face. (*Right*) Skeletal pathways.

and (S)oft palate based on the anatomical structures involved [37].

The etiology of clefting is multifactorial and has both genetic and environmental influences. The genes associated with orofacial clefting identified to date are those for non-syndromic cleft lip/palate *MSX1* (chromosome 4p16.1), and *TBX22* (chromosome Xq12-q21). Cleft palate genes are located on chromosome 14 and a locus for cleft lip (IRF6) on chromosome 1q [38,39]. Development of the upper lip and the palate is completed by postconceptional weeks 7 and 9. Maternal smoking during this time increases the risk of clefting by approximately 1.3 times.

The risk for oral clefting may be as high as 20% in some subgroups with maternal smoking (e.g. American Indians/Alaskan natives). Alcohol consumption, poor nutrition (folic acid and vitamin A deficiency), viral infection, medical drugs (e.g. anticonvulsant drugs; diazepam, phenytoin, phenobarbital, carbamazepine; retinoids; systemic corticosteroids), diabetes mellitus, and teratogenic agents (organic solvents, agricultural chemicals) also increase the risk of clefting [40].

Clefting of the upper lip and nostril is the result of failure of the nasomedial process to merge with the maxillary prominences (lateral cleft lip, either uni- or bilateral) or from failure of the two-nasomedial processes to merge (rare median cleft lip or bifid nose). Hypoplasia of the palatal shelves or mistiming of palatal shelf elevation results in cleft palate. Failure to remove the tongue from between the shelves and problems with shelf elevation and contact probably account for most human cleft palates [19]. There may be a critical time in gestation beyond which the palatal shelves cannot meet and fuse. If movement of the palatal shelves from vertical to horizontal is delayed and the head continues to grow, a widening gap is produced between the shelves, and they cannot meet. Clefting of the palate may or may not be associated with a cleft upper lip because the two conditions are separate developmental entities. However, failure of lip fusion may impair subsequent closure of the palatal shelves.

#### Physiological sequelae of craniofacial malformations

#### Hydrocephalus and intracranial pressure

In a retrospective review of 1727 patients treated over 20 years, hydrocephalus occurred in patients with nonsyndromic craniosynostosis (1447 patients) with similar frequency to that observed in the normal population (0.3%) [41]. In patients with syndromic craniosynostosis, the frequency was 12%. Patients with Kleeblattschädel deformity and Crouzon syndrome were more likely to have hydrocephalus than those with other syndromes. Jugular foramen stenosis and crowding of the posterior fossa are two primary factors responsible for hydrocephalus in syndromic craniosynostosis [41]. Fusion of cranial base synchondroses produces alterations in the skull base and stenosis of the jugular foramen. The resulting venous hypertension increases the CSF hydrostatic pressure. If major calvarial sutures are open, the head will progressively enlarge and the ventricles and subarachnoid spaces will dilate. If the calvarial sutures are fused, intracranial pressure will increase but ventriculomegaly may not occur until after the synostosis is surgically released. When the posterior fossa is small and crowded, especially if the lambdoidal suture is fused, cerebellar tonsillar herniation or compression of the basal cistern may produce obstructive hydrocephalus.

Intracranial pressure may be elevated without hydrocephalus in patients with craniosynostosis. Presumably, a restrictive cranium is a factor. Renier [42] monitored intracranial pressure during sleep in 350 non-hydrocephalic patients with unoperated craniosynostosis (Table 32.3). The patients ranged in age from 6 weeks to 15 years, and 44% were less than 1 year old. The overall rate of intracranial hypertension was 23% but the proportion varied by type of craniosynostosis and age. For single sagittal synostoses (trigono- and scaphocephaly), the rates were 6% and 8%, respectively. The rate was 12% for single synostoses of a coronal suture (anterior plagiocephaly). Other authors have also reported elevated intracranial pressure with single-suture synostosis, which, in addition to cosmetics, provides a rationale for surgical correction [43,44].

In Renier's study, 26% of patients with synostoses of both coronal sutures (brachycephaly, excluding Apert

Table 32.3 Intracranial pressure before surgery

	Total	Baseline ICP (mmHg)			
	patients	≤10	11–15	>15	
Trigonocephaly	31	21	8	2	
Scaphocephaly	118	76	33	9	
Plagiocephaly	65	40	17	8	
Brachycephaly	34	17	8	9	
Oxycephaly	66	23	7	36	
Crouzon syndrome	9	3	0	6	
Apert syndrome	16	3	6	7	

Modified from Renier D. Intracranial pressure in craniosynostosis: pre- and postoperative recordings-correlation with functional results. In Persing JA, Edgerton MT, Jane JA (eds). Scientific Foundations and Surgical Treatment of Craniosynostosis. Baltimore: Williams & Wilkins, 1989, p 264, with permission.

and Crouzon syndromes) had intracranial hypertension. In extensive synostoses, usually involving both coronal and sagittal sutures (oxycephaly), intracranial hypertension occurred in 54% of patients. In Renier's study, the incidence of intracranial hypertension also increased with age. After 1 year of age, the incidence was four times greater for scaphocephaly and double for plagiocephaly. With brachycephaly, intracranial hypertension was more precocious: 22% of children below 1 year of age had intracranial hypertension compared with 31% over 1 year of age. Oxycephaly is usually not seen before 3 years of age, but can also be seen in very young infants, e.g. in syndromic forms. Eighty-five percent of children with oxycephaly had intracranial hypertension. However, clinical signs and symptoms of elevated intracranial pressure were uncommon. Intracranial volume measurements calculated from computed tomography (CT) scans were not a reliable indication of intracranial pressure (ICP), although markedly reduced intracranial volume did increase the likelihood of intracranial hypertension [43]. Raised intracranial pressure is also of concern after surgical correction and consecutive inappropriate skull growth and should be monitored in patients and followed up by regular ophthalmological examinations to rule out papilledema at least until 8-10 years of age. Papilledema may not be present despite significantly elevated ICP. In children without papilledema, ICP measurements may be indicated to rule out intracranial hypertension. These older children often complain of chronic headache.

In non-syndromic forms of craniosynostosis where the abnormality is confined to the calvarium, the effects of cranial vault expansion are predictable. In complex craniosynostosis, however, the effects are less certain. In Renier's series, 54 patients had postoperative ICP measurements. Before surgery the ICP was elevated in 74% and borderline in 11% of patients. After surgery 7% had elevated and 20% had borderline ICP. In another series 22 patients had their ICP monitored postoperatively. The ICP was elevated in 45% and borderline in 32% [45]. In this series, 34 patients with complex craniosynostosis were evaluated with magnetic resonance imaging (MRI) up to 8 years after surgery. Cerebellar tonsillar herniation was found in 52% and hydrocephalus in 41% percent of patients, over half of whom developed the hydrocephalus after surgery. During follow-up, tonsillar herniation or Chiari malformation can develop as sequelae of insufficient intracranial space. Another report covering a 20-year period noted that the incidence of postoperative hydrocephalus was 45% for patients with syndromes and 4% for patients with isolated craniosynostosis. The incidence of shunt placement was 22% and 1% respectively [46,47].

#### **Upper airway obstruction**

Severe malformations involving the face and cranial base are at high risk for upper airway obstruction and undetected obstructive sleep apnea (OSA). Almost 50% of patients with craniofacial dysostosis develop OSA and require airway intervention at some time [48-50]. OSA can be treated pharmacologically, non-surgically (CPAP, nasopharyngeal tube) or surgically, depending on its severity and cause [17,51]. Fifty percent of patients with craniofacial dysostosis are treated with tracheostomy, but nearly 7% in the early and 5% in the late postoperative phase have complications [52-56]. Beside a high incidence of tracheal cartilaginous sleeve, laryngomalacia, tracheomalacia and bronchomalacia, a reduced cranial base angle positions the pharyngeal wall forward and produces anteroposterior shortening of the nasal and oral airway [28]. In addition, the temporomandibular joint may be drawn posteriorly so that the mandible is positioned retrusively [29]. When the mandible is small and retrognathic (e.g. Pierre Robin sequence), the tongue is positioned posteriorly and impinges on the oro- and hypopharynx [26]. Midface hypoplasia and retroposition also diminish the dimensions of the nasal airway. Neurological dysfunction, such as pharyngeal hypotonia or inco-ordination, worsens airway obstruction in children with abnormal anatomy [57]. Other skeletal abnormalities, such as turbinate hypertrophy, septal deviation, and choanal narrowing or atresia (e.g. CHARGE syndrome), contribute to upper airway obstruction.

Obstructive sleep apnea is common in craniofacial syndromes [27,28,58–61]. Sher and colleagues [58] used flexible fiber-optic nasopharyngoscopy to identify the mechanisms of pharyngeal obstruction in patients with OSA. Four mechanisms were identified.

- **1.** Posterior movement of the tongue against the posterior pharyngeal wall (Fig. 32.14).
- 2. Posterior movement of the tongue with compression of the soft palate or cleft palatal tags posteriorly against the posterior pharyngeal wall; the tongue, velum, and posterior pharyngeal wall meet in the upper oropharynx.
- **3.** Movement of the lateral pharyngeal walls medially to appose each other.
- **4.** Pharyngeal constriction in a circular or sphincteric manner.

Sleep apnea may occur from brainstem compression in children with Chiari malformation.

Some patients are successfully managed with nasal continuous positive airway pressure (nCPAP) during sleep [60]. Others with severe airway obstruction may require tracheostomy. Of 251 patients with craniofacial anomalies who underwent surgery over a 5-year period, 20% required tracheostomy to relieve chronic airway obstruction or to

Figure 32.14 Anatomical features of the larynx. (A) Normal child. (B) Child with mandibular hypoplasia. Posterior placement of tongue makes the larynx appear to be more anteriorly situated than normal. Reproduced from Handler SD et al. Ann Otol Rhinol Laryngol 1993; 92: 401 with permission from Annals Publishing Company.

manage the airway in the perioperative period [62]. Patients with craniofacial synostosis (Crouzon, Pfeiffer or Apert syndromes) had the highest rate of tracheostomy (48%). Those with mandibular facial dysostosis (Treacher Collins or Nager syndromes) had the next highest rate (41%). Twenty-two percent of patients with oculoauriculovertebral sequence (Goldenhar and hemifacial microsomia) required tracheostomy. The mean duration of cannulation in infancy or in early childhood was 4 years. Patients who had tracheostomy after 4 years of age required cannulation for less than 6 months, and 60% underwent decannulation 1 week after tracheostomy.

Ear, nose and throat consultation is recommended to determine if an adenoidectomy or tonsillectomy is required prior to craniofacial surgery. Some cases of sleep apnea are effectively treated by adenotonsillectomy.

Patients with Robin sequence, especially non-syndromic patients, who have airway obstruction that is unresponsive to prone or lateral positioning alone respond to nasopharyngeal/nasotracheal intubation or glossopexy (tongue-lip adhesion, TLA). These procedures often relieve airway obstruction during the first months of life while the mandible grows and the airway expands [57,63,64]. In some syndromes (e.g. Treacher Collins and Apert), the anatomical inter-relationships become progressively distorted and the obstruction may worsen, not improve [26,58,65]. To minimize morbidity, the least invasive treatment should be used first. If conservative treatment, including wearing a soft palate plaque (e.g. Tübinger type) [66], does not resolve the problem, further management should be based on the oxygen saturation,

feeding difficulties, and endoscopic findings. A more aggressive approach is the TLA or a perimandibular fixed extension device. Distraction osteogenesis can be used in older children [67]. Finally, if all else fails, a tracheostomy might be indicated.

#### **Associated anomalies**

With syndromic craniofacial anomalies, many systems may be malformed, particularly the CNS, the cardiac, and pulmonary systems. Cranial sensory and speech organs can also be malformed, and hearing, vision, and speech may be impaired. Cervical spine anomalies, including intervertebral fusion, occur commonly in Goldenhar syndrome and with craniosynostosis syndromes such as Crouzon, Apert, and Pfeiffer [68–70].

## Craniofacial reconstruction: surgical procedures

Paul Tessier introduced major craniofacial surgery in Paris in 1967. He developed the first craniofacial dysjunction procedures that cleaved the face away from the base of the cranium by using both an intracranial and an extracranial approach [71,72]. Over the past 40 years, these techniques have been used to treat a variety of complex congenital and acquired deformities of the face and cranium, including traumatic and neoplastic entities [73]. A co-ordinated interdisciplinary approach is required for this surgery to succeed. There are many reasons for doing the surgery, including improving neurological,

**Figure 32.15** After bicoronal incision for intracranial upper and midface procedures, the face is peeled back for wide exposure of the facial skeleton bone.

ocular, nasal, dental and auditory functions as well as improving cosmetic appearance and psychological function [74]. The basic objective of craniofacial surgery is to correct skeletal deformity first and soft tissue afterwards. The basic treatment of the deformed skeleton comprises cutting, disjoining, mobilizing, repositioning, augmenting, and fixing the involved bony structures. Wide exposure of the skeleton is required. Therefore, the soft tissues, including the orbital contents, are extensively dissected and mobilized away from their bony attachments. Intracranial and extracranial approaches are utilized and scalp, pre-auricular, and intraoral incisions are made to avoid producing scars on the face. For intracranial and for upper and midface procedures, the surgical approach is through a bicoronal scalp incision that extends from ear to ear and from which the soft tissues of the scalp and face are reflected forward over the facial mass (Fig. 32.15). This provides wide exposure of the facial skeleton down to the maxillary alveolus. A craniotomy is done, the frontal lobes of the brain are retracted, and the anterior cranial base is exposed. To effectively provide anesthesia for major craniofacial surgery, the anesthesiologist must clearly understand both the lesion and the proposed surgical procedure.

#### **Cranial and facial remodeling**

Surgery for cranial and facial remodeling is performed with the goal of normalizing the child's appearance, ensuring sufficient head size and growth, and establishing normal function of the skull structures and related organs. In most cases, these aims cannot be fully met but significant improvement is possible. In the past, surgical techniques were employed that often did not take into account the substantial variations in the underlying pathology, the patient's age, and the skill of the surgical team. The first technique employed was to open the fused suture, with the hope that this would allow normal skull growth. In the past this method was not successful but recently Jimenez has had success with the procedure [75]. Since it became evident that cranial growth follows intrinsic pathways rather than mechanical rules, the entire cranial vault, including the skull base structures, have been addressed surgically. Whenever the fronto-orbital region is involved, additional maneuvers, such as frontoorbital advancement, have been used to improve facial appearance and enlarge the intracranial and orbital cavity. In multisuture craniosynostosis, restricted skull growth and potential brain and orbital constriction are the major reasons for early surgery. In addition to fronto-orbital advancement and cranial vault remodeling, posterior distraction surgery can be an option.

In principle, the main surgical goals for these patients comprise three steps: opening of the cranial vault to allow the brain to expand, fronto-orbital advancement to ensure frontal brain expansion and eye protection, and midface advancement to improve nasopharyngeal pathways and dental alignment. Additional procedures may be necessary for orbital malposition and facial clefts.

The typical skin opening for cranial or craniofacial remodeling is a coronal incision. The incision can be straight, curved or zigzag to prevent visible scarring. Attempts should be made to minimize unnecessary blood loss when dividing the galea [76].

#### Timing and general preparation for surgery

Timing of craniofacial repair is often controversial. As long as there is sufficient head growth, as occurs in most single-suture craniosynostoses and other craniofacial disorders that do not involve the cranial vault, surgery is scheduled in the second half of the first year, usually between 6 and 8 months of age. At that time, the hematological status is stabilized and the bony structures are firmer and easier to remodel than at younger ages. All systemic functions are checked to minimize the overall risk.

Multisuture craniosynostoses can lead to severe skull constriction and require early or even emergency procedures to relieve ICP; elevated ICP significantly increases the risks of surgery and anesthesia. These patients require early evaluation for cardiac, kidney, airway, and hematological disorders.

Parents must be informed about all aspects of craniofacial surgery, including early and late changes in the esthetic appearance of their child, potential surgical risks (mainly blood loss and the need for transfusion of blood and coagulation factors), and the possibility of infection. They should be prepared for significant facial swelling during the first postoperative days, but should also be assured that brain damage and severe complications are rare despite the extent of the surgical procedure. Longterm follow-up is important to detect late intracranial hypertension or recurrent deformity, both of which may require reoperation.

#### Craniectomy

The principle of craniectomy is to remove a piece of the cranial vault to permit directional skull expansion. Several forms of craniectomy have been used from simple suturectomy, to strip craniectomies, to wide vertex craniectomies in scaphocephalic patients. Barrel stave incisions and lateral strip craniectomies have been utilized to promote lateral skull expansion. Total removal of the cranial vault has been performed, with acceptable outcomes in some cases. Since craniectomies require spontaneous bone regeneration to reshape the skull and protect the brain, these techniques are not recommended in children older than 8–10 months of age.

Strip craniectomy improves craniofacial contour only for isolated sagittal synostosis. For other synostoses, removing, reshaping, and repositioning bone accomplish cranial remodeling. Cranial remodeling may involve any part of the cranium or the entire cranial vault. For complex craniosynostoses that involve the cranial base and face, the sutures involved are commonly those of the anterior cranial vault (coronal, sagittal or metopic sutures) as well as the anterior cranial base (frontosphenoidal, frontoethmoidal, and sphenozygomatic sutures). The surgery releases sutures and advances the upper part of the face forward (fronto-obital advancement) away from the cranial base (Fig 32.16). The principal functional objectives of the surgery are to open the cranium to allow

**Figure 32.16** Fronto-orbital advancement. Both frontal bone flaps (B) or a coherent bifrontal flap are displaced forward together with the fronto-orbital bandeau (A). Rigid fixation with miniplates or wire loops or tight suturing keeps the bone segments in place.

normal brain expansion, to open the nasopharyngeal airway, to provide greater support and protection for the eyes, and to achieve proper alignment of the upper and lower dental arches. This surgery usually requires at least two steps: (1) frontocranial remodeling, with release of the synostosis and advancement of the frontal-supraorbital area, and (2) midface advancement. The segments are fixed in place with wires or resorbable/non-resorbable miniplates, and bone grafts are used to fill gaps. In some cases the forehead is left "floating" with a wide osseous defect.

#### Cranial vault reconstruction

Total or partial reconstruction of the cranial vault is the method of choice when reshaping and stability of the skull are the aim of the operation. Vault craniotomies are performed and the bony plates are remodeled and transposed to reshape the skull. Stable fixation of bone with wire loops, stitches or miniplates (either titanium or lactic acid polymer) is necessary. Titanium miniplates tend to grow inwards and must be removed after 3 months. Cranial expansion is another surgical aim of total cranial vault reconstruction. Again, cranial plates are excised, transposed, and refixed, leaving substantial gaps in between the bone edges, but the intracranial cavity is enlarged [77]. This technique is indicated for children with multisuture involvement or secondary intracranial hypertension, e.g. after scaphocephaly correction. Larger bone defects (>2 cm) will not close spontaneously after the second year of life, making it necessary to do this surgery before that time. Defects in the calvarium can be filled with autologous grafts, e.g. calvarian split grafts. Children with severe occipital deformity or flattening, e.g. in brachyturricephalic heads, undergo occipital advancement, including a suboccipital bone flap. For mechanical reasons a rigid fixation is necessary.

#### Fronto-orbital advancement

For anterior skull expansion and correction of the orbital portion, the fronto-orbital advancement has been the standard technique since first described by Tessier and modified by Marchac [78,79]. First a bifrontal flap is excised and removed, then the fronto-orbital bandeau, cutting the edges in a tongue-and-groove fashion. In trigonocephaly or anterior plagiocephaly, the bandeau and the frontal bones are reshaped and sometimes rotated to create the desired fronto-orbital shape. Refixation of bone may be with wire loops, miniplates or tight stitches in older children. In multisuture synostoses, when the primary goal is to enlarge the cranial cavity, fronto-orbital advancement is combined with total vault reconstruction. Shallow orbits are always enlarged to protect the eyes (Fig. 32.17).

**Figure 32.17** During fronto-orbital advancement, the primary goal is the enlargement of the cranial cavity which is combined with total vault reconstruction. After that both orbits are exposed.

Figure 32.18 Le Fort I, II, and III osteotomies.

#### **Distraction osteosynthesis**

Another method of enlarging the volume of the skull is based on the Ilizarov principle of bone distraction. For midface and mandibular correction, distraction osteosynthesis has become standard. The application of distracting devices to transected vault sutures or parts of bone flaps for dynamic skull expansion is less well established.

#### Additional neurosurgical procedures

Hydrocephalus is relatively common in multisuture or syndromic craniosynostosis and contributes to the elevated intracranial pressure. Ventriculoperitoneal shunting is the procedure of choice in these cases, but interferes with keeping cranial sutures or newly created gaps open as long as possible after cranioplasty procedures. Alternatively, an endoscopic third ventriculostomy can be done in selected cases.

As a consequence of insufficient skull growth, the expanding brain moves downward and causes a Chiari malformation with brainstem compression and secondary hydrocephalus. In some of the affected children, a craniocervical decompression (Gardner decompression) becomes necessary.

#### Midface advancement

Craniofacial dysjunction and midface advancement are delayed until the patient is at least 4 or 5 years of age. Certain indications or personal preferences lead surgeons to select a specific operative procedure, which usually includes a Le Fort osteotomy (Fig. 32.18). At the beginning of the 20th century, a French surgeon, René le Fort, found that the maxilla, naso-orbital complex, and zygoma fracture in predictable ways at weak points, i.e. the linea minoris resistentiae [80]. These fracture lines are used to produce controlled osteotomies for the correction of skeletal anomalies.

The Le Fort 1 osteotomy is the most common and most useful midface osteotomy (Fig. 32.19). Malocclusion of the teeth is always present and is treated by an interdisciplinary team of maxillofacial surgeons and orthodontists. Surgery is performed through an intraoral incision. Horizontal cuts are made across the nasal floor, the anterior maxilla, and through the pterygomaxillary junction. The maxilla is mobilized downward, advanced, and fixed. The occlusion is secured by arch bars and by a dental splint. Because of the intraoperative intermaxillary fixation, nasotracheal intubation is required. Bone grafts can be used to fill the spaces.

Le Fort II osteotomy is done less often and is used to advance the lower maxilla and entire nose forward (Fig. 32.20). Normally a bicoronal scalp incision and soft tissue reflection are combined with an intraoral incision to expose the midface. There are many variations of midface osteotomies. The osteotomy crosses the nasal bridge and then goes bilaterally down the lateral nasal bones through the inferior orbital rim and across the maxilla to the pterygomaxillary junction. The segment is mobilized and advanced. Bone defects are filled with bone grafts, and the entire segment is fixed with rigid miniplates or wires. Intermaxillary fixation is not really needed when rigid internal fixation plates are used.

Figure 32.19 Le Fort I osteotomies. Reproduced from Bardach J, Salyer KE. Surgical Techniques in Cleft Lip and Palate, 2nd edn. St Louis: Mosby Year Book, 1991, p.251 with permission.

Figure 32.20 Le Fort II osteotomies. Reproduced from Bardach J, Salyer KE. Surgical Techniques in Cleft Lip and Palate, 2nd edn. St Louis: Mosby Year Book, 1991, p.255 with permission.

Midface hypoplasia typically results in an Angle class III malocclusion (a relative mandibular prognathia) with an anterior overbite. A Le Fort III osteotomy is indicated, but an additional Le Fort I osteotomy is often necessary to achieve an intermaxillary relationship that enables stable occlusion. Le Fort III osteotomy (Fig. 32.21) is used for complete underdevelopment of the midface, typical of Apert, Crouzon, Pfeiffer and similar syndromes. It permits the nose, maxilla, and orbits to be advanced after dysjunction of the entire midface. A bicoronal scalp incision is made, the soft tissues are reflected forward over the midface, and the orbital contents are dissected free. The basic osteotomy starts at the frontozygomatic suture and then passes through the orbits below the supraorbital rim and across the nasal bridge. The pterygomaxillary junctions are separated, and the nasal septum is separated from the skull base. The facial block is advanced after down-fracture and side-to-side and rotary manipulations (see Fig. 32.21). The spaces are filled with bone grafts and the bones are fixed in place. The use of rigid internal fixation plates precludes the need for intermaxillary fixation.

Monoblock frontofacial advancement moves the frontal and orbitofacial blocks forward simultaneously. While the early functional results are good, the complication rate is high and the poor postoperative midface growth makes a reoperation more difficult [81]. The supraorbital area and the facial mass are mobilized *en bloc* and

**Figure 32.22** After osteotomies and removal of a central block of bone, the orbits are shifted medially. Orbits can be considered as boxes containing the eye. Each orbit can be moved in any plane.

**Figure 32.21** Le Fort III osteotomy. Rowe disimpaction forceps are used to "down fracture" the posterior maxillary wall and allow advancement of the midface. Reproduced from Persing JA et al. Surgical treatment of craniosynostosis. In: Persing JA, Jane JA (eds) Scientific Foundations and Surgical Treatment of Craniosynostosis. Baltimore: Williams and Wilkins, 1989, p.229 with permission.

advanced. The frontal bone flap is remodeled when necessary, e.g. exorbitism.

Various combinations and modifications of these osteotomies are performed either simultaneously or in stages. The transverse maxillary osteotomies (Le Fort 1 and II) are usually delayed until adolescence to avoid disruption of the permanent dentition.

Pediatric temporomandibular joint (TMJ) dysfunction from soft tissue or skeletal disorders may be congenital or acquired. The diagnosis and classification of TMJ disorders determine treatment options [82]. In cases of TMJ reconstruction or discontinuity defects of the mandible after trauma, hemimandibulectomy for tumor excision, condylar damage with juvenile idiopathic arthritis or congenital diseases (e.g. hemifacial dysplasia), the goal is to maximize function and cosmesis, preserve quality of life, and restore mastication, speech, and appearance [83]. Treatment includes autogenous bony, cartilage, and condylar grafts, free vascularized flaps, or alloplastic TMJ prosthesis until the skeleton matures [84-87]. A variety of donor sites have been used for this purpose, including the iliac crest, radius, scapula, and fibula. TMJ diseases occurring during growth result in dentofacial deformity and require reconstruction of the occlusion plane. Surgical correction with total joint prostheses can be performed in a single-stage operation with a mono- or bimaxillary orthognathic osteotomy [88]. During surgery the occlusion has to be checked.

## Surgical correction of hypertelorism and orbital malposition

Surgical correction of orbital malposition is performed to facilitate correction of strabismus, to normalize facial appearance, and to possibly achieve binocular vision. Surgery is usually performed at about 5 years of age unless there are mitigating circumstances. The orbit can be thought of as a box housing the eye. To correct hypertelorism or other orbital malposition, the box is freed from contiguous bone and repositioned (Fig. 32.22). In moderate and severe degrees of hypertelorism, an intracranial approach is employed: a bicoronal scalp incision is made; soft tissues, including orbital contents and nasal mucosa, are reflected down to midface; a frontal craniotomy is performed; and the frontal lobes of the brain are retracted to expose the anterior cranial fossa. Intra- and extraorbital osteotomies convert the anterior orbit into a mobile box (see Fig. 32.22). A central block of bone (frontal, nasal, ethmoidal) is removed from between the orbits. The orbits, with the globe and other soft tissues, are then moved medially and fixed in place (Fig. 32.23). Bone grafts are inserted into the gaps created at the lateral orbital walls. The nose is rebuilt with bone grafts if necessary. For minor degrees of hypertelorism, an extracranial approach is possible; this eliminates the frontal craniotomy and brain retraction. Extensive soft tissue dissection is still required, but the osteotomies are less extensive. There is also danger of piercing the cribriform plate and causing CSF leakage.

## **Reconstruction of facial clefts: major facial and mandibular malformations**

The anatomical defects of the major facial and mandibular malformation syndromes are skeletal and soft

Figure 32.23 Orbits after medial shift and fixation with miniplates.

tissue hypoplasias. Hypoplasia may involve any part of the face and cranium. Reconstruction of these lesions often requires multiple staged surgical procedures. The skeleton must be normalized, the soft tissues augmented, ears and nose reconstructed, and sometimes the face must be reanimated. For the hypoplastic skeleton, displacement osteotomies, repositioning of bones into more normal positions, and calvarial bone grafts are used to augment surfaces and fill spaces.

Soft tissue hypoplasia can involve skin, subcutaneous tissue, cartilage, and the muscles of mastication and facial expression. Various approaches can be taken to augment and restructure soft tissues. Skin and mucosal flaps from local or distant sites may be used. To add bulk and appropriate contours, dermis fat grafts from the groin can be placed subcutaneously. Contour can also be improved with inlay bone grafts. Temporal muscle transfers to the face also add bulk. These procedures may require extensive dissection of soft tissue. Facial nerve palsy can be compensated for with nerve transfer from the motor branch of cranial nerve V; if the malformation is unilateral, cross-face nerve grafts, facial-hypoglossal nerve anastomosis, and microneuromuscle transfers can be attempted.

Traditionally, mandibular reconstruction has followed the same principles as other craniofacial procedures: cut, mobilize, reposition, augment, and fix. In the past the mandible was mobilized through an intraoral incision with bilateral sagittal osteotomies and rotated and advanced into a normal position. Distraction osteogenesis is now replacing the traditional method in many cases (see below). New mandibular parts are constructed from costochondral rib grafts or split cranial grafts. This surgery is usually done before eruption of the permanent teeth.

#### **Distraction osteogenesis**

Patients with severe craniofacial dysostosis who require early surgical correction of their deformity before skeletal maturity have clearly benefited from distraction osteogenesis (DO) compared to conventional osteotomy [89]. Distraction osteogenesis is done by producing a bone callus (by osteotomy) and then distracting the proximal and distal ends of the callus. It has been used by some orthopedic surgeons for years to lengthen limbs but did not gain widespread acceptance because of the associated morbidity. In 1988, Ilizarov, a Russian orthopedic surgeon, described using distraction osteogenesis that required only corticotomy and minimal disruption of the periosteum and endosteum; this reduced the incidence of complications and allowed wider application of the technique [90].

Rosenthal first described distraction osteogenesis for widening the mandible in 1930 [91]. Its principal application in craniofacial surgery is for mandibular lengthening [92]. The technique consists of percutaneous insertion of pins into the mandible that are proximal and distal to a corticotomy. The pins are attached to an external fixator-lengthening device, and the mandible is lengthened 1 mm/day by turning a bolt. The authors reported mandibular lengthening of 18–24 mm.

The procedure is considered minimally invasive and achieves an approximately 2-3-fold advancement compared to the conventional procedure. Using conventional osteotomy beyond the age of skeletal maturity has the advantage of a shorter treatment period and greater patient comfort. Distraction is often associated with less blood loss, less tissue exposure, and no need for bone grafting. With DO the postoperative morbidity is decreased, the operation time is reduced, and the procedure can be performed on younger children. Several authors believe that mandibular distraction also induces facial soft tissue growth [93-95]. The disadvantage of this technique is the need for high patient compliance and the high psychological impact [96]. The major complication of extraoral devices is the development of hypertrophic scars when the pins migrate through the skin

Since the original description, mandibular distraction has become increasingly popular for the treatment of mandibular hypoplasia and asymmetry [95,96,97]. Enoral (internal) distracters eliminate facial scars and are less likely to loosen or dislodge. Mandibular distraction has also been used to successfully alleviate the symptoms of respiratory distress and obstructive sleep apnea. A tracheostomy (if in place) can be removed. Mandibular distraction has been applied to infants as young as 14 weeks of age [98]. Both internal and external lengthening devices are being applied to distract the midface [96].

Patients with cleft lip and palate often have severe maxillary hypoplasia in the vertical, horizontal, and

transverse dimensions. Traditional protocols rely on combined surgical-orthodontic treatment, including Le Fort I maxillary advancement, maxillary and alveolar bone grafting, and rigid internal fixation. Long-term results of this approach have been disappointing because relapse occurs in more than 20% of the cases. Trans-sinusoidal (TS-MD) placement of a distracter is a possible alternative for patients with cleft lip and palate. The major part of the TS-MD is done within the maxillary sinus and does not interfere with function during distraction and retention or with the patient's social life. Compared with headframe-based extraoral devices for midface distraction, TS-MD is easier for the patient and does not leave extraoral scars after removal of the device. Threedimensional planning enables the surgeons to plan the distraction vector in three dimensions, but a correction of the vector by distraction is not possible, as it is with the headframe device (Fig. 32.24).

#### Cleft lip and cleft palate reconstruction

Surgical reconstruction of a cleft lip, palate, and/or nose is undertaken for cosmetic, psychological, and functional

**Figure 32.24** The TS-MD on a stereolithographic model of the midface. (A) Before and (B) after distraction.

purposes. Functional goals are to separate the nasal and oral cavities, to improve speech and swallowing, to prevent middle ear disease, to improve hearing, and to provide normal dental occlusion (Fig. 32.25).

The treatment of children with cleft lip and palate starts during the first weeks after birth with preoperative orthopedics, such as presurgical nasal alveolar molding (PNAM). The PNAM appliance differs from traditional intraoral alveolar molding devices by having nasal prongs as part of the device [98]. An orthodontist adjusts the acrylic appliance by adding and removing material from the leading edge of the maxillary segments weekly. Despite the lack of long-term outcome studies, PNAM is used by many multidisciplinary cleft teams to reduce the width of the alveolar cleft and the corresponding soft tissues of the cleft lip [99].

Primary cleft lip repair is usually performed at 3-6 months of age and often includes a primary rhinoplasty. Cleft palate reconstruction is done at 12-20 months of age before speech develops. There are many ways to close the lip that have excellent results, each with its own advantages and disadvantages. The final result depends on the degree of primary dysmorphology, scarring (surgical technique), the experience of the surgeon, and the time schedule [100]. Tissue deficiency and displacement contribute to anatomical defects. Surgical reconstruction involves dissecting and freeing anatomical elements, undermining the tissue, repositioning the involved muscles in a correct anatomical position, and creating flaps for rotation and advancement of the lip. Reconstruction of the bony palate requires creating bone or mucoperiosteal flaps and also bone grafting. For example, mucoperiosteal flaps can be made from the

Figure 32.25 Timing and general procedures for cleft patients. PNAM, presurgical nasal alveolar molding. Reproduced from Tollefson et al [98] with permission from the American Medical Association.

palatal shelves and positioned medially to fill the cleft or they can be turned off the vomer and joined to the edge of the bony cleft to close it. If the cleft is sufficiently narrow, paring of the medial palatal edges and elevation of nasal and palatal mucosa may allow closure. Free bone grafting is required traditionally after orthodontic palatal expansion (8–11years of age) of the alveolar ridge. This occurs when 30–60% of the canine tooth roots have developed but before eruption of the tooth into the cleft void. Bone is generally taken from the iliac crest.

#### **Pharyngeal flap**

Velopharyngeal incompetence is failure of the velum (soft palate) and posterior pharynx to close or contact appropriately during speech and swallowing. It occurs in 10–30% of patients after cleft palate repair. It can also occur if there is any anatomical or neuromuscular abnormality of the palate or pharynx [101]. Velopharyngeal incompetence causes hypernasal, misarticulated speech. Nasal regurgitation of food and liquid occurs with swallowing.

Diagnosis of velopharyngeal incompetence has greatly improved with videofluoroscopy and nasal endoscopy, which provide a dynamic view of the velopharynx. Direct visualization can identify the closure pattern and contributions of the velum, the lateral and posterior pharyngeal walls, and Passavant ridge to speech [102]. Surgical correction of this defect is commonly attempted by creating a pharyngeal flap in which flaps of mucosa and muscle are raised from the posterior pharynx and attached to the velum (Fig. 32.26). This results in a permanent midline connection between the palate and posterior pharynx. Alternatively, a sphincter pharyngoplasty is performed, in which small lateral pharyngeal flaps are tucked under a wide medial flap to create a bulky transverse roll in the posterior pharynx, which narrows the pharynx and allows contact with the velum.

The result of these procedures is a narrowed nasopharyngeal vault and the potential for obstructed nasal airflow. Obstructive sleep apnea is not uncommon after a pharyngeal flap is created, especially with the Robin sequence [103-105]. Velocardiofacial syndrome is the most common syndrome causing palatal clefting and velopharyngeal insufficiency. It is associated with medially displaced carotid arteries that increase the risk of pharyngoplasty [106]. Velopharyngeal insufficiency can be identified by nasoendoscopy but not with endoral examination. Blind nasal tracheal intubation or insertion of a nasogastric tube should not be attempted in patients who have a pharyngeal flap. However, Kopp reported performing nasotracheal intubation in patients with a pharyngeal flap by first passing a flexible suction catheter to determine the patency of each naris and to identify the pharyngeal flap passages [107]. When the catheter

**Figure 32.26** Pharyngeal flap. A flap of mucosa and muscle is raised from the posterior pharyngeal wall and attached to the soft palate. Reproduced from Shprintzen RJ et al. Cleft Palate J 1979; 16: 50 with permission from the American Cleft-Craniofacial Association.

emerges through the ostium created by the flap, it is grasped with a clamp and the endotracheal tube gently passed over it.

## Anesthesia for craniofacial reconstruction

#### **Preoperative evaluation**

Many factors influence the emotional state of patients and families who face major craniofacial surgery [108-11]. Pediatric patients with craniofacial anomalies often have behavioral problems, poor self-image, anxiety, introversion, and negative social experiences. These problems are rarely profound and represent limitations rather than severe psychopathology [111]. Most children with craniofacial anomalies make social and psychological adjustments to their appearance without functioning in a psychosocially deviant range. Surgery is stressful for the patient and parents [112]. They have fear of pain and of physical jeopardy because the surgery is extensive and potentially life threatening. Older children may also fear loss of identity because of the impending changes in their appearance. Parents may be very protective. Many patients undergo multiple surgical procedures over many years, and the child and family have invested great emotion in the process.

It is important to establish rapport and gain the confidence and acceptance of the patient and parents. One can be sensitive yet open and candid in discussing the anomalies. It helps to encourage the child and parents to express their concerns and expectations. The child may have problems with sight, hearing or speech, and these must be accommodated during preoperative preparation. Various hospital activities such as puppet plays, movies, storybooks, and other play therapy may help to prepare the child for the coming events.

It is appropriate to be reassuring to the patient and family, because the procedure offers hope and the surgical results are usually good. Eighty-seven percent of patients report subjective improvement in appearance after surgery [113]. In addition to increased satisfaction with body image and improvement in their emotional state, some patients also have improved behavior and school performance. Ninety-one percent of parents of small children and 77% of adolescents would undergo the surgery again [109,114].

A complete preoperative medical evaluation is required. There are potential differences between craniofacial and isolated orofacial procedures. Patients undergoing craniofacial surgery should have preoperative evaluation, including sleep studies. The possible need for ICP monitoring should be discussed with the parents preoperatively. Patients with craniofacial anomalies often have syndromes and have anomalies of other systems. Relevant and comprehensive information about rare diseases is available on the internet (www.orpha.net). Associated CNS pulmonary and cardiac anomalies are especially noteworthy. Because of the nature and extent of the surgery, a careful history of bleeding tendencies should be obtained. Twenty to 37% of patients undergoing major craniofacial surgery have airway problems [115,116]. Sixty-five percent of patients with mandibular dysostosis (Treacher Collins, Goldenhar or hemifacial microsomal syndrome) and 53% of patients with craniofacial synostosis have problems with their airways.

It is important to evaluate thoroughly and comprehensively the airway because not all airway abnormities are readily apparent. Patients often undergo multiple procedures, so a history of airway problems during previous procedures and how they were managed should be reviewed. If airway management is expected to be difficult and a tracheostomy may be required, this should be discussed with the patient and parents before surgery.

Certain facial, upper airway and neck anomalies make airway management by mask and tracheal intubation difficult. It is difficult to get a good mask fit and seal when there is facial asymmetry, malar hypoplasia or nasal deformities. Anatomical anomalies, such as choanal atresia or stenosis, macroglossia, micrognathia, and diminished nasopharyngeal space, may cause airway obstruction. Secretions or adenoidal hypertrophy may further obstruct small air passages. Awake patients may have signs of airway obstruction, e.g. mouth breathing. Other signs, such as snoring, noisy breathing, and apnea, may be present only during sleep. Snoring with frequent sleep arousals, abnormal movements during sleep, daytime somnolence, nocturnal enuresis, and morning headaches are signs of sleep apnea. A history of sleep apnea can be elicited by asking whether the child snores and holds his or her breath between snores. Poor attention spans and school performance and/or personality and behavioral changes are also symptoms of obstructive sleep apnea. In severe cases, the child may be underweight and have pulmonary artery hypertension or cor pulmonale. Patients with upper airway obstruction during sleep may have airway obstruction during premedication-induced somnolence, during mask induction of anesthesia, and after extubation of the trachea.

Airway anomalies may render direct visualization of the larynx difficult or impossible. Mandibular hypoplasia or micrognathia, microstomia, macroglossia, trismus, and restriction of TMJ movement may make laryngoscopy difficult. Certain anatomical features should be carefully studied, including shape, size, and symmetry of the mandible, anteroposterior distance from the chin to the hyoid bone, tongue size, shape of the palate, movement of temporomandibular joints during mouth opening and during anterior displacement of the jaw, and mouth size when open (interincisor distance). Range of motion of the neck, especially extension, should be determined. Vertebral anomalies, such as cervical vertebral fusion in patients with Goldenhar, Apert, Crouzon, and other craniosynostosis syndromes, may limit neck motion [117]. During endotracheal intubation, retroflexion of the head may be necessary. Patients with Chiari malformation may have brainstem compression during flexion or severe extension of the head. Discussion should take place with the family and surgeon preoperatively about possible consequences of intubation maneuvers. It may be better to accomplish tracheal intubation with a fiber-optic bronchoscope without moving the head from a neutral position.

#### Laboratory evaluation

When large blood loss is expected, the minimal laboratory testing required in otherwise healthy children usually consists of hemoglobin or hematocrit and type and crossmatching of blood. Tests of coagulation (e.g. prothrombin and partial thromboplastin times, platelet count, and bleeding time) should be considered, especially in young infants. Other laboratory evaluations, such as chest x-ray, electrocardiography (ECG), pulmonary function tests, arterial blood gases, and serum electrolytes, may be required, depending on co-existing conditions.

#### **Preoperative medication**

Preoperative medication can be used to augment but not to substitute for psychological preparation. The use of preoperative medication must take into account the need for sedation and the presence of co-existing conditions and airway anomalies. For example, patients with increased intracranial pressure or potential airway obstruction may not safely tolerate respiratory depressants. Optimal sedation should smooth the induction process. Oral benzodiazepines are generally well tolerated for this purpose. Benzodiazepines, pentobarbital, and chloral hydrate can be administered orally or rectally. Fentanyl can be administered in a transmucosal form. Painful intramuscular injections should be avoided when possible. A local anesthetic cream patch (2.5% lidocaine and 2.5% prilocaine) placed above a vein can minimize the pain of inserting a venous catheter. The patch is usually removed 1h prior to puncture. Antisialagogs can be included with oral premedication but should be used with care because they may cause a dry mouth and fever after the procedure.

#### Intraoperative anesthetic management

Successful anesthetic management requires close communication between the surgeon and anesthesiologist, especially when the surgeon is working near the airway or when rapid blood loss occurs. Anesthesia management is influenced by the patient's co-existing conditions, airway anomalies, and by particular features of the craniofacial procedure. In general, standard operating procedures (SOP) written by anesthesiologists and surgeons help standardize the intraoperative management of the patient and assure optimal quality of care.

#### Associated conditions

Associated respiratory, cardiac, and neurological anomalies or disorders will influence anesthetic management. The presence of cervical vertebral anomalies can influence head positioning or the procedure being done. If the patient has complex craniosynostosis, consideration must be given to the possibility for raised ICP, as previously discussed. Signs and symptoms of elevated ICP are uncommon. Even when the ICP is normal, intracranial complications may occur in some areas if the cranial vault inadequately accommodates the brain in all dimensions. Anesthetic induction and maintenance techniques and agents should decrease not increase the ICP of these patients.

#### **Airway anomalies**

Unexpected airway obstruction may occur during the induction of anesthesia. Physical appearance is not always a reliable indication of potential airway obstruction, and a past uneventful anesthetic course does not preclude the occurrence of airway problems this time, especially when a cleft palate has been repaired or pharyngeal flap procedure has been done in the interim. When difficulty with the airway is anticipated, a general plan of how to deal with the problem should be formulated ahead of time – no single technique is foolproof. The plan should include provision for several alternative techniques, and the availability of a variety of equipment, especially laryngeal mask airways and small tracheal tubes. It is advisable to proceed cautiously with the anesthesia induction. Spontaneous ventilation offers a margin of safety. Airway catastrophes can be avoided by allowing the patient to breathe spontaneously until it is verified that controlled ventilation is possible and easy to establish.

Difficulty with the facemask fit can be overcome by building up the face with gauze, applying a large mask over the entire face, and by using high gas flows. Clear masks with moldable air cushions often fit best, but care should be taken to assure that the cushion does not impinge on the eyes or obstruct the nares. Some patients develop upper airway obstruction during light levels of anesthesia. This can be prevented or attenuated by clearing the nasal passages of secretions before the induction of anesthesia and by maintaining the "sniffing" position, opening the mouth, applying gentle positive airway pressure (5–10 cmH<sub>2</sub>O), and employing a "jaw thrust" when the patient is sufficiently anesthetized to tolerate it. Nasopharyngeal and oral airways may also be useful.

With mandibular hypoplasia and other oral and cervical malformations, direct laryngoscopy may be impossible or possible only with unconventional maneuvers. The larynx of these patients is often described as being "anteriorly placed." The larynx is actually in normal position with respect to other cervical structures but the tongue, which is attached to the hypoplastic mandible, is more posterior than normal and overhangs the larynx, giving the impression that the larynx is anteriorly placed [118]. It is often impossible to open the mouth adequately and displace the tongue sufficiently to allow visualization of the larynx.

Laryngeal mask airway (LMA) and fiber-optic bronchoscopy are important tools for airway management of patients with craniofacial malformations. The LMA can be inserted in awake infants (with topical anesthesia) or after induction of anesthesia in infants and children to aid blind or fiber-optic guided tracheal intubation. A mobile "difficult airway" cart, including all devices for unexpected or expected airway difficulties, is recommended (see Chapter 14) [119–121].

Many reports describe difficulty with airway management in patients with craniofacial malformations. Before LMA and fiber-optic bronchoscopy were available, some unconventional maneuvers for obtaining an airway

**Figure 32.27** Single-handed usage of a Bonfils rigid optical scope for tracheal intubation in a difficult airway situation of a 3-year old child. (A) Optical unit. (B) LED light source. (C) Tube connector with oxygen insufflation. (D) Monitor.

were described, such as forcefully pulling the tongue out with a suture, forceps or custom-made retractors or using a Jackson anterior commissure laryngoscope with an "optical stylet." Blind or tactile tracheal intubation, with and without lighted guides, has also been described [122–125]. Video-assisted rigid endoscopes are now available to facilitate tracheal intubation of patients with a difficult airway. Oxygen is insufflated via the connector tube to prevent hypoxemia during video-assisted tracheal intubation. It is also helpful to use a laryngoscope to open the airway before inserting the rigid scope (Fig. 32.27).

Some patients require a tracheostomy for airway management. In some centers elective tracheostomy is performed when extensive facial osteotomies are planned in small children or when the airway would be difficult to manage if intraoperative reintubation were necessary [126]. When rigid internal fixation with plates is used rather than using intermaxillary ligation, tracheostomy can sometimes be avoided. Some patients already have a tracheostomy in place to treat severe respiratory obstruction. The complications and hazards of tracheostomy in pediatric patients include accidental decannulation of the trachea, tube obstruction, hemorrhage, and air leaks (pneumothorax, pneumomediastinum, and subcutaneous emphysema).

#### Features of the craniofacial procedure

Several features of craniofacial surgical procedures will influence anesthetic management: the procedure may be long with extensive tissue exposure; massive blood loss may occur; the procedure may be intracranial; and the airway may be in the surgical field.

#### Long procedure with wide tissue exposure

Major craniofacial procedures average 4–5h but can last for more than 12h. Operating time is reduced with an experienced surgical team [127,128]. Meticulous attention must be paid to protecting the anesthetized patient during prolonged surgeries. This includes proper positioning with the joints comfortably flexed, peripheral nerves protected, and pressure points, including the head, adequately padded. The patient may be in a supine, prone or modified prone position for the surgery (Fig. 32.28).

During a long period of wide tissue exposure, large amounts of body heat are lost. Temperature homeostasis is maintained by employing measures to conserve and provide heat, including minimizing the amount of time the patient is exposed to cold air before draping, warming the room to 23-24°C, and using a heat lamp before draping. A warming blanket or forced-air warming device should be used, along with passive insulation (plastic or cloth covers) around the body. Irrigation and intravenous fluids and blood should be warmed, and airway gases should be heated and humidified. When large portions of the cranium are exposed, the skull should be repeatedly bathed in warm irrigation fluid. Corticosteroids are often administered before craniofacial surgery to reduce postoperative facial swelling, but there is little evidence to support doing so.

#### **Excessive blood loss**

The magnitude of blood loss is related to the extent and duration of the surgical procedure and may equal multiples of the patient's blood volume for major craniofacial surgery. Blood loss reportedly decreases with greater experience of the team [127,128]. In one study, patients undergoing craniosynostosis repair had a mean estimated red cell volume loss of 91% of total estimated volume (range, 5–400%) [129]. The amount of red cell volume loss was greater for infants less than 6 months of age, for complex versus simple synostosis, and for complex vault remodeling compared to forehead reconstruction and strip craniectomy. Infants who underwent strip craniectomy lost about 60% of their blood volume [130].

Bleeding from the osseous venous plexus is generally continuous and may be quite brisk during osteotomy and bone mobilization. Rapid loss of large volumes of blood can occur with uncontrolled arterial bleeding or inadvertent opening of a dural sinus. For example, the internal maxillary artery may be divided during mandibular osteotomy, and the palatine artery may be cut during a Le Fort 1 procedure. The severed artery may be difficult to identify and clamp if it retracts into an inaccessible location. Irregularities on the internal surface of the cranium (e.g. bone spurs invaginating the dural sinuses) cause dural sinus tears and hemorrhage that often cannot be controlled rapidly. Other sources of major bleeding are

Figure 32.28 Positions in craniosynostosis surgery. (A) Supine position for frontal, frontoparietal and orbitofacial lesions. (B) Supine with head inclination for frontal and parietal and frontobasal lesions. (C) Prone position for parieto-occipital and suboccipital lesions. (D) Prone position with head reclination for total cranial vault exposure.

the major extradural and pharyngeal veins. Scarring and adhesions increase persistent bleeding and make major arterial, sinus, and venous bleeding more likely during repeat operations [131–134].

Blood loss should be aggressively replaced milliliter for milliliter in infants. It is unwise to fall behind in blood replacement as sudden, rapid blood loss may occur. For larger children and adolescents, initial blood loss replacement can be with appropriate volumes of crystalloid or colloid solutions until a reasonable level of hemodilution is achieved. Much of the blood loss is unmeasurable because it is hidden in the surgical field and drapes. Close communication with the surgeon about the pace of bleeding and close monitoring of the patient's intravascular volume are necessary. Normovolemia should be maintained with a combination of packed red blood cells and fresh frozen plasma. Because the child's blood volume is small, serial blood gas analyses should be made and include hematocrit and the level of lactic acidosis to detect decreased tissue perfusion.

Blood and blood components should be available in the operating room. At least two relatively large-bore intravenous (IV) catheters should be in place to permit swift infusion of blood. Blood transfusion may be rapid and massive and have all the attendant problems (e.g. hypocalcemia, hyperkalemia, and coagulopathy). When blood replacement exceeds one blood volume, coagulation factors, especially platelets, may need replenishment. Osteotomies, especially of the maxilla, may continue to ooze after surgery, so the child's hematocrit should be adequate when he or she leaves the operating room. Induced hypotension is used to limit blood loss and create a drier surgical field, but there is no consensus on its utility and no objective data to support its use in cranial surgery.

Both induced hypotension and hyperventilation can cause cerebral hypoxia [135,136]. Therefore, it is probably unwise to combine the two. Regional brain ischemia may occur even when global perfusion is normal (e.g. when the frontal lobes are retracted). For these reasons, deliberate hypotension may be better suited to extracranial rather than intracranial procedures, although it has been used for both. Nowadays these techniques are seldom used. Other techniques that have been used to reduce or eliminate homologous blood transfusion during craniofacial surgery include preoperative administration of erythropoietin and intraoperative autologous blood salvage [137]. The cost of erythropoietin treatment makes its routine use prohibitive. The usefulness of intraoperative autologous blood salvage in small children is limited because transfusion is usually required before sufficient autologous blood can be collected. Further miniaturization of the available devices may make this technique more attractive.

For many years, antifibrinolytic agents such as aprotinin and tranexamic acid were used to decrease intraoperative blood loss [138]. Since the withdrawal of aprotinin from the market, only tranexamic acid (TXA) is available for this purpose. The optimal dose for intraoperative use has not been defined. Recent evidence from pediatric scoliosis or cardiac surgery recommends 100 mg/kg as a bolus plus 10 mg/kg/h with a maximum dose of 2 g [139]. These doses are very high and care must be taken because of seizures or convulsion which could be seen after administration of TXA in children as well as in adults. Recent recommendations exclude children <1 year of age from therapy with TXA. In our institution we have significantly decreased the dosage of TXA down to 10 mg/kg as a bolus followed by 3mg/kg/h. If there is excessive bleeding, recombinant factor VIIa (rFVIIa) can be administered. rFVIIa is not approved for intraoperative use in coagulation disorders but is frequently used off label. It is an interesting substance that has promising effects on refractory non-surgical bleeding [140].

#### Intracranial procedures

Anesthetic techniques that decrease intracranial volume should be employed for intracranial procedures. Frontoorbital procedures require brain manipulation and retraction to allow adequate exposure of the anterior cranial fossa and facial bones. Reducing the brain bulk decreases the amount of brain retraction necessary. Therefore, anesthetic agents such as halothane, enflurane, and ketamine, which increase intracranial volume, should be avoided. Narcotics, benzodiazepines, thiopental, propofol, isoflurane, sevoflurane, and desflurane, in combination with mild hyperventilation (end-expiratory measured CO<sub>2</sub> between 30 and 35 mmHg) are preferred. Other measures used to decrease intracranial volume include 20-30° head-up positioning and use of diuretics (mannitol and furosemide) [141,142]. The respiratory pattern during mechanical ventilation should not inhibit intracranial CSF and venous drainage. Therefore, positive endexpiratory pressure (PEEP) should be avoided, and mean airway pressure should be maintained as low as is consistent with adequate oxygenation by using a long expiratory time, if possible.

Potential hazards during intracranial procedures include dural sinus tears, cerebral edema, and venous air embolism. Dural sinus tears may produce rapid, massive blood loss. Manipulation and retraction of the brain may cause cerebral injury and edema. Air embolism occurs through open venous channels because the open cranium is usually positioned above the central circulation [142– 144]. Meticulous surgical technique may prevent this complication.

#### Intraoperative airway management

During a Le Fort midface advancement, the surgeon must work around the airway. With maxillary osteotomy and down-fracturing maneuvers, the nasotracheal tube may be lacerated, transected, or dislodged from the trachea. Pilot tubes for endotracheal tube cuffs are easily cut. A plan should be formulated ahead of time between the surgeon and anesthesiologist for how an endotracheal tube will be replaced should this become necessary. Usually, the surgical field is quickly covered with sterile drapes, and the anesthesiologist is allowed access to the airway. Replacement tubes, catheter guides, and other appropriate equipment for reintubation must be readily available.

When the tracheal tube is in the surgical field, care must be taken to ensure an adequate airway despite lack of access to the face. The anesthesia circuit should be lightweight and all connectors should be well secured. The head of the operating table may be turned 180° from the anesthesia machine. Consequently the airway circuit must have adequate length to allow this. If the surgeon will move the head during the procedure, it must be determined that the endotracheal tube and circuit are unencumbered. Care must be taken when initially positioning the endotracheal tube to avoid either tracheal extubation when the neck is extended or when the maxilla is advanced or endobronchial intubation when the neck is flexed. The maxilla or mandible can be advanced by as much as 3cm. The tracheal tube should be secured with wires or sutures tied around teeth, nasal septum, mandible, or alveolar ridge. Nasotracheal intubation is required when the procedure is intraoral or when intermaxillary fixation is required. Armor tubes prevent compression of the airway by surgical manipulation. Close communication between surgeon and anesthesiologist is required prior to tracheal intubation to determine the best position for the tracheal tube. Care must be taken to prevent nasal necrosis when a nasotracheal tube will be in place for hours. The hypopharynx should be packed to prevent intraoperative aspiration of blood, bone chips, and tissue. At the end of the procedure, the nose, mouth, and pharynx should be cleared and the stomach aspirated of gas, blood, and other material.

Postoperative swelling of the face and scalp may be severe. The swelling after bilateral midface and mandibular osteotomies may dictate that the tracheal tube remain in place for 12–48h. This is especially true when intermaxillary fixation and occlusive intraoral prostheses limit access to the airway. Persistent oropharyngeal bleeding, cerebral edema, or pulmonary disease may also delay tracheal extubation. Tracheal extubation should occur when the patient is fully awake, has intact airway reflexes and an empty stomach, and is able to follow commands. Provisions should be made for immediately re-establishing an artificial airway (including wire cutters to release intermaxillary fixation wires) should this become necessary.

#### Other anesthetic considerations

Anesthetic drugs should be chosen on the basis of the preceding considerations. Depth of anesthesia can be balanced with muscle relaxation to prevent coughing, bucking, or patient movement with erratic surgical stimuli. Preferably, the patient should be awake and comfortable at the end of the procedure so that neurological assessment can be made. This can be accomplished by using a potent narcotic or "balanced" technique or by titrating narcotic when the patient is emerging from anesthesia. Extracranial bone graft sites (rib or iliac crest) may cause more postoperative pain than the cranial sites.

Fluids should provide maintenance requirements, replace interstitial and evaporative losses, and maintain urine output above 0.5 mL/kg/h. The exact amount of fluid required to accomplish these goals will depend on the extent of tissue dissection and exposure. For small infants, electrolyte solutions, like Ringer-acetate with 1% of glucose, provides optimal maintenance of fluids and blood glucose concentrations. A urinary bladder catheter should be placed to prevent bladder distension and for intravascular volume monitoring. Serial blood analyses of arterial pH and blood gases, hemoglobin, electrolytes, ionized calcium, glucose, and coagulation parameters are made.

A high level of physiological monitoring is required. Routine anesthesia monitors, such as ECG, pulse oximeter, temperature, and airway gas and pressure monitors, are used. In addition, an intra-arterial catheter is placed to allow direct blood pressure monitoring and blood sampling. Central venous oxygen saturation can be used to estimate cardiac output in children. A central venous oxygen saturation of <50-60% should prompt detailed evaluation of the patients circulatory condition. Arterial blood pressure and waveform are good indicators of intravascular volume. A broad-based pressure wave, with the dichrotic notch in the upper half of the downslope of the curve and little or no variation with respiration, is a good indicator of normovolemia. A central venous catheter is useful for monitoring intravascular volume and for rapidly infusing drugs and fluids. During intracranial procedures, evidence of venous air embolism should be sought with a capnograph and a precordial Doppler because the open cranium is generally above the central circulation. A central venous catheter may occasionally allow aspiration of entrained air, although early detection and prevention of further entrainment are more important than trying to aspirate the gas.

## Perioperative hazards and complications

Although large series of major craniofacial surgery attest to its relative safety, significant morbidity and mortality can occur [145]. Intraoperative death has occurred with massive blood loss and air embolism. Postoperative death has resulted from cerebral, respiratory, and circulatory causes (e.g. cerebral edema, massive extradural hemorrhage, respiratory arrest, respiratory obstruction or tracheal extubation, tracheostomy blockage, and hemorrhage) [146–148]. A recent study analyzed 8101 major craniofacial procedures and determined the mortality rates and major morbiditiy. The authors found that serious complications have significantly decreased and suggested that protocols for airway management, blood salvage and replacement, age-appropriate deep venous prophylaxis, and timing of subcranial midfacial advancements might further reduce the mortality rate [149].

Other reported intraoperative complications include cardiac arrest from severe blood loss, air embolism, and pneumoperitoneum (a complication of tracheostomy), pneumothorax during rib graft procurement, subdural hematoma, and bradycardia from the oculocardiac reflex [150–152]. Stimulation of any sensory branch of the 5th cranial nerve (maxillary, mandibular, ophthalmic) can cause reflex bradycardia and asystole. Reflex bradycardia and asystole have also been noted during maxillofacial and temporomandibular surgery [152]. Ocular pressure should be avoided because it too can cause severe bradycardia.

Several complications related to the endotracheal tube have been reported, including intraoperative tracheal extubation (usually during midface advancement), endotracheal tube blockage by kinking (also during midface advancement), and endotracheal tube laceration [118]. Pilot tubes for cuffed endotracheal tubes have also been lacerated. There are several reports of emergency endotracheal tube replacement intraoperatively. Complications of tracheostomy have included tube kinking, laceration of the posterior tracheal wall, esophageal perforation, and cardiac arrest from pneumoperitoneum [118,153,154]. Subgaleal or epidural drains require special care, especially when placed next to venous sinuses. The vacuum used for drains is related to the size of the used subgaleal or epidural drains. Rapid opening of the suction can cause significant blood loss. Non-fatal postoperative complications have included respiratory obstruction after tracheal extubation, pulmonary edema, cerebral edema, extradural hematoma, subgaleal hemorrhage, seizures, infection, blindness, CSF leaks, facial nerve damage, bone resorption, and hydrocephalus [155].

#### Anesthesia for cleft lip and cleft palate reconstruction

#### **Preoperative evaluation**

The anesthesiologist's approach to patients with a cleft lip and palate is similar to that described in the preceding section for patients with other craniofacial deformities. In this case, however, the surgical procedure is less extensive. By the time the infant with cleft lip comes for surgery at 3 months of age, the parents have usually overcome their initial reactions to their malformed infant and are hopeful that surgery will restore normal appearance and function. Preoperative preparation must accommodate the older child with a cleft palate who may have communication problems due to poor speech and hearing. Many children require multiple procedures. Every effort should be expended to ensure that the anesthetic experience is not unpleasant for either the parent or child.

A complete medical evaluation should be made, with special attention to the presence of other anomalies and syndromes. All patients with a cleft palate have eustachian tube dysfunction and usually have chronic serous otitis with clear rhinorrhea. Acute otic infections should be resolved before surgery. Preoperative sedation is appropriate for children who have no airway compromise.

#### Intraoperative management of anesthesia

#### Induction

Most patients with an isolated cleft lip or palate present no difficulty with airway management. Only 3% of 800 patients undergoing repair of cleft lip and palate had difficult laryngoscopy [156]. Those with a difficult airway had retrognathia and/or were less than 6 months of age [157]. The protruding premaxilla associated with extensive bilateral clefts of the lip and alveolus sometimes prevents visualization of the laryx. While the incidence of failed intubation is low [154], it does occur. Therefore, it may be wise to induce anesthesia while the patient is spontaneously breathing. It is useful to have a second anesthesiologist to help with the airway management. The ability to manage the airway should be assessed before the patient is rendered apneic. Airway obstruction may occur if the tongue is impacted in a palatal cleft. This is easily remedied when recognized. Care must be taken to avoid injuring a protruding premaxilla during laryngoscopy. Antisialagog drugs are useful for oral procedures. Inserting a preformed, curved tracheal tube (RAE tube) that lies flat against the face minimizes the potential for tube kinking and dislodgment. A stylet can be used to facilitate tracheal tube insertion when necessary. The tube should be fixed in the midline, with the lip immobile and not distorted (Fig. 32.29).

**Figure 32.29** "Kilner Dott" mouth gag in place for cleft palate repair in a patient with Pierre Robin sequence (bifid uvula). The metal armored tube is safely secured under the lower part of the mouth gag.

#### Maintenance

There are several intraoperative special anesthetic considerations for cleft lip and palate reconstruction procedures. The first is that the airway is shared with the surgeon. Thus, the tracheal tube must be well secured to prevent inadvertent dislodgment. Adequacy of the airway should be continuously assessed, especially after patient positioning and placement of a mouth gag or pharyngeal packs. For palate and pharyngeal procedures, correct positioning may require exaggerated neck extension, which may bring the endotracheal tube up and out of the trachea. A mouth gag provides surgical exposure and stabilizes the ET tube, but it may also occlude the tracheal tube (see Fig. 32.29). Pharyngeal packs are placed to prevent aspiration of blood. Compression or kinking of the ET tube may occur with these maneuvers.

Other anesthesia considerations are routine. Fluid and temperature homeostasis must be maintained. Blood loss is rarely sufficient to require transfusion, although it is occasionally necessary in palate and pharyngeal procedures. Inhalation anesthesia is commonly used, but the choice of anesthetic agent is not crucial as long as the considerations outlined here are accommodated.

#### **Postoperative management**

The most common acute postoperative problems are bleeding and airway obstruction. At the conclusion of palate and pharyngeal surgery, the pharynx must be inspected for bleeding and the presence of pharyngeal packs. Leaving a pharyngeal pack in place can be lethal when the endotracheal tube is removed. Placing the infant or child in the lateral position permits drainage of blood and secretions from the pharynx. Extubation of the trachea should be delayed until the patient is fully awake and has regained normal neuromuscular function to minimize potential airway obstruction from either anatomical causes or from bleeding. Applying a mask or artificial airways may damage a lip or nose repair, so it is advisable to delay extubation until the patient can maintain a patent airway without assistance. After lip procedures, infants are restrained with arm boards to prevent them from disrupting the repair.

After a palatoplasty or pharyngoplasty, the infant or child awakens from anesthesia with an altered upper airway. The presence of constricting flaps and nasopharyngeal edema compromises the nasal airway and may abruptly convert the child to a mouth-breather. This problem is magnified in patients who have Pierre Robin complex. After pharyngoplasty, 10% or more of patients experience temporary obstructive sleep apnea [157]. Sleep apnea is completely eliminated when the surgical technique is modified and a nasopharyngeal airway is kept in place for the first 48 h after surgery. Fifty-seven percent of patients are predominantly or exclusively mouthbreathers after palatoplasty or pharyngoplasty [158]. Up to 72% of patients develop sleep apnea after pharyngoplasty. Pharyngeal anomalies are common with craniofacial syndromes and place the patients at high risk for airway obstruction, especially after pharyngoplasty [158]. The anomalies may be structural (pharyngeal narrowing related to malformation of the basicranium (Treacher Collins syndrome)) or mandibular (Robin sequence). They may also be functional, e.g. the pharyngeal hypotonia of the velocardiofacial syndrome. One patient died 4 weeks after surgery [159].

Acute postoperative airway obstruction caused by massive lingual swelling has also been reported after palatoplasty. The mouth and tongue should be carefully inspected before tracheal extubation, particularly if the mouth gag has been in place for more than 2h. If the mouth gag must be up for 2h, it should be let down for a few minutes to allow the tongue to be perfused. The lingual swelling is often the result of a reperfusion injury.

Infiltration of local anesthetic will decrease the need for postoperative analgesia. Non-narcotic analgesics are preferred, but when narcotics are required, they should be titrated to effect. Infraorbital nerve blocks can be performed while the patient is asleep to prevent pain after cleft lip surgery [160,161]. Postoperative pain therapy can be guided by using pain scales [162–164].

#### CASE STUDY

#### Introduction

A 4-year-old, 11.5kg, 85-cm-tall, boy was scheduled for repeat craniofacial surgery to treat his dysostosis craniofascialis (Crouzon-Syndrome). Crouzon syndrome is characterized by premature closure of calvarial, cranial base, orbit and maxillary complex (craniosynostosis) sutures. His medical history included mild mental and linguistic development retardation. The child had a small mouth, a hypoplastic maxilla, and relative mandibular prognathism. Consequently, it was suspected that pulmonary ventilation and tracheal intubation might be difficult, although during previous surgery he could be ventilated with a bag-andfacemask and it was possible to insert a laryngeal mask airway (LMA). A recent routine diagnostic ophthalmologic consultation showed evidence of residual chronic, subacute elevated intracranial pressure in the fundus of his eyes, papilledema, and beginning optic atrophy.

A sleep study was postponed until after surgery. Routine preoperative laboratory test were within normal limits (Table 32.4).

## Considerations for anesthesia Blood and blood products

Because it was suspected that a large amount of blood might be lost during surgery, packed red blood cells (PRBC) and fresh frozen plasma (FFP) were available for the patient preoperatively. Use of an antifibrinolytic agent, e.g. Tranexamic acid (TXA), (initial dose 10 mg/kg BW by bolus followed by 3 mg/kg/h) was considered but rejected because of the patient's history of seizures. The anesthesiologist and surgeons decided to administer blood and blood components (FFP) early in the case to prevent abnormally low hemoglobin concentrations (Hb) and maintain normal oxygen carrying capacity in this child who had increased intracranial pressures. It was felt this also would prevent hypovolemia, hypoperfusion, and dangerous levels of lactic acidosis. The decision to administer blood products at the start of surgery was based on the expected level of blood loss and on the retrospective history of blood loss and the need for transfusion of similar patients at our institution.

#### Induction and maintenance of anesthesia

Anesthesia was induced with propofol (2.5 mg/kg) and remifentanil ( $1\mu\text{g}/\text{kg}$ ) with oxygen. The lungs were ventilated to maintain a normal PaCO<sub>2</sub>. Fiberoptic tracheal intubation was facilitated by administering rocuronium (1 mg/kg). No further muscle relaxation was needed during the case. Salivation was prevented by slowly administering atropine sulfate (0.5 mg) 30min before the induction of anesthesia. A nasogastric tube and a urinary catheter and *Continued*  temperature probe were placed into the urinary bladder after induction of anesthesia. Sevoflurane and remifentanil  $(5-20\,\mu g/kg/h)$  were used to maintain anesthesia. Sufficient oxygen was administered to maintain a normal SaO<sub>2</sub>. Thirty minutes before the end of anesthesia, a longer acting opioid and a nonsteroidal anti-inflammatory agent (NSAID) was administered.

#### Cardiovascular monitoring

A double lumen 5 French central venous catheter was inserted in to the right subclavian vein. The left radial artery was cannulated with a 24-gauge catheter for on-line arterial blood pressure monitoring and blood sampling. Monitoring in the perioperative period consisted of continuous measurement of arterial and central venous pressures, temperature (via the urinary catheter), oxygen saturation by pulse oximetry, end-expired CO<sub>2</sub>, and urine output. Blood gases, pH, electrolytes, and glucose and lactate concentrations were measured every 1h or more frequently, as required. Central venous oxygen saturation was determined from central venous blood samples and used to estimate cardiac output and blood volume status.

#### Airway management

Preoperatively it was suspected that oral tracheal intubation might be difficult because of the patient's hypoplastic maxilla and prognathic mandible. His mouth opening was also limited. Consequently, equipment for fiberoptic tracheal intubation was available in the operating room before anesthesia was induced. Because it was known from his previous surgeries that bag-and-mask ventilation was possible and that a laryngeal mask could be inserted and used to ventilate the lungs, general anesthesia was induced before attempting fiberoptic tracheal intubation. If this information had not been available, we would have considered doing fiberoptic tracheal intubation with the patient sedated but with spontaneous ventilation. Because the patient would be in the prone position and it would be necessary to recline the neck during surgery, an armored oral tracheal tube was inserted. Care was taken to fix the tracheal tube securely with wires to the teeth to avoid accidental tracheal extubation during surgery. Because surgery would last several hours, great care was taken to prevent compression of soft facial tissues (eyes, nose) when the patient was placed in the prone position (see Fig. 32.27).

#### Body temperature

Care was taken to prevent intra-operative hypothermia for several reasons. First, to prevent inhibition of the coagulation system; second, to prevent hypoperfusion and local ischemia (e.g. metabolic acidosis and lactate production); and third to prevent hypoventilation and respiratory acidosis once spontaneous ventilation returned and the trachea was extubated. Prevention of hypothermia would also avoid the negative effects of shivering and cardiovascular depression after surgery.

#### Intraoperative management

After induction of anesthesia and insertion of the tracheal tube, the surgeons and anesthesiologists together, positioned the patient for surgery. Maintenance fluid consisted of Ringer's solution with 1% dextrose added (4mL/kg/h) to maintain a normal glucose concentration. Volume losses were initially replaced with 4mL/kg/h of Ringer's solution without dextrose as needed. During reflection of the scalp, which was difficult because of adhesions that formed after the earlier surgery, packed red blood cells and fresh frozen plasma (5 mL/kg each) were administered. Once the scalp and bone were reflected and surgical coagulation was accomplished, PRCBs and FFP were given as needed to maintain a normal hemoglobin concentration and prevent bleeding. Despite prophylactic administration of PRBCs, Hb/Hct concentrations decreased below initial values (Table 32.4). The estimated blood loss during surgery was 340 mL, about 40% of his blood volume. These losses were initially replaced with Ringer's solution and then with PRBCs and FFP. Heat loss was prevented by wrapping the patient's extremities with sheet wadding and by actively warming him with a thermal blanket and warmedhumidified inspired gases. Despite this he initially lost about 1°C in body temperature. Anesthesia was maintained with a combination of sevoflurane and remifentanil, as described above. Because the intraoperative period was uneventful and because spontaneous ventilation returned and was adequate, the trachea was extubated in the operating room once the child was awake. He was transferred to the PICU to monitor for bleeding and for signs of elevated intracranial pressure. Postoperative blood loss was 75 mL, which was replaced with PRBCs. Tracheal extubation occurred at the end of surgery because it was felt that it would be easier to monitor for signs of increased intracranial pressure if the patient was awake and spontaneously breathing. Postoperative fluid administration was restricted to that which maintained about 1 mL of urine output/kg/ hr. This (fluid restriction) was done to reduce the likelihood of increasing intracranial pressure and of causing pulmonary edema. The day after surgery all monitoring lines were removed, and the patient was transferred to the ward in good condition. He was discharged home several days later and has done well.

#### Conclusions

This case demonstrates several important points.

 Patients with Crouzon abnormalities often have some degree of increased intracranial pressure, which this child had (papilledema and beginning optic atrophy). Because of the intracranial hypertension, the arterial blood pressure and  $ETCO_2$  were maintained within normal preoperative limits to prevent unwanted increases in intracranial pressure and reduced cerebral blood flow.

- The oxygen content of the blood needs to be maintained throughout surgery. Blood loss is common in these cases, especially when there has been previous surgery. This child lost 340 mL of blood during the case despite an infusion of PRBCs and plasma at the beginning of the case and attempts to maintain normal clotting. Adequate fluid and blood products were administered to maintain normal arterial and central blood pressures and to prevent metabolic acidosis.
- It is important to take measures to maintain a normal body temperature during surgery, especially when one wants to extubate the trachea at the end of the surgery. Hypothermia may cause hypoventilation, increased PaCO<sub>2</sub>, and increased intracranial pressure. If the case lasts long enough, hypothermia may cause clotting abnormalities and increase intraoperative bleeding. Maintaining a normal body temperature must be bal-

anced against the fact that a  $1-2^{0}$  reduction in brain temperature is neuroprotective (see Chapter 7).

- Many children with Crouzon abnormalities have a difficult airway. This child had a small mouth, a hypoplastic maxilla, and prognathism, all of which can be associated with a difficult airway. At times the facemask does not fit the face due to the mid-face hypoplasis. As a result it is difficult to ventilate the lungs with a bagand-facemask. If the mid-face hypoplasia occludes the nostrils, closing the mouth during attempted bag-andmask ventilation may completely obstruct the airway. If this occurs, an oral airway should be inserted to keep the mouth and airway open. Knowing that the lungs could be ventilated with a bag-and-mask during previous surgeries was very helpful in this case.
- Measuring intravascular pressures and urine output during surgery helped determine the adequacy of fluid and blood products replacement. Urine glucose concentrations were measured several times during the case because high concentrations of glucose in the blood may cause an osmotic diuresis that gives the false impression of normal urine flow, even in hypovolemic patients.

### Introduction

The management of pain and related symptoms is part of the daily practice of pediatrics, pediatric anesthesiology, and pediatric intensive care. In this chapter, we will outline some aspects of how the experience of pain changes with age, how analgesics act at different ages, and how to treat some common acute and chronic pain conditions in pediatrics.

## Developmental neurophysiology of pain

Studies by Fitzgerald and others have shown that there is considerable maturation of peripheral, spinal, and supraspinal neurological pathways necessary for nociception by late in the second trimester of human gestation [1]. Although the general architecture of the sensory nervous system is established by midgestation, there are some differences in preterm and term neonates compared to older infants as patterns of connections and functions mature over the first months of life. Peripheral sensory fibers involved in nociception have larger, more overlapping, receptive fields and lower thresholds for impulse activation in infant animals, compared to mature animals [2]. Descending pain inhibitory pathways, such as the dorsolateral funiculus [3], tend to develop postnatally. This has been interpreted as suggesting that neonates and young infants may perceive pain more intensely or have hyper-responsiveness to pain compared to older infants and children with a more mature nervous system.

Many of these initial studies emphasized maturation of peripheral and spinal mechanisms and simple withdrawal reflexes. More recently, attention has focused on cortical representation of responses to injury in neonates and young infants [4]. Studies of brain activation using near-infrared spectroscopy have shown that a noxious stimulus to the heel of a neonate evokes increased signals overlying the contralateral cerebral cortex [4]. This implies that a specific pattern of activation occurs in response to a noxious stimulus as opposed to the global, non-specific pattern of activation seen with autonomic arousal. This and other evidence suggests that painful stimuli reach the cerebral cortex in infants although this evidence does not establish that pain is perceived as a conscious experience or as suffering in neonates. Despite the delay in the development of spinal descending pathways and neurotransmitters,  $\alpha$ -adrenergic agonists and opioids administered via epidural or spinal routes exert analgesic effects in newborn animals [5,6] and humans [7,8].

Several studies have been interpreted as providing evidence that infants are able to form implicit memory of pain and that there are potentially negative behavioral consequences of untreated pain in infants. Taddio showed that infants who were circumcised with little or no analgesia had significantly increased pain behaviors at their 2-, 4-, and 6-month immunizations when compared to infants who were uncircumcised or who had received adequate analgesia [9]. Studies of adult rats who had received persistent inflammatory stimuli as neonates showed longterm changes in the dorsal horn synaptic organization and nociceptive functioning [10]. When newborns undergoing major surgeries were randomized to relatively light versus relatively deep anesthetic techniques they showed better suppression of stress responses with deeper anesthetic techniques, as well as some reductions in postoperative morbidities [11-14]. Conversely, studies of critically ill newborns undergoing mechanical ventilation have not shown a clear benefit from routine administration of morphine infusions, compared to controls who just received intermittent morphine prior to suctioning or other painful procedures [15].

#### Pain assessment in infants and children

Assessing pain in infants and children is a fundamental aspect of pediatric care and serves as the foundation for treating pain. Most pain assessment tools for infants, toddlers, and preschool children are based on the developmental age of the child and often combine behavioral and physiological parameters, since self-report measures may not be possible in preverbal children or accurate in hospitalized young children. Readers interested in this topic are referred to a consensus statement on pediatric pain measurement [16]. Studies indicate that healthcare providers tend to underestimate pain using observational measures compared to parents' or children's own ratings. Children who are ill, hospitalized and confronted with strangers may not co-operate with self-report measures; pain assessment tools designed for younger children may be more useful in these cases.

Pain assessment in infants and preterm babies is particularly challenging. Infants rely on caregivers to interpret their behavior and other signs in determining whether they have pain. Numerous studies have examined pain responses in infants and have shown that infants exhibit predictable response patterns with respect to stress hormone levels, behavior patterns, and changes in heart rate, oxygen saturation, blood pressure, and other physiological patterns. Neonates who are subjected to repeated heel lancing for blood analyses consistently swipe at the affected foot, indicating their ability to localize to the site of pain. Infants display gradations in heart rate, blood pressure, and oxygen saturation in response to varying intensities of pain, indicating their ability to discriminate severity of pain. Nevertheless, physiological parameters are non-specific indicators of pain and can reflect fear, hunger, anxiety and emotional distress as well as pain [17].

As a result of these studies and others, pain assessment tools in infants are typically composite pain scores that combine observed distress behaviors such as facial grimacing, sleep-wake cycles, and body posture with physiological parameters, including heart rate, oxygenation, and blood pressure measurements. Behavioral responses to pain in premature infants may be much more subtle than those observed in full-term infants. In addition, behavioral and physiological pain scales are not applicable in critically ill infants who may be septic, hemodynamically unstable or mechanically ventilated. The Premature Infant Pain Profile (PIPP) (Table 33.1) is a pain assessment tool for procedural pain that has been validated in premature and full-term infants [18]. The PIPP is unique in that gestational age is included in the scoring system in addition to distress behaviors, heart rate, and oxygen saturation. The Faces, Legs, Activity, Cry, Consolability (FLACC) scale combines five types of pain behaviors, including facial expression, leg movement, activity, cry, and consolability, and has been shown to have good inter-rater reliability and validity in children (Fig. 33.1) [19]. It is widely used because it is quick, versatile, and can be applied to infants and older children, including those with developmental disabilities [20].

Concrete thinking and variations in cognitive and language development in toddlers and preschool age children can make pain assessment challenging in this age group. Preschool age children are often able to give simple measures of self-report such as location of pain but cannot provide more abstract details such as quality of pain. It is generally useful to involve parents or other familiar caregivers when questioning young children about their pain.

A variety of pain assessment tools have been developed for young children. Studies indicate that many children tend to prefer faces scales where pictorial representations of faces are used to denote varying degrees of pain. Young children are able to differentiate pain intensity when presented with facial expressions although more than five choices seems to interfere with the child's ability to reliably indicate pain. The Oucher scale (Fig. 33.2), the Wong–Baker scale (Fig. 33.3), and the Bieri faces scale are examples of faces scales that have been validated for use in children as young as 4 years of age. The Oucher scale, developed for use with children of all ethnicities, uses actual photographs of children and is available in several versions, each tailored to child ethnicity. Among

Categories	Scoring				
	0	1	2		
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw		
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up		
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid or jerking		
Cry	No cry (awake or asleep)	Moans or whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints		
Consolability	Content, relaxed	Reassured by occasional touching, hugging or being talked to, distractable	Difficult to console or comfort		
Each of the five categories (F) Face; (L) Legs; (A) Activity; (C) Cry; (C) Consolability is scored from 0–2, which results in a total score between zero and ten.					

Figure 33.1 Faces, Legs, Activity, Cry, Consolability (FLACC) scale.

Table 33.1 Premature Infant Pain Profile (PIPP)

Indicators	0	1	2	3
GA in weeks	≥36 weeks	32 to 35 weeks and 6 days	28 to 31 weeks and 6 days	<28 weeks
Observe the NB for 15 sec				
Alertness	Active	Quiet	Active	Quiet
	Awake	Awake	Sleep	Sleeping
	Opened eyes	Opened eyes	Closed eyes	Closed eyes
	Facial movements present	No facial movements	Facial movements present	No facial movements
Record HR and SpO <sub>2</sub>				
Maximal HR	↑ 0 to 4 bpm	↑ 5 to 14bpm	↑ 15 to 24bpm	↑ ≥ 25 bpm
Minimal Saturation	↓ 0 to 2.4%	↓ 2.5 to 4.9%	↓ 5 to 7.4%	$\downarrow \ge 7.5\%$
Observe NB for 30 sec				
Frowned forehead	Absent	Minimal	Moderate	Maximal
Eyes squeezed	Absent	Minimal	Moderate	Maximal
Nasolabial furrow	Absent	Minimal	Moderate	Maximal

Absent is defined as 0 to 9% of the observation time; minimal, 10% to 39% of the time; moderate, 40% to 69% of the time; and maximal as 70% or more of the observation time. In this scale, scores vary from zero to 21 points. Scores equal or lower than 6 indicate absence of pain or minimal pain; scores above 12 indicate the presence of moderate to severe pain.

GA, gestational age; NB, newborn.

the different faces scales, in our view there are some psychometric advantages to the Faces Pain Scale – Revised version by Hicks et al (Fig. 33.4) [21].

Parental responses can affect a child's levels of observed behavioral distress; increased parental anxiety tends to correlate with increased levels of self-report pain scores in children undergoing painful procedures. Older schoolage children and adolescents have the emotional and cognitive maturity as well as the language development to use self-report scales. Self-report is sometimes not accurate in this age range due to issues regarding behavioral control and self-esteem. Illness, hospitalization, and separation from parents may cause some older children and adolescents to regress emotionally, making pain scales designed for younger children more applicable. The meaning that pain has for a child also can influence their
self-report. The Color Analog Pain Scale (Fig. 33.5) is a slide-rule device where gradations of color are used to denote degree of pain which has been validated for use in children as young as 5 years [22].

Figure 33.2 Oucher pain scale.

Pain assessment should be part of everyday practice in caring for hospitalized children. A successful, hospitalwide pain assessment program requires a committed, multidisciplinary team of healthcare providers, standard protocols of assessment methods and documentation, staff and parental education programs, and protocols for reassessment after pain treatment interventions. Essential to pain assessment is the use of validated, age-appropriate pain assessment tools as well as consideration of the child's developmental level, presence of fear and anxiety, parental factors, and the context of the child's pain.

# Principles of developmental analgesic pharmacology in infants and children

A number of pharmacokinetic and pharmacodynamic factors produce age-related differences in response to analgesics [23]. Neonates and young infants have immature hepatic enzyme systems involved in conjugation, glucuronidation, and sulfation of analgesics such as opioids and amide local anesthetics, causing prolongation of elimination half-life and increasing the risk of drug accumulation. Rates of maturation of individual enzyme functions vary but for most analgesics, metabolism has matured by around age 6 months. Glomerular filtration and renal tubular secretion are reduced in the first several weeks of life. Along with slower elimination of some native drugs that depend primarily on renal clearance, renal immaturity also results in slower elimination of glucuronides of morphine and hydromorphone (which produce analgesia, sedation, respiratory depression, and excitatory reactions) and slow elimination of MEGX, a principal metabolite of lidocaine, which can cause seizures.

Neonates and young infants have reduced levels of  $\alpha$ 1-acid glycoprotein and albumin, leading to decreased plasma protein binding for many drugs and increased concentrations of free, pharmacologically active, unbound drug. Infants have immature ventilatory reflexes in response to hypoxia [24,25] and hypercarbia [26]. The increased risk of hypoventilation in response to

Figure 33.3 Faces (Wong–Baker pain scale).

Figure 33.4 Faces Pain Scale Revised (FPS-R) version.

In the following instructions, say "hurt" or "pain", whichever seems right for a particular child.

"These faces show how much something can hurt. This face [point to left-most face] shows no pain. The faces show more and more pain [point to each from left to right] up to this one [point to right-most face] – it shows very much pain. Point to the face that shows how much you hurt [right now]."

Score the chosen face 0, 2, 4, 6, 8, or 10, counting left to right, so '0' = 'no pain' and '10' = 'very much pain'. Do not use words like 'happy' and 'sad'. This scale is intended to measure how children feel inside, not how their face looks.

Figure 33.5 Color Analog Pain Scale.

opioids in infants observed in clinical case series [27] probably reflects a combined effect of pharmacokinetic and pharmacodynamic immaturity, as well as the impact of disease states that are over-represented in hospitalized infants.

## **Non-opioid analgesics**

Non-opioid analgesics include acetaminophen, aspirin, the non-steroidal anti-inflammatory drugs (NSAIDs), and the selective cyclo-oxygenase 2 (COX-2) inhibitors. COX enzymes convert arachidonic acid to various prostaglandins that have diverse physiological roles, contributing to pain, hypersensitivity, inflammation, thermoregulation, vasodilation, and protection of gastric mucosal integrity. The cyclo-oxygenase iso-enzymes differ in their distribution and function in a variety of peripheral tissues and in the central nervous system. Aspirin and NSAIDs act on a broad spectrum of COX enzymes. Aspirin's irreversible inhibition of COX-1 in platelets contrasts with the reversible action of NSAIDs; this accounts for the much longer duration of aspirin's antihemostatic actions. The COX-2 inhibitors were developed to specifically inhibit the COX isoenzyme subtype 2, which is expressed preferentially in leukocytes and other cell types involved in inflammation, as well as in neurons and glial cells in the peripheral and central nervous systems. While these drugs are commonly regarded as "peripheral" analgesics, analgesia from all of these drugs involves a combination of peripheral and central actions [28].

# Ontogeny of prostanoid biosynthesis and cyclo-oxygenases

Studies by Ririe and co-workers have shown that administration of a COX-1 inhibitor does not reduce

hypersensitivity to mechanical stimuli in infant rats. This lack of efficacy of COX-1 inhibitors in infant rats appears to be a result of developmental differences in the COX-1 expression in the spinal cord [29]. These data raise the question of whether commonly used analgesics acting on COX isoforms might be ineffective in infants due to delayed maturation of COX-mediated processes in spinal microglia.

## Acetaminophen

Acetaminophen is one of the most widely used analgesics and has a good safety record for use in pediatric patients. It is often combined with opioids for additional analgesic effect. Acetaminophen is also sometimes dosed alternating with ibuprofen, although there are no clinical trials examining the effectiveness of this approach. Although the actual mechanism of analgesic and antipyretic action is somewhat controversial, acetaminophen seems to have effect at the COX-3 isoenzyme, on endogenous cannabinoid receptors, and on TRPV1 receptors [160]. CB1 and TRPV1 receptors are involved in pain and thermoregulatory pathways. Acetaminophen's analgesic actions appear to occur largely via sites within the central nervous system, though there is controversy regarding the importance of central COX-3 inhibition in acetaminophen's analgesic effects [30].

When compared to NSAIDs, acetaminophen exerts minimal peripheral anti-inflammatory effects and is associated with significantly less gastropathy, platelet dysfunction, and anti-inflammatory effect. Approximately 90% of acetaminophen undergoes sulfation and glucuronidation to water-soluble products, which are then eliminated by the kidneys. A small percentage of acetaminophen is metabolized by the CYP450 system to a toxic metabolite that binds to glutathione to form a non-toxic conjugate. Inadvertent dosing errors have led to fulminant hepatic necrosis and failure in infants and children when large doses overwhelm the binding capacity of existing hepatic glutathione stores. Therapeutic oral doses of 10-15 mg/ kg result in peak plasma concentrations at 2-3h. Rectal dosing can be used in anesthetized children or those unable to tolerate oral administration. Peak drug levels generally occur at 70 min but can vary considerably with rectal dosing due to variable absorption. Because rectal absorption is so inefficient, some studies have recommended much higher dosing than traditionally prescribed; rectal dosing with a first dose of 30-45 mg/kg followed by 20 mg/kg every 6-8h produced generally therapeutic blood concentrations in several studies [31]. Even though the overall bio-availability of rectal acetaminophen is roughly half that of oral formulations, previous American Academy of Pediatrics (AAP) recommendations have listed the same daily maximum doses for oral and rectal acetaminophen.

The analgesic efficacy of acetaminophen in newborns has not been established. It remains unclear whether these negative results reflect a true lack of efficacy due to delayed maturation of the analgesic targets of acetaminophen, inadequate sensitivity of the pain models used, insensitivity of the pain measures used or wash-out of treatment effects by the choice of an overly generous rescue analgesic regimen [32].

### Non-steroidal anti-inflammatory drugs

The NSAIDs are widely prescribed as antipyretics, analgesics, and anti-inflammatory agents in children and, considering their widespread use, have a very good safety margin. They are often combined with opioids for improved analgesic effect and to reduce opioid use and side-effects. They are often first-line therapy for inflammatory pain. They produce their anti-inflammatory effect by reversibly inhibiting COX-1 and COX-2 isoenzymes and inhibiting the conversion of arachidonic acid to prostanoids. The clearances of several NSAIDs are slower in neonates and infants but more rapid in young children aged 3-10 years when compared to adults [33]. In postsurgical patients randomly assigned to receive an NSAID or placebo, with parenteral opioids as rescue analgesics, the NSAID groups typically show both lower pain scores and a 30-40% reduction in opioid use. Other studies have shown that standard doses of NSAIDs produce more effective analgesia than 30-60 mg of codeine in adults following surgery [34].

The incidence of serious side-effects from NSAIDs is very low in children 6 months and older, particularly with short-term use. A large-scale study in young children less than the age of 2 years receiving ibuprofen showed a very low incidence of serious side-effects [35]. There are few efficacy data on the use of NSAIDs in neonates. Much of the pharmacokinetic and safety data for use in neonates come from the use of ibuprofen and indometacin in treating patent ductus arteriosus; ibuprofen appears to have less renal toxicity and less risk of hyponatremia than indometacin in this age group. Much of the safety data for long-term use of NSAIDS are based on experience in treating juvenile rheumatoid arthritis [36]. Although children frequently complain of mild gastrointestinal upset with long-term NSAID use, serious gastropathy, gastrointestinal bleeding, and renal toxicity appear to be less common in children than adults. The risk of NSAIDinduced renal toxicity can be increased in states of dehydration, with concomitant use of other nephrotoxic drugs, use in pre-existing renal disease, and hypotension.

The use of NSAIDs in children undergoing tonsillectomy remains controversial. NSAIDs are an attractive choice in patients with obstructive sleep apnea who are at risk for airway obstruction and hypoventilation with opioids after a tonsillectomy. Moreover, in a large number of analgesic trials for tonsillectomy, NSAIDs do provide good analgesia. However, since life-threatening immediate and delayed postsurgical bleeding can occur after a tonsillectomy, there has been concern that use of NSAIDs in this setting will increase the risk of bleeding via inhibition of platelet aggregation and prolongation of bleeding time. Various studies in patients having tonsillectomies have shown that NSAIDs provide good analgesia and a reduction in nausea and vomiting after tonsillectomy. Three meta-analyses which examined the use of NSAIDs in children having tonsillectomies produced conflicting results [37-39]. One meta-analysis found that the use of NSAIDs did not result in increased perioperative bleeding and did reduce the incidence of nausea and vomiting compared to other analgesics. Another meta-analysis found a threefold increase in the incidence of serious bleeding with NSAID use. Because of conflicting results among clinical trials and meta-analyses, the practice at our institution is to avoid the use of NSAIDs perioperatively in patients undergoing tonsillectomy, although there are many other centers that consider this practice safe and effective. COX-2 inhibitors for tonsillectomy are reviewed in a subsequent section.

Another controversy surrounding the use of NSAIDs is the concern about bone healing in postsurgical patients who require active bone formation, such as children with scoliosis who have undergone posterior spinal fusion and instrumentation. NSAIDs and COX-2 inhibitors clearly do provide good analgesia and reduced opioid requirements for several types of orthopedic surgery [40]. NSAIDs are thought to interfere with bone healing, since prostanoids produced by osteoblasts are associated with new bone formation and are involved in the balance between bone formation and bone resorption. Recent meta-analyses of case-control and cohort studies have suggested that the effects of short-term use of NSAIDs in most patient groups are clinically minor [39]. Reviews of heterotopic bone formation in adult patients after hip replacement have suggested a higher frequency of nonunion; however, patient groups were small and other risks for non-union may have been present. A metaanalysis of the effects of NSAIDs in adult patients with spinal fusions showed that short-term use of normal-dose NSAIDs appeared to be safe after spine fusion but highdose ketorolac increased the risk of non-union, implying that the risk may be partly dose dependent [40]. In general, children seem much less likely than adults to have impaired bone healing after surgery.

Our recommendation is to adopt a middle course pending more specific data on clinical outcomes and risks. For children at high risk for non-union or impaired bony fusion, NSAIDs probably should be avoided. Conversely, for children who are at comparatively low risk of non-union, who have had severe and difficult-tocontrol side-effects from opioids or who have significantly increased risks from opioids, an NSAID or COX-2 inhibitor is administered for 1–2 days postoperatively. Some studies suggest that selective COX-2 inhibitors are less likely to inhibit bone formation than traditional NSAIDs.

Ketorolac is a commonly prescribed parenteral NSAID often used as an adjuvant to opioids in the postoperative period. Despite the common belief regarding the "magic" of a parenteral route, ketorolac provides no stronger analgesia than other NSAIDs when given in recommended or equitoxic doses. Typical doses are 0.25 mg/kg every 6h for a maximum of approximately 5 days. The recommended duration of 5 days is based on the pivotal adult studies used to obtain FDA approval for postoperative use and because of an impression that more prolonged use further increases the risks of adverse events, especially gastropathy. In a randomized controlled trial of infants and children undergoing cardiac surgery, ketorolac did not increase the risk of surgical bleeding or gastrointestinal bleeding [41]. Small case series have not reported harm with use after surgeries in neonates and young infants [42,43], though larger prospective studies are needed to better define the risks of NSAIDs in those age groups.

Prostanoids produced by COX-1 isoenzymes are associated with protection of gastric muscosa and platelet aggregation. Randomized controlled trials in adult patients show that COX-2 inhibitors provide the antiinflammatory effects of traditional NSAIDs but with lower incidence of gastrointestinal symptoms and bleeding. Anti-inflammatory effects, analgesic efficacy, and incidence of renal toxicity with COX-2 inhibitors are comparable to other NSAIDs. NSAIDs and COX-2 inhibitors both alter the balance of pro- and antithrombotic products of arachidonic acid. For adults with risk factors for coronary artery disease, peripheral vascular disease, and carotid artery disease, COX-2 inhibitors appear to increase risks of cardiovascular events. Rofecoxib and valdecoxib were withdrawn from the market due to reports of cardiovascular complications in adult patients; celecoxib and meloxicam remain available in the US but with warnings regarding these potential risks.

With a few exceptions (e.g. children with genetically based hypercoagulability, children with Moya Moya disease), there is little basis to anticipate significant cardiovascular risks from COX-2 inhibitors in children [36]. We consider them to have a potentially favorable risk/benefit ratio for selected children with inflammatory pain who have severe gastrointestinal side-effects with traditional NSAIDs or those with underlying bleeding disorders, such as children with hemophilia. Certain modified non-acetylating salicylates with relatively mild gastric effects, including salsalate, diflunisal or

choline-magnesium salicylate, may also be considered in children who have gastrointestinal side-effects with NSAIDs. Since COX-2 inhibitors have minimal antiplatelet/antihemostatic effects, they should in principle be ideal analgesics for children undergoing tonsillectomy. Available data on the efficacy of COX-2 inhibitors are mixed; some trials found COX-2 inhibitors equal to NSAID comparators and better than placebo [44] while other trials found COX-2 inhibitors either inferior to an NSAID or not distinguishable from placebo [45,46]. Overall numbers of subjects in these trials were small, and there is the potential for failing to identify analgesic effects due to type II error, or for washing out of treatment effects by scheduled use of other analgesics. We could not identify a meta-analysis to assign a confidence interval for their odds ratio for post-tonsillectomy bleeding.

Table 33.2 shows dosing guidelines for commonly used non-opioid analgesics.

## **Opioids**

Opioids are widely used for the treatment of moderateto-severe pain in infants and children. Safe and effective administration of opioids requires careful patient selection, knowledge of age-related differences in metabolism, dose titration, and aggressive treatment of opioid sideeffects. Historically, pediatric patients, particularly infants and young children, received inadequate doses of opioids, partly because of a lack of understanding of how opioids are metabolized and limitations in the ability to assess pain in children. A greater understanding of the pharmacokinetics of opioids, developmental neuroanatomy, and validated pain scores has led to more appropriate dosing and the widespread use of opioids for pain management in infants and children.

## Table 33.2 Dosing guidelines for non-opioid analgesics

	Dose <60 kg	Dose >60 kg
Acetaminophen	10–15 mg/kg q 4h PO	650 mg q 4 h PO
Naproxen	5mg/kg q 12h PO	250–500 mg q 12 h PO
Ibuprofen	6–10mg/kg q 6–8h PO	400–600 q 6h PO
Celecoxib	2–4 mg/kg q 12 h PO	100–200 mg q 12 h PO
Ketorolac	0.5 mg/kg q 6–8 h IV, not for >5 d	30 mg q 6–8 h IV, not for >5 d

Dosing guidelines listed herein refer to children >1 year of age. Further modifications in dosing are required for use of these agents in term and preterm neonates in infants. Modifications are detailed in the text. PO, orally; q; every.

#### **Ontogeny of opioid actions**

Opioid receptors are present by midgestation in a widespread distribution in forebrain, brainstem, and spinal cord. Functional maturation occurs gradually in prenatal and postnatal life. For example, while the infant rat (postnatal day 5) has an extensive complement of opioid receptors in brainstem and forebrain distributions, coupling to Gi/o proteins, as assayed by the ratio of GTP binding to DAMGO binding in brain striosomal preparations, is less than 5% of that seen in adult rat brain preparations [47].

There is an extensive series of animal studies of the effects of acute or chronic opioid administration on subsequent development. For example, chronic opioid exposure in prenatal and early postnatal life in the rat can lead to reductions in brain size, neuronal packing density, and dendritic development, with corresponding functional impairments in learning and locomotion [48]. Chronic opioid exposure in infant rats produces tolerance, withdrawal syndromes, and opioid-induced hyperalgesia [49].

The effects of opioids, ketamine, and other drugs on the developing animal are also modified by the presence of pain, injury, and/or inflammation. In some models, there are apparent long-term benefits of administering opioids prior to injury or inflammation [50]. Thus, extrapolations from animal studies regarding either benefit or harm of analgesics for newborns undergoing intensive care should be very cautious, in part because most animal models do not fully simulate all the types of perturbations seen with prolonged intensive care in humans.

Newborns undergoing intensive care are subjected to a large number of noxious procedures and mechanical ventilation, which per se produces stress and distress. Several studies have examined analgesia, side-effects and potential long-term consequences of opioids for ventilated newborns, given either on schedule or around specific noxious procedures. In the NEOPAIN trial, infants receiving chronic morphine infusions did not show more longterm neurological impairments compared to controls, but there was essentially no evidence of benefit on distress measures, and increased open-label episodic morphine administration for distress was associated with worse outcomes [51]. Moreover, morphine has only mild effect on behavioral indices of distress during painful procedures in preterm neonates [52]. At present, there is very little consensus regarding either benefit or harm from opioids or sedatives in critically ill neonates. A recent summary of these issues can be found in Durrmeyer et al [53]. A review by Anand and co-workers of opioid tolerance and dependence in neonatal and pediatric intensive care was recently published [54].

The specific choice of opioids depends on numerous factors including the ability to tolerate oral intake and gut absorption, side-effects, severity of pain, and whether pain is escalating. Oral routes are preferred for mild-tomoderate pain in children who are able to tolerate oral intake and who have adequate gastrointestinal absorption. Intravenous (IV) routes should be used for children who have severe pain that needs to be rapidly controlled, for rapidly escalating pain, and for those who cannot tolerate oral opioids.

Codeine is considered a weak opioid and is often combined with acetaminophen to improve analgesia. It is also used as an antitussive agent. Compared to other opioids, codeine seems to be associated with a higher risk of nausea. Analgesic effect is through the hepatic metabolism of codeine to morphine by CYP2D6 although there is significant variability in both the pharmacokinetics and pharmacodynamics of codeine. In a British cohort of children coming for surgery, 47% had reduced CYP2D6 enzyme concentrations and 36% had no detectable levels of morphine or metabolites after a parenteral dose of 1.5 mg/kg of codeine [55]. In children who lack or have significantly reduced enzyme levels, codeine is essentially inactive and provides no analgesia. Conversely, for patients with CYP2D6 gene duplication or with an ultrarapid metabolizing allele, codeine may cause respiratory depression or death [56]. It is for these reasons that we discourage the use of codeine.

Oxycodone is an oral opioid frequently used for children with mild-to-moderate pain and is often used in the postoperative setting of converting from parenteral to enteral opioids. While historically oxycodone was used for moderate pain in relatively fixed doses, studies in adults showed that the dose of oxycodone, like morphine, can be escalated for moderate-to-severe pain. Oxycodone undergoes hepatic metabolism to oxymorphone, an active metabolite that is renally eliminated. A pharmacokinetic study of oxycodone in infants showed great variability in both clearance and in the elimination half-life, especially in neonates [57]. Oxycodone is available as an elixir for children unable to swallow pills and as a controlledrelease preparation for a small subset of older children with severe or prolonged postoperative pain, e.g. for pain due to cancer or other serious illnesses. Dosing for immediate release is 0.1–0.2 mg/kg/dose every 4h as needed.

Morphine is generally considered the first-line opioid for parenteral use. Metabolism occurs in the liver, primarily through glucuronidation to morphine-3-glucuronide, which has neuroexcitatory actions, and morphine-6glucuronide, which has analgesic, sedative, and respiratory depressant actions. Both glucuronides are renally eliminated and can accumulate in patients with renal failure, which accounts for the prolonged response and increased side-effects seen in patients with renal failure. Accumulation of morphine-3-glucuronide can contribute to delirium, myoclonus, agitation, and seizures. There is some evidence that morphine is preferentially metabolized in neonates to morphine-3-glucuronide and has an increased risk of seizures in this age group [58]. The elimination half-life of morphine in neonates and young infants is more than twice that of older children and is even more prolonged in premature infants [58]. Clearance of morphine in premature infants is less than half that measured in adults.

Studies of morphine efficacy in neonates have yielded mixed results, with some studies showing no apparent analgesic effect of morphine infusion in ventilated neonates in response to endotracheal suctioning. Because of the significant variation in pharmacokinetics of morphine among patients, dosing should be based on age, weight, side-effects, and careful dose titration [58]. Erythema and local urticaria at the site of IV administration are sometimes seen and do not imply an allergy to morphine. Morphine is generally well tolerated with minimal hemodynamic changes during infusions in blinded studies [59] but rapid bolus dosing can be associated with hypotension. Morphine and other opioids produce dose-dependent depression of ventilation by decreasing the brainstem response to hypoxia and hypercarbia and by interfering with central ventilatory centers. Morphine reduces the sense of air hunger in children with cancer and end-stage lung disease and can be given sublingually in this setting for ease of administration and for more rapid onset than enteral dosing. Dosing guidelines for morphine can be found in Table 33.3.

Hydromorphone has similar duration of action to morphine and is frequently used in patient-controlled analgasia (PCA) and epidural analgesia. Like morphine, it is commonly given orally and intravenously, although there is no long-acting preparation available. It differs from morphine in that it is slightly more lipid soluble and approximately five times more potent in steady state when given intravenously [60]. Like morphine, it is metabolized principally by glucuronidation. Hydromorphone is often prescribed for patients with renal insufficiency but this practice is not evidence based. Excitatory effects of either morphine or hydromorphone in patients with renal insufficiency correlate poorly with plasma concentrations of glucuronides [61]. While individual patients may report differences in analgesia or side-effects between morphine and hydromorphone, randomized blinded comparisons have found few clinically meaningful differences in the frequency of side-effects [62].

Methadone is a long-acting opioid that is supplied as a racemic mixture of d- and l-isomers. It has a prolonged elimination half-life, resulting in a long duration of analgesia. There is, however, wide variation in elimination half-life, ranging from 6 to 30h. The bio-availability is quite high, approximately 70–90%. Because of these unique properties, methadone can be dosed intermittently, either orally or intravenously, and can provide

Drug	Equi-anal	lgesic doses	Usual starting subcutaneous do	intravenous or P bses and intervals C	arenteral Dral dose	Usual st	arting oral doses and i	intervals

Doses are for patients	: over 6 months	of age. In infants un	der 6 months, initial per	- kiloaram doses should beain a	at roughly 25	% of the per kiloara	m doses recommended h	here. Hiaher doses

are often required for patients receiving mechanical ventilation. All doses are approximate and should be adjusted according to clinical circumstances. Recommendations are adapted from previous summary tables, including those of a consensus statement from the World Health Organization and the International Association for the Study of Pain.

<sup>a</sup> Methadone requires additional vigilance because it can accumulate and produce delayed sedation. If sedation occurs, doses should be withheld until sedation resolves. Thereafter, doses should be substantially reduced, the interval between doses should be extended to 3 to 12 hours, or both.

<sup>b</sup> The use of meperidine should generally be avoided if other opioids are available, especially with long-term use, because its metabolite can cause seizures.

Table 33.3 Initial dosing guidelines for opioids

prolonged, steady-state analgesia similar to a continuous infusion or controlled-release preparations of other opioids.

The l-isomer of methadone acts as a  $\mu$  opioid; the d-isomer acts as a non-competitive antagonist at the N-methyl-D-aspartate (NMDA) subgroup of excitatory amino acids receptors in the brain, spinal cord, and peripheral nerves. NMDA receptor antagonism results in analgesia, reduction in hyperalgesia, and partial reversing of tolerance to µ opioids [63]. Methadone's combined effect of µ receptor agonism and NMDA antagonism results in incomplete cross-tolerance so that dose conversion between methadone and other opioids depends, in part, on the patient's degree of opioid tolerance [64]. In opioid-naïve patients, the average daily requirement of IV methadone is approximately 30% of the corresponding IV morphine requirement. However, in opioid-tolerant patients, the average daily methadone requirement may be as little as 10% of the total daily morphine dose. This is especially relevant when converting from morphine to methadone in children who are opioid tolerant and when weaning non-ventilated infants and children from prolonged opioid therapy [65].

Because of incomplete cross-tolerance, slow and unpredictable elimination half-life, and variability in plasma concentrations, methadone dosing requires careful titration and frequent assessment for respiratory depression. Methadone has been associated with prolongation of the QT interval, especially when combined with other drugs known to cause prolonged QT. For patients showing oversedation or mild hypoventilation, it may be necessary to hold multiple doses rather than make small incremental changes due to the prolonged duration of action.

For opioid-naïve patients in the postoperative period, our practice is to dose methadone on a "sliding scale" every 4h where patients receive 0.075 mg/kg for severe pain, 0.05 mg/kg for moderate pain, and 0.025 for mild pain. After 24h of this dosing regimen, patients are then placed on a more regular dosing schedule, with shorter-acting opioids such as morphine or hydromorphone offered for rescue therapy.

Methadone is particularly useful in children with cancer who have nociceptive as well as neuropathic pain. It can be dosed in small children with chronic pain who are unable to swallow sustained-release pills.

Fentanyl is highly lipophilic, that is 70–100 times more potent than morphine in single-dose administration and 30–50 times more potent when given as a continuous intravenous infusion. Because fentanyl has a rapid onset and brief duration, it is often used for brief painful procedures, such as lumbar punctures, bone marrow biopsies, and dressing changes, either by itself or in combination with benzodiazepines or general anesthesia. Doses of 0.5-1µg/kg, titrated every 1-3min generally provide good analgesia for brief painful procedures in non-ventilated patients. Fentanyl primarily undergoes conversion in the liver to inactive metabolites, making it useful in patients with renal failure. The effect of a single dose of fentanyl is terminated in large measure by rapid redistribution [66,67]. However, with repeated doses or continuous infusion, termination of the fentanyl effect is more determined by elimination rather than redistribution, resulting in prolonged duration of action. The context-sensitive half-life of fentanyl is particularly prolonged in neonates receiving continuous infusions [68]. Rapid administration may cause glottic and chest wall rigidity; treatment can consist of neuromuscular blockade, assisted ventilation, and in some cases administration of naloxone.

Oral transmucosal fentanyl is also used for brief painful procedures [69] and for children with cancer breakthrough pain. The oral transmucosal dose is partially absorbed through the buccal mucosa and partially swallowed so that the overall bio-availability is approximately 50%. The peak analgesic effect occurs at 30–45 min. Most children tolerate oral transmucosal fentanyl well, although almost 90% experience facial pruritus.

Transdermal fentanyl is used in selected children with cancer pain [70]. It is also used for a very small number of children with chronic pain who require regular dosing of opioids and have a better side-effects profile with fentanyl than other opioids. Transdermal fentanyl is also used for patients who have difficulty with oral opioids or who have limited intravenous access. Following initial application or with dose escalation, approximately 12-24h are required to reach steady-state plasma levels because of depot accumulation of fentanyl in the skin; this also accounts for continued absorption of the drug at a declining rate after the transdermal fentanyl is removed. Because of these properties, it is not useful in patients with acutely fluctuating pain. Additional short-acting opioids are required with initial application and dose escalation. Drug uptake can be influenced by a number of patient factors, including skin temperature, thickness, adiposity, and inflammation. Transdermal fentanyl should be used only in patients who are opioid tolerant and who have fairly constant pain. Adverse events, including deaths, have been reported among opioidnaïve adult and pediatric patients who were treated with transdermal fentanyl for acute postsurgical pain.

Meperidine is approximately 10 times less potent than morphine. It is metabolized in the liver through hydrolysis and N-demethylation to normeperidine, a metabolite that is renally eliminated. The elimination half-life is 3–4h. Accumulation of normeperidine can cause hyperreflexia, agitation, delirium, and seizures. Life-threatening events have occurred with the use of meperidine in patients taking monoamine oxidase inhibitors and in those with untreated hypothyroidism. Doing so has resulted in metabolic and hemodynamic changes, excitability, seizures, and death. Meperidine is unique among opioids in that it reduces rigors associated with general anesthesia and the administration of blood products. Beyond its use in low doses for rigors or shivering, we generally recommend against use of meperidine for analgesia in children.

Table 33.3 shows initial dosing guidelines for opioid analgesics.

# Methods of opioid administration Intermittent opioid bolus dosing

Intermittent parenteral dosing of opioids can be useful for episodic pain or for initial loading doses in the treatment of acute pain. Particularly with longer dosing intervals, this approach results in wide fluctuations in plasma opioid concentrations and fluctuations in side-effects and pain intensity. Continuous infusions and patient- (or nurse-) controlled analgesia are often used instead of intermittent parenteral bolus dosing to avoid fluctuations in plasma opioid concentration, analgesia, and opioid side-effects.

## **Continuous opioid infusions**

Continuous opioid infusions are useful for maintaining steady-state plasma opioid concentrations [58,71,72]. This approach is often used in intensive care units for ventilated patients who have relatively constant levels of pain; intermittent boluses of opioids are administered for any increases in pain, such as endotracheal tube suctioning. Although continuous infusions achieve steady-state plasma opioid levels and near-constant levels of analgesia, patients who have fluctuations in pain, such as with coughing, chest physiotherapy or getting out of bed, may have increased levels of pain which are not readily relieved by a continuous infusion of drug. In this setting, additional opioid boluses are required. Typical starting dose for continuous infusions of morphine is 0.025 mg/ kg/h. Because of patient variations in opioid metabolism and pain intensity, effective starting doses vary considerably. Neonates and young infants require lower starting doses, ranging from 0.005 mg/kg/h in preterm neonates to 0.015 mg/kg/h in young infants aged 2–6 months.

## Patient- and nurse-controlled analgesia

Patient-controlled analgesia (PCA) takes into account individual variations in opioid pharmacokinetics and individual fluctuations in pain intensity that cannot be treated by intermittent opioid bolus dosing or continuous infusions [73–76]. PCA involves a delivery system that administers a small preset dose of opioid, usually intravenously, when the patient depresses a button. There is a preset lock-out time during which no additional boluses can be administered, even if the button is depressed. PCA can also administer a continuous opioid infusion in addition to the intermittent boluses.

Patient-controlled analgesia has been shown to be safe and effective in children aged 7 years and older. Some children as young as 4 or 5 years are able to effectively use PCA. However, there is a higher incidence of failure in younger children because of their inability to understand the causal relationship between depressing the button and obtaining medication for pain relief. PCA is widely used for a variety of painful conditions such as postoperative pain, painful vaso-occlusive crises, and cancer pain. There are conflicting data comparing PCA to continuous opioid infusions. Some studies indicate that PCA use tends to reduce patients' overall opioid use, with fewer opioid side-effects and similar or lower pain scores. Other studies did not find lower total opioid use with PCA compared to continuous opioid infusions.

Nurse-controlled analgesia (NCA) is commonly used for infants and children who are unable to push the PCA button, either due to lack of cognitive abilities or due to physical limitations. Outcome studies indicate that nursecontrolled analgesia is generally safe and effective in children, with good patient, nurse, and parent satisfaction [75,76]. NCA is commonly used in pediatric hospitals for opioid administration to young children following surgery.

Parent-controlled analgesia is widely accepted for use in children with advanced cancer pain and in palliative care, in both home and hospital settings. There is, however, controversy surrounding parent-controlled analgesia for opioid-naive children or in the setting of acute postoperative pain. Advocates of parent-controlled analgesia point out that parents know their children best, especially children with developmental or physical disabilities. The counter-argument is that parents, unlike nurses, do not have the training or expertise to effectively assess risks of opioid dosing or impending respiratory depression. There have been several serious adverse events, including deaths, with the use of parent-controlled analgesia by well-meaning parents. Our view is that parent-controlled analgesia for opioid-naive patients should be restricted to hospitals that have formal education parent programs, protocols for close nurse observation and assessment, and electronic cardiorespiratory monitoring [76].

Opioids commonly used for PCA include morphine, hydromorphone, and fentanyl. Some studies have shown that adding a basal infusion at night for postsurgical patients improves sleep and pain scores. Other studies have shown that basal infusions with PCA increase the risk of desaturation episodes, especially at night. Whether to add a basal infusion depends on a number of factors, including severity of pain, tolerance to opioids, and underlying patient condition that may increase risk of hypoventilation or airway obstruction. In general, patients with mild-to-moderate pain experience good analgesia with demand-only PCA. Our practice is to use PCA bolus dosing without a background basal infusion for children who have received a peripheral nerve block intraoperatively, who have increased risks of respiratory compromise, and for those who are expected to have mild-to-moderate but not severe surgical pain. We do tend to include a basal infusion for children who have cancer pain or pain from vaso-occlusive crises. For these patients, we tend to provide approximately 40-50% of their daily opioid dosing through basal infusions to provide effective analgesia without the need for frequent demand boluses. We often add a basal infusion for 1-2 days postoperatively for patients who have had surgeries expected to result in severe postoperative pain, such as scoliosis surgery or major hip surgery. When fentanyl is chosen for PCA, such as for patients who have had reactions to other opioids, a basal rate is often used because fentanyl is shorter acting than morphine or hydromorphone. Typical starting doses for PCA (and NCA) are listed in Table 33.4.

## **Opioid side-effects and treatment**

Opioids are associated with a range of side-effects, including nausea, vomiting, constipation, urinary retention, pruritus, sedation, and respiratory depression. Although some children may experience different side-effect profiles with different opioids, there are few data to suggest that side-effects differ greatly among commonly used opioids. To many children, severe opioid side-effects, such as relentless nausea or pruritus, may be as distressing as pain. Opioid-sparing approaches to postoperative analgesia, including the use of NSAIDs, should be considered to avoid the complications of opioids on postoperative recovery [77].

Opioid side-effects occur by actions at both peripheral and central sites [78]. For example, opioid-induced nausea and vomiting involve agonist activity at receptors in the

 Table 33.4 Typical starting doses for patient-controlled (nurse-controlled) analgesia

Drug	Bolus dose (μg/kg)	Continuous rate (µg/kg/h)	4-h limit (μg/kg)
Morphine	20	4–15	300
Hydromorphone	5	1–3	60
Fentanyl	0.25	0.15	4

chemoreceptor trigger zone as well as in the gastrointestinal tract. Some opioids produce pruritus by peripheral release of histamine; however, small doses of intrathecal morphine are associated with profound pruritus, implying a more central cause of signaling and neurotransmission in the spinal dorsal horn and nucleus caudalis.

Opioid side-effects should be anticipated and treated aggressively. A proactive program with protocols for side-effect management allows for rapid implementation of treatment. The evaluation of the patient with opioid side-effects should include assessment of the severity of side-effect, the degree of patient distress, the expected duration of opioid therapy, and careful consideration of other factors that may masquerade as opioid side-effects. For example, severe itching may be a result of opioids but may also be due to an allergic reaction to other medications.

Constipation is nearly universal among patients receiving opioids, even with short-term use. Stimulant laxatives should be routinely used for all patients anticipated to require more than 1–2 doses of opioids. Methylnaltrexone has decreased ability to cross the blood–brain barrier and acts as a peripheral opioid antagonist [78]. It has been used for opioid-induced constipation that is refractory to laxatives. Doses of methylnaltrexone for children are extrapolated from adult studies.

Opioid-induced pruritus can be relentless and as distressing as pain to some patients. Pruritus occurs in approximately 13% of patients receiving parenteral opioids and 20-80% of patients receiving intrathecal or epidural opioids. Opioid-induced pruritus is thought to occur through activation of opioid receptors in the brain and substantia gelatinosa. Although antihistamines have traditionally been used to treat pruritus, there is good evidence for use of µ receptor antagonists such as naloxone infusions for both opioid-induced pruritus and opioidinduced nausea. In addition, antihistamines can exacerbate sedation, constipation, and urinary retention caused by opioids. In a prospective, randomized trial of 46 children receiving low-dose naloxone infusion (0.25µg/ kg/h) and morphine PCA postoperatively, the incidence and severity of opioid-induced pruritus and nausea were significantly reduced [79]. There was no increase in pain scores or increase in morphine use with the administration of low-dose naloxone. Ultra-low dose naloxone infusions show differential binding to opioid receptors coupled to G-stimulatory versus G-inhibitory proteins so that analgesia is not reversed. Nalbuphine is a widely used µ receptor antagonist used for opioid-induced nausea and vomiting although there are conflicting efficacy data among pediatric patients [80].

Nausea and vomiting are a major source of distress for patients, especially in the postoperative period. There is a strong relationship between postoperative nausea and vomiting and the amount of opioids used postoperatively [81] but other causes should also be considered such as electrolyte abnormalities or impaired kidney function. Ondansetron is a selective 5HT3 receptor antagonist often used in the treatment of nausea and vomiting. Phenothiazines, butyrophenones, and metoclopramide have traditionally been used but have the associated risk of extrapyramidal reactions. There is good evidence to support the use of low-dose naloxone infusions in the treatment of nausea and vomiting associated with opioids. The typical dose of low-dose naloxone used in the treatment of opioid-induced pruritus and nausea is  $0.25 \,\mu g/kg/h$ .

Children with advanced cancer often experience fatigue and somnolence, and opioid use often exacerbates these symptoms. Other treatable causes of fatigue should be considered, such as anemia, sleep disturbances, and depression. A cross-sectional study of the parents of 141 children who died of cancer reported that 96% of children had fatigue and nearly 50% experienced significant suffering from fatigue [82]. Only 13% of children with fatigue received directed treatment. More aggressive treatment of pain with opioids may further exacerbate fatigue and somnolence [83]. Methylphenidate is a stimulant that acts as an adrenergic receptor agonist to indirectly increase the release of dopamine and norepinephrine. Studies in adults support the use of methyphenidate to antagonize opioid-associated sedation and fatigue. Methylphenidate can also provide additional analgesic and antidepressant effects, which can be particularly beneficial for children with advanced cancer.
