List of Contributors, vii

Preface, xii

List of Abbreviations, xiii

## Part 1 Principles of Pediatric Anesthesia

- 1 Ethical Considerations, 1 David B. Waisel
- 2 History of Pediatric Anesthesia, 15 Burdett S. Dunbar & Dean B. Andropoulos
- **3** Educating Pediatric Anesthesiologists: What's Best for the Kids?, 27 *Alan Jay Schwartz*
- **4** An Introduction to the Ethical Design, Conduct, and Analysis of Pediatric Clinical Trials, 40 *Myron Yaster, Jeffrey Galinkin & Mark S. Schreiner*
- 5 Developmental Physiology of the Cardiovascular System, 60
   Wanda C. Miller-Hance, Ivan Wilmot & Dean B. Andropoulos
- 6 Developmental Physiology of the Respiratory System, 95 Susan H. Guttentag, Maria Victoria Fraga & Dean B. Andropoulos
- 7 Developmental Physiology of the Central Nervous System, 117
   *Ken M. Brady, R. Blaine Easley & Bruno Bissonnette*
- 8 Developmental Physiology of the Liver, Gastrointestinal Tract, and Renal System, 139 Peter N. Bromley, Ellen Rawlinson & James Bennett
- **9** Pharmacology, 168 *Jean X. Mazoit*

- **10** Fluids, Electrolytes, and Nutrition, 205 *Claire Brett & Danton Charr*
- **11** Coagulation, Bleeding, and Blood Transfusion, 224 Bruce E. Miller & Jeanne E. Hendrickson
- 12 Cardiopulmonary Resuscitation, 255 Todd J. Kilbaugh, Alexis A. Topjian, Robert M. Sutton, Vinay M. Nadkarni & Robert A. Berg

#### Part 2 Pediatric Anesthesia Management

- 13 Preoperative Evaluation and Preparation, Anxiety, Awareness, and Behavior Change, 273 Andrew Davidson, Kelly Howard, William Browne, Walid Habre & Ursula Lopez
- 14 Pediatric Airway Management, 300 John E. Fiadjoe, Paul A. Stricker & Ronald S. Litman
- **15** Induction, Maintenance, and Emergence from Anesthesia, 330 *Jerrold Lerman, Venkata Sampathi & Stacey Watt*
- **16** Postanesthesia Care Unit Management, 361 *Warwick Ames & Allison Kinder Ross*
- 17 Monitoring and Vascular Access, 381 Dean B. Andropoulos
- **18** Pediatric Regional Anesthesia, 419 *Claude Ecoffey*

# Part 3 Practice of Pediatric Anesthesia

**19** Anesthesia for Fetal Intervention and Surgery, 444 Mark D. Rollins & Mark A. Rosen

#### vi Contents

- **20** Anesthesia for Premature Infants, 475 *George A. Gregory*
- 21 Anesthesia for the Full-Term and Ex-Premature Infant, 497 Neil S. Morton, Ross Fairgrieve, Anthony Moores & Ewan Wallace
- 22 Anesthesia for the Adolescent and Young Adult Patient, 520 Loren A. Bauman, Joseph R. Tobin & Dean B. Andropoulos
- **23** Anesthesia for Neurosurgical Procedures, 540 Bruno Bissonnette, Ken M. Brady & R. Blaine Easley
- **24** Anesthesia for Thoracic Surgery, 569 Grant McFadyen, Stefan Budac, Michael Richards & Lynn D. Martin
- **25** Anesthesia for Congenital Heart Disease, 588 *Kirsten C. Odegard, James A. DiNardo & Peter C. Laussen*
- **26** Anesthesia for Spinal Surgery in Children, 654 *Joseph D. Tobias*
- **27** Anesthesia for Transplantation, 678 Stephen A. Stayer, Glynn Williams & Dean B. Andropoulos
- **28** Anesthesia for Abdominal Surgery, 720 Lena S. Sun, Neeta R. Saraiya & Philipp J. Houck
- **29** Anesthesia for Pediatric Urological Procedures, 740 *Ira S. Landsman, Laura N. Zeigler & Jayant K. Deshpande*
- **30** Anesthesia for Orthopedic Surgery, 757 Cathy Lammers & Cecile Wyckaert
- **31** Eyes, Ears, Nose, and Throat Surgery, 777 Olutoyin A. Olutoye & Mehernoor F. Watcha
- **32** Anesthesia for Plastic and Craniofacial Surgery, 810 Ehrenfried Schindler, Markus Martini & Martina Messing-Jünger
- **33** Pain Management in Children, 845 Charles Berde & Christine Greco
- **34** Outpatient Anesthesia, 875 Joseph A. Scattoloni, Olubukola O. Nafiu & Shobha Malviya

- **35** Anesthesia for Burns and Trauma, 896 Patrick J. Guffey & Dean B. Andropoulos
- **36** Anesthesia and Sedation Outside the Operating Room, 919 *Robert S. Holzman & Keira P. Mason*
- **37** Pediatric Intensive Care, 946 Patrick A. Ross, Robert Bart III & Randall C. Wetzel
- **38** Anesthesia for the Patient with a Genetic Syndrome, 993 *David Mann, Priscilla J. Garcia & Dean B. Andropoulos*
- **39** Pediatric Anesthesia in Developing Countries, 1140 *Adrian T. Bosenberg*

#### Part 4 Quality, Outcomes, and Complications in Pediatric Anesthesia

- **40** Clinical Complications in Pediatric Anesthesia, 1152 *Randall Flick*
- **41** Impact of Pediatric Surgery and Anesthesia on Brain Development, 1183 *Andreas W. Loepke & Sulpicio G. Soriano*
- **42** Patient Simulation and Its Use in Pediatric Anesthesia, 1219 *Anita Honkanen & Michael Chen*
- **43** Databases and Outcome Research in Pediatric Anesthesia, 1239 Donald C. Tyler, Laura Schleelein & Harshad Gurnaney
- 44 Electronic Anesthesia and Medical Records, 1257 James Edward Caldwell & David Robinowitz
- **45** Operating Room Safety, Communication, and Teamwork, 1279 *Thomas L. Shaw & Stephen A. Stayer* 
  - Appendix A: Pediatric Anesthesia Drugs and Other Treatments in the Perioperative Period, 1293 *Dean B. Andropoulos*

Appendix B: Pediatric Normal Laboratory Values, 1300 Dean B. Andropoulos

Index, 1315

# **List of Contributors**

### **Warwick Ames**

MBBS, FRCA Assistant Professor of Anesthesiology and Pediatrics Duke University Medical Center Durham, NC, USA

#### **Robert Bart III**

MD Assistant Professor Department of Anesthesiology Critical Care Medicine Children's Hospital Los Angeles University of Southern California Keck School of Medicine Los Angeles, CA, USA

### Loren A. Bauman

MD Associate Professor Department of Anesthesiology Wake Forest University School of Medicine; Pediatric Anesthesiologist Wake Forest University Baptist Medical Center Winston-Salem, NC, USA

#### **James Bennett**

MBBS, FRCA Consultant Anaesthetist Birmingham Children's Hospital and Honorary Consultant Anaesthetist Liver Unit Queen Elizabeth Hospital Birmingham, UK

#### **Charles Berde**

MD, PhD Sara Page Mayo Chair in Pediatric Pain Medicine Chief, Division of Pain Medicine Department of Anesthesiology, Perioperative and Pain Medicine Children's Hospital Boston; Professor of Anaesthesia (Pediatrics) Harvard Medical School Boston, MA, USA

#### Robert A. Berg

MD Professor of Anesthesiology and Critical Care Medicine The University of Pennsylvania School of Medicine; Russell Raphaely Endowed Chair Division Chief, Critical Care Medicine The Children's Hospital of Philadelphia Philadelphia, PA, USA

#### **Bruno Bissonnette**

MD Professor of Anesthesia Department of Anesthesia University of Toronto; President and Founder Children of the World Anesthesia Foundation Toronto, Ontario, Canada

### Adrian T. Bosenberg

MB,ChB, FFA(SA) Director of Anesthesia Seattle Children's Hospital; Professor, Department of Anesthesiology and Pain Management University of Washington Seattle, WA, USA

#### Ken M. Brady

MD Associate Professor Department of Anesthesiology and Pediatric Baylor College of Medicine; Texas Children's Hospital Houston, TX, USA

#### **Claire Brett**

MD Professor of Anesthesia and Perioperative Care Department of Anesthesia and Perioperative Care University of California San Francisco San Francisco, CA, USA

#### **Peter N. Bromley**

MBBS, FRCA Consultant Anaesthetist Birmingham Children's Hospital; Honorary Consultant Anaesthetist Liver Unit Queen Elizabeth Hospital; Honorary Senior Lecturer in Clinical Medicine University of Birmingham Birmingham, UK

#### **William Browne**

MBBS, FANZCA Department of Aneasthesia and Pain Management Royal Children's Hospital Parkville, Australia

### **Stefan Budac**

MD Acting Assistant Professor Department of Anesthesiology and Pain Medicine University of Washington School of Medicine; Attending Anesthesiologist Seattle Children's Hospital Seattle, WA, USA

#### James Edward Caldwell

MB ChB Professor and Vice Chair Department of Anesthesia and Perioperative Care University of California San Francisco San Francisco, CA, USA

#### **Danton Charr**

MD Instructor of Anesthesiology Department of Anesthesia Stanford Hospital and Clinics Stanford University Stanford, CA, USA

#### **Michael Chen**

MD

Department of Anesthesia Stanford Hospital and Clinics; Assistant Professor of Anesthesia Stanford University Stanford, CA, USA

#### Andrew Davidson

MD, MBBS, FANZCA Associate Professor Department of Anaesthesia and Pain Management Royal Children's Hospital Parkville, Australia

#### Jayant K. Deshpande

MD, MPH Professor of Pediatrics and Anesthesiology University of Arkansas for Medical Sciences Arkansas Children's Hospital Little Rock, AR, USA

# James A. DiNardo

MD

Senior Associate in Anesthesia Cardiac Anesthesia Service Children's Hospital Boston; Associate Professor in Anaesthesia Harvard Medical School Boston, MA, USA

#### **Burdett S. Dunbar**

MD

Professor, Anesthesiology and Pediatrics Baylor College of Medicine; Former Chief, Pediatric Anesthesiology Texas Children's Hospital Houston, TX, USA

# **R. Blaine Easley**

MD Associate Professor Department of Anesthesiology and Pediatrics Baylor College of Medicine; Texas Children's Hospital Houston, TX, USA

#### **Claude Ecoffey**

MD Chairman Service d'Anesthésie-Réanimation Chirurgicale Hôpital Pontchaillou University of Rennes Rennes, France

#### **Ross Fairgrieve**

MBChB, FRCA Consultant in Paediatric Anaesthesia and Pain Management Royal Hospital for Sick Children Glasgow, Scotland, UK

# John E. Fiadjoe

MD Assistant Professor of Anesthesiology University of Pennsylvania School of Medicine; Attending Anesthesiologist The Children's Hospital of Philadelphia Philadelphia, PA, USA

# Randall Flick

MD Consultant, Department of Anesthesiology Mayo Clinic; Assistant Professor of Anesthesiology College of Medicine Rochester, MN, USA

#### Maria Victoria Fraga

MD Department of Anesthesiology and Critical Care Medicine The University of Pennsylvania School of Medicine; Neonatology Fellow The Children's Hospital of Philadelphia Philadelphia, PA, USA

# **Jeffrey Galinkin**

MD, FAAP Department of Anesthesiology and Pediatrics The Children's Hospital; Associate Professor, Anesthesiology and Pediatrics University of Colorado at Denver Aurora, CO, USA

#### Priscilla J. Garcia

MD Assistant Professor Anesthesiology and Pediatrics Baylor College of Medicine; Staff Pediatric and Obstetric Anesthesiologist Texas Children's Hospital Houston, TX, USA

#### **Christine Greco**

MD Director, Acute Pain Services Department of Anesthesiology, Perioperative and Pain Medicine Children's Hospital Boston; Assistant Professor (Anesthesia) Harvard Medical School Boston, MA, USA

#### **Patrick J. Guffey**

M

Department of Anesthesiology University of Colorado School of Medicine; Children's Hospital Colorado Aurora, CO, USA

#### **Harshad Gurnaney**

MBBS Assistant Professor of Anesthesiology and Critical Care The University of Pennsylvania School of Medicine; Anesthesiologist The Children's Hospital of Philadelphia Philadelphia, PA, USA

#### Susan H. Guttentag

MD Department of Anesthesiology and Critical Care Medicine The University of Pennsylvania School of Medicine; Associate Professor of Pediatrics The Children's Hospital of Philadelphia Philadelphia, PA, USA

#### Walid Habre

MD, PhD Associate Professor Department of Anaesthesiology, Pharmacology and Intensive Care University Hospitals Geneva, Switzerland

#### Jeanne E. Hendrickson

MD Aflac Cancer Center and Blood Disorders Service Associate Medical Director Blood and Tissue Services Children's Healthcare of Atlanta; Assistant Professor of Pediatrics and Pathology Emory University School of Medicine Atlanta, GA, USA

#### **Robert S. Holzman**

MD, FAAP Senior Associate in Anesthesia Department of Anesthesiology, Perioperative and Pain Medicine Children's Hospital Boston; Associate Professor of Anaesthesia Harvard Medical School Boston, MA, USA

#### List of Contributors ix

#### Anita Honkanen

#### MD

Service Chief, Anesthesia Clinical Professor of Anesthesia Department of Anesthesia Stanford Hospital and Clinics; Associate Professor of Anesthesia Stanford University, Stanford, CA, USA

#### **Philipp J. Houck**

MD

Assistant Professor of Anesthesiology Columbia University College of Physicians and Surgeons New York, NY, USA

#### Kelly Howard

BSc(Hons), MPsych (Clinical Child), PhD Department of Anaesthesia and Pain Management Royal Children's Hospital Parkville, Australia

#### Todd J. Kilbaugh

MD Assistant Professor of Anesthesiology and Critical Care Medicine The University of Pennsylvania School of Medicine; The Children's Hospital of Philadelphia Philadelphia, PA, USA

#### Laura N. Zeigler

MD Assistant Professor of Clinical Anesthesiology Monroe Carell Jr Children's Hospital at Vanderbilt and Department of Anesthesiology Vanderbilt University Medical Center Nashville, TN, USA

# Preface

Many changes have occurred in the practice in pediatric anesthesia during the past few years. This, the fifth edition of *Pediatric Anesthesia*, reflects these changes. The book is now the work of multiple new authors from several continents and many countries, which gives all of us the opportunity to broaden our view of pediatric anesthesia. It is also the work of Dean Andropoulos who is now the co-editor of this book. Both the authors and Dean have helped move the book to a new and higher level.

The book is divided into several parts that include: Principles of Pediatric Anesthesia; Pediatric Anesthesia Management; Practice of Pediatric Anesthesia; and Quality, Outcomes, and Complications in Pediatric Anesthesia. The latter part includes new chapters addressing important contemporary issues, including anesthetic neurotoxicity; simulation; databases and outcomes research; electronic anesthesia and medical records; and operating room safety, communication, and teamwork. Also included are appendices on drug dosing and normal laboratory values. This edition is published in full color, to better present the myriad images that illustrate the unique features of pediatric anesthesia. New with this edition are online videos of common anesthesia procedures that concisely and effectively show how to do the procedures. There are also cases presented at the end of each clinical chapter that highlight the main concepts presented in that chapter. One goal of the book has not changed, i.e., to provide pharmacological and physiological data pertinent to each chapter. Without this information, the clinician often must provide care by rote. Many children do not respond well to rote! If the clinician understands the pharmacology and physiology of the situation, he/she can effectively respond to problems. Knowledge of physiology and pharmacology also allow better planning for anesthesia and surgery.

We thank Rob Blundell and Helen Harvey of Wiley-Blackwell for their constant support and help in the production of this book. Their clear understanding of our vision has provided the guidance necessary to produce the book in the way we envisioned.

And last but not least, we thank the residents and fellows for teaching us as much, or more, than we taught them. Their insightful questions, thoughts, and prodding is what academic medicine is about. This probing forces everyone to get out of her/his comfort zone and think differently. We also thank the surgeons and nurses for their support. Most of all, we thank the patients for giving us the privilege of caring for them and for their continuing to teach us every single day. They are the best teachers!

> George A. Gregory Dean B. Andropoulos

# **List of Abbreviations**

3-D	three-dimensional	AHG	antihuman globulin
5HT3	5-hydroxytryptamine-3 receptor	AHI	apnea-hypopnea index
6-MP	6-mercaptopurine	AHRQ	Agency for Healthcare Research and
α1-ATD	α1-antitrypsin deficiency		Quality
AA	artery-to-artery	AICD	automatic implantable cardiac
AAA	asleep-awake-asleep		defibrillator
AAG	α1-acid glycoprotein	AIMS	anesthesia information management
AAP	American Academy of Pediatrics		system
ABA	American Board of Anesthesiology	AKI	acute kidney injury
ABC	ATP-binding cassette	ALI	acute lung injury
ABG	arterial blood gases	ALL	acute lymphocytic leukemia
ABP	arterial blood pressure	ALT	alanine aminotransferase
ACA	anterior cerebral artery	AML	acute myeloid leukemia
ACD	active compression-decompression	AMM	anterior mediastinal mass
	device	AMPA	alpha-amino-3-hydroxy-5-methyl-4-
ACE	angiotensin-converting enzyme		isoxazole-propionic acid
ACEi	angiotensin-converting enzyme	ANA	antinuclear antibody
	inhibitor	ANH	acute normovolemic hemodilution
ACGME	Accreditation Council for Graduate	ANP	atrial natriuretic peptide
	Medical Education	AoDP	aortic diastolic blood pressure
ACh	acethylcholine	AP	anterior-posterior
ACP	antegrade cerebral perfusion	APL	adjustable pressure limiting
ACRM	anesthesia crisis resource management	APS	acute pain services
ACS	acute chest syndrome/abdominal	APSF	Anesthesia Patient Safety Foundation
	compartment syndrome/American	APTT	activated partial thromboplastin time
	College of Surgeons	AQI	Anesthesia Quality Institute
ACTH	adrenocorticotropic hormone	AR	adrenergic receptor
ADH	antidiuretic hormone	ARDS	adult/acute respiratory distress
ADP	adenosine diphosphate		syndrome
ADPKD	autosomal dominant polycystic kidney	ARF	acute renal failure
	disease	ARRA	American Recovery and Reinvestment
ADT	admission, discharge, and transfer		Act
AED	automated external defibrillator	ASA	American Society of Anesthesiologists
aEEG	amplitude-integrated EEG	ASC	ambulatory surgery center
AFP	α-fetoprotein	ASCA	anti-Saccharomyces cerevisiae
AGA	appropriate for gestational age	ASD	atrial septal defect/autism spectrum
AGP	α1-acid glycoprotein		disorder
AHA	American Heart Association	ASIS	anterior superior iliac spine
AHCPR	Agency for Health Care Policy and	ASO	arterial switch operation
	Research	AST	aspartate aminotransferase

AT	antithrombin	CHF	congestive heart failure
ATG	antithymocyte globulin	CIOMS	Council of International Organization
ATP	adenosine triphosphate		and Medical Sciences
AUC	area under the curve	CK	creatine kinase
AV	arterial-venous/atrioventricular	CKD	chronic kidney disease
AVM	arteriovenous malformation	CLD	chronic lung disease
AVP	arginine vasopressin	CLE	congenital lobar emphysema
BBB	blood-brain barrier	cLMA	classic larvngeal mask airway

# Introduction

Although physicians may think of medical ethics in dramatic terms - withdrawing life-sustaining therapy, allocating organs for transplant - medical ethics floods our daily practice. Consider an anesthesiologist who recommends postponing surgery in an infant because of a borderline upper respiratory infection (URI) [1]. How should the anesthesiologist respond to a parental request to proceed? These decisions are often framed as medical decisions based on the characteristics of the URI and the surgery. But within the decisions lie the ethical components of informed consent and obligations to the child and family. How do we decide how much weight to give the parents' strong desire to proceed? Does it matter why they want to proceed (convenience because grandma is in town to care for siblings? concern about being able to get time off from work again? scheduling because the child spends the summer with an out-of-town parent, effectively delaying the operation until fall? etc.). Should we even consider the effects on the family? What if there is concern that the parents will not reschedule surgery?

Ethical dilemmas occur when a physician is faced with "oughts" – that which a physician is bound by duty to do – that conflict. In the above example, anesthesiologists ought to base proceeding with surgery solely on the child's best interest. Anesthesiologists also ought to ensure that a child receives necessary healthcare within the realistic complexities of family life. Medical ethics provides the process by which to resolve these apparently conflicting "oughts."

Resolving ethical dilemmas is not solely a matter of being a moral person. Identifying, diagnosing and managing ethical conflicts requires the same extent of expertise that is required to identify, diagnose, and manage myocardial ischemia. Training and experience in resolving ethical dilemmas enable ethics consultants to identify critical facts, apply ethical principles and case-based analysis, articulate precise questions, and have the moral imagination to create more palatable solutions.

Ethics committees and their consultation services provide the resources to help resolve dilemmas. Anesthesiologists may find consultation services particularly helpful with concerns about disagreements among

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

patients and clinicians, appropriate decision-making roles for adolescents, and decisions about end-of-life care. A typical free-standing children's hospital has between six and ten ethics consultations each year, but some perform as many as 50 consultations annually [2].

Members of ethics committees include representatives throughout the hospital such as chaplains, administrators, social workers, nurses, and physicians. Many committees also include a local community representative. Depending on local practice, consultations may be performed by an individual, a small group or the entire ethics committee. Most ethics consultation services permit patients, parents and anyone with standing to request a consultation. Standing is defined broadly as participating in the care of the patient. Most services enter a written report into the clinical record. The standard of care is that ethics consultation services advise only and have no formal authority [3]. A committee with a strong record, however, does have substantial informal authority. The case study at the end of the chapter provides an example of an ethics consultation.

The law is not a desirable substitute for resolving ethical dilemmas. Most importantly, the law represents a lower boundary for acceptable behavior, whereas ethics articulates a standard to which we should aspire. Pragmatically, the law does not provide clear guidance because most law surrounding ethical dilemmas is case law. In addition, the frequently adversarial legal process may pollute future relations. Crude statutes and regulations are unable to govern complex medical care. Consider the Baby Doe regulations regarding withdrawing therapy for neonates. The rigid regulations devastated the ability to apply thoughtful, tailored therapy to individual neonates [4–6].

Ethics committees also provide formal education sessions, ward ethics rounds, and institutional consultation. An example of an institutional consultation would be to determine and implement the necessary infrastructure to ensure compliance with an adolescent's refusal to receive transfusion therapy.

# Informed consent process for pediatric patients

The doctrine of informed consent centers on the belief that patients have a right to self-determination [7]. The right to self-determination is actualized through the legal concept of competency. Except in specific situations, minors are not legally competent to consent for healthcare. But minors do have varying degrees of decisionmaking capacity, and should be included in medical decision making to the extent permitted by the child and situation (Box 1.1). **Box 1.1** Elements of consent and assent as defined by the American Academy of Pediatrics Committee on Bioethics [7]

#### Consent

- Adequate provision of information including the nature of the ailment or condition, the nature of the proposed diagnostic steps or treatment and the probability of their success; the existence and nature of the risks involved; and the existence, potential benefits, and risks of recommended alternative treatments (including the choice of no treatment).
- 2. Assessment of the patient's understanding of the above information.
- **3.** Assessment, if only tacit, of the capacity of the patient or surrogate to make the necessary decisions.
- Assurance, insofar as it is possible, that the patient has the freedom to choose among the medical alternatives without coercion or manipulation.

#### Assent

- 1. Helping the patient achieve a developmentally appropriate awareness of the nature of his or her condition.
- Telling the patient what he or she can expect with tests and treatment.
- Making a clinical assessment of the patient's understanding of the situation and the factors influencing how he or she is responding (including whether there is inappropriate pressure to accept testing or therapy).
- Soliciting an expression of the patient's willingness to accept the proposed care.

The process of pediatric informed consent depends on the age of the child (Table 1.1). The concepts of best interest, informed permission and assent are used when considering pediatric informed consent. For convenience, the term "parent" will be used to describe the child's surrogate decision maker. Parents are not always the legal surrogate decision maker and parental authority may be limited in adolescents. The term "decision maker" will refer to those involved in the specific decision and may include parents, children. and their advisors.

The primary lesson of this chapter should be to respect the experiences and opinions of children. The American Academy of Pediatrics emphasizes that "no one should solicit a patient's views without intending to weigh them seriously. In situations in which the patient will have to receive medical care despite his or her objection, the patient should be told that fact and should not be deceived" [7].

# Informed permission and the best interest standard

To recognize the fact that ethical informed consent only can be given by the patient, the American Academy of 
 Table 1.1 Graduated involvement of minors in medical decision making
 [7,9]

Age	Decision-making capacity	Techniques
Under 6 years	None	Best interest standard
Age 6–12 years	Developing	Informed permission Informed assent
Age 12–18 years	Mostly developed	Informed assent Informed permission
Mature minor	Developed, as legally determined by a judge, for a specific decision	Informed consent
Emancipated minor	Developed, as determined by a situation (e.g. being married, in the military, economically independent)	Informed consent

This broad outline should be viewed as a guide. Specific circumstances always must be taken into consideration. When children are in the upper range of an age bracket, limited or full inclusion of a higher technique, such as the use of assent for a 6 year old, may be appropriate.

Pediatrics uses the term "informed permission" for when the parent provides legal consent and ethical decision making for the child [7]. This conceptual framework highlights the limits of parental decision making. It does not affect the legal obligation to obtain informed consent from the parents as defined by local statutes.

Children younger than the age of 7 years have insufficient decision-making capacities to effectively participate in the informed consent process. When children cannot participate, the best interest standard guides decision making. Best interest does not mean the best care as defined by the clinicians. There are often several acceptable options, and clinicians rely on parents to determine what is in the child's best interest. Parents are given considerable latitude in decision making because society values the role of family, parents want the best for their children, and families often have to live with the result of the choices. Parental values are also a reasonable approximation of the child's future values [4].

Parental decisions should be scrutinized if they appear to fall outside the boundaries of acceptable care. Boundaries are determined by the extent and likelihood of potential harms arising from the intervention or its absence, the likelihood of success, and the overall risk-tobenefit ratio. When parents appear to choose unacceptable treatments, anesthesiologists should seek other clinicians to assess the acceptability of the decision and, if necessary and appropriate, to participate in the discussion [8]. Anesthesiologists should seek to resolve disagreements without resorting to legal intervention. However, the state has an interest in protecting those who cannot protect themselves. If other options have failed, anesthesiologists should report parents they believe to be choosing unacceptable treatments to child welfare authorities for possible legal action.

# Informed assent: the role of the patient

Children should participate in decision making to the extent their development permits [7]. For children between the ages of 7 and 13, anesthesiologists should seek both informed permission from the parent and assent and participatory decision making from the child. Common decisions in which children participate include whether a 6 year old wants sedation prior to an inhalation induction, whether a 10 year old wants inhalation or intravenous induction of anesthesia and whether a 12 year old wants an epidural for postoperative analgesia.

Anesthesiologists should assume that adolescents older than 13 years have sufficient decision-making capacity to fulfill the ethical obligations of informed consent. Adolescents have likely developed adult levels of abstract thought, complex reasoning and abilities to foresee and anticipate outcomes. However, adolescent decisionmaking abilities are limited by emotional impulsiveness and a tendency to undervalue long-term consequences. For these reasons, the influence an adolescent has on decision making is tempered by their maturity and the risks of the decision. Decisions are considered higher risk when they include an increased likelihood of permanently lost opportunities that have noteworthy consequences. For example, delayed scoliosis surgery may increase the extent of the curve, subsequently impairing cardiopulmonary function. These impairments can affect the quality of life, future morbidity, and lifespan. In determining the extent of risk in a decision, the quality and relevance of the data must be rigorously considered. This is particularly important when predicting future outcomes for infants.

# Emancipated minors and the mature minor doctrine

Emancipated minors are minors who have a statutory right to legally consent for their own healthcare decisions. States often award this status to patients who are in the military, who are married, who have children and who are economically independent. To be declared a mature minor, the patient must be determined by a judge to be legally and ethically capable of giving legal consent in a specific situation. Judges consider mature minor status based on the extent of the risk in the decision and the developmental maturity and age of the child [9].

### Disclosure

The reasonable person standard, the legal standard for most of the United States, requires that the information disclosed satisfies the hypothetical reasonable person. For the most part, however, the exact information to be disclosed to decision makers is not itemized. Further, preferences vary for the extent of disclosure and the desire to participate in decision making [10,11]. For example, in one typical survey, 74% of parents wanted to know all possible risks of anesthesia, while 24% wanted to know only those likely to occur, and 2% wanted to know only those that may result in a significant injury [12]. Rather than rely on a rote informed consent process, anesthesiologists should seek to satisfy the needs of the decision makers by meeting their information and decisionmaking needs. Because sociodemographic characteristics do not reliably predict preferences for disclosure and decision making, anesthesiologists should seek to meet the needs of the decision makers through patient-driven interactions. Anesthesiologists can do this by informing decision makers about that which the anesthesiologist feels must be communicated and about options that affect the perioperative experience (e.g. regional versus general anesthesia). The anesthesiologist can then ask if the decision makers wish to know more. Patient-driven interactions likely reduce malpractice lawsuits. The likelihood of being sued based on informed consent malpractice issues is very rare [13]. But the improved satisfaction that comes from patient-driven interactions (or, more simply, from listening to and responding to the decision makers' needs and requests) leads to decreased complaints and lawsuits in general [14,15].

# **Informed refusal**

Informed refusal of a recommendation requires anesthesiologists to more fully inform decision makers about the risks, benefits and alternatives than if the decision makers were following the recommendation. This helps ensure that decision makers are as knowledgeable as possible about the risks of selecting a less desirable path. Anesthesiologists who believe parents are refusing necessary care for a child without decision-making capacity should use the best interest standard. Children with significant decision-making capacity (perhaps around the age of 10 years but certainly by the age of 13 years) might refuse non-emergency procedures. Anesthesiologists should respect this refusal of assent and conscientiously avoid pressuring the child. Coercing or manipulating a child into having a procedure damages the child's trust of the medical profession and impairs future co-operation with their care. Maintenance of trust is particularly important in children with chronic medical conditions.

Strategies for resolving conflicts center on maintaining communication, clarifying misunderstandings about the anesthetic and surgical experience, and decreasing the anxiety of both the child and parents. The goal is to resolve the problem without impairing the relationships among clinicians, patient, and parents. Anesthesiologists may want to emphasize that nothing will happen without the child's approval, *but only if that is true*. Moving the discussion away from the preoperative area or letting the child dress in street clothes will often reduce stress and improve communication.

Anesthesiologists should recognize the distinction between using pharmacological agents to calm an anxious adolescent to enable proceeding and using pharmacological agents to manipulate the adolescent into proceeding. Consider the 15 year old who becomes overwhelmingly anxious and refuses surgery. It would be inappropriate to unilaterally administer midazolam for the purpose of getting the patient to co-operate. On the other hand, it is wholly appropriate to seek the patient's assent to receive sufficient anxiolysis so that upon return to the preoperative area, the patient is able to undergo the procedure. Time, respect, and simple strategies often resolve issues satisfactorily and efficiently.

# **Confidentiality for adolescents**

Physicians are obligated to protect patient information from unauthorized and unnecessary disclosure. With adolescents, confidentially is crucial for even the banal. Adolescents concerned about confidentiality withhold pertinent information and defer necessary treatment [16]. Anesthesiologists may want to ask sensitive questions without the parents present. Squarely addressing confidentiality concerns often improves truthfulness.

Anesthesiologists in possession of sensitive information should encourage the adolescent to share the relevant information with the parents. It is useful to engage adolescent specialists or social workers to enable the adolescent to communicate successfully with the parents and to ensure future care. However, anesthesiologists should honor the adolescent's right to confidentiality. It is ethically justifiable to breach confidentiality only when complying with reporting statutes or when breaching confidentiality will prevent serious harm to the child or another. Anesthesiologists should confer with legal counsel to determine if a presumed legal obligation requires breaching confidentiality.

State statutes may limit the anesthesiologist to informing only the adolescent about a positive pregnancy test [17]. In addition to ethical principles and practical reasons, these statues are specifically present to address concerns about child abuse in pregnant adolescents.

The ethical complexity increases logarithmically when a pregnant adolescent does not want to inform her parents and it is appropriate to postpone the procedure. Even though anesthesiologists must postpone the case in a manner that does not breach confidentiality, the details of how the postponement is communicated affects the ability to maintain confidentiality. For example, anesthesiologists can issue a terse communiqué to the parents that the procedure will be postponed. While this approach avoids explicit lying, its oddness may confuse parents and trigger a cascade of questions, leading to a loss of confidentiality. On the other hand, anesthesiologists may choose to deceive more actively. These clinicians would argue that if parents have no right to that information, then their obligations to the adolescent demand their best effort to maintain confidentiality.

Although peculiar in a medical textbook, perhaps a short course in deception is useful. Anesthesiologists should deceive in ways that will be successful, not require diagnostic or therapeutic interventions and not unduly worry parents. For example, while intimating about unavailable operating room space and emergency surgeries may be useful, the excuse is rather weak if stated in the morning, when the family could offer to wait until something is available. Using a "new murmur" as an excuse may worry parents and cause unnecessary consultations. More simple deceits, such as postponement due to concerns about inadequate fasting or upper respiratory infections, tend to minimize unintended consequences.

The rules surrounding parental involvement in elective abortions are confusing [18]. Although many states require either parental consent or notification prior to an elective abortion, the exceptions to parental involvement make it prudent to consult with hospital counsel. In general, though, parental consent requires permission from parents while parental notification only requires informing parents. There are times when parental involvement in abortion may harm adolescents [18,19]. To ensure that adolescents can seek an abortion confidentially in states with parental involvement laws, states must have a judicial bypass procedure to preclude parental involvement. In a judicial bypass hearing, the judge interviews the adolescent to determine if she is sufficiently mature to consent for an abortion. Even if the judge determines that the adolescent is insufficiently mature, the judge may grant permission for the abortion if the judge believes it is in the adolescent's best interest.

#### **Emergency care**

Emergency therapy is considered desirable and should be given to the minor who does not have a parent available to give legal consent or informed permission [20]. Anesthesiologists should err on the side of treating if they are unsure whether to wait for parental consent.

Emergency therapy becomes more complex when adolescents nearing the age of majority refuse to assent to care. Urgency may not permit the extended evaluation necessary to determine whether the minor has sufficient decision-making capacity. Anesthesiologists should use the best interest standard to guide therapy acutely. Consider a 15 year old with an acute cervical fracture who refuses emergency stabilization, which may cause irrevocable harm. The typical adolescent's decidedly short-term outlook and overvaluation of physical abilities make it unlikely that the adolescent possesses sufficient decisionmaking capacity in the acute situation. It is hard to imagine honoring an adolescent's refusal of emergency therapy in this case.

# **Children of Jehovah's Witnesses**

Jehovah's Witnesses interpret biblical scripture to mean that anyone who takes blood will be "cut off from his people" and not receive eternal salvation [21,22]. Adults may refuse potentially life-sustaining transfusion therapy. The presumption is that they are making an informed and voluntary decision. But the courts routinely authorize transfusion of children of Jehovah's Witnesses. The courts base these decisions on the doctrine of *parens patriae*, the obligation of the state to protect the interests of incompetent patients.

Anesthesiologists should directly address transfusion therapy when caring for a child of Jehovah's Witnesses. The patient and family should be informed that, as with all patients, attempts will be made to follow the family's wishes within the standard of care. Because refusal of transfusion therapy is deemed a "matter of conscience," the anesthesiologist should clarify acceptable interventions. Deliberate hypotension, deliberate hypothermia, and hemodilution are often acceptable techniques. Synthetic colloid solutions, dextran, erythropoietin, desmopressin, and preoperative iron are usually acceptable. Some Jehovah's Witnesses will accept blood removed and returned in a continuous loop, such as cell saver blood. The family should be informed that in critical situations, the anesthesiologist will transfuse while concomitantly seeking legal authorization. Anesthesiologists should be familiar with the hospital's preferred mechanism for obtaining legal authorizing. In instances where the likelihood of requiring blood is high or the local judiciary is not that familiar with case law for Jehovah's Witnesses, anesthesiologists may choose to obtain the court order preoperatively if there is a likelihood of transfusion.

Elective procedures may be postponed until the child is of sufficient age and maturity to decide about transfusion therapy. But delays may increase the risk of morbidity or the quality of outcome. Factors affecting whether to proceed include the quantitative and qualitative changes in risks and benefits.

# Consent for pediatric procedures without direct benefits

Pediatric anesthesiologists may encounter children undergoing bone marrow donation for siblings who would benefit from hematopoietic stem cell transplantation [23]. The stem cell donor receives no direct medical benefit from the donation. The major risks of donation are the anesthetic and the potential need for transfusion.

The benefit of donation is commonly considered to be the psychosocial benefit of helping a family member and pediatric donors report that the benefits of donations outweigh the physical harm [24]. As can be expected in such a complex dynamic, however, donation can result in moderate post-traumatic stress. Some donors felt they did not have a choice about being a donor and that they may be responsible for unsuccessful transplants.

Given the risks and benefits and the unique position of families in society, the American Academy of Pediatrics believes it is ethically permissible for minors to donate bone marrow when certain requirements are met, including a close relationship between donor and recipient, a likelihood of benefit to the recipient and an absence of a suitable medically equivalent adult relative.

### The temporarily impaired parent

Chemically intoxicated parents may be disruptive, dangerous, and incapable of fulfilling surrogate responsibilities. Anesthesiologists should use the least restrictive means to protect patient and parent confidentiality while ensuring the safety of the child, the impaired parent, and others present [25].

Although it seems ethically and legally prudent to postpone routine treatment until informed permission and legal consent can be obtained from an unimpaired parent, anesthesiologists will have to weigh the benefits of postponement with the risk that impaired parents may not reliably return. It may be in the child's best interests to proceed with a routine procedure even thought the impaired parent is unable to give informed permission and legal consent. Anesthesiologists should consult with legal and risk management colleagues for guidance.

# **Molecular genetic testing**

The combination of genetic testing and electronic medical records permits anesthesiologists to be aware of testing used to confirm a diagnosis, determine carrier status or for asymptomatic testing for disorders of late onset [26]. While genetic testing provides substantial benefits, it can also do harm by informing people about their genetic lineage without the patient's consent or adequate preparation.

Whether to test is particularly hazardous with minors. Genetic testing may affect personal psychosocial development and business opportunities and removes the opportunity to choose whether to obtain that genetic information. Testing should be performed only when there are immediate medical benefits to the child or when there are medical benefits to a family member and no expected harm to the child. Otherwise, testing should be deferred until the child can display an understanding of the consequences of genetic testing [26].

# Forgoing potentially life-sustaining therapy

#### **Do-not-resuscitate orders**

Do-not-resuscitate orders enable patients to forgo potentially life-sustaining treatment (LST) because the likely burdens outweigh the potential benefits. Benefits of receiving LST may include prolongation of life (understanding that the continuation of biological existence without consciousness may not be a benefit); improved quality of life after the life-sustaining medical therapy has been applied (including reduction of pain or disability); and increased "physical pleasure, emotional enjoyment, and intellectual satisfaction" [27]. Burdens should be viewed from the patient's perspective and may include "intractable pain; irremediable disability or helplessness; emotional suffering; invasive and/or inhumane interventions designed to sustain life; or other activities that severely detract from the patient's quality of life" [27]. Benefits and burdens should be considered in terms of both short- and long-term goals.

Children with do-not-resuscitate orders seek benefits from procedures that decrease pain, provide vascular access, enable living at home or treat an urgent problems unrelated to the primary problem (e.g. fractures). Potential burdens from procedures may be due to either the resuscitation attempt or to function or cognitive decrements that may follow resuscitation.

The American Society of Anesthesiologists, the American Academy of Pediatrics and the American College of Surgeons recommend mandatory re-evaluation of the do-not-resuscitate order before going to the operating room [28–30].

Re-evaluating the order prior to surgery requires clarifying the goals for the procedure and end-of-life care through discussion with the patient, parents, and relevant clinicians such as surgeons and primary care physicians. Children should be involved in a developmentally appropriate manner. In practice, the re-evaluation of the do-notresuscitate order for the perioperative period should result in either full resuscitation or a goal-directed approach toward perioperative resuscitation.

Discussions with the relevant decision makers should emphasize the differences between the operating room and the ward. Perioperative care permits a more personalized, real-time determination of whether resuscitation efforts would be consistent with the end-oflife goals. In the operating room, specific clinicians care for the patient for a defined period of time. Detailed knowledge of the goals for end-of-life care permits anesthesiologists and surgeons to tailor the extent of resuscitation to the likelihood of achieving those goals. In the dynamic surgical environment, the ability to respond flexibly, based on goals, is necessary to allow clinicians to thoughtfully enact limits on resuscitation. Additional information to give decision makers is listed in Box 1.2 [30].

**Box 1.2** Components of the discussion to re-evaluate do-not-resuscitate orders for the perioperative period [29,30,32]

- Planned procedure and anticipated benefit to child
- Likelihood of requiring resuscitation
- Reversibility of likely causes that require resuscitation
- Description of potential interventions and their consequences
- Chances of successful resuscitation, including differences between outcomes to witnessed and unwitnessed arrests
- · Ranges of outcomes with and without resuscitation
- Discussion of the response to iatrogenic events
- Intended and possible venues and types of postoperative care
- Postoperative timing and mechanisms for resuscitation and for re-evaluation of limitations on resuscitation
- Establishment of an agreement through a goal-directed approach or revocation of the DNR order for the perioperative period
- Documentation

Do-not-resuscitate directives that list acceptable interventions (e.g. tracheal intubation, chest compressions, etc.) are impractical in the operating room. Reaching an agreement can be difficult because of unclear distinctions between anesthetic practice and resuscitation [31]. Inflexible directives increase the chance that physicians will get "caught" in a technicality that is inconsistent with the patient's desires. For example, a restriction on tracheal intubation that is intended to limit a lengthy intensive care unit stay is not intended to refuse a presumably short-term tracheal intubation resulting from opioidinduced apnea during monitored anesthesia care. This "do what I mean, not what I say" dissonance leads to physicians using their reasonable beliefs to violate directives. But using a system that requires physicians to violate patient directives to fulfill patient wishes will eventually result in unnecessary and harmful violations. In addition, it inexorably weakens the perceived importance of following policies and directives.

Goal-directed approaches permit patients to guide therapy by prioritizing outcomes (e.g. "I don't want to suffer in the ICU for 2 weeks before I die"). After decision makers define goals, operating room physicians can use their clinical judgment to determine whether and to what extent resuscitation will help achieve these goals. The decision about whether to use a certain intervention, such as chest compressions, will likely be more consistent with the end-of-life goals if the decision is made when the etiology of the event is known. This model encourages the ethically redoubtable strategy of trialing therapies. A trial of chest compressions that do not achieve specific goals provides evidence that continuing the therapy would be inconsistent with the goals of end-of-life care. Witnessed arrests in the operating room often have a better outcome than unwitnessed arrests due to the more immediate intervention and the greater likelihood that the cause of the arrest is known [29,32]. For these reasons, decision makers may choose to modify their previous limits on resuscitation for the perioperative period.

From clinical experience, the vast majority of decision makers that choose to use a goal-directed approach authorize temporary therapeutic interventions to manage quickly and easily reversible events, but reject those interventions that will likely result in permanent sequelae, such as neurological impairment or dependence upon life-sustaining technology [29]. For example, a brief bradyarrhythmia that responds to intravenous epinephrine and chest compressions would be consistent with the authorization to treat events that are temporary, easily reversible and unlikely to have significant sequelae. On the other hand, if the bradyarrhythmia resulted in an extended resuscitation, continued therapy would require unacceptable burdens that in any case would be unlikely to achieve the patient's return to previous functional status. In that case, it would be appropriate to cease resuscitation efforts.

This common goal-directed preference can be documented as "The patient desires resuscitative efforts during surgery and in the PACU only if the adverse events are believed to be both temporary and reversible in the clinical judgment of the attending anesthesiologists and surgeons."

The goal-directed approach requires determining the appropriate extent of postoperative therapy. Patients may want a trial of therapy before concluding that the burden of continuing therapy outweighs the benefits. In pediatrics, precisely defining and documenting postoperative plans is often less essential, because parents are often available in the postoperative period to make decisions regarding therapy. Parents are often cognitively capable of participating in discussions of withdrawal of therapy because they have already grappled with analyzing the benefits and burdens of end-of-life care. The presence of parents permits greater trials of perioperative resuscitation while still respecting the decision to limit the burdens.

# Barriers to honoring perioperative limitations on life-sustaining therapy

Barriers to honoring perioperative limitations on LST center on insufficient knowledge about policies, law, and ethics. Many anesthesiologists and surgeons still believe that do-not-resuscitate orders must be revoked when patients come to the operating room.

Others worry, wrongly, that honoring limitations on LST may result in being sued. Statutes that address requirements for do-not-resuscitate orders often include immunity provisions that protect physicians from liability [33]. Indeed, the risk of liability for honoring an appropriately documented do-not-resuscitate order is likely to be lower than the risk of not honoring it [33].

Perhaps a more subtle barrier to honoring these directives is the response of clinicians to iatrogenic events [34]. Some anesthesiologists will initiate resuscitation solely because the etiology was iatrogenic rather than the patient's disease [35-37]. But by instituting perioperative limitations on LST, decision makers have declared that their sole concern is the physical and mental status following the arrest [38]. Anesthesiologists should initiate and continue resuscitation based solely on achieving the patient's goals.

Attitudes affect end-of-life care [39-41]. Clinicians are more likely to honor a refusal of resuscitation for a palliative procedure than for an elective procedure [30]. Clinicians prioritize imminence of death when considering the appropriateness of a patient's desire to limit LST while patients, on the other hand, prioritize functional status when choosing to refuse LST [34]. This dissonance affects the ability of clinicians to implement perioperative LST.

# Concepts of inadvisable care and futility

Most of the confusion surrounding the concept of futility comes from imprecise terminology [42]. Futile therapy should be considered as treatments that cannot accomplish a specific, intended goal. In that sense, dilemmas about whether to use futile therapy rarely arise. Treatments with low likelihood of success, on the other hand, may be considered inadvisable because of the benefits and burdens of proceeding, but they cannot be considered futile. A treatment may be considered inadvisable because of burdens to the child, cost or uncertain benefit.

At the clinician level, discussions about inadvisable care center on the benefits and burdens to the child. Qualitative and quantitative considerations should be defined carefully and physicians should explain whether the information used to form the estimation is based upon intuition, clinical experience or rigorous and sufficiently relevant scientific studies. Complicating matters is the dubiety in predicting the likelihood and range of outcomes of therapeutic interventions in very young children. In the end, in the absence of national standards, *decision making for a child near the end of life should be based on the best interests of the child and not on cost*.

Hospitals should have established processes for resolving conflicts. However, the ethical underpinnings of conflict resolution prioritize parental preferences as determined by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (Table 1.2) [4]. Clinician preferences only supersede parental preferences if a therapy is clearly beneficial.

 Table 1.2 Suggested grid for resolving disputes about appropriate care (modified) [4]

	Parents prefer to accept treatment	Parents prefer to forgo treatment
Physicians consider treatment clearly beneficial	Treat	Provide treatment during review process
Physicians consider treatment to be of ambiguous or uncertain benefit	Treat	Forgo
Physicians consider treatment to be inadvisable	Review	Forgo

# Withdrawing mechanical ventilation therapy

The extent and type of sedation given when mechanical ventilation therapy is being withdrawn should be based on benefits and burdens. The benefits of administering sedation to minimize discomfort and suffering usually outweigh the burdens of an ever-diminishing likelihood of survival. Providing skillful withdrawal therapy is difficult and anesthesiologists should not assume that without training or experience they can provide highquality end-of-life care [43-45]. Anesthesiologists should not use paralytic agents to hide patient movements during withdrawal of therapy [46]. Even though patient movements may upset parents, use of paralytic agents will hide the signs of distress that physicians use to titrate analgesia and sedations. Explaining this to family members may help them tolerate otherwise upsetting movements or event.

# Other topics in pediatric anesthesiology

#### **Research in pediatric patients**

The anesthesiologist Henry K. Beecher was one of the first to recognize that research in pediatric patients requires greater oversight than research in adults [47]. Research subjects requiring surrogate consent are vulnerable to abuse. Pediatric research exposes children to unknown risks of long-term harm because research interventions occur during growth and development of the child.

The increased risk of harm and lack of direct benefit to the child increase the obligation to obtain the developmentally appropriate assent from the child. This obligation is not always met, particularly in diseases that have a strong emotional overlay, like cancer [48,49]. Assent may be waived if there is the prospect of direct benefit to the child that is available only through participation of research. Although undesirable, assent also may be waived if the study exposes the child to no more than minimal risks or if the study could not sensibly proceed without the waiver [50,51].

Federal guidelines define four categories of pediatric research (Box 1.3). The hallmark of these categories is that potential benefits must increase commensurate with potential risks. Most controversy about pediatric research relates to the interpretations of minimal risk and minor increase over minimal risk [52].

Minimal risk is defined as "the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests" Box 1.3 Federal classifications for pediatric research [50]

#### Research not involving greater than minimal risk

- (a) Institutional review board (IRB) determines minimal risk
- (b) IRB finds and documents that adequate provisions are made for soliciting assent from children and permission from their parents or guardians

#### Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual subject

- (a) IRB justifies the risk by the anticipated benefit to the subjects
- (b) The relation of the anticipated benefit to the risk is at least as favorable as that presented by available alternative approaches
- (c) Adequate provisions for assent and permission

Research involving greater than minimal risk and no prospect of direct benefit to individual subjects, but likely to yield generalizable knowledge about the subject's disorder or condition

- (a) IRB determines the risk represents a minor increase over minimal risk
- (b) The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social or educational situations
- (c) The intervention or procedure is likely to yield generalizable knowledge, which is of vital importance for the understanding or amelioration of the subject's disorder or condition
- (d) Adequate provisions for assent and permission

Research not otherwise approvable which presents an opportunity to understand, prevent or alleviate a serious problem affecting the health or welfare of children

[50,51]. The common interpretation is that minimal risk refers to risks encountered by healthy children, such a playing sports and riding in a car [53,54]. Some use a more relative interpretation, basing the standard of "daily life" on the events to which children enrolled in the research are routinely exposed. In other words, if a child enrolled in the study routinely receives lumbar punctures as part of therapy, then it may be acceptable to expose a child to the risk of a lumbar puncture for study purposes.

The category "greater than minimal risk and no prospect of direct benefit to individual subjects, but likely to yield generalizable knowledge about the subject's disorder or condition . . . which is of vital importance" defines when it is acceptable to expose a child to a "minor increase over minimal risk" [50]. "*Minor increase over minimal risk*" has been interpreted as pain, discomfort or stress that is transient, reversible and not severe [53]. Risk assessment is based on the combined exposure to risks throughout the study and the relationship between the risks and the patient population. For example, although drawing blood in healthy 15 year olds may be considered acceptable, drawing blood from 15 year olds with severe autism spectrum disorder may be unacceptable because their inability to understand may cause intolerable stress [55].

"Condition" is used to mean characteristics "that an established body of scientific or clinical evidence has shown to negatively affect children's health and wellbeing or to increase the risk of developing a health problem in the future" [53,55]. For example, consider a protocol to assess insulin resistance in obese children who do not have type II diabetes. If the investigator presented sufficient scientific support to the institutional review board that obese children are at increased risk of developing diabetes because of their obesity, then those obese children would be acceptable research subjects for this study. Svelte children would not be acceptable, because they would not be considered at risk for developing diabetes [55].

Stringent regulations certainly hinder necessary and beneficial research [56,57]. But regulations are often responses to previous transgressions. At some point, relaxation of regulations will reanimate the abuses that beget the regulations. It is difficult to identify that line until it is crossed.

Improving the institutional review board process may minimize the inaccurate estimations of risk that hinders appropriate research and permits inappropriate research. An individual's intuition about the risk level of an activity is hampered by cognitive biases, such as familiarity, control of activity and reversibility of the potential harms [54]. Systematizing evaluation of research risks may reduce inaccurate estimations of risk. One approach is to use a standardized scale to categorize the extent and likelihood of each potential harm and then compare the potential harms with comparative activities [58].

#### Advocacy and good citizenship

Physicians owe their ability to train, practice and thrive to society's largesse. The implicit social contract therefore obligates physicians to manage matters within their sphere of influence, with a special obligation to address issues that "directly influence individuals' health" in the physician's community [59,60]. "Community" may refer to a physical location or a type of patient to whom the physician is particularly obligated. Pediatric anesthesiologists have a special obligation to further pediatric healthcare.

Pediatric anesthesiologists have actively taken up this obligation (Fig. 1.1). One of the more notable activities has been the development of specialty organizations, like the Society for Pediatric Anesthesia and the American Academy of Pediatrics Section on Anesthesiology and Pain Medicine. Organizing engages the wisdom and energy of like-minded individuals to identify concerns, define goals and implement solutions. For example, the pediatric anesthesiology fellowship programs advocated becoming an ACGME-accredited fellowship to ensure a standard for training programs for pediatric anesthesiologists [61].

Collaborative projects gather data about rare events to help determine ways to prevent them. The Pediatric Perioperative Cardiac Arrest Registry began in 1994 and has provided useful information in understanding the causes of pediatric cardiac arrest. Wake Up Safe is a similar registry designed to assess serious adverse events and recommend how they can be prevented. It is every anesthesiologist's obligation to participate in efforts like these.

**Figure 1.1** Obligations of pediatric anesthesiologists. Pediatric anesthesiologists are obligated to these four communities. Individual anesthesiologists are not expected to fulfill every obligation. "Units" of anesthesiologists such as private practice groups, academic departments, and state societies should fulfill these obligations collectively. A few examples are given. Physicians should fulfill obligations to society by participating in activities that are consistent with the individual's "expertise, interests and situations" [60]. For pediatric anesthesiologists, one appropriate approach would be to participate in the initiatives of relevant professional organizations. Anesthesiologists should consider addressing relevant public health issues such as pediatric obesity, pediatric tobacco use and second-hand smoke, and socio-economic disparities in healthcare and healthcare access [60,62–64].

#### Safety and quality care initiatives

Anesthesiologists have an obligation to foster patient safety. This obligation requires participation in surveillance data collection and compliance with policies intended to improve care, such as perioperative time-outs to ensure the right patient is receiving the right procedure [65,66]. Implementation of seemingly unnecessary policies often meets with resistance but it is difficult for individual physicians to appreciate the broad perspective from their individual perches. Anesthesiologists need to accept the limitations of their vantage point and willingly incorporate safety activities to further the common good. But they also should voice concerns through appropriate channels about poor or inadequate policies. Resorting to workarounds prevents policy remediation and encourages selective following of policies, which in turn causes more medical errors.

#### Apology and disclosure

Parents wish to be informed about medical errors that harm or may harm their children [67,68]. They also wish to receive appropriate apologies. Yet clinicians discount these clear desires. Barely half of pediatricians would disclose a serious error and fewer than a quarter would apologize for the same error [69]. Principles of respect of autonomy and truth-telling require physicians to be forthright about medical errors.

Most arguments against apology about and disclosure of errors center on increasing the risk of being successfully sued and on protecting the patient from unnecessary anxiety regarding the event or future care. Upon examination, these arguments are weak. An apology is an expression of regret or sorrow. A sincere apology followed by actions consistent with regret is invaluable; an insincere apology is costly. Even though more than half the states have laws prohibiting the admission of apology or sympathy as evidence of wrongdoing, it is conceivable that an apology may increase the risk of being sued or losing a suit [70]. But lore and literature indicate that the best protection against being sued is a good patientdoctor relationship [14]. Hiding, dissembling or being indifferent about an event will likely do more to galvanize a lawsuit and destroy trust than a sincere apology.

For example, some recommend apologizing for the effect on the patient but not to take responsibility for the actual event. This apology is appropriate for a rash caused by an appropriately administered antibiotic but it seems bizarre not to take responsibility when an anesthesiologist errantly injects a neuromuscular blocking agent instead of an anticholinesterase agent when attempting to antagonize muscle relaxation. Common sense suggests that not taking responsibility in that case (unless there was a good reason) would aggravate parents.

Thoughtful full disclosure should commence upon recognition of the problem [71,72]. Ethics aside, anesthesiologists should ignore the temptation to withhold disclosure. Parents will eventually learn what happened and will wonder, likely with animosity, why such information was withheld. Anesthesiologists should share what is known but should not make assumptions about what is not known, particularly about fault. Decision makers should be informed about the medical implications of the event and any necessary treatment. Because disclosure is a process over time, the patient and family should be given a contact person who will be available to answer questions, arrange meetings, explain the results of the investigation and describe the plan to prevent comparable events.

Parents are naturally sensitive about the perioperative experiences of their children. Anesthesiologists should consider apologizing or at least sympathizing about unpleasant experiences such as multiple, painful attempts to insert an intravenous catheter or an out-of-control inhalation induction of anesthesia. These discussions can include an acknowledgment that it was a bad experience and recommendations for the future. For example, an anesthesiologist could say, "I am sorry the intravenous catheter took so many sticks" and "Next time, we should probably give oral sedation prior to attempting the intravenous catheter." These comments simply acknowledge what happened, express regret and educate the family for the future.

#### **Production pressure**

Production pressure is the ubiquitous "internal or external pressure on the anesthetist to keep the operating room schedule moving along speedily" [73]. As a consequence, anesthesiologists may feel pressure to curtail preoperative discussions, inadvisably proceed with cases or prematurely extubate the trachea to speed turnover. Anesthesiologists should be aware of pressures to provide anesthesia inconsistent with their level of skill or to permit surgery in inappropriate settings. For example, the "routine" tonsillectomy for a child with achondroplastic dwarfism may be too complex for some anesthesiologists or some surgery centers. Anesthesiologists have an obligation to their patients and to themselves to only provide care for which they are competent and to recognize when economic and administrative pressures induce them to do otherwise.

#### Suspicion of child abuse

Physicians are legally obligated to report even the suspicion of child abuse [74,75]. It is natural to downplay concerns because of a hesitancy to inform authorities, particularly if the parents are from a socio-economic class similar to the physician's. But child abuse should never be minimized as a one-time event. Early intervention minimizes disastrous consequences. Anesthesiologists may be the first to recognize child abuse because evidence of abuse frequently occurs on the arms, hands, head, face, neck, and mouth [76,77]. Signs of abuse include bruises or burns in shapes of objects, injuries that fit a biomechanical model (e.g. a handprint), fractures in infants and developmentally inappropriate injures that are not explained by the offered history. Anesthesiologists should be aware that child abuse might occur in the hospital during diagnostic or therapeutic care [78,79]. Munchausen by proxy is a type of abuse in which parents either cause or fictionalize clinical problems in their children [80]. The signs and symptoms of the resultant diseases are often difficult to explain coherently.

# CASE STUDY

This case study is designed to emphasize that superficially defining cases such as "a 17 year old wants to refuse transfusion therapy" overlooks relevant complexities; to examine the process and relevant factors in determining maturity for medical decision making in an adolescent; to provide an example of how dilemmas may be evaluated; and to provide an example of the content in an ethics consultation. Characteristics of consultations include clarifying medical issues, identifying stakeholders and their relative extent of influence, defining the ethical questions providing an assessment and issues, and and recommendation.

#### Summary

Seventeen-year-old Candace has a rare type of rhabdomyosarcoma. She presents for resection of a tumor intertwined with major blood vessels. Candace is a Jehovah's Witness and wants to refuse transfusion therapy during and after the resection of the tumor.

#### **Medical questions**

This type of rhabdomyosarcoma is too rare to be able to reliably predict outcome. The best guess, though, is a 5-year survival of 5–10%. While there is a low likelihood of significant bleeding during the operation, the position of major blood vessels presents the possibility of sudden, rapid and substantial bleeding.

#### Family

Candace is the daughter of Linda and Larry. Through a friend, Larry began exploring the Jehovah's Witness community 9 years ago and became baptized as a Jehovah's Witness 6 years ago. Linda describes herself as spiritual but

has no interest in organized religion. She very much supports the authority of Candace's decision making.

Candace "was very skeptical the first month of learning about [the Jehovah's Witness religion]. I had friends who had 'found' religion . . . but it never made sense to me." Jehovah's Witness "made sense to me, in an easy to understand manner. This is it, this is the right religion." Following thorough study, at age 14 she chose to become a baptized member to show her dedication to being a Jehovah's Witness.

Candace leads an active high school life. She is a starting wing on the field hockey team and she frequently participates in school theater productions. She leads bible study and weekly youth group meetings. She is an accomplished public speaker, speaking to groups "over 100 people" about being a Jehovah's Witness.

Linda and Larry like the person Candace has become. Candace, Linda and Larry share decision making about family matters. They have the normal disputes about things like curfew.

Candace is an active participant in her care. She asks appropriate and extensive questions about options and short- and long-term implications.

In private discussions with Candace, she emphasized that she did not want to die. However, because she believes that Bible and God forbid taking blood, receiving blood would fill her with incredible guilt and sadness because she had disappointed her God. While she was concerned that taking blood would separate her from God, her primary concern was the overwhelming sense of failing her God. When asked whether being transfused forcibly or while unconscious would ease her conscience, she answered that she would feel the same because she had actively put herself in a position in which she could involuntarily receive blood. She equated being transfused forcibly while unconscious as "rape." She stated in a factual and calm way that "if I woke up and found I was getting blood, I would rip it out of my arm."

Candace coherently articulates her religious and spiritual faith. Her beliefs are consistent with the teachings of her chosen faith community. She views herself as able to reason and be responsible for acting on personal moral judgments. She can imagine separating from the Jehovah's Witness community if so guided by her conscience.

#### **Ethical questions**

- **1.** If individuals of majority age have the right to refuse potentially life-sustaining transfusion therapy, do minors have this right?
- **2.** What characteristics and criteria can be used to determine whether a minor possesses sufficient decision-making capacity and maturity to make this decision?
- **3.** What issues should be discussed to ensure that their desired blood therapy wishes be followed?

Maturing adolescents are granted increasing authority in decision making. Relevant characteristics that give evidence of adolescent maturity and decision-making capacity include an understanding of their options and associated consequences, an internally coherent rationale, an ability to articulate their positions, an intellectual and emotional freedom to entertain alternative perspectives, and an indication of mature relationships with older individuals. Not all characteristics need to be present for an adolescent to be considered mature. The threshold for the evidence necessary to have decision-making capacity for a specific decision increases as the consequences of the decision increase.

The case of Phillip Malcolm describes a child without decision-making capacity. Phillip and his parents were not permitted to refuse transfusion when the almost 18-year-old Phillip was acutely diagnosed with severe anemia and cancer [81]. Transfusions were recommended to stabilize his clinical status. The court learned that although the family had joined the religion 3 years earlier, Phillip did not become interested until 1 year ago. Phillip understood the "basic tenet of the religion's prohibition regarding blood transfusions" but had rudimentary knowledge about the Bible. He did not consider it a sin if the court ordered a transfusion. Phillip had not shown independent or shared decision making in his relationship with his parents.

Legitimate concerns about adolescents being overly influenced by short-term consequences should not be tainted by less relevant concerns that preferences may change as adolescents become older. Mature individuals are able to change their minds based on experience and evidence. That adolescents may change their mind as they mature does not invalidate current choices inasmuch as sufficient decision-making capacity is present.

Pragmatism affects considerations about whether to force adolescents to receive undesired healthcare. Adolescents are most capable of physical protest, either by yanking intravenous catheters or by not presenting for therapy. For example, Billy Best, a 16 year old with Hodgkin lymphoma, ran away so that he would not have to complete his chemotherapy regimen [9]. On the other hand, following an accident, 16-year-old Greg Novak was thought to urgently require transfusion therapy [82]. Being Jehovah's Witnesses, Novak and his parents refused transfusion therapy. However, a court-appointed guardian requested transfusion therapy. Novak was physically restrained and transfused.

#### Assessment

The advisory committee believes that Candace meets the requirements of being a mature individual with substantial decision-making capacity who understands the gravity of her choice. Her active participation outside the Jehovah's Witness community indicates a wider view of the world rather than a more narrow view that may be present with exposure only to the Jehovah's Witness community. Given her beliefs and her extensive missionary and teaching activities, we believe that she has thoughtfully chosen to become a Jehovah's Witness. She has a loving and comprehensive relationship with her parents. Although her refusal of potentially life-sustaining therapy may lead to significant morbidity or death, we believe she exceeds the criteria to make these decisions.

#### **Recommendations**

- **1.** The committee believes that Candace should be considered primary decision maker.
- 2. We are aware that the surgeon requests a court order permitting Candace to be able to consent for refusal of potentially life-sustaining transfusion therapy. We encourage Candace and her family to seek as much information about this process as possible, including the process of seeking this status, the possible drawback of pursuing and securing mature minor status, the role of the parents after achieving this status and the use of healthcare proxies. A court order may minimize chances that wayward individuals may transfuse Candace.
- **3.** To ensure fidelity in regard to the hospital's implicit promise to honor her preferences, a cadre of clinicians committed to honoring Candace's wishes must be identified. Necessary clinicians include operating room nurses and technicians, anesthesiologists, trainee *Continued*

anesthesiologists and surgeons, and postoperative nurses and physicians, particularly ICU physicians. Arrangements must be made to ensure willing clinicians in case of an emergency reoperation. The needs of these clinicians (e.g. to meet Candace) should be met.

**4.** This consultation is solely advisory. Our comments are restricted to the ethical interpretation of the issues facing Candace, her family and the care team. You may wish to contact the Office of Legal Counsel for their input on existing regulations as well.

*Postscript*. A court order granted Candace the authority to make decisions about transfusion therapy. In informal conversation later, the judge declared that one of his primary considerations aside from Candace's maturity was the very low likelihood of survival. If her possible survival had been higher, he would have been much less likely to grant her the legal authority to make decisions about transfusion therapy.

# Introduction

# Any examination of the history of pediatric anesthesiology requires considering the general history of the specialty of anesthesiology as well as the contexts in which changes in the specialty have occurred over time. We shall review the relatively short time over which today's widely recognized subspecialty began, grew and matured, mostly within the past 60 years. Early pediatric anesthesiology practitioners, some still living today, will be noted. These can fairly be termed pioneers or foundation makers. It is also necessary to describe the close interplay between pediatric anesthesiology practitioners and their colleagues in general and cardiovascular surgery, neonatology, critical care medicine and pain medicine. Although short by most historical standards, the specialty's history is rich in achievement, whether one considers the beginnings from the 1840s to the 1940s, the acceleration of growth from about 1950 to 1990, or the maturation of our specialty into its current status. We continue to expect further accomplishments in children's healthcare in the 21st century.

# Inhalation of ether marked the initiation of modern anesthesia. The person who gave the first anesthetic is no longer in doubt; it was Dr Crawford Long (Fig. 2.1) in Jefferson, Georgia, in 1842. His report of his activities was delayed until 1849 [1]. Thus, the dentist William T.G. Morton (Fig. 2.2) is recognized as the first to publicly demonstrate ether anesthesia in Boston in October, 1846 [2]. The published report of this success, by the Boston physician Henry J. Bigelow, spread around the world both in knowledge and practice in less than 1 year [3].

The first 100 years

Inhalation anesthesia in children began with Dr Long whose third patient in 1842 was an 8-year-old boy who underwent a toe amputation; this is reported in his 1849 publication. In London, John Snow (Fig. 2.3), now recognized as a founder of the specialty of anesthesiology, reported on inhalation anesthesia in both adults and children and marked the changes from ether inhalation to chloroform inhalation. He reported in 1857 a series of over 100 children less than 1 year of age. It is to Dr Snow that we owe the recorded observation that onset and

effect of inhaled anesthetics, in this case chloroform, occurred "more quickly" in infants and children than adults [4].

For the next 100 years it appears that large numbers of children were anesthetized successfully by both inhalation and regional techniques [5]. Chloroform inhalation, especially in unskilled hands, proved dangerous, even deadly. Its use, especially in the United States, was largely replaced by diethyl ether, commonly "ether." It was usually given by the "open drop" method, where the liquid ether was poured (dripped) onto a mask device covered in gauze mesh, which covered the patient's nose and mouth, so the patient's breathing vaporized the ether.

It required 75–80 years before sufficient technology developed to produce more accurate flow meters and more reliable vaporizers, making possible the shift from open drop to more sophisticated inhalation techniques.

Children in this era were treated like small adults. An evolutionary change in this attitude occurred only as the subspecialty of pediatric surgery began to develop in the late 1930s into the 1940s.

# Surgery and anesthesiology for children

Major advances in surgery for children developed in the hands of only a few, but one surgeon, William E. Ladd MD, at Boston Children's, can fairly be said to have laid the foundation for the development of pediatric surgery [6]. His work as a teacher and clinician was carried on by Robert M. Gross MD who first ligated a patent ductus arteriosus in 1939 [7]. While a signal accomplishment, the legacy of Ladd and Gross is probably best defined by the many surgeons whom they trained. This next generation had skills and ambitions which coupled well with developing skills of pediatricians to advance the surgical care of infants and children. This progress compelled further refinement in the techniques and skill needed by anesthesiologists.

# The 1940s and 1950s

In the decade before World War II, fundamental changes occurred which accelerated and matured in the decade after the end of the war. The most important major step was the establishment of the first academic anesthesia department at the University of Wisconsin under Ralph Waters. Waters-trained anesthesiologists became the leaders of the specialty in the 1950s, 1960s, and 1970s. The emphases in Waters' program were on clinical excellence, research, and education, a tradition carried on today among the "second and third generation" of Watersinfluenced leaders. Waters himself published his early experiences with a forerunner of outpatient anesthesia in his downtown anesthesia clinic [8]. He also contributed a device which allowed exhaled CO<sub>2</sub> adsorption by soda lime so that cyclopropane, a common anesthetic gas used well into the 1960s and 1970s, could be administered by to-and-fro breathing [9]. Although a now archaic method, the Waters canister added portability, reliability and utility for surgery lasting more than an hour. Its size was easily scaled down for pediatric practice and it was widely used through the 1960s.

Few anesthesiologists devoted themselves solely to pediatric practice prior to the 1950s [10]. In North America, Charles Robson (Fig. 2.4) at Toronto Sick Children's Hospital, starting in 1919, and in London, Robert Cope (Fig. 2.5) at the Hospital for Sick Children, Great Ormond Street (appointed 1937), were recognized pediatric anesthesiologists prior to World War II. These practitioners and their few trainees added clinical experience to the emergence of new knowledge about children's physiology and pathology, providing the basis for finally defining that infants and children were not small adults. Dr M. Digby Leigh (Fig. 2.6), who trained with Waters before World War II, became the anaesthetist-in-chief at Montreal Children's Hospital in 1940. In 1947, he published, with his associate Kay Belton, the English language text *Paediatric Anaesthesiology*, a first [11]. Dr Leigh moved to Vancouver in 1947 and organized the University Department of Anesthesia from the existing clinical departments at Vancouver General Hospital and the Infants' and Children's Hospitals. In 1954, he became

Figure 2.6 M. Digby Leigh. Reproduced with permission from Springer.

Director of Anesthesia at the Children's Hospital Los Angeles, and Professor of Anesthesiology at the University of Southern California. Dr Leigh continued for another two decades to be an outspoken teacher as well as an advocate for children, until his retirement in 1970. His contributions included descriptions of the use of spinal anesthesia in children, a low dead space, non-rebreathing valve and a scaled-down CO<sub>2</sub> absorber circle system, endotracheal anesthesia with avertin for cleft palate surgery, and bradycardia following succinylcholine in children. The annual teaching conference devoted to pediatric anesthesia at the Children's Hospital Los Angeles began under Dr Leigh's direction, and continues to this day.

The importance of Leigh's and colleagues' contributions, which established, maintained and taught high standards of anesthesia care for children, cannot be overstated. They resulted in significant early advances in the US, United Kingdom and Canada in the care of children undergoing surgery in the late 1940s, especially in the areas of airway care and respiratory physiology.

Another important evolution occurred in pediatric surgery: the earlier and better recognition of the complementary role required between anesthesiologists and surgeons. This mutual co-operation was essential to overcome the many and often previously unrecognized technical problems arising as surgical skills advanced and anesthetic techniques and agents improved. As events moved into the 1950s, the stage was set for explosive growth and change.

World War II (1941–1945 for the US) provided young physicians - both surgeons and anesthesiologists - with experience under widely varying conditions, but nearly all practiced with the growing confidence that technical hurdles could be overcome with skill and even daring. As this cadre of physicians returned to civilian practice, many sought further specialty training. These men, and almost all were men at the time, became the staff members of departments of surgery and anesthesiology in the 1960s and 1970s. Surgeons led by Ladd, Gross, and C. Everett Koop tackled increasingly complex pediatric problems requiring surgery. Robert M. Smith at Boston Children's (Fig. 2.7), Robert McQuiston at Chicago Children's and Herbert Rackow at Columbia in New York City began work in postwar departments which advanced training and practice in pediatric anesthesiology [12–15]. G. Jackson-Rees in Liverpool, England, developed the techniques of endotracheal nitrous oxide-oxygen inhalation with muscle relaxants (Liverpool technique), which Rees felt was especially useful in sick children and neonates [16]. Jackson-Rees modified a T-tube nonbreathing system originally devised by Ayre for use with an endotracheal tube in cleft palate repair [17] (Fig. 2.8). Versions of the Jackson-Rees system are in use today. The

Figure 2.7 Robert M. Smith. Reproduced with permission from Children's Hospital, Boston, MA, USA.

**Figure 2.8** (A) Operation of the Ayre's T-piece. During inspiration, the patient inspires fresh gas from the reservoir tube. During expiration, the patient expires into the reservoir tube. Although fresh gas is still flowing into the system at this time, it is wasted because it is contaminated by expired gas. In the expiratory pause, fresh gas washes the expired gas out of the reservoir tube, filling it with fresh gas for the next inspiration. In the reservoir tube, the volume must be greater than the patient's tidal volume, otherwise the inspired gas will be contaminated by the surrounding air. (B) Jackson-Rees modification of the Ayre's T-piece. Reproduced with permission from Ayre's T-Piece: Anesthesia Service and Equipment. http://asevet.com/resources/circuits/ayres.htm.

Ayre's T-piece and Jackson-Rees systems are valveless non-rebreathing systems (NRBS). Another, valved NRBS, much less frequently used today, also arose during this period: the Mapleson systems, in A-D versions, well recalled and equally loathed by several generations of candidates attempting to pass their American Board of Anesthesiology certifying exams [18].

The results of these early successful attempts to better control airway management and ventilation improved surgical outcomes further, raising expectations and demands for more anesthesiologists to continue or expand this level of care. Related evolutions in blood banking, fluid administration, thermal homeostasis and circulatory control or support all advanced interdependently with advances in surgical and anesthesia care. Examples of congenital problems successfully approached in this era include congenital heart disease, congenital diaphragmatic hernia (CDH) and problems in patients' developing gut, such as omphalocele, malrotation, and pyloric stenosis. The separation of conjoined twins began in this era as advancing techniques in diagnostic imaging became more accurate. It is further testament to the improved care of these infants that they are no longer brought to the operating room in extremis for urgent surgical correction.

Mortality remained high for these patients into the 1990s but with the application of extracorporeal membrane oxygenation (ECMO) to patients with CDH, mortality overall has been reduced in the last decade. However, problems, often severe, remain related to underdeveloped lung tissue on the herniated side. Anesthesia care for the patient with congenital heart defects has become a specialty of its own, with ever more complex procedures carried out on sicker and younger infants, with the expectation that mortality will remain low. It is beyond the scope of this chapter to address the progress that continues to be made in solving complex problems in this group of patients. However, early attempts at cardiac surgery by surgeons such as Blalock in Baltimore required skilled anesthesia care. This new era required thinking about circumstances that had never occurred before. Despite this, reports like those of Harmel on the care of patients undergoing repair of congenital pulmonary stenosis noted generally favorable outcomes under primitive conditions [19].

Pediatric anesthesiology, firmly established in the 1960s, continued to lead the field of general anesthesiology in the areas of monitoring vital function, airway control, sedation, and pain management. Equipment modification by manufacturers increased as large numbers of children required anesthesia care. Hand-fashioning basic equipment such as blood pressure cuffs as described by Dr Smith and others before him became a thing of the past [20]. It is worth noting that in many instances, the equipment modifications were often done by nurse anesthetists in the eras before 1960. Tracheal intubation, the indications and need for which continued to be argued into the late 1960s, became commonplace and a standard of care in infants and children [21]. Care of the wounded

during the Vietnam conflict along with the development of non-reactive plastic polymers for producing endotracheal tubes finally laid the arguments pro and con to rest, although problems with prolonged intubation were recognized in the mid-1960s [22]. Postintubation hoarseness ("croup"), a concern during the use of red rubber tubes, became less so with plastic tubes and is a rarity now. Pediatric precordial stethoscopy has been a hallmark of monitoring in anesthesia care since the 1950s, supplanted only in the last decade with the current monitoring applied to children, especially pulse oximetry.

Thermal homeostasis, with warm rooms, overheated surgeons, warm humidified respiratory gases and limb and head wraps, began in the 1950s; with the advent of forced warm air circulating blankets, temperature control is now much easier but remains a hallmark of quality patient care. The use of controlled hypothermia in cardiac surgery has a history of its own, beginning with McQuiston's report of its use in 1949 to reduce oxygen consumption [14].

### Unique contributions to pediatric anesthesia, neonatal, and intensive care: 1950s to 1970

#### The introduction of halothane

As new agents were introduced to practice, especially halothane in 1958, a new era emerged which permitted better control of perioperative conditions by the anesthesiologist [23]. Flammable agents were abandoned by the 1970s. Electrocautery became a primary mode for hemostasis, driving down past dangers of exsanguination in such conditions as the excision of sacrococcygeal teratoma.

#### Premedication

Premedication of the anxious child prior to the 1980s involved diverse agents and combinations of drugs administered by a variety of routes, which had a mixed history of consistent success in smoothing the transition from parents' arms to the operating room. Bachman and colleagues in Philadelphia advocated the use of a parenteral combination of pentobarbital, morphine and scopolamine to circumvent preoperative anxiety and its consequence: the screaming, agitated child [24]. Work published with his colleague, Freeman, followed earlier work by Eckenhoff in documenting regression of behavior postoperatively in the unpremedicated child [25]. Those early experiences, even though with a markedly different inhalation agent from those used now, seem to continue to resonate with current experience about the preoperatively agitated child.
# Neonatal and pediatric intensive care

The perioperative experience modified and supported by the practices of pediatric anesthesiologists built on experiences in these major areas: fluid requirements, antibiotic use, oxygen regulation and airway humidification. The era of polio epidemics in the 1950s showed the need for effective ventilation and respiratory care. The demonstrated effectiveness of continuing the airway control techniques from the operating room into the then new postanesthesia care unit illustrated the need to co-ordinate anesthesia practice methods, medications, and equipment beyond the operating room [26]. The growth of specialty practice pediatricians' ability to care for ill newborns, especially those with respiratory distress syndromes (RDS), produced neonatologists and the neonatal care unit, with early emphasis on respiratory support using intubation, oxygen supplementation and subsequently endotracheal ventilatory support. These efforts progressed into the late 1960s. Among the leaders were pediatric anesthesiologists Alan Conn in Toronto and Bachman and Downes in Philadelphia [27,28]. Gregory in San Francisco established early that continuous positive airway pressure (CPAP) was effective in improving survival in infants with RDS [29]. The stage was set for the rapid evolution of intensive care units.

First established in 1955 by Feychtung in Sweden, multidisciplinary pediatric intensive units were opened in Liverpool and Melbourne between 1960 and 1964. John Downes established the first North American unit in 1967 at the Children's Hospital of Philadelphia, and in the following 4 years, such units were established in Pittsburg, New Haven, Boston (Massachusetts General Hospital), and Toronto [30].

Diverse contributions from fields outside pediatrics greatly influenced and improved care of critically ill pediatric patients. In the 1950s and 1960s, the development of transistors and integrated circuits permitted large improvements in miniaturization of equipment, and the development of ventilators with complex cycles to better support ventilation. Primary pediatric ventilator computers allowed real-time monitoring and trend analysis with ever more compact equipment. The development of nonreactive extrudable plastic polymers produced better tracheal tubes and more effective and smaller means for vascular access equipment.

# Virginia Apgar: the Apgar score

Virginia Apgar (Fig. 2.9) was a pediatric and obstetric anesthesiologist at Columbia University in New York City, trained under the auspices of Ralph Waters in Wisconsin and Emery Rovenstein at Bellevue Hospital. Using the skills of astute clinical observation so common in the pioneers of that era, she devised the famous Apgar score to assess the circulatory and respiratory status of

Figure 2.9 Virginia Apgar. Reproduced with permission from Columbia University Library. http://library.cpmc.columbia.edu/hsl/archives/ HSTimeline.html, accessed August 8, 2010.

the newborn infant, which is universally utilized today throughout the world and has improved the assessment, research, and care of neonates ever since. It is appropriate that her first report of the Apgar score was published in the journal *Anesthesia & Analgesia* [31].

Box 2.1 summarizes some of the major developments in pediatric anesthesiology from 1842 until the late 1960s.

# The modern history of pediatric anesthesia: major pediatric anesthesia research and clinical advances, late 1960s to 2010

Since the late 1960s there have been a number of seminal contributions by pediatric anesthesiologists that have greatly advanced our knowledge of the pathophysiology of conditions encountered in pediatric anesthesiology, surgery, and intensive care and significantly improved the outcomes and experiences for patients. These achievements further spurred the development of the subspecialty of pediatric anesthesia and define the modern history of the field. Several of the important advances are detailed in this section.

# **Malignant hyperthermia**

The familiar story of the 21-year-old young man with the tibial and fibula fracture who underwent halothane anesthesia in 1960 in Melbourne, Australia, and had the first recognized case of malignant hyperthermia (MH) led

**Box 2.1** Major developments in pediatric anesthesia, 1842–late 1960s

- First description of general anesthesia in a child by Long (1842)
- Snow's series of general anesthesia: over 100 infants less than 1 year (1857)
- Robson becomes Chief of Pediatric Anesthesia at Toronto Sick Children's Hospital (1919)
- Ayre's T-piece developed (1938)
- Harmel and Lamont's first description of anesthesia for congenital heart disease (1946)
- Smith appointed director of anesthesia at Children's Hospital Boston (1946)
- Leigh and Belton publish first textbook of pediatric anesthesia (1947)
- Apgar devises and publishes newborn resuscitation score (1953)
- Jackson-Rees produces his modification of the Ayre's T-piece, studies curare and develops the Liverpool technique of controlled endotracheal ventilation with muscle relaxation for surgical anesthesia (1950–55)
- Keats' descriptions of anesthesia for open heart surgery in infants (1955–60)
- Denborough's description of malignant hyperthermia (1960)
- Establishment of multidisciplinary pediatric intensive care units (1955–67)

to the recognition by 1970 of a number of additional cases, and a realization that children under the age of 18 comprised the majority of patients [32]. In the ensuing 40 years, the work of anesthesiologists, both pediatric and adult, as well as basic scientists and geneticists has made major advances in discovering the etiology, triggering agents, prevention, testing, and treatment of this disease.

The discovery that all potent halogenated inhalation agents and succinylcholine are triggering agents has allowed anesthesiologists to avoid these drugs. The widely published clinical descriptions, case series, and grading scales have increased early recognition of this disorder, and the discovery that dantrolene treatment can control the hypermetabolic state has greatly reduced the mortality of an MH episode. The advent of the halothanecaffeine contracture test to help determine susceptibility, and the genetic mutation of the ryanodine receptor on chromosome 19 present in some MH patients, has greatly improved identification of susceptible patients [33]. All these advances have decreased the rate of an MH episode with general anesthesia from approximately 1:5000 anesthetics in the 1970s to 1:100,000 today. In addition, when an MH episode does occur, the mortality rate has decreased from 70% to 5% or less. The MH success story is an excellent example of anesthesiologists recognizing a significant problem and, through basic, translational, and

clinical research, transforming this disease into one that is manageable.

### Postanesthetic apnea

With the advent of neonatal intensive care in the 1960s and 1970s, more premature infants required anesthesia and surgery. The special set of problems occurring in this fragile group of patients soon became evident. In 1981, Gregory reported that 25% of preterm infants had apnea after general anesthesia [34]. In 1982, Steward reported that six of 33 premature infants experienced apnea [35] and in 1983, Liu et al, in the first prospective study of 41 premature and 173 full-term infants, reported that six of the premature infants had postanesthetic apnea [36]. These reports resulted in widespread awareness of the problem, and in yet larger clinical studies that defined a risk profile, including anemia, pre-existing apnea, younger gestational age at birth and during anesthesia, and use of IV sedation during regional anesthesia. The resulting improvement in perioperative outcomes in premature infants has been significant, and the change in anesthetic practice to avoid elective anesthetics in vulnerable patients, and to institute postoperative cardiorespiratory monitoring in those who must undergo anesthesia, has prevented a large number of adverse events in these patients.

### High-dose fentanyl for neonatal anesthesia

Another problem that became evident with the advent of neonatal intensive care was the patent ductus arteriosus (PDA) in the premature infant, which would lead to congestive heart failure, pulmonary edema, and respiratory insufficiency. Once again, pediatric anesthesiologists had a major role in the recognition of this condition and its treatment. The neonatal intensive care physicians at the University of California in San Francisco, including Gregory, were the first to publish a series of patients with this condition, including diagnosis and surgical treatment [37]. However, it was evident in those early days that even with successful surgical closure, these premature infants had a high mortality rate postoperatively, with nine of 21 dying of respiratory insufficiency or bowel ischemia. Of the 21 infants, 10 received halothane, nine fluroxene, and two ketamine. Other anesthetic regimens in use at that time for PDA ligation included N<sub>2</sub>O, oxygen, and d-tubocurarine.

Responding to the concerns over hemodynamic instability from halothane or insufficient anesthesia when only  $N_2O$  was used, Robinson and Gregory published a series of 10 premature infant PDA ligations using 30–50µg/kg of fentanyl as the anesthetic [38]. This anesthetic prevented an increase in systolic blood pressure and heart rate in response to incision and provided excellent hemodynamic stability. This publication ushered in the era of high-dose opioid anesthesia for unstable premature and full-term neonates, exemplified by the pioneering work of Anand and Aynsley-Green who demonstrated with a controlled study design that the addition of fentanyl to nitrous oxide anesthesia dramatically reduced the hormonal stress response in premature neonates undergoing PDA ligation [39]. This was followed by a controlled trial of halothane-morphine versus high-dose sufentanil in full-term neonates undergoing complex cardiac surgery with cardiopulmonary bypass, demonstrating a similar reduction in stress response, and a significantly lower mortality, with opioids [40]. These contributions permanently changed the practice of neonatal anesthesia.

### Age and anesthetic requirement

Halothane became available in 1958 and as the advantages of this agent were evident, including minimal pungency and airway irritation, allowing for a smooth inhalation induction in children, there were reports that young children required higher inspired halothane concentrations for induction and maintenance of anesthesia. In 1969, Gregory, Eger, and Munson published their landmark paper entitled "The relationship between age and halothane requirement in man" and for the first time there were data substantiating the clinical impression that young children did require more anesthesia, and an objective measure, the minimum alveolar concentration (MAC), was used to demonstrate this [41]. (That the elderly required less anesthetic was also reported in this paper.) This model became the framework for the more detailed and precise study of later anesthetic gases including isoflurane, desflurane, and sevoflurane, including specific studies of the full-term neonate less than 30 days and also the premature infant [42]. The important knowledge that different agents behave differently, and that the premature infant requires dramatically reduced concentrations of the halogenated agents, arose out of these early data, generated by a pediatric anesthesiologist who was an expert clinician, precise observer, and clinical scientist who devised rigorous studies to answer this important clinical question.

## Latex allergy

In the late 1980s case reports and case series began to appear describing severe anaphylactic reactions, some fatal, apparently in patients sensitized to natural latex proteins from surgical gloves and other medical devices and equipment [43]. Many of these were pediatric or young adult patients with a history of multiple surgical procedures during childhood, with procedures such as myelomeningocele repair or other surgeries where a mucosal surface had prolonged exposure to the surgeon's gloves. By the early to mid 1990s there was widespread recognition of this problem and through the efforts of many pediatric anesthesiologists, allergist-immunologists, and others, the at-risk patient population was better defined, skin and serum testing was developed and validated, and protocols for pretreatment and for the provision of latex-free environments for at-risk patients were developed [44]. With advocacy by pediatric anesthesiologists, patient groups, and others, latex products were gradually replaced with latex-free substitutes and at the present time the operating room and anesthetic environment are virtually latex free, and the problem of anaphylaxis to latex has essentially disappeared. Overcoming the latex allergy problem is another example of the leadership of pediatric anesthesiology in identifying and solving problems to improve patient care and outcomes.

# **Out-of-operating room anesthesia**

Since 1990, the rapid and sustained increase in diagnostic and therapeutic procedures in children done outside the operating room setting has necessitated that children undergo sedation and anesthesia with increasing frequency, especially for procedures such as magnetic resonance imaging (MRI) examination. Pediatric anesthesiologists worldwide have assumed a major role in both providing these services and in developing and supervising hospital programs for non-anesthesiologists to provide this sedation. Pediatric anesthesiologists have been leaders in establishing safe guidelines for monitoring, drugs and doses, recovery and discharge, and screening, evaluation, and triage of patients [45-47]. These efforts have greatly increased the safety of these procedures and improved outcomes. Indeed, up to 25% or more of anesthetics delivered by many pediatric anesthesia programs are now outside the operating room and have extended to such areas as endoscopy and bronchoscopy suites, interventional radiology, bone marrow aspiration/intrathecal chemotherapy, auditory brainstemevoked responses, botulinum toxin injections, and many other locations and modalities. These developments in the recent history of pediatric anesthesia have permanently changed practice as the advantages of expertise in providing pain-free and minimally stressed experiences for children have been recognized.

# Pediatric Perioperative Cardiac Arrest Registry

The Pediatric Perioperative Cardiac Arrest Registry (POCA) was formed in 1994 under the auspices of the AmericanAcademy of Pediatrics Section on Anesthesiology and the American Society of Anesthesiology [48]. Its purpose was to investigate the causes of cardiac arrest under or soon after anesthesia in children, with the eventual goal of preventing these devastating events. As such, the POCA was a pioneer of a multi-institutional outcomes registry and database, with voluntary anonymous reporting of major adverse events in great detail, with a panel of experts assigning a cause. In a series of landmark reports, the POCA has demonstrated that infants under 1 year of age account for the majority of anesthesiarelated cardiac arrests [48], and that halothane was a major cause of medication-related cardiac arrests, which diminished greatly after the drug was replaced by sevoflurane [49].

Cardiovascular causes account for about 40% of cardiac arrests [49]. In addition, the dramatically higher number of reports of cardiac arrest in patients with underlying congenital heart disease, as well as the lower rate of successful resuscitation, has highlighted the vulnerability of this group of patients [50]. The early leadership of pediatric anesthesiology in pioneering this approach to improving quality and outcomes qualifies the POCA Registry for a place in the recent history of the specialty.

### Pediatric cardiac anesthesia

Congenital heart disease is present in about eight per 1000 babies born worldwide, and is one of the most common birth defects, and is the most common defect requiring invasive treatment, including surgery. As such, the development of congenital heart surgery in the 1950s obligated the development of the field of pediatric cardiac anesthesia. The most prominent early pioneer in this field was Arthur S. Keats MD (Fig. 2.10), working at Texas Children's Hospital with the surgeon Denton A. Cooley. From 1955 to 1970, this team performed more surgeries for infants and children than any in the world, and Keats' numerous publications of anesthetic techniques and surgical outcomes from that era give us an important perspective of the daunting task facing these physicians. The descriptions of approaches to premedication, airway management, induction and maintenance of anesthesia, arrhythmias and their intraoperative treatment, perfusion, and the invention of a postoperative mechanical ventilator in 1958 set the standard for many of our modern practices [51–53]. Among other Keats landmark descriptions was anesthesia for cardiac catheterization in children in 1958 and the reversal of heparin with protamine in 1959 [54,55]. The importance of these early contributions by Keats and colleagues to the development of pediatric cardiac anesthesia as a subspecialty cannot be overstated.

In the 1970s and 1980s Hansen and Hickey at Children's Hospital, Boston, encouraged by the surgical leadership of Dr Aldo Castaneda, established the first anesthesia service dedicated solely to providing care to infants and children undergoing surgery, and other procedures in infants and children with cardiac disease. Among their many contributions was the description of anesthesia for

Figure 2.10 Arthur S. Keats MD. Reproduced with permission from Baylor College of Medicine, Houston, TX, USA.

the first Norwood Stage I palliation of hypoplastic left heart syndrome, high-dose fentanyl and sufentanil for complex neonatal cardiac surgery and its ablation of the stress response leading to improved survival, a description of anesthetic complications, and a recognition of, and treatment strategies for, severe perioperative pulmonary hypertension in infants undergoing congenital heart surgery [56–59].

In the late 1980s and early 1990s Greeley and co-workers at Duke were among those pediatric anesthesiologists making important contributions to the field of congenital cardiac anesthesia and surgery. The first was a landmark series of clinical studies using Xe<sup>133</sup> technology to measure cerebral oxygen consumption during cardiopulmonary bypass and deep hypothermia, including circulatory arrest. These investigators conclusively demonstrated the vulnerability of the brain to prolonged periods without oxygen delivery and correctly extrapolated the "safe" duration of circulatory arrest [60]. In addition, this group was the first to demonstrate the efficacy of intraoperative echocardiography, and that the correction of residual defects during the initial repair in the operating room led to decreased mortality and morbidity, an approach that became a cornerstone of the surgical treatment of congenital heart disease [61].

Throughout the 1990s and early 2000s, many centers developed specialized pediatric cardiac anesthesia services, and efforts to provide ongoing education and forums for discussion began at the major anesthesia meetings in North America and Europe. The rapid advances in the field, including emphasis on primary complete repair of complex congenital heart lesions in the neonatal period, highlighted the difficulty and complexity of mastering the knowledge base in the pathophysiology of the cardiac condition, the neonate, and the technical aspects of invasive monitoring, echocardiography, and pharmacological management of the circulation during open heart procedures. In 2004 the Congenital Cardiac Anesthesia Society was formed under the auspices of the Society for Pediatric Anesthesia in the United States, which has grown to a membership of over 600, including representation from Europe, Australia, and Asia. This society holds a successful annual meeting with over 250 attendees, and has recently published recommendations for fellowship training in pediatric cardiac anesthesia [62].

# Anesthetic neurotoxicity

In 1999 Olney et al published a paper in Science describing neuroapoptosis in the developing rat brain in response to ketamine, commonly used for sedation and analgesia in pediatric patients [63]. This paper was little noticed at the time by the pediatric anesthesia community, but the follow-up paper by this group in 2003, describing widespread apoptosis to commonly used anesthetic agents interacting with the GABA receptor, including isoflurane, midazolam, and nitrous oxide, certainly gained widespread attention in the pediatric anesthesia field, and anesthesiology in general. The longer term persistent learning deficits in these animals were particularly concerning [64]. This problem has led to an explosion of research, both in the animal and tissue culture laboratories as well as clinical research, to determine the extent of this issue in the clinical setting, as well as strategies to ameliorate this problem. These include the use of regional anesthesia alone, different anesthetic agents (opioids, dexmedetomidine), neuroprotective strategies, and the avoidance of elective sedation and anesthesia in the neonatal and early infancy periods altogether. This problem has led to the formation of a public-private partnership in the US to study this problem, involving the Food and Drug Administration, International Anesthesia Research Society, Society for Pediatric Anesthesia, and the National Institute of Child Health and Development [65]. This vitally important question potentially affecting the millions of children who undergo anesthesia and sedation annually around the world will likely be the prime driver of research and change in clinical practice for the next generation of pediatric anesthesiologists [66].

# Teaching, research and professionalism through the 1980s and beyond

By the early 1980s the stages had been set and many of the players were in place to take the next steps in specialty development and maturation. Clinical practices continued to improve. Airway management became more consistent. Ability to monitor peripheral oxygen saturation and exhaled gases added precision to the administration of newer inhaled agents such as sevoflurane and desflurane, which had less cardiac depression, especially during induction [67,68]. Halothane is now largely abandoned in North American clinical practices. Fluid management and blood replacement guidelines became more standardized. Increasing numbers of individuals were attracted to advanced training for 6 months to 2 years in pediatric anesthesia and pediatric critical care, insuring a supply of practitioners devoted solely to the anesthetic care of children. These changes paralleled the continuing advances in surgery such as cardiac surgery in infants, transplantation of solid organs and increasingly complex and lengthy procedures to correct congenital anomalies of the face and skull. Attention turned more and more to the outpatients, the patient requiring anesthesia outside the operating room, sedation, pain management and regional techniques.

Teaching programs evolved, increased in size and became more rigorous. "Fellowship" training beyond the required training for certification by the American Board of Anesthesiology began in the 1970s and continues to grow. This prompted a lengthy, detailed examination of many variables which could better define the needs of children undergoing anesthesia and surgery as well as addressing the growing concerns about how better to recognize the practitioners who anesthetize children and institutions where that is done. Led by Hackel at Stanford and Gregory in San Francisco, this work produced the publication of guidelines for requirements that hospitals needed to meet in order to safely provide anesthesia to children [69,70]. Hackel and many others pursued a parallel effort which led to the recognition and accreditation of training programs in pediatric anesthesia [71].

Teaching and scholarly pursuits best characterize a maturing specialty area such as pediatric anesthesiology. From a single text in the nascent field in 1945, there are now dozens devoted to the specialty. Another hallmark of maturity is the quality and quantity of investigative work produced by pediatric anesthesiologists. Using only one criterion, there is remarkable activity. In the past 15 years the annual meeting data of the American Society of Anesthesiology (ASA) shows growth from about 20 pediatric anesthesia scientific abstracts in 1995, to 66 in 2000, to 106 in 2010 [72].

In addition, a vital, well-attended specialty meeting is held twice a year: once for a day in connection with the ASA annual meeting each fall and once in late winter/ early spring with 3 days devoted entirely to pediatric anesthesiology. Two US specialty groups recognize pediatric anesthesia practitioners. The older of the two is a fellowship section of anesthesiology of the American Academy of Pediatrics (AAP) begun in the late 1960s [21]. This group requires that a major part of one's practice must be pediatric. In the 1980s the Society for Pediatric Anesthesia was established with a more encompassing goal: a member must have an interest in pediatric anesthesia, but need not practice it exclusively or even part time [21]. Obviously the two groups' members overlap and share similar goals. It is testimony to their willingness to share, not compete, that the annual spring meeting combines both groups and was attended in 2010 by over 700 practitioners.

In the US, fellowship training in pediatric anesthesiology was formally recognized in 1997 by the Accreditation Council on Graduate Medical Education, with the requirements that it be a 12-month fellowship with a specified didactic curriculum, supervision and clinical teaching by qualified faculty, and expertise and exposure to a wide variety of clinical components in pediatric anesthesia [71]. There are currently 46 programs accredited in the United States [73]. In 2009, the American Board of Anesthesiology Directors voted to support the development of an examination process that would lead to subspecialty certification in pediatric anesthesiology, further evidence of the recognition and support for organized anesthesiology in this field.

# International development of pediatric anesthesiology

In parallel with and even preceding professional society development in the US, pediatric anesthesiology has developed as an organized subspecialty in Canada, Europe, Asia, and Australia/New Zealand, and is beginning in Africa. A partial listing of societies of pediatric anesthesiology includes the Asian Society of Paediatric Anesthesiologists (2000), Japanese Society of Pediatric Anesthesiology (1971), the Canadian Pediatric Anesthesia Society (2004), the Association of Paediatric Anaesthetists of Great Britain and Ireland (1973), the European Society of Paediatric Anaesthesia (2009), Association des Anesthetistes Reanimateurs Pediatriques d'Expression Francaise (1998), the Italian Society of Neonatal and Paediatric Anaesthesia and Reanimation (1995), and the Society for Paediatric Anaesthesia in New Zealand and Australia (1998). The pervasiveness of the internet and the increasing ease of and opportunity for international travel have greatly increased international collaborations among these societies, and a number of joint meetings

have been held in the last decade. The international makeup of the editorial board of a major clinical journal, *Paediatric Anaesthesia*, and the wide geographic contribution of the scientific and clinical articles, editorials, and letters to the editor in this and other major international journals are evidence of the ongoing international development of pediatric anesthesiology.

Box 2.2 summarizes some of the major developments in pediatric anesthesiology from the late 1960s to 2010.

# Conclusion

As stated at the beginning of this chapter, pediatric anesthesiology has a short history but is long in achievement and success. The accomplishments have a broad base now, although the foundation 60–70 years ago was narrow. It is important to recognize our indebtedness not only to the pioneers chronicled here but also to others, often unheralded, whose continuing efforts on behalf of children underpin the progress to date and our hopes for the future. Expectations are that the upward trajectory will continue as the 21st century progresses.

Education (is) an essential leg for anesthesiology's fourlegged stool! [2]

# Introduction: why pediatric anesthesiology education? The needs assessment

Educating anesthesiologists about pediatric patients is essential if children are to receive the most effective and efficient anesthesia care. The importance of this concept was one of the major impetuses for the push to develop accredited subspecialty educational programs in pediatric anesthesiology [3]. What specifically justifies the existence of a special subspecialty of anesthesia patient care devoted to children and the need for education specially focused on this clinical care area?

Pediatric patient care data alone are a compelling justification. The Federal Census Bureau has projected that by July 2011, the US population will include >79,000,000 people from birth through 18 years of age [4]. This number represents 25% of the US population projected to total >311,00,000 in the same time period [4]. In 2007, birth statistics documented newborns as a growing segment of the US population (Box 3.1) [5]. While more recent trends indicate a small decrease in the total number of births and the birth rate, it is obvious from the data that a large number of babies are born each year. An appreciable portion of these newborns present with clinically significant morbidity necessitating surgical and non-surgical diagnostic and therapeutic procedures which can only be accomplished with the assistance of pediatric anesthesia patient care.

Approximately 1 in 33 babies born in the US has a birth defect [6]. While these defects may be minor abnormalities, others may significantly affect the infant's physiology. One in every 100–200 babies has a congenital cardiac defect, which constitutes between 25–33% of all birth deformities [6]. Neural tube, orofacial and urinary tract abnormalities represent some of the other significant pathphysiological birth defects. Birth anomalies predispose newborns to a greater chance of acute illness and long-term disability than babies without birth defects and are the leading cause of more than 20% of all infant deaths (Box 3.2) [6,7].

On a yearly basis, up to 25% of children (>39,000/day) sustain an injury mandating medical attention [8], a clinically significant number of which will need diagnosis and

- 7. Bacterial sepsis of newborn
- 8. Respiratory distress of newborn
- 9. Diseases of the circulatory system
- **10.** Neonatal hemorrhage

therapy requiring pediatric anesthesia patient care. For older, healthy children, pediatric anesthesia patient care needs also exist. Contact sports are the primary cause of trauma in children [9]. Data on sports injuries include children 6 years and older and indicate, for example, that basketball is associated with an injury rate of 1 in 525 children engaging in this sport (1900 injuries/1,000,000 times children play this sport); approximately 180 of these children fracture bones and 160 will require surgery [9]. Football is even more risky, being associated with an injury rate of 1 in 250 children engaging in this sport; approximately 910 of these children fracture bones and 270 will require surgery [9].

The number of children needing anesthesia patient care is large yet the distribution of pediatric patients in hospitals is quite uneven. There are more than 5800 hospitals in the US [10]. There are 57 children's hospitals performing an estimated 640,000 operations each year [11]. The full range of resources specifically geared to pediatric patients (pharmaceuticals, equipment and knowledgeable, skilled and psychologically savvy physicians and paraprofessionals) is obviously more plentiful in hospitals that only care for children and their families.

In a 2005 report in the Newsletter of the American Society of Anesthesiologists (ASA) [12], Hackel and Gregory highlighted the clinical practice dilemma for everyone to ponder. It is recognized that pediatric patients and their anesthesia patient care needs are clearly different from those of the adult population; recognition and acceptance of this resulted in the development of special practice guidelines for pediatric anesthesia patient care, published in 1999–2004 by the ASA, American Academy of Pediatrics (AAP) and the Society of Pediatric Anesthesia (SPA) [13–15]. Yet most community hospitals, with less than the full complement of pediatric resources, are faced with a need to care for children, albeit a small number of such patients each year.

In all pediatric patient care settings, pediatricians, pediatric surgeons and pediatric subspecialists want anesthesiologists who are knowledgeable and skillful in pediatric anesthesia patient care. As the public has become more informed about pediatric healthcare, with understandable health information easily accessed on publicly available Internet websites (see Appendix 3.1), parents have also requested, and in some instances demanded, anesthesia patient care for their children provided by anesthesiologists knowledgeable and skillful in pediatric practice. "Data from other areas of medicine support this demand and show that fewer complications arise the more often practitioners perform a procedure" [12,16].

The intuitive assumption is that all of this is transferable to pediatric anesthesia patient care and this requires sufficient manpower (anesthesiologists with pediatric anesthesiology expertise) and sufficient sophistication (fully educated as pediatric anesthesiologists) to care for all of the children (all acuity, patient care scenarios).

# What constitutes pediatric education for anesthesiologists (the curriculum) and how is the need for pediatric anesthesia patient care met? (accredited pediatric anesthesiology education)

In the US, the Accreditation Council for Graduate Medical Education (ACGME) is the organization that assures uniform education of physicians after completing their undergraduate education from an accredited medical school and embarking upon specialty practice education. Each specialty develops, implements, and evaluates its specialty educational process through an ACGME Residency Review Committee (RRC). Program requirements for the specialty education are developed through a peer review process based upon established standards and guidelines; program requirements grow through a consensus building process. What pediatric anesthesiology education does the Anesthesiology RRC sponsor via its program requirements? The answer to this question depends upon whether the pediatric anesthesiology education is for anesthesiology graduate trainees learning the basics of anesthesia practice (core residency 4-year continuum) or those who have successfully completed the basic anesthesiology education and are devoting additional time (1-year fellowship) to education exclusively devoted to the subspecialty aspects of pediatric anesthesia patient care [17].

The Anesthesiology RRC defines the program requirements in pediatric anesthesia patient care for the core education of residents in the following manner [18].

Int.B.2.b). (4)

During the 36 months of clinical anesthesia training, there must be a minimum of two identifiable one month rotations in . . . pediatric anesthesia . . . If the program director judges that a resident has gained satisfactory skills and experience in clinical anesthesia in . . . [the subspecialty]...before completion of the second required month, the resident may pursue other experiences that augment learning of perioperative care in the subspecialty during the time remaining in the second month. For example, a resident who has gained sufficient experience in [pediatric] anesthesia (see IV.A.5.a) Patient Care) before completion of the second month of a [pediatric] anesthesia rotation may benefit from other perioperative experiences [in pediatric related clinical settings] . . .

### Int.B.2.b). (5)

Additional subspecialty rotations are encouraged, but the cumulative time in any one subspecialty may not exceed six months during the CA-1 through CA-3 years [36 months].

IV.A.5.a). (1). (c)

Care should be provided for: 100 patients less than 12 years of age undergoing surgery or other procedures requiring anesthetics. Within this patient group, 20 children must be less than three years of age, including five less than three months of age.

The core resident therefore need only complete two of 36 months or 6% of their full clinical anesthesia educational program learning pediatric patient care and only care for 20 children less than 3 years of age, of which only five need be less than 3 months of age. Successful completion of the examination requirements of the American Board of Anesthesiology (ABA) therefore only guarantees that a certified anesthesiologist has been exposed to this relatively limited pediatric anesthesiology experience. Subspecialty (fellowship) education in pediatric anesthesiology provides a 1-year immersion in the full depth and breadth of anesthesia care of children added to what has already been experienced during the prerequisite core residency pediatric anesthesiology education described above.

I.B.

The clinical training in pediatric anesthesiology [fellowship] must be spent caring for pediatric patients in the operating rooms, other anesthetizing locations, and in intensive care units. The training will include experience in providing anesthesia both for inpatient and outpatient surgical procedures and for non-operative procedures outside the operating rooms, as well as pre-anesthesia preparation and post-anesthesia care, pain management, and advanced life support for neonates, infants, children, and adolescents. [19]

The Anesthesiology RRC has not specified minimum numbers of cases that a fellow must complete in specific pediatric anesthesia patient care settings as it has done for the core residency. The Anesthesiology RRC has been collecting case log data from all pediatric anesthesiology fellows on a yearly basis to document their experiences. The data document the average experience for a pediatric anesthesiology fellow in specified categories of clinical care, i.e. "index cases" (Table 3.1) [20]. The fellowship program requirements do elucidate an extensive array of clinical and didactic components for the curriculum in pediatric anesthesiology (see Appendix 3.2) [19].

The question that everyone (anesthesiologists, the patients they care for, the families of these patients, the pediatricians and pediatric surgeons caring for the patients, the hospital administrators in whose institutions this care takes place and the public) must answer is what type of pediatric anesthesiology education is appropriate and sufficient for the best care of children; pediatric anesthesiology education that is 6% of the total anesthesiology educational curriculum or pediatric anesthesiology education that is one full year of education focused exclusively on the care of pediatric patients? What makes this question difficult to answer is that there are varying degrees of acuity of pediatric patients; it seems very appropriate for anesthesiologists who are ABA certified, having completed the core residency education, to care for somewhat older, otherwise healthy pediatric patients, even if on a less frequent and inconsistent basis and for anesthesiologists who are graduates of the full year accredited pediatric anesthesiology subspecialty fellowship and have ongoing pediatric anesthesia experience to care for the youngest, very high-acuity pediatric patients, on a regular and consistent basis. There are extensive data supporting the view that better care is provided when a

 
 Table 3.1 Pediatric Anesthesiology Graduating Residents (Fellows) Report (Abridged), 2008–2009 reporting year, Residency Review Committee, administered anesthetics

	Average	Maximun

Central neuraxis blocks	12	200
Percentage of patients ASA 3 or greater	33	100

OR, operating room; TEF, tracheoesophageal fistula. Number of residents (fellows), 118. consistent and sufficient volume of similar patients (case types) are cared for by specialty and subspecialty educated physicians who, therefore, have more frequent opportunity to hone and apply their specialized knowledge, skills and attitudes [12,16]. The SPA supports subspecialty certification in advanced pediatric anesthesiology to "... provide a means to gauge the knowledge and problem-solving ability of those practicing in a distinct and very well-defined area of medicine. There can be no doubt that once subspecialty certification in pediatric anesthesiology exists, it will raise the bar for all practicing within the specialty. That, in turn, can only benefit [pediatric] patients" [21].

Pediatric anesthesiology education during residency and fellowship is very important yet insufficient. To remain current, lifelong education is essential. Reviewing and refreshing knowledge, skills and attitudes is the way to assure that anesthesiologists stay current; this is especially true for anesthesiologists who do not care for a large volume or a broadly diverse population of pediatric anesthesiology patients. Learning new knowledge, skills and attitudes that came into existence after an anesthesiologist's primary education will only take place through a continuing medical education (CME) process.

American Board of Anesthesiology certification prior to 2000 was without a time limit; since 1 January 2000, ABA certification has had a 10-year limit. To address the timelimited certification and provide for continuing education and lifelong learning, the ABA's Maintenance of Certification in Anesthesiology (MOCA) has been developed for anesthesiologists as similar maintenance of certification programs have been developed for all American Board of Medical Specialties disciplines [22]. The MOCA consists of four components: assessments of professional standing, cognitive expertise (knowledge test), and practice performance, and participation in and documentation of lifelong learning and self-assessment [21,23]. While not solely devoted to a single subspecialty within the discipline of anesthesiology, the MOCA is the vehicle that incentivizes all anesthesiologists, including pediatric anesthesiology subspecialists, to stay current and benefit from the many CME programs offered in their areas of practice expertise.

# What are the fundamental principles of education for all aspects of anesthesia patient care? The educational design [24–28]

# Education is change in behavior based upon experience

This definition speaks to the essential ingredients of education: individuals (students and teachers), behaviors (the student's baseline knowledge, skills and attitudes and the teacher's curriculum) and experiences (the activities that constitute the learning, i.e. student-teacher interaction and the environment in which this takes place). The ingredients, when mixed properly, result in effective and efficient education. The proper mixing of the ingredients is addressed with answers to the question: "How shall who teach what to whom for what purpose now and in the future?" (DE Greenhow, personal communication, 1982). This question asks for answers about what defines the teaching goals and describes the students, the teachers and the teaching methods.

The *teaching goals* for pediatric anesthesiology have been outlined above; the student learns specific information unique to the care of children to become a knowledgeable and skilled provider of anesthesia patient care to this special patient population, the ultimate goal being the provision of the best outcomes possible for the patients.

The *student of pediatric anesthesiology* is an adult learner [29]. When providing medical care, everyone agrees that children are not small adults. An analogous concept applies when it comes to education: *adult learners are not large children*. Adult learners are unique and very different from child learners [29]. Adult learners:

- are highly motivated to seek out goal-directed learning (want to learn pediatric anesthesiology for future medical practice opportunities)
- tend to pick and choose some, not necessarily all, of the educational activities available because their learning is goal oriented toward relevant life-centered needs (a future anesthesiology patient care practice)
- enter new learning possessing vast knowledge gained prior to the current learning (have successfully completed a minimum of 4 years of undergraduate medical education and the 4-year continuum of anesthesiology resident education)

• interact with teachers who are physician peers. [29] Adult learners have life commitments and specific intentional attachments including, among others, marriage, child rearing, financial responsibility that often includes debt incurred for medical education up to the time of residency or fellowship and coping with aging parents, all of which affect how their decisions are made about whether and for how long additional education will be embarked upon. Education must provide for the inherent differences among adult learners that tend to increase with aging and include, among others, differences in style, time, place, and pace of learning. The time factor for adult learners is especially crucial. Adults perceive that time passes rapidly; to the adult learner there is less time available to learn, or do anything, for that matter. With time perceived to be in short supply, adult learners tend to be selective in their learning so they use what time they have more efficiently. The pediatric anesthesiology learner may devote time to learning in the operating room and weekly departmental case conference but may choose to skip the journal club to spend time with their family [24].

Recognizing and acknowledging the unique characteristics of adult learners enable teachers to tailor their educational programs to these special students, resulting in a welcoming environment for a better educational outcome than would occur if the teacher imposed on the learner what the teacher alone thinks is right.

The most current data for graduate medical education in the US (2008–2009) document 108,176 residents in all specialty education programs, of which 5208 (5%) are core anesthesiology residents and 296 (0.003%) are subspecialty anesthesiology fellows; included in the fellow group are 129 (0.001%) pediatric anesthesiology fellows [30].

The teachers of pediatric anesthesiology comprise a small group within the total teaching faculty for the specialty. Pediatric anesthesiology is taught by physician anesthesiologists, many of whom have themselves completed fellowship education in this subspecialty. Full-time anesthesiology faculty positions in United States medical schools in 2007-2008 numbered 6117 [31]. Anesthesiologists represent 5.5% of the clinical teachers and 4.8% of all American medical school teaching faculty [31]. The 6117 anesthesia faculty in medical schools (as of 1 December 2007) assumed the major responsibility for teaching some or all of the 70,349 enrolled undergraduate medical students, the 5222 graduate trainees in anesthesiology residency and fellowship educational programs, as well as many of the approximately 106,012 physician house staff trainees [31]. The actual number of anesthesiologists who devoted the majority or all of their educational commitment to pediatric anesthesiology is unknown and contained within the 6117 total anesthesiology faculty positions in the US.

Teachers of pediatric anesthesiology, like almost all medical teachers, are ill equipped for this responsibility [32]. While these physicians are experts in their medical practice discipline, they, like almost all physicians, have never formally learned how to be a teacher; they have learned how to teach from their teachers who have role modeled teaching, although they too have never studied education in a formal manner. It is as though watching someone change an automobile transmission "qualifies" the observer to teach someone else how to accomplish this task and they in turn will be "qualified" to teach others what they have observed. It is doubtful that one would feel safe driving the vehicle in which a new transmission was installed under these conditions; it is very curious that we do feel safe to accept medical care from individuals who have been educated under these

conditions. It is also very curious that a major portion of the teaching responsibility falls upon the shoulders of the relatively inexperienced junior faculty as opposed to more senior experienced faculty [33].

Physicians need not feel they are without resources that would help them learn to become effective teachers of medicine and pediatric anesthesiology in particular. Physicians can look to the medical literature for the latest "science" about education and teaching just as they would read the journal *Anesthesiology*, for example, to learn the latest science about anesthesia patient care.

*Academic Medicine* is the official, peer-reviewed journal of the Association of American Medical Colleges. The journal serves as an international forum for the exchange of ideas, information, and strategies to address the major challenges facing the academic medicine community as it strives to carry out its missions in the public interest. The journal's areas of focus include: education and training issues . . . [34]

Effective teaching has been studied and the principles identified (Box 3.3) are clearly applicable to teaching pediatric anesthesiology [35].

An example of how studying education may improve learning outcome for the student deals with the student– teacher relationship and philosophy of education. There are at least two student–teacher relationships with associated philosophies: teacher in total control (Tylerian approach [36]) or student in a peer position as partner with the teacher (Dewey's progressive education approach [37]). It becomes intuitively obvious that for students of pediatric anesthesiology, a philosophy of education

Box 3.3 Characteristics of an effective clinical teacher

- Allocates dedicated time for teaching
- · Creates a trusting learning environment
- Demonstrates clinical credibility
- Provides an initial orientation and final evaluation for the teaching event
- Engages learners by expecting them to present cases, the pertinent details and educational benefit of which are managed by the teacher
- Enhances clinical case material with complementary didactic sessions
- Role models physician-patient relationships through bedside teaching
- Encourages student consideration of and interactive discussions about the psychosocial aspects of medical care
- Transfers the teaching responsibility to the students who are the future medical educators

Modified from Schwartz [24].

that values a student-teacher partnership will be more effective.

An example of these two philosophies put into action clarifies their differences. Let us consider teaching/ learning how to manage a patient who is being mechanically ventilated in the operating room. The Tylerian teacher might lecture to the [fellows] on how to use the ventilator. It is hoped that the [fellows] will remember what they heard and be able to put what they learned into action. In contrast, the teacher using Dewey's approach might create a patient simulation exercise in which [fellows] can "experiment" with differing ventilator setups to infer what might occur clinically. A much more meaningful learning environment might be provided by the simulation - coupled with the anesthesiologist faculty member's reactions to and guidance about how the [fellows] tinkered with the ventilator - than might be provided by the lecture format. In addition, the teacher using Dewey's philosophy might be more likely to encourage the student with prior experience, like [fellows] who used different types of ventilators during their internship [and residency], to share their know-how with other, less experienced, peers. [24]

Anesthesiologists who study pediatric anesthesiology are often students of pediatrics as well. Many have successfully completed a 3-year pediatric residency. They enter pediatric anesthesiology fellowship as very knowledgeable and skilled pediatricians with a wealth of prior pediatric understanding upon which to build their new anesthesiology subspecialty education. If they are lucky enough to have teachers who understand the concepts of adult learning and Dewey's philosophy, their prior knowledge will be accepted by their teachers and their learning will flourish.

The teaching methods available for effective pediatric anesthesiology education include, among others, the tried and true standards such as formal didactic lectures, interactive conferences, problem-based learning discussions (PBLD), journal club discussions to consider the classic and current literature, interactive patient care teaching in clinical settings such as the operating room, intensive care unit, and pre-anesthesia evaluation clinic, computer-based "surfing the Web" and simulation exercises.

To be the most effective teachers, physicians must learn the nuances of the standard teaching methods. How to ask a student a question so that the student will demonstrate the full extent of their understanding, as an example, depends upon teachers understanding the difference between closed and open questions [38]. There is a huge difference between the question "What is the dose of lidocaine for a caudal block of a 7 kg baby?" compared to "Why would you perform a caudal block on a 7kg baby undergoing inguinal hernia repair?". Teaching psychomotor skills is another example of a standard teaching method that requires an intricate understanding of the component steps and their proper sequencing [38]. The "See one, do one, teach one" method of teaching delicate skills, especially those to be performed upon the tiniest and highest acuity premature babies, is an unacceptable way to teach and learn pediatric anesthesiology skills [38].

There is a vast array of print materials (textbooks and journals) providing information about pediatric anesthesiology and its related subjects. Although there is a constant attempt to update textbooks, it is almost impossible to have current, complete and up-to-date print material. The internet solves the problem of potentially being out of date with one's print resources. Search engines, databases, and Internet links make an encyclopedic amount of up-to-date information available to the learner of pediatric anesthesiology (see Appendix 3.1). A caution reminds the viewer of internet resources to be discerning of materials that may not be accurate, peer reviewed or impartial, i.e. always consider the source of the material. It would be nice to state that the list of web-based resources in Appendix 3.1 is all-inclusive but by its very nature, the internet is constantly changing. The pediatric anesthesiology teacher, student, and practitioner are encouraged to use the listing in Appendix 3.1 as a springboard to continually explore this vast educational reservoir as a lifelong learning exercise.

Simulation is the most current, new teaching methodology (see Chapter 42), which has been embraced by most medical educators. Simulation permits imitation of a reallife clinical situation using a mannequin. This allows learning experiences, in repetitive fashion if desired, with zero risk [39]. A great number and variety of simulation devices for medical education have been developed over the past several decades, many of which are directly applicable to education of pediatric anesthesiologists.

Evidence has been accumulated that simulation results in a better educational outcome for the learner. Schwid and colleagues [40] randomized anesthesiology residents and faculty into two learning groups (textbook reading versus computerized ACLS [Advanced Cardiac Life Support] simulation education) preparing for performance evaluation at an ACLS mock resuscitation. Computer simulation-prepared learners were judged to perform better than textbook-prepared learners during standardized mega codes that required treatment protocols for clinical simulation of cardiovascular life-threatening scenarios with supraventricular tachycardia, ventricular fibrillation, and second-degree type II atrioventricular block. [25] Arrhythmia recognition and treatment is an example of a very pertinent simulation activity that can be geared to pediatric anesthesiology education.

Simulation augments clinical education by adding a more sophisticated aspect to the learning, i.e. teamwork and improved processes of care. By employing simulation exercises as the teaching vehicle, multidisciplinary teams can learn to work effectively together to develop the best care for patients. Crew resource management (CRM) concepts can be effectively learned using group simulation exercises [25,41]. Holman [42] and Grogan [41] have demonstrated that CRM (anesthesia crisis resource management) enhances interpersonal communication, situational awareness, and appropriate management of available patient care resources [42] and fatigue management, adverse event recognition, team decision making, and performance feedback [41]. CRM is so timely a topic that an entire supplement issue of Quality and Safety in Health Care entitled "Simulation and Team Training" [43], described the state of the art [25].

Simulation is ideal for addressing the concern that the teaching-learning situation presents in pediatric anesthesiology.

Atul Gawande has made a critically important medical education dichotomy and dilemma transparent to the public in his book Complications: A Surgeon's Notes on an Imperfect Science in the chapter entitled "Education of a Knife," writing that there is an "... imperative to give patients the best possible care and [at the same time] to provide novices with experience" [44]. To accomplish these two conflicting imperatives in the past, learning clinical care (pediatric anesthesia, for example) was most often a process of application of knowledge and trial of techniques, both new to the student, on high acuity/low physiologic reserve patients in real-time patient care settings. This scenario was characterized by high anxiety for the student and significant risk of complications to the patient cared for by the novice. For the present and future, Gawande makes it clear that the traditional medical education paradigm is no longer acceptable:

"By traditional ethics and public insistence (not to mention court rulings), a patient's right to the best care possible must trump the objective of training novices" [25,44].

The aviation industry long ago recognized this dilemma when teaching pilots. Acknowledging the high-stakes nature of flying, simulation technology was instituted to teach and evaluate a pilot's competence rather than allow her/him to fly a jumbo-jet and risk loss of hundreds of lives. Learning to apply the knowledge and perform the techniques before entering the "cockpit" reduces the risk of a "crash disaster." Medical care in general and anesthesia patient care in particular, especially of very high-risk [narrow margin pediatric anesthesiology] patients, is analogous to the jumbo-jet situation and logically calls for a similar approach to education, that is, use of simulation [45]. The public is no longer willing to accept teaching on patients [25,46].

# How do we know that the educational activity is effective? Evaluation of the educational process

Undertaking an educational activity requires that several essential steps be accomplished:

- defining that education is necessary, i.e. completing a needs assessment
- characterizing the participants in the learning setting, i.e. understanding who the students and teachers are
- designing and implementing an educational experience, i.e. developing the curriculum and transmitting it via teaching methods.

Like the classic medical model (diagnosis = the need of a patient, prescription = therapy for the problem, monitoring = assessment of the effect of the treatment, and disposition = maintaining or adjusting therapy), the teaching/learning process is incomplete without an evaluation to maintain or modify the educational activity.

The ACGME requires that its educational programs, such as fellowship programs in pediatric anesthesiology, be evaluated on an ongoing basis and in multiple ways (faculty evaluate fellows, fellows evaluate faculty, and everyone evaluates the program) [19]. The primary assessment method is a program's voluntary request to be evaluated against ACGME program "standards" (program requirements). Accredited programs participate in this assessment every 5 years or sooner [47]. The component parts of the ACGME accreditation and reaccreditation process include the program's completion of a Program Information Form (PIF) describing and quantifying the program components and experiences, the ACGME's site visit to view the program and interview representatives of the program and others who interact with the program, and based on review of the PIF and report of the site visit, the ACGME Anesthesiology RRC assesses, evaluates, and makes decisions about and recommendations to the program [19,47].

Evaluation of the pediatric anesthesiology fellow's performance during the course of (formative evaluation) and at the conclusion of (summative evaluation) their education is the basis upon which judgments can be put forth on the quality of the fellow's mastery of knowledge, skills, and attitudes important for the subspecialist to acquire and upon which the quality of the educational program can be gauged. The ACGME program requirements for education in pediatric anesthesiology explicitly outline evaluation of fellows.

X.A.

Faculty responsible for teaching subspecialty [fellows] in pediatric anesthesiology must provide critical evaluations of each [fellow's] progress and competence to the pediatric anesthesiology program director at the end of 6 months and 12 months of training. These evaluations should include attitude, interpersonal relationships, fund of knowledge, manual skills, patient management, decision-making skills, and critical analysis of clinical situations. [19]

At the present time, ABA certification of pediatric anesthesiologists does not exist. However, as of this writing, the American Board of Medical Specialties has approved the ABA's request for subspecialty examination and certification in Pediatric Anesthesiology, and certification is expected to be available within the next several years. Therefore, there is no standardized test that must be passed by each fellow to evaluate their knowledge base in the subspecialty. The data that are collected document the pediatric anesthesiology clinical case experience (see Table 3.1) which allows evaluative inferences to be made about the quantity and diversity of cases that each fellow completes compared to the average for their peer group. No data exist that specify the minimum number of cases that, when successfully completed, will define a competent pediatric anesthesiologist.

Evaluating the quality of the teaching is vital to the recognition of outstanding faculty. A recent study of teaching effectiveness demonstrates that systematic collection and analysis of data about education of anesthesiology residents will define who the best teachers are and these teachers can in turn become the teachers of others with a pronounced positive ripple effect on educational process and outcome [48,49].

Whether the evaluation is of the program, the learners or the teachers, it is only through some type of formalized and standardized assessment process that pediatric anesthesiology fellowships can be recognized as being on a par with or better than similar programs elsewhere. It is also true that the recognition of program deficiencies (of the learners, teachers and/or the curriculum and teaching methods) may never occur to guide corrective measures if an evaluation system is not in place.

# Educating pediatric anesthesiologists: what's best for the kids? The conclusion = the starting message

Anesthesiology education is a vibrant activity. The enterprise is vast. In the USA in 2007 and 2008, (a)

accredited Graduate Medical Education (GME) programs included 129 core anesthesiology residencies and 126 subspecialty fellowship programs educating 5208 residents and 296 subspecialty anesthesiology fellows; included in the fellow group are 129 pediatric anesthesiology fellows, (b) 70,349 medical students received some modicum of anesthesiology education, (c) 6117 full-time clinical anesthesiology faculty were responsible for providing anesthesiology education and (d) 100,690 GME trainees in non-anesthesiology specialties [including pediatrics and pediatric subspecialties] (an 8% increase from 2002) clamored for anesthesiology related education (e.g. airway management, vascular access, safe local anesthetic use). [2]

Education is an essential leg for anesthesiology's fourlegged stool! Starting with this premise is essential for the most effective and efficient education of physicians wanting to learn anesthesia patient care; it is equally important for anesthesiologists wanting to learn sophisticated subspecialty anesthesia care for pediatric patients. While it is true children are resilient and that they do not "break" easily, the margin of safety when caring for them is narrow. Systematic, standardized, practice parameterdriven care based on evidence-based pediatric anesthesiology medical understanding provides the best opportunity for pediatric anesthesiologists to learn the best care possible for this patient population. Including education in the topics for pediatric anesthesiologists to learn will given our discipline the best possible opportunity to provide both the best care for children and the best education for their anesthesiologists.

Appendix 3.2 Abridged Program Requirements for Graduate Medical Education in Pediatric Anesthesiology [19]

#### V.B. Clinical components

The subspecialty resident in pediatric anesthesiology should gain expertise in the following areas of clinical care of neonates, infants, children, and adolescents:

- V.B.1. Preoperative assessment of children scheduled for surgery
- V.B.2. Cardiopulmonary resuscitation and advanced life support
- V.B.3. Management of normal and abnormal airways
- V.B.4. Mechanical ventilation
- V.B.5. Temperature regulation
- V.B.6. Placement of venous and arterial catheters
- V.B.7. Pharmacologic support of the circulation
- V.B.8. Management of both normal perioperative fluid therapy and massive fluid and/or blood loss
- V.B.9. Interpretation of laboratory results
- V.B.10. Management of children requiring general anesthesia for elective and emergent surgery for a wide variety of surgical conditions including neonatal surgical emergencies, cardiopulmonary bypass, and congenital disorders
- V.B.11. Techniques for administering regional anesthesia for inpatient and ambulatory surgery in children
- V.B.12. Sedation or anesthesia for children outside the operating rooms, including those undergoing radiologic studies
- V.B.13. Recognition, prevention, and treatment of pain in medical and surgical patients
- V.B.14. Consultation for medical and surgical patients
- V.B.15. Recognition and treatment of perioperative vital organ dysfunction, including in the postanesthesia care unit
- V.B.16. Diagnosis and perioperative management of congenital and acquired disorders
- V.B.17. Participation in the care of critically ill infants and children in a neonatal and/or pediatric intensive care unit
- V.B.18. Transport of critically ill patients between hospitals and/or within the hospital
- V.B.19. Psychological support of patients and their families

In preparation for roles as consultants to other specialists, subspecialty residents in pediatric anesthesiology should have the opportunity to provide consultation under the direction of faculty responsible for teaching in the pediatric anesthesiology program. This should include assessment of the appropriateness of a patient's preparation for surgery and recognition of when an institution's personnel, equipment, and/or facilities are not appropriate for management of the patient.

#### V.C. Didactic components

The didactic curriculum, provided through lectures and reading, should include the following areas, with emphasis on developmental and maturational aspects as they pertain to anesthesia and life support for pediatric patients:

- V.C.1. Cardiopulmonary resuscitation
- V.C.2. Pharmacokinetics and pharmacodynamics and mechanisms of drug delivery

- V.C.3. Cardiovascular, respiratory, renal, hepatic, and central nervous system physiology, pathophysiology, and therapy
- V.C.4. Metabolic and endocrine effects of surgery and critical illness
- V.C.5. Infectious disease pathophysiology and therapy
- V.C.6. Coagulation abnormalities and therapy
- V.C.7. Normal and abnormal physical and psychological development
- V.C.8. Trauma, including burn, management
- V.C.9. Congenital anomalies and developmental delay
- V.C.10. Medical and surgical problems common in children
- V.C.11. Use and toxicity of local and general anesthetic agents
- V.C.12. Airway problems common in children
- V.C.13. Pain management in pediatric patients of all ages
- V.C.14. Ethical and legal aspects of care
- V.C.15. Transport of critically ill patients
- V.C.16. Organ transplantation in children
- V.C.17. All pediatric anesthesiology residents should be certified as providers of advanced life support for children.

Subspecialty conferences, including morbidity and mortality conferences, journal reviews, and research seminars, should be regularly attended. Active participation of the subspecialty resident in pediatric anesthesiology in the planning and production of these conferences is essential. However, the faculty should be the conference leaders in the majority of the sessions. Attendance by residents at multidisciplinary conferences, especially those relevant to pediatric anesthesiology, is encouraged.

# Introduction

Pharmacology and physiology, drug behavior and organ function are the fundamental underpinnings of perioperative anesthetic practice. At our core, anesthesiologists are physiologists and pharmacologists; we titrate drugs against an individual patient's response to achieve a desired therapeutic goal. Understanding the pharmacokinetics (uptake, distribution, elimination, and sensitivity of a drug's effects in an individual patient) and pharmacodynamics (clinical effects of the drug on effector sites; hemodynamic, respiratory, renal, and central nervous system function) of the drugs we administer is essential for the safe provision of anesthesia. But more fundamentally, how do we know if a therapy will be effective in the first place? Or if we are given a choice of therapies, which one is best? Further, although we titrate drugs to an individual patient's response, how do we know the population kinetics on which to determine how much drug to administer to produce the average or typical response? Or, over what period of time should a drug be administered and be expected to last? Equally important, how are outcomes determined or tested and over what period of time?

Historically, most studies involving anesthetic drugs and techniques look at the perioperative period as the time frame for outcome. However, what if the effects of these drugs or techniques only reveal themselves weeks or years later? At one time, this would have been considered preposterous. However, we now know from longterm studies where follow-up was years rather than days that the consequences of how an anesthetic was delivered can have profound effects years later [1]. Studies examining the effect of variations in perioperative anesthetic management of adults with coronary artery disease and newborn infants undergoing anesthesia have revealed significant effects years after the anesthetic was provided [1–3].

The randomized, double-blind, placebo-controlled trial (RCT) is the "gold standard" for determining the efficacy

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

<sup>© 2012</sup> Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

and safety of therapeutics. No other study design can provide better evidence for cause and effect between an intervention and an outcome. Unfortunately, ethically acceptable RCTs are very difficult to design when children are participants and there are numerous impediments to practical implementation. When a RCT is not feasible, clinicians must rely on weaker forms of evidence from other trial designs such as cohort studies, casecontrol studies, and even anecdote. While all of these are valuable, their results are less convincing due to confounding and bias.

No matter what the specifics of the study design, performing a clinical trial is challenging, often expensive and, when done to Good Clinical Practice (GCP) standards, excruciatingly difficult to perform [4]. Clinical trials strain resources and patience and are often viewed by investigators as an ordeal to overcome rather than as a welcomed ally.

New therapies approved for adults rapidly assume the mantle of the "standard of care" for pediatric patients, increasing the barrier to conducting an RCT and encouraging off-label prescribing which is rampant in pediatric practice [5–9]. Psychologically, this creates a very narrow window of time during which investigators are willing to conduct clinical trials of new therapies for children. When either clinicians or patients accept a therapy as effective, they do not want to participate in a study with the risk of enrolling into a placebo or control arm. However, using drugs off-label in children exposes them to ineffective care and untoward side-effects. Children who receive offlabel drugs during an inpatient hospitalization have nearly double the likelihood of having an adverse drug reaction [10-12]. It is well established that children can have unique responses to drugs (e.g. weight gain, decreased growth), require different dosages and delivery methods, and often fail to show a therapeutic response even when the therapy provided is very effective for identical problems in adults (e.g. the use of triptans for migraine headaches or selective serotonin reuptake inhibitors (SSRIs) for depression) [13,14].

Given that it is not possible to predict whether children from neonates to adolescents will respond to drugs in the same way as adults, RCTs remain essential. The alternative to evidence is perpetual uncertainty with acceptance of unproven therapies as if they were effective. In this chapter, we will provide an introduction to clinical trials and discuss the special problems of performing them in infants, children, and adolescents.

# What is a clinical trial?

A clinical trial is a planned experiment that involves administration or implementation of an intervention to a group of subjects and is intended to determine the efficacy and safety of the intervention (Fig. 4.1). Although vital, for the purposes of this chapter, we will not discuss clinical trials that involve a single group, such as pharmacokinetic studies. The intervention need not be limited to drugs, biological agents or devices, but could include diets (e.g. preoperative fasting interval), a method or processes of delivering care, or any other procedure that can be manipulated by the investigator. At a defined point in time, the outcomes between one or more groups of subjects who receive the test intervention are compared with those of one or more parallel comparable populations of subjects in a control group.

# **Common impediments**

Nothing can be more frustrating for investigators than to realize that there is a clinical question that requires an RCT for a definitive answer but to be unable to address the question because of organizational, design or execution issues. This can be true not just for investigatorinitiated single-center trials; obstacles can also impede industry- or government-sponsored multicenter trials as well. Common impediments in all trials include inadequate planning, protocol development issues, unavailability of subjects, and lack of funding. Furthermore, almost all clinical trial investigators, both in industry and in academia, have unrealistic or overly ambitious timelines for study completion. Indeed, data from the National Institutes of Health (NIH) indicate that 85% of clinical trials fail to complete on time.

Overly ambitious objectives or rushed timelines also result in the need for multiple revisions to protocols, an inability to get contracts between trial sponsors and centers finalized, and investigational review board (IRB, also referred to as research ethics committee) approval delays [15]. (A sponsor or sponsoring agency is the institution, organization or foundation that provides the fiscal and often the administrative and scientific support for a given clinical trial or project.) Inappropriate subject selection and incomplete data collection due to inadequate instructions or collection forms can result in unnecessary adverse events that can compromise the entire study. Unrealistic or overly ambitious timetables may also raise doubts in the minds of the investigators about their ability to participate, forcing them to opt out rather than taking part in the trial. These factors result in approximately 30% of sites in multicenter studies failing to enroll even a single subject. Alternatively, some investigators who are frustrated by the time required to perform a proper trial may begin an inadequately designed trial before all the necessary procedures and support systems have been adequately tested and developed. This not only endangers the trial but, worse, exposes subjects to unnecessary risks of a trial that produces unusable data.

# Getting started

To avoid many of these pitfalls, an organized step-wise approach, involving teamwork and an understanding of clinical trials methodology, is necessary [16–18]. More than ever, clinical research is a collaborative venture between clinicians, research methodologists, statisticians, study co-ordinators, IRBs and study participants.

#### Defining the research question

Research begins with the research question that derives from a clinical problem. The research question is a general formulation and addresses the global question of interest such as "does this drug or medical procedure or device work?" This is insufficient by itself and needs to be refined and translated into specific study objectives. It can take considerable time and negotiation between investigators and sponsors to arrive at mutually agreed study objectives and endpoints and to create universally acceptable definitions for the study measurements. Nevertheless, the time it takes to do this is vital for the success of a trial. The efforts expended upfront will avoid disappointment and potential failure later on.

After collectively reading thousands of protocols, it is clear to the authors that there is confusion about the meaning of three related but distinctly different terms – objectives, endpoints, and hypotheses. The study *objectives* serve as a statement of the general purpose of the clinical trial. In general, they are written in the form "to determine the . . ." and this is followed by the thing to be determined such as "the efficacy of the study drug for the treatment of . . . or "the pharmacokinetics of oral study drug . . ." An example may help. Assume that a clinical trial will test a new antihypertensive drug and the primary objective could be to determine the efficacy of the study drug for the treatment of moderate-to-severe hypertension in adults age 18–65 years of age. The primary objective serves as the basis for the sample size calculation (see below) while the secondary objectives are often exploratory (inadequate sample size to definitely address the objective).

The study *endpoints* convert each objective into an explicit operational definition that clearly defines how the objective will be measured and achieved. The endpoints specify the comparison groups, the time points at which the comparison will be made, and the exact measurements or evaluation that will be used for the comparison. In our antihypertensive example, the primary endpoint might be the difference in the change in non-invasively measured systolic (or diastolic) blood pressure in mmHg at 4 weeks compared to baseline in the study drug group compared to the placebo control group.

Lastly, there is frequent confusion about where to place the study *hypotheses*. They are often mistakenly included with the study objectives but in reality belong in the protocol statistical method section. The hypotheses are expressed in statistical terms as a null hypothesis and as an alternative hypothesis (see below).

After development of the objectives and endpoints, the next question in any clinical trial is simply: "Is it worth the effort to mount a trial in the first place?" The answer to this question is predicated on the following questions: What is already known about the research question? Is this question worth the time and effort to answer? If I had the results today how would it change my practice? Is it ethically permissible to conduct this study in humans? and finally, Is it feasible to answer this research question with a clinical trial or would an alternative approach be better?

#### Choice of control group

The choice of the test and control treatments is the obvious and most important next step in designing a clinical trial [19]. The groups must differ from one another and investigators and subjects must be willing to enroll into both. The principle of equipoise is one approach for determining whether or not it is ethically permissible to conduct a comparative trial [20]. When low-quality evidence accumulates suggesting that one treatment may be superior to another, investigators may be reluctant to participate in the trial because they are unwilling to randomize their patients. However, even when the investigator is convinced that the experimental intervention will be superior to the alternative, provided that there is genuine uncertainty within the clinical community based on the available evidence, then the research question is in a state of equipoise and it is ethical to proceed. There is a long history of unexpected results in clinical trials, often with the placebo group having a survival advantage compared to what was perceived as the preferred treatment [21]. In 50% of the Children's Oncology Group clinical trials, the new study drug fails to outperform the standard treatment arm, emphasizing that frequently we are in a state of true equipoise [22].

By the time pediatric clinical trials begin, data from adults frequently suggest that the drug is active and effective, at least to some extent, for the proposed indication. In this situation, there may not be a state of equipoise. The requirement for true equipoise can be quite constraining and a number of alternative formulations have been proposed to substitute for it [23-25]. Many ethicists contend that in this situation, the decision about whether or not it is ethical to conduct the trial hinges on the risks associated with assignment to the control group (the less advantageous arm of the study). When the potential harms are minor and temporary then it may still be ethical to conduct the trial [26]. For example, a trial of a drug to replace acetaminophen for tension headache or a new treatment for allergic rhinitis could be ethically conducted because in neither situation would subjects suffer undue harm from assignment to a placebo.

The control group may be historical or concurrent and assignment to groups may be via a randomized or nonrandomized process. While it is tempting to simply use an historical control to compare to a study intervention, the practice should be avoided. Considerable experience has shown that trials using historical controls are much more likely to conclude that a new therapy is more effective than those using concurrent controls [27].

Choices for concurrent controls include placebo, different doses of the same intervention (dose-ranging or doseresponse studies), a different intervention (active control) or a combination of all of the above. The International Conference on Harmonization (ICH) "Choice of Control Group and Related Issues in Clinical Trials" document provides an extensive discussion of the advantages and disadvantages of each of these options [19].

The use of placebo controls remains a contentious and controversial topic [24,28–32]. The US Food and Drug Administration (FDA) has a clear mandate from Congress to only approve drugs, biologics, and devices that have proven to be safe and effective. In making their determinations, it is obvious that the FDA's clear preference is for placebo-controlled trials. Active controlled trials that seek to demonstrate equivalence suffer from the conundrum that if no difference is found between the two intervention arms, then it is possible that neither worked or both worked. As many as 40% of clinical trials for drugs for the treatment of depression, pain, and hypertension (amongst other conditions) fail to demonstrate superiority to placebo, contributing to the reluctance of the FDA to rely on active-controlled trials [32]. Placebo provides assay sensitivity, which means the ability to distinguish an active drug from an inactive one. Placebos also allow an accurate estimation of the magnitude of effect and help distinguish low-frequency adverse events caused by the intervention from background.

While a more complete discussion of this issue is beyond the scope of this chapter, in general, it is ethically permissible to use a placebo control in the following circumstances: whenever there is no proven treatment for the condition or disease, if the available treatments work poorly or have undue toxicities, if the participant has failed to respond to existing alternative therapies, or if there will be no undue discomfort or serious or permanent morbidity as a consequence.

Receipt of placebo is not usually equivalent to the absence of treatment. Frequently subjects receive standard care plus or minus the study intervention. In addition to standard care, there are two other methods that can be included to provide a margin of safety. First is an option for early escape – the study ends when the subject reaches an endpoint rather than after a fixed duration; the second is the use of immediate rescue treatment [19]. For example, in placebo-controlled pain studies, intravenous (IV) patient-controlled analgesia (PCA) morphine has been used as a rescue if the placebo (or study drug or procedure) is ineffective. The use of the rescue, the time to rescue, and the difference in the amount of rescue treatment have been used in some trials as the study endpoints rather than pain scores [33].

For many clinical trials involving anesthetic agents, it is not possible to use a placebo control but it often is for adjuvant therapies. As a result, trials of many anesthetic drugs focus on pharmacodynamics rather than efficacy. For example, trials of a muscle relaxant focus on dose– response, the time of onset and duration of effect rather than on comparisons in efficacy between agents.

# Ensuring validity: randomization and allocation concealment

Clinical trials rely on two processes for their validity: masking (or blinding) of allocation assignment and randomization [34]. Masking has two components: concealment of the allocation assignment at the time of randomization and prevention of discovery of the assignment during the trial. We prefer the term masking to blinding because blinding has the potential for confusion, particularly when used in conjunction with a trial where loss of vision is the outcome measure or in a trial involving patients who have lost their vision. Indeed, a common phrase in many studies that we find comical is "the investigators were blinded . . ." It doesn't really mean that the investigators were actually "blinded," rather, it means that the allocation groups were masked. Randomization assures that all confounding variables, known and unknown, are distributed at random and hopefully equally between the two groups. A variety of techniques can be used to generate the treatment assignment including use of a table of random numbers or computergenerated sequences [35–37].

Simple random assignment can result in large imbalances in the number of subjects between the two groups in a trial. There are alternative techniques that ensure that the randomization sequence keeps the number of subjects in both groups relatively equal, both for the study as a whole and, for multicenter trials, within centers [38]. The most frequent approach is to randomize subjects in blocks such as groups of two, four or six subjects, to ensure that the number of subjects is equal within each block. For example, if the block size is two, then subjects are randomized to treatments A and B in the order AB or BA. However, if the treatment assignment is discoverable (e.g. the masking is incomplete), then knowledge of the first subject assignment in each block could permit prediction of what the next subject's assignment would be. Using a larger block size increases the number of possible treatment assignment combinations and makes it harder to predict the subject's assignment.

Another method used to ensure balance between the study groups is permuted block sizes. In this technique, two different size blocks are used at random, making it very difficult to predict treatment allocation. For example, some blocks would consist of four subjects and some would include six. Without knowledge of the block size, it becomes impossible to predict the next subject's treatment group assignment.

The treatment group allocation process must not only be random but the outcome must be concealed, which is the first part of masking. If the investigator knows the group assignment for the next subject, then this can affect their willingness to enroll the subject, can bias the consent process or could lead to measures to manipulate procedures to influence the assignment. There are reports of studies where investigators have held sealed envelopes up to bright lights or found other measures to defeat the randomization schedule to choose the subject's group assignment.

To prevent discovery of the treatment assignment, the statistician should not reveal either the randomization schedule or the block size to any member of the investigative team. In a single-center trial, someone other than the investigator should generate and maintain the randomization sequence. If the study is a drug trial, having a pharmacist not otherwise associated with the trial prepare the study drug for administration is a very effective way of concealing assignment.

When the outcome measure is subjective, the subject, the investigator, and the statistician should ideally all be masked to the subject's treatment assignment. Concealment of treatment assignment after start of the intervention limits expectation bias on the part of the subject and biased assessments by the investigator. If the outcome measure is unbiased, for example death, then it may be less important to maintain masking. Since concealment is key to a valid study, an assessment should be made and included in any publication of the extent to which the masking was preserved during the clinical trial [39].

In comparing two active treatments, it may not be possible to disguise the drugs because of method of administration, size or color of the drug. Using a double dummy approach where both active treatments have matching placebos can be an effective alternative. Each subject takes one of the two active treatments and a placebo to match the other treatment.

For many anesthesia and pain studies, it may be quite difficult to mask the treatment if it involves a volatile anesthetic whose concentration must be monitored or if the intervention is invasive (e.g. an epidural nerve block). When treatment assignment cannot be concealed from the investigator, it may still be possible to prevent the subject from discovering their treatment assignment and to have someone other than the investigator perform the assessments of outcome to minimize bias.

#### **Outcomes measures**

Meaningful clinical trial outcomes include clinical events that change an individual's health in some discrete and meaningful way, e.g. prevention of death, prolongation of life, prevention of morbidity, change in quality of life or an improved economic endpoint [40]. All other outcomes, such as change in a physiological variable or a biological measure, are surrogate endpoints [41]. Surrogate endpoints are frequently used in place of clinical events because the variable measured is believed to be correlated to the clinical outcome of interest and because of its perceived utility in detecting treatment differences. Surrogates may be easier to assess but unless proven to predict the outcome of interest, they are poor substitutes for pivotal trials. In the Cardiac Arrhythmia Suppression Trial (CAST), those patients receiving encainide or flecainide had less ventricular ectopy (surrogate outcome) but nearly three times the number of deaths as the placebo group [21].

In a hypothetical clinical trial designed to determine which of several different anesthetics had the best outcome for children with upper respiratory infection, hemoglobin-oxygen saturation <94% would be considered a surrogate measure of adverse respiratory outcome compared to pneumonia requiring hospitalization, brain injury or death. However, the relationship of hemoglobinoxygen saturation <94% to death, morbidity, quality of life or cost is in fact very tenuous. Therefore, it is always better to select an outcome directly related to something that matters to the patient or the healthcare system (cost).

### Sample size and power

Even an experienced investigator must consult with a biostatistician early in the protocol development process. As experienced an investigator as David Sackett has sagely advised that "If you don't start looking for a biostatistician co-principal investigator the same day that you start formulating your study question, you are a fool, and deserve neither funding nor a valid answer" [17].

A key decision in any clinical trial is to determine the number of patients needed to detect a clinically important difference in outcome with specified type I and II error protection [18,42]. A type I error is the probability of rejecting the null hypothesis when it is true and is usually designated in most formulas by the Greek letter alpha ( $\alpha$ ). The null hypothesis postulates no underlying difference in the population or groups being compared with the factor, trait, characteristic or condition of interest. In clinical trials this means that the true underlying effect of the test treatment, as expressed by a specified outcome measure, is no more or less than that for the control treatment. A type II error is the probability of accepting the null hypothesis as true when it is false and is usually designated in most formulas by the Greek letter beta ( $\beta$ ) with power defined as 1- $\beta$ . Power in this context is the probability of rejecting the null hypothesis when it is false. Thus, calculations based on type I and II error and power will determine the number of patients needed in a trial and will often determine a trial's feasibility, cost, and the number of study sites needed to perform the study.

Typically power is chosen as either 0.8 or 0.9, which means that if a real difference exists of the magnitude specified, the trial has an 80% or 90% chance of detecting that difference. The variables in the power calculation include the magnitude of the clinically important difference, the number of events observed, and the variability (standard deviation). The greater the difference or the number of events anticipated, the fewer the number of subjects required. The greater the variability in outcome of interest (i.e. the wider the standard deviation), the greater the number of subjects required in a trial. Unfortunately, few treatments have as dramatic an effect as most investigators presuppose. Indeed, a 25% effect is large [43]. Overestimating the efficacy of the new treatment will result in an underpowered trial and has enormous ethical impact. If a trial is underpowered, the study cannot achieve its stated objectives and exposing/ enrolling patients into it is considered ethically unacceptable because it exposes patients to unnecessary risk [44,45].

In our experience, the variables that enter into the power calculation are amongst the most manipulated and debated elements in a study design. Often, when the number of patients needed is large, event rates are adjusted or the magnitude of the anticipated effect is exaggerated. With or without these manipulations, in worse-case situations, if the number needed to study is so large, it may make the study impossible to perform and will force cancellation of the study in its entirety. On the other hand, if the study is manipulated to make it easy to perform by manipulating the pre-trial assumption regarding the number or outcome events, the results of the study may become inconsequential or invalid. Many have called for a re-evaluation of the methods used to estimate sample size, preferring the use of the width of confidence intervals or effect sizes rather than simply performing power calculations. This further underlines the importance of collaborating closely with a biostatistician during the initial planning phases of a trial [44,45].

Deciding on the number of subjects needed for a trial may take months of interactions between the investigators, biostatisticians and, when a new drug is being used, the pharmaceutical sponsor and the regulatory agencies supervising the study. Although it is beyond the scope of this chapter to discuss the details of how one calculates for type I and II errors or estimates the required sample size, we have referenced several good reviews and textbooks that will provide an overview [46-48]. Interestingly, the choice of type I and II error protection is somewhat arbitrary. At first blush, the study team may want a trial that prevents both types of error. In reality, this may not be possible and the final decision as to which factor should take precedence may depend on the medical and practical implications of the two kinds of errors. Thus, relatively high error rates ( $\alpha = 0.10$  and  $\beta = 0.2$ ) are usually used for preliminary trials that are likely to be replicated. On the other hand, smaller error rates ( $\alpha = 0.01$ and  $\beta = 0.05$ ) are used when replication is unlikely.

### Single center versus multicenter

Anesthesiologists (the authors included) have most frequently resorted to single-center trials because they are relatively easy to mount and carry out. The research personnel are all located within the same institution, know each other, and can achieve a higher degree of uniformity in the execution of the study procedures and data collection. Perhaps most importantly, they are significantly less expensive and more efficient to perform because the bureaucratic structure required to design, execute, and supervise a multicenter trial is unnecessary. The publication and academic promotion issues that are so critical for academic investigators are more clear-cut and without conflict.

Indeed, in our opinion, publication and the recognition investigators receive for publication are amongst the most important driving forces creating resistance to participation in multicenter pediatric clinical trials; it is also one of the least publically discussed issues. Promotion at most academic institutions is based on the number, quality, and originality of, and authorship position in published papers. In single-center trials, the investigator's name will be listed and may even be the first or senior author, the most prized position for academic promotion. On the other hand, in multicenter trials, pharmaceutical sponsors often base authorship on recruitment success and not on intellectual contribution. Indeed, most investigators are often only listed in the footnotes of the journal article within the membership of the study group. Furthermore, if the study is an industry-sponsored trial, authorship is often considered "tainted." Some have advocated abandoning authorship for contributorship, where each individual's role in the research is listed at the end of the publication rather than perpetuating the current inaccurate system [49]. Academic centers and promotion committees would need to agree to reward contributions listed rather than just authorship for this model to take hold.

While most academicians prefer the single-center model, there are serious limitations to this model. One center, with only a few investigators, may find it difficult, if not impossible, to recruit enough participants in a timely fashion. Further, when all the subjects come from within the same geographic area and are treated by a small group of clinicians, the results may have internal validity but may lack external validity, making them less generalizable to other practice settings [50]. Medical care has fortunately also reduced the number of poor outcomes, making differences in discrete clinical events that much harder to detect. For example, survival for childhood cancer has improved dramatically. Similarly, death related to anesthesia has dropped precipitously over the past 30 years. As a result of these successes, the size of the expected differences in outcome between two treatment groups has grown smaller. Since power is based on the number of events, not the number of subjects, better outcomes overall have translated into the need for larger and larger sample sizes.

The only realistic way to conduct many trials that address vital questions is to collaborate on large, simple trials, with multiple sites involved in enrolling, treating, and following up subjects using a common study protocol and data collection tool [51]. Obviously, the physical separation between sites requires a more systematic approach to documentation and data collection and an administrative and organizational structure to make it all happen, all of which are very expensive [52]. The NIH has been creating a mechanism to facilitate multicenter trials through networks such as the Clinical Translational Science Award centers (CTSA), and various subspecialty component groups focusing on rare diseases and at-risk populations have done so as well (e.g. cystic fibrosis, sickle cell disease, Marfan syndrome, etc.). Additionally, multicenter data management software has made computerization and standardization of data entry much easier. Before embarking on a clinical trial, it is important for the investigator to check for these institutional resources because they can be invaluable (and often free) in setting up a clinical trial.

# Funding

All clinical trials cost money, lots of money. Where the money comes from and how much there is to spend are two of the key stumbling blocks in all clinical trials. Ideally, funding should come from a mix of private and public sources, including the government, the drug and device industry, and health insurance companies. Unfortunately, this ideal is rarely met and much of the funding comes from the government, private grants, and the pharmaceutical industry. The NIH, the primary healthcare research funding agency of the US government, rarely funds perioperative anesthetic research. Indeed, there is no specific institute within the NIH for anesthesiology. Further, the NIH cannot possibly bear the full burden of anesthesia-based research because of its priorities to primarily fund basic science research. Also, until very recently, industry was also unwilling to mount pediatric clinical trials because the pediatric market was viewed as too small to justify the return on investment, particularly because, as we will discuss shortly, most drugs used in pediatrics are used off-label anyway.

There is no easy answer to the lack of funding conundrum in pediatric perioperative anesthetic and analgesic trials. Despite the difficulties, it is essential to try. Giving up without a significant effort only assures failure. It has been our experience that if the project is worth doing, funding will be found either from traditional sources like the government and industry or from not so traditional sources like private and public foundations or local philanthropists. Often overlooked, there are anesthesiaspecific foundations and societies that fund both novice and well-established investigators. These include the Foundation for Anesthesia Education Research (FAER), the Anesthesia Patient Safety Foundation (APSF), the International Anesthesia Research Society (IARS), and the subspecialty anesthesia societies, such as the Society for Pediatric Anesthesia (SPA). Additionally, many public foundations, such as the Mayday Fund and the Bill and

Melinda Gates Foundation, provide research funding for pediatric clinical trials, particularly pain trials.

Another funding source that is closer to home, and one that is often poorly mined by anesthesiologists, requires raising funds from within the community in which the trial will take place. Within every locality there are philanthropists, corporations, and community organizations that can be recruited to support anesthetic research, education, and patient care. Although hospitals in general and children's hospitals in particular are very good at this, anesthesia departments are notoriously poor at it.

Developing and raising money for research endowments or endowed chairs specifically designed to provide seed money for young and established investigators is essential for clinical trials and for our specialty.

Finally, regardless of how one obtains funding, the funding source(s) must always be disclosed to the IRB, the institutional conflict of interest office, and to the public when patients are being recruited to enter into the trial and when the data and conclusions generated by the trial are presented in public forums or published in the lay or scientific press.

# Phases of testing a new drug

A considerable proportion of anesthesia research involves testing of drugs. All studies involving investigational new drugs require an Investigational New Drug (IND) application issued by the FDA before testing can move from animals to humans.

The first stage of testing a new drug is called phase I (Fig. 4.2). Phase I trials generate preliminary information on the absorption, distribution, metabolism, elimination and safety of a drug. Phase I studies typically involve 20–80 subjects and are usually conducted in healthy adult

human volunteers. However, some phase I trials, for example chemotherapeutics targeted to pediatric cancer, may need to be conducted in children. In contrast to phase I studies in adults, pediatric participants must have the target disease or condition. Phase I studies are rarely if ever done with a comparison group; if one is included, it is typically the study drug at a different dose.

After phase I studies have established the basic pharmacology and safety profile for the new drug, testing proceeds to phase II. These trials explore the efficacy in individuals with the disease or condition of interest, usually using surrogate measures of efficacy (e.g. decrease in blood pressure or reduction in tumor size rather than mortality). These are well-controlled trials designed to provide preliminary evidence of efficacy, explore the useful dosage range of the drug, and supplement the data about the safety profile of the drug. They often include additional pharmacokinetic testing during repeat dosing and at the anticipated therapeutic dose. Phase II trials frequently involve a few hundred individuals.

Phase I and II studies frequently explore the relationship between the dose administered and the physiological response. Typically, five or six doses are needed to establish the complete range of responses – ranging from the highest no-response dose, the lowest dose with a meaningful response and up to the dose beyond which either no further effect or undue side-effects are seen. When only two or three doses are studied, then the trial is more appropriately termed a dose-ranging trial. Given the expected intraindividual variation, dose-ranging trials generally require dosages that are a factor of 3–4 to clearly distinguish one dose from the other. Failure to establish the correct dose prior to conducting efficacy studies can result in failed efficacy trials or unnecessary toxicity [53].

**Figure 4.2** All studies investigating new drugs go through a process of preclinical testing in animals, several phases of human clinical trials, and culminate in a new drug application and approval by the FDA. The process takes years, with failure possible all along the way.

At the end of phase II testing, preliminary evidence of efficacy and safety has been established. For chemotherapeutic drugs, it is also necessary to identify the maximal tolerated dose (MTD). Based on dose–response studies, the dosage for confirmatory trials of efficacy is selected. At the end of phase II testing the sponsor and the FDA meet to establish the endpoints to be used for the phase III or pivotal trials.

Phase III trials are the final stage of new drug development and are designed to enable drug approval and labeling by the FDA. The drug label, distributed as a package insert, is the document approved by the FDA and furnished by the manufacturer of a drug for use when dispensing the drug. It lists a summary of the basic information about the pharmacology of the drug, its approved uses (conditions, populations, recommended dosage), contraindications, and potential side-effects.

Phase III trials are usually large, randomized, controlled clinical trials designed to confirm both the efficacy and safety of the drug. It is a given that all drugs provide a trade-off between their benefits and their side-effects. The results must be generalizable to the wider population. Surrogate measures of efficacy are no longer sufficient to support a labeling indication. For a cancer chemotherapy drug, improved survival would need to be established rather than simply reduction in tumor size. A new pain medication would need to not only demonstrate a statistically significant difference in pain score between groups, the difference would need to be large enough to be considered clinically important.

When the sponsor believes that they have established the efficacy and safety of the drug for a specific indication, they submit a New Drug Application (NDA) to the FDA to label and market the drug to the public. Of every 1000 drugs that enter preclinical testing, only 100 drugs enter phase I testing in humans, approximately 70 go on to phase II testing and 30–40 make it into phase III testing. Only about 12–15 result in an NDA submission and of those, only nine or 10 are approved (see Fig. 4.2).

Once a drug is approved, the sponsor must continue to conduct postmarket surveillance. Surprisingly, many serious adverse drug effects and interactions are only discovered after a drug has been approved for use and released into the marketplace. In reality, this shouldn't be surprising at all. At the time of initial approval, most newly approved drugs have actually been tested in only 1000–5000 people. Although to investigators and sponsors this is a huge number of people, in reality it is too small to detect rare but potentially very important sideeffects. Most rare but serious side-effects occur in less than1:10,000 individuals [54]. Obviously, this incidence would be below the radar and will not be reliably detected at the time of drug approval if less than 5000 people were studied. This underscores the importance of postmarket surveillance and explains the headline-making news accompanying the withdrawal of an approved drug from the marketplace, a process that occurs in approximately 1.5–5% of all newly approved drugs, depending on the epoch [55].

Some of the recently withdrawn drugs include rofecoxib, a COX-II inhibitor removed because of an increased risk of myocardial infarction, rapacuronium, a short-acting muscle relaxant, removed because of severe or fatal bronchospasm, hydromorphone extended-release because of the risk of accidental overdose, and ximelagatran, removed because of hepatotoxicity. Rare cases of idiosyncratic hepatotoxicity and increased risk of myocardial infarction may be difficult to detect in phase III trials. The safety of rosiglitazone has recently been the subject of considerable public debate, due to increased risk of cardiac events [56]. The absence of large, well-controlled trials focused on detecting increased cardiac risk contributed to the FDA's decision not to withdraw the drug from the market and only restrict marketing. However, the drug has been withdrawn in Europe.

None of the risks associated with these drugs was detected during initial testing and the risks came to light from postmarketing surveillance rather than as the result of phase IV trials. However, when common patterns emerge, the FDA and its European counterpart the European Medicines Agency (EMA) can impose additional requirements for the approval of all new drugs. For example, as the result of several drugs (e.g. astemazole, terfenadine and cisapride) being withdrawn due to cardiac arrhythmias in the 1990s, all new drugs are now tested for possible effects on prolonging the QTc interval.

To ensure and evaluate the long-term safety and efficacy of the newly approved drug following FDA approval and drug licensure, the FDA may require phase IV trials [57]. The pharmaceutical sponsor may also choose to explore additional indications for the drug or to study the drug in wider populations than studied in the phase III trials. Unfortunately, many phase IV studies do not have sound scientific designs and are funded by the pharmaceutical sponsor as seeding trials to increase interest in the drug and to generate sales.

# Timing of pediatric clinical trials

Ideally, all new therapeutic interventions would be rigorously tested before introduction into clinical practice. The reality is far different, with clinical adoption of new therapies far outstripping a solid evidence base on which to make these therapeutic judgments. As stated previously, there is often a very narrow window of time during which it is feasible to test a new therapy, particularly for children. After introduction into practice, interventions approved for adults become "standard of care" for children, even without the benefit of adequate evidence of their efficacy or safety in children. Indeed, this is one of the ongoing conundrums of small case reports, case series, and other forms of uncontrolled trials that flood the medical literature. The recent mandate to conduct clinical trials in children has clearly demonstrated that trials are not only feasible but also essential. Children have been shown to experience unique adverse effects (e.g. growth impairment and suicidality), require different dosage levels or formulations, and may fail to respond to a drug in the same way that adults do, even when the disease is the same (e.g. triptans for migraine headache and SSRIs for depression) [13,14]. Clearly, the adage that "children are not small adults" has been proven true over and over again.

Therefore, the ideal time to start pediatric trials is before or just after a new treatment is first approved, before preconceived notions regarding its merit develop. Unfortunately, this is rarely the case because as we will describe, the planning, organization, and structure of a proper trial take a fair amount of time, patience, discipline, and money – qualities that many investigators unfortunately lack.

# Anesthetic and pharmacological research in pediatrics

Although most children can't swallow pills, few drugs are available in liquid formulations. While pharmacies can make extemporaneous formulations, these must be used without information about bio-availability or palatability. Changes in formulation and route of administration affect uptake, distribution, and ultimately efficacy in unpredictable ways. "Inadequate information exposes children to age-specific adverse reactions, ineffective treatment due to inappropriate dosing, and lack of access to new drugs because physicians tend to prescribe less effective known medications" [58]. Additionally, insurance companies and other third-party payers may refuse payment for off-label use of medications. Indeed, in the past, so little pharmacokinetic and pharmacodynamic testing was performed in children that by 1968 they were termed "therapeutic orphans" [59].

To remedy the lack of appropriate labeling in children and in pediatric subpopulations (newborns, infants, school age, and adolescents), the US Congress enacted the FDA Modernization and Accountability Act (FDAMA) of 1997, its successor, the Best Pharmaceuticals for Children Act (BPCA, 2002) and the Pediatric Research Equity Act (PREA, 2003). Taken together, these laws were intended to promote standards and requirements for the use and labeling of drugs in children. The FDAMA and BPCA offered pharmaceutical companies incentives to study pediatric indications for approved drugs while the PREA required that all new drugs and biologics, all new formulations and indications for approved drugs be tested and studied in children. The PREA and BPCA were reauthorized into a single law as part of the FDA Amendments Act (FDAAA, 2007). These programs have been tremendously successful, with labeling changes documented for well over 100 drugs and counting [12–14,60,61].

Despite the major advances in labeling drugs for children made since 1997, most of the drugs used in infants, children, and adolescents during the perioperative period are still administered off-label, that is, they have not been thoroughly tested for efficacy or safety in pediatric trials. One of the main reasons for this is that most anesthetic and pain management drugs are older and had no patent life or exclusivity remaining at the time the FDAMA was signed into law. However, some drugs, including desflurane, ondansetron, midazolam, milrinone, oxycodone, tramadol and sevoflurane, have been studied under the FDAMA or BPCA. Looking forward, all new drugs must be studied under the PREA.

Unfortunately, off-label administration of older medications to pediatric patients often goes beyond the indications on the approved label and by routes of administration neither tested nor approved even in adults. It is hard to extrapolate the data available from the relatively healthy adult participants in most phase III trials to chronically ill adults, the aged, pregnant women, infants, children, adolescents, and to both adult and pediatric critically ill patients without consideration of the maturation of drugmetabolizing enzymes or alterations in sites of action over the normal course of aging. To deal with the issue of older drugs, the BPCA included funding for off-patent drugs under a partnership between the NIH and the FDA. Studies are under way for nitroprusside and lorazepam but progress has been quite slow.

# Ethical aspects of clinical trials

#### **Overview**

There is a long history of shame involving human research, from the Nazi war crimes in which lethal medical experiments were conducted on Jews and other subjugated people, to the Tuskegee syphilis study, which was conducted by the US Public Health Service from 1932 to 1972, in which minority men with syphilis were enrolled to study natural disease progression without being informed that they had the disease and were not treated after penicillin became available.

In the United States, the Belmont Report written by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research identified beneficence, respect for persons, and justice as the essential ethical principles that should underpin research involving human subjects [62]. These principles are not merely ideals; they have been translated into the federal research regulations known as the Common Rule (45 CFR 46) and into the FDA research regulations (21 CFR 50 and 56). An excellent review has proposed that there are seven requirements for ensuring the ethical conduct of clinical research, referring back to the fundamental principles articulated in the Belmont Report [63]. Despite considerable progress, the death of Jesse Gelsinger in a gene transfer trial at the University of Pennsylvania in 1999 served to increase the attention on compliance with federal regulations, conflicts of interest in research, and clinical trials oversight by institutions [64]. For more information concerning federal regulations, we refer the reader to the federal websites [65–67].

# Investigational review board review and approval

All institutions in the United States who receive federal funding for research must have a Federal Wide Assurance (FWA) issued by the Office for Human Research Protections (OHRP). The FWA is the institution's assurance to the government that it will follow the federal regulations guiding human research. Worldwide, the Declaration of Helsinki first adopted by the World Medical Association in 1964 and amended repeatedly (most recently in 2008) serves as an important expression of clinical research ethics worldwide. The Declaration is important for international trials but does not supersede American law and federal regulations. The FDA has recently adopted the International Conference on Harmonisation Guidelines on Good Clinical Practice to supplant the Declaration [68]. Other organizations with important clinical research ethics statements include the Council of International Organization and Medical Sciences (CIOMS) guidelines on the ethical conduct of clinical trials and the World Health Organization (WHO) operational guidelines for ethics committees that review biomedical research. Some organizations have produced more specific guidelines for pediatric clinical trials, including the EMA [69]. All these organizations share a common ethical perspective, namely, that the well-being of the individual research subject must take precedence over all other interests.

A fundamental principle of all clinical research mandated by US federal regulations (as well as by the CIOMS, WHO, EMA and the Declaration of Helsinki internationally) is the requirement for independent review and approval by a research ethics committee prior to initiation of any research protocol involving human subjects. In the United States these ethics committees are known as institutional review boards (IRBs) and consist of five or more individuals with diverse backgrounds in clinical research, medicine, law, research ethics, biostatistics, nursing, and, when children are involved, pediatrics [70]. To ensure independence and outside perspectives, at least one member of the IRB must be unaffiliated with the institution in which the research takes place and at least one member must be a non-scientific person, who preferentially is representative of the community surrounding the trial site's institution. Research that is no more than minimal risk can be reviewed using expedited procedures with review by just the chair of the IRB. Some types of minimal risk research are even eligible for waiver of informed consent (Box 4.1). In reality, most clinical trials are greater than minimal risk and require review by the convened board of the IRB. IRBs generally have a very formal application process that requires extensive documentation of the elements of the trial. Assembling and preparing this documentation is laborious, time consuming, and expensive, with many IRBs charging a fee for submission that can run into thousands of dollars. This cost and the cost of preparing the documentation for submission are often overlooked in trial design and implementation.

Typically, the documentation required by the IRB includes copies of the protocol, the informed consent form and assent documents (see below), copies of any advertisements and brochures that will be used to recruit

#### Box 4.1 Waiver or alteration of consent for minimal risk research

To approve such a waiver or alteration, the IRB must find and document that:

- the research involves no more than minimal risk to the subjects
- the waiver or alteration will not adversely affect the rights and welfare of the subjects
- the research could not practically be carried out without the waiver or alteration
- whenever appropriate, the subjects will be provided with additional pertinent information after participation.

Source: US Department of Health and Human Services Regulations: 45 CFR 46.116(d)

Examples of minimal risk research not requiring informed consent from patient, parent, or guardian:

- retrospective medical record review of anesthetic techniques for several hundred patients, where the process of finding patients and obtaining consent would prevent the study from being done
- retrospective medical record review of hundreds or thousands of anesthetics for complications, e.g. laryngospasm
- research from already existing large databases, i.e. state Medicaid databases, University Health Consortium, U.S. Agency for Healthcare Research and Quality Kids' Inpatient Database (KID), Child Health Corporation of America (CHCA) Database
- research involving only materials (data, documents, records, or specimens) that have been collected, or will be collected solely for non-research purposes (such as medical treatment or diagnosis).
   Examples: excess waste blood or urine for a novel biomarker assay technique; height and weight data from a large population of children to determine incidence of obesity in a given population presenting for anesthesia.

study participants, study data collection instruments, the investigational drug Investigators' Brochure, funding sources, and revelation of any conflicts of interest by the study investigators. Increasingly, many IRBs also require a detailed plan for data management, genetic specimen security and for how protection of subject privacy and confidentiality of data will be maintained. Finally, many institutions require documentation confirming that participating investigators have taken and passed institutionally mandated courses in research ethics, patient safety, billing, and confidentiality protection.

For multicenter research studies, a "central" IRB offers many potential time-saving, organizational efficiencies, and cost advantages [71]. A central IRB acts on behalf of a local IRB by reviewing and approving a trial proposal. Its organizational composition and process of review are identical to a local IRB. However, unlike a local IRB, the central IRB can simultaneously serve as the IRB of record for numerous sites. Central IRBs can be located either in an academic center or, as is most common, in one of many for-profit centers. Although the cost of submission and processing is often higher than a local institution's IRB, it is both much cheaper in the short and long term because of its center-by-center cost and is much more time efficient. Some have even advocated that the ethical oversight is superior when just one IRB takes responsibility for the trial [72]. Indeed, nothing is more expensive in a trial than not being able to start and enroll patients while awaiting IRB approval. Because of this, it is a favored method of the pharmaceutical industry.

Regardless of how a proposal is reviewed, the process often takes 3 months or more. For many investigators and sponsors, this delay becomes a source of friction and frustration. Although this is understandable, it can be made significantly more onerous if the IRB submission itself is inadequate or poorly conceived and written. It is our experience that many IRB reviews are prolonged by sponsor or investigator revisions, amendments, and by the rush to submission itself. Our mantra in protocol development and submission is to "measure twice and cut once." The trial planning process should ensure that there is sufficient time for both the initial IRB review as well the review of the IRB's requested modifications to the application, protocol, and consent documents. Finally, contracting issues also take time and are more frequently the rate-limiting step in getting a trial started. Again, it is our experience that it is far better and more efficient to do these in tandem than sequentially.

# Special considerations when children are participants

The principle of respect for persons, which encompasses the right of the individual to self-determination, requires that investigators obtain the informed consent of participants prior to enrolling them in a clinical trial. Since children cannot legally give their consent and may be unable to comprehend the information about the trial, they are considered a vulnerable population in clinical research. Subpart D of both the Common Rule (45 CFR 46) and the FDA research regulations (21 CFR 50 and 56) contains additional protections for children. Extraordinary risk of harm is permissible when those risks are outweighed by the prospect for direct benefit, such as in an oncology trial. When the research offers no prospect of direct benefit, Subpart D limits the amount of risk to which the child can be exposed. It also delineates the requirements for parental permission and child assent. There are four ascending categories of risk/benefit that have corresponding increased levels of scrutiny (Box 4.2) (45 CFR 46 and 21 CFR 50: Subpart D).

Box 4.2 Federal classification for pediatric research

# §46.404 and § 50.51: Research not involving greater than minimal risk

- IRB determines minimal risk
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian
- In the State of Maryland, even this level of study must be of direct benefit to the patient

§46.405 and §50.52: Research involving greater than minimal risk but presenting the prospect of direct benefit to the child

- IRB justifies the risk by anticipated benefit to the child
- The anticipated benefit-to-risk ratio is at least as favorable as the current available alternative therapy
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian

§46.406 and §50.53: Research involving greater than minimal risk and no prospect of direct benefit to the child but likely to yield generalizable knowledge about the disorder or condition

- IRB determines that the risk represents a minor increase over minimal risk
- The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social or educational situations
- The intervention or procedure is likely to yield generalizable knowledge which is of vital importance for understanding or amelioration of the subject's disorder or condition
- Adequate provisions are made for soliciting assent from the child and consent from the parent or guardian

§46.407 and § 50.54: Research not otherwise approveable that presents an opportunity to understand, prevent or alleviate problems affecting the health and welfare of children

Informed consent is not simply a document that requires a signature; it is a process that involves detailed ongoing explanations regarding the purpose of the trial, the nature of the procedures, the risks and potential benefits, and the alternatives to the research intervention and procedures. Components of the informed consent process include an assessment by the physician of the competence and decision-making capacity of the subject, disclosure, and the assurance, as much as is possible, that the individual has the freedom to choose the medical alternatives without coercion or manipulation. Further, subjects must be told explicitly that they can withdraw their consent and discontinue trial participation at any time without affecting the quality of their care and by whom and where it is provided.

Since children cannot legally or developmentally provide consent, the child's parents or guardians serve as surrogate decision makers for them and provide permission to participate. Just as in clinical care, there is an expectation that parents will make their decision for research participation based on the best interests of their child. Studies that have greater than minimal risk (see Box 4.2) without prospect for direct benefit to the child must be approved under the provisions of §46.406 or 407 or §50.53 or 54. These regulations require an added protection: the need to get the permission of both parents (when it is practical to do so).

The assent of the child is required whenever the child is deemed capable of comprehending the required information [73,74]. Assent must be active and affirmative; failure to disagree does not constitute assent. In contradistinction to the requirements for consent, assent does not require the child to make a risk/benefit assessment. The assent process should disclose the purpose of the research, the nature of the procedures, and the right to withdraw assent at any time. Obtaining the assent of child participants requires an awareness of the child's cognitive abilities and the investigator's ability to describe the therapy, procedure, and trial objectives in terms that the child or adolescent can understand in age-appropriate language. In general, children less than 7 years of age are thought to be incapable of decision-making capacity and of providing assent. Children between 7 and 14 are in a gray zone and IRBs are quite variable in their requirements. In practice, we try to obtain assent for research trials in all mentally competent children older than 7 years of age. When assent is required, the requirement for documentation will be determined by the local IRB. Some require a separate written assent form and others just documentation of assent on the consent form [75,76].

# Level of acceptable risk

Perhaps the unique aspect of pediatrics clinical research concerns the limits of acceptable risk. The definitions of minimal risk and a minor increase over minimal risk are key to understanding when research is approvable. When a clinical trial has risks that are no greater than minimal, any child can take part (§46.404 and §50.51). However, if the risks are more than a minor increase above minimal, than the trial is not possible unless there is a prospect for direct benefit to the child (§46.405 and §50.52). The definition of minimal risk is inherently confusing because embedded in it are two separate standards: the routine examination standard and the daily life standard. While the risks of routine examination are essentially trivial, the risks of daily life are considerable [77]. Almost all IRBs will consider a clinical trial involving administration of an investigational drug, no matter how innocuous, to be at least a minor increase above minimal risk.

It is ironic that the gravest risk for a considerable proportion of pediatric research is the risk of auto accident during the trip to the clinic. The risk of death from a car ride (adult driver) varies from 0.06 to 0.6 per million car trips. The daily cumulative likelihood of death, predominantly from car accidents and drowning, is 1.5 per million children per day. The likelihood of hospitalization and an emergency department visit varies between 1.0-2.1 and 6.4–64 per million children per day depending on the age of the child [77]. American Society of Anesthesiologists physical status I or II children undergoing general anesthesia currently have an estimated risk of death of approximately 4-5 per million (1:200,000). Thus, riding in a car, which is part of the risks of daily life, would be considered minimal risk, whereas receiving a general anesthetic, which is riskier, is at least a minor increase above minimal risk.

To avoid the possibility of exposing children to too high a level of risk, some within in the research ethics community believe that there should be just a single standard for risk and generally they favor risks closer to the routine examination standard [78]. Adoption of this unified standard would have a chilling effect on pediatric research. Part of the discrepancy between various IRBs in their decision making is due to the difference in their threshold for these two definitions.

# **Benefits**

Benefits in clinical research can be direct, indirect or both. Research offers a prospect for direct benefit when there is a reasonable and plausible expectation, based on prior research, preclinical data or other basis, that participants will receive a meaningful clinical benefit [78]. Clinical trials that have greater than a minor increase above minimal risk are only permissible for studies that offer a prospect for direct benefit. As long as the prospects for benefit outweigh the risks and are at least as good as the alternatives available outside the research, the IRB can approve the research (§46.405 and §50.52).

If the research or a component of the research is purely for research purposes and is not for the participants' direct benefit, the IRB can only approve the research if the risks are limited to a minor increase above minimal risk (§46.406 or §50.53). Since the definition of minimal risk is controversial, it should be expected that the definition of minor increase is controversial too. Rid et al have recently proposed a rubric for assessing risk which requires that all the probabilities for all negligible, small, moderate, significant, major, severe, and catastrophic harms be defined for each intervention and then compared to the risks of daily life [79]. Investigators know much more about the procedures proposed than the IRB. It is their responsibility to provide the IRB with as much data as possible about the probability and magnitude of all possible harms from the procedure or intervention to assist the IRB in making its determination.

States also differ in what is permissible. In the extreme, Maryland does not allow non-therapeutic pediatric research unless there is a prospect for direct patient benefit, even for minimal-risk research. In an important case involving one of the author's (MY) medical institutions (Grimes v. Kennedy Krieger Institute 366 Md 29, 782, A2d, 807, 2001), the plaintiffs were children enrolled in a study to evaluate different methods of lead paint exposure and abatement in Baltimore city homes [80]. The plaintiffs alleged that they were encouraged to remain in the study houses so that their lead levels could be monitored, even if the houses still had lead paint. In the study, one child had elevated blood lead levels but his parents were never informed of this finding. The Maryland court of appeals ruled that "otherwise healthy children should not be subjects of non-therapeutic research that has the potential to be harmful to the child. It is first and foremost the responsibility of the researcher to see to the harmlessness of such non-therapeutic research. Consent of parents can never relieve the researchers of this duty." Litton and Miller express the more common view that there are differences and limits to the duties of an investigator compared to a clinician [81].

#### **Coercion and undue inducements**

Recruiting subjects can create or cross a very real line between persuasion and coercion. Coercion of subjects can include manipulating or misusing information, or instilling fear that non-participation will result in withdrawal of or inferior medical care. Many institutions consider it coercive to be both the principal investigator and also the individual's primary physician. Coercion is a threat and should be distinguished from undue inducement, a reward so generous that subjects ignore their better judgment and assume risks that they would not otherwise be willing to endure. Undue inducement means payment so excessive that it makes it hard for subjects with limited means (economically vulnerable subjects) to decline participation. Examples of inducements can include indirect benefits of participation such as increased access to care or excessive financial remuneration. Indirect benefits of participation such as access to clinical experts, reduced waiting time for clinic visits, door-to-door transportation, and free care including study drugs during and after the trial can be quite persuasive incentives. The provision of free care and drugs and shortened wait times can be very powerful incentives to participate indeed.

There can be a fine line between fair subject payment and undue inducement. Reasonable compensation is ethical and gives all individuals the opportunity to take part in research without experiencing financial hardship. There is no evidence that moderate payment negatively affects subjects' judgment [82]. The object in designing a budget should be to try to make payment neutral.

Payments can be broken down into four components: reimbursement for expenses, compensation for time and effort, gifts of appreciation, and incentives [83]. Incentives are almost universally forbidden by IRBs. Appreciation gifts to subjects should be of nominal value. If participation imposes no travel or other burdens, then it may be inappropriate to include any payment. When subjects must return to the hospital or clinic for follow-up, payment of travel costs (reimbursement) and lost work time of the parents (compensation) is absolutely fair and expected [84]. When the child participant has to complete procedures, such as diaries, or must forego leisure activities, it is fair to compensate them for their time and effort as well as their parents [85,86]. Payments to children need to be age appropriate; children less than 9 years generally don't understand the relationship between the amount of effort and size of payment and should be paid with a fixed-size payment [73].

# Operational planning and trial execution

As with any large-scale project, a clinical trial has several stages that must be managed for the trial to be run and completed successfully. Each has specific features and timelines for completion and each is associated with pit-falls that, if not dealt with, will lead to failure and frustration. For most clinical trials, the stages include initial design, feasibility assessment, protocol development, data management and document preparation, subject recruitment/screening and enrollment, study treatment and follow-up, close-out and study termination and an optional post-trial follow-up (Fig. 4.3). Once the enrollment and follow-up are complete, the data must be

**Figure 4.3** The primary stages of a clinical trial. Each major phase shown as a diamond has components shown as rectangles that are shared across the clinical trial.

checked to ensure that they are accurate (data cleaning) and only then can analysis commence. Obviously, there is overlap across each of these stages.

## Initial design stage

The initial design stage specifies the rationale, purpose, and objectives of the clinical trial. A literature review is essential to identify pertinent background information about the target disease or condition and the proposed study intervention. Pharmaceutical trials compile this information in an Investigators' Brochure but it is up to the investigators to establish what is already known about the safety and efficacy of the intervention. Although confirmation of previous results has some value, it is usually a waste of time and resources to repeat work that has been done previously. Exposing subjects to risk when the answer to the research question is known is also unethical [63].

In our experience, the best approach is to start by creating a synopsis or concept protocol. This is a 2–4-page document that outlines the primary and most important secondary objectives, the proposed study population (inclusion and exclusion criteria), the details of the proposed intervention(s) (study drug, device or other procedure), the choice of control group, the method of assignment to study treatment arms and the methods of concealing treatment allocation. The primary and secondary endpoints should be formalized, the required sample size estimated, and the statistical plan for the analysis of the primary endpoint specified. Only when all members of the protocol development team have agreed on the synopsis should the study planning proceed.

As the details of the concept protocol are being finalized, the details of the recruitment plan should also be considered to determine how many sites would be needed for the study. A preliminary timetable for the trial, the organizational structure, subject safety, and plans to ensure data integrity, quality, and security all need to be developed and implemented. Finally, it is at this point that funding proposals are sought, written, and submitted.

# Feasibility and recruitment planning

With the protocol synopsis in hand, the principal investigators next need to assess whether the plans are operationally feasible. A realistic appraisal of the likely number of available subjects will determine whether or not the study can be conducted at a single site or whether other institutions will be needed to increase the pool of available subjects. Starting a clinical trial is a timeconsuming process and unless the proposed study is feasible, it should not be started. Most ethicists consider underpowered or unfeasible studies unethical and many IRBs will not approve a study that has no hope of being completed [87].

If it has not already been done, it is at this moment of protocol planning that the principal and co-investigators must include and obtain the advice of their clinical coordinators. The study co-ordinator co-ordinates and administers research study-associated activities. The coordinator will either make or break a study. The coordinator assists in project planning and ensures that pre-established work scope, study protocol, and regulatory requirements are followed. The co-ordinator recruits and co-ordinates research subjects, as appropriate, and serves as principal administrative liaison between the study's administrative co-ordinator oversees and co-ordinates the provision of administrative and staff services to the site investigators and maintains record-keeping systems, regulatory binders, and procedures.

Recruitment planning requires the input and planning of each study site and is often a collaborative effort between the study investigator and co-ordinator. The first step is to review the potential available population, keeping in mind the inclusion and exclusion criteria. If it appears that there will be insufficient numbers of potential participants, then the options are to loosen the inclusion/exclusion criteria to increase the available pool of subjects, increase the number of sites participating, or plan for an advertising campaign to widen the potential audience (see Fig. 4.3). In general, investigators greatly overestimate their ability to enroll subjects and the majority of trials fail to complete enrollment on time. In our experience of co-ordinating multicenter trials, a quarter to a third of sites fail to enroll even a single subject while the best 25% of the sites enroll 75-90% of the subjects. Since it is very difficult to predict which sites will successfully enroll subjects, it is usual to recruit more sites than would be expected to ensure study completion.

During the actual recruitment process, the study coordinator should track all subjects from screening to completion. The 2010 CONSORT guidelines provide an excellent resource on how and why patients should be tracked through the recruitment process and includes a recruitment table that should be provided in any randomized controlled trial for publication [88,89].

The nature of the study will determine how, when, and by whom prospective subjects will be approached. For anesthesia and pain trials, this could include review of the operating room schedule, solicitation in surgeons' offices or one or more publicity schemes, such as advertising in print, on the internet or radio.

# Protocol development and operational planning

If the planned study appears feasible without modification, the next step is to flesh out the synopsis or concept into a complete protocol. It is at this stage that the nuts and bolts of the protocol are elaborated and put into writing ("cast in stone"). The objectives, endpoints, and inclusion and exclusion criteria will come from the study synopsis. However, many other items need to be specified, such as the time windows for screening and followup examinations, procedures for management of known or suspected complications related to the disease or therapy, and treatment algorithms for how the individual patient is to be monitored and treated if complications arise. Box 4.3 presents an example of a protocol table of contents for a clinical trial.

Most protocols provide very detailed scientific background sections but are left wanting when it comes to detailing the actual study procedures. The mark of a wellwritten protocol is that the study co-ordinator can read the protocol and know which procedures to perform and how to perform them for each study visit, the data manager can design the requisite case report forms, and the biostatistician can perform the study analyses.

The study procedures section should contain a visit schedule listing each and every measurement that is to be made during that encounter. Often, a simple bullet point list will do and usually a summary table is created as well. Having a complete list of visit-by-visit procedures is key to ensuring that all measurements are made as required at each time point. For clinical trials that take place in the operating room, the visits might be separated by minutes or hours rather than by days.

To assist with this, the study evaluations and measures section should specify how each evaluation will be performed. Continuing with our previous example of a clinical trial of an antihypertensive drug, it is not enough to state that systolic blood pressure will be measured. Rather, the protocol must describe exactly how it will be measured (which arm, which device, whether the subject is to be seated, lying or standing, after how many minutes of rest, and how many measurements will be averaged).

When completed, the protocol becomes the blueprint for the study execution and once put into place, its recipe must be followed to the letter, if the trial is to be successful. Indeed, it is this "cast in stone" rigidity that so befuddles many clinicians and represents the fundamental difference between a clinical trial and routine clinical care [81]. In routine clinical care, physicians use their best judgment to make treatment decisions. On the other hand, in a clinical trial, the investigator's responsibility is strict adherence to the protocol, not to his or her own judgment. This is absolutely essential to ensure the fidelity of the trial. For example, if a 6-year-old postoperative patient has an oxygen saturation of 92% in the postanesthesia care unit (PACU), some clinicians might decide to watch and wait, whereas others may prescribe and administer supplemental oxygen. However, if a study protocol treatment algorithm requires a subject to receive oxygen if their oxygen saturation decreases below 94%, then oxygen must be administered even if this is not the investigator's individual clinical practice. Put another way, if a study protocol requires that subjects eat green Jell-O, the clinician/investigator must provide green Jell-O, even if they would prefer red.

# Data management and document preparation

When the protocol is finalized, the informed consent and assent forms and the case report forms (CRF), paper or electronic, can be developed. Data should be recorded first in the source document, which is a medical chart,

anesthesia record or data collection form, and then transferred to the CRFs. If data collection forms will be used, they should be tested for usability. The data management team should be organized and must develop the data storage, back-up, and security plans. In multicenter trials, the data team will produce the randomization and treatment allocation schedules and develop protocols for data transfer from each site to the data center.

All clinical trials need a data quality control plan. If the study is conducted at a single site, the principal investiga-

tor will be responsible. For a multicenter trial, the sponsor or contract research organization (CRO) will be responsible for site monitoring and for reviewing performance and outcomes during the course of the trial. These procedures establish the plan for collecting, processing, and verifying study data accuracy and for on-site monitoring to ensure that the protocol is being adhered to and that the data forms actually are being completed correctly.

Finally, the data monitoring group must develop guidelines for data security and access to study data by investigators within and outside the study and this access must be weighed by the rights of patients to privacy and confidentiality. The co-ordinating center may also be responsible for ancillary documents for the study staff to help ensure that the study procedures are followed precisely as well as to prepare any diaries or instructions for participants.

The Standards for Privacy of Individually Identifiable Health Information (the Privacy Rule) established, for the first time, a set of national standards for the protection of certain health information. The US Department of Health and Human Services (HHS) issued the Privacy Rule to implement the requirement of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). The Privacy Rule standards addressed the use and disclosure of individuals' health information (called "protected health information") by organizations subject to the Privacy Rule (called "covered entities"), as well as standards for individuals' rights to understand and control how their health information is used. Within HHS, the Office for Civil Rights (OCR) has responsibility for implementing and enforcing the Privacy Rule with respect to voluntary compliance activities and civil money penalties. The effect of the Privacy Rule on the conduct of clinical trials has not been major and largely involves expansion of the mandated confidentiality language in the informed consent document.

### Informed consent document

The principal investigator is usually responsible for the development of the informed consent template document. The consent forms must follow the federal regulatory required elements of informed consent (45 CFR 46.116(a) and 21 CFR 50.25). The document should be written in plain language, with a target reading level of 6–8th grade. Approximately 12% of Americans have a below Basic health literacy proficiency and 22% are at the Basic level. Thus, if the informed consent form is written at greater than 8th-grade level, over a third of the participants will be unable to comprehend what they are reading [90].

### Safety monitoring plan

All clinical trials require monitoring of unanticipated problems involving risks to subjects or others, including serious adverse events (SAEs). In multicenter studies, SAEs are usually reported promptly to the study sponsor. The sponsor is responsible for reporting these events to the regulatory agency overseeing the study. However, not all SAEs have to be reported to the IRB. Both the FDA and the OHRP have published guidelines on reporting of adverse events to the IRB [67,91]. Regardless of the guidelines, investigators need to adhere to the policies in place at their local institution.

Safety monitoring should be tailored to the complexity of the study and the potential for harm to subjects. For a single-center study with a relatively low level of risk, the principal investigator's oversight should suffice. For a single-center trial with a moderate level of inherent risk, an internal data safety monitoring committee (DSMC) made up of the principal investigator and other knowledgeable individuals unassociated with the study would be advisable. For multicenter trials involving lifethreatening conditions or risky therapies, an independent DSMC would be appropriate [92–95].

For all drug trials enrolling pediatric subjects, the American Academy of Pediatrics strongly recommends a DSMC for monitoring [96]. When the intervention has a track record of safety in adults and the condition of interest is not life-threatening, this level of oversight can be an unnecessary burden and adds substantially to the overhead costs of the study. Regardless of the oversight mechanism, meeting schedules and endpoints for interim analyses (if any) need to be defined and agreed upon. For trials involving life-threatening conditions, the protocol should contain stopping rules and procedures for early termination of the trial if serious unanticipated risks emerge. Only rarely should a trial be stopped for benefit and then only when one arm demonstrates a large margin of superiority [97,98].

### Authorship and registration

Deciding exactly how the results of the study will be disseminated and by whom is a step often overlooked in the pretrial planning process. In our experience, failure to make this decision before embarking on a trial often leads to bad blood and ill will amongst the study investigators. As stated previously, for many investigators, authorship is essential for academic promotion. The order of authorship for study papers (and for ancillary studies) should be established and agreed upon by all investigators before starting a study. Ideally, a formal steering committee should be charged and entrusted with acting impartially on behalf of all the investigators early in a study design. The steering committee should establish procedures for review and approval of all publications and presentations made by members of the investigative group before professional and lay scientific committees. At this stage it is also important to clarify trial roles. Some journals now request the exact role of each investigator at the time of publication. Finally, it is also important to establish safeguards that protect against premature disclosure of study results or the publication of the study results by a "minority" within the study group.

The final step within the protocol development stage is establishing the budget and staffing requirements for the trial. Does each prospective participating center have the manpower and skills to safely, effectively, and efficiently conduct the trial? Do they have enough potential participants to enroll in a timely manner? How will oversight be performed and by whom? How will study drugs be packaged, labeled, distributed, and safeguarded? How will the study be funded and by whom? Who will do all the regulatory work required for the trial?

Funding and projected budgets are the keys to successful and unsuccessful trials. Inadequate funding, just like undercapitalization of a business, leads to failure. Indeed, it has been our experience that the real costs of conducting a study, including protocol development and site approval, are often underbudgeted which often results in contract delays and misadventures.

Because many if not all of the studies conducted by pediatric anesthesiologists involve drugs, and most if not all have invariably not been approved for use in children, approval by the FDA and its European counterpart the EMA may be required. It is beyond the scope of this chapter to discuss the process of obtaining an IND Application from the FDA but several useful sources are available at the FDA website (www.FDA.gov/CDER).

Finally, all phase II, III and IV trials require prospective registration in a national trial registry, such as www. clinicaltrials.gov in the United States. These registries are often funded by government entities and are designed to keep investigators from manipulating study endpoints by prespecifying the study objectives, intervention, subject population, sample size, and analysis plan of a trial before a trial is started. The databases are publically available and are searchable. Most journals use and require trial registration for any trial submitted for publication.

#### Trial execution: treatment and follow-up

It is only after all the preliminary development, feasibility assessments, protocol development, and regulatory approval have been organized that the investigators are ready for subject recruitment and actually conducting the trial. For all multicentered trials there is usually an investigators' meeting held before the first subject is enrolled at which required training, standard operating procedures, and data management are finalized.

For most perioperative pediatric anesthesia trials, the local investigator or his or her study co-ordinator recruits subjects from an in- and an outpatient operative list. Viewing and accessing these lists are subject to HIPAA rules and must be cleared with the IRB and the HIPAA compliance office within the institution. Advertising and liaisons with medical and lay societies that are so important in other adult and pediatric trials are often unnecessary. On the other hand, it is essential to inform the surgeons and the local referring pediatricians whose patients could be enrolled about the study and to get their tacit approval prior to recruiting subjects into the trial.

When it will be difficult to obtain consent and assent on the day of surgery, one approach is to screen the operative schedule and send letters to prospective study participants to inform them in general terms of the study objectives and procedures. Obviously, these letters are part of the regulatory binder and must be part of the IRB approval process. Without this prescreening and notification, there can be insufficient time to allow prospective participants to consider the risks, benefits, and alternatives to more complicated studies, making an informed decision difficult if not impossible. Thus, a successful recruitment plan often requires the investigator and coordinator to screen and recruit in the surgeon's or pediatrician's office.

Before agreeing to take part in a clinical trial, both the investigator and the prospective participant need to understand that care provided during research is different from usual clinical care. The investigator's obligation is to adhere to the protocol and not to individualize care to the participant's need. It is not known whether or not the participant will benefit directly from their participation; to promise benefit is to presuppose the outcome from the trial. Failure to understand the difference between clinical care and research is termed "therapeutic misconception" [99–101]. The investigator must ensure that the prospective participant understands the difference so that expectations are aligned with reality.

The data quality review, site monitoring visits, and meetings of the study steering committee, DSMC and other study committees take place at regularly scheduled intervals. At these meetings, recruitment progress and projected time lines for completion of the study are reviewed to ensure that the study is meeting its goals.

### **Close-out and termination stage**

Once the last subject has had their last visit and the final data queries issued by the data management team are resolved, sites can be closed. In practice, low-enrolling sites are closed well before this point so that there are sufficient monitoring resources to rapidly lock the study database. The site monitoring team will direct the disposition of equipment, supplies, drugs and other stored materials. Once all data queries are resolved, the database can be locked, which means that no further changes will be made, even if small errors are discovered. As long as subject identifiers remain in the database used for analysis, the study must remain open and be approved by the IRB. For multicenter trials, most sites can submit a request for study closure once the sponsor has conducted the close-out visit.

The study's statisticians might or might not conduct the planned analyses blinded to treatment assignment. The statistician prepares results summarized in tables and figures. A formal study report is usually prepared and investigators and participants can be informed of the study's findings. The results of the study are submitted for publication and to regulatory agencies. Finally, if indicated, this is the time to plan for follow-up studies.

### Conclusion

The randomized, blinded, placebo-controlled clinical trial is the indispensable "gold standard" in determining the efficacy of therapeutics. Trials are time consuming, maddeningly difficult and often very expensive to perform, and frustrating from inception to execution to completion. However, the failure to properly perform a trial results in perpetual uncertainty. Performing a proper trial takes time to develop a protocol, create and test the data collection forms, obtain support and funding and establish the structure for data intake and analysis. Once completed, the results of the trial must be published and made available to the public and regulatory agencies. Finally, above all else, all aspects of trial conduct must adhere to accepted ethical standards.

### Introduction

The understanding of both normal and abnormal cardiac development and physiology is crucial in providing anesthetic care to infants and children. The explosion of knowledge over the past several decades regarding the extensive changes in the cardiovascular system during fetal, neonatal, and early childhood periods requires thorough review so the anesthesiologist can apply these complex principles to patient care. This chapter will first present normal cardiac embryology and development, and then review the abnormal cardiac development that results in the most common congenital cardiac defects recognized clinically. Then the normal physiological changes from the fetus to the neonate, and from infancy to childhood, will be reviewed. Finally, the pathophysiology of congenital heart disease, regulation of systemic and pulmonary vascular tone, and receptor signaling in disease states will be presented.

## Cardiac embryology and normal development

The pathogenesis of congenital heart disease is not completely understood. Developmental mechanisms that include cell migration, hemodynamic function, cell death, and extracellular matrix proliferation have all been proposed in the etiology of cardiovascular malformations. Multiple genetic pathways have been identified that contribute to cardiac development and whose disruption

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

may result in structural defects [1–6]. These genetic controls influence cardiac-specific mechanisms such as cardiogenesis, looping of the heart tube, chamber specification, cardiac septation, conotruncal and aortic arch development, valvular formation, and ventricular function [4,7].

A foundation in human embryology and, in particular, in the areas of cardiac morphogenesis and normal development provides a window into the complex series of events that may result in abnormalities of the cardiovascular system. As such, a basic understanding of embryology and critical events during the various stages of cardiac development should be of relevance to those who care for infants and children, in particular those affected by congenital heart disease.

This section provides an overview of the normal developmental program of the cardiovascular system, highlighting important events during cardiac morphogenesis and consequences of abnormal development, as relevant to the practice of pediatric anesthesiology. The data presented derive from a combination of descriptive or classic embryology, experimental work on other species, and current knowledge regarding human cardiac development.

The heart represents the first functional organ in the embryo. Cardiac development in most vertebrates is considered to follow a similar pattern from the formation of the cardiogenic plate to the complex fully developed organ, with minor variations across species.

The critical stages of cardiovascular development in the human encompass events between the second and eighth weeks of gestation (Fig. 5.1). The review that follows emphasizes main aspects of embryological development of the heart and great vessels during this period. To facilitate this discussion, a perspective that focuses on the origin and evolving changes of the major cardiovascular structures throughout embryonic development has been selected over a strict chronological approach. For a more exhaustive review of the subject, the reader is referred to several outstanding resources [8–14].

### Early cardiogenesis

The earliest developmental stage of the heart and vascular system is seen following the second week of gestation. On the 15th day of gestation, mesoderm is derived from ectoderm. The "middle skin" or mesoderm will in turn give rise to the various cardiovascular structures. On the 18th day of gestation, the mesoderm-derived cardiogenic crescent forms the precursor to the heart (Fig. 5.2A). Cavitation of the mesoderm results in formation of the intraembryonic celom, from which all body cavities, including pericardial, pleural, and peritoneal, will be eventually derived.

### Straight heart tube

On the 15th day of gestation, the cardiogenic crescent has developed into the primitive heart tube [15]. Blood in this midline tube enters caudally via the inflow and exits cranially via the rudimentary outflow tract. The linear heart tube will eventually give rise to the atria, ventricles, bulbus cordis, and truncus arteriosus (Fig. 5.2B). The bulbus cordis and truncus arteriosus contribute to formation of the ventricles and great vessels respectively.

### Cardiac looping

On the 21st day of gestation, cardiac loop formation takes place. The straight heart tube is fixed at both ends (the sinus venosus and truncus arteriosus segments) by pericardium. Differential growth of the straight heart tube results in the sinus venosus portion being positioned posteriorly, the common ventricle anteriorly, and the bulbus cordis anteriorly and superiorly. This accounts for cardiac looping and the ventricular relationship.

Looping of the heart tube to the right gives rise to the normal ventricular relationship (*d*-loop), where the right ventricle is ultimately positioned rightwards (Fig. 5.2C). In contrast, looping to the left results in an abnormal ventricular relationship (*l*-loop), where the right ventricle is positioned leftwards (*I*-looped ventricles) (Fig. 5.2D). Molecular cues determining cardiac looping remain poorly understood.

#### Atrial septation

Atrial septation begins in the fourth week of gestation and continues into the fifth week (Fig. 5.3). Ingrown tissue along the superior aspect of the atria initially results in a septum primum. In a curtain-like fashion, this septum primum extends inferiorly towards the embryonic endocardial cushions. Two foramina are associated with the septum primum: the superior foramen or ostium secundum and the inferior foramen primum. The foramen secundum arises from perforations in the septum primum and remains open until birth. The foramen primum is transient, as continued growth of the septum primum and endocardial cushions obliterates this communication.

The septum secundum forms during the fifth and sixth weeks of gestation, arising to the right of the septum primum. Similarly to the septum primum, the septum secundum extends inferiorly. The foramen secundum is closed by the inferiorly extending septum secundum. The superior septum secundum and inferior septum primum create the foramen ovale.

The foramen ovale acts as a one-way valve in fetal life, allowing oxygenated blood from the inferior vena cava to course from the right atrium to the left atrium. Functional closure of the foramen ovale occurs postnatally as a result of increased pulmonary blood flow and left atrial pressure exceeding that of the right atrium. This occurs as the

septum primum moves against the septum secundum. Fusion of the septum primum and septum secundum following birth results in anatomical closure of the foramen ovale and complete atrial septation.

### Development and incorporation of the sinus venosus

Initially, the segment corresponding to the sinus venosus is positioned in the midline of the posteriorly positioned primordial atrium. On the 26th day of gestation, the right and left horns of the sinus venosus develop (Fig. 5.4A). The right horn is connected to the right umbilical, vitelline, anterior cardinal and common cardinal veins, and inferior vena cava. The left horn is connected to the left umbilical, vitelline, anterior and common cardinal veins. There is a progressive shift of drainage of venous blood from left- to right-sided structures. This result in an enlarging right horn and the sinoatrial orifice moving rightwards, towards the primordial atrium. This process culminates in the incorporation of the right horn of the sinus venosus into the future right atrium (Fig. 5.4B).

**Figure 5.4** Fate of the sinus venosus. (A) Dorsal view of the heart (approximately 26 days) demonstrating the primordial atrium and sinus venosus. (B) Dorsal view at 8 weeks after incorporation of the right sinus horn into the right atrium. The left sinus horn has become the coronary sinus. (C) Internal view of the fetal right atrium showing: (i) the smooth part of the wall of the right atrium (sinus venarum) derived from the right sinus horn and (ii) the crista terminalis and the valves of the inferior vena cava and coronary sinus derived from the right sinuarily valve. The primordial right atrium becomes the right auricle, a conical muscular pouch. Reprinted from Moore and Persaud [12] with permission from Elsevier.

The smooth portion of the mature right atrium, the sinus venarum, is derived from sinus venosus (Fig. 5.4C). The rough atrial appendage and conical muscular pouch of the right atrium are derived from the primordial atrium. Internally, the demarcation between the smooth sinus venarum posteriorly and the rough primordial atrium anteriorly is evidenced by a ridge of cardiac muscle tissue referred to as the crista terminalis. This is also marked externally by a groove, the sulcus terminalis. Both the right anterior cardinal and common cardinal veins contribute to the formation of the superior vena cava during the eighth week of gestation. The right horn receives all the blood from the head and neck via the superior vena cava, and from the caudal regions and placenta through the inferior vena cava. The smaller left horn eventually becomes the coronary sinus.

The sinus venosus contributes to the conduction system of the heart. The sinoatrial node develops from the sinus venosus during the fifth week of gestation. This is located along the high right atrium at the junction between the right atrium and superior vena cava. The atrioventricular node develops from the inferior portion of the sinus venosus in combination with cells from the atrioventricular region. The atrioventricular node arises slightly superior to the endocardial cushions (discussed below) with the atrioventricular bundle coursing into the ventricles.

### **Development of the systemic veins**

The development of the venous structures associated with the heart occurs during the fourth week of gestation. Three paired veins drain blood into the tubular heart: the vitelline, umbilical, and common cardinal veins (Figs 5.5, 5.6A, 5.7).

The vitelline veins return poorly oxygenated blood from the yolk sac. The umbilical veins carry oxygenated blood from the placenta to the sinus venosus portion of the developing heart. As the liver develops, the umbilical veins lose their connection with the heart (Fig. 5.6B). The left umbilical vein courses through the liver. The inferior portion of the left umbilical vein becomes the ductus venosus, bypassing the liver parenchyma, and enters the inferior vena cava. The right umbilical vein degenerates at the end of the embryonic period.

The cardinal veins return deoxygenated blood from the body of the embryo to the sinus venosus. The superior and inferior cardinal veins join to form the common cardinal vein. The superior vena cava eventually develops from the right anterior cardinal vein and common cardinal vein as previously indicated (Fig. 5.6C). The subcardinal and supracardinal veins subsequently largely replace the posterior cardinal veins. The subcardinal veins give rise to several structures, including a segment of the inferior vena. During the seventh week of gestation, the supracardinal veins appear. The cranial portions of the supracardinal veins give rise to the azygous and hemiazygous veins. The caudal portion of the left supracardinal veins degenerates, with the right portion becoming the inferior portion of the inferior vena cava.

The inferior vena cava develops as a result of a shift of primordial venous drainage from the left to right side of the body (see Fig. 5.7). The inferior vena cava is composed of four main segments, each originating

**Figure 5.5** The embryonic vascular system in the middle of the fourth week. At this stage, the heart has begun to beat and circulate blood. The outflow tract is now connected to four pairs of aortic arches and the paired dorsal aortae that circulate blood to the head and trunk. Three pairs of veins, umbilical, vitelline, and cardinal, deliver blood to the inflow region of the heart. Reprinted from Larsen et al [13] with permission from Lippincott, Williams and Wilkins.

from primordial venous structures. This includes the hepatic segment (derived from the right vitelline vein), prerenal segment (derived from the right subcardinal vein), renal segment (derived from the subcardinal and supracardinal anastomosis), and postrenal segment (derived from the right supracardinal vein).

### Development of the pulmonary veins

Pulmonary development begins as a ventral outgrowth from the foregut, termed the respiratory diverticulum. The respiratory diverticulum develops with its most caudal segments represented by lung buds. A capillary plexus called the splanchnic plexus surrounds the lung buds (Fig. 5.8).

The primitive pulmonary veins arise from the splanchnic plexus. The pulmonary venous plexus shares venous drainage with the splanchnic plexus, which is connected to the cardinal and umbilical venous systems in early embryonic development. Consequently, the initial pulmonary venous drainage is via the cardinal and umbilical venous systems [16,17]. A primordial endocardial outgrowth from the superior margin of the left atrium forms the primordial pulmonary vein. It is the connection of this primordial pulmonary vein with the pulmonary venous plexus that allows pulmonary venous blood to flow into the left atrium. Once this connection to the left atrium is established, the pulmonary venous plexus loses its connection with the cardinal and umbilical veins. The eventual lack of obliteration of these connections is considered to result in anomalies of pulmonary venous drainage [18].

The left atrium is largely derived from the incorporation of the pulmonary veins. As the primordial pulmonary vein and its branches are incorporated into the primordial atrium, the four pulmonary veins incorporate into the left atrial wall. Areas of the left atrium derived from the pulmonary veins are smooth, whereas those derived from primordial atrium (left atrial appendage) have a rough surface.

#### Development of the atrioventricular valves

Development of mesenchymal tissue swellings, otherwise known as endocardial cushions, along the atrioventricular canal begins in the fourth week of gestation (Fig. 5.9). The superior and inferior endocardial cushions are located in continuity with the interatrial and interventricular septa [19]. The formation of separate right and left atrioventricular valves is the result of simultaneous ingrowth of the lateral endocardial cushions. In addition to the endocardial cushions, additional embryonic structures that contribute to the formation of the atrioventricular valves include the dextrodorsal conal crest and the ventricular walls.

The cushions perform a valve-like function, preventing blood flow from the ventricle into the atria during systole,

thus facilitating forward blood flow (Fig. 5.10) [20]. Initially these regions are muscular in nature, and through a process of cellular differentiation they become thin and membranous [21].

#### Ventricular development and septation

Ventricular septation begins in the fifth week and continues into the seventh week of gestation (Fig. 5.11). The primordial interventricular septum arises from a median muscular ridge between the right and left ventricular masses. Increased growth and dilation of the ventricles, combined with fusion of the medial ventricular wall, result in enlargement of the muscular ventricular septum. A crescentic interventricular foramen between the free edge of the septum and endocardial cushion exists up until the seventh week of gestation. Closure of the primary interventricular foramen (bulboventricular foramen) results from tissue ingrowth from the right and left bulbar ridges, and the endocardial cushion.

The membranous portion of the septum is derived from tissue ingrowth from the right side of the endocardial cushion to the muscular region of the interventricular septum. The atrioventricular septum, or region of the septum that separates the right atrium from the left ventricle, originates from the inferior cushion of the atrioventricular canal.

Cavitation of the ventricular walls begins during the fifth week of gestation. This leads to an increase in the ventricular sizes. Several of the remaining muscle bundles will form the trabeculae carneae (muscle bundles on the ventricular free wall), whereas others will eventually give rise to the future papillary muscles and their chordal attachments to the atrioventricular valves. With respect to the embryological origin of the ventricles, it has been suggested that the inlet region originates from the endocardial cushions, the trabecular area from the primordia of the trabecular portion of the ventricles, and the outlet region from conal tissue [22]. Other studies propose that the inlet and trabecular components are derived from the same primary ventricular septum [23].

### Partitioning of the bulbus cordis and truncus arteriosus

Extensive experimental work in the chick embryo has provided insights into the development of the conus and truncus arteriousus [24–26]. These observations strongly suggest that these developmental sequences are similar in the chick and the human.

Neural crest cells originating in the posterior rhombencephalon are known to migrate into the pharyngeal arches. Continued migration of these cells contributes to the formation of the conus and great arteries (aorta, aortopulmonary septum), aortic arch branches, ductus arteriosus, and cardiac ganglia [27–30]. It is thus not surprising

**Figure 5.8** Development of the pulmonary veins. (A) At 27–29 days of gestation, the primordial lung buds are enmeshed by the vascular plexus of the foregut (splanchnic plexus). No direct connection to the heart is present at this stage. Instead, the multiple connections are present to the umbilicovitelline and cardinal venous systems. A small evagination can be seen in the posterior wall of the left atrium to the left of the developing septum secundum. (B) By the end of the first month of gestation, the common pulmonary vein establishes a connection between the pulmonary venous plexus and the sinoatrial portion of the heart. At this time, the connections between the pulmonary venous plexus and the splanchnic venous plexus are still patent. (C) Subsequently the connections between the pulmonary venous plexus and the splanchnic venous plexus involute. (D) The common pulmonary vein (CPV) incorporates into the left atrium so that the individual pulmonary veins connect separately and directly to the left atrium. LA, left atrium; LCCV, left common cardinal vein; LLB, left lung bud; RA, right atrium; RCCV, right common cardinal vein; RLB, right lung bud; UV, umbilical vein. that the neural crest has been implicated in the pathogenesis of several cardiovascular anomalies [31].

Partitioning of the bulbus cordis and truncus arteriosus begins in the fifth week of gestation (see Fig. 5.11). Neural crest cells migrate into both the bulbus cordis and truncus arteriosus, forming bulbar and truncal ridges respectively. These ridges undergo 180° of rotation, causing the formation of a spiral aortopulmonary septum. Development of these ridges into the aortopulmonary septum divides the future aorta from the main pulmonary artery. The bulbus cordis contributes to the development of both ventricles. In the right ventricle, it forms the conus

Figure 5.9 Sections of the heart illustrating successive stages in the development of the atrioventricular valves, tendinous cords, and papillary muscles. (A) At 5 weeks. (B) At 6 weeks. (C) At 7 weeks. (D) At 20 weeks. Reprinted from Moore and Persaud [12] with permission from Elsevier.

arteriosus or infundibulum that gives rise to the pulmonary trunk. In the left ventricle, it forms the aortic vestibule or aortic region inferior to the aortic valve. Partitioning of the bulbus cordis and truncus arteriosus nears completion in the sixth week of gestation.

At the end of the fifth week of gestation, the interventricular foramen is still patent (ventricular septal defect). The heart is largely septated into a double or parallel circulation at this stage. The third, fourth, and sixth aortic arches are present. The dorsal aorta and ductus arteriosus are formed. Continued neural crest cell migration aids in the formation of the infundibulum and great vessels. The ventricles continue to develop at this stage. The mitral valve, left ventricle, and aorta align with the interventricular foramen. On the 32nd day of gestation, the main pulmonary artery and ascending aorta septate, and

**Figure 5.10** Sagittal sections of the primordial heart during the fourth and fifth weeks illustrating blood flow through the heart and division of the atrioventricular canal. (A–C) The arrows are passing through the sinoatrial orifice. (D) Coronal section of the heart at the plane shown in C. Note that the interatrial and interventricular septa have started to develop. Reprinted from Moore and Persaud [12] with permission from Elsevier.

shortly thereafter the atrioventricular valves septate. The right ventricle enlarges at this time with concurrent movement of the interventricular septum leftwards. The interventricular septum aligns underneath the atrioventricular canal as it moves leftwards. Failure of this interventricular alignment has been implicated in the etiology of double outlet right ventricle.

### Semi-lunar valve development and great artery relationships

The semi-lunar valves originate from subendocardial tissue swellings in the aortic and pulmonary trunk. These swellings subsequently become hollow and form the valve cusps.

On the 30th day of gestation, the pulmonary valve begins its movement to its final position, anterior and leftwards of the aorta. This migration continues through the 36th day of gestation. During the course of this complex process, various observations have been made regarding the position of the great arteries with respect to each other that resemble known pathological relationships. On days 30–32 of gestation, the semi-lunar valve relationship is similar to that of *d*-transposition of the

great arteries. On the 33rd day of gestation, the semilunar valve relationship is side by side, similar to that seen in Taussig–Bing malformation. On the 34th day of gestation, the semi-lunar valve relationship resembles that seen in tetralogy of Fallot.

### Fates of the vitelline and umbilical arteries

Development of the dorsal aortae, vitelline, and umbilical arteries is complete by the fourth week of gestation. The vitelline artery, supplying the yolk sac, will in turn supply the primordial gut. In the mature fetus, the vitelline artery will form the celiac, superior mesenteric, and inferior mesenteric arteries. The umbilical arteries transport poorly oxygenated blood from the body of the fetus to the placenta. These paired umbilical arteries will in turn form the internal iliac arteries (proximally), superior vesical arteries (proximally), and degenerate distally to form the medial umbilical ligament.

### Development of the aortic arches

The mature aortic arch evolves from contributions of the aortic sac, aortic arches, and dorsal aortae (Fig. 5.12). Six pairs of aortic arches have been identified in the human

**Figure 5.11** Incorporation of the bulbus cordis into the ventricles and partitioning of the bulbus cordis and truncus arteriosus. **Figure 5.12** Arterial changes that result during transformation of the truncus arteriosus, aortic sac, pharyngeal arch arteries, and dorsal aortas into the adult arterial pattern. (Vessels not colored are not derived from these structures.) (A) Pharyngeal arch arteries at 6 weeks; by this stage, the first two pairs of the arteries have largely disappeared. (B) Pharyngeal arch arteries at 7 weeks; the parts of the dorsal aortae and pharyngeal arch arteries that normally disappear are indicated with broken lines. (C) Arterial arrangement at 8 weeks. (D) The arterial vessels of a 6-month-old infant. Note that the ascending aorta and pulmonary arteries are considerably smaller in C than in D. This represents the relative flow through these vessels at the different stages of development. The ductus arteriosus normally becomes functionally closed within the first few days after birth, eventually becoming the ligamentum arteriosum, as shown in D. Reprinted from Moore and Persaud [12] with permission from Elsevier.

embryo. Aortic arch development begins with the first pair of arches forming in the beginning of the fourth week of gestation. By the 26th day of gestation, the first aortic arches have involuted. A portion of these contributes to the development of the maxillary and external carotid arteries. At this time the second and third arches are formed, and the fourth and sixth arches are beginning to form. The second aortic arches eventually disappear; only a dorsal portion persists, giving rise to the stapedial artery. The third aortic arches contribute to the development of the carotid arteries.

During the sixth and seventh weeks of gestation, the arch and its branching pattern is established. If altered, these series of events can lead to vascular anomalies. The fourth aortic arch forms a portion of the aortic arch, innominate and proximal right subclavian arteries. The fifth aortic arch regresses during normal development. The first, third, fourth, and sixth aortic arches contribute to the formation of the mature arch. The sixth aortic arch forms the proximal left and right pulmonary arteries, and ductus arteriosus. The seventh intersegmental artery gives rise to the left subclavian artery. A summary of the aortic arches and their future vascular structures can be found in Table 5.1.

Normally various interruptions of the aortic arch system occur, resulting in a left aortic arch. These include involution of the right ductus arteriosus or sixth arch, the ductus caroticus (dorsal aorta segment between the third and fourth arches), and the right dorsal aorta distal to the seventh intersegmental artery (part of the embryonic right subclavian artery) [32].

Aortic arch sidedness is defined by the course of the arch over the mainstem bronchus. A left aortic arch courses over the left mainstem bronchus. Arch sidedness is determined by regression of the dorsal aortic arches. If

#### Table 5.1 Derivatives of the aortic arches

Aortic arch	Derivative
First aortic arch	Maxillary artery, external carotid arteries
Third aortic arch	Common carotid arteries Internal carotid arteries
Fourth aortic arch	Proximal right subclavian artery Transverse aortic arch (between left common carotid and left subclavian artery)
Sixth aortic arch	Proximal left and right pulmonary artery Ductus arteriosus
Seventh intersegmental artery	Distal right subclavian artery Left subclavian artery

the left dorsal aortic arch persists, the result is a left aortic arch; if the right dorsal arch persists the result is a right aortic arch. If both arches persist, the result is a double aortic arch.

### Intersegmental arteries

The aortic arch arises from the aortic sac as a paired structure. The paired dorsal aortae soon fuse, caudal to the pharyngeal arches, to form a single dorsal aorta. Arising from the dorsal aorta are at least 30 intersegmental arteries, providing blood supply to anterior body structures. The anterior intersegmental arteries in the neck join to form the vertebral arteries. The majority of the connections between the intersegmental arteries and dorsal aorta eventually regress. In the thorax, however, the dorsal intersegmental arteries persist as intercostal arteries. In the abdomen, several of these persist as lumbar arteries, where the fifth pair of lumbar intersegmental arteries forms the common iliac arteries.

### **Development of the coronary arteries**

The coronary arteries appear relatively late during cardiac development. During early cardiac morphogenesis, nutrients to the cardiac mass are derived directly from surrounding circulating blood, and subsequently from intramyocardial communications, also termed sinusoids. The appearance of subepicardial vascular networks during the fifth week of development is thought to give rise to the distal coronary vasculature.

Theories regarding the origin of the proximal coronary arteries are more controversial [33]. Several different mechanisms have been implicated [34–37]. These include penetration of the subepicardial vascular networks across the aortic wall to reach the aortic sinuses and the existence of coronary buds around the arterial trunks that eventually communicate with the subepicardial vascular network. The former concept is considered most likely to be the case.

### Defects resulting from abnormal cardiac development

### **Defects of cardiac positioning**

The position of the normal heart with the cardiac mass in the left thorax and apex pointing to the left is known as levocardia. Cardiac malpositions may result from extrinsic or intrinsic factors [38]. Dextrocardia, a positional abnormality, is considered to result from rightward rotation of the cardiac mass. This may or may not be associated with other defects. Dextrocardia with situs solitus (also known as isolated dextrocardia) is frequently seen in the context of severe cardiac anomalies that include atrioventricular discordance (*l*-looped ventricles), single ventricle, transposition of the great arteries, and heterotaxy syndrome. Dextrocardia with situs inversus is less likely to be accompanied by cardiac defects.

### **Defects of atrial septation**

Defects resulting from the abnormal formation of the atrial septum represent a large proportion of congenital heart lesions [39]. Atrial septal defects can occur in isolation or may be seen in association with other cardiovascular malformations. Communications at the interatrial level include the following: patent foramen ovale, ostium secundum defect, ostium primum defect, sinus venosus defect, and common atrium.

A patent foramen ovale may be found in up to a fourth to a third of the population. This results from failure of fusion of the primum and secundum septae. Ostium secundum defects are the most common type of communications at the interatrial septum. They are typically located centrally in the interatrial septum. These defects result from a combination of excessive resorption of the septum primum and large foramen ovale defects. Ostium primum defects are seen in up to 20% of children with Down syndrome. These are communications in the lower portion of the atrial septum and are associated with a cleft in the mitral valve. These defects are considered a form of endocardial cushion defect. Primum defects result from lack of fusion of the primum septum with the absent endocardial cushion. Sinus venosus defects, located near the entrance of either the superior or inferior vena cava into the right atrium, result from defects in the sinus venosus portion of the atrial septum. They are associated with partial anomalous pulmonary venous connections. Complete absence of the atrial septum results in a common atrium. This may be part of the heterotaxy syndrome.

### Defects of the atrioventricular canal and atrioventricular valves

Atrioventricular canal defects, also referred to as atrioventricular septal defects or endocardial cushion defects, result from failure of fusion of the superior and inferior endocardial cushions [21,40]. These defects can vary in severity and complexity [41]. The pathology involves a combination of the following: an atrial communication, a ventricular communication, and abnormal development of the atrioventricular valves. The complete form of the defect involves all three of these components and a common atrioventricular valve. The less severe forms involve only one or two of the above defects. Children with canal-type defects may have displacement of the conduction system, an important issue that has surgical implications. Atrioventricular septal defects are frequently associated with Down syndrome. In fact, nearly 80% of all infants with atrioventricular septal defects have a chromosomal anomaly, syndrome, non-syndromic organ anomaly or deformation [42].

Tricuspid and mitral valve defects result from failure of normal formation of the two separate valves, chordae tendinae, and ventricular cavitation. Ebstein anomaly is characterized by an apically displaced tricuspid valve with an atrialized portion of the right ventricle. The tricuspid valve is often dysplastic and regurgitant [43]. Valve stenosis may be seen. Isolated mitral valve anomalies in children are relatively rare.

### **Defects of ventricular septation**

Ventricular septal defects are one of the most common types of congenital heart lesions [44]. These defects encompass four major portions of the ventricular septum: membranous, muscular, inlet, and outlet. Defects in the membranous region (referred to as membranous or perimembranous) predominate. These result from failure of fusion of endocardial tissue ingrowth, aorticopulmonary septum, and muscular septum. Muscular defects are the second most common type of defects in the ventricular septum. These can be single or multiple and can be located anywhere along the muscular or trabecular portion of the septum. Multiple muscular defects in close proximity or that may coalesce together are colloquially referred to as "Swiss cheese" defects. Defects in the inlet septum are associated with endocardial cushion defects. These result from failure of fusion of the medial endocardial cushions and formation of the inlet ventricular septum. Outlet defects may also be referred to as conal, supracristal, subarterial or doubly committed defects. These are located in the right ventricular outflow tract immediately below the pulmonary valve. When examined from the left ventricular aspect, these defects lie just below the aortic valve. This anatomical relationship is a substrate for aortic valve prolapse or herniation of the valve cusps into the defect and may lead to aortic insufficiency.

### Defects of conotruncal development and semi-lunar valve formation

Defects of conotruncal development and semi-lunar valve formation account for a large number of congenital heart defects [45,46]. These include truncus arteriosus, *d*transposition of the great arteries, tetralogy of Fallot, and aortopulmonary window. Several of these conotruncal malformations have been linked to abnormal aortopulmonary septation under the influence of the neural crest [28,47,48].

Truncus arteriosus results from failed formation of the truncal ridges and aorticopulmonary septum. A single aorticopulmonary trunk with underlying ventricular septal defect (VSD) gives rise to the pulmonary, coronary, and systemic circulations [49]. Several subtypes of this anomaly exist with variants based on the anatomical origin of the pulmonary arteries.

Failure of spiral septation of the aorticopulmonary septum can result in several congenital cardiac defects. Both transposition of the great arteries and tetralogy of Fallot can be explained by this mechanism. Transposition of the great arteries is thought to be the result of failed spiral septation. This results in the pulmonary artery arising from the posterior left ventricle and the aorta originating from the anterior right ventricle [50]. Tetralogy of Fallot results from unequal partitioning of the aorta and pulmonary artery. Anterior deviation of the conal septum results in a diminutive right ventricular outflow tract, over-riding aorta, and secondary right ventricular hypertrophy [51]. Failure of fusion of the conal septum with the bulbus cordis results in the ventricular level communication in this malformation. Pulmonary atresia is considered within the spectrum of tetralogy of Fallot as a severe form. Extreme anterior deviation of the aorticopulmonary and conal septae in this case results in lack of a pulmonary outflow tract.

An aortopulmonary window results from failed aorticopulmonary septation. In this defect there is a communication between the aorta and pulmonary artery, but typically no ventricular septal defect is present [52].

### Defects in aortic arch development

Normal aortic arch development relies on sequential development and regression of the aortic arches. Failure of these processes can lead to a number of aortic arch anomalies.

Two developmental events that can result in aortic arch obstruction include hypoplasia of the arch and the presence of ductal tissue in the aorta at its site of insertion. The aortic arch is derived proximally from the aortic sac, distally from the fourth aortic arch, and at the isthmus from the fourth and sixth aortic arches. Failure of development of each of these segments can lead to underdevelopment of the aortic arch or interruption. Although the specific level of arch obstruction is variable among these lesions, perfusion to the lower body is often dependent on patency of the ductus arteriosus.

Aortic arch anomalies can result in a vascular ring, double aortic arch or pulmonary artery sling [53]. These variations in the arrangement of the great arteries can be further explained by considering the embryological development of the aortic arch and pulmonary arteries.

The embryonic aortic arches encircle the embryonic foregut (trachea and esophagus). Normal development results in regression of the right sixth aortic arch and involution of the right dorsal aorta, thus avoiding formation of a vascular ring. Failure of this normal development or regression can lead to variations in pathological anatomy that result in vascular encirclement or compres-

#### Table 5.2 Aortic arch anomalies

Anomaly	Cause
Left aortic arch with retroesophageal right subclavian artery (aberrant right subclavian artery)	Absence of right fourth aortic arch
Left aortic arch with retroesophageal diverticulum of Kommerell	Absence of right fourth aortic arch, persistence of right sixth arch (right ligamentum arteriosum)
Right aortic arch with mirror image branching	Absence of left dorsal aorta
Right aortic arch with diverticulum of Kommerell	Absence of left fourth aortic arch, persistence of left sixth arch (left ligamentum arteriosum)
Right aortic arch with retroesophageal left subclavian artery (aberrant left subclavian artery)	Absence of left fourth and sixth aortic arches
Double aortic arch	Persistence of right and left fourth aortic arches

sion of the trachea and/or esophagus, in some cases associated with obstructive symptoms.

Selected defects in aortic arch development are listed in Table 5.2. We initiate this discussion reviewing variants associated with a left aortic arch. The formation of a left aortic arch with an aberrant or retroesophageal subclavian artery (branching pattern: right carotid, left carotid, left subclavian, and anomalous right subclavian artery) is the result of abnormal regression of the right fourth aortic arch. This is the most common arch variant occurring in 0.5% of the general population. The right sixth aortic arch regresses normally in this defect, and no vascular ring is formed. In contrast, a left aortic arch with retroesophageal diverticulum of Kommerell also has abnormal regression of the right fourth aortic arch, but persistence of the right sixth aortic arch as the right ligamentum arteriosum. This defect results in a vascular ring encircling the trachea and esophagus.

The formation of a right aortic arch with mirror image branching is the result of regression of the left dorsal aorta. The branching pattern in this case is as follows: first arch vessel, left innominate artery that branches into left subclavian and left carotid arteries; second vessel, right carotid artery; and third vessel, right subclavian artery. This substrate is almost invariably associated with intracardiac disease.

A right aortic arch with a retroesophageal diverticulum of Kommerell results from regression of the fourth aortic

arch, persistence of the left sixth arch as the ligamentum arteriosus and of the left dorsal aorta. This results in a vascular ring. A right aortic arch with aberrant subclavian artery (branching sequence: left carotid, right carotid, right subclavian, and anomalous left subclavian artery) can be accounted for by regression of the left fourth and sixth aortic arches. The absence of the left sixth arch, or ductal arch, prevents formation of a vascular ring. Many of these children have conotruncal malformations. The formation of a double aortic arch is the result of persistence of both the right and fourth aortic arches. The presence of both arches results in a vascular ring and frequently the left arch is atretic. This anomaly is associated with symptomatology in infancy related to tracheal and esophageal compression.

A cervical aortic arch occurs when the arch extends into the soft tissues of the neck, above the level of the clavicle. This rare anomaly has also been referred to as "high aortic arch." Various arrangements including normal and anomalous arch branching patterns, in addition to pathology such as aortic arch obstruction, have been reported in affected patients. A number of embryological explanations (atresia of the fourth primitive aortic arch associated with persistence of the third arch, failure of normal caudal aortic arch migration) have been proposed to account for the various subtypes.

### Defects in coronary artery development

The coronary arteries arise from epicardial blood islands in the sulci of the developing heart. These in turn connect to the sinuses of Valsalva and form capillary networks with veins connected to the coronary sinus. Buds from the pulmonary arteries also connect to the coronary arteries, but regress during normal development.

Persistence of this pulmonary connection can lead to anomalous origin of the left coronary artery from the pulmonary artery [54]. Affected children become symptomatic as the pulmonary vascular resistance declines following birth. The diminished perfusion pressure of the left coronary artery accounts for myocardial ischemia and ventricular dysfunction.

### Defects of the venous system

Defects of the superior and inferior vena cava rarely occur [55]. Among systemic venous anomalies, persistence of the left superior vena cava draining into the coronary sinus is most common. This is due to persistence of the left anterior and common cardinal veins. Interruption of the inferior vena cava with azygous and hemiazygous continuation of flow into the right atrium may be seen, most frequently in the setting of complex congenital heart disease. In these patients the inferior vena cava is interrupted above the renal veins and blood eventually enters the heart via alternative venous pathways. Failure of formation of the hepatic portion of the inferior vena cava is thought to account for these anomalies.

### Defects in pulmonary venous drainage

During the early stages of human development, the vascular plexus of the foregut, also known as the splanchnic plexus, which forms the pulmonary vasculature, has no direct connection to the heart. Defective development or regression of the pulmonary venous plexus and its connection to the primordial or common pulmonary vein can lead to anomalous pulmonary venous connections and/ or drainage.

Anomalous pulmonary venous drainage can occur in a total or partial manner, meaning that all veins or a selected number do not enter the left atrium [56]. In total anomalous pulmonary venous drainage, the pulmonary veins drain into the right atrium or other vascular structures either above or below the liver. In partial anomalous pulmonary venous drainage, at least one vein empties normally into the left atrium with one or more pulmonary veins draining elsewhere. In some instances, mixed anomalous drainage may be present, with pulmonary venous connection to various sites.

### Developmental cardiac physiology and pathophysiology

The circulatory system in congenital heart disease continually changes and develops in response to both normal and pathological stimuli. Response to anesthetic and surgical interventions must be understood within this framework, and is often radically different from the usual, expected pediatric and adult situations with a "normal" cardiovascular system. This section will review developmental changes of the cardiovascular system from fetal life through adulthood, both in the normal and pathophysiological states associated with congenital heart disease. As little is known about the development of the normal and diseased human heart, much of the information discussed in this chapter is derived from animal models. Undoubtedly, new information will be discovered as more studies on human myocardiocal tissues are undertaken.

### **Development from fetus to neonate** Circulatory pathways

The fetus receives oxygenated and nutrient-rich blood from the placenta via the umbilical vein, and ejects desaturated blood through the umbilical arteries to the placenta, and thus the placenta, not the lung, serves as the organ of respiration. Blood flow thus largely bypasses the lungs *in utero*, accounting for only about 7% of the fetal combined ventricular output [57]. Pulmonary vascular

**Figure 5.13** Transition from fetal to mature circulation. (A) Fetal circulation. (B) Transitional circulation. (C) Mature circulation. Circled numbers are oxygen saturations, uncircled numbers are pressures in mmHg. resistance is high, and the lungs are collapsed and filled with amniotic fluid. This is the basis for the fetal circulation, which is a parallel one, rather than the series circulation seen postnatally. Three fetal circulatory shunts exist to carry better oxygenated blood from the umbilical vein to the systemic circulation: the ductus venosus, ductus arteriosus, and foramen ovale (Fig. 5.13A). Approximately 50% of the umbilical venous blood, with an oxygen tension of about 30-35 mmHg, passes through the ductus venosus and enters the right atrium. There, it streams preferentially across the foramen ovale, guided by the valves of the sinus venosus and Chiari network into the left atrium. Thus the brain and upper body preferentially receive this relatively well-oxygenated blood, which accounts for 20-30% of the combined ventricular output. Blood returning to the inferior vena cava represents about 70% of the total venous return to the heart, and two-thirds of this deoxygenated blood passes into the right atrium and ventricle. About 90% of the blood flows through the ductus arteriosus to supply the lower fetal body.

With inflation of the lungs and increasing arterial oxygen tension at birth, there is a dramatic fall in pulmonary vascular resistance and increase in pulmonary blood flow. The placental circulation is removed and all these changes lead to closure of the ductus venosus, constriction of the ductus arteriosus, and reversal of pressure gradients in the left and right atria, leading to functional closure of the foramen ovale. This results in a state called the transitional circulation (Fig. 5.13B), characterized by high pulmonary artery pressures and resistance (much lower than *in utero*, however), and a small amount of leftto-right shunting through the ductus arteriosus. This is a labile state, and failure to maintain lower pulmonary vascular resistance can rapidly lead to reversal to fetal circulatory pathways, and right-to-left shunting at the level of the ductus arteriosus and foramen ovale. This maintenance of fetal circulatory pathways is necessary for survival in many congenital heart lesions, particularly those dependent on patency of the ductus arteriosus for all or a significant portion of systemic or pulmonary blood flow, or in the settings of atresia of atrioventricular valves. Maintenance of ductal patency with prostaglandin E1 is essential in these lesions. In the two-ventricle heart with a large intracardiac communication, maintenance of the fetal circulation leads to right-to-left shunting at the foramen and ductal levels, and thus arterial desaturation.

Conversion to the mature circulation (Fig. 5.13C) in the normal heart occurs over a period of several weeks, as pulmonary vascular resistance falls further, and the ductus arteriosus permanently closes by thrombosis, intimal proliferation, and fibrosis. Factors favoring the transition from the fetal to a mature circulation include normal oxygen tension and physical expansion of the lungs, normal pH, nitric oxide, and prostacyclin. Factors favoring reversion to fetal circulation include low oxygen tension, acidosis, lung collapse, and inflammatory mediators (leukotrienes, thromboxane A2, platelet activating factor) as seen in sepsis and other related conditions, and endothelin A receptor activators [58].

### Myocardial contractility

The fetal myocardium is characterized by a poorly organized cellular arrangement, and fewer myofibrils with a random orientation, in contrast to the parallel, wellorganized myofibrillar arrangement of the adult myocardium [59] (see below). Fetal hearts develop less tension per gram than adult hearts because of increased water content and fewer contractile elements. Calcium cycling and excitation-contraction coupling are also very different, with poorly organized T-tubules and immature sarcoplasmic reticulum, leading to more dependence on free cytosolic ionized calcium for normal contractility in the fetal heart. Despite this immature state, the fetal heart can increase its stroke volume in a limited fashion up to left atrial pressures of 10–12 mmHg according to the Frank–Starling relationship, as long as afterload (i.e. arterial pressure) is kept low [60]. These features continue throughout the neonatal and early infancy period.

### Development from neonate to older infant and child

At birth, the neonatal heart must suddenly change from a parallel circulation to one in series, and the left ventricle in particular must adapt immediately to dramatically increased preload from blood returning from the lungs, and increased afterload as the placental circulation is removed. The very high oxygen consumption of the newborn necessitates a high cardiac output for the first few months of life. However, animal models have demonstrated that the fetal and newborn myocardium develops less tension in response to increasing preload (sarcomere length), and that cardiac output increases less to the same degree of volume loading [61,62]. Resting tension, however, is greater in the newborn compared to the mature heart. These data suggest that the newborn heart is operating near the maximum of its Frank-Starling curve, and that there is less reserve in response to both increased afterload and preload. This observation is borne out clinically in newborns after complex heart surgery, who are often intolerant of even small increases in left atrial pressure or mean arterial pressure. The newborn myocardium also has only a limited ability to increase its inotropic state in response to exogenous catecholamines, and is much more dependent on heart rate to maintain cardiac output than is the mature heart. One reason for this is the high levels of circulating endogenous catecholamines that appear after birth, necessary to make the transition to extrauterine life [63]. As these levels decrease in the weeks after birth, contractile reserve increases.

The neonatal myocardium is less compliant than the mature myocardium, with increased resting tension as noted above, and a significantly greater increase in ventricular pressure with volume loading [64]. This implies that diastolic function of the neonatal heart is also impaired compared to the mature heart [65]. The myofibrils of the newborn heart also appear to have a greater sensitivity to calcium, developing a greater tension than

adult myofibrils when exposed to the same free calcium concentration *in vitro* [66].

It must again be emphasized that nearly all of these data are derived from animal work, and although the information appears to agree with what is observed clinically, there is a need for non-invasive studies of normal human hearts from the neonatal period through adulthood to confirm these impressions of developmental cardiovascular physiology.

### Innervation of the heart

Clinical observations in newborn infants have led to the hypothesis that the sympathetic innervation and control of the cardiovascular system are incomplete in this age group compared to older children and adults, and that the parasympathetic innervation is intact [59]. Examples of this include the frequency of bradycardia in the newborn in response to a number of stimuli, including vagal and vagotonic agents, and the relative lack of sensitivity in the newborn to sympathomimetic agents. Histological studies in animal models have demonstrated incomplete sympathetic innervation in the neonatal heart when compared to the adult, but no differences in the number or density of parasympathetic nerves [67,68].

Autonomic cardiovascular control of cardiac activity can be evaluated by measuring heart rate variability in response to both respiration and beat-to-beat variability in systolic blood pressure [69]. The sympathetic and parasympathetic input into sinoatrial node activity contribute to heart rate variability changes, with greater heart rate variability resulting from greater parasympathetic input into sinoatrial node activity [70]. Studies using these methodologies for normal infants during sleep suggest that the parasympathetic predominance gradually diminishes until approximately 6 months of age, coinciding with greater sympathetic innervation of the heart similar to adult levels [71].

#### Development from child to adult

Beyond the transition period from fetal to newborn life and into the first few months of postnatal life, there is limited human or animal information concerning the exact nature and extent of cardiac development at the cellular level. Most studies compare newborn or fetuses to adult animals [72]. Cardiac chamber development is assumed to be influenced by blood flow [73]. Large flow or volume load in a ventricle results in ventricular enlargement. Small competent atrioventricular valves, as in tricuspid stenosis, result in decreased blood flow and ventricular hypoplasia. Increases in myocardial mass with normal growth, as well as in ventricular outflow obstruction, are mainly due to hypertrophy of myocytes. Late gestational increases in blood cortisol are responsible for this growth pattern, and there is concern that antenatal glucocorticoids to induce lung maturity may inhibit cardiac myocyte proliferation. In the human infant, it is assumed that the cellular elements of the cardiac myocyte, i.e. adrenergic receptors, intracellular receptors and signaling, calcium cycling and regulation and interaction of the contractile proteins, are similar to the adult by approximately 6 months of age. Similarly, cardiac depression by volatile agents is greater in the newborn, changing to adult levels by approximately 6 months of age [74].

### Normal values for physiological variables by age

It is useful for the anesthesiologist to be aware of normal ranges for physiological variables in premature and fullterm newborns of all sizes, and in infants and children of all ages (Fig. 5.14). Obviously, acceptable ranges for these variables are highly dependent on the individual patient's pathophysiology, but the wide range of "normal" values may reassure the practitioner to accept "low" blood pressure, for example, if other indices of cardiac function and tissue oxygen delivery are acceptable.

### Cardiomyocyte receptor function in normal and diseased hearts

### The adrenergic receptor

The adrenergic receptors (AR) are part of a large superfamily of receptors that mediate their biological responses through the coupling of a specific guanine nucleotide regulatory protein or G protein [75]. This superfamily of receptors shares a common structural motif, characterized by seven hydrophobic domains spanning the lipid bilayer. The seven domains are attached by three internal loops and three external loops between the amine terminus and the cytoplasmic carboxy terminus. The function of this receptor family is dependent on a specific agonist (or ligand) binding to the receptor, which causes a conformational change in the receptor. This structural change permits the interaction between the intracellular portion of the receptor and guanine nucleotide regulatory protein (or G protein). This interaction, also referred to as coupling, inevitably links the activated receptor to a specific biological response. The regulation of the biological response is initiated by the specificity of the receptor for a particular extracellular agonist and the coupling of a specific G protein to that activated receptor.

Once an extracellular ligand (or agonist) is specifically recognized by a cell surface receptor, the receptor undergoes conformational changes that expose a specific region of the receptor complex to the intracellular side of the plasma membrane [76] (Fig. 5.15). This confirmation change triggers the interaction of the G protein with the amino acids of the third intracellular loop of the receptor, hence leading to G protein activation. There are three different G proteins: stimulatory G protein (Gs), inhibitory G protein (Gi) and Gq (heterotrimeric G protein). Under

**Figure 5.15** Molecular structure of the  $\beta$ -adrenergic receptor, demonstrating its three domains. The transmembrane domains serve as ligand-binding pockets for agonists (dashed arrows) and antagonists (solid arrows). The cytoplasmic domains interact with G proteins and  $\beta$ -adrenergic receptor kinases. Reproduced from Moss and Renz [75] with permission from Elsevier.

normal conditions, all the adrenergic  $\beta$  receptors interact with Gs,  $\alpha 1$  interacts with Gq and  $\alpha 2$  interacts with Gi. Each G protein is a heterotrimer made up of three subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ . The activation of the G protein-coupled receptor causes an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP) within the  $\alpha$  subunit and initiates the dissociation of the  $\beta/\gamma$  subunit from the  $\alpha$  subunit. The GTP-activated  $\alpha$  subunit modulates the activity of a specific effector enzyme within a specific signaling pathway by catalyzing the hydrolysis of GTP to GDP and inorganic phosphate. This causes the transference of a high-energy phosphate group to an enzyme and in turn causes the deactivation of the  $\alpha$ subunit. This process will eventually lead to the deactivation of the  $\alpha$  subunit and the reassociation with the  $\beta/\gamma$ complex. This cycle is continuously repeated until the agonist becomes unbound from the receptor. Downstream of enzyme activation, the production of a second messenger regulates the biological response.

Adrenergic receptors have been subdivided into two principals,  $\alpha$  and  $\beta$ , based on the results of binding studies using a series of selective agonists and antagonists [77]. This has been validated repeatedly with the development of drugs that function to selectively antagonize the  $\alpha$ receptor with no effect on the  $\beta$  receptor. Soon after the distinction between the  $\alpha$  and  $\beta$  receptor type was recognized, it became more evident that the separation of these receptors was not sufficient to explain pharmacological studies using rank order of potency for an antagonist, differing from an agonist because it blocks the biological response. With the advent of radioligand-labeled antagonists and new molecular cloning techniques examining receptor gene expression, it became clear that the two principal receptor groups could be further subdivided into additional subtypes.

To date, within the  $\beta$  adrenergic group, four different subtypes have been identified: \(\beta1\), \(\beta2\), \(\beta3\), \(\beta4\). Pharmacologically,  $\beta 1$  and  $\beta 2$  are differentiated by their affinities for different catecholamines: epinephrine, norephinephrine, and isoproterenol. β1 has similar affinity for epinephrine and norepinephrine, while  $\beta 2$  has a higher affinity for epinephrine than norepinephrine. Both  $\beta$ 1 and  $\beta$ 2 have the same affinity for isoproterenol. The  $\beta$ 3 and  $\beta$ 4 receptors have minor roles in cardiovascular function and will not be discussed further here.

The expression and distribution of each receptor subtype are highly dependent on the organ, which adds another level of specificity. Distribution of a particular receptor in two different tissue types may result in two different functions. When examining cardiovascular response to adrenergic stimulation, the  $\beta$ 1 receptor is predominantly expressed in heart tissue. The stimulation of the receptor subtype leads to both inotropic and chronotropic effects on cardiac function, resulting in an increase in the myocardial contractile force and a shortening of contractile timing, respectively. While B2 can also be found in the heart, it is mostly expressed in vascular smooth muscle tissue. The distribution and function relevance of this receptor subtype in the heart are controversial and may change with alterations in cardiac function. The percentage of  $\beta 2$  receptors in the non-failing heart averages about 20% in the ventricle [78] and 30% in the atrium. The percentage of  $\beta$ 1 to  $\beta$ 2 receptors is approximately 75%:25% in the ventricles of younger hearts [79,80].

Each signaling pathway is specific to each adrenergic receptor. Once the agonist binds to the  $\beta$ 1 receptor, causing the coupling of the G protein, the G protein  $\alpha$  subunit becomes activated, followed by an increase in adenylate cyclase (AC) activity, which induces the conversion of ATP to cyclic adenosine monophosphate (cAMP). The second messenger, cAMP, phosphorylates protein kinase A (PKA). The function of a kinase is to phosphorylate other target proteins which initiate a biological response (see Fig. 5.15). PKA phosphorylates many effector proteins and the phosphorylation of each one functions to increase the concentration of intracellular calcium.

The  $\beta$ 2 receptor has also been shown to function through the cAMP signaling pathway, causing the activation of PKA, but not nearly to the extent of  $\beta$ 1 in cardiomyocytes [81]. The response of this stimulation appears to have a larger effect on smooth muscle, for example the vascular smooth muscle. In this tissue type, the stimulation of  $\beta$ 2 and the subsequent increase in cAMP promotes the vasodilation of vascular smooth muscle and may lead to alterations in blood pressure. In these tissues, the effect of  $\beta$ 1 stimulation appears to be minimal, due to lack of  $\beta$ 1 receptors in the smooth muscle.

Similar to the  $\beta$  receptor, the  $\alpha$  receptors can be pharmacologically subdivided into  $\alpha 1$  and  $\alpha 2$ . The  $\alpha 1$  receptor is distributed in most vascular smooth muscle and to a lesser extent the in the heart. The  $\alpha 2$  receptor has been

found in some vascular smooth muscle but its major functional importance is as a presynaptic receptor in the central and peripheral nervous systems. The use of molecular techniques has identified three additional subtypes of the  $\alpha$ 1 receptor ( $\alpha$ 1A,  $\alpha$ 1B, and  $\alpha$ 1D) and three additional subtypes of the  $\alpha 2$  receptor [75]. Binding of an agonist to an  $\alpha$ 1 receptor in the heart or vascular smooth muscle results in activation of the Gq subunit of the G protein, which activates phospholipase C (see below), producing diacylglycerol and inositol-1,4,5-triphosphate, which releases calcium from the sarcoplasmic reticulum and increases vascular smooth muscle tone or cardiac contractility. A schematic classification of adrenergic receptors incorporating recent knowledge of molecular pharmacology and signal transduction is presented in Figure 5.16 [75].

The adrenergic receptor concentration in cardiac tissue is very small and measured as femtomoles per milligram of protein. However, the response to stimulation of the receptor is greatly amplified by the signal that occurs downstream of the receptor. In rat ventricular myocytes, the ratio between the  $\beta$  receptors and the next two downstream signaling components ( $\beta$  receptor: G protein: adenylate cyclase) is 1:200:3 [82]. This demonstrates how a large response can be initiated by the activation of a small number of receptors. In addition, it also demonstrates that the rate-limiting component that ultimately regulates intracellular production of adenylate cyclase.

Figure 5.16 Classification of adrenergic receptors. Reproduced from Moss and Renz [75] with permission from Elsevier.

### Developmental changes in adrenergic receptor signaling

Information concerning changes in adrenergic receptor function during the transition from neonatal to more mature myocardial development is limited to a few animal studies. As noted above, the neonatal heart has a limited inotropic response to catecholamine administration.

β-adrenergic receptor density is higher in the ventricular myocardium of neonatal versus adult rabbits, but the inotropic response to the same concentration of isoproterenol is significantly greater in adult tissue [83]. In the neonatal rat, the mechanism of β-adrenergic mediated increase in contractility is entirely due to β2 stimulation, whereas in the adult rat it is due solely to β1 receptor activation. Coupling of the β2 receptor to Gi protein action is apparently defective in the neonatal rat, because the ratio of Gi to Gs subunits is much higher in the neonate. The relative proportion of β1 and β2 receptors is the same in neonatal and adult hearts (17% β2), and approximates the ratio measured in children with simple acyanotic congenital heart disease, which is about 22% [84].

There is animal and human evidence to indicate that  $\alpha$ -adrenergic receptor-mediated chronotropic and inotropic effects on the cardiac myocyte change with development. In the neonatal animal model,  $\alpha$  stimulation produces positive inotropic and chronotropic effects, whereas in the adult it produces negative effects [85,86]. The chronotropic response to  $\alpha$ 1 stimulation diminished with increasing age in children being evaluated for autonomic dysfunction after vagal and sympathetic blockade [87].

#### Calcium cycling in the normal heart

Calcium assumes a central role in the process of myocardial contraction and relaxation, serving as the second messenger between depolarization of the cardiac myocyte and its contraction mediated by the actin-myosin system. The role of calcium in this excitation-contraction coupling in the normal mature heart will be reviewed briefly before discussion of developmental changes and changes with heart failure [88].

Cardiac muscle cell contraction depends on an increase in intracellular calcium above a certain threshold, and relaxation ensues when intracellular calcium falls below this threshold. Two major regions of calcium flux occur: across the sarcolemmal membrane (slow response), and release from internal stores: the sarcoplasmic reticulum (rapid release and reuptake) [89] (Fig. 5.17). The primary site of entry of calcium through the sarcolemmal membrane is through the L-type or low voltage-dependent calcium channels, which occurs in two types: a lowthreshold, rapidly inactivating channel and a higher threshold, more slowly inactivating channel [90]. Depolarization of the sarcolemmal membrane triggers opening of these channels, resulting in the release of large amount of calcium from the sarcoplasmic reticulum (SR), the major internal calcium storage organelle. Calcium entry through the slowly inactivating channels serves to fill the SR with adequate calcium stores. Removal of calcium from the cytoplasm to the exterior of the cell occurs via two major mechanisms: the sodium-calcium (NaO-Ca<sup>2+</sup>) exchanger and the calcium-ATPase pump. The NaO-Ca<sup>2+</sup> exchanger usually serves to exchange three sodium ions (moving into the cell) for one calcium ion (moving out of the cell), although the reverse action, as well as a 1:1 exchange, are possible [91]. The calcium-ATPase pump actively transports calcium (in a 1:1 Ca<sup>2+</sup>/ATP ratio) out of the cell in an energy-dependent high-affinity but lowcapacity manner [92]. The affinity of the sarcolemmal calcium-ATPase pump is enhanced by calmodulin, which binds free cytoplasmic calcium.

Although the calcium movement through the sarcolemma plays an important role in balancing internal and external calcium concentrations and in supplying calcium to replenish SR calcium stores, and in initiating the calcium-induced release of calcium from the SR, it is important to recognize that the amount of calcium flux is far less than across the SR, the far more important mechanism for excitation-contraction coupling in the mature heart [93]. The sarcolemmal calcium flux mechanisms play a much more important role in the excitationcontraction coupling of the neonatal (immature) heart.

The massive release and reuptake of calcium responsible for activation and deactivation of the actin-myosin complex and cardiocyte contraction and relaxation occur at the level of the SR. This is a closed, intracellular membranous network that is intimately related to the myofilaments responsible for contraction [94] (Fig. 5.18). The SR is connected to the sarcolemmal membrane via the transverse tubule (T-tubule) system. Depolarization of the sarcolemmal membrane leads to transfer of charge down the T-tubules to the SR, resulting in the opening of SR calcium channels and the release of large amounts of calcium into the cytoplasm, where it can then bind to troponin and initiate the actin-myosin interaction. The SR is divided into longitudinal SR and terminal cisternae; the latter connect to the T-tubules. The terminal cisternae are primarily involved in the release of calcium, and the longitudinal SR in its reuptake [95].

The primary calcium release mechanism of the SR is the ligand-gated calcium release channels that bind to the drug ryanodine (also known as the ryanodine receptors). The channels are activated by two primary mechanisms: depolarization via the T-tubules and binding of intracellular calcium itself; the predominance of one mechanism over the other differs in cardiac versus skeletal muscle. The close proximity of the L-type sarcolemmal calcium

channels in the T-tubules to the ligand-gated calcium release channels allows the depolarization to rapidly allow calcium into the cell and open the SR calcium channels. These ligand-gated calcium release channels close when the cytosolic calcium concentration increases; normally it opens at  $0.6 \mu M \text{ Ca}^{2+}$  and closes at  $3.0 \mu M \text{ Ca}^{2+}$ .

The reuptake and sequestration of calcium leads to relaxation of the cardiac myocyte, and is an active transport mechanism, primarily involving hydrolysis of ATP by the sarcoplasmic reticulum calcium-ATPase (SERCA), located in the longitudinal SR [96]. It binds two calcium ions with high affinity and rapidly transports them to the inside of the SR. This transport system differs from the sarcolemmal membrane: it has higher affinity, allows for more rapid transport, and is not sensitive to calmodulin. Calcium is stored in the SR by calsequestrin, a highcapacity, low-affinity protein that acts as a calcium sink.

There are two other proteins with essential roles in the regulation of calcium flux: phospholamban and calmodulin [97,98]. Phospholamban is associated with the SERCA, and can be phosphorylated by at least four different protein kinases (see above): cAMP dependent, calcium / calmodulin dependent, cyclic guanosine monophosphate (cGMP) dependent, or protein kinase C. When phosphorylated, phospholamban increases the affinity of the SERCA for calcium, facilitating calcium flux back into the SR, thus affecting the inotropic and lusitropic state of the heart. Phospholamban plays an important role in the βadrenergic mediated increase in the inotropic state of the heart. Calmodulin is a calcium storage protein with four binding sites, found in the cytoplasm, which interacts with the sarcolemmal calcium ATPase (increasing its affinity for calcium), the SR ligand-gated calcium release channel (inhibits its activity at optimal cytoplasmic

calcium), and binds to the calcium/calmodulin-dependent protein kinase [98].

The increase in intracellular cytoplasmic calcium initiates the contractile process. Myosin is the major component of the thick filaments, which make up the microscopic structure of the myofibril, and its interaction with actin (the major component of the thin filaments) provides the mechanical basis of cardiac muscle cell contraction [99]. Actin and myosin make up approximately 80% of the contractile apparatus, and are arranged in a parallel, longitudinal fashion, projecting from a Z-line or band (Fig. 5.19) to form the basic contractile unit called the sarcomere. A three-dimensional lattice is formed, consisting of interdigitated thick and thin filaments in a hexagonal array with three thin filaments in close proximity to each thick filament. The actin and myosin are linked by projections on the myosin protein called S1 cross-bridges, which bind to actin and, via an energy-dependent hingelike mechanism, produce the sliding filament cross-bridge action that is thought to produce sarcomere shortening and lengthening. The lattice is held together by connecting proteins such as titin, nebulin, and  $\alpha$ -actinin [100].

The actin-myosin interaction is initiated when calcium binds to troponin, a protein closely connected to actin which consists of three subunits: a calcium binding subunit (TNC), a tropomyosin binding unit (TNT), and an inhibitory subunit (TNI). TNC can bind up to four calcium ions and this produces a conformational change on the thin filament, which allows the S1 myosin head cross-bridges to attach [101]. This also changes the TNI subunit's conformation and allows tropomyosin, another protein integral in filament interaction, to move aside and expose the binding sites on actin, allowing the strong binding to the S1 cross-bridges. With calcium

Figure 5.19 (A) Single thick and thin filament showing the S1 cross-bridge and hinge mechanism. (B) Relationship of actin to tropomyosin and the three troponin subunits. See text for explanation. Reproduced from Michael [154] with permission from Lippincott, Williams and Wilkins.

present, actin causes myosin ATPase to hydrolyze one ATP molecule, providing energy that causes the S1 myosin head to pull on the thin filament, resulting in sarcomere shortening. Troponin C is the most important aspect of the regulation of cardiocyte contraction, and has a steep response curve to local levels of calcium. The reuptake of calcium into the SR causes calcium levels to decline rapidly and the inhibitory form of the troponin-tropomyosin-actin complex returns, resulting in reversal of the cross-bridge binding and thus sarcomere relaxation.

Besides calcium, many other regulatory mechanisms exist to influence the interaction and sensitivity of calcium binding to troponin. These mechanisms include  $\beta$ adrenergic stimulation, thyroid hormone, and phosphorylation by cAMP-dependent protein kinases.

### Developmental changes in calcium cycling

Several aspects of the excitation-contraction system are unique in the immature heart. The T-tubule is not fully formed [102], the SR has less storage capacity and less structural organization [103], less mRNA expression [104,105], and less responsiveness to chemical blockade [106,107]. The inhibitory subunit of troponin (TNI) changes from a predominantly cAMP-insensitive form to a cAMP-responsive form by 9 months of age, an additional factor contributing to the increased responsiveness seen with  $\beta$ -adrenergic stimulation after the neonatal period [107]. All of this information has led to the theory that the neonatal cardiac myocyte is more dependent on free cytosolic calcium fluxes than is the mature heart, and more susceptible to blockade of the L-type calcium sarcolemmal channels as a mechanism of myocardial depression. The latter is thought to be the mechanism producing greater myocardial depression observed with halothane in neonatal rat models compared with sevoflurane, and the same phenomenon seen clinically [108]. A summary of the major differences in cardiac development and function between the neonatal and mature heart is presented in Table 5.3.

### Thyroid hormone

Tri-iodothyronine (T3) has a critical role in both the development of the cardiovascular system, and also in acute regulation and performance. Normal T3 levels are essential for normal maturation and development of the heart through expression of genes responsible for the production of the cardiac contractile proteins, elements of the calcium cycling apparatus, and development and density of  $\beta$ -adrenergic receptors [109]. There are cell nucleusmediated effects from exogenous T3 that occur via an increase in protein synthesis and require at least 8 h to develop. These include an upregulation of β-adrenergic receptors, increase in cardiac contractile protein synthesis, mitochondrial density, volume, and respiration, and SR calcium-ATPase mRNA, and changes in myosin heavy chain isoforms. However, there are acute effects of T3 on cardiac myocytes that occur in minutes from interactions with specific sarcolemmal receptors, and include stimulation of L-type calcium pump activity, stimulation of SR

Feature	Neonatal	Mature
Physiology		
Contractility	Limited	Normal
Heart rate dependence	High	Low
Contractile reserve	Low	High
Afterload tolerance	Low	Higher
Preload tolerance	Limited	Better
Ventricular interdependence	Significant	Less
Calcium cycling		
Predominant site of Ca <sup>2+</sup> flux	Sarcolemma	Sarcoplasmic reticulum
Dependence on normal iCa <sup>2+</sup>	High	Lower
Circulating catecholamines	High	Lower
Adrenergic receptors	Downregulated, insensitive	Normal
	$\beta 2, \alpha 1$ predominant	β1 predominant
Innervation	Parasympathetic predominant	Complete
	Sympatheticpredominant	Incomplete
Cytoskeleton	High collagen/water content	Lower collagen/water content
Cellular elements	Incomplete SR	Mature SR
	Disorganized myofibrils	Organized myofibrils

calcium-ATPase activity, increased protein kinase activity, and decrease in phospholamban [110]. Cardiac surgery and cardiopulmonary bypass interfere with the conversion of thyroxine (T4) to T3, and serum levels decrease significantly after cardiac surgery in infants and children [111]. T3 infusions improve myocardial function in children after cardiac surgery and reduce intensive care unit stay [112].

### Regulation of vascular tone in systemic and pulmonary circulations

The regulation of vascular tone is an important consideration in the understanding and treatment of congenital heart disease. Both the systemic and pulmonary circulations have complex systems to maintain a delicate balance between vasodilating and vasoconstricting mediators in normal patients. Abnormal responses may develop which lead to pulmonary or systemic hypertension or, conversely, vasodilation. A schematic representation of some of these mediators is shown in Figure 5.20. To some extent, the control mechanisms reviewed are present in both the systemic and pulmonary circulations; however, certain mechanisms are more important in one circulation. For example, the endothelial-mediated systems (nitric oxide-cGMP pathways, etc.) predominate in the pulmonary circulation (low-resistance circulation), and the phospholipase systems in the systemic circulation (high-resistance circulation).

### **Pulmonary circulation**

Vasoactive metabolites of arachidonic acid, called eicosanoids, are produced in cell membranes. Eicosanoids metabolized via the lipoxygenase pathway will form leukotrienes, and those metabolized via the cyclo-oxygenase pathway form the prostaglandins (PG). Important vasodilating prostaglandins include PGE1, which also promotes and maintains patency of the ductus arteriosus. Prostacyclin, PGI2, is a potent pulmonary vasodilator [113]. Prostaglandins act in vascular smooth muscle of the systemic and pulmonary circulations by binding to receptors in the smooth muscle cell membrane, activating adenylate cyclase and increasing cAMP concentrations, which lead to lower calcium levels and a reduction of vascular tone. Thromboxane A2 is a potent leukotriene that has the opposite effect to the prostaglandins, producing vasoconstriction and platelet aggregation. Imbalance in this system caused by chronic hypoxia can lead to chronic pulmonary hypertension.

Nitric oxide (NO) is an endothelium-derived factor that causes relaxation of vascular smooth muscle cells after diffusing into the cell and activating guanylate cyclase, increasing the concentration of cGMP, leading

Figure 5.20 Some major mediators of vascular tone in the pulmonary circulation. ET, endothelin-1; PROET, proendothelin-1; ECE, endothelin converting enzyme. See text for explanation. Reproduced from Haynes and Webb [155] with permission from Portland Press.

to a reduction in the local concentration of calcium and thus reducing vascular tone [114]. Calcium-sensitive potassium channels contribute to the vasodilation caused by NO via a cGMP-dependent protein kinase [115]. NO is formed from L-arginine by NO synthase, and is almost immediately inactivated by binding to hemoglobin. Phosphodiesterase V breaks down cGMP, so the phosphodiesterase-inhibiting drugs, like sildenafil, potentiate NO-mediated vasodilation [116].

Endothelins are powerful endothelium-derived vasoactive peptides, and endothelin-1 (ET-1) is the best characterized. ET-1 is produced from proendothelin-1 by endothelin-converting enzymes in the endothelial cells of systemic and pulmonary vasculature. Increased pressure, shear stress, and hypoxia can lead to increased production of ET-1 in the pulmonary circulation. Two ET-1 receptors, ETA and ETB, mediate effects on smooth muscle vascular tone [117]. The ETA receptor is found on the smooth muscle cell membrane and mediates vasoconstriction, while the ETB receptor is located on the endothelial cell itself and results in increased NO synthase activity, producing vasodilation. The primary activity of ET-1 appears to be to stimulate the ETA receptor, and indeed increased levels of ET-1 are found in many pulmonary hypertensive states such as Eisenmenger syndrome and primary pulmonary hypertension [118].

### Systemic circulation

There are multiple levels of control over the peripheral circulation. Neural control by the sympathetic and parasympathetic nervous systems is produced by stimulation of receptors on the afferent limb such as stretch receptors within the walls of the heart, and baroreceptors in the walls of arteries, such as the aortic arch and carotid sinuses. Stretch in the arterial wall stimulates the baroreceptors, producing vasodilation and heart rate slowing mediated by the vasomotor centers of the medulla [119]. Atrial stretch receptors inhibit secretion of vasopressin from the hypothalamus.

The efferent limb of the autonomic nervous system consists of sympathetic and parasympathetic nerve fibers. The sympathetic nerves can be divided into vasoconstrictor and vasodilator fibers. When stimulated, the vasoconstrictor fibers release norepinephrine activating  $\alpha$ -adrenergic receptors and producing vasoconstriction. The vasodilator fibers release acetylcholine or

epinephrine, and are mainly present in skeletal muscle. Parasympathetic fibers are vital in control of heart rate and function, but have only a minor role in controlling the peripheral circulation [120].

Hormonal control and receptor-mediated intracellular signaling are other important mechanisms. Norepinephrine primarily stimulates peripheral  $\alpha$  receptors and causes vasoconstriction. It is secreted by the adrenal medulla and by sympathetic nerves in proximity to the systemic blood vessels. Epinephrine is also secreted by the adrenal medulla, but its primary action is to stimulate the  $\beta$ 2 receptors in the peripheral circulation, causing vasodilation through cAMP-mediated reductions in intracellular calcium concentrations.

Angiotensin II is produced by activation of the reninangiotensin-aldosterone axis in response to reduced flow and pressure sensed by the juxtaglomerular apparatus in the kidney. Renin produces antiotensin I by cleaving angiotensinogen, and angiotensin II is produced by angiotensin-converting enzyme when angiotensin I passes through the lung. Angiotensin II is a potent vasoconstrictor and also induces the hypothalamus to secrete vasopressin (antidiuretic hormone), which also has vasoconstrictor properties.

Atrial natriuretic factor (ANF) is released from atrial myocytes in response to stretch (elevation of right or left atrial pressure) on the atrium. ANF has vasodilatory and cardio-inhibitory effects, and leads to sodium retention from decreased tubular reabsorption of sodium in the kidney [121]. B-type natriuretic peptide (BNP) is released by ventricular myocardium, also in response to stretch, and causes an increase in cGMP, leading to vasodilation in both arterial and venous systems. In addition, it increases urinary sodium and water excretion [122].

Second messenger systems affect the activation of receptors on systemic vascular cell membranes, leading to changes in vascular tone. The phosphoinositide signaling system is the common pathway for many of these agonists[119] (Fig. 5.21). Membrane kinases phosphorylate phosphatidylinositol, which is an inositol lipid located mainly in the inner lamella of the plasma membrane, producing phosphatidylinositol 4,5 biphosphate.

**Figure 5.21** Phospholipase C system. The major receptor-activated pathways for production of inositol 1,4,5-triphosphate (IP3) and 1,2-diacyglycerol (1,2-DAG). The binding of an agonist to a receptor R with seven membrane-spanning domains results in the activation of the phosphatidylinositol-specific phospholipase C $\beta$  (PI-PLC $\beta$ ), whereas the stimulation of tyrosine kinase receptors (TKR) by polypeptide growth factors will activate phosphatidylinositol-specific phospholipase C $\gamma$  (PI-PLC $\gamma$ ). Both pathways will result in the hydrolysis of phosphatidylinositol 4,5-biphosphate (PIP2) and the formation of IP3 and 1,2-DAG. In addition, agonists that act on the heterotrimeric receptors may stimulate phosphatidylcholine (PtdCho) hydrolysis, and activation of tyrosine kinase receptors will stimulate the production of phosphatidylinositol 3,4,5-triphosphate (PIP3). DGK, diacylglyceral kinase; PAPH, phosphatidic acid phosphohydrolase; G\*, activated G protein subunit;  $\beta$  subunits; PLD, phospholipase D; PKC, protein kinase C; PI-3K, phosphatidylinositol 3-kinase; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; EGF, epidermal growth factor; PDGF, platelet-derived growth factor; PLA2, phospholipase A2; AA, arachidonic acid. Reproduced from Izzard et al [119] with permission from Lippincott, Williams and Wilkins.

The second messenger, inositol 1,4,5-triphosphate, is produced from this compound by the action of the enzyme phospholipase C (PLC) [123]. The sequence begins with the binding of an agonist, such as angiotensin II, vasopressin, norepinephrine or endothelin, to a receptor with seven membrane-spanning domains. This receptor is linked to the activated Gq protein subunit, which in turn stimulates phosphatidylinositol-specific PLC (PI-PLC) to produce inositol 1,4,5,-triphosphate, which causes release of calcium from the SR, activating the actin-myosin system in the smooth muscle cells and thus producing vasoconstriction. Another second messenger, 1,2-diacylglycerol, is also produced, which goes on to activate protein kinase C, which in turn has a role in mitogenesis and thus proliferation of smooth muscle cells.

There are many isozymes of PLC; the form implicated in this series of events is the PLC $\beta$  form. The PLC $\gamma$  isoform is activated when cell growth factors such as plateletderived growth factor bind to their receptors on the cell surface and active tyrosine kinases. This results in the production of phosphatidylinositol 3,4,5-triphosphate, which is also implicated in mitogenesis.

Vasodilation of the systemic circulation results from the formation of NO by nitrovasodilators, or by activation of  $\beta$ 2-adrenergic receptors in the peripheral vasculature, both of which result in the activation of guanylate cyclase and the production of cGMP, which reduces intracellular calcium concentrations, producing vasodilation [124].

The vascular beds in various peripheral tissues differ in the amount of local metabolic control of vascular tone. For example, pH has much more influence on the pulmonary circuit, with low pH leading to vasoconstriction and higher pH leading to vasodilation, than in the vascular tone of other tissues. Local CO<sub>2</sub> concentration is much more important to central nervous system vasculature, with high levels leading to vasodilation. Decrease in oxygen tension will often lead to vasodilation, as adenosine is released in response to the decreased oxygen delivery; however, decreased oxygen tension increases tone in the pulmonary circulation. Autoregulation, or maintaining relatively constant blood flow over a wide range of arterial pressures, predominates in the cerebral circulation but is not as critical in other tissue beds. Autoregulation and CO<sub>2</sub> responsiveness are both blunted in the fetal and immature brain [125].

# Receptor signaling in myocardial dysfunction, congenital heart disease, and heart failure

A discussion of receptor signaling and calcium cycling in myocardial dysfunction is useful to serve as the basis for understanding many of the therapies discussed later in this text, and this section will focus on receptor physiology and calcium flux in three settings: acute myocardial dysfunction as seen after cardiac surgery and cardiopulmonary bypass, changes seen as responses to chronic cyanotic heart disease, and those seen with chronic congestive heart failure and cardiomyopathy.

### Receptor signaling in acute myocardial dysfunction

Acute myocardial dysfunction, such as that sometimes seen after cardiopulmonary bypass, is often treated with catecholamines. These drugs may not be effective, especially when used in escalating doses. In children, the number and subtype distribution of  $\beta$ -adrenergic receptors in atrial tissue are not affected by cardiac surgery with bypass; however, the activation of adenylate cyclase by isoproterenol is significantly reduced after bypass [126]. There is an uncoupling of  $\beta$ -receptors from the Gs protein-adenlyate cyclase complex. Densensitization to moderate or high doses of catecholamines may occur after only a few minutes of administration, because increased cAMP concentrations results in uncoupling from the Gs protein [127].

Only a few minutes of high-dose catecholamine administration may result in inactivation of the phosphorylated adrenergic receptors from sequestration. These receptors can be sequestered by endocytosis, in a process involving a protein called  $\beta$ -arrestin, which binds to the receptor, and a sarcolemmal protein called clathrin (Fig. 5.22). These sequestered receptors may be either recycled back to the cell membrane surface or destroyed by lysosomes [128]. This permanent destruction and degradation of receptors occurs after hours of exposure to catecholamines, and is accompanied by decreased mRNA and receptor protein synthesis, resulting in prolonged decrease in adrenergic receptor concentrations, which is reversed by decreasing exogenous catecholamines, but only as fast as new receptors can be synthesized.

Neonatal hearts may exhibit a different response to the acute or prolonged administration of catecholamines. Instead of desensitization, neonatal animal models demonstrate an enhanced  $\beta$ -adrenergic receptor response, accompanied by an increase in adenylate cyclase activity [129]. Desensitization as described above occurs later in development. The exact translation of these data to humans is not clear.

Treatment with catecholamines may also increase the concentration of Gi protein subunits, decreasing the sensitivity of the  $\beta$ -adrenergic receptor. This relative decrease in the ratio of Gs to Gi protein subunits has been demonstrated in rat and dog models [130,131]. Another possible mechanism of catecholamine-induced desensitization of the neonatal myocyte was demonstrated in a rat model, where prolonged exposure to norepinephrine caused an initial increase in functional L-type calcium channels on the sarcolemmal membrane. Continued exposure caused

**Figure 5.22** Desensitization and downregulation of the  $\beta$  adrenoreceptor ( $\beta$ -AR). (1) Agonist binding. (2) Phosphorylation of the  $\beta$ -AR by G proteincoupled receptor kinases (GRK). (3)  $\beta$ -arrestin binds to the GRK-phosphorylated  $\beta$ -AR, which is bound to the Gs protein. The receptor is then sequestrated to the endosomal compartment (4–7) to be dephosphorylated, and then either recycled back to the sarcolemma (8) or translocated to lysosomes for further degradation (8). AC, adenylate cyclase; GRP, G protein-coupled receptor phosphatase; P, inorganic phosphate groups;  $\beta$ -arr,  $\beta$ -arrestin. Reproduced from Booker [76] with permission from Wiley-Blackwell.

a decrease in L-type calcium channel mRNA to 50% of control values [132]. Sarcoplasmic reticulum calcium-ATPase concentrations are reduced with chronic norepinephrine administration in the dog [133]. Finally, exposing adult or neonatal rat myocytes to high concentrations of catecholamines for 24h leads to increased apoptosis of myocardial cells, a genetically programmed energy-dependent mechanism for cell death and removal [134,135]. This effect was mediated through  $\beta$ -adrenergic receptors in the adult model and  $\alpha$  receptors in the neonatal model.

All these studies provide the theoretical basis for the argument that administration of catecholamines to patients with acute myocardial dysfunction should be limited in dose and duration. Obviously, this is difficult to accomplish in the setting of weaning a hemodynamically unstable patient from cardiopulmonary bypass. Strategies that may limit catecholamine dose include administering low doses of catecholamines together with phosphodiesterase inhibitors, as well as adding corticosteroids, tri-iodothyronine, and vasopressin [136].

#### Receptor signaling in congenital heart disease

In the past decade, new information has become available concerning adrenergic receptor signaling in patients with congenital heart disease. A study of 71 infants and children undergoing cardiac surgery used tissue from the right atrial appendage to study  $\beta$ -adrenergic receptor density, distribution of  $\beta 1$  and  $\beta 2$  receptor subtypes, and coupling to adenylate cyclase [137]. This study found that patients with severe or poorly compensated acyanotic (e.g. congestive heart failure) or cyanotic (e.g. severe cyanosis) disease had significantly reduced β-adrenergic receptor densities. Outside the newborn period, this downregulation was  $\beta 1$  selective but in newborns with critical aortic stenosis or transposition of the great arteries, there was additional significant downregulation of the  $\beta$ 2 subtype. In patients with tetralogy of Fallot, those treated with propranolol had a significant increase in the number and density of  $\beta$ -adrenergic receptors, when compared with untreated patients. β-adrenergic receptor downregulation correlated with increased circulating norepinephrine levels. Finally, in severely affected patients, adenylate cyclase activity was reduced, demonstrating a partial decoupling, as noted above.

Other studies have determined that symptomatic tetralogy of Fallot patients, i.e. those with cyanotic spells, have a significantly greater number of  $\beta$ -adrenergic receptors in their right ventricular outflow tract muscle, and their adenylate cyclase activity was greater when

compared to patients without cyanotic spells [138].  $\alpha$ 1-Adrenergic receptors are also affected by congenital heart disease. A study of atrial tissue excised at surgery in 17 children evaluated  $\alpha$ - versus  $\beta$ -adrenergic receptor stimulation with pharmacological agents. The  $\alpha$  component was responsible for 0–44% of the inotropic response, and  $\beta$  stimulation for 56–100% of the response, with the degree of right ventricular hypertrophy and pressure load correlating with the amount of  $\alpha$  stimulation found [139].

# Receptor signaling in congestive heart failure and cardiomyopathy

Like adults with heart failure, children with congestive heart failure due to chronic left-to-right shunting and volume overload have elevated levels of circulating norepinephrine. This leads to a downregulation in  $\beta$ -adrenergic receptor density [140]. The degree of elevation of pulmonary artery pressure and amount of left-to-right shunting correlate with the plasma catecholamine levels, and are inversely correlated with  $\beta$ -adrenergic receptor density. All these abnormalities return to normal levels after corrective surgery.

The degree of receptor downregulation in congestive heart failure correlates with postoperative morbidity in infants and children. Children with an intensive care unit stay of greater than 7 days or those who died during the early postoperative period (nine of the 26 in a published report) had significantly less  $\beta$ 1 and  $\beta$ 2 mRNA gene expression than those who had better outcomes [141]. In addition, children receiving propranolol for treatment of their congestive heart failure had higher  $\beta$ -adrenergic receptor mRNA levels and tended to have improved outcomes. Finally, children with dilated cardiomyopathy also have a reduced response to catecholamines, with one study showing no significant increase in ejection fraction during a dobutamine stress test, with infusion of dobutamine at 5 and then  $10\mu$ g/kg/min [142].

The preceding has been a brief discussion of receptor signaling in pediatric heart disease. This emerging field has many implications for treatment strategies, and the reader is referred to excellent reviews for more detailed information on this subject [143].

#### Myocardial preconditioning

Myocardial preconditioning refers to the finding that repeated, brief exposure of the myocardium to ischemia, volatile anesthetics or other stresses induces a protective effect against a later (i.e. 12–24h), more prolonged, ischemic insult, resulting in decreased myocardial infarction size and improved myocardial function after the insult [144]. Chronic cyanosis also induces a similar protective effect in the myocardium, although the effect size is smaller and more long-lasting, i.e. beyond 24h. The mechanisms of myocardial preconditioning are complex but are thought to involve release of various neurohormonal agents and peptides such as adenosine, bradykinin, and nitric oxide via a cGMP-dependent mechanism, which then triggers a series of signal transduction events within the cardiomyocyte that confer a "memory" effect that protects the myocardium from future ischemic insults. The signal transduction effects include protein kinase C, tyrosine kinases, mitogenactivated protein kinases, glycogen synthase kinase 3 $\beta$ , and other enzymes [145]. This series of events allows activation of mitochondrial and sarcolemmal potassium-ATP channels, which leads to the preconditioning by elusive mechanisms.

One recently discovered candidate for this end effector is the mitochondrial permeability transition pore (MPTP) [145]. This is a non-specific channel that spans both mitochondrial membranes and when opened for a prolonged period, leads to dissipation of mitochondrial electrical potential, inhibition of ATP synthesis, and ultimately mitochondrial swelling, rupture, failure of cellular energy metabolism, and cell death. Agents and stimuli that confer myocardial preconditioning have been found to keep the MPTP closed, thus possibly elucidating further the subcellular mechanisms involved.

Several studies in pediatric cardiac surgical patients have been published elucidating the potential effects of myocardial preconditioning, which could have the beneficial effect of ameliorating the myocardial stunning observed in infants after surgical interventions that required long aortic cross-clamp times [146]. In a study of 90 infants randomized to sevoflurane, propofol or midazolam anesthesia for maintenance, plus a sufentanil infusion for analgesia, patients receiving sevoflurane had a very strong trend toward lower troponin T concentrations in the first 24h after surgery, potentially signifying less myocardial injury due to the pre-bypass exposure to sevoflurane [147].

In a novel variation of myocardial preconditioning, remote ischemic preconditioning (RIPC) produced by inflating a blood pressure cuff on a lower extremity to produce a 5-min period of limb ischemia, for four cycles before cardiopulmonary bypass, was studied in 37 children undergoing cardiac surgery. Patients who underwent RIPC had lower peak troponin I levels (17 versus  $22\mu g/L$ , p = 0.04), and lower inotrope score in the RIPC group at both 3 and 6 h post bypass [148]. This interesting phenomenon of RIPC may work through modulation of the inflammatory response through some as yet unknown humoral mechanism. The entire area of myocardial preconditioning, whether ischemic, anesthetic induced, remote or other variation, is an important field of future study that may well have several translations into clinical care.

# Introduction

Aerobic cellular respiration is critical for survival and requires the efficient exchange of oxygen for carbon dioxide at the alveolar surface. The alveolar surface area must be able to accommodate the tremendous range in oxygen consumption - from 250 mL/min at rest to 5500 mL/min at peak exercise [1]. As a result, the gas exchange surface area of the adult lung will attain  $50-100 \text{ m}^2$  with a final total lung capacity of 2.5-3.0 L. Lung organogenesis expands the lung surface area to meet these needs. This chapter will discuss the development of lung, chest wall, and diaphragm structure, development of the pulmonary vasculature, lung fluid physiology, transition in pulmonary function and circulation at the time of birth, and the postnatal development of lung structure and pulmonary function. Then the developmental pathophysiology of three diseases commonly encountered by the anesthesiologist will be presented: asthma, bronchopulmonary dysplasia, and cystic fibrosis.

# Embryology of the lungs, chest wall, and diaphragm

#### Prenatal lung development

Lung formation begins early in human gestation and growth extends well into childhood [2,3]. Although lung development is organized into stages (embryonic, pseudoglandular, canalicular, saccular, and alveolar), there is considerable temporal overlap of each stage that can be modified by prenatal and postnatal events (Fig. 6.1).

The embryonic phase of lung development is marked by the formation of the lung bud and initial branches of the airways. The primordial lung is a foregut derivative,

first recognizable at 25 days in the human fetus as a laryngotracheal groove in the ventral foregut. The more distal aspect of the groove closes, resulting in the only remaining connection between foregut in the region of the developing hypopharynx and larynx. Failure of closure results in a spectrum of tracheo-esophageal fistulas, from the most common proximal esophageal pouch with a distal fistula between trachea and esophagus, typically at the level of the carina (87%), to the less common isolated esophageal atresia (8%), H-type fistula (4%), and esopha-

geal atresia with either proximal (1%) or proximal plus distal (1%) fistula [4]. Upon closure of the laryngotracheal groove, the lung bud begins a series of dichotomous divisions that give rise to the conducting airways and five primordial lung lobes (two left and three right). Failure of the lung bud to divide can result in pulmonary agenesis, most typically of the right lung.

The pseudoglandular stage of lung development marks the establishment of the large conducting airways of the lung. Divisions that establish the trachea, segmental and subsegmental bronchi are completed by 7 weeks in the human fetus, and all bronchial divisions are completed by 16 weeks. It is important to remember that although the conducting airways will enlarge as the fetus and newborn grow (airway diameter and length increase 2–3fold between birth and adulthood), large airway branching ceases after 16 weeks of gestation.

The canalicular phase of lung development is marked by completion of the small conducting airways through the level of the terminal bronchioles, the last airways with cartilaginous support. Respiratory bronchioles no longer invested with cartilage mark the beginning of the gas exchange region of the lung. A respiratory bronchiole and all its associated alveolar ducts and alveoli constitute an acinus, which is the basic gas exchange unit of the lung. A terminal bronchiole with all its associated acinar structures constitute a lobule. Branching of the terminal and respiratory bronchioles during the canalicular phase will ultimately result in a total of 23 airway subdivisions, and completes the branching of the airways.

The saccular phase of lung development begins at roughly 24 weeks of human gestation and continues until just prior to term gestation. During this phase there is evolution of the relationships between the airspaces, capillaries and mesenchyme, although the alveolocapillary membrane (the distance from the lumenal surface of the airspace/alveolus to the lumenal surface of the capillary) is sufficient to participate in gas exchange (0.6  $\mu$ m) by approximately 24 weeks. Beyond this point, the efficiency of gas exchange is determined by the available surface area, not by the width of the alveolocapillary membrane. Lengthening and widening of the smooth-walled airspaces of terminal sacs expand the gas exchange surface area which remains invested with a double capillary network.

The alveolar phase of lung development is the final stage that is initiated during fetal lung development, but alveolarization will not be completed until much later (see Postnatal lung development). While branching morphogenesis establishes the conducting airways of the lung, alveolarization will establish the large surface area involved in gas exchange [5]. This process will result in a 20-fold increase in surface area between birth (with between 0 and 50 million alveoli) and adulthood (>300 million alveoli). Primitive saccules develop low ridges

(primary septa) that subdivide the saccule into an alveolar duct containing primary alveoli, and outpouchings between the ridges (secondary septa) that establish secondary alveoli. Regions destined for secondary septation exhibit increased elastin deposition [6], and elastin localizes to the tips of the secondary crests as they form. Septae contain a connective tissue core separating two capillary membranes, suggesting that the septum is formed by the folding of a capillary on itself. Septation also leads to the development of the pores of Kohn, allowing gaseous continuity between acini. Formation of secondary crests and the maturation of the microvasculature are critical elements of this stage of lung development, which only begins at roughly 36 weeks gestation in the human. Thus, the human lung is not fully mature structurally, even at term delivery. The completion of alveolar development is discussed below.

# Development of the chest wall and diaphragm

Formation of the ventral body wall is initiated in the fourth week post fertilization with the formation of the lateral body wall folds. The folds consist of lateral plate mesoderm and overlying ectoderm, and the folds will move ventrally to meet in the midline of the developing embryo [7]. Failure of closure may occur anywhere along the midline, resulting in congenital malformations of the thoracic body wall (ectopia cordis, sternal cleft) and abdominal body wall (omphalocele, bladder exstrophy). The sternum arises from parallel bands of condensed mesenchyme in the 6th week and will fuse in the 10th week [8]. Formation of cartilage appears in the sternum immediately but ossification will not begin until the 6th month. Ossification of the ribs begins in the 7th week of gestation and will be completed by early adulthood. Equally important are changes in the configuration of the chest wall. The orientation of the ribs is horizontal in infancy and will begin to slope downwards so that by age 10 years the ribs have reached the adult configuration. As a result, the contraction of the diaphragm and intercostal muscles, lifting the ribs like a bucket handle, is more effective in increasing intrathoracic volume, and thus negative pressure, in adulthood than it is in infancy.

The diaphragm is critical for separating the developing lung within the thorax from the abdominal cavity with the developing gut and solid organs of the abdomen. Closure of the pleuroperitoneal folds is initiated in the pseudoglandular phase, and is completed by 7 weeks in the human fetus. During this time, the midgut resides within the umbilical cord and returns to the peritoneal cavity at 10 weeks. Thus, failure of diaphragm formation results in continuity between thoracic and peritoneal cavities, allowing peritoneal contents (stomach, intestine, and/or liver) to migrate into the thoracic cavity. This restricts the space into which the lung grows, leading to pulmonary hypoplasia of the lung ipsilateral to the diaphragmatic defect. Pulmonary hypoplasia can also extend to the contralateral lung due to shifting of the mediastinum as abdominal viscera accumulate within the thorax.

Owing largely to ossification of the rib cage and increasing chest wall muscle mass, the chest wall stiffens with age. Compliance of the chest wall in infants is 2-6 times higher than the compliance of the lung tissue, even more so in preterm infants, but will decrease to nearly equal lung tissue compliance in childhood and adulthood. Unchecked, this leads to problems in maintaining adequate lung volume at end-expiration in infancy. As a result, term infants actively maintain resting lung volume by prolonging expiratory time constants via a braking maneuver. A given percentage of passively exhaled breath will require a constant time for exhalation regardless of the starting lung volume, given constant lung mechanics. This is the time constant of the lung ( $\tau$ ) and is the product of airway resistance  $(R_{aw})$  and lung compliance (C). Braking consists of interrupting expiratory flow before full relaxation of respiratory muscles, thus prolonging  $\tau$ , and is no longer necessary beyond 1-2 years of age due to stiffening of the chest wall [9].

# Development of the pulmonary vasculature and its relationship to alveoli

The pulmonary vasculature consists of the vascular supply to the acini and the bronchial circulation [10]. During early fetal life, the airways act as a template for pulmonary blood vessel development. Early pulmonary blood vessels form by vasculogenesis, which is de novo differentiation of mesenchymal cells into endothelial cells and then capillaries. As each new airway buds into the mesenchyme, a new plexus forms and adds to the pulmonary circulation, By 5 weeks of human gestation, a capillary network surrounds each bronchus and circulation of blood between the right ventricle and the left atrium via this network is evident. By the canalicular stage of lung development, new blood vessels form from pre-existing vessels via angiogenesis in which endothelial cells proliferate and sprout from established vessels. Vasculogenesis is the primary mode of pulmonary vascular development until the 17th week of gestation when all preacinar airways are complete, whereas angiogenesis becomes the predominant mode in the later stages of lung development. Interconnections between vascular networks arising from both angiogenesis and vasculogenesis increase in the saccular phase of lung development.

In the human lung, a second circulatory system, the bronchial circulation, arises from the dorsal aorta supplying systemic blood. The bronchial vasculature develops after the pulmonary circulation, with bronchial vessels first apparent by 8 weeks. The network of bronchial vessels is extensive, with bronchial arteries demonstrated as distal as the alveolar ducts in the adult respiratory tree. The inappropriate branching of bronchial vessels from the dorsal aorta is implicated in the formation of bronchopulmonary sequestration, a space-occupying lung malformation that can result in hypoplasia of the ipsilateral lung.

Vasculogenesis and angiogenesis are the primary mechanisms of vascular development throughout intrauterine life. The human lung at term contains only a small portion of the adult number of alveoli, and the airspace walls are represented by a thick "primary septum" consisting of a central layer of connective tissue surrounded by two capillary beds, each of them facing one alveolar surface [3]. This double capillary network is not present in the adult lung. As alveolar architecture changes with the appearance of secondary septa, folding of one of the two capillary layers occurs within the secondary septa. Microvascular maturation involves fusion of the double capillary network into a single capillary system. The expansion of surface area and luminal volume compresses the interstitium, bringing the capillary networks in close proximity to potential airspaces and thereby promoting both alveolar surface area expansion and capillary bed fusion. By the third postnatal week, lung volume increases by 25% and there is a 27% decrease of the interstitial tissue volume that is believed to promote microvascular fusions. Subsequently, there is preferential growth of fused areas that continues until ~3 years of age. Lung volume increases about 23-fold between birth and young adulthood, while capillary volume expands 35-fold. It has been recently shown that this increase in capillary volume occurs by insertion of capillaries in the absence of capillary sprouting. This new concept in capillary network growth has been named intussusceptive microvascular growth and involves the formation of transluminal tissue pillars within existing vessels that then expand to increase capillary surface area [3].

Muscularization can be detected early in development of the pulmonary arteries [10]. Initially the muscular investment of the vasculature is derived from the migration of bronchial smooth muscle cells from adjacent airways. Muscularization of preacinar and resistance arteries of the pulmonary vasculature begins in the canalicular stage and continues through the remainder of gestation. This second phase of smooth muscle cells investing pulmonary vessels develops from the surrounding mesenchyme. A third phase of vascular muscularization has been described, largely in the very distal lung, in which capillary endothelial cells undergo a process of endothelial-mesenchymal transition that encompasses endothelial cell division, separation and migration from the endothelial layer, and expression of smooth muscle cell markers. Normal muscularization of pulmonary arteries extends down to the level of the terminal bronchiole, and is minimal to absent in vessels surrounding respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying from persistent pulmonary hypertension of the newborn and in severe bronchopulmonary dysplasia.

Recent evidence suggests that the pulmonary capillary bed actively promotes normal alveolar development and contributes to the maintenance of alveolar structures throughout life [11]. The observation that combined abnormalities in the airways and vasculature occur in bronchopulmonary dysplasia supports this hypothesis. Intra-acinar arteries and veins continue to develop after birth by angiogenesis as long as alveoli continue to increase in number and size. This may well be a reciprocal process because vascular growth around the distal airspaces suggests an inductive influence from the alveolar epithelial cells.

## Lung fluid physiology

Fetal lung fluid is a product of the epithelial cells lining the developing lung [12], and averages 4-6mL/kg/h. Laryngeal abduction creates resistance to the passage of lung fluid out into the amniotic fluid, providing endexpiratory pressure of approximately 2–4 cmH<sub>2</sub>O. As a result, fetal lung fluid accumulates to a total volume of 20–30 mL/kg during gestation. The composition of fetal lung fluid is distinct from both amniotic fluid and plasma, as illustrated in Table 6.1. The increased chloride content of fetal lung fluid, as compared to serum, is the result of active chloride secretion by the tracheal and distal pul-

 
 Table 6.1 Composition of human fetal lung fluid compared to other body fluids

Component	Lung fluid	Interstitial fluid	Plasma	Amniotic fluid
Sodium (mEq/L)	150	147	150	113

Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
рН	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

monary epithelium. Fetal lung fluid secretion can be enhanced by prolactin, keratinocyte growth factor, and prostaglandins E2 and F2, while it is inhibited by a variety of mediators, including  $\beta$ -adrenergic agonists, vasopressin, serotonin, and glucagon.

While fetal lung fluid is an essential component of lung development, it presents a significant obstacle to the transition to air breathing upon delivery. Three important events must occur to decrease the amount of fetal lung fluid and its potential impact on alveolar surface tension: absorption, bulk removal, and maturation of pulmonary surfactant. Conversion of the epithelial surface from secretory to absorptive is largely due to enhanced sodium transport across the alveolar epithelium during the third trimester [12]. Much evidence suggests that induction of components of the epithelial sodium channels (ENaC) around the time of birth is a major factor in promoting sodium transport with water passively following the movement of sodium. Induction of ENaC components occurs at a transcriptional level in response to changes in extracellular matrix components, glucocorticoids, aldosterone and oxygen. By comparison, agents that increase intracellular cAMP levels (i.e. β-agonists, phosphodiesterase inhibitors and cAMP analogs), while not increasing the number of sodium channels, increase the probability of a channel being open to sodium transport. Glucocorticoids and thyroid hormones play an important role in priming the lung epithelium to the actions of β-adrenergic agonists on sodium transport across lung epithelia near term. Water channels consisting of aquaporins are also induced during the late fetal period to facilitate fluid movement, but their importance remains unclear.

Conversion to an absorptive surface is not sufficient to minimize the fetal lung fluid at the time of term delivery. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants delivered by cesarean section without the benefit of labor. Upon delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. However, animal studies have shown that the magnitude of the benefit of thoracic compression during labor is only modest [13]. The primary mechanism by which labor facilitates clearance of lung fluid is through hormonal effects on fluid clearance, especially through catecholamine-induced changes in the open probability of ENaC. The onset of air breathing with increased intrathoracic negative pressure assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels. The amount of residual liquid in the lung after transition is approximately 0.37 mL/kg bodyweight.

### Pulmonary cell types, development and release of surfactant

#### **Proximal airways**

The proximal airway epithelium is tall and columnar, decreasing to a more cuboidal appearance distally [14,15]. The endodermal epithelial lining cells of the trachea and bronchi partition into four cell types: undifferentiated columnar, ciliated, secretory/goblet, and basal cells. Ciliated cells critical to the process of mucus clearance are first apparent between 11 and 16 weeks of human gestation and become less prevalent in more distal airways. Three types of secretory cells – those with largely mucous granules, those with serous granules, and some with both types of granules – can be seen as early as 13 weeks. The number of mucin-producing goblet cells in airways peaks at midgestation in the fetus, and declines into adulthood. Finally, immature basal cells expressing epidermal keratin have been noted as early as 12 weeks of gestation.

Cartilaginous support of the tracheobronchial tree proceeds in a centrifugal fashion, beginning in the primitive trachea at 4 weeks of human gestation, reaching the main bronchi by 10 weeks, and proceeding to the most distal terminal bronchioles by approximately 25 weeks. Cartilaginous investment of airways is complete by the second month postnatally. Submucosal glands are found in the interstitium between the cartilaginous tissue and surface epithelium, and play a major role in airway host defense. The airways of infants and children contain relatively more submucous glands than adults. The glands are lined by mucous cells proximally and serous cells more distally, the latter comprising 60% of the total epithelial cell content of the glands. Serous cells secrete water, electrolytes, and proteins with antimicrobial, antiinflammatory, and antioxidant properties, while the mucous cells produce primarily mucins. In addition to this host defense role, submucosal glands also contain a population of basal cells that respond to injury of the airway by replenishing the airway epithelium.

Muscular investment of the airways begins as early as 6-8 weeks of gestation as smooth muscle cells are identifiable around the trachea and large airways. Fetal airway smooth muscle is innervated and able to contract during the first trimester. It is also responsive to methacholine challenge that is reversible with  $\beta$ -adrenergic agonists. Muscularization increases through fetal life and childhood such that there is an increase in the amount of smooth muscle relative to airway size compared to adults. Furthermore, there is a rapid increase in bronchial smooth muscle immediately after birth, whether born at term or prematurely.

Pulmonary neuroendocrine cells (PNEC) are found throughout the airways, often in innervated clusters

known as pulmonary neuroendocrine bodies (NEB) located at branch points in the bronchial tree [16]. Solitary PNEC are sensitive to stretch- and hypoxia-mediated secretion, producing both amines (i.e. serotonin) and peptides (i.e. bombesin) that are important in regulating bronchial tone. Pathological conditions recently associated with PNEC/NEB, most often characterized by hyperplasia, include bronchopulmonary dysplasia, disorders of respiratory control (congenital central hypoventilation syndrome and sudden infant death syndrome (SIDS)), cystic fibrosis, and pulmonary hypertension. Neuroendocrine hyperplasia of infancy (NEHI) is a rare form of interstitial lung disease of infancy associated with expansion of the number of PNEC and NEB, but little is known about the mechanism of disease.

#### **Distal airways**

The bronchiolar epithelium differs from the more proximal airway epithelium and contains progressively fewer ciliated cells and goblet cells, which are ultimately absent from the terminal bronchioles. Clara cells are found in increasing numbers and density down the conducting airways, such that they are the most abundant cell of the terminal bronchiole [14]. Clara cells are first evident by 16-17 weeks of human gestation, initially exhibiting large glycogen stores that are replaced by secretory granules. Between 23 and 34 weeks there is a dramatic increase in Clara cell numbers in distal bronchioles. Clara cells play an important role in host defense and in the detoxification of gaseous components of the air we breathe. This specialized cell produces the highest levels of cytochrome P450 and flavin mono-oxygenases in the lung. While critically important in detoxification, these enzymes participate in the bio-activation of procarcinogens as well, placing the Clara cell at risk as a target of toxic metabolites. The Clara cell also plays an important role in immunoregulation in the distal airways. Important host defense products of the Clara cell include Clara cell secretory protein (CCSP or CC10), surfactant proteins A, and D, leukocyte protease inhibitor, and a trypsin-like protease. The secretion of antiproteases from Clara cells suggests that they modulate the proteaseantiprotease balance in the distal lung.

#### Alveoli

During the 4th through 6th months of gestation the epithelial cells lining the acini begin to differentiate further [17]. The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. The large glycogen pools provide a ready source of substrate required for the production of increasing amounts of surfactant phospholipids, and they decrease in size as surfactant production advances in the fetal lung. In cells destined to become type 2 cells, lamellar bodies become larger, more numerous and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type 1 cells, upon losing their relationship to mesenchymal fibroblasts, lose the prelamellar vesicles and become progressively thinner, thereby adopting a phenotype more suitable for gas exchange. Alveolar type 1 and 2 cells are readily identified early in the saccular stage of fetal lung development. There remains considerable controversy regarding the origin of type 1 cells. In culture, these cells demonstrate very slow turnover, with a doubling time estimated to be between 40 and 120 days, suggesting that in vivo they are functionally terminally differentiated. In response to epithelial damage, type 2 cells proliferate to re-establish epithelial continuity, and then lose phenotypical features such as lamellar bodies while acquiring markers of type 1 cells, suggesting that rapid repopulation of type 1 cells requires a type 2 cell intermediary.

There is increasing appreciation that the alveolar type 1 cell is more than a passive membrane for gas exchange [18]. The large surface area and small cytoplasm/nucleus ratio provides for a thin alveolocapillary membrane to facilitate gas exchange. However, this large surface area also provides a large absorptive surface in the lung. The presence of water and ion channels, some distinct from those in type 2 cells, helps to ensure that the alveolus remains relatively dry. Type 1 cells may also regulate cell proliferation locally, signal macrophage accumulation, and modulate the functions of local peptides, proteases and growth factors.

While most notable for its role in surfactant production, the alveolar type 2 cell provides additional important functions in the alveolus [19]. Alveolar type 2 cells are local progenitor cells, as mentioned previously. Like type 1 cells, alveolar type 2 cells contain specialized ion and water channels as well as ion pumps in both the apical and basal membranes that contribute to the movement of water and ions across the epithelium. Type 2 cells also produce important antioxidants (SOD-1, -2, -3, glutathione) and molecules of innate host defense (SP-A, SP-D, lysozyme) to participate in detoxification and sterilization of the alveolar microenvironment.

More recently, it is becoming clear that alveolar type 2 cells may also play a part in exacerbating alveolar pathology. The type 2 cell participates in the coagulation– fibrinolysis cascade through the production of fibrinogen, urokinase-type plasminogen activator, and tissue factor, especially under pathological circumstances. Type 2 cells are increasingly recognized as a source of cytokine and chemokine production in the lung, as well as growth factors that can promote fibrosis. Finally, cross-talk between epithelial cells, cell matrix, interstitial cells, and local inflammatory cells can foster the resolution of injury and inflammation, or prolong lung remodeling after injury with detrimental effects such as lung destruction and fibrosis. Therefore, while previously heralded as the defender of the alveolus, the alveolar type 2 cell plays a much more complex role in alveolar health and disease.

### Surfactant

Pulmonary surfactant is essential to alveolar health. A thin layer of liquid is constantly secreted into the alveolar lumen to protect the delicate alveolar epithelium. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the end of expiration owing to the Law of LaPlace, which states that the collapsing pressure on the alveolus is directly proportional to the surface tension while inversely proportional to the radius of curvature of the alveolus. The presence of pulmonary surfactant at the air–liquid interface lowers surface tension as alveolar surface area decreases, thereby preventing end-expiratory atelectasis, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflations.

Pulmonary surfactant is a complex mixture of phospholipids (80% by weight), neutral lipids (10%), and proteins (10%) that is synthesized, packaged, and secreted by alveolar type 2 cells [20]. Storage of surfactant occurs in the lamellar body, a lysosome-derived membrane-bound organelle that undergoes regulated secretion in response to a variety of stimuli, including stretch. In the alveolus, surfactant phospholipids transition through an extracellular storage form, tubular myelin. Phospholipid and protein components are recycled out of the surfactant monolayer at the air–liquid interface, and taken back into the alveolar type 2 cell where they can be repackaged into lamellar bodies. Alveolar macrophages engulf and degrade surfactant components as well.

Saturated phosphatidylcholine makes up 45% of surfactant by weight, with unsaturated phospholipids accounting for 25% of surfactant and other phospholipids (most notably phosphatidylglycerol at 5%) contributing 10%. The predominant saturated surfactant phospholipid is dipalmitoyl phosphatidylcholine, or DPPC. DPPC is the only surface-active component of lung surfactant capable of lowering surface tension to nearly zero. The presence of unsaturated phospholipids and other lipid components like cholesterol enables the monolayer to remain fluid at body temperature during the respiratory cycle. The phospholipid content of the developing fetal lung increases with advancing gestation due to increased activity of enzymes responsible for phospholipid synthesis within alveolar type 2 cells. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, are not only developmentally regulated but are also induced by hormones. The inductive hormones that

have direct clinical relevance are glucocorticoids and agents that increase intracellular cAMP, such as the  $\beta$ -adrenergic agonist (and tocolytic) terbutaline.

Surfactant contains a group of specific proteins important for surfactant function and host defense that contribute up to 5% of surfactant by weight; the remaining 5% of the protein content of surfactant comes largely from serum proteins. The four surfactant proteins, SP-A, -B, -C, and -D, are subdivided based upon their physical characteristics into either hydrophobic (SP-B and -C) or hydrophilic (SP-A and -D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense, immunomodulation, and surfactant clearance and metabolism.

Together, the hydrophobic proteins facilitate the mobilization of surfactant phospholipid from tubular myelin to the surface monolayer, promote spreading of phospholipids in the surfactant film, and assist in film stability at end-expiration [20]. SP-B plays a central role in alveolar health due to its critical function in surfactant homeostasis. It is a secretory protein that exhibits strong association with membranes, unlike SP-C which contains a membranespanning domain and covalently attached fatty acids (palmitate) that render it integral to phospholipid membranes [21]. Both SP-B and SP-C are synthesized as large precursor proproteins that undergo extensive posttranslational processing as they pass through the secretory pathway, ultimately reaching the lamellar body. SP-B is essential for the process of lamellar body formation, and the alveolar type 2 cells of infants with inherited deficiency of SP-B are devoid of lamellar bodies. Because the lamellar body is where SP-C processing is completed, infants with inherited deficiency of SP-B are also deficient in mature SP-C, instead accumulating a larger, nonfunctional precursor of SP-C. Thus, patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with very poor surface tension properties due to the absence of both SP-B and SP-C. Conversely, because SP-C does not play either a direct nor indirect role in SP-B protein processing, animals with SP-C deficiency have normal SP-B, normal lamellar bodies, and relatively normal surfactant function, and exhibit no perinatal lethality due to surfactant dysfunction.

Like the enzymes of surfactant phospholipid production, SP-B and SP-C exhibit developmental and hormonal regulation of expression [22]. In human fetuses, SP-C mRNA is detected as early as 12 weeks of gestation and SP-B mRNA by 14 weeks, yet the mature proteins are not detectable in fetal lung tissue until after 24 weeks. SP-B protein is not detectable in amniotic fluid until after 30 weeks' gestation, increasing towards term [23]. This is due to developmental regulation of post-translational events in the proteolytic processing of proSP-B and proSP-C [24]. Consequently, infants delivered prematurely have reduced levels of both surface-active components of surfactant, phospholipid and hydrophobic surfactant proteins, due to the developmental regulation of surfactant proteins and the enzymes of phospholipid production in alveolar type 2 cells. The rate of type 2 cell differentiation, and secondarily surfactant production by the fetal lung, is modulated by levels of endogenous corticosteroids and is accelerated by administration of antenatal glucocorticoid to women in preterm labor. The response of the surfactant system to glucocorticoid involves all the lipid and protein components, and occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type 2 cell maturation as well as on clearance of lung fluid at birth. Certain proinflammatory cytokines (e.g. tumor necrosis factor and transforming growth factor  $\beta$ ) inhibit surfactant production in experimental systems and may downregulate surfactant in conditions such as sepsis and inflammation.

### Physiological changes in lung and pulmonary blood flow at birth

Two critical events in fetal development play a major role in the adaptation to air breathing that occurs at birth: removal of fetal lung liquid and changes in fetal circulation. Each is considered separately below but they are interdependent in the process of neonatal transition.

While fetal lung fluid is critical for early lung development, it is essential that fluid is cleared in preparation for the onset of air breathing [25]. Because fluid reabsorption depends largely upon regulation of the sodium channel, management options during labor and delivery that impair the catecholamine-induced maturation of ENaC (i.e. cesarean section without the benefit of labor) can impair lung fluid clearance, resulting in retention of fetal lung fluid, known as transient tachypnea of the newborn. Transient tachypnea of the newborn is a relatively benign condition generally requiring supportive care in the form of supplemental oxygen to allow for drainage of the excess fluid via lymphatics, or continuous positive airway pressure (CPAP) to facilitate clearance of lung fluid from the alveoli. It is important to recognize that retained fetal lung fluid can complicate other neonatal respiratory conditions such as meconium aspiration syndrome and bacterial and viral pneumonias. Furthermore, retained fetal lung fluid may complicate the transition from fetal to adult circulatory physiology and thereby contribute to

the development of persistant pulmonary hypertension of the newborn described below.

The other critical event during neonatal transition is the adaptation of the circulatory pattern. During fetal life, the organ of gas exchange is the placenta. Thus, the circulatory pattern of the fetus is adapted to optimize blood flow to/from the placenta and minimize blood flow to/ from the lungs to 5-10% of cardiac output. This is achieved through the low resistance/high capacitance of the placenta, the high resistance of the pulmonary vasculature, and the ductus arteriosus. The large surface area and lacunar structure of the placenta contribute to the low resistance/high capacitance of this organ. The low partial pressure of oxygen in the fetal lung and circulating vasoconstrictors, such as endothelin-1, leukotrienes, and Rho kinase, in the face of low production of vasodilators, including nitric oxide and prostacyclin, contribute to high pulmonary vascular tone [26]. As a result, pulmonary and systemic pressures are roughly equivalent. The high pulmonary vascular resistance and equivalent pulmonary and systemic pressures together favor the flow of oxygenated blood returning from the placenta (via the umbilical vein and ductus venosus) to the right atrium across the foramen ovale to the left atrium and out to the systemic circulation. The ductus arteriosus, a blood vessel developing from the sixth aortic arches, bridges between the pulmonary artery and the aorta at the bifurcation of the left pulmonary artery, and approximately at the level of the left subclavian artery as it branches from the aortic arch. The high pulmonary vascular resistance and low systemic vascular resistance in utero favor flow of oxygenated blood passing from right atrium to right ventricle and pulmonary artery, through the ductus arteriosus, and into the aortic arch to supply the systemic circulation. In addition to optimizing flow of oxygenated blood systemically, the combination of atrial and ductal level shunts allows for sufficient blood flow to all the chambers of the heart, facilitating their development during fetal life, and this explains the greater muscularization of the right ventricle in the newborn period relative to the left ventricle.

In the transition to air breathing, the circulatory pattern must undergo change to establish the lung as the organ of gas exchange [27]. Clamping and transection of the umbilical cord at delivery removes the placenta from the systemic circulation, resulting in a precipitous increase in systemic vascular resistance. This has at best a modest effect on changing blood flow centrally, instead improving blood flow to the lower body. Initiation of air breathing inflates the lungs and increases oxygen tension across the alveolar capillary bed, facilitating a precipitous decrease in pulmonary vascular resistance. Pulmonary stretch receptors elicit reflex dilation of the pulmonary vasculature independently of the effects of enhanced oxygen tension. The net effect of these events is that left atrial pressure becomes higher than right atrial pressure, leading to functional closure of the foramen ovale. These changes also reduce flow through the ductus arteriosus by 24% soon after birth, but are not sufficient to eliminate ductal flow for 48h after birth. Cessation of ductal blood flow and ultimately scarring of this structure, which becomes the ligamentum arteriosum, occur over the first 2-3 weeks of life. Increasing hypoxemia of the muscle media of the ductus due to reduced blood flow through the ductal lumen promotes vasoconstriction of the ductus. Ductal constriction enhances muscle media hypoxia by collapsing the vasa vasorum, the other source of oxygen to the ductus. Together, these adaptations lead to the adult circulatory pattern with the lung in series with the systemic circulation, enabling efficient oxygenation.

These physiological changes are dynamic and capable of reverting to a fetal pattern over the first days of life. While pulmonary vascular resistance decreases precipitously in the first minutes to hours of life, it does not achieve adult levels for weeks to months postnatally, and the pulmonary vasculature is prone to vasoconstriction in response to hypoxia and acidosis during that time. In addition, events associated with reduced systemic vascular resistance, such as septicemia, can lower systemic vascular resistance enough so that even the normal pulmonary vascular tone in the first days of life can lead to pulmonary pressures becoming suprasystemic, leading to enhanced right-to-left blood flow.

Persistent pulmonary hypertension of the newborn, also known as persistent fetal circulation, can occur in association with other neonatal diseases such as septicemia or meconium aspiration, or can be idiopathic in nature [26]. The disorder is characterized as suprasystemic right ventricular pressure, right-to-left flow of deoxygenated blood through the ductus arteriosus, and severe hypoxemia. Primary pulmonary hypertension of the newborn (PPHN) can result from lung parenchymal disease leading to pulmonary vasoconstriction, from pulmonary vascular remodeling in the absence of lung parenchymal disease, or from primary or secondary pulmonary hypoplasia. Animal studies have elucidated pathways for targeted therapies such as nitric oxide/ cGMP, prostacyclin/cAMP, and endothelin to lower pulmonary vascular resistance. Optimization of oxygenation and ventilation while providing specific pulmonary vasodilatation with nitric oxide has lowered the morbidity and mortality of this disorder and reduced the need for more aggressive therapies such as extracorporeal membrane oxygenation (ECMO).

Ductal patency can also complicate the management of prematurely born infants [28,29]. The ductus arteriosus of premature infants is thin-walled and thus depends only on luminal blood flow for oxygenation. As a consequence,

the ductal muscle media does not become as hypoxic with constriction of the premature ductus, thus contributing to a prolonged delay in anatomical closure. As pulmonary vascular resistance decreases in preterm infants in response to lung inflation and surfactant administration, the high systemic vascular resistance favors left-toright flow across a patent ductus arteriosus resulting in pulmonary edema. Both are responsive acutely to elevated positive end-expiratory pressure. The pulmonary overcirculation can also be associated with vascular steal from the cerebral and mesenteric vasculatures, increasing the risk of intraventricular hemorrhage and intestinal ischemia. Closure of a patent ductus arteriosus can be achieved by treatment with agents that reduce prostaglandin synthesis, such as indometacin and ibuprofen, but success is inversely related to gestational age. When repeated indometacin therapy fails and the patent ductus arteriosus is felt to be a major factor in pulmonary symptoms, surgical ligation through a left thoracotomy approach is possible. There is some controversy regarding the long-term morbidity of surgical ligation of a patent ductus arteriosus.

### Lung development after birth

As with fetal lung development, postnatal lung development can be subdivided into several stages, also illustrated in Figure 6.1 [3]. True alveoli containing secondary septae (described above) become evident as early as 36 weeks in the human fetus, initiating the alveolar phase of fetal lung development which extends through 1-2 years of age. Postnatal alveolarization begins with a phase of bulk alveolarization occurring within the first 6 months postnatally, with a more modest addition of secondary alveoli through the remainder of this period. The alveoli of the infant lung are different from adult alveoli. These immature secondary alveoli contain a double capillary bed, whereas adult alveoliare invested by a single capillary bed. Microvascular maturation, the next phase of postnatal lung development, occurs between the first few postnatal months of life through 3 years of age (discussed above).

There is considerable controversy regarding when the lung ceases to add alveoli. Estimates have ranged from as early as 2 years to as late as 20 years in humans. This is further complicated by the observation that alveolar expansion can occur in response to pneumonectomy in adult animals and humans. The acquisition of alveoli after the maturation of the microvasculature has been termed late alveolarization. This activity has been most often demonstrated in subpleural regions of the lung and likely invokes mechanisms similar to the formation of secondary alveoli.

The addition of alveoli is not the only means of expanding the surface area of the lung. While alveolarization wanes over the first 3 years of life in the human, growth of the lung continues to expand the gas exchange surface. Between 2 years of age and adulthood, lung tissue expands with lung volume roughly proportional to the increase in bodyweight of the child. Thus, owing to the combined processes of prenatal lung development, postnatal lung development, and lung growth, there is tremendous potential for expansion of the gas exchange surface area that is developmentally programmed into the fetal lung to account for the growing needs of the infant, child, and adult for aerobic cellular respiration. The extent to which these developmental mechanisms can be harnessed after premature birth, with or without superimposed lung injury, is a topic of active investigation.

# Normal values for pulmonary function with age

In neonates and children, developmental changes discussed above lead to rapid transformations in the mechanical properties of the respiratory system and influence pulmonary function. Unlike many physiological parameters that do not vary with age (i.e. arterial pH), predicted values of pulmonary function depend upon age, height, gender, and race [30]. Consistent normalization of pulmonary function test results, based on weight or height, is important to the interpretation of results and for comparison to reference values. When tests rely on the subjective effort of an infant or young child, technique can have profound effects on measurements and efforts to standardize pulmonary function testing. For example, several studies have compared compliance measurements from preterm infants with and without bronchopulmonary dysplasia to term infants to determine their diagnostic or prognostic value. However, there was a large overlap between the groups, with the majority of infants with bronchopulmonary dysplasia (BPD) having compliance measurements within the 95% confidence interval of the control group [31]. This observation suggests that measurements in individual infants are of limited value as a diagnostic or prognostic tool. However, in a research setting, consistency can best be obtained in a pulmonary function laboratory, although infant and pediatric ventilators now provide opportunities to make measurements in the intensive care setting. The discussion below presents an outline of basic parameters and descriptions of how pulmonary function changes with age where applicable, including normal references only where they are considered consistent standards (Table 6.2).

	Infant	Child	Adult
Compliance (cc/cmH₂O/kg)	1.5–2.0	2.5–3.0	0.1 L/cmH <sub>2</sub> O <sup>a</sup>
Resistance (cmH <sub>2</sub> O/L/s)	20–40	20–40 <sup>b</sup>	1–2
Functional residual capacity (cc/kg)	20–25	20–25°	1.9–2.4 L <sup>a</sup>
Tidal volume (cc/kg)	4-8 <sup>d</sup>	4–8	6–8
Respiratory rate (breaths/min)	20–60	20–30	12–20
Minute ventilation (cc/kg/min)	240–480		5–8ª

 Table 6.2
 Standards for lung mechanics and pulmonary function in infants, children, and adults

 $^a$  note different units;  $^b$  up to 2 years;  $^c$  up to 18 months;  $^d$  preterm 3–5 mL/kg.

#### Compliance

The elastic characteristics of the lung are described by the changes in volume (V) per unitary change in transpulmonary pressure (PL) under conditions of zero flow, or lung compliance ( $CL = \Delta V/\Delta PL$ ). The systematic change in both pressure and volume during inflation and deflation allows a static pressure–volume curve of the lungs to be plotted. Lung compliance ranges from 1.5 to 2mL/cmH<sub>2</sub>O/kg in newborns to 2.5–3mL/cmH<sub>2</sub>O/kg in children and adults [32].

#### Resistance

Airway resistance (Raw) reflects the non-elastic airway and tissue forces resisting gas flow. Lung resistance is determined predominantly by frictional resistance to inspiratory and expiratory air flow in the larger airways (80%), while tissue resistance (19%) and inertial forces (1%) also contribute [33]. By definition, resistance to airflow is equal to the resistive component of driving pressure ( $\Delta P$ ) divided by the air flow (Q),  $R_{aw} = \Delta P/Q$  with units of cmH<sub>2</sub>O/L/s. Poiseuille's Law states that resistance to flow increases by a power of 4 with any decrease in airway diameter ( $R_{aw} = 8\eta L/\pi r^4$ , where  $\eta$  is the gas viscosity, L is length and r the radius of the airway). Resistance is also dependent on the number of airways, lung volume, and respiratory rate. The diameter of airways in infants and children is much smaller than adults, resulting in increased Raw. Airway resistance in normal healthy infants up to 2 years of age ranges from 20 to  $40 \text{ cmH}_2\text{O}/\text{L/s}$ , whereas  $R_{aw}$  in adults is  $1-2 \text{ cmH}_2\text{O}/\text{L/s}$ .

### Total lung capacity

Measurement of total lung capacity (TLC) is effort dependent and thus cannot be obtained readily in infants. Postmortem studies have demonstrated that lung volume is linearly related to body length during childhood [34]. On average, girls reach their maximal height and lung volume earlier than boys [35,36]. However, for any given age and stature, boys have larger lung volumes than girls as a result of increased numbers of alveoli and respiratory bronchioles. These sex-dependent differences are absent below 2 years of age.

#### **Functional residual capacity**

Functional residual capacity (FRC) is defined as the static resting volume of the lung. Functionally, FRC is achieved when the opposing forces resulting from the outward elastic recoil of the chest wall and the inward elastic recoil of the lung, which determine the static resting volume of the lung, are balanced. The balance of the elastic recoil forces of the lung and chest wall in the infants predicts a supine FRC of only 10% of TLC, whereas in adults FRC accounts for approximately 50% of TLC in the upright position [32]. This intuitively seems incompatible with appropriate stability and patency of the peripheral airways to achieve gas exchange. As described above, infants incorporate larvngeal braking during expiration to maintain FRC, and will initiate inspiration before achieving balance between elastic recoil of chest wall and lung tissue. In infants, the postinspiratory activity of the inspiratory muscles and the laryngeal control of expiratory flow ("grunting") modify respiratory mechanics to maintain the patency of small airways and alveoli. The net result of these breathing strategies is that measured values of FRC (i.e. using gas dilution technique) in infants remain approximately 40% of TLC. Mean values for FRC range from 20 to 25 mL/kg in infants up to 18 months of age [32].

#### **Tidal volume**

Tidal volume is the volume of each breath and is measured during inhalation or exhalation, or averaged for the entire respiratory cycle. The value should be normalized to bodyweight or length. During spontaneous breathing, normal values in healthy neonates range from 5 to 10 mL/kg, although >8.5 mL/kg has been generally accepted as overdistension [37]. Very small preterm infants may have spontaneous breathing tidal volumes as low as 3–5 mL/kg.

#### **Minute ventilation**

Minute ventilation is the product of tidal volume and respiratory rate. The respiratory rate of most preterm and term infants is 20–60 breaths/min, and the normal range for minute ventilation is 240–480 mL/kg/min [37].

# Pathophysiology of important respiratory diseases affecting infants and children

#### Asthma

Asthma is a chronic, recurrent disease characterized by reversible bronchoconstriction, accompanied by inflammation and increased mucus production in the small airways. Asthma exacerbations are manifest by expiratory wheezing and obstruction to expiratory and sometimes inspiratory airflow, cough, and varying degrees of respiratory distress. Because of the broad definition and heterogeneous nature of the disease prevalence estimates vary, but 6-9 million children in the United States have asthma, making it the most common chronic respiratory disease and a condition commonly encountered by the pediatric anesthesiologist [38,39]. Total asthma prevalence in the United States in 2009 was 8.2%, with 9.6% of children aged 0-17 years having the disease. Children 5-15 years of age have a particularly high prevalence, with 12-13% of males in this age group suffering from this condition. About half of these patients have an asthma attack annually, and in 2007 157,000 children were hospitalized for asthma, and there were 185 asthma deaths in children in the US [40].

For many children, the disease originates in infancy. Many infants wheeze with viral upper and lower respiratory tract infections, particularly with respiratory syncytial virus (RSV) and rhinovirus. Many of these children will only wheeze during their preschool years, and thus do not develop chronic asthma. In some children, RSV infection is felt to increase the risk of developing chronic asthma, through a combination of genetic, environmental, and immune response mechanisms that are not clearly elucidated. Those who have recurrent bronchospasm events after age 6 years are diagnosed with asthma; many of these patients will have their disease resolve completely or greatly diminish after adolescence. Those with asthma persisting into adolescence often have an atopic/ allergic component to their disease. Up to 75% of young children who wheeze with viral respiratory tract infections will have complete resolution of symptoms by adulthood [39-42].

The inciting events for an episode of bronchospasm are legion. As noted above, viral respiratory infections, especially with RSV, are a frequent inciting event in children. Other viruses known to be associated with asthma exacerbations include rhinovirus, influenza, parainfluenza, and coronavirus. Allergic sensitization and innate immune response to the virus exposure play a role in these exacerbations [39]. Other infections, such as chlamydia, mycoplasma, and bacterial infections of the respiratory tract, can provoke asthma exacerbations. Allergic responses with antigen-specific IgE antibodies to aeroallergens is another important mechanism that usually does not occur until at least 2–3 years of age. This mechanism increases during later childhood and adolescence, and peaks in the second decade of life. Dust mites, animal dander, trees and grass pollens are among the most frequent inciting factors for allergic asthma. Another very important risk factor for childhood asthma is exposure to tobacco smoke, which is thought to be the single most important environmental factor for asthma exacerbation in infants and children [42]. Other factors for asthma exacerbation, particularly in older children, include exercise-induced asthma, allergy to non-steroidal antiinflammatory agents, including aspirin (5-10% of adult asthmatics), gastroesophageal reflux, and psychosocial stressors.

The genetic components of asthma are complex and multifactorial, and although the atopic phenotype has a familial component, recent genome-wide association studies and other gene candidate studies have had limited success in elucidating the genetic origins of asthma. Several groups have reported markers on chromosome 17q21 that were reproducibly associated with childhoodonset asthma in families from the United Kingdom and Germany, and other populations. This association appears to be strongest in young children with tobacco smoke exposure. There are several candidates identified, but as yet no definitive asthma genes have been designated [43].

The pathophysiology of an asthma exacerbation is complex, keeping in mind that it is an acute episode superimposed upon an abnormal airway with chronic changes of inflammation, increased airway smooth muscle resulting in airway remodeling and chronic loss of lung function, and increased mucus production. In addition, the asthma phenotype has been divided into a number of subphenotypes. Airway inflammation is a fundamental abnormality in asthma pathogenesis, with mast cells, eosinophils, neutrophils, CD4<sup>+</sup> T-lymphocytes all playing a role. In allergic asthma, antigen exposure in the airway to IgE-specific antibodies incites a T-helper cell 2 (Th2) type lymphocyte response, which in turn generates a cytokine response. The cytokine response attracts mast cells, eosinophils, and basophils, which in turn are activated and release mediators of airway smooth muscle tone, including histamine, leukotrienes (including slow reacting substance of anaphylaxis), and prostaglandins, and resulting in acute

**Figure 6.2** Inflammatory and remodeling responses in asthma with activation of the epithelial mesenchymal trophic unit. Epithelial damage alters the set point for communication between bronchial epithelium and underlying mesenchymal cells, leading to myofibroblast activation and increase in mesenchymal volume, and induction of structural changes throughout the airway wall. Reproduced from Holgate and Polosa [45] with permission from Elsevier.

bronchospasm [44]. The chronic inflammation effects on the airway epithelium are now known to be crucially important to asthma pathogenesis. Bronchial biopsies in moderate-to-severe asthma show areas of epithelial metaplasia, thickening of the subepithelial basal membranes, increased numbers of myofibroblasts, and evidence of airway remodeling including hypertrophy and hyperplasia of airway smooth muscle, mucus gland hyperplasia, angiogenesis and an altered deposition and composition of extracellular matrix proteins [44,45] (Fig. 6.2). This means a chronically abnormal airway characterized by increased smooth muscle, an immune system primed to respond to allergen exposure, and airways chronically narrowed by this inflammation and mucus production will constrict further with acute airway smooth muscle constriction. Particularly in small pediatric patients, the narrow small airways diameter means that a relatively small degree of airway smooth muscle

constriction can result in more severe bronchospasm symptoms, given that resistance to airflow is inversely proportional to the fourth power of the airway radius with laminar flow, and the fifth power of the radius with turbulent flow.

Evaluation of asthma in young children involves careful history of frequency and severity of episodes, response to treatment, and ascertaining environmental allergens and exposures. Clinical examination is important, and active wheezing in the preanesthetic period is cause for concern and should merit cancellation of elective surgery. Pulmonary function testing, particularly forced expiratory volume in 1 sec (FEV<sub>1</sub>) and forced expiratory flow at 25–75% of the expiratory volume (FEF<sub>25-75</sub>), is important in older children, to gauge both baseline status and response to treatment during an acute exacerbation. Obviously, young children will not co-operate for pulmonary function testing so clinical examination and

history are the primary methods for evaluation. Chest radiography is important to assess degree of hyperinflation and rule out infectious causes.

Treatment of asthma depends on the age of the patient and the severity of the asthma. Acute exacerbations of as thma are usually treated with a short-acting  $\beta$ -agonist by inhalation route (nebulized or metered dose inhaler), such as levalbuterol, which will enhance the action of cyclic AMP and thus relax airway smooth muscles. Halogenated inhaled anesthetics are well known to relax airway smooth muscle via inhibition of Ca<sup>2+</sup> influx. (See Chapter 9 for a complete discussion of the pharmacology of inhaled anesthetics.) In the rare case of acute severe bronchospasm with general anesthesia where gas exchange is so compromised that any inhaled agent does not reach the airways, intravenous β-agonists (epinephrine, isoproterenol), as well as intravenous magnesium sulfate, can acutely relax airway smooth muscle and allow inhaled agents to reach the airways. The US National Institutes of Health published evidence-based asthma evaluation and treatment guidelines in 2007 [46]. For intermittent asthma, episodic treatment with shortacting  $\beta$ -agonists as needed is recommended. As the severity and chronicity of asthma increase, additional chronic treatments such as inhaled corticosteroids, cromolyn (mast cell stabilizer), montelukast (leukotriene receptor inhibitor), longer acting β-agonists or oral corticosteroids are added (Fig. 6.3).

#### **Bronchopulmonary dysplasia**

Bronchopulmonary dysplasia (BPD) was described over 40 years ago by Northway et al, in a series of 32 preterm infants following mechanical ventilation for respiratory distress syndrome (RDS). The disease featured prominent interstitial fibrosis, alveolar overdistension alternating with regions of atelectasis, and airway abnormalities, including squamous metaplasia and excessive muscularization [47]. In those early days of survival of preterm infants, ventilator therapy often included high FIO<sub>2</sub> and high ventilating pressures and volumes, features now known to cause significant lung injury and which contributed to the severe chronic lung disease in many early BPD patients. In recent years, with survival of more and more premature infants, and recognition of pulmonary oxygen toxicity and the adverse effects of excessive pressures and volumes with mechanical ventilation, the BPD phenotype has changed to a histological pattern of arrest of airway and alveolar development: alveolar numbers are reduced and the alveoli are larger than normal in diameter; the more severe changes are absent [48,49] (Fig. 6.4). The most common current definition of the "new" BPD is a premature infant who had a diagnosis of RDS, and requires supplemental oxygen at 36 weeks postconceptional age, whether or not they required mechanical ventilation. A joint US National Institute of Childhood Health and Development/National Heart Lung and Blood Institute workshop further classified mild BPD as the need for supplemental oxygen at  $\geq$ 28 days' but not at 36 weeks' postconceptional age; moderate BPD was defined as the need for supplemental oxygen at FIO<sub>2</sub> ≤0.30 at 36 weeks' postconceptional age; and criteria for severe BPD included the need for supplemental oxygen at 28 days' and at 36 weeks' postconceptional age, and the need for mechanical ventilation and/or FIO<sub>2</sub> >0.30 [48].

The incidence of BPD varies by center, but in recent studies of infants born at 24–31 weeks' gestation at 500–1500 g, BPD rates average 25–30% using the definition of oxygen requirement at 36 weeks, but intercenter variability means these rates vary from about 5% to 60% [48]. The overall incidence of BPD is stable or actually increasing slightly, presumably due to increasing survival of more premature infants. Risk factors for BPD include lower gestational age and birthweight, intrauterine growth retardation, male sex, family history of asthma, not receiving antenatal glucocorticoids, and likely a genetic component that is not yet fully elucidated.

Theories about pathogenesis of the new BPD include lung injury in very preterm infants at critical stages of lung development during the late canalicular and saccular phases (see above), resulting in arrested development of lung structures and disrupted repair at critical stages [50]. Proposed risk factors for this lung injury include chorio-amnionitis and fetal inflammatory response, ventilator-induced lung injury (volutrauma, pressure trauma, stretch trauma), oxygen toxicity (oxygen free radical production and lipid perioxidation), lack of surfactant, and disruption of vasculogenesis (inhibition of vascular endothelial growth factor (VEGF) pathways) [50].

Strategies to reduce the incidence and severity of BPD include non-invasive forms of ventilation, in lieu of endotracheal intubation in prematures with RDS. Both nasal CPAP and nasal intermittent positive pressure ventilation (NIPPV), delivered via specially designed nasal prongs, have been used for this purpose. As a primary treatment for respiratory failure secondary to RDS, non-invasive ventilation may avoid endotracheal intubation in some infants, but so far trials have not shown a consistent ability to reduce the incidence of BPD with these modalities. Non-invasive ventilation is well established as a postextubation therapy to reduce the duration of endotracheal intubation and mechanical ventilation. However, these modalities used after extubation have not been conclusively demonstrated to reduce the incidence of BPD [49]. Modern conventional

Compone	nts of sourceity	Classification of asthma severity (0–4 years of age)				
Components of severity			Persistent			
		Intermittent	Mild	Moderate	Severe	
	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day	
Impairment	Nighttime awakenings	0	1–2x/month	3–4x/month	>1x/week	
	Short-acting beta <sub>2</sub> -agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day	
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited	
Rick	Exacerbations	≥2 Exacerbations in 6 months requiring oral sy 0–1/year corticosteroids, or ≥4 wheezing episodes/1 year >1 day AND risk factors for persistent asth				
Nisk	systemic corticosteroids	Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time. Exacerbations of any severity may occur in patients in any severity category.				
Recommended step for Initiating therapy		Step 1	5 1 Step 2 Step 3 and consider short course of oral systemic corticosteroids			
(See figure 6–3c for treatment steps.)		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed in 4–6 weeks, consider adjusting therapy or alternative diagnoses.				

Key: EIB, exercise-induced bronchospasm

Notes

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

mechanical ventilation techniques employ microprocessor technology, allowing patient-triggered synchronized ventilation, volume-targeted ventilation, and flow-cycled ventilation, all of which are proving to have advantages in reducing the incidence of ventilator-induced lung injury. Permissive hypercapnia reduces the duration of mechanical ventilation but the incidence of BPD with this technique is unchanged. High-frequency oscillatory ventilation is often used in preterm infants with RDS; this strategy has also been found to reduce the incidence of BPD in some studies [49]. Oxygen toxicity has been postulated to have an important role in the pathogenesis of worsening RDS and BPD, and in recent studies, targeting an SpO<sub>2</sub> in the 85-89% range, rather than the 94-97% range, appears to have some effect in reducing the severity of lung injury and of BPD; meta-analysis of combined trials is underway to further elucidate the magnitude of this effect [51].

Drug therapies used to reduce the severity of RDS include a single course of antenatal glucocorticoids (dexamethasone or betametasone) to accelerate the maturation of the surfactant system in the fetal lung; there is no evidence that this intervention reduces the risk of BPD, probably because of an increase in survival. Surfactant therapy significantly reduces the incidence and severity of RDS, but again does not reduce the incidence of BPD likely because of the survival benefit. Caffeine therapy, originally used to reduce apnea of prematurity, also reduces the incidence of BPD. Inhaled nitric oxide (iNO), the potent pulmonary vasodilator, has been used in prematures with hypoxemic respiratory failure, but in randomized controlled trials has demonstrated an inconsistent effect on survival and incidence of BPD in premature infants, and is not recommended as routine therapy in RDS. Other drug therapies that have been used in infants with RDS and evaluated to reduce the incidence of BPD include systemic or inhaled corticosteroids, furosemide,  $\beta$ -receptor agonist or anticholinergic inhaled drugs, indometacin and ibuprofen, vitamin E, and superoxide dismutase; these agents have not reduced the incidence of BPD. Therapies shown to be effective at reducing BPD incidence include vitamin A and inositol supplementation in the diet [51].

When caring for a patient with a diagnosis of BPD, the anesthesiologist must thoroughly review the history and current chest radiographs. The severity of BPD, according to the criteria noted above, should be assessed. Severe "old" BPD in a chronically ventilated infant with a tracheostomy is rare in the modern era. Examination often reveals an infant receiving supplemental oxygen by endotracheal tube, nasal CPAP or conventional nasal cannula, with varying degrees of tachypnea, intercostal and subcostal retractions, and signs of increased lung water or bronchial reactivity such as fine rales and expiratory wheezing. It is important to understand the patient's baseline oxygen saturation and PaCO<sub>2</sub>, often available from capillary or venous blood gases. Ventilatory strategies in the operating room should be designed to minimize barotrauma, volutrauma, and oxygen toxicity, and allow permissive hypercapnia to the patient's normal PaCO<sub>2</sub>. Decreases in lung compliance, increases in resistance, and the increased risk for postoperative mechanical ventilation must all be anticipated and planned for in the infant with BPD. Additional doses of diuretics or bronchodilators may be needed to optimize perioperative pulmonary outcomes.

#### **Cystic fibrosis**

Cystic fibrosis (CF) is an autosomal recessive disorder caused by a defect in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. It is present in approximately 30,000 children and adults in the United States, with about 1000 new cases diagnosed annually. With improvements in early diagnosis and care, life expectancy has increased markedly over the past several decades, with median life expectancy at more than 37 vears [52]. CFTR is an adenosine triphosphate (ATP)binding protein that regulates chloride and bicarbonate transport across epithelial cells via cyclic adenosine monophosphate (cAMP). CFTR also regulates the airway surface liquid depth through regulation of other proteins, most prominently the epithelial sodium channel. Absent or dysfunctional CFTR results in abnormal electrolyte and fluid content on the epithelia of the lung, pancreas, intestine, hepatobiliary tract, sweat gland, and vas deferens. Patients with CF have thick, dehydrated, hyperviscous mucus that severely deters effective mucus clearance (Fig. 6.5). Patients with CF are susceptible to chronic infection with pathogens such as Staphylococcus aureus and Pseudomonas aeruginosa that are nearly impossible to eradicate once established. Inflammation occurs both secondary to chronic infection and independent of microbial disease. Chronic infection and inflammation precipitate a cycle of tissue destruction, bronchiectasis, and airway obstruction, a process that eventually leads to respiratory failure. Slowly progressive lung injury is often accompanied by episodic pulmonary exacerbations, followed by periods of relative disease stability [53] (Fig. 6.6).

Standard therapies for CF include daily airway clearance maneuvers with chest physiotherapy by vibropercussion, hand-administered therapy or specially designed vests which assist with mucus clearance. Inhaled nebulized recombinant human DNase thins excessive DNA debris in sputum that accumulates due to the bacterial burden and the large influx of neutrophils into the airway lumen. This therapy improves pulmonary function, decreases the frequency of CF exacerbations, and improves quality of life [52]. Nebulized hypertonic saline has also been shown to be effective in some

**Figure 6.5** Pathogenesis of cystic fibrosis lung disease is characterized by absent or dysfunctional cystic fibrosis transmembrane conductance regulator (CFTR) at the epithelial surface (1), resulting in disordered ion transport and a depleted airway surface liquid layer (2). This contributes to delayed mucociliary clearance (3), setting the stage for colonization and chronic infection with bacterial pathogens (4) and a robust inflammatory response (5). Therapeutic approaches to each feature are indicated. ASL, airway surface liquid; PMN, polymorphonuclear cell. trials. Early and aggressive antimicrobial therapy targeted at the patient's specific organisms and susceptibilities is believed to be responsible for a large component of the improvement in quality of life and reduction in exacerbations in patients with CF in recent years. Regular parenteral antibiotic therapy (i.e. every 3 months) is used in some centers, with agents including aminoglycosides, ceftazidime, and meropenem. Antibiotic resistance is a major problem, especially with resistant Pseudomonas species, and other resistant organisms such as Burkholderia cepacia. Inhaled nebulized tobramycin has been shown to be effective at preventing CF exacerbations. Anti-inflammatory therapy with low-dose corticosteroids or non-steroidal anti-inflammatory agents is also used in some patients [52]. CFTR-modulating drugs are under development and in some clinical trials; gene transfer therapy would be the ideal treatment but faces significant obstacles and clinical use is not imminent. Lung transplantation is reserved for patients with severe CF and a life expectancy of 2 years or less.

Cystic fibrosis patients present to the anesthesiologist for a variety of procedures, including vascular access procedures, lung biopsies, bronchoscopy, feeding gastrostomy, endoscopic sinus surgery, and lung transplantation. A very thorough review of history, medications, diagnostic testing, and physical examination is important.

## Introduction

The child is not merely a small adult. At birth, central nervous system (CNS) development is incomplete and will not be mature until the end of the second year of life. Because of this delay in maturation, several specific pathophysiological and psychological differences ensue. Neurodevelopment follows a complex interplay between timed genetic events and activity-dependent structural modifications. The vigorous cellular plasticity of the brain is in contrast to its unforgiving metabolic vulnerability when exposed to conditions of substrate deprivation. Care of the critically ill child susceptible to neurological injury is best carried out with a comprehensive understanding of the physics of the intracranial compartment, vascular physiology of the brain and developmental peculiarities of the nervous system.

### Embryology of the developing brain and spinal cord, changes from fetus to neonate to child

### Embryogenesis of the brain

The CNS development begins from a relatively simple single layer of cells and progresses to a very complex, multilayered central structure that eventually connects with every part of the body. The processes of CNS embryogenesis follow three steps: (1) neurulation, (2) canalization, and (3) retrogressive differentiation (Table 7.1).

Within 2 weeks of conception, a groove is formed in a plate of embryonic ectoderm, which contains the cells that will become brain and spinal cord. By 1 month, *neurulation* is complete and the lateral edges of this groove are fused to form the neural tube (Fig. 7.1). At this time, neural crest cells are excluded from the tube closure and subsequently

migrate and differentiate to populate diverse neuronal structures such as the sympathetic chain ganglia, the enteric neuronal plexi, the dorsal root ganglia and adrenal medulla, in addition to becoming melanocytes in the skin.

Rostrally, the neural tube undergoes differential growth, expansion and folding, to form the three primary brain vesicles: the prosencephalon, mesencephalon and rhombencephalon. Caudally, the neural tube and surrounding mesoderm retain segmental characteristics and form the portion of spinal cord from the medulla to the midlumbar segments. Secondary brain vesicles are

Figure 7.2 Brain development from the neural tube. The neural tube gives rise to three primary brain vesicles, which in turn form five secondary brain vesicles before completing development into the mature brain.

formed as the primary vesicles subdivide. The prosencephalon divides into the telencephalon (cerebral cortex and basal nuclei) and the diencephalon (thalamus, hypothalamus and retinae). The mesencephalon (midbrain) does not subdivide. The rhombencephalon divides into the metencephalon (pons and cerebellum) and the myelencephalon (medulla) (Fig. 7.2).

#### Embryogenesis of the spinal cord

The spinal cord from the medulla to the midlumbar segments is derived from the caudal portion of the neural tube. The posterior neuropore closes within a month of gestation, and subsequently elongates to form the distal spinal cord and conus medullaris. *Canalization* is the fusion of the notochord and neural epithelium into a caudal cell mass to form sacral and coccygeal segments between 1 and 2 months of gestation. Microcysts develop and coalesce within this mass. *Retrogressive differentiation* is the necrosis of excess cells formed by canalization in the caudal neural tube, leaving the filum terminale and cauda equina, a process that continues into the early postnatal period. Vertebral column growth exceeds spinal column growth, resulting in ascension of the conus medullaris from the L3 vertebral segment at birth to the L1 vertebral segment at adulthood (Fig. 7.3).

#### Neural tube defects

A neural tube defect is any defect that may occur during the development of the CNS. Defects occurring during neurulation can be classified into (1) those involving the brain and spinal cord, (2) those involving the brain only and (3) those involving the spinal cord only. For example,

Figure 7.3 Asymmetric growth of the spine and its vertebral canal causes a change in the position of the conus medullaris with respect to the vertebral column with growth from neonate (A) to adult (B).

when there is failure of neurulation in early development, a condition of total dysraphism occurs within both the brain and spinal column. If only the brain fails to close, the condition is termed anencephaly.

Later in development, many malformations of the brain can occur which have clinical relevance for the pediatric anesthesiologist, including congenital hydrocephaly. Abnormal neuronal migration results in cortical malformations that may be appreciated on gross surface anatomy [1].

Schizencephaly (clefts in the cerebral wall), pachygyria (sparse, broad gyri), and polymicrogyria are examples of anomalies strongly associated with migrational abnormalities. Lissencephaly (smooth brain) is a severe anomaly that may be produced by either migrational anomalies or earlier disruptions in neurogenesis. Partial or complete agenesis of the corpus callosum may be associated with any of the above anomalies but it is believed to be a migrational abnormality in and of itself. Failure of canalization results in a myelocele if the lesion is flat or myelomeningocele if there is an additional dorsal outpouching of the meninges/neural tissue.

#### **Proliferation and migration**

The second month of brain development, following closure of the neural tube, is marked by an exponential

cellular proliferation, and this continues into the second trimester. The second trimester is, therefore, a time when the central nervous system is prone to global insult from teratogen exposure. Radial migration is a robust element of cortical development and has been well characterized. Cells destined to populate the neocortex, as both glial and neuronal varieties, originate from the rapidly dividing periventricular cell layer and migrate along a glial network. They populate the six-layered cortex by migrating past the last formed layer, such that the youngest cells are found at the outermost layers. At term, cellular proliferation in the cortex is largely completed. However, when an infant is born prematurely, especially at the limits of viability near the beginning of the third trimester, residual germinal matrix is present in the caudothalamic groove adjacent to the lateral ventricles. This ongoing germinal activity is accompanied by a transient network of fragile vascular overgrowth, and is a site of hemorrhage in the premature neonate [2,3].

#### Synaptogenesis and myelination

The third trimester of neuronal development starts a period of neuronal growth, synaptic proliferation, axonal growth, and myelination. The myriad interneuronal connections forming an incomprehensible network of logical units in the human brain are the result of interplay between genetically determined anatomic directives and environmentally determined plasticity. The basic strategy of the network formation is to excessively populate and interconnect neuronal networks and then thin cell populations by apoptotic mechanisms, prune inactive synapse formations, and reinforce functional, active connections. The viability of neurons and synaptic connections is determined by their activity patterns. The resultant functionality of the network is, therefore, dependent on sensory and environmental input, and some of these inputs are known to be time sensitive.

Amblyopia is the most striking example of synaptogenesis gone awry for lack of appropriate sensory input during a critical stage of development. Spatially organized and synchronized neuronal activity along the visual pathway is required for normal development of the occipital cortex. Activity-dependent synapse reinforcement of the occipital cortex begins in darkness, *in utero*, as waves of electrical activity spontaneously pass across the retina, reinforcing spatially co-ordinated synaptic connections throughout the visual pathway [4]. After birth, further synaptic reinforcement is dependent on light-mediated excitation in the retinae. If the retinae receive inadequate or disconjugate light stimulus through the critical development period up to 2 years of age, the corresponding cortical network is irreversibly pruned and the result is permanent blindness of the affected eye [5–7].

Critical periods for other neurodevelopmental processes are less well defined, but the perinatal surge in synapse formation is known to continue through early childhood to the preteen years. The existence of a critical period distinguishes developmental, primary synaptogenesis from other forms of neural plasticity, which continue throughout life. The relative permanence of synaptogenic modulation during infancy and childhood is even postulated to create a critical period for development of intellect, behavior, and affect. Environments rich in stimulation, interaction and socialization promote increased synapse retention, whereas neglectful, stimuluspoor developmental environments yield synapsedepleted cortical networks, and may lead to permanent cognitive deficits [8-11]. The dendritic arborization of cortical pyramidal neurons has been shown to be environment dependent even in the mature mammalian brain (Fig. 7.4). Furthermore, the introduction of a consistently noxious environment during critical developmental stages may yield undesirable affective changes.

**Figure 7.4** Age-related patterns of dendritic arborization of cortical pyramidal neurons. Mature pyramidal neurons (A) can undergo a stimulus-dependent process of stabilization and even increase in synaptic interconnection and dendritic branching (B,C). Alternatively, without stimulus input, the mature neuron can undergo synaptic pruning and regressive loss of dendritic arborization (D–F). Reproduced from Diamond [155] with permission from Academia Brasileira de Ciencias.

#### **Myelination**

Myelination and axonal maturation also start in the third trimester, with a peak density of immature oligodendrocytes in the cortical white matter between 23 and 32 weeks' gestation, a time of white matter vulnerability in the premature infant [12]. Myelination continues through childhood and into the teen years, mirroring brain growth. The brain is 450 grams at birth, 1000 grams at 1 year, and 1400 grams at 18 years, growth that is accounted for by myelination and increases in cell size and organization, not cellular proliferation. Developmental milestones are also observed to follow patterns of myelination. For instance, myelination of the corticospinal tract begins at 36 weeks' gestation and is completed at around 2 years of life. Myelination of this tract progresses from short to long fibers, giving an anatomic explanation for the headto-toe disappearance of hyper-reflexia and increased tone seen in normal development. Axonal maturation of the speech-dominant frontotemporal pathway continues through late childhood and adolescence, along with the development of increasingly sophisticated language competency [13]. As with synaptogenic processes, myelination patterns are activity dependent [14].

Immature patterns of myelination are seen on magnetic resonance imaging (MRI) of term infants with congenital heart disease. An estimated 25% of infants with congenital heart disease have lesions on MRI before undergoing bypass, and brain immaturity is a risk factor for new MRI lesions after cardiopulmonary bypass. Many of these lesions are diffuse white matter injury, similar in nature to periventricular leukomalacia seen in preterm infants [15].

# Development of pain pathways and responses

The relatively new specialty of pediatric anesthesia has arguably made its greatest contribution in the understanding of nociception and the effects of "pain" on the developing infant and child. The nociceptive systems develop during the second and third trimesters of gestation with further maturational changes occurring during the first 2 years of life. Historically, pediatric pain was undertreated during the neonatal period and infancy due to a belief that the pain system was underdeveloped during these times [16]. However, although a "verbal" response to pain may not be present, the "physiological" responses were recognized and prompted a careful exploration into the physiological basis of nociception.

Nociception begins with the sensation of the stimulus at the level of the peripheral nervous system [17]. Unlike the adult-specific sensations of touch, pressure, heat or cold, there are no specific pain sensors in the developing fetus. Rather, the "pain" stimulus is sensed by free nonspecific nerve endings. Rapidly adapting pressure receptors are the first to appear during fetal life, followed by the development of slowly adapting pressure receptors, and then rapidly adapting mechanoceptors. The depolarization responses of these receptors to mechanical injury, chemical irritants, and inflammatory mediators are similar to those of adult receptors [18]. Cutaneous sensory receptors appear in the perioral area at 7 weeks' postconceptual age (PCA), spread to the hands and feet by 11 weeks' PCA, and are present at all cutaneous and mucous surfaces by 20 weeks PCA [19,20]. The development of these sensory reflexes is preceded by synaptogenesis between afferent fibers and sensory neurons in the dorsal horn of the spinal cord.

The sensation of pain is mediated via free nerve endings of A- and C-fibers. These fibers do not demonstrate fatigue, but rather repeated or continuous stimulation increases the ease of transmission of the impulse. Histological studies show that the density of nociceptive nerve endings in the newborn skin is similar to that of adult skin [21]. More importantly, the neurophysiological properties of the earliest nociceptors are also similar to those of adults. Myelinated fibers are the first to grow into the developing spinal cord and form connections with deeper layers of the dorsal horn, with collaterals to neurons in the substantia gelatinosa. With the ingrowth of C-fibers (unmyelinated fibers) and synaptogenesis with superficial dorsal horn neurons, these collaterals undergo developmental degeneration. Nociceptive stimuli in fetal life (and in the extremely premature neonate) are transmitted by myelinated A-fibers until the maturation of C-fiber connections [22].

The first-order neuron, whose cell body lies in the paravertebral ganglion, carries the nociceptive input into the dorsal horn of the spinal cord. The first-order neuron synapses with a second-order neuron in the dorsal horn of the spinal cord. The second-order neuron then crosses the midline and ascends in various pathways, including the spinothalamic tract, synapsing in the thalamus with a third-order neuron which projects to the sensory cortex [23]. In the dorsal horn of the spinal cord, nociceptive input is modified (amplified and inhibited) by descending fibers from the central nervous system and interneurons within the dorsal horn. This modulation is mediated via various chemical compounds (substance P, adrenergic agents, serotonin, and endogenous opioids), which bind to the first- or second-order neuron via specific receptor systems (Fig. 7.5).

In the first trimester of pregnancy, development of the spinal cord and central nervous system begins with the closure of the neural canal. At this time, the dorsal horn begins to appear. Electron microscopic and immunochemical studies demonstrate that the development of the various neuronal cell types in the dorsal horn, with their laminar arrangement, interneuronal connections, and

**Figure 7.5** Pain transmission is modulated by descending inhibitory pathways and spinal interneurons at the level of the spinal cord.

expression of specific neurotransmitters and receptors, begins before 13 weeks of gestation and is completed by 30-32 weeks PCA. Initially, the receptive fields of dorsal horn neurons are very large with an extensive overlap between the receptive fields of adjacent neurons. As maturation occurs, the receptive fields of individual dorsal horn cells progressively decrease and can be more precisely defined [24]. On a cellular level, the transmission of nociceptive impulses through the dorsal horn of the spinal cord is mediated and modulated via the release of excitatory neurotransmitters (Fig. 7.6), such as substance P, glutamate, calcitonin gene-related peptide (CGRP), vasoactive intestinal polypeptide (VIP), neuropeptide Y, and somatostatin. Modulation of this nociceptive transmission occurs by the release of metenkephalin from local interneurons and norepinephrine, dopamine, and serotonin from descending inhibitory axons.

These descending inhibitory axons originate in supraspinal centers and terminate at all levels of the spinal cord and brainstem. During the first and second trimesters and up until the latter half of the third trimester, there is an imbalance between the mechanisms that favor the facilitation rather than the inhibition of nociceptive input. Of the nociceptive neurotransmitters, substance P, CGRP, and somatostatin are expressed in the dorsal horn by 8–10 weeks' PCA. Glutamate, VIP, and neuropeptide Y appear at 12–16 weeks' PCA. Modulation of incoming noxious stimuli in extremely premature infants may occur through the local release of metenkephalin, which is first expressed at 12–16 weeks' PCA. However, this mechanism is unlikely to be effective in diminishing the transmission of intensive painful stimuli. In the latter half of the third trimester, with the maturation of the descending inhibitory pathways from supraspinal centers, inhibition of incoming sensory stimuli can occur with the release of dopamine and norepinephrine in the dorsal horn of the spinal cord. These neurotransmitters are first expressed at 34–38 weeks of human gestation followed by serotonin, which develops during the postneonatal period [25,26].

Conduction of nociceptive impulses to the supraspinal centers occurs via the spinothalamic, spinoreticular, and spinomesencephalic tracts located primarily in the anterolateral and lateral white matter tracts of the spinal cord. Lack of or decreased myelination in these tracts was previously proposed as an index of immaturity of the neonatal CNS and was used to support the argument that neonates cannot feel pain or do not react to it in the same manner as adults. This argument was widely supported despite the common knowledge that incomplete myelination does not imply lack of function, but merely imposes a slower conduction velocity in the central nerve tracts of neonates. Additionally, any slowing in the central conduction velocity would be completely offset by the shorter interneuronal distances that must be traveled by the

Figure 7.6 Neurotransmitters found in the spinal cord modulating activity of the pain pathway are shown with the gestational age at which they are first expressed.

impulse when comparing an infant to the much larger (and longer) adult [27]. The nociceptive tracts to the brainstem and thalamus are completely myelinated by 30 weeks of human gestation and the thalamocortical pain fibers are fully myelinated by 37 weeks. The timing of the thalamocortical connection is of crucial importance for cortical perception since the majority of sensory pathways to the neocortex have synapses in the thalamus. In the primate fetus, thalamic neurons produce axons that arrive in the cerebrum before midgestation. These fibers remain just below the neocortex until migration and dendritic arborization of cortical neurons are complete and finally establish synaptic connections at 20–24 weeks' PCA [27].

The functional maturity of the cerebral cortex is suggested by the presence of fetal and neonatal electroencephalographic (EEG) patterns and by the behavioral development of neonates. Intermittent EEG bursts in both cerebral hemispheres, first seen at 20 weeks' PCA, become sustained at 22 weeks and are bilaterally synchronous at 26-27 weeks' PCA. By 30 weeks, the distinction between wakefulness and sleep can be made on the basis of EEG patterns [28,29]. Cortical components of somatosensory, auditory, and visually evoked potentials have been recorded in preterm babies before 26 weeks' PCA [30]. Several forms of behavior imply cortical function during fetal life. Well-defined periods of quiet sleep, active sleep, and wakefulness occur even in utero, beginning at 28 weeks' PCA. In addition to specific behavioral responses to pain, neonates have various cognitive, co-ordinative,

and associative capabilities in response to visual and auditory stimuli, attesting to the presence of cortical function and intact processing of nociceptive input. Several lines of evidence suggest that the complete nervous system is active during prenatal development and that detrimental or developmental changes in any part can affect the entire system [23].

# Development of the response to pain stimulation

The human fetus is capable of spontaneous movements and complex responses early in gestation. Reflex movement in response to direct stimulation begins at 7.5 weeks' PCA, initially localized to the head and neck region [31]. Sensitivity develops in a craniocaudal direction with the lower limbs responding by 14 weeks' PCA. Data from the immature rat and other animals show that responses to stimulation are initially inconsistent, non-specific, and poorly localized [32]. However, if a response is achieved, it can be extremely exaggerated and long-lasting [33]. These observations tie in well with neurophysiological data in animals and clinical work with preterm human infants.

Single cell studies from the dorsal root ganglion of the rat show that cutaneous receptive fields are present in the hindlimb as soon as innervation to the skin has taken place [34]. The firing rates and durations are lower than those in the adult but even at this stage, different classes of afferent responses to noxious stimuli can be demonstrated. Initially stimulation of cutaneous afferents fails to produce suprathreshold excitation in dorsal horn cells but by birth, depolarization can be produced from light touch alone [32]. However, while the synaptic linkage remains weak at birth, suprathreshold stimulation provokes a long-lasting hyperexcitable state in the dorsal horn cells [34].

Polymodal nociceptors which pass to the dorsal horn via C-fibers show fully mature responses to pinch, heat, and chemical stimulation by birth [35]. However, despite their observed anatomic connections, these C-fiber afferents fail to evoke activity in the dorsal horn cells until a week after birth. Thus, while the C-fiber connections remain immature at birth and fail to directly transmit their nociceptive input, they may greatly increase the response to other noxious (A-fibers) and non-noxious inputs. Together with the large receptive fields observed in dorsal root ganglion cells, this may increase the likelihood of a central response from the relatively immature nervous system. The lack of functional descending inhibitory pathways from higher centers also contributes to the potentially excitable and poorly damped responses to afferent inputs.

#### **Central integration of afferent inputs**

In the human, complex central integration of afferent sensory and nociceptive input is present at 30 weeks' gestation. Visual and auditory evoked potentials are present and complex EEG reactions to external influences are seen at this time [28,29]. Klimach and Cooke demonstrated the presence of somatosensory evoked potentials (SSEPs) in the preterm neonate [30]. In fact, SSEPs have been measured in infants as young as 28 weeks' gestation. These investigators also demonstrated that the velocity of both peripheral nerve conduction and central conduction increased with gestational age. However, there was considerable variability in peripheral velocity and central processing in the younger infants, suggesting that there are large individual differences in maturation rates. SSEPs continue to mature during infancy [36]. Subarachnoid injections of lidocaine in the ex-premature infant cause rapid loss of SSEPs corresponding to the onset of motor and sensory blockade. The offset of the block can be monitored with the return of SSEPs and shortening of the latency back to the baseline [37]. Positron emission tomography scans in the infant have shown that glucose utilization is maximal in the sensory areas of the cerebral cortex, implying a high level of activity [38].

There is also recent evidence to suggest that cortical activation occurs after painful stimuli in preterm neonates [39]. Bartocci et al, using near infrared spectroscopy in preterm infants 28–36 weeks' PCA, have demonstrated increased blood flow in the somatosensory cortex, but not the occipital cortex, after venepuncture [40]. In a similar study, Slater and colleagues recorded cortical activation

after heelpricks in 18 infants between 25 and 45 weeks' PCA [41]. No cortical response was noted after tactile stimulation even when this stimulation was accompanied by reflex limb withdrawal. Taken together, these studies provide additional evidence that the conscious sensory perception of painful stimuli is present even in preterm newborns. Table 7.2 summarizes the behavioral and physiological nociceptive responses of the neonate.

#### Interneuronal connections

The impression that emerges from these and related human studies is that even the very preterm infant has complex interneuronal connections capable of integrated responses to tactile or nociceptive input. These infants also show inconsistent responses to external stimuli, which may reflect the late functional connections of sensory afferents (particularly C-fibers) within the spinal cord. However, the combination of larger receptive fields, recruitment of non-nociceptive afferents, and reduced inhibitory controls results in "underdampened" responses (long-lasting, exaggerated and poorly localized) once afferent stimuli have achieved central activation above a threshold level. Inconsistency of response to more complex noxious stimuli may also reflect the profound effects that conscious state and other external responses have on behavior [42,43].

#### Molecular basis of pain perception

Studies of developmental cytochemistry in the animal models have focused on substance P, opioid peptides and receptors, N-methyl-D-aspartate (NMDA) receptors, and the expression of the *C-fos* gene. While transmitters can be demonstrated to be present early in gestation, their concentrations are usually very low and they may not always be found at sites that suggest a functional role [44]. By contrast, receptors are often seen in higher

Table 7.2 Main physiological responses to pain

Assessment	Effect of pain stimulation
Middle cerebral artery pulsatility index	Decrease
Intracranial pressure	Increase
Systemic blood pressure	Increase
Heart rate	Increase (inconstant in neonates)
Transcutaneous oxygen tension	Decrease
Vagal tone (amplitude of sinus arrhythmia)	Decrease
Palmar sweating	Increase
Near infrared spectroscopy	Decrease

densities and have a more widespread distribution than in adult life, which may facilitate responses at a time when only low levels of transmitter are available [17]. The transient appearance of receptor populations that have ceased to be expressed by birth remains puzzling and demonstrates that a large gap still exists between the in vitro cytochemical findings and our understanding of in vivo nociception [45]. Opioid receptors change both in numbers and in receptor type during development. Zhang and Pasternak demonstrated that in newborn rats, high-affinity binding sites for a tritriated enkephalin ligand increased up to threefold in the first 2 weeks of life while during this period, a large rise in analgesic response to morphine occurred [46]. In contrast, the effects of morphine on ventilatory drive during this period (2-14 days after birth) were constant. Other studies have confirmed the increase in the number of opioid receptors and changes in their binding affinities during in utero and postnatal development [47].

The ability to evaluate and analyze gene and protein expression on a cellular and tissue level has led to a more systems-based approach to the adaptation to nociceptive triggers, resulting in new insights into the physiological responses to painful stimulus. The implication of such varied responses in rodent models allows us to assess the earliest alterations in gene expression within peripheral nerves, the spinal cord, and brain in both acute and chronic pain response models [48]. The results of proteomic and microarray techniques have demonstrated previously unrecognized alterations in actual transcribed and activated proteins from within a specific cell line and/or tissues [25,49]. One important example of these techniques is the identification of genetic variations and altered expression within the opioid receptor. Following the studies of Pasternak et al, these techniques have identified gene-splice variants as well as single nucleotide polymorphisms within animal and human populations that can better explain the clinical variability in analgesia seen between drugs based on altered opioid-binding kinetics and molecular responses [46,50]. Future directions in molecular pain research will develop molecular signatures of neuronal and receptor responses that correlate with our phenotypical definitions of acute and chronic nociception as well as leading to more personalized pain treatments based on these molecular characterizations (pharmacogenomics) [51].

### The intracranial compartment

The mature brain is both protected and threatened by its bony encasement. The brain cannot tolerate acute mass effect because of the lack of elasticity of the skull and dura. The risks of herniation and stroke from elevated intracranial pressure (ICP) have been described for nearly two centuries as the Monro–Kellie doctrine [52,53]. Elastance in the skull is not linear, as in the normal brain there is a reserve mechanism of cerebrospinal fluid movement from the brain into the spinal canal. When this reserve compliance is exhausted, further increases in intracranial volume cause blood volume to be pushed out of the skull, and finally, terminal increases in intracranial volume cause herniation of brain matter.

Historically, intracranial elastance was estimated by injections of small volumes of artificial cerebrospinal fluid into patients while intracranial pressure was monitored. Now, most practitioners are content with simple intracranial pressure monitoring when indicated. Recently, an analysis of the pulse amplitude behavior of the intracranial pressure waveform has been developed to delineate three clinical states of intracranial elastance. The correlation coefficient (R) between the pulse frequency amplitude (A) and the mean pressure value (P) of the intracranial pressure wave across periods of slow change in mean intracranial pressure gives an index termed the RAP [54,55]. In the normal state, RAP is near zero because the pulse amplitude of intracranial pressure is low and unchanging within a compliant skull. As compliance reserve is exhausted and the elastic properties of the skull and dura begin to dominate, the pulse frequency amplitude of the intracranial pressure becomes passive to slow changes in mean intracranial pressure and RAP trends toward 1. Finally, when intracranial pressure is terminal and herniation is imminent, further increases in intracranial pressure push blood out of the skull and diminish the pulse amplitude of the intracranial pressure, so the RAP becomes negative (Fig. 7.7). Patients with critical ICP have improved elastance as estimated by the RAP when they undergo decompressive craniectomy [56].

Eight major bones separated by eight suture lines and six fontanelles form the intracranial compartment. Delayed ossification of these bones permits deforming compression of the skull by the birth canal during parturition. The corollary concept that fontanelles allow expansion of the cranial vault in the setting of acute mass effect is erroneous. Slow growth and expansion of the sutures and fontanelles can occur in the setting of subacute mass effect, but the fibrous interosseous connections are not compliant, nor do they accommodate mass added acutely to the intracranial compartment. Although it serves no protective role in the setting of acute intracranial mass effect, physical examination of the anterior fontanelle is an important monitor of intracranial pressure. Tonometry has been applied to the anterior fontanelle to measure ICP non-invasively when ICP monitoring is desirable but not invasively accessible [57]. By 2 years of age, the fontanelles are closed and suture lines are replaced with bone, but the fibrous sutures permit ongoing bone growth.

Figure 7.7 Intracranial pressure waves are schematized as a product of fixed cardiac stroke volume pulsations, occuring at different positions on the intracranial pressure-volume curve. Intracranial compliance reserve can be delineated with RAP: correlation (R) between intracranial pressure pulsation amplitude (A) and mean intracranial pressure (P). Three states of intracranial compliance reserve have been defined with this method. (1) RAP = 0, intracranial pressure pulse amplitude does not change with increases in mean intracranial pressure, volume changes are easily absorbed by intracranial compliance reserve. (2) RAP = 1, intracranial pressure pulse amplitude is correlated to changes in mean intracranial pressure. Patients on the ascending portion of the intracranial pressure-volume curve have diminished compliance reserve. (3) RAP < 0, intracranial pressure pulsations are inversely correlated to changes in mean intracranial pressure. When the RAP is negative, intracranial compliance reserve is exhausted and herniation is imminent

The intracranial compartment is subdivided by the tentorium, a dural separation between the brainstem and cerebellum posteriorly and cortex and diencephalic structures anteriorly. Because many children have posterior compartment neoplasms, and ICP is monitored in the anterior compartment, it is important to know that the pressures in the two compartments can be distinct. Posterior compartment mass effect causes deformation of the brainstem, with signs of coma, bradycardia, and hypertension that can exist without bulging fontanelles or elevated anterior compartment pressures.

### **Cerebrospinal fluid**

Derangements of cerebral spinal fluid production, flow and reabsorption account for significant morbidity in the pediatric population. Normal cerebrospinal fluid physiology is well described in adults who have an average 150 mL of cerebrospinal fluid (CSF), 30-40 mL contained in the ventricles, and produce 20 mL/h CSF at the choroid plexus. This causes a replacement of the entire volume of CSF 3-4 times a day. The flow of CSF through the extracellular spaces of the brain and reabsorption through the arachnoid granulations are driven by a constant small pressure gradient between the spinal fluid space and the sagittal sinus. Age-dependent rates of cerebrospinal fluid production have been described in children with external ventricular drains. Given the pathologies associated with the clinical need for drain placement, it is not surprising that a wide range of cerebrospinal fluid production was documented. Nevertheless, spinal fluid production was seen to increase logarithmically during the first year of life and reaches 60% of adult production levels at 2 years of age [58].

# Vascular anatomy of the central nervous system

#### Brain vascular anatomy

A healthy 3kg infant with a normal, 500g brain has a cardiac output of 250 mL/kg/min, and a cerebral blood flow of 25 mL/100 g/min (= 42 mL/kg/min). The infant brain therefore consumes 17% of cardiac output, but also accounts for 17% of the body mass. For comparison, a healthy, 50 kg teenager with a 1400 g brain and a cardiac output of 100 mL/kg/min would have a normal cerebral blood flow of 22 mL/kg/min. The mature brain therefore comprises just over 2% of total body mass, but utilizes 25% of the cardiac output.

Blood flow is supplied to the brain by an extensive network of arteries originating from paired internal carotid and vertebrobasilar arteries. These arteries branch into the anterior cerebral arteries and the posterior cerebral arteries, respectively, which anastomose with each other on the ventral surface of the brainstem to create the anterior and posterior segments of the circulus arteriosus cerebri (circle of Willis), which is completed by the anterior and posterior communicating arteries. The circle of Willis provides collateral blood flow to the brain parenchyma; therefore, damage to any one vessel typically
does not result in clinically significant ischemia. However, incomplete formation, damage or obstruction of any one of the major cerebral vessels may result in a cerebrovascular accident (CVA). The vessels comprising the circle of Willis are prone to the formation of berry aneurysms, which are congenital birth defects related to defective arterial wall formation. Although these berry aneurysms are present at birth, they rarely rupture until early to middle adulthood.

Another congenital vascular abnormality of significance is arteriovenous malformation (AVM), which is the most frequently occurring cerebrovascular malformation. AVM results in the shunting of blood from the arterial to the venous side secondary to anomalous dilated capillaries. Fifty percent of patients will present with seizures or neurological deficits as a result of compression or a steal phenomenon, while the other 50% will present with hemorrhage. The vast majority of AVMs occur in the supratentorial compartment (typically in a lobar region), while only 10% occur in the infratentorial region.

The cerebral veins run in the pial layer while the large collecting veins run in the subarachnoid layer. They eventually traverse the subdural space and open into the cranial venous sinuses. The venous drainage system of the brain is primarily made up of the venous sinuses located between the dura mater and the cranial periosteum. The walls of the venous sinuses lack both valves and muscle. Although the brain is insensitive to pain, the cerebral dura mater demonstrates nociceptive responsiveness, particularly around the venous sinuses.

There are other sinuses within the venous drainage system that may be of importance to the anesthesiologist, including the superior sagittal sinus which, because of its relatively superficial midline location, is particularly vulnerable to damage during surgical correction of craniosynostosis or during a morcellation craniectomy. The superior sagittal sinus ends by becoming continuous with the right transverse sinus 60% of the time, while in the remaining 40% it becomes continuous with the left. The transverse sinus courses laterally to the sigmoid sinus superior to the tentorium cerebelli. The S-shaped sigmoid sinus (hence its name) is located within the posterior cranial fossa and eventually enters the venous enlargements known as the internal jugular venous bulbs. Most of the venous drainage system empties into the sigmoid sinuses and subsequently into the internal jugular vein, excluding the inferior petrosal sinuses, which enter the internal jugular veins directly. The sigmoid sinus is separated anteriorly from the mastoid antrum and mastoid air cells by only a thin plate of bone. The occipital sinus, which lies along the foramen magnum, ends in the confluence of sinuses. The cavernous sinus, which surrounds the sella turcica, joins the superior petrosal sinuses draining into the transverse sinus.

# Spinal cord vascular anatomy

The arterial supply of the spinal cord primarily arises from a single anterior spinal artery and two posterior spinal arteries, both originating from the vertebral artery. Supplemental blood flow is also received from radicular arteries originating from spinal branches of the ascending cervical, deep cervical, intercostal, lumbar and sacral arteries. The anterior spinal artery supplies the ventromedial aspect of the spinal cord that includes the corticospinal tracts and motor neurons. The two posterior spinal arteries, forming a plexus-like network on the cord surface, supply the dorsal and lateral aspects of the spinal cord, which includes the sensory tracts responsible for such sensations as proprioception and light touch [59].

The anterior spinal artery courses ventrally on the spinal cord to supply the white matter tracts and penetrates the cord parenchyma where it divides in the gray matter. However, the anterior spinal artery is not functionally continuous along the length of the spinal cord, so frequently one of the anterior radicular branches which arises from the aorta, called the arteria radicularis magna (great radicular artery of Adamkiewicz) which has a variable origin and is most commonly located between T9 and L5, on the left side, is responsible for supplying blood to as much as the lower two-thirds of the spinal cord. The ventral spinal cord is quite dependent on collateral flow through radicular arteries as there is essentially no collateral blood flow between the anterior and posterior circulations (Fig. 7.8). Only 6-8 of the 62 radicular vessels present during intrauterine development persist into adulthood and up to 45% of the general population have less than five. Generally, most individuals possess 1-2 cervical, 2-3 thoracic, and 1-2 lumbar radicular arteries. This results in a spinal cord that is particularly susceptible to ischemia at the upper thoracic and lumbar areas, especially during aortic or spinal surgery and following trauma.

The venous return of the spinal cord consists of two median longitudinal veins, two anterolateral longitudinal veins, and two posterolateral longitudinal veins, which drain into the vertebral venous plexus [60]. The venous drainage consists of an internal and external plexus, which communicate with each other as well as with the segmental systemic veins and the portal system. The internal plexus, consisting of thin-walled, valveless veins, connects to a vein from the spinal cord and basivertebral vein at each spinal segment and communicates through the foramen magnum with the occipital and basilar sinuses. The internal plexus empties into the intervertebral veins that pass through the intervertebral and sacral foramina to the vertebral, intercostal, lumbar and lateral sacral veins. The external plexus is formed by joined veins that exit from each vertebral body to form the anterior

**Figure 7.8** Spinal cord blood supply. (1) Posterior spinal arteries. (2) Anterior spinal artery. (3) Anterior radicular artery. (4) Sulcal branch arteries. (5) Pial arterial plexus.

vertebral plexus. The posterior vertebral plexus is formed by the veins that pass through the ligamentum flavum.

# **Cerebral vascular physiology**

Normal adult cerebral blood flow is considered to be 50-75 mL/100 g/min, an average of diverse values that have been collected over decades following the groundbreaking work of Kety and Schmidt [61-64]. Wide variability between subjects in these reports is not due to imprecision of the methods, but because cerebral blood flow itself is variable and substrate delivery is tightly matched to the cerebral metabolic rate of oxygen consumption. The adaptation of the technique for children 3–10 years old showed that the preteen child has a cerebral blood flow nearly twice that of adults [65]. Subsequent measurements in the healthy infant and preterm infant without respiratory distress syndrome (RDS) showed that, at birth, cerebral blood flow is roughly one-third of adult values, and in many infants appeared to hover near the ischemic threshold of 20 mL/100 g/min [66–69]. The normal developmental changes in cerebral blood flow across age are depicted in Figure 7.9.

The cerebral blood flow developmental pattern recapitulates the trend of cellular growth, synaptogenesis, and myelination that occur in the first years of life. When global cerebral metabolism was quantified as a function of age, the same trends persist: infants have rates of cer-

**Figure 7.9** Developmental changes in cerebral blood flow. At birth, blood flow to the brain is low compared with adult levels of cerebral blood flow. During the first years of life, blood flow rates increase sharply to a peak at 4 years of age and then taper off during adolescence to adult values.

**Figure 7.10** Cerebral metabolism, quantified by the local cerebral metabolic rate of glucose ( $LCMR_{glc}$ ) utilization, is low at birth, increases in the first years of life and tapers during adolescence. This pattern recapitulates and explains the developmental pattern of cerebral blood flow changes.

ebral metabolism that are 30% lower than adults, and between birth and 4 years of age, cerebral metabolism increases to exceed adult rates by twofold [70,71] (Fig. 7.10).

The brain lacks appreciable glycogen stores and is intolerant to the pH changes associated with anaerobic metabolism. The brain is therefore unique among organs in its requirement of a constant supply of oxygen and glucose. Paradoxically, the brain is also injured by excessive cerebral blood flow due to the elastance of the intracranial compartment. Several layers of servomechanisms contribute to the homeostasis of cerebral metabolic demand and substrate delivery. These mechanisms operate at different frequencies, with distinct precision, and with varying regional specificity in the brain. This chapter presents four separate mechanisms of cerebral blood flow control. The first three are presented sequentially as increasingly precise mechanisms working in concert to fine-tune cerebral blood flow in a dynamic pressure flow system: the systemic vasoconstrictive response, pressure autoregulation and neurovascular coupling. Next, the cerebral vascular responses to homeostatic perturbations of arterial carbon dioxide, oxygen and glucose concentration are discussed. Developmental considerations of the mechanisms are considered independently.

Neurovascular regulation as a generic principle requires complete vascularization and development of muscular arterioles capable of reactivity. The term brain has a fully functional vascularity, but cerebral vasculature is both anatomically incomplete and underdeveloped in infants born at the current limits of viability. As mentioned above, persistence of the germinal matrix is accompanied by a fragile periventricular vascular overgrowth in the premature infant that is prone to hemorrhage. Penetrating arterial growth from the pial surface into deep white matter structures is also incomplete in the premature neonate. The adult brain has a redundant arterial network in the white matter circulation where the premature infant has poorly anastamosed white matter circulation that is vulnerable to ischemic injury [72,73]. According to studies in fetal sheep, vasoreactivity to arterial pressure changes occurs at 2/3 of gestation, which would correspond to the current limits of viability. However, the limits of reactivity are much closer to resting blood pressure than in the term animal [74]. Development of the muscularis layer of arteries and arterioles involved in vasoreactivity occurs during the third trimester first in larger, pial vessels, and then in progressively smaller arterioles. This anatomy would predict that vasoreactivity would be coarse in the extremely preterm infant and more fine-tuned with increasing gestational age. Apparently normal preterm infants have been shown to spend significant portions of time with pressure-passive circulation, a state seen in adults with shock or intracranial pathology [75].

# Systemic vasoconstrictive response

The most blunt of the mechanisms that preserve cerebral blood flow is the systemic vasoconstrictive response, which renders cerebral blood flow independent of cardiac output. Decline in cardiac output results in increased sympathetic tone, activation of the renin-angiotensinaldosterone axis, and increased vasopressin activity. All three of these axes exert a vasoconstrictive response that is differentially asserted between the systemic and cerebral circulations. The net effect is to preserve cerebral perfusion at the expense of systemic perfusion [76–79]. For example, normotensive shock can result in renal failure and necrotizing enterocolitis without neurological sequelae. When systemic vasoconstrictive responses are functional, the brain takes a variable percentage of total cardiac output to maintain cerebral blood flow [80–82]. Even during cardiopulmonary bypass, cerebral blood flow is preserved as long as perfusion pressure is adequate, regardless of the flow rates [83].

Because of the systemic vasoconstrictive response, it is said that the brain is not dependent on cardiac output, and it is also said that what is good for the brain is not good for the splanchnic organs. The antagonistic relationship between cerebral and systemic perfusion is seen in profoundly septic patients who lose digits and renal function after pressor therapy titrated to maintain cerebral perfusion. This balance is also relevant in the care of children with cardiac disease, as afterload reduction is a mainstay of therapy and increases survival in the setting of congestive heart failure. In this setting, the clinician must balance reduction of systemic vascular resistance against the need for adequate cerebral perfusion pressure. Even adult patients (for whom the limits of cerebral perfusion pressure are more defined) suffer symptoms of cerebral hypoperfusion when aggressively treated for cardiomyopathy. The pediatric patient has the same risk, but is less likely to report presyncopal symptoms. Infants on cardiopulmonary bypass are frequently maintained at critically low perfusion pressures with vasodilator therapy. This strategy is associated with improved renal and splanchnic perfusion and survival, but also with predictably decreased cerebral perfusion [84-86]. The impact of this therapy on the high incidence of neurological injury in this population has not been elucidated (Fig. 7.11).

The sympathetic nervous system develops early in gestation, and the parasympathetic nervous system develops and increases parasympathetic tone near term [87]. Preterm vasculature has less reserve in the systemic vasoconstrictive response, and consequently has less ability to maintain perfusion pressure to the brain. The preterm heart also has limited ability to modulate output, operating near maximal contractility and at elevated heart rates. Hence, the preterm infant is vulnerable at birth due to lack of the first homeostatic cerebral blood flow mechanism: maintenance of perfusion pressure. This is manifest as hypotension, especially in the first hours and days of life, when transition from the low-resistance placental circulation places afterload on the underdeveloped myocardium [88].

# **Pressure autoregulation**

The next layer of cerebrovascular control is commonly referred to as pressure autoregulation – the maintenance of constant cerebral blood flow across a range of cerebral perfusion pressure. Pressure autoregulation, like the systemic vasoconstrictive response, allows the brain to steal and shunt blood flow to and from the systemic vasculature. Pressure autoregulation is a function of reactivity of

**Figure 7.11** Cerebrovascular pressure autoregulation was quantified in children during cardiac surgery by correlation between arterial blood pressure and cerebral oximetry (COx), which indicates pathological pressure passivity with increasingly positive values. (A) When normotensive, subjects showed intact pressure autoregulation that was increasingly disturbed with progressive hypotension. (B) The majority of time during the recordings was from normotensive periods with intact autoregulation. (C) Hypotensive recordings with impaired autoregulation occurred most frequently during cardiopulmonary bypass.

the cerebral vasculature to changes in arterial pressure, in contrast to the systemic vasoconstrictive response, which is responsive to changes in both arterial pressure and cardiac output. Response times for pressure autoregulation are much faster than systemic vascular responses, occurring within 4–10 sec of a change in arterial blood pressure in an adult study, and within 2sec of a change in blood pressure in a study of neonates [89,90]. Pressure autoregulation allows changes in cerebral blood flow at the pulse and respiratory frequencies, but acts as a highpass filter, preventing fluctuations of cerebral blood flow that persist longer than 10–20 sec.

Autoregulatory activity can be seen in physiological recordings of intracranial pressure, blood volume, blood flow, blood flow velocity, and oxygenation during slow changes of arterial blood pressure lasting between 20 and 300 sec. In the normal autoregulating brain, blood volume and intracranial pressure are inversely related to blood pressure at these low frequencies. This inverse relationship is caused by reactive dilation and constriction of the resistance arterioles mediating autoregulation. The result is constant cerebral blood flow, flow velocity, and oxygenation during slow blood pressure changes. At blood pressures below the lower limit of autoregulation, unresponsive cerebral vasculature dilates and constricts passively to changes in arterial blood pressure. In this setting, cerebral blood volume, intracranial pressure, cerebral blood flow, flow velocity and oxygenation are all positively correlated with slow changes in arterial blood pressure. These distinctions between intact and perturbed autoregulation form the basis of physiological monitoring of the state of autoregulation [91-94] (Fig. 7.12).

Pressure autoregulation response times and limits of operation are variable and influenced by CO<sub>2</sub> tension. The lower limit of autoregulation, originally described at 50 mmHg in adults by Lassen, is now understood to have a wide interpatient and situational variability [64,95] (Fig. 7.13).

The lower limit of autoregulation has not been well defined for pediatric populations, but infants on cardiopulmonary bypass have shown a lower limit between a mean arterial blood pressure of 30 and 40 mmHg [84,86]. Preterm infants have shown intact pressure autoregulation at surprisingly low pressures, and many have a lower limit somewhere between 25 and 30 mmHg mean arterial pressure [96,97]. Absolute safe arterial blood pressure recommendations cannot be made for specific ages because the data do not exist. Such recommendations would likely not be applicable to critically ill populations, as clinical factors related to critical illness may impair autoregulatory function and shift the limits of intact pressure autoregulation. For instance, newborn piglets without intracranial pathology have an average lower limit of autoregulation at a cerebral perfusion pressure of 30mmHg, and piglets with hydrocephalus have an average lower limit of autoregulation at 50mmHg [98]. Even monitoring intracranial pressure would not account for the shift in autoregulation function seen in that study. Without information about the state of autoregulation, blood pressure and cerebral perfusion pressure

**Figure 7.12** Pressure autoregulation and vascular reactivity can be quantified and monitored. Recordings from a normotensive piglet (A,B) of arterial blood pressure (ABP), intracranial pressure (ICP), cerebral blood volume (CBV) and cerebral blood flow (CBF) show intact autoregulation. Slow waves of ABP cause reactive dilation and constriction of resistance arterioles, which is reflected in both CBV and ICP as slow waves that are inverted when compared with the ABP tracing. CBF is constant in this state of intact autoregulation. The pressure reactivity index (PRx) quantifies the inverted ICP–ABP relationship with a negative Pearson's coefficient of correlation, indicating healthy vascular reactivity. In a hypotensive piglet (C,D), ABP, ICP, and CBV are all in phase at the slow-wave frequency, indicating pathological pressure passivity. CBF is fluctuant in this state of impaired autoregulation, and the PRx is positive.

**Figure 7.13** The lower limit of autoregulation (LLA) is not necessarily 50 mmHg. Individual determinations of the LLA were made for pediatric and adult populations during cardiac surgery. The blood pressure threshold associated with pressure-passive cerebral oximetry was determined for each subject in the study. Pediatric patients, in general, tolerated lower blood pressures than adult patients, and intersubject variability was high, suggesting that a single blood pressure threshold is not adequate for hemodynamic management guidelines [86].

**Figure 7.14** More than half of cerebral metabolism (CMR) is utilized for the maintenance of voltage gradients discharged during neuronal activity. EEG silence, induced with barbiturate administration, ablates this metabolic activity and results in a concomitant reduction of cerebral blood flow (CBF) as flow–metabolism coupling is maintained.

management is still crudely applied to the protection of the pediatric brain.

Impairment of pressure autoregulation is a state of vulnerability to secondary injury of the brain from hypoperfusion and hyperemia. Patients are more likely to survive traumatic brain injury with intact pressure reactivity [99]. This finding has been verified in pediatric patients, and pressure autoregulation has been shown to be a function of blood pressure management [100,101].

# **Neurovascular coupling**

In 1890, 54 years before the Kety–Schmidt technique was first applied to measure cerebral blood flow, a relationship between neuronal activity and cerebral blood flow was observed.

We conclude, then, that the chemical products of cerebral metabolism contained in the lymph which bathes the walls of the arterioles of the brain can cause variations of the calibre of the cerebral vessels: that in this re-action the brain possesses an intrinsic mechanism by which its vascular supply can be varied locally in correspondence with local variations of functional activity. Roy and Sherrington, 1890 [102]

The method employed by Roy and Sherrington to show activity flow coupling in the brain was a direct measurement of a regional brain volume change brought about by electrical stimulation of exposed sensory nerves in dogs. Since then, with the advent of sensitive regional blood flow measurement techniques, neurovascular interactions have been a major focus of research. The model currently used to explain activity-dependent flow is a neurovascular unit in which an astrocyte anatomically bridges a collection of synapses and penetrating arterioles [103]. From these studies, we have learned that neurovascular coupling is a fast response, affecting vascular diameter change within 1 second of neuronal activation, and it is spatially specific, affecting only flow in the immediate region of neuronal activation. Neurovascular coupling is a finer control of cerebral blood flow when compared to the relatively slow and global pressure autoregulation mechanism.

Metabolic regulation of cerebral blood flow can cause large changes in cerebral blood volume, as seen with the induction of barbiturate coma for treatment of elevated intracranial pressure. Cerebral oxygen consumption and cerebral blood flow decrease concomitantly with increasing doses of barbiturate. At doses sufficient to produce EEG silence, cerebral blood flow and volume are half of awake values. Further increase in barbiturate dosing doses not further reduce cerebral blood flow (Fig. 7.14) [104].

Similar effects are seen with propofol administration to burst suppression [105]. This technique is helpful for reduction of brain volume to improve the surgical field, and to decrease intracranial pressure in patients with acute intracranial mass effect. When temperature reduction is used to suppress brain metabolism, the plateau at EEG silence is not observed, and reductions in temperature continue to reduce both cerebral blood flow and volume because of slowing of cellular metabolism not related to the discharge and maintenance of membrane voltage potentials. The moderately hypothermic brain has a cerebral blood flow that is half that of the normothermic brain, and deep hypothermia yields a cerebral blood flow that would be below the critical threshold for ischemia in a normothermic brain [106–108].

Both hypothermia and electrical suppression therapies maintain and utilize the coupling of metabolism and cerebral blood flow. When hypocarbia is used to reduce cerebral blood flow, however, cerebral blood flow is reduced below metabolic demand. Uncoupling metabolism and cerebral blood flow creates an ischemic vulnerability, and patients with head trauma have worse outcomes when prophylactic hypocarbia is applied [109].

# Flow response to homeostatic derangements

The three mechanisms of cerebral blood flow control outlined above are flow and pressure control mechanisms, which are over-ridden during states of non-physiological chemical perturbation. Examples, which have been well characterized, are disturbances of arterial carbon dioxide, oxygen and glucose. It is logical that the brain would have fail-safe vascular compensations during states of inadequate substrate delivery, even when perfusion pressure is adequate.

# Cerebrovascular response to carbon dioxide

Acute decreases in arterial carbon dioxide tension cause vasoconstriction of the cerebral vasculature while acute increases in arterial carbon dioxide tension cause cerebral vasodilation. The carbon dioxide response of the cerebral vasculature is most active across the physiological range of carbon dioxide and is correlated with changes in cerebrospinal fluid pH. Neuronal function is adversely affected by low pH in the cerebrospinal fluid, and the blood–brain barrier is impermeable to hydrogen ions. However, carbon dioxide diffuses freely into the cerebrospinal fluid.

Cerebrospinal fluid pH is tightly regulated by a combination of two mechanisms. First, there is robust metabolic buffering by rapid spinal fluid turnover with high carbonic anhydrase activity in the ependymal cells of the choroid plexus. Second, the coupling of cerebral blood flow to arterial carbon dioxide tension modulates the removal of carbon dioxide from the cerebral spinal fluid. The time course of cerebral blood flow responses to changes in carbon dioxide is partially explained by spinal fluid buffering. The initial vasoreactive response to a change in arterial carbon dioxide is mediated within seconds and reaches steady state within 10 min. This is followed by a gradual return toward baseline cerebrov-ascular resistance over 3–6h, consistent with the time course of pH regulation [110,111]. Persistent hypercapnia results in late hyperemia, not explained by this model, that does not return to normal after normalization of serum carbon dioxide.

The use of arterial carbon dioxide as a drug to effect change in the cerebral blood flow is a common practice in pediatric anesthesia. Decreasing cerebral blood volume by hyperventilation facilitates craniotomy in the presence of elevated intracranial pressure. The use of hyperventilation to manage intracranial volume is done at the expense of cerebral blood flow, and disrupts normal metabolic coupling to cerebral blood flow. Ischemic injury occurs in pediatric patients with traumatic brain injury when hyperventilation is used prophylactically to manage intracranial pressure and that practice is contraindicated by the Brain Trauma Foundation except for transient use during surgery or to prevent impending herniation.

Conversely, hypercarbia is often employed in the management of the patient who has a single ventricle and a large left-to-right shunt. In this setting, serum hypercarbia and acidosis increase pulmonary vascular resistance, but hypercarbia and acidosis in the cerebrospinal fluid cause decreased cerebral vascular resistance. The combination effect is to mitigate pulmonary overcirculation and enhance cerebral oxygen delivery.

When arterial carbon dioxide modulation is used as a therapy to change cerebral blood flow, the effect is mediated by changes in spinal fluid pH. Because of the rapid CSF turnover and high range of responsiveness of carbonic anhydrase during CSF production, the duration of a pH change in the CSF is blunted after 3-6h. Because serum and spinal fluid buffers are separated by the blood-brain barrier, the brain pH returns to normal even if the serum pH remains abnormal. Buffering of the spinal fluid limits the duration of effectiveness of carbon dioxidemodulating therapies. Furthermore, caution should be exerted when normalizing the serum pH of a patient after prolonged respiratory acidosis or alkalosis. For instance, low serum pH and high serum carbon dioxide tensions at the time of initiating rescue cardiopulmonary bypass are associated with stroke and hemorrhage [112–114].

## Cerebrovascular response to oxygen delivery

Arterial oxygen tensions between 60 mmHg and 300 mmHg do not appreciably change cerebrovascular tone. However, when oxygen delivery is impaired by arterial hypoxia or anemia, cerebral vascular resistance is decreased and cerebral blood flow increases [115–117]. The response of the cerebral vasculature is in contrast to

the carbon dioxide response, which is most active in the normal physiological range of arterial carbon dioxide tension. There is no vascular response to fluctuations of arterial oxygen delivery within the physiological range, and it is only when oxygen delivery reaches a critical threshold that the autoregulatory mechanisms are disrupted by global hypoxic vasodilation.

# Cerebrovascular response to glucose delivery

Although adult brain metabolism is 7.5 times that of the average tissue metabolism, the brain has very little stored glycogen, only about 2 minutes' worth in neurons. The lack of a local glucose buffer makes the brain dependent on a constant capillary supply. Insulin is required for glucose transport from the serum to the intracellular space in most cells, but glucose diffuses readily into neurons even in the absence of insulin. Glucose deprivation in the adult brain leads to vasodilation only after unconsciousness and EEG changes have occurred, but in the newborn brain the vasodilatory response has a higher threshold, with vasodilatory changes occurring at serum glucose levels of 30 mg/dL, without loss of consciousness or EEG changes [118–120].

# Electroencephalogram

Electroencephalogram (EEG) monitoring has been used perioperatively to identify abnormalities and potential periods of cerebral injury or malfunction. When appropriately applied, the EEG provides a continuous recording of electrical activity between reference electrodes placed at specific positions on the scalp. This electrical activity is thought to originate from the postsynaptic potentials of the dendrites of cortical neurons. The EEG waveforms are classically divided according to frequency as  $\delta$  (1–3/sec),  $\theta$  (4–7/sec),  $\alpha$  (8–12/sec) and  $\beta$  (13–20/sec) (Fig. 7.15). These waveforms are altered by many factors including age, state of awareness/alertness, tasks (like eye opening), medications, and various disease states. In particular, sleep can manifest in unique alterations, like sharp waves (K complexes) and sleep spindles (regular 12-14/sec) confined to the central electrodes. Seizure or epileptiform activity is characterized by combinations and locations of spike and slow-wave activity and may interfere with processed EEG validity. Therefore, adequate interpretation of continuous EEG tests requires good lead contact and continuous analysis by a trained technician/clinician.

Because of these limitations, comprehensive and continuous EEG monitoring has only had limited usage in the intensive care unit (ICU) and operating room (OR) despite results demonstrating potential for clinical benefit

**Figure 7.15** The electroencephalographic (EEG) waveforms are classically divided according to frequency as  $\delta$  (1–3/sec),  $\theta$  (4–7/sec),  $\alpha$  (8–12/sec) and  $\beta$  (13–20/sec). Notice that  $\delta$  waves are also characterized by a higher amplitude (>75  $\mu$ V), while  $\beta$  waves have a very low amplitude (<10  $\mu$ V). These waves are interpreted based on the clinical state of the patient (i.e. level of arousal or seizure activity). The propensity and distribution of these various waveforms change throughout life and during different mental activities. For example, sleeping adult subjects monitored with EEG have increased  $\delta$  wave activity while adult subjects who are awake and thinking have more  $\alpha$  and  $\beta$  wave activity.

and management. For instance, EEG has been used during cardiopulmonary bypass to titrate cooling strategies, detect intraoperative events, and monitor for seizures postoperatively. The EEG is affected by maturation of the brain and by a host of environmental factors, such as anesthetic agents, pain, cerebral metabolism, and temperature. Preoperative EEG monitoring has been used in premature infants to detect seizure and ischemic events. These studies have utilized both comprehensive as well as processed EEG [121].

In most patients, EEG is isoelectric during cardiopulmonary bypass (CPB) [122]. With deep hypothermic cardiac arrest, waiting to achieve an isoelectric EEG during cooling before initiating circulatory arrest is potentially neuroprotective [123]. There is much interpatient variability in the degree of hypothermia required to induce electrocerebral silence. Temperatures at which electrocerebral silence on EEG occurs are lower than when evoked potentials disappear, making EEG a more reliable method of neuromonitoring during cooling [124].

Electroencephalogram activity resumes upon cerebral reperfusion and rewarming. The temperature at which continuous EEG activity returns is predictive of postoperative neurological dysfunction as this appears to be related to intraoperative brain injury. In adult studies, the risk of postoperative confusion or stroke significantly increases with every degree higher at which continuous EEG activity resumes [125].

In addition, perioperative EEG monitoring detects seizures that clinically would be missed due to pharmacological neuromuscular blockade and sedation, including subclinical seizure activity [126]. Seizures may occur secondary to cerebral injury and worsen pre-existing or ongoing neuronal damage. Clancy et al performed EEG monitoring on 183 infants after cardiac surgery and identified that 11% of the patients had EEG-detected seizure activity postoperatively, though there were no clinically apparent seizures [126]. Most recently, postoperative, diffuse EEG slowing has been reported in children during

**Figure 7.16** The standardized placement of scalp electrodes for a classic EEG recording has become common since the adoption of the 10/20 international system. (A) In the sagittal view, the "10/20" orientation of the electrodes can be related to the relative percentages of distance between the nasion-inion and other fixed points. These points are marked as the frontal pole (Fp), central (C), parietal (P), occipital (O), and temporal (T). The midline electrodes are marked with a subscript *z*, which stands for zero. (B) In the coronal view, subscripted odd numbers are used to indicate positions over the left hemisphere and even numbers over the right.

the first 48h following cardiac surgery. However, EEG slowing was not associated with neurological deficits or MRI changes [127] (Fig. 7.16).

# Processed EEG monitoring

Processed EEG monitoring was pioneered in clinical anesthesia practice by Maynard and Prior. Multiple studies described the use of comprehensive and processed EEG signals to help in the identification and management of patients at risk for adverse perioperative events. Prior and Maynard divided the clinical applications of such neurophysiological monitoring into three categories: (1) where it had been shown conclusively to reduce the risk of iatrogenic harm to an at-risk patient during elective procedures; (2) where it had provided additional useful information not obtainable by other means; and (3) where monitoring could have been of potential value but its advantages in terms of reduced morbidity or mortality remained unproven [128,129]. However, the use of a processed EEG monitor that eliminates the need for a technologist/neurologist interpretation is appealing to perioperative clinicians.

These studies and methods represent fundamentally the current development of processed EEG monitoring devices used today in perioperative care of infants and children. A recent publication by Davidson provides an excellent review of this monitoring principle in children [130]. For the purposes of this text, we will focus on the available techniques/technologies in current clinical practice.

Amplitude-integrated EEG (aEEG) uses the P3-P4 positions and ground Fz to monitor the vulnerable watershed region in neonates. The signal is amplified and passed through an asymmetrical band-pass filter that strongly attenuates activity below 2Hz and above 15Hz in order to minimize artifacts from such sources as sweating, muscle activity and electrical interference. Additional processing includes semi-logarithmic amplitude compression, rectification and time compression. aEEG recordings with a cerebral function monitor, such as the "BraiNZ" monitor (Natus Medical Incorporated, San Carlos, CA, USA), obtained continuously from two biparietal electrodes, have also been shown to be useful in the early prediction of the severity of brain injury. Of 35 infants with a moderately abnormal or suppressed tracing and/or seizures, 27 died or survived with neurological abnormalities on follow-up at 18-24 months. Of 21 babies with normal amplitude, 19 were normal on follow-up [131]. One of the challenges of the aEEG is training of the bedside clinician to recognize and interpret the background amplitudes and to correlate the pattern with the clinical status of the patient [128].

Continuous comprehensive EEG can be technically difficult to use and interpret in the operating room. However, limited channel EEG-based technologies with automated interpretation have correlated electrical brainwave activity with depth of anesthesia and awareness in adults. Commercially available devices are the Bispectral Index® (BIS) monitor (ASPECT Medical Technologies, Norwood, MA, USA) and most recently the SEDLine<sup>™</sup> monitor (SEDLine Inc., Irvine, CA, USA). These monitors use algorithm-based analysis of multiple EEG characteristics and integrate these into a single dimensionless number. Unlike routine EEG, these monitors utilize placement of a single sensor containing multiple electrodes positioned easily on the forehead and temple in a specific pattern. The BIS utilizes a unilateral sensor array, while the SEDLine utilizes a bilateral sensor. Glass et al demonstrated that BIS recorded from several different electrode arrangements (or montages) provided similar results [132]. They used a frontal (Fp1 and Fp2) to CZ electrode montages, as well as an alternative placement (FPz–At) that approximates the BIS sensor electrode positions. At this time, only the BIS has an approved pediatric probe.

The SEDLine uses a bilateral four-channel frontal array (FP1, FP2 and F7, F8) to generate the Patient State Index or PSI.

Although these monitors have US FDA approval to assess anesthetic depth, there have been multiple reports of additional applications of these monitors (i.e. burst suppression, sedation monitoring) throughout the perioperative period [130,133,134]. The PSI and BIS indices both range from 0 (isoelectric EEG or electrocerebral silence) to 100 (awake) although studies have demonstrated differences in the actual interpretation of these scales in relation to depth of anesthesia. For instance, there are multiple studies correlating increased BIS values (>80) with awareness and decreased BIS values with depth of anesthesia and hypothermia during bypass [135] while similar studies evaluating the range of PSI values from 25 to 50 have been demonstrated to provide protection from awareness while avoiding issues of delayed emergence (PSI <25) [136,137].

There are limited studies to date evaluating the SEDLine in children. However, recent studies have evaluated the utility of the BIS monitor in children younger than 2 years of age and demonstrated good correlation with prior adult studies in predicting depth of anesthesia, despite the BIS algorithm being based on adult subjects [138].

There are many other processed EEG monitors available with similar functionality but differing lead array placement and signal analysis. The Cerebral State Monitor<sup>™</sup> (Danmeter A/S, Odense, Denmark) is a handheld wireless device that also uses a proprietary algorithm and a 0–100 scale, with 40–60 indicating an adequate depth of hypnosis. The Cerebral State Index (CSI) that is calculated by the device is derived from the time and frequency domain analysis, which inputs into a fuzzy logic inference system that calculates the index. In a comparative study, both the BIS and the CSI had a predictive probability statistic for depth of anesthesia of 0.87, which demonstrates good performance. The CSI performed better for deeper levels of anesthesia than the BIS, which was better at lighter levels [139].

The Narcotrend<sup>TM</sup> monitor (MonitorTechnik, Bad Bramstedt, Germany) is another monitor that processes raw EEG signals using one-channel or two-channel recordings from different electrode positions. Early models graded the depth of hypnosis into five stages from A (awake) to F (very deep level of anesthesia). The latest Narcotrend software (version 4.0) now calculates the Narcotrend Index, another dimensionless 0–100 scale that is similar to those calculated by the monitors described above. When compared with BIS, the performance of the Narcotrend Index in terms of prediction probability of depth of sedation was slightly better than BIS (predictive probability statistic 0.88, as compared with 0.85) [140].

Additional approaches to brain monitoring in the ICU and OR include response entropy and state entropy [141]. The irregularity of the EEG signal can be quantified and, by using an algorithm that is in the public domain, quantified to reflect depth of sedation. This Entropy<sup>TM</sup> Monitor (GE Healthcare, Fairfield, CT, USA) utilizes the electromyography (EMG) signal, which may provide information useful for assessing whether a patient is responding to an external stimulus, for instance a painful stimulus. The combination of EEG and EMG is presented as the response entropy, and the lower frequency EEG signals alone are presented as the state entropy. The prediction probability values of the entropy indices for differentiating between consciousness and unconsciousness are high and comparable with those for BIS [142]. Noxious stimulation does increase the difference between response entropy and state entropy, but an increase in the difference does not always indicate inadequate analgesia [143].

# Evoked potential monitoring

Assessment of the integrity of the neural pathways, both ascending and descending, can be undertaken with a variety of evoked potential (EP) monitoring methods. An EP is an electrical response that follows stimulation of the CNS by a specific stimulus of the visual, auditory, sensory or motor system. The perioperative EP assessment tools and their application are summarized in Table 7.3.

# Perioperative electrophysiological monitoring

Germane to this chapter, the complex and sometimes dynamic interaction between patient-related factors and clinical management necessitates an understanding of the basic neurophysiology of these tests [144–153]. Like the EEG, state of arousal, presence of various anesthetic agents, metabolic derangements, and temperature can dramatically affect these monitoring modalities. For ascending (dorsal/posterior) pathway monitoring, a stimulus is applied peripherally and supracortical monitors detect the change in cortical electrical activity. This allows for assessment of amplitude, latency and decay. The experience of the team and availability of resources to perform continuous evoked potential monitoring limit its consistent utilization. Certainly with spine surgery, SSEPs have become a widely accepted practice standard.

For assessment of the descending (anterior) pathways, the cerebral cortex is stimulated and the resulting periphTable 7.3 Perioperative electrophysiological monitoring [144–153]

eral motor response is assessed. Motor evoked potentials or MEPs can be done in conjunction with SSEP monitoring to provide dual assessment of anterior and posterior spinal cord integrity. The use of intraoperative MEP is a growing practice in pediatric anesthesiology, but like other EP monitoring modalities, it is susceptible to alterations based on the neurodevelopment of the patient, along with other operative and anesthetic factors. In a retrospective study of children aged 2-12 undergoing surgery for idiopathic scoliosis, a strong correlation between MEP thresholds and age was demonstrated [147]. Although the exact mechanisms responsible for this finding are subject to debate, it agrees with the prior observations of Parano et al [154] who hypothesized that delayed conduction and decreased EP amplitudes were significantly diminished in the youngest children secondary to delayed neuronal maturational changes with age, specifically multifactorial issues of ongoing synaptogenesis, incomplete nerve integration, and decreased myelination. This dynamic difference makes empiric numbers less useful, and often forces clinicians to use each patient as their own baseline. In addition, the impact that various anesthetic agents have on these monitoring modalities is also highly variable and changes with both the age of the patient and agent used. Because of these issues, many centers favor intravenous anesthetic techniques to minimize or eliminate the use of inhalational agents [147,148].

# Conclusion

For safe and effective perioperative care of infants and children at risk of neurological injury, the pediatric anesthesiologist must have a working knowledge of the unique neurodevelopmental events and neurophysiological principles relevant to the pediatric patient. Our specialty has contributed to the growing body of knowledge that will reduce the toxicity of critical illness to the developing human brain. We can expect further refinement of anesthetic practices designed to protect normal neurodevelopmental processes. Neuromonitoring modalities will continue to adapt, and provide an increasingly complex real-time data set to the anesthesiologist caring for a critically ill child. When this information is combined with an understanding of neurodevelopmental principles, the physics of the intracranial compartment, and neurovascular physiology, we will more effectively choose care practices that yield improved outcomes for our patients.

# The liver

The embryological development of the liver, its subsequent transition at birth and maturation in infancy constitute a hugely complicated subject. Hypoglycemia, jaundice and impaired drug metabolism are common in the first weeks of life. Knowledge of the principles of hepatic development allows the anesthesiologist to understand the susceptibility of the liver to disease in infancy.

# **Embryology of the liver**

The liver and gastrointestinal tracts arise from modifications of the primitive gut (see embryology of the gastrointestinal tract, later in this chapter) [1,2]. The liver develops from a thickening of the endoderm on the ventral surface of the foregut. These endodermal cells proliferate to form the hepatic diverticulum, which gives rise to cords of hepatoblasts within the mesenchyme of the transverse septum. The hepatoblasts are undifferentiated cells which can become hepatocytes, bile canaliculi or hepatic ducts under the influence of Notch signaling; abnormalities of this process are associated with Alagille syndrome, described towards the end of this section. The hepatocytes divide rapidly and arrange themselves around vitelline veins to form hepatic sinusoids.

The transverse septum is an important area and develops at a junctional site in the embryo – internally between foregut and midgut, and externally where the endoderm of the yolk sac meets the ectoderm of the amnion. The mesenchyme of the transverse septum also gives rise to the stromal cells which provide the serous and fibrous tissues of the liver, such as the liver capsule and the falciform ligament. The various connective tissues and smooth muscle of the biliary tracts also form from this mesenchymal tissue.

**Figure 8.1** Development of the liver, gallbladder and pancreas and their duct systems from endodermal diverticula of the duodenum. (A) The liver bud sprouts during the 4th week and expands in the ventral (anterior) mesentery. (B) The cystic diverticulum and ventral pancreatic bud also grow into the ventral mesentery, whereas the dorsal pancreatic bud grows into the dorsal mesentery. (C) During the 5th week, the ventral pancreatic bud migrates around the posterior side (former right side) of the duodenum to fuse with the dorsal bud. (D) The main duct of the ventral bud ultimately becomes the major pancreatic duct, which drains the entire pancreas. Reproduced from Schoenwolf et al [1] with permission from Elsevier.

The gallbladder and cystic duct originate from a thickened portion of the ventral duodenum just below the hepatic diverticulum at around 4 weeks; this is known as the cystic diverticulum. As the connection between the hepatic diverticulum and foregut (duodenum) narrows, the hepatic ducts form. The cystic duct and hepatic ducts form the common bile duct which enters the duodenum, initially anteriorly, later from the left (see gut rotation). The growth of the liver and biliary tracts is rapid and by the 9th week the liver accounts for about 10% of the weight of the fetus (Fig. 8.1).

## Fetal hematopoiesis

Hematopoietic stem cells capable of producing erythrocytes, megakaryocytes and macrophages migrate from the yolk sac to the liver, where hematopoiesis begins [3]. There is a second influx of hematopoietic stem cells originating from mesoderm surrounding the dorsal aorta. These cells are later programmed to migrate to the bone marrow and other lymphatic tissue. The immature fetal erythrocytes are bigger than mature red cells and, like white cells and platelets, they increase in number throughout gestation.

# Development of the circulation in the fetal liver

The circulation in the fetal liver is complex and the reader is advised to refer to Chapter 5.

The arterial supply to the liver, like the rest of the foregut, originates from the vitelline arteries arising from the yolk sac [4]. A plexus of arteries between the vitelline vessels and the dorsal aorta coalesces to form three

distinct arteries, supplying the whole of the gut from the aorta as the yolk sac shrinks. The celiac artery supplies the foregut, the superior mesenteric artery supplies the midgut and the inferior mesenteric artery supplies the hindgut. The arterial supply to the liver and gallbladder is the common hepatic artery, which originates from the celiac artery.

Venous blood is received into the two horns of the sinus venosus from three bilaterally symmetrical venous systems: the vitelline veins return blood from the developing gut, the umbilical veins return oxygenated blood from the placenta and the cardinal veins return blood from the embryo.

The vitelline veins originate as a network of vessels in the yolk sac, which in time form the venous drainage of the primitive gut. A plexus of vessels arises between the paired vitelline veins in the septum transversum, and as the hepatic diverticulum expands in the transverse septum, hepatic cords arrange themselves around this venous plexus to form primitive hepatic sinusoids. Caudal to the liver, the vitelline veins form numerous anastomoses; the left vitelline vein receives blood from the splenic and superior mesenteric veins, and the distal right vitelline vein regresses. The anastomosis between the left and right vitelline veins becomes the distal part of the portal vein. The proximal part of the portal vein is formed from the proximal right vitelline vein. The proximal left vitelline vein disappears at the time when the left sinus horn regresses to form the coronary sinus, and a series of transverse anastomoses carry blood to the right vitelline vein. Cephalad to the liver, an enlarged right vitelline vein returns all of the blood to the heart, which in time will become the inferior vena cava.

The two umbilical veins receive blood from the chorionic villi of the placenta and thus deliver oxygenated blood, rich in nutrients, to the developing fetus. In the second month of development the right umbilical vein regresses; possibly abnormalities in this process can cause abdominal wall defects (see Chapter 21 for clinical management of abdominal wall defects). The remaining left umbilical vein carries oxygenated blood to the fetus, entering the ductus venosus and then, via the inferior vena cava, the right atrium. Early in the neonatal period, the umbilical vein atrophies since blood is no longer flowing through it, forming the ligamentum teres. The atrophic ductus venosus forms the ligamentum venosum. In the presence of portal hypertension these ligamentous remnants can recanalize.

# **Functional development**

The liver constitutes 10% of the weight of the fetus at 9 weeks' gestation, decreasing to 4% of the neonate and

around 2% of adult bodyweight. The fetal hepatocytes are smaller than the mature cells, lack many enzyme systems and are deficient in glycogen.

# Carbohydrate metabolism

Neonatal hypoglycemia is a common problem and highlights the crucial role that the liver plays in glucose metabolism. The fetus receives all its glucose from the mother, via the placenta; following birth, the newborn rapidly acquires the ability to maintain independent glucose homeostasis [5]. By the 9th week of gestation the fetal hepatocytes are able to synthesize glycogen. At term, stores of glycogen are high (40–60 mg/g of liver), providing some reserve for the neonate until milk production and digestion start. A healthy term baby can withstand a fast of 12 hours by the liver generating and releasing glucose by glycogenolysis [6]. Glycogenolysis is catalyzed by glycogen phosphorylase, the activity of which is promoted by glucagon and epinephrine. Following delivery, there is a rise in glucagon and a fall in insulin levels. Premature neonates lack the ability to effectively store and break down glycogen and so are at greater risk of hypoglycemia.

Following birth and before the establishment of effective feeding, glucose is in short supply and ketogenesis has yet to commence. The neonate depends on gluconeogenesis from lactate and pyruvate, which is thought to be stimulated by the high circulating levels of glucagon and catecholamines following delivery.

Gluconeogenesis is insignificant in the fetal liver [7], probably due to high insulin levels and low levels of the rate-limiting enzyme phosphoenolpyruvate carboxykinase, the activity of which rises rapidly following birth. Similarly, levels of hepatic galactokinase, the enzyme responsible for phosphorylation of galactose, increase near term. This allows the newborn to metabolize galactose in its diet. Interestingly, the utilization of glucose by the fetal liver is low, using amino acids and lactate for energy instead. Following birth, there is little glucose utilization by the liver of the neonate; instead, galactose is preferred for carbohydrate synthesis, and glucose is utilized preferentially by peripheral tissues. Glucose-6-phosphatase activity, needed to convert glucose-6-phosphate into glucose, is low in the fetal liver. Thus glucose production is low, promoting the storage of glycogen to the required high level. Levels of this enzyme also increase near term.

The transition of glucose metabolism from the fetus to the newborn is highly complex and the controls of the enzyme systems responsible for glucose metabolism are still a matter of research. Delivery and suckling also have a role in the initiation of glucocorticoid pathways and the decrease in insulin levels.

# Amino acid metabolism

The majority of protein catabolism occurs in the liver, producing amino acids which may be used for protein synthesis. Amino acids may also be deaminated by aminotransferases and used to produce glucose, ketones or fatty acids. Ammonia is produced as a product of deamination and is converted into urea.

Animal studies suggest that amino acids provide about 40% of the energy requirements of the fetus, with even essential amino acids utilized as fuel. *In utero*, the fetal liver has a high uptake of amino acids, which declines following delivery. The urea cycle enzymes are well established in the second trimester, and the fetal liver accounts for the majority of ammonia clearance. Accumulation of ammonia is toxic and contributes to the raised intracranial pressure and encephalopathy seen in acute liver failure.

Nearly all amino acids cross the placenta from mother to fetus by active transport, the exceptions being glutamate, serine and aspartate which are produced by the fetal liver. The enzyme systems necessary for the regulation of amino acids are expressed at birth, but the appearance of p-hydroxyphenyl pyruvate oxidase may be delayed. This enzyme is responsible for the breakdown of tyrosine, and may account for a transient tyrosinemia following delivery.

# Lipid metabolism

The oxidation of fatty acids provides a major source of energy for the developing fetus [8]. Fatty acids may be synthesized by the fetus, non-esterified fatty acids may diffuse from the placenta or, in the case of some long chain fatty acids, undergo active transport across the placenta to the fetus. Free fatty acids are stored in the liver and adipose tissue, but are not used by peripheral tissues.

Animal models suggest relatively low levels of acetyl coenzyme A carboxylase (responsible for fatty acid synthesis) in the fetal liver, as compared to adults. Ketones and glucose from the mother may act as precursors for fatty acid synthesis in the fetus.

Following birth, the accumulated fat in the fetal liver is mobilized for oxidation to produce energy as adenosine triphosphate (ATP), and for ketone body formation, which may be used peripherally in tissues. This ability to oxidize fatty acids matures rapidly in the first few days of life, in response to falling insulin and rising glucagon levels. The liver is the most important source of ketone bodies (acetoacetate, 3-hydroxybutyrate and acetone). Fat stores are particularly important for preterm infants, due to immature glucose metabolism.

Following birth, the newborn suckles and takes milk, which is relatively high in fat but low in carbohydrate compared to solid foods (see below). Long and medium chain fatty acids in the diet stimulate gluconeogenesis, by increasing the supply of gluconeogenic substrate for the liver. Weaning increases the amount of carbohydrate in the infant's diet, and the ability of the liver to produce fat is again increased.

# Drug metabolism

The liver's central role in the metabolism of substances absorbed by the gut means that it has many of the enzyme systems necessary to alter alien substances (xenobiotics), such as drugs. Liver immaturity may alter the ability to clear drugs, as well as rendering it susceptible to damage from them and their breakdown products. Infant drug metabolism is complex as it depends on liver mass (usually relatively greater than in adults), protein binding and blood flow, as well as enzymatic metabolism and clearance processes.

The metabolism of most drugs involves chemical processes to modify their structure, followed by conjugation to make them more polar (water soluble), so allowing excretion. These are termed phase 1 and phase 2 reactions. Phase 1 reactions are the result of electron transfers carried out by the cytochrome P450 enzymes – nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH-cytochrome c reductase. They cause oxidation by electron removal or sometimes reduction by electron addition. Phase 1 reactions also include hydrolysis of esters and amides, sulfation, dehalogenation, N-dealkylation and O-demethylation.

Cytochrome P450 (CYP) is a group of iron-containing membrane-bound enzymes found in endoplasmic reticulum and mitochondria. There are at least 57 human CYP genes producing enzymes which are classified according to the degree of amino acid homogeneity shown [9]. There are at least 18 families of CYP enzymes; they are named "CYP" plus the family number, followed by a letter, then a final number. Great variation is therefore possible between individuals, explaining some differences in drug handling.

Phase 2 reactions involve conjugation with a substrate to form a more polar and water-soluble conjugate, for example a glucuronide, sulfate or acetylated derivative. Glucuronidation involves the addition of an activated form of glucose (uridine diphosphate glucuronic acid, UDPGA) by the enzyme glucuronyl transferase. The glucuronide compounds so formed are readily excreted in urine or, in the case of larger compounds, in bile. Bilirubin is excreted in this way; however, glucuronyl transferase activity is low in the newborn, so a significant amount of hemolysis will overload the conjugating capacity of the enzyme and result in an unconjugated hyperbilirubinemia. Phenobarbital may be used to induce the enzyme.

The expression of CYP enzymes is an important factor in the development of drug metabolism in the fetus and newborn. CYP enzymes are active in the human liver early in intrauterine development; indeed, many systems are available for xenobiotic metabolism before 8 weeks' development. There is a gradual increase in activity throughout fetal development, and a major increase following birth.

To analyze the development of all the CYP enzymes is beyond the scope of this chapter, so we will attempt to highlight some examples of the CYP enzyme groups. The CYP 3A family serves as a good example of development; it is the most abundant of the CYP enzymes and is involved in the metabolism of many common drugs [10]. CYP 3A7 is the most abundant CYP enzyme in the fetus, is present during organogenesis and plays a role in steroid metabolism. Expression of this enzyme ceases at delivery. Conversely, CYP 3A4 is the most abundant member of the CYP 3A family following birth and is involved in the metabolism of over 70 drugs; its expression is low in the fetus but increases to 50% of adult levels by 1 year of life. CYP 2E1 is involved in the metabolism of alcohol and is responsible for the conversion of acetaminophen to the hepatotoxic metabolite N-acetyl-P-benzoquinone-imine. CYP 2E1 expression is low in the fetus, increasing to around 40% of adult levels at 1 year of age and is not fully expressed until 10 years.

The development of the phase 2 enzymes is less well understood; however, there are significant differences in gene expression between infancy and adulthood, as well as genetic polymorphism. The uridine glucuronyl transferase enzymes catalyze the glucuronidation of bilirubin, as well as agents such as morphine and acetaminophen. In the midterm fetus the glucuronidation of morphine is only 10–20% of adult levels. Following birth, morphine glucuronidation reaches mature levels at around 2–6 months, but this may be delayed until 2 years of age. Similar polymorphism has been identified for other glucuronyl transferase enzymes. Abnormalities of uridine glucuronyl transferase 1A (UGT1A) are responsible for Crigler–Najjar syndrome and Gilbert syndrome, which are described later in this chapter.

# Development of bile formation and secretion

The liver is responsible for the excretion of bilirubin, bile acids and xenobiotics with bile into the small intestine, for ultimate elimination in the feces. It plays an important role in nutrition, as excretion of bile acids into the intestinal lumen is involved in the absorption of long chain fatty acids and fat-soluble vitamins as well as a number of drugs and hormones. This is of particular importance in the nutrition and thus growth of infants with cholestasis.

The immaturity of bile synthesis and secretion is clinically apparent in the susceptibility of the sick neonate to develop cholestasis in response to sepsis, administration of parenteral nutrition (PN), as well as the phenomena of physiological jaundice and breast milk jaundice in the healthy baby. However, understanding of the development of bile formation and secretion in the fetus is limited.

The composition of bile in the newborn is different to that in the adult, with higher concentrations of hyocholic acid as well as some unusual bile acids. Soon after birth, the concentrations of the bile acids cholate and chenodeoxycholate increase rapidly. Bile secretion starts at 4 months' gestation and thereafter the biliary system always contains bile, which secreted into the gut gives meconium its distinctive color [11]. Bile secretion appears to be low in the neonate and increases throughout infancy. Similarly, the ability of the gallbladder to empty in response to a test feed occurs soon after birth, but is reduced in preterm neonates of 27–32 weeks' gestation.

Bile flow is driven by the secretion and enterohepatic circulation of bile acids. Bile acids absorbed from the small intestine are taken up from portal blood by the Nadependent bile salt importer proteins. They are rapidly transported across the hepatocyte cytoplasm, and then secreted into the bile canaliculi by the bile salt export pump (BSEP), against a steep concentration gradient. Mutation of the gene responsible for BSEP is responsible for progressive familial intrahepatic cholestasis 2 (PFIC 2); this and related conditions are described in the section concerned with metabolic causes of conjugated hyperbilirubinemia.

Conjugated bilirubin is secreted into bile by means of a separate transporter protein, MRP2, mutation of which leads to Dubin–Johnson syndrome. This autosomal recessive condition results in a mild conjugated hyperbilirubinemia with normal liver function tests. Dubin–Johnson syndrome is asymptomatic, and affected individuals have a normal lifespan (Fig. 8.2).

# Cholestasis

Cholestasis is classically regarded as due to an anatomical blockage or obstruction of part of the biliary tree. However, the various constituents of bile are secreted by different transporter proteins and thus deficiencies, or abnormalities, of these may cause cholestasis. The hepatocyte is the main cell responsible for the manufacture and secretion of bile acids and bile; thus the liver is the organ most likely to be damaged by bile acid retention, when bile flow is reduced. The intracellular accumulation of bile acids appears to be the most significant pathological consequence of cholestasis.

Obstruction of the biliary tree, as in biliary atresia, or impaired secretion by the hepatocyte (e.g. PFIC2) can lead to a high concentration of bile acids in the hepatocyte cytoplasm. Bile acids exert their deleterious effects by a number of mechanisms; they may act as detergents which alter membrane structure and function, or by altering

**Figure 8.2** Roles for critical hepatic transporters in the formation of bile and adaptation to cholestasis. On the left is a representation of the sinusoidal surface and on the right, a canalicular surface. Diseases associated with defects in specific canalicular transporter genes are noted in italics. Note that bile acids have several means of transport across the sinusoidal membrane, both import and export, whereas there is one canalicular bile acid transporter, BSEP. These transporters allow for fine-tuning of intracellular bile acid concentrations as a way of adapting to a variety of cholestatic conditions. The principal means for bile acid flux across the hepatocyte is shown by the dotted line. NTCP, Na+ /taurocholate co-transporting polypeptide; OATP, organic acid transporting polypeptide; OST, organic solute transporter; MRP, multidrug resistance-related protein; FIC1, familial intrahepatic cholestasis 1; BSEP, bile salt export pump; MDR, multidrug resistance protein; PFIC, progressive familial intrahepatic cholestasis. Official gene designations: *FIC1 (ATP8B1), BSEP (ABCB1), MDR3 (ABCB4), and MRP2 (ABCC2).* Reproduced from Karpen [12] with permission from Cambridge University Press.

cellular signaling pathways and gene expression. CYP 450 pathways are activated to detoxify the liver; Kupffer cells, stellate cells and myofibroblasts are also activated, potentially leading to fibrosis [12].

# **Neonatal jaundice**

The following section deals with jaundice in infancy; it is not intended to be an exhaustive list of differential diagnoses but rather an illustration of the pathophysiological mechanisms described previously. Some of the conditions are rare, and a few only become manifest later in childhood; however, the jaundiced baby is a problem commonly encountered by the pediatric anesthesiologist. Neonatal jaundice has a variety of causes which may require investigation, and of crucial importance is the diagnosis of treatable conditions, such as biliary atresia. The causes of neonatal jaundice described below are divided into unconjugated and conjugated hyperbilirubinemia.

# Unconjugated hyperbilirubinemia

The excretion of bilirubin, a breakdown product of heme, is one of the principal roles of the liver. Bilirubin is a toxic molecule, and diffusion of its free form into neural tissue, particularly the basal ganglia, can cause kernicterus in the premature neonate. As bilirubin is bound tightly to albumin, the usually low free levels may be increased by hypoalbuminemia or by drugs which displace bilirubin from its binding sites, e.g. sulfonamides and furosemide.

# Physiological jaundice

Transient neonatal jaundice occurs in around 50% of babies in the first week of life [13,14]. It is due to immaturity of glucuronyltransferase, leading to an unconjugated hyperbilirubinemia. Occasionally the jaundice may be significant, with a serum bilirubin over 12mg/dL, which may be associated with prematurity, bruising and breast feeding. Physiological jaundice peaks at day 3 of life and declines thereafter, but the hyperbilirubinemia may persist for as long as 14 days. Treatment is usually unnecessary as the jaundice is self-limiting; however, if it is slow to clear, phototherapy can be used, which is an effective treatment.

# Breast milk jaundice

Unconjugated hyperbilirubinemia associated with breast feeding is common. Jaundice tends to occur after day 4 of life, may overlap with physiological jaundice, and can sometimes be protracted. The etiology is still to be elucidated but hypotheses include enhanced enterohepatic recirculation of bilirubin due to free fatty acids in breast milk, and the action of  $\beta$ -glucuronidase causing deconjugation of bilirubin. The diagnosis is clinical and no treatment is usually required, other than reassurance and exclusion of more sinister causes of liver disease.

# Crigler-Najjar syndrome

Crigler–Najjar syndrome is an autosomal recessive condition resulting from deficiency of the enzyme bilirubin uridine diphosphate glucuronyltransferase (UDPGT). The syndrome is divided into two types: type 1 has no UDPGT present, and in type 2 levels of the enzyme are reduced. Consequently, type 1 is the more severe condition and presents in the newborn with rising unconjugated bilirubin levels, with the risk of kernicterus.

Management of type 1 Crigler–Najjar syndrome often involves phototherapy. Acute exacerbations may be precipitated by sepsis and require plasmapheresis or exchange transfusion. Liver transplantation is a longterm option to avoid neurological deterioration. Type 2 Crigler–Najjar syndrome follows a more benign course.

# **Gilbert syndrome**

Gilbert syndrome is a condition leading to mild unconjugated hyperbilirubinemia and results from a defect of the UDPGT gene. The affected individual, usually male, has mild jaundice worsened by intercurrent illness. Presentation is typically in teenage years, but heterozygotes for the genetic defect may present in the neonatal period. Treatment is unnecessary.

#### Conjugated hyperbilirubinemia

The identification of conjugated hyperbilirubinemia essentially allows the clinician to distinguish jaundice which is due to liver disease from the more common but generally more benign causes, which present with unconjugated hyperbilirubinemia.

The liver synthesizes all of the clotting factors except for the von Willebrand fraction of factor VIII, which is derived from vascular endothelium. Factors II, VII, IX and X require vitamin K for their synthesis, so their levels are liable to fall if there is any biliary obstruction, because the fat-soluble vitamin K is poorly absorbed from the gut, unless dietary fat is emulsified by bile salts. Vitamin K deficiency bleeding (VKDB) occurs in 1:10,000 babies. It may occur on the first day or in the first week of life (classic). In around half of cases it may occur after the first week, and is usually associated with breast feeding or liver disease. The risk of intracranial hemorrhage is high in this group. Vitamin K supplementation at birth is routine in Europe and North America.

# Acquired cholestasis

# Cholestasis associated with sepsis

Sepsis originating outside the liver is the most common cause of cholestasis in infants. It appears not to involve damage to hepatocytes but is rather an impairment of hepatocyte function, perhaps explaining the particular susceptibility of the immature liver to various insults. In animal models the administration of endotoxin lipopolysaccharide invariably leads to a sustained reduction in bile flow. The mechanism appears to be due to endotoxinmediated cytokine release from Kupffer cells, inducing signaling changes in the sinusoidal membranes of neighboring hepatocytes to reduce bile formation [15]. There are also endotoxin receptors on the membranes of hepatocytes, implying a direct action of endotoxin.

The liver also plays a central role in the acute-phase response to infection and injury. This is mediated by endotoxin, and results in expression of genes coding for a host of proteins and enzymes necessary to fight infection and repair tissue, whilst suppressing expression of hepatocyte transport proteins. Within an hour of endotoxin exposure, both BSEP and MRP2 proteins are reduced significantly, thus reducing bile secretion.

#### Cholestasis secondary to parenteral nutrition

Cholestasis associated with PN administration is particularly common in the neonatal population. The clinical scenario is familiar to the pediatric anesthesiologist – a premature neonate, who has undergone extensive bowel resection, is in trouble with sepsis and requires PN administration.

The mechanisms of PN cholestasis are unclear but prematurity, infection, short gut and toxic or missing components in the PN regimen all probably play a role. The inherently immature ability of the neonatal liver to produce bile and handle drugs suggests that neonatal livers are particularly susceptible to cholestatic insults. It is interesting that PN-associated cholestasis is rare in older children and adults. Recurrent central venous catheter infections will often provoke acute rises in serum conjugated bilirubin. A lack of oral intake interrupts the enterohepatic circulation of bile acids and may contribute to cholestasis, possibly secondary to abnormal gut hormone secretion. Bacterial overgrowth in the small intestine may lead to bacterial translocation and endotoxin production. The absence or presence of certain constituents within PN remains an attractive explanation but to date, there is little strong evidence to implicate any particular compound. However, PN regimens low in lipid and supplemented with taurine and carnitine may be associated with less cholestasis.

The striking feature of PN-associated cholestasis is the association with prematurity, intestinal failure and sepsis [16]. This provides the clinician with a therapeutic rationale to support the infant nutritionally, allowing growth and development while avoiding the progression of cholestasis to liver cirrhosis. Attention to strict aseptic technique is crucial to avoid central venous catheter infections. Innovative intestinal surgical techniques may lessen the chance of bacterial translocation and reduce the risk of sepsis. If possible, an increase in enteral feeding is

Figure 8.3 Classification of biliary atresia. Type 1: atresia affecting the common bile duct, often associated with proximal biliary cyst. Type 2: atresia affecting the common hepatic duct. Type 3: obliteration and atresia affecting the whole of the extrahepatic biliary tree. Reproduced from Millar [17] with permission from Wiley-Blackwell.

encouraged, to reduce PN administration, stimulate gut hormone secretion and support the enterohepatic circulation. The PN formulation should contain sufficient trace elements, amino acids and essential fatty acids.

# Structural abnormalities

# **Biliary atresia**

Biliary atresia accounts for about a third of cases of neonatal cholestasis. It is an important condition, as delay in diagnosis and treatment can result in irreversible liver damage. It remains the most common indication for liver transplantation in children [17].

Biliary atresia is characterized by a progressive inflammation and destruction of the extrahepatic bile ducts, as well as damage to intrahepatic bile ducts; if left untreated, hepatic fibrosis and biliary cirrhosis develop. The most accepted classification system is based on the anatomical location of the damage (Fig. 8.3).

The condition has an incidence of around 1:10,000– 15,000 in the United Kingdom and the United States. The etiology of biliary atresia remains obscure but the association with other anomalies makes an embryological hypothesis attractive (syndromic biliary atresia). Approximately 10% of infants with biliary atresia have associated anomalies including polysplenia, abnormal portal vein, interrupted inferior vena cava and cardiac defects.

Infants with biliary atresia are typically healthy term babies who initially appear normal, but soon develop persistent jaundice and pale stools. Lethargy, pruritus and poor weight gain soon become apparent. Hepatomegaly is often noted and as the condition progresses, signs of portal hypertension such as splenomegaly and ascites appear.

On confirmation of the diagnosis, the surgical treatment is the Kasai portoenterostomy, which involves excision of the atretic portion of the biliary tree, formation of a Roux-en-Y loop of jejunum and its anastomosis to the transected tissue at the porta hepatis, to allow bile drainage. As biliary atresia is a progressive inflammatory condition, many children proceed to liver cirrhosis despite achieving apparently adequate bile drainage. The success rate is much worse in those older than 8 weeks or with advanced hepatic fibrosis or established cirrhosis. The Kasai procedure achieves some biliary drainage in 70% of infants which may be adequate to ensure survival to 5 years in around 60% of cases; however, in around 30% of infants, the symptoms and signs of hepatic dysfunction occur despite successful surgery [18,19].

Many children progress to cirrhosis and suffer symptoms of portal hypertension, which include splenomegaly, variceal hemorrhage and ascites. Liver transplantation offers excellent results in this group of children. See Chapter 27 for a discussion of the anesthetic management of liver transplantation.

# Choledochal cyst

Choledochal cysts are congenital localized swellings of the bile ducts with an incidence of 1:100,000; they are more common in girls (female:male ratio 5:1). Interestingly, the condition is more prevalent in Japan. The position of the cysts is variable, leading to a number of classification systems; they are most frequently found on the common bile duct, but may occur anywhere along the biliary tree (Fig. 8.4). The etiology of the cysts remains obscure.

Presentation may occur at any age and antenatal diagnosis on antenatal scanning sometimes occurs. Symptoms are classically of pain and jaundice with a palpable abdominal mass. Diagnosis is confirmed by ultrasound scanning or magnetic resonance cholangiopancreatography. Secondary stone formation, cholangitis, pancreatitis and spontaneous rupture may occur; the cysts also have a potential for malignant change in the long term. Portal hypertension may occur due to portal vein compression or as a result of cirrhosis. Treatment is by surgical excision of the cyst with biliary drainage via a Roux-en-Y anastomosis. The prognosis is generally very good and reversal of portal hypertension has been reported.

**Figure 8.4** Classification of choledochal cysts. Type I dilations may be cystic (Ic) or fusiform (If) and typically associated with pancreaticobiliary malunion. Other types are II (diverticulum), III (choledochocele), IVa (multiple cystic dilations of the extrahepatic and intrahepatic ducts), IVb (multiple extrahepatic cysts), and V (single or multiple intrahepatic duct cysts). Reproduced from Millar [17] with permission from Wiley-Blackwell.

# Alagille syndrome

Alagille syndrome is a rare autosomal dominant disorder affecting 1:100,000 deliveries and is characterized by the paucity of interlobular bile ducts. It is caused by a mutation of the *Jagged1* gene [20], which encodes for proteins involved in the Notch signaling pathway. The syndrome is characterized by triangular facies, butterfly hemivertebrae and peripheral pulmonary stenosis often leading to pulmonary hypertension. The cardiac abnormalities are variable and may include hypoplastic pulmonary arteries, pulmonary valve stenosis and ventricular septal defect. The affected infants are often developmentally delayed and short in stature. The severity of the liver disease is variable, with many children having mild disease, but pruritus is often severe. Treatment is supportive with management of pruritus, nutritional support and in some cases corrective cardiac procedures. Liver transplantation is an option for those with decompensated liver disease or in whom pruritus is intolerable; however, the outcome following transplantation may be affected by the associated cardiac disease, and careful planning and assessment are necessary.

# **Metabolic conditions** α1-Antitrypsin deficiency

 $\alpha$ 1-Antitrypsin deficiency ( $\alpha$ 1-ATD) is the most common inherited disorder causing neonatal jaundice, with an incidence of 1 in 1600 livebirths. Only a few patients with the deficiency develop liver disease, but it is a common cause of emphysematous lung disease in adults [21].  $\alpha$ -1-antitrypsin is a protease inhibitor produced by the liver, which is an acute-phase reactant and responsible for inactivation of leukocyte elastase. Deficiency is due to mutation of its gene which is found on chromosome 14. Over 70 phenotypes are described but the PiZZ phenotype (Pi stands for protease inhibitor, ZZ is the isoelectric focusing banding pattern of the abnormal  $\alpha$ -1-antitrypsin protein) is the most significant, with homozygous PiZZ individuals at risk of progressive liver disease. The pathogenesis of the condition remains obscure and is associated with a build-up of an abnormal  $\alpha$ 1-antitrypsin molecule in the hepatocyte. However, as not all individuals with the genetic defect develop liver disease, other pathophysiological processes are likely to be important.

The clinical presentation is similar to biliary atresia: a jaundiced baby with pale stools and hepatomegaly. Infants who are homozygotes have a low serum  $\alpha$ 1-antitrypsin level. Liver biopsy reveals histological findings of neonatal hepatitis and periodic acid–Schiff (PAS)-positive granules within the hepatocytes. Management consists of nutritional support, fat-soluble vitamin supplementation and treatment of pruritus. The prognosis is variable; many individuals do well, but a proportion progress to cirrhosis and may deteriorate precipitately, requiring liver transplantation. The outcome following liver transplantation in  $\alpha$ 1-antitrypsin deficiency is good.

#### Progressive familial intrahepatic cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of autosomal recessive disorders associated with abnormalities of bile canalicular transport proteins [22]. PFIC-1 is caused by mutation of the FIC gene, which is expressed in the bile canaliculi; it is characterized by cholestasis, diarrhea and pancreatitis presenting in the first months of life. Bile duct paucity is seen on liver biopsy. Treatment is generally supportive but external biliary diversion has been used in some cases. Liver cirrhosis occurs in early childhood and may progress to require liver transplantation. PFIC-2 is due to deficiency of the bile salt export pump and is similar to PFIC-1, except pancreatitis is not seen. It has a worse prognosis and children often require liver transplantation in the first decade of life. PFIC-3 is due to a defect in the canalicular phospholipids transporter MDR3, presents with intrahepatic cholestasis but with an elevated  $\gamma$ -GT, unlike PFIC-1 and PFIC-2. The condition is similar to PFIC-1, but presentation is often delayed into adult life and the prognosis is variable.

## **Cystic fibrosis**

Cystic fibrosis affects around 1:3000 livebirths and is the most common life-threatening autosomal recessive condition. It affects the lungs, pancreas, sweat glands and liver.

There is great variation in the severity of liver disease; it affects one-third of individuals with cystic fibrosis but is the most important non-pulmonary cause of death. Liver disease usually presents in the teenage years but may rarely present in infancy with neonatal cholestasis, inspissated bile ducts or meconium ileus [23]. The latter presentation is particularly important, as it may be associated with sepsis and PN administration. The neonatal cholestasis usually resolves spontaneously, and appears not to predict future liver disease.

The reader should understand that although the causes of liver disease are varied, the pattern of progression to advanced liver disease may be similar. Therapeutic advances in hepatology and transplantation offer much hope to children with liver disease, but present an array of challenges to the pediatric anesthesiologist.

# Developmental physiology of the gastrointestinal tract

# **Overview**

Anesthesiologists tend not to take much notice of the gastrointestinal tract, except perhaps to wonder if the preoperative nil per os (NPO) period has been long enough. It probably merits more attention than this. The proper functioning of the gastrointestinal tract is fundamental to the well-being of the organism, in some ways as much as the cardiovascular, respiratory and renal tracts, on which we concentrate so much, quite rightly. It is true that problems in the gastrointestinal tract may take longer to show their full impact, but we all know from experience of our own physiology how little we notice our gastrointestinal tract when it functions well and how ill we feel when it does not. Some of the sickest patients the anesthesiologist will ever encounter are in this desperate condition as a result of problems which have arisen in the gastrointestinal tract.

The great majority of animals, and all of those regarded as the more complex, conform to the same basic body plan: they are modified tubes and the inner surface is, or originates from, the gastrointestinal tract. The importance of this collection of structures and organs is indicated by the degree to which the developmental plan is conserved across classes of organisms which otherwise vary enormously. The genetic scientist can learn a great deal about the gastrointestinal tract of the human by studying that of the fruit fly or the nematode.

We are not so much interested in the details of the genetics of development, although the understanding of this topic has grown amazingly in the recent past, and our realization of its complexity similarly. This section will describe the embryology of the gastrointestinal tract in outline, and show how the anomalies which the anesthesiologist will encounter may have arisen. Relatively more attention will be given to those points which have a relevance to the diseases and conditions which may be seen by the practical pediatric anesthesiologist, but the management of these conditions will be covered in other chapters.

The development of the gastrointestinal tract is dictated by an unavoidable deadline. By the time a baby is born, the gastrointestinal tract must be ready to supply fully the baby's needs for fluid and electrolyte intake, to digest its food, initially completely milk, to provide sufficient energy and biochemical raw materials for extremely rapid growth and development, and to do so efficiently enough not to upset the immature homeostatic control mechanisms. At the same time, a sudden onslaught of pathogenic organisms and potential poisons has to be resisted. Within a few months of birth, the gastrointestinal tract has to be ready for weaning from its comforting milk diet to whatever the environment can be made to provide - one of the first crucial steps to independent existence. Thereafter, the demands made on the gastrointestinal tract do not alter so radically, and although there is a lot of growing to be done and full functional maturity will not be attained for some years, the processes remain more or less unchanged for the rest of the individual's life. This timescale means that the pace of development in utero is hectic, and after birth many of the remaining functional changes normally happen soon.

It will be obvious that physiological experiments on the developing gut are difficult to carry out, even in animal models, so there are gaps in scientific knowledge, sometimes glaring enough to be obvious to the non-specialist. Some (maybe even much) of what is known is extrapolated from data from other species, and although the homogeneity of gastrointestinal tract design means that this may often be accurate, some of it may not.

## **Basic gastrointestinal tract physiology**

An abbreviated account of the physiology of the gastrointestinal tract follows. It is merely intended as an *aidemémoire*. The interested reader is referred to standard physiology texts for a more complete account.

The gastrointestinal tract epithelium comprises four basic types of cell: enterocytes, goblet cells (secreting mucus), endocrine cells, and Paneth cells. The 'basic' gastrointestinal tract cell is the enterocyte, which has a brush border of microvilli facing in to the gut lumen and tight junctions with its neighboring enterocytes. It sits on a basement membrane, beneath which capillaries and lacteals provide access to the circulation and lymphatic systems. Above the basement membrane, between adjacent cells, the basolateral surfaces border the fluid-filled paracellular space, which is crucial to the handling and transport of fluid and electrolytes. The enterocytes are arranged on villi, tiny finger-like mucosal projections into the gut lumen (Fig. 8.5).

The mass of crowded villi give the healthy gut luminal surface a velvety macroscopic appearance. Between villi, pits project down into the gut submucosa – these are known as crypts (of Lieberkühn). Enterocytes originate from stem cells in the crypts and there is a continuous procession of maturing cells from the crypts out and up on to the villi, gradually working their way to the tips of the villi, from where they are shed into the lumen.

The enterocyte has numerous digestive and absorptive functions. Substances can be taken into the cell by pinocytosis, passive diffusion, facilitated diffusion, and active transport. Enormously complex neural networks coordinate activity. This is explored in more detail in the section on the development of motility.

#### Basic gastrointestinal tract embryology

An understanding of basic embryology is necessary to make sense of the common structural anomalies.

By day 5 after fertilization, the late blastocyst consists of a hollow ball of cells. The outer cells will go on to form the trophoblast, and later the structures that will make the fetal component of the placenta. An inner cell mass forms a small mass lying against the side of the blastocyst. The inner cell mass soon develops into a bilayered structure: on one side, ectodermal cells border the amniotic cavity and on the other, the endoderm borders the yolk sac. The plate-like embryo starts to curl round and over, side to side and head to tail, so that the endoderm becomes more and more the lining of the inner side, and cells migrating inwards from the primitive streak on the ectodermal side become mesodermal cells, which surround the endoderm. The endoderm still communicates with the yolk sac which lies outside the middle part of the embryo. By day 25, the caudal and cephalic ends of the endoderm have invaginated at the anterior and posterior intestinal portals to form the blind-ending tubes of the primitive gut. The gut has buds which grow out to form, in order from head to tail, the thyroid, the tracheobronchial bud, the liver, the pancreas, and the allantois, a hollow endodermal projection which still lies outside the embryo.

It is customary to describe the gut in four parts: the pharynx, which extends as far as the tracheobronchial bud; the foregut, from there as far as the liver bud; then the midgut, as far as the posterior intestinal portal, which is where the caudal blind-ending tube starts in the early embryo – in the adult, this point will be two-thirds of the way along the transverse colon. From here onwards is the hindgut.

The gut becomes an open tube at both ends; cephalad, a pit develops, which is closed by the buccopharyngeal membrane. This meets the pharynx and perforates to

#### **Regions of the small intestine**

Figure 8.5 The gut, showing the structure of the small intestine from macroscopic to microscopic. Reproduced from reference [134] with permission from Encyclopaedia Britannica.

form the proximal opening. At the end of the hindgut a similar pit grows inwards to meet the hindgut and form the common opening of the gut and urogenital system, the cloaca. In the foregut, the tracheobronchial bud develops ventrally; normally the only communication between the two is where the larynx opens into the oropharynx. The esophagus elongates as the tracheobronchial bud grows downwards and the heart descends [24].

The most common congenital defect in this area is esophageal atresia and tracheo-esophageal fistula which occurs about 1:4000 births [25]. The cause is unclear. In the most common form (over 80% of cases), the upper esophagus ends as a blind tube and the distal esophagus opens into the trachea posteriorly near the level of the carina. Other combinations are seen but esophageal atresia or stenosis without any fistula into the respiratory tract is unusual. Chromosomal abnormality (e.g. trisomy 21) is sometimes associated, but in most cases there is no other anomaly (Fig. 8.6).

The stomach starts as a dilation in the foregut. It rotates round clockwise so that the left side becomes anterior and the right side becomes posterior; as this process occurs, its mesentery is dragged behind and forms a pocket of peritoneum behind the stomach – the lesser sac. The stomach is therefore surrounded by peritoneum, preventing its fixation and allowing for the necessary movement

**Figure 8.6** Anatomical classification of anomalies of the esophagus and trachea, with approximate incidences. Type A: esophageal atresia without tracheoesophageal fistula (TEF); Type B: esophageal atresia with proximal TEF; Type C: esophageal atresia with distal TEF; Type D: esophageal atresia with proximal and distal TEF; Type E: H-type TEF without esophageal atresia. and expansion. The posterior wall (now left side) grows faster than the right, causing the distal part to be pushed out to the right. The liver bud develops from the ventral part of the duodenum; it grows up and forwards, so its upper surface lies in contact with the septum transversum and this structure, part of which gives rise to the diaphragm, is all that separates it from the base of the right lung and the heart. The duodenum also participates in this left-to-anterior rotation, so that the connection with the liver, which is drawn out into the thin common bile duct, is pulled behind the duodenum and ends up opening into the duodenum on the left side, at the papilla (see Figure 8.1).

There are two pancreatic buds, ventral and dorsal. The ventral bud is also pulled round behind the duodenum and ends up touching and partially fusing with its dorsal counterpart. It is still recognizable in the adult as the uncinate process of the pancreas, which normally lies a little below the main body. The pancreatic ducts generally fuse to form a common pancreatic duct, which opens, with the common bile duct, into the duodenum at the papilla.

From here on, the midgut grows enormously, forming a long loop. Its blood supply, the superior mesenteric artery, is pulled out in the mesentery. The midgut undergoes rotation so the distal part is pulled upwards and to the right counterclockwise, so that the dilation which will form the cecum ends up in the right upper quadrant in front of the rest of the gut and the liver. As this part later elongates to form the ascending colon, it drops down towards the right lower quadrant, so the final rotation ends up approximating 270° (Fig. 8.7).

The small bowel loops repeatedly as it lengthens, whereas the colon does not. The growth of the midgut is so rapid that it cannot be accommodated in the abdominal cavity, so it herniates out. As the abdominal cavity

Figure 8.7 Rotation of embryonic gut. Reproduced from reference [136] with permission from Health Education Assets Library.

becomes more spacious because of the growth of the whole fetus and the lifting up of the heart and liver, the midgut is gradually retracted back into the abdominal cavity by 11 weeks' gestation, the yolk sac obliterates and the abdominal wall closes over it, leaving only the umbilical cord and its vessels passing out of the body cavity. At the point where the involuted yolk sac meets the midgut, a remnant may persist (Meckel's diverticulum) which may contain ectopic stomach epithelium, or there may be a fibrous cord, sometimes containing a vitelline cyst, tethering it to the anterior abdominal wall.

The hindgut is separated from the urogenital opening by the downward growth of the urogenital septum, which meets the cloacal membrane, dividing it into two: the anterior part, derived from the allantois, which will form the urinary bladder and genital tract, and the posterior part which forms the rectum. By 9 weeks' gestation, the ectodermal anal pit perforates into the rectum, opening the distal end of the gut.

Imperforate anus occurs in around 1:5000 births and ranges from a thin membrane across the anus to complete failure of the formation of the anal canal and associated sphincters. There may be other defects in urogenital structures, and the anomaly may be associated with spinal defects, omphalocele, and aganglionosis [26].

# Congenital abdominal wall defects: gastroschisis and omphalocele (exomphalos)

In gastroschisis, there is a defect in the abdominal wall, generally to the right of the umbilicus, and usually less than 5 cm across. The etiology is uncertain; there may be more than one causative factor [27]. It could be that a failure of mesenchymal cell migration means that the abdominal wall never completely closes over the defect left by the physiological herniation of the gut, which is normally retracted into the abdominal cavity around the 10th week of gestation, and so as growth of the gut progresses, the gut reherniates. Possibly in some cases a weakness or ischemia of the abdominal wall causes it to rupture, having initially closed. The position to the right of the umbilicus may indicate defective involution of the right umbilical vein. Sometimes the liver is also herniated. The herniated gut is not covered and is exposed to amniotic fluid, and is necessarily exposed after birth. The blood supply to the herniated part can be compromised, and the ischemic gut can be reduced to fibrous bands or may contain segments of atresia. Even if this is not the case, the gut may not develop normally and its function may be impaired. Sometimes the gut is covered with a fibrinous "peel" which may form as a response to gut contents which have leaked into the amniotic fluid bathing the exposed gut; the presence of a peel predicts a worse outcome [28].

In omphalocele (also known as exomphalos), the gut herniates through the umbilical ring itself, which is wide open. The gut is covered by amnion, the membrane which surrounds the umbilical cord, which forms a sac, although this may rupture, especially if it is large. The size is variable; there may be anything from only a small amount of bowel in the sac to most of the small bowel, liver and spleen.

The incidence of the two abdominal wall defects together is around 1:2000 births but the proportion of each varies by region and in many places is changing over time, the general trend in the developed world being that gastroschisis is becoming more common while omphalocele remains the same or is declining slightly, so that in many areas, gastroschisis is seen slightly more frequently than omphalocele. Gastroschisis is related to young maternal age but is often the only abnormality, just 17% or so having other congenital abnormalities, whereas in omphalocele over 60% have anomalies elsewhere [29].

Congenital umbilical hernia resembles omphalocele but in this case, the abdominal wall originally closed normally, so when the hernia occurs, it is covered by peritoneum as well as amnion.

Prune belly syndrome is an uncommon condition, occurring in less than 1:30,000 births, almost always in boys [30]. The muscles of the anterior abdominal wall are replaced by thickened collagenous bands, perhaps due to defective migration of mesenchymal elements which normally give rise to striated muscle. The abdomen therefore looks lax, the shapes of loops of bowel can be made out beneath the wrinkled skin, which gives the condition its name, and there may be visible peristalsis. The musculature of the bladder and renal tract is also affected and there may be a large thick-walled bladder, hydroureter and renal dysplasia. The very rare megacystis-microcolon intestinal hypoperistalsis syndrome presents a similar appearance.

## Malrotation

When the embryo's midgut is outside the abdominal cavity before the 10th week of gestation, the gut rotates through 270° so that the cecal bud, which would lie at 6 o'clock if there were no rotation, comes first to lie at 12 o'clock with the first 180° of rotation, and then finally round at 9 o'clock with a further 90°, which brings the cecal bud to lie in the right upper quadrant, next to the liver, and means that the colon lies over (anterior to) the duodenum. The gut loops on the left return first, so that as the cecal bud descends with the growth of the ascending colon, these structures lie on the right. Where the gut mesentery comes to lie on the peritoneum, it may fuse and so fix the gut at that point; normally the C-loop of the duodenum, ascending and descending colon become fixed, and the small bowel loops and transverse colon retain a mesentery.

In malrotation, the gut rotation sometimes amounts to just 90°; if the left-sided structures return to the abdomen first, this will mean the distal parts will return first and

the colon (all of it) will lie on the left and the small bowel loops will lie on the right.

If the malrotation is 90° clockwise instead of counterclockwise, then the duodenum will overlie the colon rather than the other way around.

The problems with malrotations are that the gut can be obstructed by the abnormal positioning or, lacking the normal fixation of parts of the gut to the retroperitoneum, the mesenteries can twist (volvulus), causing ischemic damage, or the abnormal peritoneal bands can themselves cause obstruction. This can commonly occur when the cecum lies to the left of the duodenum, so that the fibrous bands to the cecum lie over the duodenum (Ladd's bands) [31]. Sometimes the malrotated gut can function perfectly normally, and volvulus or obstruction occurs later in life, or it may cause no trouble and never be discovered, or only incidentally as a result of imaging or surgical exploration carried out for unrelated reasons. However, over 70% of cases present before the age of 1 year, and a similar proportion will have congenital abnormalities elsewhere. Malrotations are quite common, occurring in 1:500 births.

# Intestinal atresias, stenoses and webs

The duodenum is thought to pass through a solid phase in development, the lumen being re-established by the coalescing of vacuoles in week 8–10 of gestation (there is some doubt about this account [32]). If recanalization is incomplete then a stenosis, web or atresia occurs, or if there is no connection to the lumen at all, a duplication cyst may result. Duodenal atresia is frequently (50%) associated with intrauterine growth retardation, polyhydramnios, prematurity and congenital anomalies elsewhere which may be part of the VACTERL association (vertebral, anal, cardiac, tracheo-esophageal, renal and limb anomalies [33]). Sometimes a duodenal stenosis can be surrounded by a ring of pancreatic tissue (annular pancreas), but it is not clear whether this is the cause of the stenosis or a result of it [34].

Jejunoileal atresias may be due to *in utero* interruptions in blood supply to a portion of the gut at a much later stage of development than duodenal atresias. They vary from stenosis, through cases where a small length of bowel is replaced by a fibrous band, to multiple atresias with long sections of missing gut and defects in the mesentery. Sometimes the interrupted gut may be supplied by a marginal blood vessel, and therefore a length of progressively tapering hypoplastic gut winds around it in a spiral shape, giving rise to the "apple peel" or "Christmas tree" malformation (type IIIb) [35] (Fig. 8.8). They are not particularly associated with other abnormalities. Often the gut may be dilated proximal to the obstruction and collapsed or hypoplastic distal to it, although some stenoses may show distal dilation (windsock deformity).

Colonic atresias may occur by similar mechanisms but are more unusual – less than 15% of all intestinal atresias.

# Functional development of the gastrointestinal tract – vesicles, carbohydratase enzymes, transmembrane transporters

The epithelium of the gut changes from stratified to simple columnar between the 9th and 10th weeks of gestation [36]. Some absorptive processes are possible at the stratified stage, but significant functional capability does not become evident until the columnar stage. Maturation is not uniform, either between types of cell or between regions of the gut. In general, absorptive cells mature first, then goblet and endocrine cells, and Paneth cells last. Development also proceeds from proximal to distal. Villi appear first, proliferating to such a degree that the lumen may be obliterated. Crypts develop later. Epithelial cells differentiate from stem cells in the proliferative zone, which comes to lie in the crypts; Paneth cells migrate down into the crypts, all the others up towards the tips of the villi. There are therefore two axes of development: vertically on the crypt-villus axis and along the gut on the proximo-distal axis. The interaction between the endoderm-derived epithelium and the mesodermal elements which migrate into position beneath is crucial to the organized development of the gut [37]. The villi tend to be tallest in the jejunum and get shorter more distally. The mature colon does not have villi, only crypts, but there are villi in the immature colon.

A fundamental property of absorptive cells is that they can take up substances from the lumen in vesicles. Specialized proteins associated with vesicles (e.g. clathrins and caveolin) allow for selective absorption and onward intracellular distribution of substances from the gut lumen [38,39].

Developing enterocytes are structurally different from mature ones –at around 17 weeks' gestation, giant lysosomes can be seen in the ileum. There are more lysosomes in the adult gut than in the neonate, but no giant ones [40]. The developing gut needs to absorb more macromolecules undigested (growth factors, hormones, immunoglobulins) from amniotic fluid and milk, and is therefore more permeable to these, which may account for a greater susceptibility to pathogens and allergies at this stage.

Apical carbohydratase enzyme development has been studied in some depth, particularly lactase and the double complex sucrase/isomaltase [41]. Neither enzyme appears until the epithelium becomes columnar. Thereafter levels gradually increase. From 32 weeks' gestation there is a sudden large increase in lactase and

Figure 8.8 Classification of jejunoileal atresia describes the pathology as type I (mucosal web), type II (fibrous cord), type IIIa (mesenteric gap defect), type IIIb ("apple peel") or type IV (multiple atresias). Reproduced from Welch et al [137] with permission from Elsevier.

sucrase activity. In most mammals (and most humans), lactase activity declines sharply after weaning (later childhood in humans), typically to 10% or so of its peak, leaving most adult humans lactose intolerant [42]. Lactase is the only enzyme capable of cleaving the disaccharide lactose into its component glucose and galactose moieties. Lactose intolerance is by far the most common disaccharide intolerance. Other disaccharide intolerances are much rarer and are the result of transporter defects, not enzyme deficiency. In those of northern European ancestry, lactase activity usually persists into adulthood. These populations often have a tradition of consuming domesticated animal milk and milk products, and may at one time have been dependent on it or at least, its availability conferred a survival advantage. Mutations reducing or eliminating the decline in lactase activity with age may have originated separately in several different human populations. The distribution of the enzymes also varies along both crypt-villus and proximo-distal axes; lactase is concentrated to more proximal regions of the small bowel, and towards the tips of the villi, where it is vulnerable to being sloughed off if there is any inflammatory

process. Sucrase is evenly distributed up the villus and further along the small bowel, but neither enzyme is found in the adult colon [43].

# **Development of transporters**

The principal carbohydrate transporters are SGLT-1 which is a brush border (apical) sodium co-transporter for glucose and galactose, GLUT-5, which is a brush border facilitative transporter for fructose, and GLUT-2, which is a basolateral facilitator for all hexoses. Carbohydrate transporters start to be expressed during gestation, the number and density increasing and accelerating as term approaches. At birth, SGLT-1 is found along the whole length of the villus whereas in adults, it is found only on the third nearest the tip. Therefore the absorptive capacity per unit area of intestine tends to decrease with age but the total intestinal area of course increases, approximately proportional to the bodyweight after the neonatal period or slightly less [44]. The transporters are much more numerous proximally, where high carbohydrate concentrations would be expected. At the time of weaning, the transport capacity for sugars declines

further and is at least in part genetically programmed, as it occurs even if a totally milk diet persists.

Amino acid transporters are more complicated; there are more types, absorbing different groups of amino acids, although their affinities may overlap with each other somewhat. Small peptides (mostly 2 and 3 amino acids) also have their own transporters.

There are specific transporters for bile salts which, unlike the other transporters, are much more numerous in the ileum. Curiously, they do not appear until weaning; presumably before that bile salts are absorbed passively all along the small bowel, as an enterohepatic circulation certainly exists during the suckling stage [45]. It may be that it is important for the development of colonic bacterial flora that bile salts enter the colon during suckling.

Carbohydrate malabsorption can be a dangerous problem. The consequences are that sugars reach the colon, where they cause an osmotic diarrhea. The sugars are fermented by colonic bacteria and hydrogen, methane and carbon dioxide are produced. By far the most common cause is a loss of the brush border carbohydratase enzymes, the most common being lactase deficiency. Congenital lactase deficiency in infants was usually fatal before the advent of lactose-free milk substitutes. Genetic defects in the other carbohydratase enzymes are very rare, but acquired deficiency can be caused by a range of factors which may cause mucosal damage, including inflammatory, ischemic or allergic processes.

Defects in nutrient transporters are rare. Glucosegalactose malabsorption is due to defective synthesis of SGLT-1.

# The enteric nervous system

The enteric nervous system (ENS) is essential for the functioning of the gastrointestinal tract. All the nerves of the ENS are derived from neural crest cells and are broadly arranged into two plexuses: the inner submucosal plexus, situated as its name suggests, and the myenteric plexus, which lies between the inner circular smooth muscle layer and the outer longitudinal one. The ENS is much more than an extension of the parasympathetic branch of the autonomic nervous system. It contains a vast number of neurons (as many as the spinal cord) and many different cell types, and it is capable of functioning without any input at all from outside. Its neurons, which may be sensory, motor (both muscular and secretory) or interneurons, include types which resemble those found in the central nervous system: glial cells, astrocytes, and so on. One could go as far as to say that the complexity of the ENS, and its independence, allow it to be considered a "second brain." The largest share of the relatively tiny number of nerve connections to other systems comes from the vagus nerve, and 90% of those fibers are sensory – so perhaps in some respects the ENS controls the CNS more than the other way around.

Among the properties of the neural crest cells which find their way into the ENS are that they are highly migratory, highly pluripotent, and they originate from restricted areas – the vagal neural crest of the hindbrain supplies cells which populate the whole of the gut, starting proximally and eventually reaching the whole hindgut. Some neurons which derive from other parts (neural tube and sacral somites) also contribute to the ENS, and functioning ganglia cannot be generated anywhere without all the normal components in a favorable matrix. The factors which control this migration and differentiation are extremely complex.

Hirschsprung disease is a congenital defect in the development of the ENS where ganglia are absent from a variable length of the gastrointestinal tract starting from the distal end (although occasionally, and disastrously, it may be complete). The presentation is of obstruction usually associated with megacolon. The fundamental defect is a failure of neuronal migration, and several different factors may be involved. The gene coding for a tyrosine kinase (c-RET) is clearly implicated, as are glial-derived growth factor and an endothelin receptor, ENDRB. Other genes which have a role in regulating development in neurons, *SOX-10* and *MASH-1*, can have mutations which mimic Hirschsprung in animals [46]. Clearly, the process of getting the right neuron in the right place is extraordinarily complex, and far from completely understood.

#### Motor function in the developing gut

The functionality of the immature gut is perhaps more limited by deficiencies in the motor function of the gut than by the lack of structural elements, cell types, or digestive enzymes and secretions. The development of motor function rather lags behind these other factors. It is at least 2 years before the system can be considered mature. The main movements which are required are swallowing, sucking, mixing and propulsion of gut contents, and evacuation. The esophagus, and those parts proximal to it, are striated muscle and under voluntary control. The muscle of the rest of the gastrointestinal tract, until the external anal sphincter, is smooth muscle and although neural projections and humoral influences from higher centers can modify its function, it is essentially autonomous and regulated by its own enteric nervous system and humoral factors.

# Swallowing

Swallowing movements are evident in the fetus at 16 or 17 weeks' gestation, and there is a steady increase in the volume of amniotic fluid swallowed, from less than 20 mL daily at 20 weeks to around 450 mL daily at term [47]. There is much more to this than just "practice"; amniotic

fluid contains nutrition and growth factors, and the development of the gut is promoted by it. An interruption of fetal swallowing can lead to polyhydramnios. In the premature infant, propulsive pressures in the esophagus are lower than at term, and the movement may not be completely or properly co-ordinated, and complications due to reflux and aspiration are more likely. The function of the lower esophageal sphincter (LES) is particularly important in this. Although the lower LES pressure found in premature neonates would seem to make reflux more likely, reflux episodes appear to be more related to transient relaxations in the LES [48], the causes of which are not fully clear, than to inadequate resting LES pressure.

Sucking movements can be seen from 28 to 30 weeks' gestation but effective co-ordination with swallowing and breathing is generally not achieved until 37 weeks or so. Babies more premature than this may still be able to suckle by stopping breathing for short periods and then resting.

In both stomach and small bowel, the smooth muscle shows a typical pattern of slow-wave electrical activity, the periodicity of which is controlled by the pacemaker activity of the interstitial cells of Cajal. A muscle contraction is caused by a spike potential causing an additional depolarization on top of the slow wave and over the threshold for muscle contraction.

In the mature stomach and small bowel, in the fasting state the characteristic feature is the migrating motor complex (MMC), which is a wave of contraction passing from the stomach to the rectum. In the adult, these are seen every 90min or so. Feeding abolishes them and for 3 or 4h only segmentations and short peristaltic waves are seen, before the MMC re-establishes. A fully developed MMC is not seen until nearly full term [49,50] but this mature electromyographic pattern is not essential for successful enteral feeding. Gastric emptying can be seen up to 6 weeks before the appearance of the MMC, and contractile activity long before that, but in more premature infants nasojejunal feeding may be needed to overcome inadequate gastric emptying. It is clear that enteral feeding promotes the development of effective motor activity and so in conditions where full enteral feeding is impossible, at least some enteral feed is beneficial. Certainly in some animals, bacterial colonization is also required for normal gut development.

The rate of gastric emptying is of course of great interest to the anesthesiologist wishing to provide safe anesthesia for his or her patient. Unfortunately, it is highly variable. Very dogmatic adherence to a protocol NPO period before anesthesia rather implies a lack of understanding of gastrointestinal physiology. The half-time for gastric emptying in premature infants is usually 20–40 minutes, rather slower than it is for term babies, and it will be slower for formula feed than for breast milk. The colon also shows propagated waves of contraction when mature, and the passage of fecal material into the rectum may lead to reflex relaxation of the internal anal sphincter and defecation. The frequency of these contraction waves decreases with age from several times per hour in the term infant, especially just following a feed, to once or twice per day in the adult. Most babies pass their first stool within 2 days of birth, but it may be longer than that in the case of prematurity. There is normally no passage of meconium into the amniotic fluid *in utero*, and evidence of it is often considered a sign of fetal distress.

Many factors can interrupt the normal process of gastrointestinal tract motor maturation, including some which appear to be outside the gut; babies with hypoxic brain injury are much more likely to have problems with reflux and experience delays in establishing enteral feeding.

Meconium ileus is most commonly seen in infants with cystic fibrosis. Cystic fibrosis (CF) is caused by a defect in the gene coding for a protein which forms a cAMP-dependent chloride channel (cystic fibrosis transmembrane conductance regulator, CFTR). The disease is characterized by abnormally thick, viscid mucus, which typically causes blockage and infection in the respiratory tract or causes pancreatic insufficiency. There are other changes in CF goblet cell secretions and intestinal mucus apart from lack of chloride – for example, it contains more protein, specifically more albumin. The result is that the sticky meconium causes an intestinal obstruction. Rare cases which occur without CF may be due to motility disorders, for instance defective interstitial cells of Cajal.

# Immunity in the gastrointestinal tract

The very purpose of the gastrointestinal tract is to take substances in from the environment and transport them into the organism; it follows that this process is a major liability when that environment teems with potential pathogens. To protect the organism effectively from these myriad threats requires an extremely sophisticated multimodal defense system.

#### Innate immunity

The goblet cells secrete a mucus which forms a physical barrier, which also contains antimicrobial compounds, protecting the mucosa from pathogens. The number of goblet cells increases in inflammatory conditions and in response to some parasites. The enterocytes may contribute to immunity by an unusual mechanism [51]. The lifespan of enterocytes after birth is short, around 3–5 days. As these cells die and are shed into the lumen, they release histones, which are components of the cell nucleosome but which also seem to have significant antimicrobial activity (similar compounds are present in

macrophages). So many enterocytes are shed into the lumen that this could be an effective protection, and it is not otherwise apparent why their lifespan needs to be so short; Paneth cells (originating from the same precursors) live much longer, as do fetal enterocytes in their sterile environment. Enterocytes therefore seem to have an immune function which is secondary to their main function but for Paneth cells, their primary function is immunological. Paneth cells secrete a range of bactericidal compounds. They contain numerous granules (like neutrophils), and the granules seem remarkably similar, containing lysozyme, phospholipase A2, and peptides known as  $\alpha$ -defensins. All these components show antimicrobial activity. Most, and possibly all, of the Paneth cell granules are released into the lumen and so their antimicrobial activity occurs outside the cell, unlike neutrophils and macrophages, and also unlike those cells of myeloid lineage, Paneth cells are fixed, in the epithelium of the crypts. Paneth cells can be detected in humans at about 13-14 weeks of gestation and produce low levels of defensins straight away. The levels increase markedly around the time of birth but still, defensin levels are several times lower in neonates than in adults.

#### Acquired immunity

A detailed account of the mechanism of cellular and humoral immunity is outside the scope of this chapter, so we will assume some knowledge of these systems. The fundamental problem that the gastrointestinal tract poses to the immune system is that while the organism must be capable of defending itself against a vast array of pathogens which may attack by this route, it is unavoidable that the ingestion of food will also present an enormous range of foreign antigens and to respond to every one would be unfeasible, wasteful, detrimental and potentially disastrous. Therefore there must be an accurate and subtle method for inducing tolerance to antigens which are harmless (and may be required), whilst maintaining immune vigilance against genuine threats. Perhaps needless to say, the precise and complete details of how this is achieved are not known and anyway, the complexities of what is known need not trouble us too much for the purposes of this account.

Lymphocytes appear in the gastrointestinal tract in three broad areas – as intraepithelial lymphocytes, in Peyer's patches, and in the lamina propria.

Intraepithelial lymphocytes appear at around 11 weeks' gestation and increase continuously, so by 27 weeks about 70% of the infant level is reached [52]. In the lamina propria, B- and T-cells are present from 12 to 14 weeks' gestation, and similarly increase their number towards birth. The cell subsets present are distinctly different in these two areas and cell proliferation is seen throughout, whereas in the adult, proliferation is confined to the

Peyer's patches: these can be seen from around 18 weeks' gestation, mostly in the ileum, as in adults. There are typically around 100 at birth, increasing to 250 or so in teenagers, thereafter gradually declining. As soon as they appear, the epithelium overlying the patches changes from columnar to cuboidal, and the enterocyte-derived M-cells appear – their function is to transport antigens from the lumen and present them to lymphocytes [53]. Mature M-cells are surrounded by clusters of lymphocytes.

*In utero*, the sterile conditions do not test the immune system but at birth there is a sudden influx of antigens. Premature infants are capable of mounting both humoral and delayed hypersensitivity-type reactions, but the response is less reliable than in term babies. After birth, the immune system continues to develop quickly, at least in part stimulated by luminal antigen (the process is less effective in parenterally fed infants), and normally after 1 year of age there are three times as many intraepithelial lymphocytes as in the neonate.

B-cells and the immunoglobulins they produce are crucial to the protection of the huge mucosal surface of the gastrointestinal tract. Peyer's patches are fundamental to the production of activated plasma cells. The clonal expansion of specific cell lines is carried out there, and the maturing cells disperse out into the circulation and so are distributed to the whole of the lamina propria. Immunoglobulin-secreting plasma cells produce predominantly IgA which is packaged with a secretory component and exported into the lumen by the enterocytes. In the neonate, significant amounts of IgA are supplied by the mother's breast milk, compensating to some extent for the immature humoral immune system.

# Breast milk, the suckling period, and bacterial colonization

Breast milk is considered to provide many advantages over artificial alternatives [54]. The composition of human breast milk alters as the baby ages, is not uniform during a single feed, and varies quite a bit between individuals. For the first few days postpartum, colostrum is produced; the volume is rather lower and its composition different from more mature milk.

#### Milk proteins

There are a very large number of milk proteins, which are classified into two groups according to whether they clot, forming a curd on exposure to acid (caseins), or not (whey). Caseins form micelles in the watery milk environment, containing ions, especially calcium and phosphorus. The principal caseins in human milk are  $\beta$ - and  $\kappa$ -casein. Of the whey proteins, those with the highest concentrations are  $\alpha$ -lactalbumin, lactoferrin, secretory IgA (sIgA), and serum albumin.

Secretory IgA (90% of milk immunoglobulin) has an obvious immunological utility; the clonal varieties will be directed against antigens that the mother has encountered and are therefore tailored to the probable local environment. Immunoglobulins are resistant to degradation in the infant gut.

In addition, there are small amounts of important enzymes in milk, such as bile salt-activated lipase, which assists in the digestion of milk fat content. This enzyme, and the plasma membrane which encloses milk lipid droplets as they are secreted in the mammary gland, ensures that milk fat is particularly easily digestible.

Some growth factors, for example insulin-like growth factor, transforming growth factor and epidermal growth factor, promote gastrointestinal tract cell proliferation, which can be extremely rapid after the first feed, intestinal mass as much as doubling within 3 days in piglets [55].

Hormones present in milk include insulin, thyroxine, and glucocorticoids and these, and other factors such as nucleotides, may have important roles in gut maturation.

Cytoprotective substances such as prostaglandins and phospholipids are also present.

#### Non-protein components of milk

Mature human milk (produced at least 3 weeks postpartum) contains typically [56] 4% fat, almost all triglycerides of medium-or long-chain fatty acids, 7% carbohydrate, almost all lactose, and 1–1.5% protein (about 40% caseins, 60% whey).

Colostrum contains less fat and carbohydrate (about 75% of that in mature milk) and much more whey protein (about double) which includes up to 5–12 times as much sIgA, as well as high concentrations of trophic factors, especially in the first day or two [57,58]. By comparison, cow's milk is very different – it contains about half as much lactose, a little less fat, about three times as much caseins, and has a higher electrolyte concentration.

The infant stomach does not produce much acid – the pH in the neonate's stomach is 4–5, so pepsin activity and hence protein digestion are very limited. The stomach is much more important in the digestion of milk fat. Gastric lipase activity is very high in the neonate (even if premature) and it seems that this enzyme is required to start the breakdown of the membrane-coated milk fat globule, which otherwise resists the activity of bile-salt activated lipase (a milk constituent).

Initially there is significant transport of macromolecules unaltered across the gut mucosa. This certainly occurs *in utero*, and factors present in amniotic fluid appear in the fetal circulation. Later, the gut becomes much less permeable, a process known as closure. The precise timing of closure is difficult to determine; it happens rather earlier in humans than in some other mammals – in the rat, closure occurs long after birth. Certainly the human gut is more permeable in the neonatal period, and factors in breast milk may promote closure; this may be protective against infection.

Bacterial colonization is clearly an important event in the neonate, and is inevitable within a few days of birth. The neonatal gut is relatively more aerobic and this suppresses colonization by obligate anaerobes. The first organisms found are usually bifidobacteria, Escherichia coli, Enterobacter, and staphylococci. It might seem intuitive that these organisms are derived from the mother's gut flora but in fact, this is not always the case, even in unhygienic conditions. The infant gut is often colonized by organisms which are rarely found in the adult gut, such as Klebsiella and Citrobacter. Clostridia are found more often in babies than in adults, and are not necessarily pathogenic – up to 30% of healthy babies carry them. Bacteroides and lactobacilli generally appear later [59]. Usually the flora in formula-fed babies resembles that of adults more than breast-fed babies, and breast feeding confers some protection against urinary tract infection, septicemia, diarrhea and necrotizing enterocolitis. Weaning promotes the transition to an adult-type gut flora. Infants are, however, much more susceptible to infection by Salmonella, Campylobacter and pathogenic E. coli strains than adults. The use of antibiotics, and just being in a hospital environment, tends to disturb the establishment of a normal gut flora, and makes diarrheal illness more likely.

Recently, interest has been aroused in the proposition that inadequate exposure to bacteria increases the risk of food allergy and atopic illnesses. It is true that components of *E. coli* can improve the induction of immune tolerance to food protein, and that rates of allergy and atopy are much higher in hygienic Western countries.

# **Necrotizing enterocolitis**

Necrotizing enterocolitis (NEC) is the most common gastrointestinal disorder found in the neonate. Despite its frequency, and a large volume of research, the causes remain obscure [60]. It is much more prevalent in premature babies, affecting about 10% of babies born less than 1500 g, and the more prematurely the baby is born, the more likely it is to develop NEC. The condition is unusual in babies born later than 35 weeks' gestation. When it does occur in a term neonate, the onset is typically within a few days, but may be several weeks after birth in very premature babies.

It is attractive to ascribe an infective cause and it is true that in advanced severe cases, the clinical picture is of sepsis. Cases also sometimes cluster, suggesting an epidemic etiology. However, it is clear that no one particular organism is responsible. Many cases of NEC show heavy gut colonization with Clostridia, but these are commonly found in healthy babies and this finding is not universal. In a breast-fed infant, bifidobacteria tend to predominate, and counts of these species are lower in NEC cases; possibly giving probiotics to enhance their growth may be protective [61]. Breast milk has a protective effect against NEC and contains anti-inflammatory substances, sometimes in higher concentrations in the milk of mothers of premature babies [62]. It seems likely that NEC is a result of a combination of gut ischemia, bacterial translocation, an inflammatory response and defective immune modulation of that response.

The clinical picture is often of a premature baby who may initially progress well on enteral feeds but then becomes feed intolerant, and may have abdominal distension and vomiting. Apneas are common, and the baby may seem lethargic or appear to be uncomfortable. Radiographs may show dilated bowel loops and gas in the gut wall or, if the condition progresses to full-thickness ischemia and intestinal perforation, free gas in the peritoneum. Systemic signs may be hypothermia, acidosis and other electrolyte disturbances, and eventually cardiovascular collapse and multiorgan failure.

Treatment is to rest the gut (parenteral nutrition may be required), general supportive measures and antibiotic therapy, and celiotomy if the condition worsens. Sections of ischemic gut may have to be resected, and stoma formation may be necessary. Mortality remains high, up to 50% in babies weighing less than 1500 g at birth. Survivors may run into trouble later as a result of short gut or malabsorption disorders.

# Developmental physiology of the renal system

Developmental abnormalities of the kidney and urinary tract are the most common cause of childhood renal failure in the United States [63]. Defects occur in as many as 1:100 livebirths and range from benign, asymptomatic duplications to lethal conditions such as bilateral renal agenesis [64].

# **Embryology and development** Kidney and urinary tract

The definitive kidney has two embryonic precursors: the pronephroi and mesonephroi. Although ultimately both degenerate, they are essential for normal renal development. The pronephroi arise from intermediate mesoderm early in the 4th week and are rudimentary, non-functional kidneys, composed of simple tubules in the neck region [63]. The pronephroi drain into bilateral ducts, precursors of the Wolffian (nephrogenic) ducts, which elongate caudally to fuse with the cloaca. The mesonephroi develop caudally to the pronephroi at the end of the 4th week. They comprise well-developed nephrons and vascular glomeruli that drain into the Wolffian duct and function as interim kidneys for about 4 weeks. They regress at the end of the first trimester although they have several adult derivatives in the male [65].

Development of the permanent kidneys begins early in the 5th week. A diverticulum known as the ureteric bud arises from the caudal end of the mesonephric duct and is the precursor of the ureter and renal collecting system (Fig. 8.9). It penetrates a specialized area of intermediate

Figure 8.9 The three sets of excretory systems in an embryo during the 5th week. (A) Lateral view. (B) Ventral view. The mesonephric tubules have been pulled laterally; their normal position is shown in (A). Reproduced from Moore and Persaud [65] with permission from Elsevier.

**Figure 8.10** Development of the permanent kidney. (A–D) Successive stages in the development of the metanephric diverticulum or ureteric bud (weeks 5–8). mesoderm at the level of the hindlimb termed the metanephric mass, which is the precursor of the renal parenchyma. The ureteric bud elongates to form the ureter and branches to form calices and collecting tubules. The end of each collecting tubule induces cells of the metanephric mass to form vesicles that elongate to become definitive tubules (Fig. 8.10).

Nephron development commences around the 8th week. It occurs in a centrifugal pattern with cortical nephrons formed after juxtamedullary ones. The rate of development increases rapidly after 18 weeks' gestation and is complete by 34–36 weeks, with each kidney possessing between 800,000 and 1,000,000 nephrons [66]. Renal growth after this is mainly due to elongation of the proximal convoluted tubule and an increase in interstitial

tissue. Premature and low-birthweight infants have fewer nephrons, leading to high nephron filtration rates and glomerular hypertrophy [67]. These changes are associated with the development of hypertension, cardiovascular disease and increased susceptibility to renal disease in later life [68,69]. Abnormalities in ureteric bud induction of nephrogenesis underlie many congenital defects; details of common ones are given in Table 8.1.

# **Urinary bladder**

The cloaca is partitioned by the urorectal septum into a ventral urogenital sinus and dorsal rectum. The bladder arises mainly from the vesical part of the urogenital sinus, with the trigone derived from the caudal ends of the mesonephric ducts. As the ducts are incorporated, so the ureters come to open into the bladder, their orifices moving superolaterally as a result of "traction" from the ascent of the kidneys. The bladder is initially contiguous superiorly with the allantois (a vestigial structure) which constricts to become the urachus, represented in adults by the median umbilical ligament. If fetal bladder emptying is obstructed, the urachus may remain patent, allowing urine to leak out around the umbilicus.

# Renal migration and blood supply

The kidneys initially lie close to each other in the pelvis and attain their abdominal, retroperitoneal adult position by the 9th week. This apparent migration is due to embryonic growth caudal to the kidneys rather than movement of the kidneys themselves, and abnormalities in this process are common (see Table 8.1).

Renal arteries and veins start as branches of the common iliac vessels; as the kidneys ascend, they receive new branches from successively more superior points of the aorta and inferior vena cava. Inferior vessels usually degenerate but their persistence explains much of the variation seen in the renal vasculature. A single renal artery to each kidney is present in only 75% of adults, and 25% of kidneys have 2–4 accessory arteries [70]. These usually drain into the hilum but accessory arteries may be end-arteries, rendering portions of a kidney vulnerable to ischemia, and those to the lower pole may obstruct the ureter and cause hydronephrosis [71].

# Fetal urine production and the oligohydramnios sequence

Urine production by the fetal kidney begins by week 10 and is responsible for 90% of amniotic fluid volume by week 20. Production increases from 0.1 mL/min at 20 weeks to 1 mL/min at 40 weeks' gestation, which is far in excess of urine production rates in the term neonate [72]. The absence of adequate amniotic fluid gives rise

Condition	Embryological etiology	Clinical effects				
Renal agenesis	Failure of ureteric bud to contact metanephric	Unilateral – 1:1000 livebirths. Usually detected incidentally, may be associated with higher risk of chronic kidney disease in later life				
	Complete involution of a severely dysplastic kidney	Bilateral – 1:10–30,000 livebirths. Absence of fetal urine leads to oligohydramnios sequence (see text). Usually fatal				
Urinary tract duplication	Ureteric bud division Duplication of ureteric bud	Bifid ureter with either a divided kidney or a supernumerary kidney Two ureters each with their own kidney on the affected side				
Renal ectopia	Arrested or aberrant migration +/- fusion while kidneys lie in fetal pelvis	<ul> <li>Pelvic kidney – unilateral failure to ascend. No symptoms but may be confused with tumors or damaged during surgery</li> <li>Crossed renal ectopia – one kidney migrates to contralateral side. May occur with fused kidneys</li> <li>Discoid or "pancake" kidney – complete fusion in pelvis. Kidney mass lies above bladder with short ureters</li> <li>Horseshoe kidney – 1:500 livebirths (7% of those with Turner syndrome). Fusion of kidney poles (usually inferior). U-shaped kidney lies in hypogastrium as normal ascent is prevented by root of inferior mesenteric artery. Usually no symptoms</li> </ul>				
Dysplastic or hypoplastic kidneys	Failure of induction of nephrogenesis by the ureteric bud	From small kidneys with low numbers of normal nephrons to normal-sized kidneys with a wide variety of tubular defects. Dysplastic kidneys may also be multicystic – these often involute spontaneously <i>in utero</i> or the first few years of life. Together, the most common cause of established renal failure worldwide. Molecular mechanisms are being elucidated [75]				
Wilms tumor	Nephrogenic rests: abnormal structures arising from failure of mesenchyme differentiation	Kidney malignancy affecting 1:10,000 children. Nephrogenic rests are found much more frequently in children with Wilms tumors [76]				

Table 8.1	Common	abnormalities	of t	the	urinary	tract	and	their	embr	yological	origins
-----------	--------	---------------	------	-----	---------	-------	-----	-------	------	-----------	---------

to the oligohydramnios sequence. Characteristic facial features, known as Potter's facies, include micrognathia, wide-set eyes, flattened nasal bridge, and large, low-set ears which lack cartilage [73]. Skeletal anomalies associated with oligohydramnios include club feet, hip dysplasia, scoliosis, torticollis, and contractures. Amniotic fluid is also essential for normal lung development; pulmonary hypoplasia is the main reason for the high mortality associated with significant oligohydramnios [74]. The fetus swallows significant volumes of amniotic fluid daily which is absorbed by the intestine. However, fetal waste products are transferred across the placenta for excretion by maternal kidneys. The kidneys do not assume their excretory role until after birth [75,76] (see Table 8.1).

# **Developmental physiology** Glomerular filtration

Glomerular filtration is the process whereby water and solutes cross the glomerular membrane. Ultrafiltrate is virtually identical to plasma apart from containing very little protein. The rate of ultrafiltration is governed by four factors: the balance of Starling forces across the capillary wall; plasma flow rate; glomerular capillary wall permeability; and total surface area of the capillaries.

Quantifying glomerular filtration rate (GFR) is important for the rational prescribing of drugs and in monitoring chronic kidney disease. Comparing direct measurements from small infants to adults requires scaling to a standard of reference. Although kidney weight cannot be directly measured, both kidney weight and absolute GFR correlate well with body surface area (BSA). Adjusting GFR for BSA removes the variability caused by the variation in pediatric body size [77]. BSA in children and adolescents may be calculated from the formula [78]:

BSA  $(m^2) = 0.024265 \times Weight^{0.5378} \times Height^{0.3964}$ 

The most common method of measuring GFR is based on the concept of clearance. The renal clearance of a substance  $x (C_x)$  is expressed by the formula:

$$C_x = U_x V / P_x$$

where  $U_x$  is the urine concentration,  $P_x$  the plasma concentration and V the urine flow rate. If a substance is freely filtered and not metabolized, synthesized or transported by the kidney then its clearance is equal to GFR.

Despite the importance of GFR, accurate measurement remains problematic. Renal clearance of inulin is still the gold standard in all age groups. However, its utility is compromised by availability, difficult assays and the practical problems of collecting urine samples in children. Urine volumes are inaccurate in the presence of vesicoureteric reflux and conditions which preclude complete voiding [79]. Creatinine is routinely measured and hence used frequently to estimate GFR in pediatric populations. It is freely filtered and secreted by tubular cells but the technique is inaccurate in children with reduced muscle mass, and tends to overestimate GFR in the presence of renal dysfunction when extrarenal clearance of creatinine is markedly increased [80]. The common and easily used Schwartz formula, which incorporated serum creatinine, height and an age- and sex-dependent constant, now appears inaccurate with newer and more precise assays for creatinine [81]. Radiolabeled isotopes are accurate but not ideal agents in children, particularly for repeated assessments.

There are two newer agents that are showing promise for measurement of GFR. Iohexol is a nonionic contrast agent already used at higher doses for radiological procedures even in the presence of renal dysfunction. Equations utilizing iohexol plasma clearance provide good estimates of GFR [82]. Further, results from blood spots collected on filter paper correlate well with venous samples which may facilitate late sampling by patients at home and the use of iohexol as an epidemiological tool [83]. The endogenous cysteine protease inhibitor cystatin C is produced constantly, independent of inflammatory conditions, sex, muscle mass and age above 1 year, and is freely filtered [84]. Estimations of GFR using serum cystatin C appear very accurate although assays are currently not widely available [82].

Glomerular filtration begins in the fetus during the 9th week. GFR reaches 12 mL/min/1.73 m<sup>2</sup> in the premature infant at 30 weeks and 20 mL/min/1.73 m<sup>2</sup> by term. Maturation continues rapidly in the postnatal period with a doubling of GFR by 2 weeks, a proportional rise that is seen in both premature and low-birthweight babies [85,86]. Adult values of GFR (corrected for BSA) are reached by 18–24 months of age [87]. Low GFR is primarily mediated by vasoconstriction through the reninangiotensin system (see below) and may represent a necessary adaptation to prevent excessive fluid and electrolyte loss secondary to tubular immaturity [88].

# Tubular function Sodium

Fractional excretion of sodium (FE<sub>Na</sub>) falls from 12.8% at 30 weeks to 3.4% at 38 weeks and 1% in the normal adult [89]. Prematurity is associated with significant salt wasting and a risk of hyponatremia. Term neonates have a limited capacity both to conserve sodium necessary for growth and to excrete a sodium load. Excessive administration of sodium to term neonates may cause extracellular volume expansion, edema and significant hypernatremia [90]. Sodium excretion usually exceeds oral intake (breast or formula milk) in the first few days of life, leading to negative sodium balance with associated weight loss. As  $FE_{Na}$  falls further and oral intake increases, birthweight is regained in 5–7 days. The ability to excrete a sodium load matures by around 1 year [91].

Sodium is reabsorbed along the entire nephron length via different mechanisms. A key component is the Na-K-ATPase enzyme, located on the basolateral membrane of tubular cells, which actively transports sodium out of the cell into interstitial fluid and the peritubular capillaries, creating an electrochemical gradient for the movement of sodium out of the tubular lumen (Fig. 8.11). This movement often occurs via specific transporter proteins to which the transfer of many other electrolytes and

**Figure 8.11** Excretion and reabsorption of water and electrolytes. Water is reabsorbed in the proximal tubule together with glucose, amino acids, phosphate, sodium and bicarbonate, and from the distal nephron under the influence of antidiuretic hormone and the hypertonic medulla. In the distal tubule sodium is reabsorbed under the influence of aldosterone with associated excretion of potassium and hydrogen ions. Reproduced from Cumming and Swainson [138] with permission from Elsevier.

compounds are coupled. In the neonate, reabsorptive mechanisms in both the proximal and distal convoluted tubule are immature. The postnatal enhancement of sodium conservation is brought about mainly by increased numbers of Na-K-ATPase and other transporter proteins in both locations [88].

#### Water

Infant nutrition is entirely liquid, so a high urine flow rate is necessary to maintain fluid balance. This is achieved with a high fractional excretion of water (FE<sub>H2O</sub>). Water reabsorption in the proximal convoluted tubule is isotonic. Neonates have reduced plasma protein, so the hydrostatic and osmotic forces acting from lumen to capillary are reduced, resulting in decreased proximal water reabsorption. Distally, water reabsorption is under the influence of antidiuretic hormone (ADH), to which even preterm babies are sensitive. Neonates are able to adjust water excretion appropriately from day 2 of life and can achieve  $FE_{H2O}$  of up to 13% (a similar value in adults would produce 20 L of urine per day) [92].

While minimum urine concentration equals adults levels of 50 mmol/kg at birth, maximum urine concentration is 600–800 mmol/kg, which is about half that of older children. This reflects both shorter loops of Henle and reduced tonicity of the medullary interstitium (urea levels are low, reflecting the anabolic state of the growing infant). Assuming a solute load of 10–15 mosmol/kg, the minimum urine flow rate required to prevent solute retention is 25 mL/kg/day [93]. This approximates to 1 mL/kg/h and is the basis for the use of this figure as an indication of renal failure.

## Potassium

The immature kidney has a reduced capacity to excrete potassium; neonates excrete 9% of the filtered potassium load whereas children and adults excrete around 15% [94]. The main site of potassium excretion is the distal convoluted tubule and cortical collecting ducts. Aldosterone acts on the principal cells of these regions to enhance the activity of the Na-K-ATPase pump on the basolateral membrane, which elevates intracellular potassium. It also increases the permeability of the luminal membrane to potassium, thus promoting its excretion. Aldosterone levels are high in infants but the cellular response is attenuated [95]. In addition, lower tubular flow rates lead to higher potassium concentrations, reducing the gradient for diffusion. Normal values are achieved by around 3 months of age. The reduced ability of infants to excrete potassium is only likely to be of significance in cases of excess administration or pathological cellular release, where hyperkalemia may ensue more rapidly.

#### Glucose

Glucose is completely reabsorbed in the early portion of the proximal convoluted tubule by a stereo-specific transported protein. The process involves secondary active transport and is saturable (see Fig. 8.11). Term infants have a threshold for glucose that is equal to older children and adults when corrected for GFR. However, premature infants demonstrate significant glucose wasting, which may be due to reduced nephron numbers, reduced basolateral Na-K-ATPase pump activity or changes in the expression and density of the transporter proteins [96].

# Phosphate

Rapid growth requires the normal infant to be in positive phosphate balance; plasma phosphate is high *in utero* and in infancy and decreases with age. Neonates demonstrate a reduced fractional excretion of phosphate that is not attributable to reduced load from a lower GFR. Rather, the immature kidney has an increased ability to reabsorb phosphate in both the proximal and distal convoluted tubules that is independent of parathyroid hormone activity and dietary phosphate. Growth hormone may have a regulatory effect, suggesting that this represents an appropriate physiological response to the need for phosphate, rather than an immature system [97].

# Acid-base balance

Neonates have a reduced capacity to maintain acid–base status for a number of reasons, including a reduced ability to reabsorb bicarbonate, secrete organic acid and produce ammonia and a low level of titratable acid, specifically phosphate. Bicarbonate is usually 85–90% reabsorbed in the proximal convoluted tubule, an energy-dependent process requiring the secretion of hydrogen ions in exchange for sodium. The renal threshold for bicarbonate (the level at which it appears in the urine) is 18 mEq/L in the premature infant, approximately 21 mEq/L in the term neonate, rising to adult levels of 24-26 mEq/L by around 1 year [95]. Decreased bicarbonate reabsorption may be due to immature luminal Na-H antiporters or a reduced activity of the Na-K-ATPase pump which lowers the driving force for sodium.

The main site of hydrogen ion secretion is the distal convoluted tubule which in maturity can excrete hydrogen against a gradient of as much as 1000:1 (compared to gradients of 4–10:1 by secondary active transport in the proximal convoluted tubule) [98]. The ability to acidify urine is acquired by 1 month, even in premature infants, suggesting that distal tubular hydrogen ion secretion is inducible independent of the gestational age of the kidney. By 2 months, the response to an ammonium chloride load is the same as for older children and adults (once corrected for GFR) [99].
## Amino acids

Infants demonstrate a transient physiological aminoaciduria in the first few weeks of life. This is unlikely to represent a generalized disorder as not all are wasted to a similar degree [100]. Amino acids are freely filtered at the glomerulus; adults reabsorb 98-99% in the proximal convoluted tubule, against a concentration gradient, using secondary active transport across the luminal membrane and facilitated diffusion across the basolateral membrane (see Fig. 8.11). These specific transport systems exist from birth but do not function at full capacity for reasons which remain unclear [101]. Neonates and infants are more susceptible to dietary protein inadequacies. For example, taurine, which is important for retinal development, has been shown to be low in plasma of lowbirthweight infants receiving parenteral nutrition without supplementation [102].

#### **Control systems**

Plasma renin is high in the fetus and is approximately twice adult levels at term. Levels increase for the first few weeks of life and then start a gradual decline until adult levels are reached at around 6-9 years of age. As renin is the rate-limiting step in angiotensin II (AII) production, levels of the latter follow a similar pattern. All has important trophic effects on the developing renal system. Maternal administration of angiotensin-converting enzyme inhibitors (ACEi) during the second and third trimesters results in renal dysplasia, renal failure, oligohydramnios and pulmonary hypoplasia [103]. All is a potent systemic vasoconstrictor in adults; it reduces renal blood flow but preserves GFR by constriction of efferent arterioles. This pressor response is present but reduced in neonates, possibly due to high occupancy of AII receptors by existing high levels of AII.

#### Renal blood flow

The proportion of cardiac output distributed to the kidneys is 2–3% in the fetus, 4–6% in the first 12 hours of life and 8–10% by 1 week. Effective renal plasma flow reaches adult levels (corrected for BSA) by 12-24 months [104]. The neonatal kidney can autoregulate its blood flow at appropriately lower systemic perfusion pressures although the response appears to be less efficient. Intrarenal blood flow is distributed differently, with a higher proportion of neonatal blood flow going to juxtamedullary nephrons, leaving cortical nephrons at higher risk of ischemia. The rise in renal blood flow with maturation is probably due to alterations in cardiac output, perfusion pressure and renovascular resistance. While AII seems important in maintaining a basal tone, other vasoactive agents may also play a role, including ADH, atrial natriuretic peptide, adenosine and endothelin [105].

## Pediatric renal disease Acute kidney injury

Acute kidney injury (AKI) is characterized by the inability of the kidney to fulfill its excretory functions and manage fluid and electrolyte balance appropriately. Causes of AKI may be divided into prerenal injury, intrinsic renal disease and obstructive uropathies (Table 8.2). Etiology is age dependent; cortical necrosis and renal vein thrombosis are more common in neonates, whereas hemolytic uremic syndrome (HUS) is more

Table 8.2 Etiology of acute kidney injury in neonates and children

Туре	Etiology
Pre-renal	<ul> <li>Decreased intravascular volume</li> <li>dehydration</li> <li>salt wasting renal or adrenal disease</li> <li>hemorrhage</li> <li>third space losses – sepsis, trauma</li> <li>Renal hypoperfusion (with normal intravascular volume)</li> <li>cardiac failure/ tamponade</li> <li>hepatorenal syndrome</li> </ul>
Intrinsic renal disease	<ul> <li>Acute tubular necrosis <ul> <li>ischemic/ hypoxic injury</li> <li>drug induced, e.g. aminoglycosides, contrast agents</li> <li>toxins <ul> <li>endogenous, e.g. hemoglobin, myoglobin</li> <li>exogenous, e.g. methanol, ethylene glycol</li> </ul> </li> <li>Interstitial nephritis <ul> <li>drug induced, e.g. penicillins, NSAIDs, sulphonamides</li> <li>idiopathic</li> </ul> </li> <li>Rapidly progressive glomerulonephritis</li> <li>Vascular lesions <ul> <li>renal artery or vein thrombosis</li> <li>cortical necrosis</li> <li>hemolytic-uremic syndrome</li> <li>Uric acid nephropathy and tumor lysis syndrome</li> <li>Congenital abnormalities</li> <li>hypoplasia/ dysplasia with or without obstruction <ul> <li>idiopathic</li> <li>maternal drugs, e.g. ACEi, NSAIDs</li> </ul> </li> </ul></li></ul></li></ul>
Obstructive uropathy	Congenital malformations – posterior urethral valves – ureteroceles – vesicoureteric reflux – prune belly syndrome Acquired obstruction – kidney stones – tumors, e.g. sacrococcygeal

ACEi, angiotensin converting enzyme inhibitor, NSAIDs, non-steroidal anti-inflammatory drugs.

common in young children, and rapidly progressive glomerulonephritis (RPGN) is generally found in older children and adolescents.

Acute kidney injury in hospitalized children is likely to be multifactorial, with prerenal as well as hypoxic/ ischemic and nephrotoxic insults being important; children receiving stem cell transplants and undergoing cardiopulmonary bypass are at particular risk.

The incidence of AKI has been estimated at 0.8 per 100,000 population [106] and rates appear to be increasing [107]. However, the precise incidence and causes of AKI are difficult to establish in children because no epidemiological studies have been conducted using an established definition of AKI [108]. The majority of definitions in use include a change in serum creatinine levels, although it is accepted that this is an insensitive and delayed marker. More sensitive biomarkers are required to allow development and implementation of early preventive measures. Most promising are panels of investigations including plasma cystatin-C and neutrophil gelatinase-associated lipocalin, and urinary interleukin-18 and kidney injury molecule-1 [109].

#### **Prerenal injury**

Prerenal injury occurs when blood flow to the kidneys is reduced. If prolonged, this may result in a hypoxic/ ischemic acute tubular necrosis. However, this process is not sudden and the insult is reversible provided the kidney is intrinsically normal [110]. Compensatory mechanisms include the relaxation of afferent arterioles under the influence of intrarenal prostaglandins, a response which may be impaired by administration of cyclo-oxygenase inhibitors. The use of indomethacin for ductus arteriosus closure in premature newborns is associated with a significant risk of renal insufficiency [111].

Urinary parameters may assist in distinguishing prerenal from intrinsic renal injury. In response to decreased perfusion, functioning tubules will appropriately conserve sodium and water, producing concentrated urine with osmolality 400–500 mosmol/L, urinary sodium 10– 20 mEq/L and fractional sodium excretion of less than 1%. The renal tubules of neonates are relatively immature so corresponding values for renal hypoperfusion are osmolality >350 mosmol/L, sodium <20–30 mEq/L and fractional excretion <2.5%.

Tubules which have sustained injury are unable to conserve sodium in this manner, producing dilute urine with osmolality <350 mosmol/L, sodium 30–40 mEq/L and fractional sodium excretion of >2%. However, these values require that initial tubular function was normal and urinary indices are difficult to interpret in those with pre-existing renal disease or who have received diuretics [112].

#### Intrinsic renal disease

Hypoxic/ischemic AKI is characterized by early vasoconstriction followed by patchy tubular necrosis, although the mechanism of cellular injury is not yet clear. ATP depletion occurs early and leads to disruption of the cytoskeleton and loss of cellular polarity, with Na-K-ATPase found on the luminal as well as the basolateral membrane. The same mechanism has been shown to contribute to kidney dysfunction in transplanted kidneys [113]. Alteration of vascular tone regulation by nitric oxide and endothelin, as well as the generation of reactive oxygen and nitrogen molecules, may also play a role [114].

Nephrotoxic injury may be caused by a wide variety of agents. Aminoglycoside toxicity is common and thought to be related to lysosomal dysfunction of proximal tubules. The incidence is dose and duration dependent, but is reversible once therapy is discontinued. Hemoglobin or myoglobin in urine produces tubular injury via several mechanisms, including vasoconstriction, precipitation in the tubular lumen and/or heme protein-induced oxidant stress [115].

Uric acid nephropathy and tumor lysis syndrome are most commonly seen in children with acute lymphocytic leukemia and B-cell lymphoma. The pathogenesis is complex, but an important mechanism relates to the precipitation of uric acid crystals in either tubules or the renal vasculature. The rapid breakdown of tumor cells can also cause severe hyperphosphatemia, and the precipitation of calcium phosphate crystals may also contribute to AKI.

#### Prognosis

Outcome in AKI is dependent upon the underlying cause. Mortality is higher when AKI is a component of multisystem failure, compared with prerenal or intrinsic renal disease. Renal function recovers in the majority of cases, although one study revealed that 34% of 176 children had reduced renal function or were dialysis dependent on discharge from a tertiary center after an episode of AKI [116]. However, even when renal function recovers initially, children with AKI are at risk of subsequent renal impairment. This is true for all ages and not only for conditions associated with significant nephron loss, such as HUS and cortical necrosis, but also for hypoxic/ ischemic and nephrotoxic insults [117,118].

## Chronic kidney disease

Chronic kidney disease (CKD) is defined as either kidney damage or GFR <60 mL/min/1.73 m<sup>2</sup> for >3 months [119]. It is characterized by progressive decline in renal function associated with significant morbidity and mortality. CKD may present at any age from the antenatal period onwards; because of the renal role played by the placenta, even

Source: Ansell et al [120].

lethal malformations may not result in biochemical disturbance for several days. Causes of established renal failure (ERF) are given in Table 8.3 [120].

Cardiovascular disease is much more common in children with ERF than age-matched controls, and accounts for around 20% of deaths in children undergoing dialysis [121]. Growth retardation is proportional to the decrement in GFR, and is more common in children undergoing dialysis than those being treated conservatively or with a transplant. Factors contributing to poor growth include metabolic acidosis; renal osteodystrophy; malnutrition; glucocorticoid therapy; and reduced responsiveness to growth hormone [122]. A variety of neurocognitive deficits have been identified, from severe developmental delay to more subtle verbal and attention deficits; improvements in dialysis, correction of malnutrition and decreased aluminum exposure have improved outcomes.

Treatment of CKD in children is not easy; dialysis and the access it requires pose particular problems (see Chapter 29). Renal abnormalities often occur with other congenital defects or as part of a syndrome and these may have a bearing on the appropriateness of treatment.

#### Polycystic kidney disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary renal disease and affects 1:400–1000 livebirths. It causes 5–10% of cases of ERF worldwide and affects all races equally [123]. Two genes are responsible for the majority of cases: *PKD1* on chromosome 16 and *PKD2* on chromosome 4 account for 85% and 15% respectively. The genes encode transmembrane proteins polycystin 1 and 2 which interact with each other, and possibly the cytoskeleton, although their precise roles remain obscure [124].

Autosomal dominant polycystic kidney disease usually presents in adult life, but 2% of cases present with severe manifestations in childhood, and prenatal diagnosis has been reported [125]. Epithelial-lined cysts arise from about 5% of tubules and detach from the parent tubule (usually at >2 cm). There is massive enlargement of the kidneys secondary to cyst growth, and progressive renal impairment. Associated features include hepatic cysts and intracerebral aneurysms. Presentation is usually with hematuria, hypertension or renal impairment. The decline in renal function is variable but survival on dialysis and post transplant is better with ADPKD than with other forms of ERF [126].

Autosomal recessive polycystic kidney disease affects 1:10–40,000 livebirths and is caused by mutations of the *PKHD1* gene on chromosome 6 which encodes a protein polyductin. Renal cysts arise from the distal collecting duct and cause progressive renal impairment without renal enlargement. Congenital hepatic fibrosis is a universal feature. Presentation is variable, with renal symptoms more common in early life and hepatic complications later. Renal failure *in utero* may lead to presentation with the oligohydramnios sequence, and those who present with severe renal disease in infancy have a high mortality. In older children, features of hepatic fibrosis and portal hypertension tend to dominate the clinical picture. Combined renal and hepatic transplantation is used successfully.

Renal cysts also occur in other disease states. Nephronophthisis (NPH) is a chronic tubulointerstitial nephritis. The infantile form is characterized by cortical microcysts and progression to ERF by 5 years of age, whereas cysts occur much later in the juvenile form [127]. Up to 20% of patients with tuberous sclerosis complex (TSC) will have multiple, bilateral renal cysts. The gene *TSC2*, which accounts for around 75% of sporadic cases of TSC, is found within 48 base pairs of *PKD1* on chromosome 16.

#### Prune belly syndrome

Prune belly syndrome (PBS) occurs in 1:29,000 to 1:40,000 livebirths [128]. It is 20 times more common in males, four times more common in twins [129], and infants of younger mothers appear to be at greater risk [130]. The syndrome comprises a triad of abnormal abdominal muscles, bilateral cryptorchidism and dilated ureters [131]. It takes its name from the characteristic wrinkled and prune-like appearance of the abdominal wall in which normal musculature fails to develop. Urinary tract abnormalities include a dilated, thick-walled bladder, tortuous, dilated and thick-walled ureters, and kidneys which may be hydronephrotic or dysplastic.

The mechanism by which PBS occurs remains unclear. Some theories emphasize early urethral obstruction which leads to bladder distension, degeneration of the abdominal wall musculature and prevention of testicular descent. However, a more convincing theory proposes abnormal mesenchymal development, termed mesodermal arrest, between weeks 6 and 10 as the underlying abnormality. This is supported by findings of abundant collagen, smooth muscle, fibrous and connective tissue throughout the renal tract, features which are difficult to explain with a purely obstructive lesion [132].

Mortality has traditionally been high, but the use of *in utero* vesicoamniotic shunts appears to be improving matters. Renal failure occurs in around 30% of survivors due to renal dysplasia and from scarring secondary to infections. The abdominal wall abnormalities do not appear to increase the complication rate associated with peritoneal dialysis if it is required [133].

## Introduction

*Children are not small adults.* Their body hydric volumes, content, and its partition between central and peripheral blood, their metabolic rates, their pulmonary volumes and cardiac and hemodynamic variables markedly differ from those of adults. However, *children are also small adults* in that they have the potential of their future in their genes. Some phenotypic expression may be absent in early life, but most genetic traits are fully expressed at birth.

## Development of uptake, distribution, protein binding, metabolism and excretion systems for drugs in the fetus, newborn, infant and child [1]

## **Uptake, disposition and elimination** Volumes, flows, rates

Body composition differs markedly among neonates, infants and adults (see Chapter 10). This is particularly

important for total body water, which decreases from 80-85% of bodyweight in 26 and 31 week' gestation infants to 75% at full term and to 60% in adolescents. The extracellular compartment, which is mainly regulated by the sodium intake after birth, decreases from 65% of bodyweight at 26 weeks' gestation to 40% at full term and 20% by 10 years [2,3]. Therefore, the volume of distribution of hydrophilic drugs, e.g. succinylcholine, is higher in newborn and infants than in older children. Membranes are also immature at birth. For example, drug efflux systems are not fully mature at birth, making cerebral bio-availability of numerous hydrophobic (the term "hydrophobic" will be used instead of "lipophilic" throughout the text) drugs higher in newborns than in children or adults [4,5]. Cardiac output is also different and is closely related to body surface area. The volume of the central compartment of volatile anesthetics is higher in neonates than in adults on a weight basis.

## Scaling [6]

Until recently, the only way of correcting for these differences was to use the rule of three, i.e. to divide by 70kg or 1.73 m<sup>2</sup> and multiply by the weight or surface area of

the subject. Different approaches are used today [7–9]. Allometric scaling considers that extensive parameters, such as metabolic rates or clearances, are related to the corresponding adult parameters raised to an empirical power:

$$CL_{Ped} = CL_{Adult} \left(\frac{BW_{Ped}}{BW_{Adult}}\right)^{\chi}$$

where  $CL_{Ped}$  and  $CL_{Adult}$  are the pediatric and adult parameters respectively (clearance in this example) and  $BW_{Ped}$ and  $BW_{Adult}$  are the pediatric and adult bodyweight respectively; *x* is the empirical scaling factor. This approach has excellent predictive powers, when incorporated into pharmacokinetic (PK) or pharmacodynamic (PD) models (Fig. 9.1) [10]. Allometric scaling cannot account for all the changes observed during development. Therefore, other approaches, such as physiological models, may provide more accurate results [9,11].

#### Uptake and absorption

The gastric pH rapidly increases from 1–3 to 5–7 immediately after birth and remains basic during the first month of life [12]. Gastric emptying and intestinal transit time are also slower in newborns than in infants and adults. The rate and extent of gastric and intestinal absorption are variable, due to immature membrane transport, pancreatic enzyme activity, and bile salt secretion. Oral medications may have erratic bio-availability and absorption rates in this age group. Also, the first-pass effect is often reduced in neonates due to immature liver metabolism. Consequently, drug potency may increase in some cases.

Absorption by other routes is often rapid in infants and children. For example, after topical anesthesia of the pharynx and larynx, peak concentrations of lidocaine may appear 2–4min later [13]. Lidocaine toxicity has occurred following infiltration of the drug for laceration repair in young patients. Because the rate and extent of absorption depend on the drug and site of injection, this topic will be discussed in the PK section for each drug.

# Transport of molecules across membranes: the effect of transporters

Drugs are small molecules that are susceptible to passive or active transport through biological membranes. Uptake and elimination transporters are found in all cell membranes. Two superfamilies of transporters, the solute carrier (SLC) and ATP-binding cassette (ABC), control molecular traffic across membranes [4,14]. While SLC transporters are usually for uptake, some are involved in bidirectional transport. ABC transporters are efflux pumps that remove chemicals from the cell.

The organic anion transporting polypeptides (OATPs), the organic cation transporters (OCTs), and the organic anion transporters (OATs) are the principal solute carrier transporters. These membrane proteins are localized to the sinusoidal boundary in heart, liver, brain, kidney, and placenta. One SLC family, the multidrug and toxin extrusion transporters (MAETs), excretes oxaliplatin, cimetidine, metformin, and procainamide from cells.

ATP-binding cassette transporters comprise the P-glycoprotein (P-gp), which is encoded by a variety of multidrug-resistant (MDR) genes, and the MDRassociated proteins. These are excretion pumps that transport endo- and xenobiotics such as unconjugated bilirubin and anticonvulsants. Like SLC transporters, these transporters are ubiquitous in the blood-brain barrier (BBB), blood-cerebrospinal fluid (CSF) barrier, gut and intestinal wall, hepatocytes, and renal tubular cells. P-gp is located at the luminal membrane of endothelial and epithelial cells. It appears in human brain as early as 22 weeks' gestational age (GA) and is almost totally mature at birth [15]. All these transporters are highly polymorphic. In conjunction with polymorphism of the 3A4 and 2C9/19 isoforms of the cytochrome P450 or of UDPglucuronosyltransferase (UGT) 1A and 2B, polymorphism of P-gp increases resistance to most antiepileptic drugs (phenytoin, carbamazepine, phenobarbital, gabapentin, felbamate, topiramate, lamotrigine, valproic acid, diazepam, lorazepam).

To date, little is known about the ontogeny of these transporters. The human fetal liver has only a small number of transporters. mRNA expression of SLC and ABC transporters increases from birth to 4 years of age and full expression is attained by 7 years [16]. Similar findings have been reported in the kidneys and gut.

P-glycoprotein has been detected as early as 22–26 weeks of human gestation in some parts of the brainstem.

By term, P-gp seems to be fully functional. Multiple drug resistance protein 1 (MRP1) is detected in the fetus at 22–26 weeks' gestation and has almost the same intensity as in adults. This is consistent with observations that the choroid plexus and tight junctions are mature before birth, which makes the blood–CSF barrier functional [5,17]. Lipids and possibly small hydrophobic molecules can cross the barrier with less selectivity until 6 months of age.

# Disposition of drugs: transport in the blood and distribution

After administration, drugs disperse within the body. Because cardiac output and the central compartment volume are larger than those of adults, distribution of drugs to target organs occurs more rapidly in young patients. Sophisticated models that tentatively explain the relationship between age, volumes, clearance, and the dose required to produce anesthesia have been described. However, population PK-PD models using age as a covariate and parameters such as the exit rate constant from the effect compartment (ke0) and the pseudo-steady state concentration leading to half maximum effect (Cpss50 or Ce50) are now used to characterize the disposition of drugs from the central to the effect compartment and the resulting effect [18,19]. The ke0 is equivalent to the rate constant for transfer from the central compartment to the effect compartment at steady state. This parameter (or T<sup>1</sup>/<sub>2</sub>ke0, the corresponding half-life) is the best indicator of a drug's rate of accessing its target. It is directly related to time to peak action. Ce50 is the concentration of the drug in the (virtual) effect compartment and is approximated by Cpss50, the drug concentration in the effect compartment at steady state. Drugs also distribute in deeper compartments, depending on plasma and tissue protein binding, hydrophobicity, pKa, steric bulk, and clearance when steady state is not attained. This distribution process is important because it is the main factor that causes differences in delay of awakening after short or prolonged administration of drugs (volatile anesthetics, propofol). This has led to the concept of context-sensitive half-time [20]. In addition, distribution of drug into deep compartments (including gastric and bowel contents) may cause recirculation of drugs like fentanyl when cardiac output and body temperature increase after surgery.

## **Protein binding**

Many drugs are bound to serum proteins, mostly albumin (human serum albumin – HSA) and  $\alpha$ 1-acid glycoprotein (AGP). Acidic drugs like thiopental and propofol bind preferentially to HSA and basic drugs to AGP. Proteinbound molecules may or may not cross barriers, depending on factors such as the nature of binding (rate of association-dissociation to the receptor) and the organ transit time [21,22]. In the liver, the presence of the Disse space slows transit times. Clearance of drugs metabolized by the liver is frequently independent of protein binding [23]. In organs with rapid transit times, such as the brain and heart, protein binding often controls the amount of drug absorbed by the organ.

Serum albumin is the most abundant protein in plasma (approximately  $0.6 \,\mathrm{mM}$ ). It contains three homologous helical domains (I–III) with binding pockets. HSA has two major high-affinity binding sites with association constants in the range  $10^4$  to  $10^6 \,\mathrm{M^{-1}}$  [24,25]. Site 1 binds warfarin, thiopental, propofol, and many other drugs. Site 2 binds endogenous carboxylic acids (eicosanoids, fatty acids), propofol, volatile anesthetics and most nonsteroidal anti-inflammatory drugs (NSAIDs), often in a stereospecific and allosteric manner. Some metabolites of NSAIDs bind covalently, leading to permanent occupation of the site. Bilirubin also binds to multiple sites on HSA [26]. Drugs such as propofol can displace bilirubin, increase the amount of free bilirubin, and possibly produce kernicterus in newborns [24].

 $\alpha$ 1-Acid glycoprotein, also called orosomucoid (ORM), is an acute-phase protein. At birth, AGP concentrations are about one-third to one-fourth of adult concentrations and increase slightly over the next 9-12 months [27,28]. The first consequence of reduced AGP is increased free drug that can cross barriers (blood-brain, blood-heart), causing increased drug effects. The second consequence of the increased amount of free drug is a greater apparent total hepatic clearance than is expected for drugs with low hepatic clearance, e.g. bupivacaine. AGP has 2-3 high-affinity sites that mostly bind basic drugs [29,30]. However, some acidic drugs (e.g. phenylbutazone) and neutral drugs also bind to AGP. Three genetic variants (A, F1 and S) cause two main forms (F1S and A) that differently bind xenobiotics. During inflammatory processes, the AGP concentration and its affinity for drugs markedly increase. During the postoperative period, the AGP concentration almost doubles (Fig. 9.2). For drugs with low to moderate hepatic extraction ratios, such as bupivacaine, this may produce time-dependent changes in total clearance (but not in the intrinsic clearance of the free drug) after surgery (Fig. 9.3) [31]. Like most basic drugs, local anesthetics and phenylpyperidine opioids (fentanyl, sufentanil, alfentanil) are primarily bound to AGP.

#### Protein-drug adducts [32,33]

Binding of drugs to proteins may be entropy driven (passive phenomenon, as with xenon) or enthalpy driven (usually exothermic). This causes strong binding of the drug (covalent, van der Waals forces). Covalent binding of drugs or their metabolites to tissue or plasma proteins produces mostly toxic protein–drug adducts. These adducts often induce immunological reactions that cause

**Figure 9.2**  $\alpha$ 1-Acid glycoprotein (AAG) concentrations in infants according to their age. AAG concentrations are very low at birth and progressively increase with age. The concentration of AAG increases rapidly after an inflammatory insult. Circles are individual values measured before surgery and triangles are the values measured 2 days later. AAG concentrations increased in all patients after surgery. Reproduced from Meunier et al [27] with permission from Lippincott Williams and Wilkins.

hypersensitivity. The toxicity of halothane, paracetamol (acetaminophen), diclofenac, sulfonamides, and valproic acid is the result of adducts.

During cardiopulmonary bypass, the concentration of unbound propofol increases significantly due to decreased protein binding [34]. This is probably true for most drugs with strong protein binding.

# Metabolism and clearances including genetic polymorphism [35]

Renal function (glomerular filtration rate and tubular function) is immature at birth. Therefore, elimination of most renally excreted drugs and their active metabolites is impaired until 2–3 years of age. For example, the-ophiline and caffeine have very low clearances at birth. In the same way, morphine-6-glucuronide, which is an active metabolite of morphine, accumulates in premature and full-term infants, increasing the risk of respiratory depression [36–38]. Drugs such as aminoside antibiotics may also be toxic. Prostaglandin concentrations are elevated in newborns to maintain an effective glomerular filtration rate. By blocking the effects of prostaglandins, NSAIDs may induce renal hypoperfusion and renal failure [3].

## Hepatic metabolism

Most drugs used for anesthesia, preoperative care, and pain control are metabolized by the liver. Hepatic metabolism of xenobiotics is by phase 1 and phase 2 reactions [39]. Phase 1 reactions are characterized by microsomal oxidative metabolism that inactivates or sometimes acti-

**Figure 9.3** Unbound (A) and total (B) bupivacaine concentration in plasma after epidural administration (bolus at T0 followed by a continuous infusion of 0.375 mg/kg/h for 2 days). Black lines are individual data and blue lines are population value fitted using NONMEM. The unbound concentration reaches steady state in less than 12 hours whereas the total concentration has not reached steady state 48 hours after initiating the infusion. The continuous increase in  $\alpha$ 1-acid glycoprotein concentration caused by the inflammatory process increases protein binding. However, the unbound concentration, which is the toxic moiety, is at steady state because intrinsic hepatic clearance remains constant. Reproduced from Meunier et al [27] with permission from Lippincott Williams and Wilkins.

vates the drug (Table 9.1). Phase 2 reactions involve conjugation and take advantage of the electrophilic properties of either the original drug or of the product of phase 1 metabolism (Table 9.2) [40,41]. Phase 2 reactions occur mainly in the liver but can occur in the gut wall, the kidney parenchyma, and the lung. Enzymes involved in phase 1 reactions are located primarily in endoplasmic reticulum, while phase 2 conjugation enzyme systems are primarily cytosolic.

Cytochrome P450 is a family of enzymes located primarily in the centrilobular portion of hepatic lobules. CYP3A4 is the most abundant isoform (Fig. 9.4) [42–46]. Two factors characterize the importance of an isoform for metabolizing a given molecule: the capacity, i.e. the abundance of the enzyme, and the affinity and rate of metabolism (Km and vm in the Michaelis–Menten equation). Xenobiotics may be substrates for, inhibitors of or

Other isoforms involved: 2C8/9: most NSAIDs, phenytoin, barbiturates, ketamine and to a small extent caffeine; 2C19: diazepam, barbiturates and proton pump inhibitors. CYP2C19 is subject to important polymorphism. The isoform(s) involved in the metabolism of thiopental and etomidate remain(s) to be characterized.

Abbreviations: +, substrate for the CYP isoform; I, inhibitor of the CYP isoform; mo, month after birth; yr, year after birth; w (GA), week (gestational age). (1) CYP3A7 is active in the fetus as early as 50–60 days after gestation, with a progressive switch to CYP3A4 after birth.

(2) The 2E1 isoform is responsible of the formation of toxic metabolites involved in hepatic toxicity.

(3) Desflurane is the least metabolized agent; sevoflurane metabolism is very low before the age of 4yrs because of immaturity of CYP2E1.

(4) Propofol is also metabolized by CYP2C to a lesser extent.

inducers of the reaction and cause drug–drug interactions that have clinical consequences. Maturation of these enzymes is variable and occurs from early in intrauterine life to several years of age. For example, morphine elimination via UGT is impaired until 9 months of age [36,37,47] whereas fentanyl, which is metabolized by the CYP3A4/3A7 isoform of cytochrome P450, is adequately metabolized by very young preterm infants [48]. Ropivacaine metabolism by CYP1A2 is not fully mature before the age of 4–6 years [49].

## Children are small adults [50]

Individuals have the potential of their future in their genes. Some phenotypic expression may be absent early

in life, but most genetic traits are fully expressed at birth. The most common factors influencing drug dosing are related to genetic polymorphism of metabolizing enzymes [51–57].

Polymorphism of CYP2D6 may increase rates of biotransformation of tramadol to the opioid receptor agonist O-desmethyl tramadol (M1) [57,58]. Codeine is also metabolized to morphine by the CYP2D6 [59,60]. One death is suggested to have occurred when a breast-feeding mother extensively metabolized codeine to morphine postoperatively [61]. The increased amounts of morphine in breast milk caused severe apnea and death of the infant. Toxic events have also been reported in infants and young children treated with codeine for more

NAT2, N-acetyltransferase type 2; SulfoT, sulfotransferase.

Diazepam strongly inhibits the metabolism of morphine and codeine; ketamine inhibits the metabolism of morphine; ranitidine inhibits the metabolism of morphine and acetaminophen. Rifampin is an inducer of metabolism of codeine, morphine, acetaminophen, lamotrigine, and propafenone. Phenobarbital (and possibly thiopental) and phenytoin are inducers of acetaminophen metabolism, which may enhance its toxicity.

(1) Lack of the 1A1 isoform induces the autosomal recessive Crigler-Najjar and Gilbert syndromes.

than one day or children with renal failure [62]. On the other hand, about 5–8% of Caucasians and 20–25% of Japanese metabolize codeine poorly and do not receive analgesic effects from the drug [63].

## Pharmacokinetics and pharmacodynamics of inhaled drugs

Gases and vapors were the first agents used for general anesthesia (ether in 1842, nitrous oxide in 1844 and chlo-

roform in 1847). Their mechanism of action is far from fully elucidated, even today [64,65]. A thermodynamic effect on biological membranes has long been thought to be their mode of action. Now specific effects of these drugs on ion channels and receptor are favored. However, a body of facts leads one to think that there is a complex combination of these actions. The Meyer–Overton theory (and other related theories) is based on the observation that anesthetics non-specifically disturb the physical organization of membranes by solubilizing into lipids. There is still debate on the validity of the Mayer–Overton rule [66,67]. Interestingly, xenon, which is a rare gas, binds non-specifically to proteins, mainly by weak van der Waals forces [68,69].

A unified theory combining non-specific thermodynamic effects on the lipid bilayer and direct inhibition on excitatory neuronal channels is emerging, tentatively explaining the specific effect of anesthetics on the spinal cord [70,71]. Indeed, all anesthetic agents provoke immobility, even when noxious stimuli induce sympathetic responses. In addition, isobolographic analysis and response-surface curves of a combination of agents (both IV and volatile) show only additivity, which is a strong argument for a common mechanism of action [72–74].

In the usual conditions of pressure and temperature, nitrous oxide and xenon are gases whereas halogenated anesthetic agents are in liquid form (desflurane boils at 22.8°C, thus necessitating special vaporizers) (Table 9.3).  $N_2O$  is now the single most important ozone-depleting substance emitted [75]. In addition, halogenated volatile anesthetics (and  $N_2O$ ) are greenhouse gases. Twenty-year global warming potential (GWP (20)) values and the carbon dioxide equivalent calculated at 1 minimum alveolar concentration (MAC) show a ratio of 2.2, 1 and 26.8 for isoflurane, sevoflurane and desflurane respectively [76].

#### Nitrous oxide

Nitrous oxide (N<sub>2</sub>O) is a gas with a molecular weight of 44Da and a blood/gas distribution ratio of 0.47. At an inhaled concentration of 70%, rapid equilibrium takes place between the inspired and expired fractions of N2O [77–80]. The kinetics of N<sub>2</sub>O is rapid; the deep peripheral compartment is no greater than 8-10 L. Severinghaus first recognized this when he demonstrated that N2O does not follow the Kety principle, thus leading to the first description of context-sensitive times. When administration is discontinued, elimination is rapid. Even after several hours of administration, elimination is only slightly delayed. In addition, because N<sub>2</sub>O is rapidly diffusible, the phenomenon of diffusion hypoxia or "Fink effect" may occur when room air is administered to patients previously breathing a mixture of  $N_2O$  and  $O_2$  [81,82]. Because of its ability to diffuse into cavities, N<sub>2</sub>O should be used with caution when middle ear or bowel pressures are critical. N<sub>2</sub>O has a MAC of at least 104% [83] and an additive effect with volatile and IV anesthetics. In addition, it has euphoric, neuroprotective, analgesic and antihyperalgesic properties, probably because of its effect on the N-methyl-D-aspartate (NMDA) receptor [84,85]. This is why a 50% mixture of N<sub>2</sub>O and O<sub>2</sub> is often used outside the operating room for sedation and analgesia. Like all anesthetics, N<sub>2</sub>O has vasodilating properties. It moderately increases CBF (cerebral blood flow) and decreases vascular resistances. The net effect on intracranial pressure (ICP) varies, but it usually increases [86].

### Xenon

Xenon (Xe) is the heaviest non-radio-active natural noble gas (molecular weight (MW) 131.3) [87]. It is colorless, odorless, and non-flammable. It is a dense monoatomic gas with a density of 5.76 and a high viscosity of 2.3 Pa/s (both under normal conditions). The high viscosity may theoretically render its use difficult in patients with increased airway resistance and in premature infants [88]. Its blood/gas distribution ratio is 0.14; its MAC is 70%. Xenon crosses biological barriers easily and reaches 90% equilibrium between inspired and alveolar gas concentration after 5 min of administration.

Despite its classifications as a noble gas, xenon binds to proteins but does not undergo biotransformation [89]. Because of its large atomic polarizability, xenon binds within cavities in all proteins [69,90]. This is why xenon has been considered to act by physical properties, such as the Meyer–Overton rule or the London dispersion forces (or weak van der Waals forces). Like N<sub>2</sub>O, xenon acts as a low-affinity use-dependent NMDA receptor antagonist, but while xenon inhibits ketamine-induced c-fos expression in the rat cortex, nitrous oxide enhances it [91,92]. In addition, xenon is a potent antinociceptive agent. This effect is thought to be independent of the opioid or adrenergic pathways. The mechanisms involved seem different from those implicated in neuroapoptosis caused by ketamine or halogenated agents.

Altogether, these data have led to the suggestion that xenon, uniquely among compounds with known NMDA receptor antagonist properties, may exhibit neuroprotective action without co-existing neurotoxicity. In preliminary studies, xenon successfully protected the brain following neonatal asphyxia [93]. Another interesting property of xenon is cardiovascular stability and cardioprotection. Xenon does not alter myocardial contractility nor does it markedly change vascular tone. Xenon preconditioning before an ischemic insult has been observed at both the neuronal and myocardial levels. Like local anesthetics, xenon modulates the inflammatory response of the immune system by decreasing the production of tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-6 by monocytes in response to stimulation by lipopolysaccharide (LPS) [91]. However, further studies are needed to assess these beneficial effects. The problem of industrial production and cost will certainly limit the use of xenon in the foreseeable future.

## **Halogenated agents**

Halogenated agents are small molecules with MW from 168 to 200 Da (see Table 9.3) [79,94–96]. They are mildly hydrophobic and dissolve rapidly in blood and tissue. Halothane is an alkane substituted with bromide, chloride and fluoride. Isoflurane, sevoflurane and desflurane are ethers, substituted with chloride and

	Halothane	Isoflurane	Desflurane	Sevoflurane	N <sub>2</sub> O	Хе

fluoride (isoflurane) or only fluoride (desflurane and sevoflurane). Halothane, enflurane and isoflurane are chiral drugs, i.e. they have an asymmetric carbon, and they are marketed as racemic mixtures. Sevoflurane is non-chiral. Degradation of sevoflurane with CO<sub>2</sub> absorbents induces the formation of compound A, which is toxic for the kidney of rats [97]. However, the risk in humans seems almost non-existent [98].

## Mode of action

The principal effect of anesthetic agents is to provoke immobility through effects that occur at the spinal cord level. Apart from the Meyer–Overton theory (see general considerations above), the mechanism of action of halogenated agents is thought to be related to interactions with ion channels and receptors in spinal cord and brain [64,65,99]. They simultaneously enhance the activity of gamma-aminobutyric acid (GABA) and glycine receptors and inhibit glutamate receptors ((2-amino-3-(5-methyl-3oxo-1, 2-oxazol-4-yl)propanoic acid) (AMPA), kainate and NMDA receptors). They also inhibit the neuronal nicotinic receptors, a mechanism that is common with  $N_2O$  and xenon. NMDA inhibitors are known to protect against ischemia reperfusion and to suppress the hyperalgesia induced by surgery. However, they also promote apoptosis through the mitochondrial pathway, particularly in the developing brain [100–102].

#### **Pharmacokinetics**

All halogenated agents bind to HSA in the following order: desflurane>isoflurane>halothane>sevoflurane [99,103–105]. HSA binds approximately 3 moles of anesthetic/mole of HSA.

Halogenated agents are absorbed and eliminated by the blood–alveolar interface. These agents, which are hydrophobic, distribute in deep compartments, and trace amounts can be measured in expired gases several weeks after anesthesia. Their hydrophobicity allows rapid transfer to the effect compartment and absorption by the fat. The agents with low solubility (see Table 9.3) rapidly reach saturation, i.e. pseudo-steady state [95,106]. The consequence is a more rapid induction of anesthesia and less context-sensitive increase in decrement time. Because an important amount of data is available on the solubility of these molecules in organs, as well as regional blood flows and volumes, physiological kinetic models have often been used to describe the time-course of halogenated agents in the body. Classic compartmental models are now preferred, mainly because they allow simple interpretation of basic parameters such as volumes, clearance and half-times, and easy application to clinical situations [107–112].

The pharmacokinetics of halogenated agents is best described by first-order kinetics, using linear mammillary models. After inhalation of a gas containing the vapor, transfer from alveolar gas to blood is rapid, and distribution to peripheral compartments, including brain (effect compartment), occurs. Elimination occurs via the same route, except for the variable amount of drug that is metabolized by the liver. The alveolar fraction of vapor (FA) is considered to reflect the arterial concentration and the inspired fraction (FI) the concentration in the invasion compartment. During induction of anesthesia, the FA/FI ratio (alveolar to inspired fraction) versus time reflects the rate of invasion (wash-in). After drug administration is discontinued, the ratio of alveolar fraction to alveolar fraction at the time of discontinuation (FA/FAO) reflects elimination (wash-out). The end tidal fraction (FET) (%) or end tidal partial pressure (mmHg) usually approximates FA.

The uptake and elimination of volatile anesthetics depend on cardiac output and the extent of ventilation. As always in pharmacokinetics, there is no direct correspondence between physiological and kinetic compartments. The volume of the central compartment depends on cardiac output and clearance; clearance depends on both minute ventilation and cardiac output. In an analogy with hepatic clearance of drugs eliminated by liver metabolism, ventilation is equivalent to intrinsic (metabolic) clearance and cardiac output (CO) to hepatic blood flow. Because CO is a major scaling factor, it would be interesting to have data relating CO to uptake and elimination in pediatrics [113]. It is also important to remember that 40% of halothane entering the body is eliminated by hepatic metabolism [107,108,114,115].

#### Context-sensitive decrement times [116]

Because the kinetics is multicompartmental (steady state is not attained before several days of administration, mainly because intercompartmental clearances are very slow), the observed decline is highly context sensitive [72,110]. After a short period of administration (less than 30 min), the decline of FA/FAo of sevoflurane or desflurane is faster than that for N<sub>2</sub>O. This is due to the fact that N<sub>2</sub>O reaches near steady state by 20–30 min whereas sevoflurane or desflurane are at about 60–80% of steady state by this time. After 90 min, the difference between agents becomes clinically significant (Fig. 9.5). As for the effects of minute ventilation and cardiac output on kinetics, pediatric data describing decrement times as a function of age are lacking. Moreover, most articles are now based on data files generated with the aid of software (GasMan®) and do not verify their adequacy with data from patients.

#### Pharmacodynamics

The measure of anesthetic action has been the subject of research for more than 40 years. The initial criterion was the MAC, leading to a specific effect in 50% of the patients studied [117]. The MAC is the equivalent of Ce50 for IV agents. The concept of the MAC is based on the strong assumption that alveolar concentration is almost immediately in equilibrium with the cerebral concentration and adequately reflects the concentration at the neuronal effect site. MAC is defined as the alveolar concentration of volatile anesthetic agent (in oxygen or in a mixture of oxygen and N<sub>2</sub>O) that abolishes 50% of the response to skin incision. One may also consider other effects, such as the cardiovascular depression induced by these agents, depression which is particularly important in neonates and in infants. The MAC has a great number of variations that have appeared over time: MACINT, which is the MAC for tracheal intubation, MACBAR, which is the MAC for abolition of sympathetic response to incision (tachycardia and increase in blood pressure), MACEXT, which is the MAC for deep tracheal extubation, etc. [118–122].

The MAC of isoflurane was found to be lower in preterm babies than in term neonates. This relatively low MAC in immature babies is thought to be a general phenomenon of all volatile anesthetics, although we lack data in this age group. At birth and during the first months of life, MAC is at its peak value for all drugs (except for halothane, which attains its peak value several months after birth). After the first year of life, there is a reversal in the relationship between age and MAC; MAC decreases with age (Fig. 9.6). In summary, infants aged 6 months have a MAC 1.5–1.8 times that observed for a mean adult aged 40 years [123–126]. Also, preterm infants are supposed to be more sensitive to cardiac depression than neonates, who are also more susceptible than older children and young adults [127].

The MAC gives the probability of inappropriate anesthesia in an average patient. The possibility of modulation of anesthesia depth in line with the patient's status now exists using several indexes obtained by EEG monitoring, such as the BISpectral Index (BIS) and the spectral entropy or Narcotrend Index [128–131]. In adults, numerous studies have shown that the population value of T½ke0 given by these indices was similar and close to the values expected from clinical experience (see Table 9.3) [132–136]. However, great interindividual variability has been observed, which is similar to that observed with

**Figure 9.5** Context-sensitive decrement times in the rich vascularized compartment (VRG), i.e. brain, heart, kidney, liver, according to the duration of volatile anesthetic administration. Reproduced from Eger and Shafer [72] with permission from Lippincott Williams and Wilkins.

propofol, for example. In addition, the correlation between different MAC methods is difficult because, as with IV agents, all these EEG-derived algorithms are perturbed because hypnosis and analgesia are measured simultaneously. In children older than 2 years, it appears that the correlation between BIS IC50 and the different MAC measures is similar to that of adults [133,137]. To date, none of these monitors can correctly predict hypnosis in infants, perhaps with the exception of using regional and general anesthesia together (Fig. 9.7) [138–141].

# Effects of volatile anesthetics on the different functions

Isoflurane and desflurane are pungent and can cause airway irritation during induction of anesthesia [142]. Only halothane – which is less and less used because of its lower margin of safety compared to other agents (see below) – and sevoflurane are used for anesthesia induction. This pungency does not increase the risk of laryngospasm after induction.

#### Specific action on the central nervous system

Volatile anesthetics depress neuronal activity in a concentration-dependent manner. High concentrations

depress the electroencephalogram (EEG) and burst suppression occurs at concentrations greater than 2 MAC [143]. Sevoflurane induces epileptic activity with epileptiform discharges at concentrations usually greater than 1. 5 MAC, but this also occurs at lower concentrations in some patients [144]. Convulsion-like movements may accompany these EEG signs. The morbidity of these manifestations is unknown, and no sequelae have yet been reported. However, it is recommended not to use sevoflurane concentrations in excess of 6% for induction of anesthesia and to maintain anesthesia with concentrations not higher than 1.5 MAC.

Volatile anesthetics are often associated with agitation during emergence from anesthesia and for many minutes afterwards [145,146]. Emergence agitation is more frequent with newer agents such as sevoflurane. Concomitant administration of opioids, propofol, regional anesthesia or ketamine may prevent emergence agitation [147]. Awareness is more frequent in children than in adults, but implicit memory seems to be less of a concern in pediatric patients [148,149]. Both midazolam and propofol inhibit conscious memory, but midazolam does not prevent implicit memory if present [150].

**Figure 9.6** Minimum alveolar concentration of isoflurane, sevoflurane, and desflurane according to age. Premature infants have a lower MAC than neonates. Reproduced from Nickalls and Mapleson [126] with permission from Oxford University Press.

**Figure 9.7** BIS values in 6 (mean)  $\pm$  3 (SD) year old children as a function of end-tidal (ET) sevoflurane. All patients had a regional block. Dotted lines are individual values and solid lines are Bayesian values calculated using NONMEM. Interestingly, in the absence of a nociceptive signal, the relationship between BIS value and ET sevoflurane is excellent and exhibits a negative correlation with age. Data from Kern et al. [141].

Apart from the possible neuroapoptosis induced by volatile anesthetics in infants and young children (see above), volatile anesthetics exert a protective effect on the nervous system that is similar to that observed for the heart [148–151]. This effect seems to be independent of the inhibition of the NMDA receptor. In addition to a direct neuroprotective effect, preconditioning with isoflurane, sevoflurane, and desflurane appears efficacious in protecting against focal ischemia and apoptosis induced by ischemia or hypoxia reperfusion. This effect seems related to the activation of various two-pore potassium channels and to the activation of inducible NO syntheses. Preconditioning seems to be particularly promising for neonatal cardiac surgery.

All volatile anesthetics increase CBF [152,153]. This increased blood flow is accompanied by a marked increase in intracerebral blood volume, which explains why increases in ICP are greater in children receiving volatile anesthesia than with IV anesthesia. Desflurane increases ICP more than isoflurane or sevoflurane. However, autoregulation is depressed in a dose-dependent manner, and the administration of less than 1–1.5 MAC seems to preserve enough autoregulation for clinical purposes, inasmuch as the main factor causing a decrease in cerebral perfusion pressure is the arterial pressure, which should be preserved [154–158].

## Effect on the respiratory system [159–161]

All volatile anesthetics depress ventilation by reducing tidal volume, which is not compensated for by a parallel increase in respiratory rate. Interestingly, halothane depresses the ventilatory response to CO<sub>2</sub> less than the other agents. However, the important clinical issue is the response to acute hypoxia, which is more depressed by halothane than by isoflurane. Sevoflurane and desflurane are the least depressive agents. In case of a sudden decrease in PAO<sub>2</sub>, desflurane and sevoflurane are safer agents. During one-lung anesthesia, no difference between isoflurane, desflurane and sevoflurane has been noticed. Also, no difference is reported between propofol and volatile anesthetics. At 0.5 MAC, all agents are bronchodilators. At higher concentrations, bronchoconstriction appears with desflurane at concentrations >0.5 MAC and with sevoflurane at concentrations higher than 1-1.5 MAC. Only isoflurane maintains its bronchodilating properties at 2 MAC. However, in children with airway susceptibility, for instance those with recent upper respiratory tract infection, desflurane markedly increases bronchial resistances, whereas sevoflurane exerts a bronchodilating effect [162,163].

#### Effect on the cardiovascular system [164–170]

All anesthetics depress contractility and inhibit sympathetic tone. Halothane significantly does so at 1 MAC, whereas isoflurane, desflurane and sevoflurane only do so at concentrations above 1.5 MAC. In addition, halothane causes marked bradycardia, whereas sevoflurane has almost no effect on cardiac rhythm below 1.5 MAC. Isoflurane and desflurane have been shown to increase heart rate in adults, but an increase in heart rate is not as critical in pediatric patients. Interestingly, depression caused by halothane is poorly corrected by atropine, whereas it increases contractility in infants and children who are anesthetized with the other three agents. This difference between halothane and other agents (mainly sevoflurane has been studied) has been observed in patients without cardiopathy or with various congenital heart diseases. This is true also in patients breathing spontaneously. In addition, only halothane significantly potentiates epinephrine-induced cardiac arrhythmias. Halothane, isoflurane and sevoflurane depress the autonomic control of arterial pressure in a similar manner. However, the bradycardia caused by halothane should be considered. Premature infants, who have an immature baroreflex, are particularly sensitive to the depression induced by anesthetics. In conclusion, halothane should be avoided when possible in infants and children, as halothane overdose has been associated with deaths in this age group.

Isoflurane, desflurane and sevoflurane possess cardioprotective effects, and both desflurane and sevoflurane have been shown to decrease postoperative mortality in adults suffering from coronary artery diseases. Indeed, the cardiac depressive effect reduces oxygen demand and may protect during ischemia. However, there is evidence of a specific effect related to pre- and post-conditioning. This may be beneficial for cardiac procedures in infants and children [165,171,172].

## Effect on muscle relaxation

Volatile anesthetics have an intrinsic effect on muscle relaxation [173–175]. Their prejunctional effect decreases the firing rate of motor fibers. In addition, they my also affect the sensitivity of the motor endplate. Volatile anesthetics interact with muscle relaxants. They do not interact with the kinetics of non-depolarizing muscle relaxants, but decrease Ce50 [176]. The dose of rocuronium or atracurium needed to achieve similar effect is decreased by about 25–30% in patients anesthetized with sevoflurane compared to those anesthetized with propofol [177]. At similar MACs, all volatile anesthetics enhance the action of pancuronium, vecuronium, rocuronium, atracurium, and cisatracurium to a similar degree [178].

### Malignant hyperthermia (see Chapter 40)

All volatile anesthetics may induce malignant hyperthermia (MH) [179–181]. Succinylcholine increases its severity. This genetic disorder of the ryanodine receptor of the skeletal muscle has a prevalence estimated at between 1:3000 and 1:8500. Indeed, the prevalence largely varies between populations. The incidence of MH associated with general anesthesia is estimated at between 1:30,000 and 1:100,000. Patients with various myopathies may be susceptible to MH [182]. Central core disease and hypokalemic periodic paralysis are particular risks [183,184].

The usual clinical presentation is an uneventful induction of anesthesia, progressive development of tachycardia and hyperthermia, and a rise in end-tidal CO<sub>2</sub> tension. The associated muscle rigidity is a direct sign of impaired intracellular calcium regulation. In patients spontaneously breathing, a progressive rise in minute ventilation is also observed. Acidosis and hyperkalemia, a serum creatinine kinase >10,000 IU/L, are the main biological manifestations. If untreated, MH may be rapidly lethal. These manifestations are not always typical, and there is a risk that the diagnosis will be missed because MH may progressively develop after discharge of the patient from the operating room or because a lethal episode may occur during a future anesthetic.

Dantrolene is the specific treatment (2–3 mg/kg up to 10 mg/kg as a bolus). Clinical signs determine the dose of dantrolene needed. Following treatment, the signs and symptoms of MH may recur, making it necessary to reinject dantrolene. This is why dantrolene must always be readily available. Dantrolene must be dissolved in sterile water (possibly warmed to 40°C), because dissolution is very difficult. It is important to change the anesthesia machine and the entire circuit, to cool the patient if necessary, and to correct acidosis if necessary. The diagnosis is ascertained by a muscle biopsy, which should always be performed. Prevention of MH in susceptible subjects consists of preparing the anesthesia machine by removing the vaporizers and changing the circuit. Total intravenous anesthesia is used and succinylcholine is avoided.

## Pharmacokinetics and pharmacodynamics of intravenous drugs

#### Benzodiazepines

Benzodiazepines interact with a specific site on the GABAA receptor, increasing the affinity of the receptor for GABA [185,186]. GABAA is the principal inhibitory neurotransmitter which increases the frequency of opening of the chloride channel. In normal conditions, chloride concentration is lower inside the cell than outside. Opening of the channel increases the concentration of chloride inside the cell and hyperpolarizes the membrane. Benzodiazepines have hypnotic and sedative properties. They are potent anticonvulsants. They are also anxiolytic and provoke antegrade amnesia. Although they are weak muscle relaxants (a central effect), they do not notably interact with peripherally acting muscle relaxants.

#### Pharmacokinetics

Benzodiazepines are weak bases bound to serum proteins, mainly AGP (Table 9.4) [187,188]. Only midazolam is water soluble. Benzodiazepines rapidly cross the BBB and quickly access the receptor: their T<sup>1</sup>/<sub>2</sub>ke0 is less than 3 min, except for lorazepam [189–192]. Conversely, the duration of action mainly depends on affinity to the receptor. Midazolam, clonazepam and lorazepam have an affinity constant to the receptor 20 times higher than diazepam and the duration of action is as follows: diazepam 2 hours, midazolam 2–4 hours, clonazepam 24 hours, lorazepam 24–72 hours.

Benzodiazepine metabolism takes place in the liver via the CYP3A4 isoform of the cytochrome P450, with the exception of lorazepam, which is metabolized by the UGT [193–195]. There is no phase 1 metabolism. Diazepam has active metabolites, mainly N-desmethyldiazepam which may accumulate in intensive care unit (ICU) patients with kidney failure. Midazolam has an active metabolite,  $\alpha$ 1-OH-midazolam, but the ratio between metabolite and parent drug remains constant, even in ICU patients. Because all these molecules have low hepatic extraction ratios, their elimination mainly depends on the hepatic function; in case of liver failure, the clearance of benzodiazepines is markedly decreased.

After oral administration, absorption of midazolam is rapid; its bio-availability is 50% and its  $T_{max}$ , the time to peak concentration, occurs 40–50 min after administration. Absorption is very rapid after rectal administration. In children,  $T_{max}$  is 10 and 15 min for diazepam and midazolam respectively. After rectal administration, bioavailability is 50–80% for diazepam and 20–50% for midazolam. The IM route has been abandoned because of unpredictable absorption. The volume of distribution is large (1–2L/kg) and the terminal half-life long (see Table 9.4) [196–199].

Apart from some inhibitors of HIV replication, such as ritonavir, few interactions between benzodiazepines and other drugs metabolized by the CYP3A4 have been described. Because of immaturity of CYP3A4, midazolam clearance is very low in preterm infants and during the first 2–3 months of life [200,201].

#### Pharmacodynamics

#### Action on the central nervous system

Benzodiazepines cause sedation through their effect on GABAA receptors. Their indications include premedication and sedation in the ICU [202]. When used as a premedicant, a paradoxical agitation reaction to benzodiazepine sometimes occurs. However, their sedative, anxiolytic and amnesic effects make midazolam one of the preferred drugs for premedication, particularly for unco-operative children or patients who have undergone multiple procedures. However, the effect on anterograde amnesia and implicit memory remains controversial [150]. Benzodiazepines have almost no effect on the CBF, ICP or cardiovascular system, which makes these drugs suitable for sedation in the ICU, particularly in neonates and in patients with head trauma, when long-term propofol administration is a risk [203].

# Action on the respiratory and cardiovascular systems

Midazolam depresses ventilation by decreasing sensitivity to CO<sub>2</sub> [204]. Narcotics potentiate this effect. Diazepam and midazolam produce only mild cardiovascular depression and a minimal reduction in blood pressure, due to a decrease in vascular resistance [205]. This effect is increased when the drug is administered concomitantly

Drug	Molecular	рКа	Distribution	Protein		T½	CL	Vc	Vss	T½ke0	Ce50

Table 9.4 Benzodiazepines and IV anesthetics. Physicochemical properties and pharmacokinetics

Ce50 is for loss of consciousness (LOC) or for a 50% decrease in the BIS value (BIS<sub>50</sub>). BIS, entropy, and various measures based on EEG give similar results.

with narcotics or other sedatives. When given to ICU patients for several days, midazolam has no significant effect on liver or adrenal function. Tolerance and tach-yphylaxis may occur, particularly with longer term infusions ( $\geq$ 3 days). Benzodiazepine withdrawal syndrome occurs with high-dose/long-term midazolam infusions [206].

### Dosing

For premedication in infants and children after the age of 3–6 months, midazolam 0.3-0.5 mg/kg orally (or rectally if the oral route is not possible) 30–40 min before induction of anesthesia, diazepam (if midazolam is not available) 0.1 mg/kg 60 min before surgery. As an adjunct for the induction of anesthesia, use 0.15 mg/kg. As the sole agent for anesthesia induction, use 0.3-0.6 mg/kg IV. The infusion dose of midazolam in critically ill patients is 0.03-0.3 mg/kg/h (30–300µg/kg/h). The dose of midazolam is adjusted in ICU patients according to the patient's clinical condition (use of a sedation score by the attending nurse is highly recommended).

Flumazenil, a specific benzodiazepine antagonist, reverses all the effects of benzodiazepines. However, its

rapid elimination kinetics makes continuous infusion of the drug necessary to maintain therapeutic efficacy [207]. The dose by IV bolus is  $5-10\mu g/kg/min$  up to  $40-50\mu g/kg$ . It may be necessary to follow this titrated dose with a continuous infusion of the drug at a rate corresponding to the titrated dose given over an hour.

#### Thiopental

Thiopental is still an important drug for induction of anesthesia in the younger patients. Like propofol, thiopental modulates the GABAA and glycine receptors, but thiopental mainly acts at the spinal cord level and preferentially on the glycine receptor [186,208–210].

## **Pharmacokinetics**

Thiopental is a weak acid (with a pKa of 7.6) and an octanol/buffer distribution ratio of 490 (LogP = 2.69) (see Table 9.4) [96,211]. It is a racemic mixture of two stereo-isomers (S-(+) and R-(-)), the S-(+) isomer being twice as potent as the R-(-) isomer. Thiopental binds to HSA with an average free fraction of 15% in adults and 28% in neonates [212,213]. Binding is enantioselective with the R-(-) slightly less bound than the S-(+) enantiomer.

Thiopental is metabolized by the cytochrome P450 system, but the precise pathway(s) remain(s) to be characterized [214]. Its terminal half-life is very prolonged [215–220]. After a bolus injection, the drug distributes rapidly, making its effect transient. Following a single injection, thiopental's pharmacokinetics is best described by a two-compartment linear model, with a terminal halflife of ≈12 hours in adult patients. Intrinsic unbound clearance and volumes of distribution of the unbound fraction are similar for both enantiomers. The rate of administration markedly influences the total dose needed to achieve a predetermined effect: because of rapid redistribution of the drug, the higher rate of administration leads to high but transient peak concentration, which is unable to correctly cross the BBB; a minimum duration of plateau concentration is needed to achieve clinical efficacy. This is consistent with an equilibration half-time (T<sup>1</sup>/2ke0) of 2.4 min between the central and effect compartments (see Table 9.4). Disposition of the drug is similar in infants, children, and adolescents. In pediatric patients older than 6 months, clearance is higher than in adults, and the average  $T\frac{1}{2}$  is 6.1 hours (see Table 9.4) [221]. With prolonged administration (for example, in patients with critically increased ICP), thiopental exhibits non-linear (Michaelis-Menten) kinetics, with an apparent terminal half-life of 15 hours [215,217]. In neonates and young infants, kinetics are not profoundly altered but the pharmacodynamics are likely different, with an ED50 (the dose leading to loss of lid reflex in 50% of children) of 3.4, 6-7, 5.5 and 4.2 mg/kg in patients aged 0-14 days, 1-6 months, 6-12 months and older than 1 year respectively [222]. Interestingly, the curve representing ED50 versus age is very similar to that of MAC versus age for halogenated agents. Studies considering allometric scaling are lacking.

## Pharmacodynamics

### Effect on the central nervous system

Thiopental is still the drug of choice for sedation of patients with increased ICP because it does not increase CBF and may decrease ICP (although the cerebral perfusion pressure may not significantly change). The very prolonged elimination that is the result of Michaelis– Menten kinetics must be taken into account in these patients.

# Effect on the respiratory and cardiovascular systems

Thiopental depresses ventilation, likely because of decreased sensitivity to  $CO_2$ . In adults, more critical respiratory events occur in the immediate postoperative period with thiopental use than with propofol, although both cause similar changes in functional residual capacity

(FRC) [223]. This increase in the number of events is likely related to the higher residual sedation associated with thiopental.

Thiopental decreases arterial blood pressure. Contrary to propofol, this decrease is related not only to decreased vascular tone but also to decreased myocardial contractile force [224]. Consequently, thiopental must be used with care in patients with cardiac failure.

### Other effects

Thiopental, like other barbiturates, may induce porphyria. Its use is absolutely contraindicated in patients susceptible to such pathology. The acidity of thiopental solutions may cause necrosis at the injection site if extravascular diffusion occurs. Inadvertent arterial injection has caused severe necrosis.

#### Dosing

Because the risk of necrosis is high following inadvertent extravascular injection, the use of dilute solutions is recommended (2.5% in children and adults, 1% in infants). When adjuncts (opioids) are used for induction of anesthesia, the usual dose of thiopental is 2.5–3 mg/kg in neonates <10 days of age, 6–7 mg/kg in infants, and 5 mg/kg in children.

When ICU patients have thiopental infused for prolonged periods of time, thiopental kinetics becomes nonlinear, in both adults and children. It may then be important to monitor thiopental plasma concentrations if the rate of thiopental administration exceeds 4–5mg/ kg/h.

#### Propofol

Propofol is progressively replacing thiopental for induction and maintenance of anesthesia. This latter indication is likely related to the emergence of computer-driven systems for drug administration, since propofol kinetics and dynamics have been extensively studied [225]. Propofol enhances gating of the GABAA receptor by GABA and slows desensitization of the receptor [208,209]. In addition, propofol presynaptically depresses excitatory synaptic transmission and decreases glutamate release. It also enhances activation of the glycine receptor by glycine.

#### Pharmacokinetics

Propofol is a weak acid with a pKa of 11.5 and an octanol/ buffer distribution ratio around 6500 [96]. Because of its high hydrophobicity, propofol is "solubilized" in lipid emulsions, initially in Intralipid®. Propofol binds to red blood cells and serum albumin, and the free fraction is <1% [226–228]. Binding is markedly decreased in patients on cardiopulmonary bypass [229] and those in ICUs who have decreased serum concentrations of HSA. The pharmacokinetics largely varies with age, explaining the differences in dosing between infants, children, and adults (see Table 9.4) [230–233]. When one compares a typical 20 kg, 5-year-old child and a typical 70 kg, 30-yearold adult, the main findings are: (1) an elimination clearance moderately higher in children than in adults, and (2) more importantly, volumes (both the central (Vc) and peripheral (Vss) compartments) are between 2 and 2.5 times greater in children than in adults, and the associated intercompartmental clearances are 1.5 greater in children than adults. When allometric scaling is performed, clearance is constant across species and age in humans: CL = 71\* (BW/70) ^ 0.78 L/min, where BW is bodyweight and 70 the standard bodyweight for adult humans [234].

Propofol exhibits marked multicompartmental kinetics and context-sensitive decrement times (Fig. 9.8) [235]. Altered kinetics (decrease in elimination clearance) has been reported in ICU patients and in neonates [233]. In premature infants less than 38 weeks' postmenstrual age, clearance is very low since maturation of metabolism occurs at birth. Interestingly, there are almost no differences in pharmacodynamic parameters across age [236-241]. The differences are mainly kinetic, i.e. Ce50, the concentration in the effect compartment needed to achieve a desired effect, is nearly similar among infants, children, and adults. Conversely, T1/2ke0 and the time to peak effect are shorter in younger patients than in adults, and the difference is identical to the difference measured for volumes and intercompartmental clearances (see Table 9.4). Interestingly, the effects on ventilation and arterial blood pressure do not have the same kinetics [242,243]. In adult patients, T1/2ke0 for respiratory depression is 2.6 min, similar to that for hypnosis, whereas T<sup>1</sup>/<sub>2</sub>ke0 for a half decrease in systolic blood pressure from baseline to

**Figure 9.8** Context-sensitive decrement times of the principal agents used intravenously. Remifentanil is not depicted in this figure since its decrement times are constant. Reproduced from Hughes et al [20] with permission from Lippincott Williams and Wilkins.

80 mmHg is 6 and 11 min in 20- and 75-year-old patients respectively.

#### Pharmacodynamics

#### Specific action on the central nervous system

Propofol has little effect on CBF or ICP when normocarbia is present [244]. This is why propofol is so popular in ICUs for sedation of patients with increased ICP [245]. Propofol is also used to treat seizures, mainly in cases of status epilepticus [246].

# Effect on the respiratory and cardiovascular systems

Like all hypnotic agents, propofol depress ventilation by decreasing sensitivity to CO<sub>2</sub>. This effect is central since the T½ke0 of respiratory depression is similar to the T½ke0 of hypnosis [243]. Propofol and thiopental decrease the functional residual capacity by similar amounts [247].

Propofol has a direct negative inotropic effect at very high (supratherapeutic) concentrations [224]. At therapeutic concentrations, its effect on contractility is insignificant [248]. The main cardiovascular effect of propofol is on vascular tone, probably because it inhibits the sympathetic nervous system. The prolonged T<sup>1</sup>/<sub>2</sub>ke0 on vascular tone strongly suggests that the effect is at least partly peripheral [242]. Propofol protects the myocardium against ischemia reperfusion injury through its ability to inhibit the mitochondrial permeability transition pore and its antioxidant and free radical scavenging properties [249,250].

#### Propofol infusion syndrome

After more than 2 days of propofol infusion in ICU patients, severe toxic effects have occurred [251,252]. This "propofol infusion syndrome" is likely caused by the uncoupling effect of propofol on the respiratory chain in the mitochondria. The clinical presentation includes lactic acidosis, rhabdomyolysis, and cardiovascular collapse (bradycardia, sometimes Brugada-like ECG, asystole). Green or red urine has been described in some patients [253]. This syndrome was initially described in children and adults with head trauma who received high-dose propofol for sedation. If sedation with propofol seems to benefit the patient, it is recommended to give <4 mg/ kg/h for less than 48 hours. Close monitoring of acidbase status, serum lactate and creatine kinase concentrations should be performed. The use of propofol for total intravenous anesthesia (TIVA) for several hours has not been reported to cause adverse effects in children.

#### Presentation and dosing

Propofol is available as a 1% or 2% emulsion. The carrier emulsion was originally Intralipid® but other

lipid emulsions are used in generic preparations. Propofol contains EDTA, sodium metabisulfite or benzyl alcohol as antimicrobial agent. Pain at the site of injection is common and may be attenuated by lidocaine (0.5-1 mg/ kg), either injected before the propofol or in the same syringe with the drug. Propofol should not be prepared in advance, since bacteria grow rapidly in the emulsion. Postoperative nausea and vomiting occur less frequently with propofol than with other agents (e.g. volatile anesthetics). To achieve similar plasma concentrations in children and in adults, the initial dose must be 2-3 times greater in children [254]. Because the volume at steady state is also markedly different, the initial 15-60 min of an infusion must be higher in children than in adults [255]. However, the significant hemodynamic effect of propofol must be taken into account, and balanced anesthesia with adjuncts seems preferable for induction of anesthesia. The usual doses for anesthesia induction are <1 month 4 mg/ kg, 1 month to 3 years 5–6 mg/kg, 3–8 years 3-5 mg/kg, >8 years 3 mg/kg. Loss of consciousness lasts for 5–10 min after a single injection. The dosing scheme for continuous infusion of the drug is provided in Table 9.5.

Table 9.5 Propofol and ketamine infusion scheme

**Propofol** infusion dosing in infants and children. After induction of anesthesia with propofol (3–5 mg/kg), anesthesia is maintained with the following scheme. Anesthesia needs to be complemented with fentanyl/alfentanil/sufentanil or regional anesthesia. Adapted from RJ Steur et al. Ped Anesth 2004; 14: 462–7.

	Time (min)					
Age	First 10	10–20	20–30	30–40	40–100	>100
<3 months	25	20	15	10	5	2.5

#### **Etomidate**

Etomidate is a carboxylated imidazole that is highly hydrophobic, has hypnotic properties, and has little effect on the cardiovascular system. It is often used for induction of anesthesia in patients with critical hemodynamic conditions, despite its suppressive effect on adrenal steroid synthesis [256,257]. Etomidate has a high degree of enantioselectivity. The R-(+) enantiomer is 10 times more potent than the S-(-) enantiomer [258,259]. The commercial preparation is the pure R-(+) enantiomer. Like propofol, etomidate interacts with the GABAA receptor, but the actions of these two drugs on the different subunits of the receptor differ [260–262]. Etomidate causes marked *in vitro* endothelium-dependent vasodilation. However, this effect is less than that observed with propofol and is reversed by adrenergic stimulation [258].

#### **Pharmacokinetics**

Etomidate is a weak base, hydrophobic (the active molecule is "solubilized" in propylene glycol or in a lipid emulsion), and is bound to AGP. Protein binding is decreased in patients with kidney and liver failure, which may increase the sensitivity of these patients to the drug [259,263].

Etomidate is metabolized in the liver by the cytochrome P450 system, but the specific isoform(s) involved remain(s) to be characterized. CYP3A2 may be involved because etomidate decreases antipyrine clearance [264]. Clearance of etomidate is decreased in cirrhotic patients [265–267]. Metabolites are inactive. In children, the volume of the central compartment is more than twice that of adults (0.66 versus 0.27 L/kg) [268]. Clearance is also higher. However, the volume of the central compartment depends on the cardiac output. If, indeed, children with normal cardiovascular function need a greater dose of drug for induction of anesthesia, those with impaired hemodynamics may require less [269,270].

#### Pharmacodynamics

#### Specific action on the central nervous system

Etomidate has no intrinsic action on CBF. It decreases ICP. Cerebral perfusion pressure is likely unchanged because of the etomidate-induced slight decrease in arterial blood pressure, which may explain the decrease in CBF and subsequent decrease in ICP.

# Effect on the respiratory and cardiovascular systems

Etomidate induces moderate respiratory depression by reducing sensitivity to CO<sub>2</sub>.

Etomidate is mainly used for induction of anesthesia (particularly in emergency cases) because of the hemodynamic stability observed [224,258,271–273]. Etomidate has no effect on heart rate, and contractility is only moderately impaired. *In vitro* and *in vivo* studies in animals and humans have shown that etomidate has an intrinsic negative inotropic effect that is similar to the effects observed with ketamine and midazolam. This effect is totally reversed by  $\beta$ -adrenergic stimulation. More importantly, etomidate only moderately impairs vascular tone. Baroreflex control is preserved, in contrast to propofol and thiopental.

## Effect on adrenal function

Etomidate blocks 11- $\beta$ -hydroxylase, thus inhibiting conversion of cholesterol to cortisol [274]. After an induction dose of etomidate, adrenal suppression lasts for about 24h. This effect may be clinically relevant, particularly in patients with septic shock who have compromised adrenal function.

## Formulation and dosing

Two formulations are distributed, depending on the solvent used. The initial formulation uses propylene glycol (35% vol/vol), and the second uses a lipid emulsion (propofol) as the carrier. Both preparations are painful on injection, but the propylene glycol preparation is particularly irritating because of its osmolality (4640 mOsm/L).

For induction of anesthesia in the emergency department, 0.2–0.3 mg/kg is used in children with compromised cardiovascular function and 0.3–0.6 mg/kg in patients in a stable condition. Myoclonus may occur with injection of the drug. In pediatric patients, rectal induction of anesthesia is possible with a dose of 6–8 mg/kg. Continuous administration of the drug is not recommended because it suppresses cortisol synthesis.

## Ketamine

Ketamine has hypnotic, analgesic, and antihyperalgesic properties and produces "dissociative anesthesia," profound analgesia, and marked sympathomimetic reactions [275]. However, ketamine has unwanted side-effects, such as hallucinations, confusion, delirium, hypersalivation and bronchial hypersecretion. Ketamine anesthesia is characterized by rapid immobility and cataleptic appearance, mydriasis, nystagmus, and increased muscular tone. Emergence from anesthesia is characterized by a state of confusion, often with hallucinations. This state, which is amplified by light and noise, is less frequent in younger children than in adults and may be prevented by administering adjunct drugs such as benzodiazepines. Ketamine has moderate effects on the cardiovascular system. It has an asymmetric carbon, with two enantiomers: R-(-)- and S-(+)-ketamine. The S-(+) enantiomer is about four times more potent than the R-(-) enantiomer [276].

Ketamine acts mainly as a non-competitive NMDA receptor antagonist. It inhibits presynaptic release of glutamate and potentiates GABAA. Ketamine also has opioid and muscarinic properties. The effects on the NMDA receptor include both the neuroprotective and proapoptotic effects of ketamine [277–281].

## **Pharmacokinetics**

Ketamine is 50% ionized and 50% non-ionized at pH 7.4. Both the parent drug and its metabolite norketamine are bound to serum proteins, with a free fraction of 40% and 50% respectively [282]. Ketamine is metabolized by CYP2B6 and 3A4 [283-286]. N-demethylation produces norketamine, which has about 30% of the activity of ketamine. Norketamine undergoes almost the same metabolism as ketamine (hydroxylation by CYP2B6 and glucuroconjugation) and has a terminal half-life of similar duration (≈4-6 hours) [287-296]. Norketamine is then considered to be responsible for some of the effects of ketamine. Access to the receptor is very rapid, with a T½ke0 of <1 min (see Table 9.4). Drug redistribution occurs rapidly (the initial distribution half-life is <15 min), and after a single 1 mg/kg IV injection, anesthesia lasts 6-10 min. Because of the multicompartmental nature of ketamine's pharmacokinetics, decrement times are markedly context sensitive.

## Pharmacodynamics

#### Specific action on the central nervous system

Ketamine has specific effects on the CNS [294,295]. It enhances EEG activity and increases CBF and cerebral metabolic rate of O<sub>2</sub> (CMRO<sub>2</sub>). Because the arterial pressure increases, there is an increase in ICP that is proportional to the increase in CBF. However, when adjuncts are used with ketamine and, more importantly, when normocarbia is maintained, ICP does not increase. Thus ketamine is often used in neurologically impaired patients. Ketamine has neuroprotective effects through its action on the mitochondria. However, the effects of ketamine on the ATP-sensitive mitochondrial K+ channel remain a subject of debate. On the other hand, ketamine also induces apoptosis via the mitochondrial pathway. This is considered a major issue in neonates and infants. The neurotoxicity of ketamine on the brains of developing animals seems clear. Consequently, this agent should probably be used with care in younger patients.

# Effect on the respiratory and cardiovascular systems

Ketamine does not depress ventilation, and the  $CO_2$  response remains intact [296]. Tidal volume and respiratory rate are unchanged. Ketamine does not alter FRC, even at high doses, but it does induce moderate bron-

chodilation. The pharyngo-laryngo-tracheal reflexes are partly conserved, leading to a relative airway protection.

Ketamine has minimal effects on myocardial contractility [297-300]. It preserves sympathetic activity and baroreflex activity. In healthy subjects, ketamine raises arterial blood pressure slightly, increases the myocardial contractile force, and increases cardiac output. However, in patients with decreased cardiac reserve, negative inotropic effects of the drug can be unmasked when myocardial contractility fails to increase with β-adrenergic stimulation. In addition, the increase in mixed venous oxygen saturation (MVO<sub>2</sub>) may be deleterious in patients who have insufficient coronary reserve. It has been reported that ketamine inhibits ischemic preconditioning via its inhibition of ATP-sensitive K+ channels, but this is still in debate. The S-(+) enantiomer is undoubtedly less deleterious on both contractility and loss of ischemic preconditioning of the myocardium than the R-(-) enantiomer.

#### Antihyperalgesic effect of ketamine

By its anti-NMDA action, subanesthetic doses of ketamine are potently antihyperalgesic [301]. Ketamine limits opioid-induced hyperalgesia and has potent morphinesparing effects. These effects are observed when ketamine is used early in the time-course of nociceptive stimulation, i.e. in the perioperative period. When ketamine is used only in the postoperative period, even when used with patient-controlled anesthesia (PCA), the results are not so clear. In pediatric patients, these effects need to be confirmed. The use of ketamine before the age of 2–4 years is still controversial because of possible neurotoxicity.

#### Effects on immune function and inflammation

Like local anesthetics, ketamine has potent immunomodulatory and anti-inflammatory properties. Ketamine decreases nuclear factor  $\kappa$  B (NF $\kappa$ B) activation and Toll-like receptor (TLR)4 expression and is more frequently used in septic and trauma patients [302]. These anti-inflammatory properties have not been shown in pediatric patients. Further studies are needed to assess the beneficial effect of ketamine in septic or cancer patients.

## Formulations and dosing

Ketamine has various formulations. The initial preparation of the racemic mixture contains benzethonium chloride as a preservative. Both the R-(–) enantiomer and the preservative are neurotoxic. In numerous countries, the S-(+) enantiomer without preservative is available because it is less toxic. However, even the pure S enantiomer may be neurotoxic at high concentrations, and its use is not being recommended as an adjuvant for epidural injection.

Numerous routes for ketamine delivery are used. For IV induction of anesthesia, 1–2 mg/kg are used. For maintenance anesthesia, 2–4 mg/kg/h of ketamine is infused. However, because of the context-sensitive half-time of the drug, it may be better to use an adapted regimen (see Table 9.5). Ketamine may also be injected intramuscularly at a dose of 5–8 mg/kg. The onset of anesthesia is slower (5–10 min) and its duration is prolonged (20–30 min). Ketamine may also be given rectally at the same dose.

The low-dose regimen used to prevent postoperative hyperalgesia consists of an IV loading dose of 0.15–0.30 mg/kg before surgery and a continuous infusion of 0.1–0.3 mg/kg/h for 24 hours. As an adjunct to PCA, the dose is 1 mg ketamine per mg of morphine. However, most pediatric studies do not show a benefit to low-dose ketamine.

## **Opioids**

Opioids interact with specific opiate receptors ( $\mu$ ,  $\delta$ ,  $\kappa$ ). Their major sites of action include the spinal cord, the medulla, and the periaqueductal gray matter [303,304].

Two main families of opioids are currently available. Long-lasting hydrophilic drugs, mainly used for postoperative or chronic pain relief, and short-acting drugs of the phenylpiperidine chemical family, used preferentially for perioperative analgesia. However, short-acting drugs are being used more and more commonly outside the operating room. These are almost pure  $\mu$  receptor agonists. Except for remifentanil, the liver metabolizes phenylpiperidines.

## Phenylpiperidines Pharmacokinetics

Phenylpiperidines are weak bases that bind to AGP [28,305,306]. They are exclusively metabolized in the liver by the CYP3A4 isoform, with the exception of remifentanil, which is degraded in plasma by non-specific cholinesterases [307-310]. These cholinesterases are ubiquitous; their deficiency is lethal. Thus, all patients are able to metabolize remifentanil. Clearance of remifentanil is very rapid in neonates. The drug's clearance decreases slightly thereafter (Table 9.6). These molecules have no active metabolites. Fentanyl, alfentanil, and sufentanil undergo hepatic metabolism, which rapidly matures (Fig. 9.9) [48]. Sufentanil is a suitable choice for opioid administration by target-controlled infusion (TCI) because it has shorter, predictable context-sensitive half-times than fentanyl or even alfentanil (see Fig. 9.8) [311]. The decrement times of remifentanil are very short and almost constant,

**Figure 9.9** (A) Fentanyl and (B) morphine clearance as a function of age. In the younger premature infants, fentanyl clearance is relatively high (about half the liver blood flow). Maturation occurs rapidly and is almost complete at 42 weeks. Morphine clearance, on the other hand, is low at birth and maturation is complete only at the end of the first year of life. Reproduced from Saarenmaa et al [48] (part A) and Lynn et al [47] (part B) with permission from Elsevier.

whereas the decrement times of fentanyl markedly increase with duration of administration [20].

#### Effect on the central nervous system

None of these agents have a deleterious effect on cerebral hemodynamics, provided the  $CO_2$  tension is normal. With normal  $CO_2$ , neither cerebral blood flow nor ICP is increased [312–314].

# Effect on the respiratory and cardiovascular systems

All narcotics depress ventilation. Muscle rigidity may be a problem in younger patients, especially when the drug is rapidly injected [315]. At equipotent doses, all phenylpiperidines reduce FRC to the same extent [316,317]. When injected slowly, these agents do not significantly decrease chest wall compliance, which allows them to be used in ICUs. Interestingly, muscle rigidity has been described following remifentanil injection in the mother [318]. All phenylpiperidines have depressant effects on myocardial contractility and vascular tone [169,319–322]. They provoke marked bradycardia. Atropine does not totally restore myocardial contractility. Remifentanil causes more bradycardia than the other drugs but at equianalgesic doses, all four drugs probably have similar effects. The incidences of respiratory depression, nausea and vomiting, pruritus, and rarely urinary retention are similar for all opioids [303] (see below).

## Fentanyl

Fentanyl is the oldest of these agents [48,323-328]. Its half-life is very long, particularly when it is used to sedate patients in ICUs. Fentanyl's hepatic extraction ratio is greater than 70-80% in children. Soon after birth, fentanyl's clearance from the body exceeds 50% of hepatic blood flow (see Fig. 9.9). Unfortunately, its important volume of distribution and slow intercompartmental clearance lead to rapid increases in context-sensitive decrement times with increased duration of administration. Moreover, fentanyl is secreted into gastric fluid, and recirculation of the drug from gastric contents and deep compartments can occur long after recovery from anesthesia. The usual dosing is  $2-4\mu g/kg$  as a bolus injection and  $1-2\mu g/kg$  for reinjections. The same dose,  $1-2\mu g/kg/h$ , is used for continuous IV infusion. Continuous infusion of fentanyl is not recommended during surgery if the plan is to extubate the trachea shortly after surgery. The time to peak effect is 5-6 min.

#### Alfentanil

Alfentanil has a short half-life, limited distribution into deep compartments, and high clearance (see Table 9.6) [326,328,329]. After an IV bolus dose of drug, alfentanil's peak effect occurs in 1–2 min. Following a prolonged infusion, decrement times increase moderately. The usual bolus dose of  $10-20\mu g/kg$  is followed by reinjections of  $5-10\mu g/kg$  for procedures of short duration.

## Sufentanil

Sufentanil's half-life is of intermediate duration [326,328,330–334]. Its effect is prolonged the least by prolonged administration of the drug, which is why its use has become very popular. Sufentanil's time to peak effect is 2–4min. The usual bolus dose is  $0.2-0.4\mu g/kg$  at the time of anesthesia induction, followed by either reinjections ( $0.1-0.25\mu g/kg$ ) or an infusion of  $0.1-0.5\mu g/kg/h$ .

#### Remifentanil

Remifentanil is a very potent opioid that has a rapid onset (<1 min) and a very short half-life [328,335–340]. Its decrement times are constant. The context-sensitive half-time, i.e. 50% decrement time, is close to 4 min no matter how long the drug is administered. When given with propofol

(3-4mg/kg) or sevoflurane (0.5-1 MAC), excellent intubating conditions are produced in children in 20-30 sec after a bolus of 2-3µg/kg. However, bolus doses of remifentanil are not recommended in neonates and infants because they may develop significant bradycardia and hypotension [319,320]. When given with 0.5-1 MAC of volatile anesthetic, a continuous infusion of 0.15- $0.25 \mu g/kg/min$  (in neonates and infants) or  $0.50 \mu g/kg/$ min (in children) gives excellent analgesia and stability, even for neonates who are more susceptible to the heart rate and blood pressure effects. However, care should be taken to (1) provide quality analgesia upon awakening and in the postoperative period because the analgesic effects of remifentanil are very short once the drug infusion is discontinued, and (2) look for occurrence of the postoperative hyperalgesia syndrome, which follows the administration of large doses of opioids. Remifentanil and sufentanil are the drugs of choice for TIVA. The usual dose of remifentenil is 0.10µg/kg/min in infants and  $0.25 \mu g/kg/min$  in children.

## Morphine

Morphine is a natural alkaloid derived from *Papaver somniferum*. It is an ampholyte, with a MW of 285 (free base), pKas of 9.85 and 7.87, an octanol: water distribution ratio of 1.42 at physiological pH, and is 35% protein bound to HSA. Morphine has four isomers, with little difference between them (codeine has the same isomeric distribution and morphine-6-glucuronide (M-6-G), the active metabolite of morphine, has two isomers).

### **Pharmacokinetics**

Morphine (like hydromorphone) does not undergo phase 1 metabolism by cytochrome P450, but undergoes direct phase 2 metabolism by the 2B7 and to a lesser extent the 1A3 isoforms of the UGT [38,40,341,342]. About 40% of morphine metabolism is extrahepatic, explaining why clearance is markedly greater than hepatic blood flow [343]. However, in patients with either a prothrombin time <40% or a liver mass that decreases functional liver by 50%, dosing must be halved (titration is unchanged) [344– 346]. Although less than 10% of morphine is transformed to M-6-G, it has major importance because M-6-G has 2-8 times the potency of morphine and because its clearance is critically low [347,348]. In cases of renal failure, M-6-G elimination is impaired, and the risk of respiratory depression increases when the creatinine clearance (CrCL) is below 30 mL/min/1.73 m<sup>2</sup> [349]. Because the production of M-6-G is delayed, its concentration rises long after morphine administration is discontinued (Fig. 9.10). In patients with a CrCL of  $15-30 \text{ mL/min}/1.73 \text{ m}^2$ , the dose of morphine should be halved. Drugs other than morphine should be given if the CrCL is  $<15 \text{ mL/min}/1.73 \text{ m}^2$ . Naloxone is efficacious for the treatment of narcoticinduced respiratory depression, but at times it must be infused for hours or even days. Peritoneal dialysis is poorly efficacious for removal of morphine, but hemodialysis (and usually hemofiltration) removes M-6-G. However, M-6-G may accumulate between dialysis sessions. Fentanyl and sufentanil are eliminated by hemofiltration, and require the use of alternative agents in ICU patients undergoing hemofiltration.

Phase 2 metabolism is immature at birth and slowly increases during the first 6–9 months of life (see Fig. 9.9) [37,47]. This fact, together with the opioid receptor immaturity during the same period of time, explains why morphine dosing is different in young infants than in older infants and children (see Table 9.6) [36,37,350–353].

Morphine is hydrophilic and does not easily cross biological membranes. Its effect concentration peaks 20 min after an IV injection (see Fig. 9.10). However, morphine concentration in the effect compartment reaches 80% of peak concentration 6 min after an IV bolus. It remains above this concentration for 80 min. Morphine's duration of action is much longer than that of fentanyl or sufentanil.

**Figure 9.10** Morphine (*top*) and M-6-G (*bottom*) concentrations in the central compartment (*solid lines*) and in the effect compartment (*dotted lines*) after a single IV injection of morphine. After an IV bolus injection, morphine concentration peaks at 20min because this hydrophilic drug slowly crosses the blood–brain barrier. M-6-G, which is more hydrophilic, peaks more than 4 hours after the morphine injection. This phenomenon explains why the effect of oral morphine is delayed (part of the effect is due to M-6-G because of the first-pass effect). Data from Mazoit et al [347].

 Table 9.6
 Opioids. Physicochemical properties and pharmacokinetics

#Morphine is a zwitterionic ampholyte with a principal pKa of 7.9. 1 Codeine is metabolized to morphine, which is the active molecule.

CL = Total Body Clearance, PMA = Postmenstrual Age.

#### Pharmacodynamics

Respiratory depression is a frequent side-effect of narcotics in neonates and infants. Respiratory rates decrease progressively, and respiratory depression increases. Depression is more associated with episodes of desaturation than with hypercarbia because of the associated sedation. However, sedation is difficult to appreciate in infants, because they normally sleep much of the time. Monitoring by transcutaneous pulse oximetry is recommended for infants, but clinical observation is also necessary, probably in the PACU (Post Anesthesia Care Unit) or an ICU (Intensive Care Unit). Apart from respiratory depression, the other side-effects of morphine include nausea and vomiting, urinary retention, pruritus, and constipation after 2-3 days of drug administration. Dexamethasone, droperidol or a 5-HT3 receptor inhibitor like ondansetron best prevent postoperative nausea and vomiting (PONV).

#### Dosing

Morphine should be titrated in infants and young children. In neonates and infants younger than 3 months of age, a continuous IV infusion of the drug is usually sufficient. The doses are between 10 and  $30\mu g/kg/h$  and are adjusted according to desired effect and the respiratory rate. Infants <3 months of age are very sensitive to the respiratory depressive effect of morphine. In infants older than 3–6 months and children <10kg BW, IV titration of the drug is begun by injecting a loading dose of  $50\mu g/kg$  before the age of 12 months or  $100\mu g/kg$  thereafter. The loading dose is followed by  $25\mu g/kg$  every 5min until the desired effect is reached. Children <40kg usually receive  $75\mu g/kg$  every 5min until the effective dose is reached. Children weighing more than 40kg may receive the adult regimen, i.e. 3mg as a bolus every 5min.

Before the age of 6–7 years, it is not appropriate to use a PCA device with the parents injecting the boluses, because of safety issues. Even after this age, this method has its limits and only a few teams continue to practice parent-controlled analgesia. Continuous infusions of narcotics have shown similar benefits and limits as PCA, i.e. the lack of efficacy on pain with movement. The infusion regimen is between 20 and  $40\mu g/kg/h$ . After the age of 6 or 7 years, children are able to understand the principle of PCA. The dosing and rules of administration for children are similar to those for adults, i.e. boluses of 15-20µg/kg every 5-10min. Continuous infusion of morphine along with the PCA has long been used, but this practice may induce respiratory depression. In patients receiving a continuous infusion of drug, nursecontrolled analgesia allows the injection of small boluses of drug and/or the modification of the infusion rate of morphine by increments or decrements of  $5\mu g/kg$  and is used in numerous centers. This is a good practice, provided all team members (including doctors and nurse) are well trained and follow rigorous protocols.

When pumps for continuous drug infusion or for PCA are not available, the intramuscular or (better) subcutaneous route can be used but when this is done, the blood concentration exhibits peaks and troughs. The oral route is also possible but when this route is used, the hepatic first-pass effect needs to be taken into account because part of the morphine dose is metabolized before reaching the general circulation. Only 10% of the metabolites are active (M-6-G). The concentration of M-6-G in the effect compartment is not significant before 6–9h after initial administration of the drug (see Fig. 9.10). The oral dose of morphine is 0.2–0.4 mg/kg, with a maximum dose of 20 mg every 6 hours.

## Other opioids Tramadol

Tramadol, a centrally acting analgesic, is a racemic mixture of cis and trans isomers that have few differences in activity, binding or metabolism. It is a weak  $\mu$  opioid receptor agonist that inhibits norepinephrine and serotine reuptake [354–356]. The (+) enantiomer has greater affinity for the  $\mu$  receptor and preferentially inhibits serotonin uptake while enhancing serotonin release. The (-) enantiomer preferentially inhibits norepinephrine reuptake by stimulating  $\alpha$ 2-adrenergic receptors. The O-desmethyl metabolite (M1) is active and (+)M1 is the principal active molecule.

## Pharmacokinetics

Tramadol is metabolized primarily by the CYP2D6, which is immature at birth [58,357,358]. Formation of M1 is impaired *in utero* and has important polymorphisms. The affinity of M1 for the  $\mu$  receptor is 300–400 times greater than that of tramadol [358]. Both forms have similar halflives [359–361]. Because M1 is at least as efficacious as the parent drug, there is a lag-time between its administration and effect. This is why the tramadol dose–effect relationship is flat and why it provides inadequate analgesia when injected immediately after surgery [362]. Hepatic failure markedly decreases the clearance of tramadol. Renal failure slightly decreases its clearance, but markedly decreases M1 clearance. CYP2D6 polymorphism may lead to inadequate analgesia in 5–6% of Caucasians because tramadol metabolism and M1 formation are reduced. In contrast, ultra-fast metabolizers of tramadol are at risk of respiratory depression. After oral administration, bio-availability of the drug is 70–90% after an oral dose. The  $T_{max}$  is 1–2 hours, depending on the formulation (drops are more rapidly absorbed).

### Pharmacodynamics

Respiratory depression with tramadol is less common than with morphine. Other side-effects include nausea, vomiting, dizziness, sweating, dry mouth, and drowsiness.

## Dosing

Tramadol is mainly used to treat mild to moderately severe postoperative pain and for intraoperative analgesia, although its analgesic properties are weaker than those of phenylpiperidines or morphine. Giving 2–3 mg/ kg IV at the beginning of surgery can provide effective postoperative analgesia for many patients. Continuous infusions of tramadol are not recommended because the lag-time for M1 formation is long. Oral tramadol 1–3 mg/ kg is given every 6–8 hours.

#### Codeine

Codeine is a natural alkaloid from opium. It mainly acts by producing morphine, which is a minor metabolite ( $\approx$ 5–6% of codeine is transformed into morphine in most Caucasian subjects) [59,63]. The main metabolite, codeine-6-glucuronide, does not appear to be active. Because of CYP2D6 polymorphism, there are large variations in morphine production. For example, about 20-25% of East Asians do not metabolize codeine to morphine; 5–6% of Caucasians fail to do so. In those adults who metabolize codeine extensively, the absorption of 50 mg codeine leads to morphine and M-6-G production with  $C_{max}(maximum observed concentration) = 27 \pm 23$  and  $41 \pm 33 \,\text{nM}$  at  $T_{\text{max}}$ (time to Cmax) = 0.7 and 1.8 hours respectively. The corresponding areas under the curve (AUC) compare with those obtained after 3-6mg of oral morphine. However, some ultra-fast metabolizers have CYP2D6 gene duplication and may produce exaggerated amounts of morphine [60]. Fatalities have been reported in babies breast fed by their ultra-fast metabolizing mothers, in infants and young children treated with codeine for more than one day, or children with renal

failure in whom M-6-G production was dramatically increased [61,62,363].

### Dosing

Codeine is sometimes used in combination with acetaminophen. In children older than 6 months of age, dosing is 1mg/kg/6–8h. For day case surgery, parents should be warned about the possible lack of effect or the very rare possibility of overdosage with drowsiness or even coma and bradypnea [364].

## Acetaminophen (paracetamol)

Acetaminophen has anti-inflammatory, antipyretic, and analgesic properties. Its mechanism of action is central and partly unknown [365,366]. Acetaminophen inhibits the COX-3 variant of cyclo-oxygenase. In addition, an active metabolite (p-aminophenol) may exert an effect through cannabinoid receptors.

Acetaminophen is poorly soluble in water. Mixing acetaminophen with mannitol and cysteine improves its solubility and stability. The time to peak plasma concentration is 30–60 min and 1–2 hours after oral and rectal administration respectively (see Table 9.6) [367–373]. Bioavailability after oral administration is 85–95% and is usually <80% after rectal administration. Metabolism of the drug is by CYP2E1, CYP1A2, and CYP3A4 in the liver (see Table 9.1). N-acetyl p-benzoquinone imine (NAPQI) is a toxic metabolite that causes hepatotoxicity by binding to cellular proteins and forming drug adducts [33,373]. Exposure to acetaminophen in infancy and early childhood may be a cause of the increasing incidence of asthma [374]. However, the role of confounding factors cannot be excluded. Neonatal icterus reduces clearance by 40%.

#### Dosing

Acetaminophen is available as tablets, an oral solution, suppositories, and as a solution for IV infusion [371,372]. The latter formulation is not available in all countries. For IV and oral administration, dosing is 10 mg/kg/6h in premature infants and neonates. However, because of the considerable variability in clearance caused by CYP polymorphism, measurement of aminotransferase is required in premature infants and neonates. Oral dosing is 15 mg/kg/6h from 1 month to 2 years and 20 mg/kg/6h from 2 to 15 years. By the rectal route, the first dose is 40 mg/kg.

## **Muscle relaxants**

The main two classes of muscle relaxants are depolarizing and non-depolarizing. Succinylcholine is the only depolarizing muscle relaxant still in use. Non-depolarizing agents include non-steroidal and steroidal agents. Both classes are non-competitive antagonists of acetylcholine (ACh).

## **Neuromuscular transmission**

Muscle contraction is elicited by release of ACh in the synaptic cleft of the neuromuscular junction [375,376]. Calcium-dependent mechanisms are responsible for release of ACh from stores in presynaptic vesicles. In the synaptic cleft, ACh is rapidly degraded by acetylcholinesterases. There is also reuptake of some of the ACh by motor nerve endings. ACh works by stimulating opening of muscle nicotinic acetylcholine receptors (nAChR), which allows sodium and calcium to enter the cells. The signal is further transmitted by sodium channels (NAv1.4) [377], which are particularly abundant around endplates. NAv1.4 density is lower in neonatal muscle. Seventeen subunits assemble numerous nAChR subtypes. Two variants of muscle type receptors, the adult  $\alpha 1\beta 1\epsilon \delta$  and the fetal  $\alpha 1\beta 1\gamma \delta$ , are present in humans (Fig. 9.11). During the first 2-4 years of life, the adult subtype progressively replaces the fetal subtype. Fetal receptors respond more slowly to ACh. Interestingly, fetal subtypes are reexpressed in ICU patients during prolonged periods of immobilization and inflammation. Neonates, infants, and young children also release less ACh into synaptic clefts than adults. However, the response of infants and children to muscle relaxants depends on numerous factors, such as the pharmacokinetics of the muscle relaxant and the binding capacity of the receptor. For example, the volume of distribution of succinylcholine and most nondepolarizing agents is increased in infants.

#### Monitoring neuromuscular blockade [378]

The only way to directly and reliably determine and prevent residual muscular blockade is by neuromuscular

**Figure 9.11** A schematic representation of the neuromuscular junction. The effect of neuromuscular blocking agents (NMBA) on the postsynaptic and presynaptic nicotinic acetylcholine receptor (nAChR) is depicted. The fetal muscle type nAChR has lower affinity and rate of response than the usual adult receptor. Reproduced from Fagerlund and Eriksson [376] with permission from Oxford University Press.

stimulation by acceleromyography. Acceleromyography measures the contraction of muscles in response to stimulation of their motor nerve. Single twitch measures the response height elicited by a single impulse. The train of four (TOF) measures the response to four successive supramaximal stimuli at 0.5 sec intervals, and the height of the fourth to the first response is determined (T4/T1 ratio, that measures the amount of fade after repetitive stimulations). This ratio measures the decrease in response (fade) to repeated stimuli and is a measure of the amount of fade. Tetanic stimulation, the result of high-frequency stimulation, causes tetanic muscle contraction. Doubleburst stimulation (DBS) consist of two short tetani (three impulses at 50 Hz) separated by an interval long enough to allow relaxation (usually 750 msec). Post-tetanic stimulation is the response to a single twitch or a TOF after a tetanic facilitation. Presynaptic neuronal nAChR is not inhibited by succinylcholine. Fade observed with nondepolarizing agents is related to the effect on presynaptic receptors; succinylcholine has no effect on these receptors so no fade is observed with this agent. This may explain why there is a lack of effect with TOF and tetanic fade [379]. All non-depolarizing drugs, on the other hand, inhibit neuronal nAChR and exhibit fade.

The most common monitoring sites are the adductor pollicis (thumb), orbicularis oculi (eyelid), and corrugator supercilii (superciliar arch). The latter is used to test for blockade of the laryngeal adductor muscles. The time course of blockade of the different muscles varies (Fig. 9.12) [380-383]. The abdominal wall and laryngeal muscles exhibit rapid onset and offset of neuromuscular blockade compared to the adductor pollicis. In addition, laryngeal adductors require higher doses of non-depolarizing drugs to achieve complete blockade than the adductor pollicis. The diaphragm is the muscle most resistant to blockade; its onset and recovery from blockade are similar to those of the adductor pollicis. The differences in T1/2ke0 at different sites reflect differences in muscle physiology (Table 9.7; see Fig. 9.12) [384]. Low degrees of neuromuscular blockade cause sufficient pharyngeal dysfunction to allow easy tracheal intubation [385]. Consequently, the corrugator supercilii is the best indicator of ease of tracheal intubation, and the adductor pollicis is the best indicator of early recovery from the block. One response out of four

 Table 9.7
 Muscle relaxants.
 Physicochemical properties and pharmacokinetics

(TOF) means that the muscular force is <10% of control. When the fourth response reappears, the force of the tested muscle has reached at least 25% of control. In clinical practice, the recovery of T4/T1 to >90% indicates that non-significant residual block remains. Reversal of muscle blockade is usually only possible if two of four responses of the TOF are present.

#### Succinylcholine

Despite succinylcholine (SCh) being the only depolarizing muscle relaxant available, its precise mechanism of action remains unclear. Its injection induces massive exocytosis of ACh and muscle fasciculation. The ensuing paralysis involves complex mechanisms that include desensitization of the receptor and inactivation of the sodium channels. SCh has a rapid onset and short duration of action, which makes it the agent of choice for rapid sequence induction.

Succinylcholine has low affinity for the presynaptic nAChR and causes a phase I block (decreased twitch amplitude, absence of fade, absence of post-tetanic potentiation). Large doses of SCh cause tachyphylaxis and a phase 2 block that resembles a non-depolarizing block.

## **Pharmacokinetics**

Succinylcholine has two molecules of ACh linked by an ester bond. It is highly hydrophilic (see Table 9.7) [386].

Like cocaine, heroin, and ester local anesthetics, SCh is hydrolyzed in serum, red blood cells, and liver by nonspecific esterases (butyrylesterases or pseudocholinesterases) [387,388]. There are many plasma cholinesterase genotypes that are responsible for wide variations in plasma cholinesterase activity. Some patients have reduced blood pseudocholinesterase activity. More than 20% of Caucasians are heterozygous for the main atypical variant. Patients with this variant have elimination halflives that are nearly double those of patients without the variant. Patients who are homozygous for this abnormal variant may remain paralyzed for hours to days following a single injection of SCh. Determining the dibucaine number is the test for lack of pseudocholinesterase. However, lack of sensitivity, specificity, and cost make its routine use unlikely. Eskimos or Australian aborigines share the same genotype and have greater risk for prolonged paralysis with SCh.

Succinylcholine rapidly accesses the neuromuscular junction. It is rapidly degraded due to its small volume of distribution and to elimination from both the central and peripheral compartments (see Table 9.7) [389]. The elimination half-life of SCh is 1 min. However, the T<sup>1</sup>/2ke0 for blockade of the adductor pollicis is 12min and is similar to that for non-depolarizing agents. The short onset of the drug's effect is aided by the high dose injected. Unfortunately, no recent data for infants and children are available [390–392]. Infants require 3 mg/kg and children 2mg/kg to produce the same intubating conditions. It is highly probable that these differences in drug dosage are the result of different volumes of distribution in the two groups. SCh is very hydrophilic. PK-PD data are needed in newborns, infants and children, and should be correlated using allometric scaling.

#### Pharmacodynamics

Succinylcholine has numerous side-effects that have caused some anesthesiologists to abandon its use.

#### Effects on the central nervous system

Succinylcholine is said to increase ICP. However, recent studies have shown that this is not the case if normocapnea is maintained. It has also been thought to increase intraocular pressure by causing contraction of the extraocular muscles. Recent evidence has shown that intraocular pressures do not increase when the trachea is rapidly intubated and the lungs are ventilated [393].

#### Effects on the cardiovascular system

Succinylcholine can cause either tachycardia or bradycardia, but bradycardia seldom occurs with the first dose of SCh. It occurs much more commonly after a second or third dose of the drug. Bradycardia is easily prevented by atropine [394]. Although not well documented, SChinduced fasciculations are said to increase cardiac output and CRMO<sub>2</sub>. This effect does not appear to have clinical relevance.

# Potassium release, effects on muscles, and malignant hyperthermia

Succinylcholine causes potassium release that usually is minimal and has no clinical consequence, unless the patient is hyperkalemic. Patients with Duchenne muscular dystrophy and other myopathies, paralysis (usually of spinal origin), rhabdomyolysis, and burns have a significant risk for developing arrhythmias with SCh due to receptor upregulation and phenotype changes in denervated muscle [395,396].

Succinylcholine may cause masseter spasm and incomplete relaxation of the jaw, particularly when it is given during halothane anesthesia. Some authors argue that this occurs because the dose of SCh was inadequate. SCh can trigger malignant hyperthermia (see the section on volatile anesthetics and Chapter 40). This is more likely when it is used with halothane or sevoflurane.

#### Non-depolarizing muscle relaxants

Non-depolarizing muscle relaxants compete with ACh at both muscle and nAChR. Non-depolarizing relaxants are either aminosteroids (pancuronium, vecuronium and rocuronium) or benzylisoquinoliniums (atracurium, cisatracurium and mivacurium) [397]. All these drugs produce a block of <40 min duration. Mivacurium's duration of action is the shortest.

## **Pharmacokinetics**

All neuromuscular relaxants are highly water soluble and have small volumes of distribution [386]. They are best described by two- or three-compartment linear kinetics (see Table 9.7) [397–407]. The volume of the central compartment is no larger than the plasma volume, and the volume of distribution at steady state (Vss) is equal to one-quarter of the bodyweight. Clearance of nondepolarizing muscle relaxants is usually relatively low, except for mivacurium, which is hydrolyzed by the same cholinesterases as SCh.

#### Metabolism

Aminosteroids are principally eliminated unchanged in urine and bile by carrier-mediated processes [408,409]. Transport is by the OCT and, to a lesser extent, by the P-gp.

Pancuronium has major renal transport and limited hepatobiliary transport [398,410]. As much as 25% of a dose of pancuronium can be recovered as 3-hydroxy metabolite, which has blocking properties half as potent as those of pancuronium. Patients with renal and/or liver failure have delayed elimination of pancuronium.

Vecuronium is excreted unchanged in urine and in bile (>50% is transported in bile) [411]. Patients who have cholestasis have reduced clearance of vecuronium. Renal failure has less effect. However, patients with end-stage renal failure also exhibit decreased clearance of vecuronium and a slightly higher sensitivity to the drug than normal subjects. Small amounts of 3-desacetyl vecuronium, a moderately active metabolite, were found in plasma after prolonged administration of vecuronium.

Rocuronium, a derivative of vecuronium, has a rapid onset and duration of action that are similar to those of vecuronium. Rocuronium is excreted unchanged in urine and feces; its metabolism is minimal. Rocuronium's elimination is only slightly impaired by renal failure. Excretion by transporters is less impaired than that by metabolism. For example, patients with cirrhosis have greater volumes; patients with cholestasis and jaundice have decreased clearance. The order of clearance is pancuronium < vecuronium  $\approx$  rocuronium, which explains their durations of action.

Atracurium has ten stereo-isomers [412]. The 1R-cis, 1'R-cis isomer is called cisatracurium. Both atracurium and cisatracurium are spontaneously degraded in plasma by Hofmann elimination and to a small degree by carboxylesterase activity. The Hofmann reaction is rate limited and temperature and pH dependent. The main end-product of atracurium and cisatracurium is laudanosine, which is toxic and may cause seizures. However, serum concentrations of laudanosine are always below the toxic threshold. Because cisatracurium is 3–5-fold more potent than atracurium, cisatracurium causes less histamine release and has less potential for causing convulsions.

Mivacurium is hydrolyzed in plasma by the same pseudocholinesterases that hydrolyze SCh [413,414]. It is a mixture of stereo-isomers; the cis-trans and the transtrans both have similar potency. A third isomer, the cis-cis, accounts for <6% of the total amount of metabolites and is about one-thirteenth as potent as the other two isomers. Unfortunately, the cis-cis isomer is poorly cleared; its T½ is about 20–30 times longer than that of the other two isomers. Patients who are heterozygous for plasma cholinesterase (those with the atypical AA variant, i.e. 20% of the Caucasian population) clear the major isomers 50% less well and have a prolonged T½ [388]. Patients who are homozygous for AA or other variants can have prolonged neuomuscular blockade. Clearance of mivacurium is moderately decreased by renal failure [414].

#### Pharmacodynamics

For neuromuscular blocking agents, ke0 is strongly correlated with logD, the distribution coefficient. Highly hydrosoluble molecules rapidly access their receptors, producing a rapid onset of action. Ce50 is inversely correlated to logD and to MW. Highly hydrosoluble molecules and those with low MW are more potent [386]. The duration of action depends on the rate of receptor access (T<sup>1</sup>/<sub>2</sub>ke0) and on affinity for the receptor. Interestingly, there is a great difference between the different sites of action. T<sup>1</sup>/2ke0 is much slower for adductor pollicis muscles than for the laryngeal muscles [380,383]. Drug access to the laryngeal muscles is 4-6 times more rapid than to the adductor pollicis and the diaphragm. The onset of action is dose dependent. Drugs with relatively short durations of action, like rocuronium, may require relatively large doses for onsets of action to be rapid. Rocuronium has the shortest T1/2ke0 and a rapid onset of action. Because of its intermediate duration of action, it is possible to use high doses of rocuronium to provide excellent intubating conditions 1 min after its injection.

#### Specific effect on organs

Non-depolarizing agents have little effect on cerebral blood flow or intracranial pressure. Atracurium, cisatracurium, and mivacurium release histamine which, when injected rapidly, can induce bronchoconstriction, hypotension, and tachycardia [415]. Pancuronium (and occasionally rocuronium) blocks muscarinic receptors and induces moderate tachycardia.

## Interactions

Volatile anesthetics and neuromuscular blocking drugs interact [416-418]. The mechanism for this potentiation remains unclear, but is likely an additive effect on the nAChR [416]. For example, sevoflurane shortens the onset and prolongs the duration of a rocuronium-induced block in children. T1/2ke0 and Ce50 are decreased by 60%, and the recovery time to T1 = 5% is prolonged by 25%. Acid-base disturbances, hypokalemia, and hypothermia may prolong the duration of action of muscle relaxants. Numerous drugs (volatile anesthetics, antimicrobials like gentamicin, lithium, and calcium channel blockers) interact with neuromuscular blocking agents and enhance the block. Magnesium sulfate potentiates the action of nondepolarizing agents by decreasing ACh release. Resistance to neuromuscular blocking drugs can be caused by phenytoin, carbamazepine, and other anticonvulsants. Giving SCh after a non-depolarizing agent prolongs the block.

## Allergy to muscle relaxants

Neuromuscular blocking agents can cause severe anaphylaxis, which is different from the release of histamine commonly observed when atracurium, cisatracurium or mivacurium is injected rapidly [419–421]. Anaphylaxis is rare in neonates and infants. The incidence of anaphylaxis increases with age and reaches its maximum in 30–60-yearold patients. Based on skin tests, rocuronium is said to cause more allergic reactions than the other drugs, but skin testing may not be the best way to determine this. Grade III (bronchospasm  $\pm$  urticaria) reactions occur in about 75% of cases.

#### Dosing

Pancuronium 0.08-0.1 mg/kg has an onset time of 3-5 min and duration of action of more than 60 min. The reinjection dose 0.02 mg/kg is given when T2 of the TOF returns. Vecuronium 0.1–0.2 mg/kg has an onset time of 1–3 min and duration of action of 30-40 min. The reinjection dose is 0.1 mg/kg. A continuous infusion at  $1-1.2 \mu \text{g/kg/min}$ is used for maintenance. Rocuronium 0.4-0.6 mg/kg has an onset of 1-2 min and duration of action of 40-60 min. The reinjection dose is 0.1-0.15 mg/kg. A continuous infusion of  $5-15\mu g/kg$  is often used for maintenance. Atracurium 0.4–0.8 mg/kg has an onset of 2–3 min and duration of action of 40-60 min. The reinjection dose is 0.1-0.2 mg/kg. A continuous infusion of  $5-15 \mu \text{g/kg/min}$ is used for maintenance. Cisatracurium 0.1-0.2 mg/kg has an onset of 2–3 min and duration of action of 40–60 min. The reinjection dose is 0.03-0.5 mg/kg. A continuous infusion of  $1-3\mu g/kg/min$  is used for maintenance. Mivacurium 0.2 mg/kg has an onset of 1–3 min and duration of action of <30 min.

## Tracheal intubation

The intubating dose of SCh is 1 mg/kg in adults, 3 mg/kg in infants, and 2 mg/kg in children. The intramuscular dose of SCh for emergency tracheal intubation is 5 mg/kg [422].

The intubating dose for rocuronium is 0.6 mg/kg in both infants and children. This dose produces excellent intubating conditions in <1 min. Older children often require the adult dose 1.2 mg/kg for rapid-sequence induction of anesthesia. This dose of drug provides excellent intubating conditions, but its duration of action is prolonged.

## **Reversal agents**

Two different classes of antagonists are used to reverse neuromuscular blockade: the quaternary ammoniumreversible acetylcholinesterase inhibitors and sugammadex.

## Acetylcholinesterase inhibitors

Acetylcholinesterase inhibitors (neostigmine and edrophonium) are quaternary ammoniums and are hydrophilic, ionized compounds.

## **Pharmacokinetics**

Neostigmine and pyridostigmine are tertiary ammonium compounds that bind covalently to acetylcholinesterase and form inactive carbamylated complexes that degrade slowly (T<sup>1</sup>/<sub>2</sub> ~30min) [423]. Edrophonium forms a weak complex that degrades more rapidly, which explains why its effects are shorter than those of neostigmine. Its halflife is shorter than that of either neostigmine or edrophonium. Neostigmine is rapidly metabolized at the neuromuscular junction by acetylcholinesterases and by erythrocytes. The nearly inactive metabolites are conjugated and eliminated by the kidney [424]. Edrophonium is metabolized to an inactive glucuronide conjugate. Interestingly, although the pharmacokinetics of both drugs is poorly understood, their terminal half-lives are longer than those of all neuromuscular blockers, including pancuronium (see Table 9.7) [425,426]. In anephric patients, elimination of neostigmine is impaired ( $T\frac{1}{2} = 181$ versus 80 min). The time to reach T1, T4/T1 and T2 is always faster in children than in adults. Moreover, recovery occurs more quickly with edrophonium in children than with neostigmine [427-434]. This is true for all blocking agents studied. Neostigmine is about 12-18 times more potent than edrophonium. In pediatric patients, the doses of edrophonium required for either 50% or 80% recovery of twitch height are comparatively greater (on a weight basis) than in adults. It is unclear if this is true for neostigmine.

#### Pharmacodynamics

Acetylcholinesterase inhibitors have numerous sideeffects that are mostly related to their muscarinic effects [415]. These include bradycardia, salivary and intestinal secretions, miosis, and bronchoconstriction. Atropine or glycopyrrolate administration can prevent or reverse these effects. In pediatric patients, atropine-induced tachycardia is rarely a problem, but bradycardia may be a problem, particularly in neonates and infants. Edrophonium causes less bradycardia than neostigmine and is preferred in pediatric patients. The bronchoconstriction induced by these drugs may be a problem, particularly in patients with asthma.

#### Dosing

In infants and children, the dose of neostigmine required to reverse the block varies between 0.03 and 0.07 mg/kg, depending on the neuromuscular blocking agent used. The author recommends a bolus of 0.05 mg/kg. The drug's peak effect occurs 10 min after injection. Edrophonium 0.75–1 mg/kg is given as a bolus. Its peak effect occurs 2–3 minutes after injection. Atropine 0.10–0.15 µg/kg should be given *before* either drug to prevent bradycardia. Glycopyrrolate  $4\mu$ g/kg in children and up to  $8\mu$ g/kg in neonates and infants effectively prevents bradycardia.

## Sugammadex

Sugammadex is a cyclodextrine that can encapsulate aminosteroid neuromuscular blockers. It has both an outer hydrophilic structure and an inner hydrophobic core. The drug was designed to specifically encapsulate rocuronium and vecuronium and, to a lesser extent, pancuronium. Sugammadex has no effect on benzylisoquinoliniums (atracurium, cisatracurium, and mivacurium). No serious side-effects have been reported, but anaphylaxis is possible.

## **Pharmacokinetics**

Sugammadex is eliminated unchanged by the kidney [435]. Its half-life exceeds that of all neuromuscular blockers [436,437]. Its clearance is 75-138 mL/min, which approximates the glomerular filtration rate (GFR). In patients with renal failure, the decreased sugammadex clearance is similar to the decrease in renal clearance [438,439]. The affinity of sugammadex for vecuronium and rocuronium differs. T1/2ke0 for vecuronium is twice that of rocuronium (see Table 9.7). This difference in the rate of access is consistent with the difference in Kd, the equilibration dissociation rate constant (0.1 µM for rocuronium versus 0.175µM for vecuronium). However, the binding capacity is similar for both drugs (the ratio of Ce50 for the sugammadex effect site is similar to the ratio of Ce50 for the neuromuscular junction effect site). After a dose of rocuronium, 2mg/kg of sugammadex is injected at reappearance of T2. The time to 90% recovery of TOF occurs after 0.6 min in infants, 1.2 min in children, and 1.2min in adults. Doses >2mg/kg do not hasten recovery.

## Dosing

For routine reversal of a block after reappearance of T2, 2mg/kg of sugammadex is adequate. However, in an emergency (e.g. failure to intubate the trachea after a large dose of rocuronium), sugammadex doses as high as 12mg/kg may be required.

## Anticholinergic agents

Two anticholinergic agents are clinically available: atropine and glycopyrrolate [440–446]. These are non-selective competitors for ACh at the muscarinic receptors and have little or no action on nicotinic receptors.

Atropine is a natural alkaloid of *Atropa belladonna*. It is a tertiary amine with a pKa of 9.9. It is highly ionized at physiological pHs and rapidly diffuses in water compartments (Vd 4.9L/kg). Atropine has a chiral carbon (the R form is almost inactive).

Glycopyrrolate is a synthetic quaternary ammonium salt that is totally ionized at physiological pHs. Its volume of distribution is small: 0.60 L/kg. In adults, the terminal half-life of atropine is 3-4 times longer than that of glycopyrrolate (2.3-3.7 versus 0.8h). In infants and children, glycopyrrolate's T<sup>1</sup>/<sub>2</sub> is very short (20min) due to its greater clearance (22mL/kg/min (infants and children) versus 9mL/kg/min (adults)). Atropine's clearance is 15.4 mL/kg/min in adults. The larger volume of distribution in neonates and infants makes the T<sup>1</sup>/<sub>2</sub> slower than in adults. Atropine is metabolized in the liver; one of its metabolites, 1-hyoscyamine, is active. Glycopyrrolate is not extensively metabolized and is rapidly excreted unchanged in urine. Elimination of glycopyrrolate is impaired by renal failure. Unlike atropine, glycopyrrolate does not cross the blood-brain barrier.

Anticholinergic agents increase heart rate, inhibit secretions, and induce bronchodilation. Atropine induces mydriasis while glycopyrrolate does not. At very low doses, both drugs can cause bradycardia. Glycopyrrolate's heart rate effects are delayed compared to those of atropine (2–3 min versus 1 min). Toxicity (tachycardia, restlessness and excitement, hallucinations, delirium, and coma with paralysis) occurs at supratherapeutic doses of atropine. Hypotension and circulatory collapse may also occur.

#### Dosing

The IV dose of atropine is  $10-15\mu g/kg$ . That of glycopyrrolate is  $4\mu g/kg$  for children and up to  $9\mu g/kg$  for infants 1 month to 2 years old. Some preparations of glycopyrrolate contain benzyl alcohol, which is toxic to neonates and infants and should not be repeated.

Following intramuscular injection,  $T_{max}$  occurs in 15–30 min. However, drug absorption by this route varies widely. IM doses are similar or slightly higher than IV doses.

## Local anesthetics

Local anesthetics (LA) block propagation of impulses along nerve fibers by inactivation of voltage-gated sodium channels, which initiate action potentials [447]. Some toxins (tetrodotoxin (TTX)) act on the outside of cells to block action potentials; local anesthetics have their effects on the cytosolic side of phospholipid membranes. Two main chemical compounds have been synthesized and used clinically as LAs: amino esters (2-chloroprocaine, procaine, tetracaine) and amino amides (lidocaine, bupivacaine, ropivacaine). Amino esters are degraded by pseudocholinesterases in plasma; they undergo minimal hepatic metabolism. Amino amides are more stable and are metabolized exclusively by the liver.

Drug	Molecular weight (Da)	рКа*	Distribution coefficient <sup>†</sup>	Protein binding	Onset of action	Duration of action	Potency <sup>‡</sup>
Esters							
Procaine	236	8.9	1.7	6%	Long	1 h	0.5

**‡**Potency is relative to lidocaine.

## Pharmacokinetics [448]

Local anesthetics are weak bases with molecular weights of 236-288 Da (Table 9.8). The pKa of all LAs is between 7.6 (mepivacaine) and 9.1 (chloroprocaine). At a pH of 7.40, 60-85% of the molecules are ionized and diffuse in the body's water compartments. LAs are also soluble in lipids and cell membranes. Bupivacaine is 10 times more soluble in membranes than lidocaine; ropivacaine is twice as soluble as lidocaine. With the exception of lidocaine, all amide LAs possess an asymmetric carbon. Although the physicochemical properties (pKa, distribution ratio) of the isomers are identical, the enantiomers have different affinities for the biological effectors (channels, receptors, proteins). Ropivacaine and levobupivacaine are pure S-(-) enantiomers. LAs are marketed as hydrochloride salts in water at pHs of 4–5 to prevent them from coming out of solution. The salts precipitate when bicarbonate is added to the solution to increase its pH.

Like most weak bases, amide LAs bind to serum proteins and red cells, which may be clinically important, especially in neonates and young infants. Neonates who have hematocrits >45% may have less unbound drug. In serum, LAs bind to both  $\alpha$ 1-acid glycoprotein and to albumin. Despite its low concentration in serum (less than 1 g/L in adults), AGP is the major protein that binds LAs. During the first 6-9 months of life, AGP concentrations progressively increase and reach adult levels by 1 year of age (see Fig. 9.2) [27]. When this occurs, the free fraction of LAs decreases [449], which may protect from LA toxicity. However, the concomitant decrease in hepatic clearance of free drug may leave clearance unchanged (see Fig. 9.3). LAs also bind to HSA, but with a very low affinity. It is only because HSA is the most abundant protein in serum that its binding capacity is significant.

## Absorption

After applying topical anesthesia to the upper airway, LAs are rapidly absorbed and can cause toxicity, particularly in children less than 4 years old. This is why it is important to use nozzles that deliver no more than 10 mg with each squeeze [450]. EMLA® (Eutectic Mixture of Local Anesthetics) cream contains equal amounts of lidocaine and prilocaine and is not absorbed in significant amounts, except in premature babies [451]. Prilocaine produces methemoglobinemia in neonates and infants, especially if they are also treated with trimethoprim-sulfamethoxazole [452]. The cream may not work in premature babies because of their very high skin blood flow.

Amide LAs have a bio-availability of 1 (metabolism is exclusively hepatic). Since these drugs are hydrophobic, they bind to tissues, which delays their absorption. This delay varies depending on the local conditions. For example, absorption occurs more rapidly after an ilioinguino-iliohypogastric block than after a caudal block. In adults, 3 hours after an epidural injection, only 70% of a dose of lidocaine and 50% of a dose of bupivacaine or of ropivacaine is absorbed, which is a safety factor [453]. From adult studies, it is clear that the speed of drug absorption decreases from head to foot and from the thoracic to the caudal portion of the epidural space. Lidocaine and bupivacaine concentrations peak about 30 min after caudal or lumbar injection in infants and adults. The T<sub>max</sub> for ropivacaine is much longer in infants than in children and in children than in adults, probably because CYP1A2, which metabolizes lidocaine and ropivacaine, is immature before 4-7 years of age [454]. This phenomenon is less important with levobupivacaine because it is metabolized by CYP3A4/7 [455].

Epinephrine reduces the peak concentrations of LAs. The usual concentration used in clinical practice is 5 mg/L (1/200,000), which is optimal in adults. It is possible that this concentration of epinephrine may decrease spinal cord blood flow in some infants and produce neurological deficits. Therefore, some authors suggest using no more than a 1/400,000 concentration of epinephrine in infants <1 year of age, since this concentration is also efficacious [456].

#### Distribution

The volume of distribution of local anesthetics at steady state (Vss) is slightly less than 1L/kg (Table 9.9) [453– 455,457–467]. Because drug absorption is delayed, volumes calculated after administration by non-IV routes are markedly overestimated. Terminal half-lives are also increased compared to values obtained after an IV injection. Total body clearance of the drug is only measured accurately following extravascular administration, but sampling must take place over a prolonged period of time. It is highly probable that LAs distribute into large volumes in neonates, infants, and adults, thus preventing high serum drug concentrations from occurring after a single injection. However, this is not the case following several injections. Ropivacaine's volume of distribution is smaller than that of bupivacaine in adults and probably in pediatric patients. At similar doses, the  $C_{max}$  of ropivacaine is higher than that of bupivacaine, despite ropivacaine's delayed  $T_{max}$ .

## Elimination

Liver cytochrome P450 enzymes metabolize all amide local anesthetics. Bupivacaine is predominantly metabolized into pipecoloxylidide (PPX) by CYP3A4/7 [468]. Ropivacaine is predominantly metabolized to 3'- and 4'-OH-ropivacaine by CYP1A2 and to a minor extent to PPX by CYP3A4 [49]. These enzymes are not fully mature at birth and have important differences in their developmental expression (see above). The extraction ratios for lidocaine (0.65–0.75) are relatively high. Lidocaine is flow limited rather than rate limited for its elimination. Therefore, any decrease in cardiac output decreases

hepatic clearance of lidocaine. The resultant increase in plasma concentration of LA may be toxic. Bupivacaine and ropivacaine, on the other hand, have a relatively low hepatic extraction ratio (0.30-0.35) and are rate limited for their elimination. Thus, hepatic clearance and free fraction are major determinants of total clearance. After surgery, serum AGP concentrations increase, which increases protein binding. This decreases total clearance but not intrinsic clearance. This resets the total serum concentration, without changing the unbound concentration (see Fig. 9.3). Bupivacaine clearance is low at birth and increases slightly during the first 6-9 months of life. Ropivacaine clearance, which is also low in neonates and infants, increases during the first 2-6 years of life [454,463,465,466]. Despite the low clearance, ropivacaine concentrations remain below toxic levels, even in younger patients.

## Pharmacodynamics

Local anesthetics cross membranes as free bases (unionized). Inside the cells, they become ionized and bind to specific amino acids within sodium channel pores and mechanically block the pores [447]. LAs also block potassium and calcium channels, but this requires slightly higher drug concentrations than those needed to block sodium channels. Voltage-gated potassium channels initiate repolarization. Some of these channels (including the human ether-à-go-go (hERG) related gene channel) are responsible for genetically induced arrhythmias, such as the long-QT, short-QT or Brugada syndromes. These channels are blocked by LA concentrations just slightly higher than those needed to block sodium channels [469,470]. Unlike the CNS and heart, peripheral nerves only express a small number of potassium channels. Both sodium and potassium channel blockade are stereospecific. The S enantiomers induce a lesser block than R enantiomers. LAs bind to L-type calcium channels, but it is unclear if blockade of these channels affects the cardiotoxicity of long-lasting LAs.

Nerve fibers are either myelinized or unmyelinized. The action potential of unmyelinated fibers propagates continuously. After initial depolarization, the sodium channels become unreceptive to stimulation (refractory period), which prevents backward propagation of impulses. Sodium and potassium channels are evenly distributed along the fibers. Conduction velocity of small fibers is low. Myelin insulates myelinated nerves, and this layer is interrupted regularly by the nodes of Ranvier. Sodium channels are situated at the node of Ranvier in concentrations of  $\approx 200,000$  channels/cm<sup>2</sup> [471,472]. Potassium channels are distributed along the myelin sheet with a higher concentration present in the juxtaparanodal region. The sudden depolarization of the node induces an electrical field, which extends to 2–3 nodes.

Action potentials "jump" rapidly from one node to the next. Because the distance between nodes is greater in heavily myelinated fibers (there are 3–4 nodes/cm in A $\alpha$ fibers and 20–30 nodes/cm in A $\delta$  fibers), the conduction velocity is faster in motor and small sensory fibers than in fibers that conduct pain signals. Because the electrical field extends over a relatively long distance, nerve fibers must be "bathed" over a relatively long distance by LAs. This progressive extinction of the signal is called decremental conduction. Fortunately, the phasic block that is induced by the high firing rate of nerves reinforces the block. Small A $\delta$  lightly myelinated fibers are blocked by less drug than is needed to block heavily myelinated fibers. This phenomenon, called differential nerve block, is explained by differences in internode distance between fibers [473]. It is unknown to what extent concentration gradients across the myelin sheet also participate in this phenomenon.

Myelinization begins during the third trimester of pregnancy and is incomplete at birth. After birth, myelinization increases rapidly and is almost complete by 3–4 years of age [471,472]. In rats, the nodes of Ranvier are fully mature at 2–3 weeks of age. Interestingly, the internode distance is similar between 2-week-old and adult rats. This may explain why infants and young children require larger volumes of LAs per kilogram than older children or adults (Fig. 9.13) [474]. Fortunately, lower concentrations of LA are needed to cause the block. Infants and children need larger volumes of solution with lower

**Figure 9.13** Duration of sciatic nerve blocks in rats after an injection of bupivacaine. The block is more protracted in newborn than in older rats. Duration of the block in 2- and 10-week-old rats was similar despite a marked difference in size and weight. It appears that the distance between nodes of Ranvier, which is fixed at its adult value by the age of 1–2 weeks, is the main determinant of the motor blockade. Data from Kohane et al [474].

**Figure 9.14** Cerebrospinal fluid flux according to age. Flux is initially low in infants, and then rapidly increases and becomes maximal in older children. Thereafter, it decreases regularly. Data from Greits and Hangers, Am J Neuroradiol 1996; 17: 431–8.

concentration of LAs to achieve blocks of similar intensity and duration as adults. Surprisingly, infants require larger doses of LAs for spinal anesthesia. Despite this, the duration of the spinal block is shorter. Some authors have attributed this difference to a larger volume and a more rapid turnover of CSF in neonates and infants than in older children and adults. Unfortunately, the pharmacokinetics of LAs in the CSF is particularly unknown in pediatric patients. The brain CSF volume and CSF turnover are lower in neonates and infants than in children and adults (Fig. 9.14) [475,476]. The major factor responsible for this rapid effect seems to be pharmacodynamic. The intensity and duration of the block depend on the number of nodes of Ranvier blocked (differential block). The distance between nodes is fixed soon after birth [471,472]. When this occurs, the short duration of spinal anesthesia in infants is not surprising.

## Effects on the central nervous system and cardiovascular systems

Like all inhibitors of sodium channels, low doses of LAs are anticonvulsive, which is why lidocaine is still used to treat intractable epilepsy in children [477]. However, the therapeutic ratio is low and the margin of safety does not favor lidocaine. At higher doses, LAs may produce convulsions and coma. At similar concentrations to those that cause convulsions, long-lasting LAs can induce cardiac arrhythmias. With the exception of nodal conduction, which depends on calcium channels, impulse conduction in the heart depends on sodium channels. This is why lidocaine is a chief class Ib antiarrhythmic agent. LAs prolong the refractory period, but the balance between the increase in effective refractory period and the decrease

in the ventricular conduction velocity does not favor LAs. Long-lasting LAs, like bupivacaine, profoundly decrease ventricular conduction velocity [478]. This phenomenon is markedly amplified by tachycardia [479]. In neonatal and adult animals, the intensity of the block is similar at similar heart rates [480]. However, because neonates and infants normally have higher heart rates than adults, they are more sensitive to local anesthetic-induced blocks than adults. LAs also impair myocardial contractility. However, to obtain the same decrease in contractile force, it is necessary to infuse 10 times more bupivacaine than is required to impair ventricular conduction.

Apart from the effect of the central block-induced sympathetic blockade, LAs have direct vasoactive properties. The S enantiomers (ropivacaine and levobupivacaine) have mild vasoconstrictive properties. These properties have been suggested as the cause of ischemia after penile block, but a direct relationship between ropivacaine and ischemia in this report seems doubtful [481].

#### Stereo-specificity

Mepivacaine, prilocaine, bupivacaine, and ropivacaine have an asymmetrical carbon. Because binding to serum proteins, hepatic enzymes, or ion channels may be asymmetrical, different stereo-specific properties are expected. Protein binding, pharmacokinetics, and nerve blocks have little stereoselectivity, which is why levobupivacaine has almost the same blocking properties as its racemic counterpart. In the heart, conduction is markedly stereo-specific, whereas contractility is unaffected by steroselectivity.

Local anesthetics have anti-inflammatory properties and inhibit platelet aggregation [482]. They decrease leukocyte priming and the production of free radicals [483–485]. Systemically administered lidocaine has antinociceptive effects, particularly on neuropathic pain [486]. Consequently, LAs are now used peroperatively to prevent postoperative hyperalgesia in adults [487]. Interestingly, LAs can prevent and even treat complex regional pain syndrome in adults and children by limiting the neuropathic inflammatory processes [488,489].

### Toxicity of local anesthetics

At the site of injection, the minimum concentration required to produce a nerve blockade is  $300-1500 \,\mu\text{M}$  for lidocaine and  $100-500 \,\mu\text{M}$  for bupivacaine. In adults these concentrations of lidocaine occasionally cause cauda equina syndrome but are more likely to cause transient neurological symptoms following spinal anesthesia. LAs can also be toxic to muscles, bupivacaine being the most toxic [490,491]. Muscle toxicity is not enantioselective. Care should be taken when regional anesthesia is provided for eye surgery in adults, for children with myopathies (bupivacaine is an *in vitro* model of Duchenne

myopathy), and perhaps for children with mitochondrial cytopathy. Peripheral blocks are more dangerous than central blocks because it is easier to inject drug directly into muscle with peripheral blocks.

After both local and regional anesthesia, the blood concentration of LAs rises rapidly and can cause neurological or cardiac toxicity. Neurological toxicity occurs in about one case per 1000 patients [492]. Because of their low protein binding and intrinsic clearance, infants are more prone to LA toxicity than adults. General anesthesia may conceal the early signs of LA toxicity in children. In addition to pharmacokinetic factors, the rapid heart rate of children increases LA toxicity. Ropivacaine and levobupivacaine (S-(-) enantiomers) are appropriate choices for younger patients because both drugs should produce less tonic block. Even if toxic events occur with ropivacaine, small doses of epinephrine should cause rapid recovery. Impaired ventricular conduction is the primary manifestation of LA toxicity. QRS widening, bradycardia, and torsades de pointe are followed by either ventricular fibrillation and/or asystole [493]. The slight decrease in myocardial contractility caused by LAs is usually not a major problem. Treatment includes oxygenation, cardiac massage, correction of acidosis, and epinephrine (which is given in small incremental boluses beginning with  $2-4\mu g/kg$ ) [494]. If ventricular fibrillation persists, defibrillation (2-4 joule/kg) is performed.

Although resuscitation measures must be initiated immediately, the specific treatment of LA toxicity is rapid administration of Intralipid<sup>®</sup>. Numerous case reports have shown that rapid bolus injections of a lipid emulsion reverse the toxic effects of LAs [495–497]. Because one mole of Intralipid<sup>®</sup> binds >3000 times more molecules of bupivacaine than a mole of buffer, the volume of distribution suddenly increases [498,499]. The recommended dose of 20% Intralipid<sup>®</sup> for pediatric patients is 5 mL/kg by IV bolus. If cardiac function does not return, this dose (up to 10–12 mg/kg) is repeated. Rather than institute a maintenance infusion of Intralipid<sup>®</sup>, patients are closely monitored and given more Intralipid<sup>®</sup> as needed. The lipid emulsion decreases LA elimination, so the cardiac effects may recur later.

Prevention of toxicity includes slow injection of small amounts of drug and frequent catheter aspiration. Some authors recommend injecting a solution that contains epinephrine. Continuous administration of LAs for postoperative pain is better than bolus injections because the latter may cause peaks and troughs of drug concentration and pain relief. If the catheter migrates into a blood vessel, continuous administration is safer. In older children, patient-controlled regional anesthesia (PCRA – see Chapter 33) works well. Also, the size of the boluses is small enough to avoid toxicity.

#### **Adjuvants**

Adjuvants are often used to prolong the duration of analgesia. Epinephrine  $(5\mu g/mL = 1/200,000)$  decreases  $C_{max}$ , without affecting the time to peak concentration. In infants <6 months old,  $2.5\mu g/mL 1/400,000$  epinephrine has been recommended [456]. However, the drug is less efficacious with long-acting S-(–)- enantiomers and has limited use with these solutions. Plain solutions of LAs *must* be used for penile, interdigital, and eye blocks.

Clonidine  $1-2\mu g/kg$ , either IV or in the epidural space, prolongs the duration of caudal blocks [500]. More than  $2\mu g/kg$  may lead to hypotension. Clonidine is not recommended for infants <3 months of age because it can cause apnea in this age group.

Some clinicians use ketamine as an adjuvant for epidural block [501]. Both the R-(–) enantiomer and the preservative are highly neurotoxic. Even the S(+) enantiomer can be toxic. Thus it may be wise to avoid the use of ketamine as an adjuvant for epidural blocks [502,503].

Opioids are often used as adjuvants for epidural block. After 6–9 months of age, adding opioids to LAs prolongs epidural analgesia for up to 24 hours. Hydrophobic agents (fentanyl, sufentanil) must be placed at the metameric level where the pain will occur [504,505]. Preservative-free morphine easily spreads rostrally and can be placed at a lower metameric level, but the risk of respiratory depression is theoretically higher. The bolus dose of morphine is 25–30 $\mu$ g/kg in the epidural space, which is followed by a continuous infusion of 1 $\mu$ g/kg/h. When continuous epidural administration of fentanyl or sufentanil is combined with local anesthetics, the doses are 0.2 $\mu$ g/kg/h and 0.1 $\mu$ g/kg/h respectively. Morphine 5–10 $\mu$ g/kg can be used as the sole agent for spinal analgesia during general anesthesia.

## Formulation and dosing

Plain solutions of amide LAs are preservative free; only solutions containing epinephrine include metabisulfite [506]. The S enantiomers (ropivacaine and levobupivacaine) are safer and cause similar quality and duration of analgesia and less motor blockade than a racemic mixture of bupivacaine. When regional analgesia is used during general anesthesia, low concentrations of LAs (2–2.5 mg/mL, i.e. 0.2–0.25%) are used. The maximum dose is 2–2.5 mg/kg for the initial caudal injection, 1.2–1.7 mg/kg for lumbar or thoracic epidural injections, and 0.5 mg/kg for peripheral blocks. Continuous infusion of LAs for postoperative analgesia uses low concentrations of drug (0.625–1 mg/mL) at a maximum rate of 0.20 mg/kg/h in neonates, 0.30 mg/kg for 1–6 months old, and 0.40 mg/kg beyond 6 months of age.

# CASE STUDY

A full-term newborn weighing 3520g was scheduled for esophageal atresia (type 3) repair 16h after birth. Cardiac, abdominal, and renal echography was normal. A small amount of stridor was noticed. An ENT surgeon was asked to evaluate the child and perform laryngoscopy prior to surgery. All blood tests were normal for the age, except the activated coagulation test, which was slightly prolonged (45 sec versus 35 sec for control). Factors VIII and IX were subsequently found to be normal, as was a preoperative thromboelastogram. The physical examination showed an apparently healthy boy who was spontaneously breathing and had mild stridor. A peripheral venous catheter was in place. A suction catheter was present in the upper esophagus to aspirate saliva. Anesthesia was induced with sevoflurane (6% inspired) with spontaneous ventilation. The ENT surgeon sprayed the larynx with 10 mg of 2% lidocaine without epinephrine. No airway abnormality was found, and the trachea was intubated.

Following tracheal intubation, the patient was given sufentanil (0.5µg) and atracurium (1 mg) over 1 min. The lungs were mechanically ventilated. An epidural was performed using levobupivacaine. Because lidocaine had been administered 30 min earlier for examination of the larynx, the initial bolus of LA was reduced (5mg or 2mL of a 2.5mg/ mL solution). The bolus was immediately followed with a continuous infusion of 0.85 mg/h, i.e. 1.4 mL/h of a 0.0625% solution. Anesthesia was maintained with sevoflurane 1.5–2% (0.5–0.6 MAC without N<sub>2</sub>O). Surgery was uneventful and the trachea was extubated after reversal of the muscle relaxant (neostigmine 350µg, atropine 75µg). In addition to the epidural, IV acetaminophen (50 mg bolus plus 25mg every 6h) was given (IV acetaminophen is approved in approximately 80 countries, including Europe, and has recently been launched in the US as Ofirmev). Unfortunately, the epidural catheter was dislodged 5 hours after surgery. The anesthesiologist prescribed a continuous IV infusion of morphine 40µg/h but because drugs already given through the epidural catheter would provide pain relief for 1-2 more hours, no loading dose of morphine was given. Six hours later, the patient's respiratory rate progressively decreased to 16 bpm. The infusion of morphine was decreased to 30µg/h and the respiratory rate returned to normal. The remainder of his postoperative course was uneventful.

#### **Key points**

**1.** Because lidocaine was used for the laryngeal examination, a smaller dose of LA was given into the epidural space. Lidocaine is rapidly absorbed following topical application to mucous membranes and may interact with levobupivacaine given for blocks.

- 2. Sevoflurane was used to induce anesthesia because it, plus the topical anesthesia, provided excellent condition for the laryngopharyngeal examination. Following tracheal intubation, a phenylpiperidine opioid and a muscle relaxant were slowly injected to prevent a "stiff" chest from developing. The drugs were also injected slowly to prevent the profound hypotension that sometimes occurs when sufentanil and atracurium are injected rapidly.
- 3. The epidural was performed (1) to provide postoperative analgesia, allow rapid tracheal extubation, and avoid postoperative mechanical ventilation, and (2) to reduce the amount of halogenated agents used and prevent their possible deleterious CNS effects. At this age, MAC is higher than that of adults. However, MAC may differ for different variables (e.g. hemodynamic variables). Balanced anesthesia with opioids and regional anesthesia is a good choice. Levobupivacaine was chosen over ropivacaine because it is metabolized by CYP3A4/3A7, which is more mature at birth. Ropivacaine is metabolized by CYP1A2, which is immature until 4 years of age. Pure S enantiomers (ropivacaine and levobupivacaine) are less toxic and induce less motor blockade, a significant problem in infants. Because the volume of distribution of hydrophilic local anesthetics is large in newborns and infants, the initial bolus dose/kg is usually the same as in older children. Since LA toxicity is additive, and because a topical spray of lidocaine was used less than a hour before the epidural block, limited amounts of levobupivacaine (1.4 mg/kg) were injected into the epidural space. This initial bolus was followed by a continuous infusion of the drug. The infusion dose was reduced because the volume of distribution would be filled after 4-5 halflives; at that point, clearance rapidly becomes the only factor governing drug concentration. Because clearance of the unbound fraction, which is responsible for LA toxicity, is low at birth and progressively increases with age, the dose varies with age. Fortunately, <4-6 month olds have excellent pain relief with smaller doses of LAs.
- **4.** Postoperative pain control is critical, not only to relieve the pain but also to reduce respiratory complications (hypoventilation). In addition to regional anesthesia, this patient received paracetamol (acetaminophen). Because metabolism of this drug is reduced during the first month of life, the child was given about half the dose of paracetamol given to older patients. No loading dose was given.

Anesthesiology 2001; 95: 96–101. This paper explains why T½ke0 for muscle relaxants may be so long when compared to our clinical impressions. The onset of effect and recovery times are different from one muscle to another. For example, T½ke0 of vecuronium is four times longer for the adductor pollicis than for the laryngeal muscles. Whether one wants to monitor the onset of action for tracheal intubation or the recovery for adequate ventilation, the muscle of interest should be different. Because it is not possible in daily practice, it is important to understand this concept to adapt our understanding of the observed phenomenon.
- 498. Mazoit JX, Le Guen R, Beloeil H, Benhamou D. Binding of longlasting local anesthetics to lipid emulsions. Anesthesiology 2009; 110: 380–6. Lipid rescue. This *in vitro* study shows that long-acting local anesthetics are rapidly (less than 30 sec) adsorbed in lipid particles by a passive (entropy-driven) phenomenon. At 37°C and pH 7.40, the mole fraction of bupivacaine between Intralipid® and buffer was 3100, i.e. 3100 molecules of bupivacaine distribute in a mole of emulsion for every one molecule found in a mole of buffer. The consequence is an immediate increase in the volume of distribution of the local anesthetics and a lower elimination rate. Recurrences of toxicity may then occur, inasmuch as the half-life of the chylomicrons is very short (6–7 min). Close patient monitoring for several hours after lipid rescue appears mandatory.

# Introduction

Mammals maintain electrolyte balance over a wide range of physiological states. In his review of early investigations of fluid and electrolyte physiology and its translation into clinical practice [1], Holliday quoted from Walter Cannon's book The Wisdom of the Body [2]. Cannon introduced the term "homeostasis" into fluid and electrolyte physiology and discussed the mechanisms for maintaining stability in spite of "dangerous conditions in the outer world, and equally dangerous possibilities within the body . . . and yet they continue to live and carry on their functions with relatively little disturbance . . . somehow the unstable stuff of which we are composed had learned the trick of maintaining stability." By his awareness of the history of our current principles of fluid and electrolyte management, Holliday encourages continued, critical, open-minded investigation and re-evaluation of clinical practice.

The ability to manage fluids and electrolytes requires an in-depth understanding of a wide range of topics encompassing renal, hepatic, cardiorespiratory, endocrine, and central nervous system physiology. Electrolyte derangements both evolve from and cause multiorgan dysfunction. For example, electrolyte and acid–base abnormalities are associated with primary renal, neurological, hematological, and/or hepatic injury and often accompany myocardial or pulmonary failure. On the other hand, fluid and electrolyte imbalance of any etiology can produce electrophysiological abnormalities that have profound simultaneous effects on multiple organ systems. Age-related differences in organ function and pharmacodynamic responses in infants and children, coupled with congenital anomalies and genetic abnormalities, add to the complexity of fluid and electrolyte management of these patients.

In this chapter, the newborn is discussed separately from the infant and child because managing perioperative fluids and electrolytes in infants requires understanding of the unique developmental aspects of distribution of total body water and of age-related renal, hepatic, cardiorespiratory, and central nervous system physiology. Following discussion of the newborn, principles of perioperative fluid and electrolytes for the older infant and child are considered. For both the newborn and the older infant/child, background information will be translated into specific recommendations and guidelines for preoperative evaluation, intraoperative monitoring, and

delivery of glucose, crystalloid, and colloid. In all age groups, meticulously anticipating and responding to the preoperative and intraoperative events sets the stage for a smooth transition to stable postoperative fluid and electrolyte status.

# **General considerations**

Intravenous (IV) fluids replete water and electrolyte losses when oral intake is inadequate or absent. Intravenous fluid administration has at least four components: (1) replacing deficits caused by being nil per os (NPO) or from excessive losses (e.g. treating dehydration/ hypovolemia), (2) calculating requirements associated with "maintenance" water and electrolytes (e.g. insensible and urinary losses), (3) estimating ongoing fluid losses (e.g. diarrhea/vomiting, bleeding, intraoperative events), and (4) identifying additional derangements (e.g. hypoor hyperglycemia, acid-base abnormalities, pathophysiological states, such as birth asphyxia, excessive secretion of arginine vasopressin (AVP)). Although this framework for analyzing fluid delivery applies to the entire spectrum of ages from newborn to the elderly, the unique developmental physiology of the newborn and young infant alters aspects of each component. For example, estimating "maintenance" fluid depends on gestational and postnatal age and the changes in normal glucose requirements that are age dependent. Finally, derangements in fluids and electrolytes accompany many disease-induced problems, but responses to a given insult vary depending on developmental stage.

At all ages, sodium is the primary cation in the plasma and chloride is the major anion. Potassium, calcium, and magnesium comprise the remainder of the cations in the extracellular space; bicarbonate, chloride, and proteins are notable anions. The intracellular fluid primarily consists of potassium and magnesium (cations) and proteins and organic/inorganic phosphate (anions) (Table 10.1).

The regulation of the extracellular compartment is closely inter-related with cardiovascular function. Blood pressure and intravascular volume, as well as serum sodium concentration, are sensed by baro- and osmoreceptors. The responses of the heart, peripheral vasculature, kidneys, and brain to changes in pressure and osmolarity are tightly regulated by complex interactions between hormones and mediators (e.g. renin-angiotensinaldosterone system (RAS), arginine vasopressin (AVP) (also known as antidiuretic hormone (ADH), atrial natriuretic peptide, catecholamines). Other mediators finetune these regulatory hormones. Thus, a variety of hormones regulates the volume and composition of the extracellular compartment, primarily by effects on renal sodium and water balance and on cardiac and peripheral 
 Table 10.1 Composition of the extracellular and intracellular fluid compartments

vasculature. For example, if the extracellular volume expands in patients with normal physiology, urine output increases in response to increased renal blood flow and glomerular filtration; as a result, extracellular volume and osmolarity are relatively normal. However, in the presence of pathology (e.g. sepsis), the blood volume and/or arterial blood pressure may not increase in response to an expanded extracellular volume due to increased capillary permeability and widespread edema and organ dysfunction (e.g. pulmonary edema).

Tight regulation of the extracellular fluid compartment ultimately determines the intracellular volume space. That is, if the osmolality of the extracellular compartment changes, water moves into or out of cells; water readily equilibrates across cell membranes in response to changes in solute concentrations. In contrast, movement of a solute depends on the permeability of the solute in a specific membrane and on hydrostatic and osmotic gradients. The mathematical relationship (Starling equation) [3] describing net water movement across a membrane includes factors for oncotic and hydrostatic pressures on either side of the membrane (e.g. interstitium and the intravascular space):

$$J_v = KF ([P_C - P_I] - \delta[\pi_c - \pi_I])$$

where  $J_v$  = the net flow across the membrane,  $K_F$  = fluid filtration coefficient of the membrane,  $P_C$  = hydrostatic pressure (e.g. capillary),  $P_I$  = hydrostatic pressure (e.g. interstitial),  $\delta$  = solute reflection coefficient (permeability of solute across a specific membrane),  $\pi_c$  = oncotic pressure (e.g. capillary), and  $\pi_I$  = oncotic pressure (e.g. interstitial). Fluid moves as a function of the product of the permeability of the membrane and net driving pressure (hydrostatic pressure minus oncotic pressure). If this relationship is disturbed (e.g. when membrane trauma decreases the reflection coefficient for proteins), the interstitial compartment may expand (i.e. edema develops). In the normal patient, oncotic and hydrostatic pressures are balanced but with various disease states, the interstitial space expands at the expense of the intravascular space. For example, increased capillary permeability during sepsis (trapping protein in the interstitial space, increasing  $\pi_i$ ) or increased venous pressure with positive pressure ventilation (increasing  $P_C$ ) may produce edema and/ or decrease intravascular volume.

# The newborn: developmental aspects of fluids and electrolytes

# Developmental changes in fluid compartments and distribution of water

In the newborn, total body water accounts for  $78 \pm 5\%$  of total bodyweight. It decreases to 60% (mostly due to loss from the extracellular fraction) by 6 months and to 57% later in childhood. Total body water is distributed into both the intracellular (ICW) and extracellular (ECW) fluid compartments (Fig. 10.1). In the fetus, the extracellular compartment predominates, contributing ~62% of bodyweight during the first trimester but only ~43% at term. At the same time, ICW increases from 25% to 32% of bodyweight [4,5]. Because the ratio of surface area to

**Figure 10.1** Body compartments: fetus to adult. Total body water, extracellular water, intracellular water as a percentage of bodyweight. Reproduced from Friis-Hansen [5] with permission from the American Academy of Pediatrics.

volume decreases with maturation, the total body water actually increases after the first month of extrauterine life. However, ECW and plasma volume remain constant as a function of surface area.

With their larger surface area, premature infants have a greater percentage of their bodyweight as total body water and a larger ECW compartment than infants born at term. The change in total body water distribution, as a function of weight, continues postnatally so that by 3 months of life, the intracellular compartment is larger than the extracellular compartment. The adult ratio of ECW to ICW is achieved by about 1 year of age. ECW is divided into plasma and interstitial compartments. The plasma compartment remains constant throughout life, comprising ~5% of bodyweight. Although two additional body compartments (slowly exchangeable areas (e.g. bone and cartilage) and transcellular) are actually extracellular, neither is a clinically important site for water exchange under normal circumstances.

The values for blood volume of normal infants and children [6] and low-birthweight infants [7] measured 4–5 decades ago remain the accepted norms for estimating a wide variety of clinically important therapy, such as blood loss and transfusion of blood products, distribution of drugs, etc. The blood volume gradually decreases (as a function of weight) with growth and development. Thus, the blood volume for premature infants is ~100 mL/kg, for full-term infants is 85–90 mL/kg, for 2 year olds is 80 mL/kg, and for older infant and adolescents is 75–80 mL/kg.

## Insensible water loss

Insensible water loss occurs primarily through evaporation from the skin (~70%) and from the respiratory tract (~30%). The total volume and source of this loss vary with ambient temperature and relative humidity [8] and are directly proportional to the exposed surface area. Because the ratio of skin surface area to bodyweight increases as gestational age decreases, most premature infants lose large amounts of water transcutaneously. Other factors, including increased permeability of and blood flow to the skin and lesser amounts of subcutaneous fat, augment transcutaneous water loss. The cornified layer of extremely low-birthweight (ELBW) infants (<1000 g) consists of only 2-3 cell layers, which provides a less effective barrier to diffusion of water, especially during the first days after birth [9]. The newborn's higher minute ventilation increases insensible water loss from the lungs. Tachypnea further exaggerates transpulmonary water loss.

#### Neutral thermal environment

In a neutral thermal environment (skin temperature  $36-36.5^{\circ}$ C with an environmental temperature of  $32-34^{\circ}$ C) [10], newborns expend the least amount of energy to

maintain a normal body temperature, which improves growth [11]. For decades, eliminating "cold stress" has been correlated with improved survival of premature infants [12,13]. Overhead radiant warmers provide stable environmental temperatures and allow easy access to critically ill infants, but they also increase transcutaneous insensible water loss, at least during the first 2-4 days of life [14]. Despite having higher fluid requirements than infants cared for in incubators, infants cared for under overhead warmers have similar long-term weight gain, length of hospital stay, and incidence of adverse outcomes (e.g. chronic lung disease, necrotizing enterocolitis, intraventricular hemorrhage). Phototherapy for treatment of hyperbilirubinemia of the newborn also increases transcutaneous water loss. Recently, investigators suggested that providing a humidified environment improves fluid and electrolyte balance and growth, especially in ELBW infants [15].

Surgery performed in either the intensive care nursery (ICN) or the operating room often necessitates moving the patient from a protected and/or humidified environment to an open bed. Overhead warming and enclosed humidifying devices cannot be used during surgery because they limit access to the patient. These warmers also cannot be used during transport of infants to an operating room for lack of electricity. To minimize heat and fluid loss during transport and surgery, newborns should be covered with plastic shields, polyethylene blankets or semi-occlusive skin barriers (e.g. Seran Wrap<sup>TM</sup>), and a hat. In addition, portable warmers placed under the infant help maintain body temperature during transport, and a variety of electrical warming devices are utilized intraoperatively.

## **Developmental physiology**

Various aspects of age-related characteristics of renal, cardiac, hepatic, hematological, and neurological function directly affect fluid and electrolyte balance in the newborn. Each will be discussed briefly.

## Renal physiology: glomerular filtration rate, tubular function (see Chapter 8)

Maintenance of normal extracellular fluid volume, electrolyte concentrations, and water balance is inter-related and undergoes significant postnatal changes that are highly dependent on renal function. By 35–36 weeks' gestation, neonates have approximately the adult number of nephrons. Thereafter, both the glomeruli and tubules increase in size. The renal vasculature matures in parallel with the nephrons. In general, fetal and neonatal renal function is characterized by low renal blood flow (high vascular resistance), low glomerular filtration rate (GFR), low excretion of solids, and limited ability to concentrate the urine. Filtration of solutes and electrolytes across the renal capillaries is the first step in urine formation. Glomerular filtration is present as early as the 10th week of gestation and increases steadily throughout fetal life (10–13mL/min/1.73m<sup>2</sup> at 25–28 weeks' gestation and 20–25mL/min/1.73m<sup>2</sup> after 34 weeks' gestation [16]) and after birth. It reaches adult levels at 1–2 years of life (~125mL/min/1.73m<sup>2</sup>, although values vary between men and women). Urine production also increases steadily throughout gestation (2–5mL/h at 20 weeks' gestation, 10–12mL/h at 35 weeks' gestation, and 35–50mL/h at 40 weeks' gestation) [17].

In spite of differences in normal vascular resistance, arterial blood pressure, blood flow, and the responses to a variety of physiological stimuli (e.g. blood loss, sepsis, hypoxia) at various stages of development, GFR always depends on the difference between hydrostatic and oncotic pressures across the renal capillaries (see General considerations, above). At any filtration pressure, GFR is a function of plasma flow and of surface area and permeability of the capillaries. As the number and size of nephrons increase during fetal life, GFR steadily increases until ~35 weeks' gestation. After birth, GFR increases dramatically, approximately doubling in the first 2 weeks of life and tripling 3 months after full-term gestation. GFR increases at a slower rate in preterm infants, especially in the ELBW infant [18]. The change in GFR reflects increasing capillary surface area and filtration pressure (arterial blood pressure) and decreasing afferent and efferent vascular resistance.

Serum creatinine is commonly used as a surrogate marker for GFR. However, at birth the infant's creatinine concentration reflects that of the mother and is higher than stable, normal values of 1–2-week-old normal term neonates (0.4 mg/dL). In fact, plasma creatinine is higher in preterm than in term infants during the first 4 weeks of life [19]. Serum creatinine concentrations did not differ at birth among 27–32-week gestation neonates and increased in all groups over the first 3 days of life, after which it gradually decreased to <0.5 mg/dL [20]. Creatinine clearance increases in all groups but increases more slowly in <27-week gestation infants.

In addition to dramatic increases in GFR and renal blood flow during fetal and postnatal life, unique and critical developmental changes occur in the renal tubules. The plasma ultrafiltrate formed from glomerular filtration is presented to the proximal tubules, which play a major role in regulating the serum concentrations of a wide variety of molecules (e.g. sodium, chloride, potassium, phosphate, acid, glucose, amino acids) and water excretion. Depending on the nutrition and metabolic state of the patient, this tightly controlled activity results in salvage or excretion of the solutes. Neonates, especially prematures, neither excrete nor reabsorb sodium as well as more mature infants. For example, 5% of the filtered sodium load is excreted by a <30-week gestation infant, but only 0.2% of filtered sodium appears in the urine of term infants [21]. Premature newborns maximally concentrate their urine to 245-450 mOsm/L, while term infants can achieve 600-800 mOsm/L; adults concentrate their urine to 1200-1400 mOsm/L. Response to 1-desamino-8-D-arginine vasopressin (DDAVP) follows a similar pattern: 30-35-week gestation infants achieve an osmolality of 520 mOsm/L, a 1-month-old term infant, 570 mOsm/L, and a 1-2-year-old child, 1300-1400 mOsm/L. After 35 weeks' gestation, infants can dilute their urine to adult levels (50 mOsm/L); <35-week gestation newborns can only dilute their urine to 70 mOsm/L [16].

Tubular immaturity accounts for other acid-base and electrolyte features of the newborn. The Na<sup>+</sup>-K<sup>+</sup>-ATPase pump exists in all mammalian cells and is critical for maintaining the normal intracellular/extracellular distribution of sodium and potassium. Located on the basolateral membrane, activity of this enzyme accounts for approximately 70% of renal oxygen consumption. The enzyme exchanges three sodium ions for two potassium ions by an active transport process (utilizes ATP). Moving sodium extracellularly maintains the inwardly directed sodium gradient, which is the driving force for several secondarily active membrane transport proteins. These transporters mediate reabsorption of glucose, amino acids, and other nutrients across the brush border membranes of the renal proximal tubules. Thus, sodiumdependent transporters salvage amino acids, glucose, phosphate, and other molecules from the glomerular filtrate that enters the proximal tubules. Sodium is cotransported down its concentration gradient, which provides the energy to move the substrate from the filtrate into the cell against a concentration gradient. At birth, the activity of the Na<sup>+</sup>-K<sup>+</sup>-ATPase transporter increases 5-10-fold [22]; the increase is often blunted in preterm infants. Similar developmental changes in other transporters (e.g. Na<sup>+</sup>/H<sup>+</sup> antiporter [23]) may account in part for differences in acid-base balance in newborns and older infants, children, and adults.

Due to immaturity of the renal tubules, reabsorption of glucose is impaired, and glucosuria occurs in preterm infants at serum glucose concentrations as low as 100 mg/dL. Similarly, bicarbonate loss due to incomplete tubular reabsorption leads to decreased serum bicarbonate concentrations (12–16mEq/L, <26–28 weeks' gestation; 18–20mEq/L, 30–35 weeks' gestation; 20–22mEq/L, term infant; 25–28mEq/L, adult) [24]. As usual, mild hyperkalemia co-exists with metabolic acidosis (i.e. intracellular potassium moves extracellularly in exchange for protons that move intracellularly).

The newborn's renal function changes with both gestational and postnatal age. Due to rapid maturation after birth, the 3-week old, ex-27 week gestation infant usually demonstrates more mature renal function than a 1-dayold term infant. It appears that exposure to solute improves filtration and tubular function.

### Arginine vasopressin

Arginine vasopressin (AVP) modulates maintenance of normal osmolality by increasing free water reabsorption by insertion of water channels (vasopressin-sensitive water channel (aquaporin 2)) into the distal tubule and collecting ducts [25,26]. In addition, AVP induces peripheral vasoconstriction that is often associated with a rise in arterial blood pressure. The concentration of AVP is elevated in the newborn, and this has been correlated with the neonate's low urine output during the first 24-48h of life. Hypoxia, lung injury (bronchopulmonary dysplasia), and central nervous system injury (intraventricular hemorrhage) increase AVP secretion in both term and preterm infants [27] which, through its effects on free water reabsorption, can cause hyponatremia. In some cases, the etiology of hyponatremia is due to abnormal release of and response to AVP (ADH). This leads to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), the diagnosis of which should be reserved for cases where circulating AVP concentrations are elevated despite the absence of both osmotic and baroreceptor-mediated stimuli [26].

Because of their limited ability to concentrate urine, newborns are also at increased risk for hyponatremia from the non-osmotic secretion of AVP (e.g. pain, nausea and vomiting, positive pressure ventilation) (see sections on Physiology of hyponatremia, Clinically relevant concepts, and Intravenous fluids and hyponatremia: current controversy). Renally produced prostaglandins (PG) counterbalance the effects of AVP. Specifically, PGE2, PGD2, and PGI2 increase renal blood flow, free water clearance, urine flow, and natriuresis [28].

### **Renin-angiotensin-aldosterone system**

The juxtaglomerular apparatus (which consists of smooth muscle cells in the wall of the afferent arteriole) responds to various inputs (e.g. decreased sodium or chloride in the distal nephron (macula densa), decreased renal blood flow, sympathetic nervous system input) by secreting renin. Renin stimulates production of angiotensin I from angiotensinogen, and angiotensin-converting enzyme mediates formation of angiotensin II from angiotensin I. The direct effects of angiotensin II include vasoconstriction, release of catecholamines from the adrenal glands, sodium and water reabsorption, and the release of aldosterone [29]. Aldosterone induces potassium secretion and sodium reabsorption in the distal tubule. Thus, AVP's role is primarily to preserve normal osmolality whereas that of the RAS system is to maintain extracellular fluid volume. However, the newborn kidney has decreased capacity to respond to either and this accounts, in part, for the high levels of these hormones over the first few weeks of postnatal life [30].

Renin is present as early as 5 weeks' gestation. While plasma renin concentration and activity are high in utero, they increase further postnatally and then slowly decrease during infancy. Similarly, the concentrations of aldosterone and angiotensin II are high in both fetuses and neonates, and plasma renin activity and aldosterone are markedly elevated in the early postnatal period in preterm infants. The increased activity of the RAS in both newborns and infants, along with the low GFR, are responsible for much of the physiology of sodium balance in the preterm, neonatal, and infant kidney. Similar to the responses to AVP, prostaglandins partly counterbalance the vasoconstricting effects of aldosterone, angiotensin, and renin. Of note, the renal dysfunction that sometimes follows the administration of indometacin (a prostaglandin inhibitor) to close a patent ductus arteriosus has been attributed to the unopposed vasoconstrictive effects of angiotensin and AVP and the absence of the vasodilatory effects of prostaglandin [28].

In addition to their vasoactive roles, angiotensin II and angiotensin-converting enzyme also mediate renal growth and development. Inhibition of angiotensin has teratogenic effects, as occurs when angiotensin-converting enzyme inhibitors are given to mothers during the second and third trimesters of pregnancy. The effects of these drugs include fetal hypotension, renal tubular dysplasia, anuria/oligohydramnios, growth restriction, hypocalvaria, and death [31].

### Atrial natriuretic peptide

This hormone counterbalances the effects of the RAS through its direct vasodilatory and naturiuretic effects and by inhibiting the release of renin and aldosterone [32]. The concentration of atrial natriuretic peptide (ANP) in newborn humans has been correlated with atrial size, status of the ductus arteriosus, and extracellular volume [33].

Thus, interactions of the renal and cardiovascular systems regulate the child's fluid and electrolyte status. Clearly, the highly variable blood pressures and intravascular volumes of critically ill newborns may elicit dramatic and even pathological responses via AVP, aldosterone, and the RAS.

# Cardiovascular physiology: cardiac output, heart rate, calcium flux

At birth, elimination of the placental circulation and initiation of ventilation decreases pulmonary vascular resistance and increases pulmonary blood flow. At the same time, systemic vascular resistance increases. Left atrial pressure rises, which functionally closes the foramen ovale. These events, and the closure of the ductus arteriosus and ductus venosus, are the most critical aspects of the cardiovascular transition from intra- to extrauterine life.

Cardiac output per kilogram bodyweight is higher in newborns than at any other age. Nonetheless, at any developmental stage, ventricular function is determined by the same factors: preload, afterload, contractility, and heart rate. However, the ability to compensate for abnormalities is narrow in the newborn, especially in the ELBW infant. That is, in preterm infants (some of whom are born at midgestation), the immature myocardium and the peripheral circulation are at significant disadvantage when the low-resistance placenta is abruptly replaced with the higher resistance pulmonary and systemic vascular beds and interventions such as positive pressure ventilation and inotropic support are introduced at birth. While volume loading the immature ventricle increases cardiac output, it does so to a far lesser extent than at older ages [34]. Finally, since the resting heart rate of the newborn is high, increasing the heart rate above normal has less effect on cardiac output. Decreasing heart rate drastically reduces cardiac output.

Differences in myocardial ultrastructure (e.g. receptors, channels, transporters, pumps, contractile proteins) and the immaturity of various intracellular structures (e.g. myofibrils, sarcoplasmic reticulum, microtubules) influence clinical management of fluids and electrolytes, especially in the often unstable perioperative period. For example, the volume of the sarcoplasmic reticulum and its ability to pump calcium increases *in utero* and postnatally. In addition, the various subtypes of sarcoplasmic reticulum are less differentiated functionally in the immature heart [35]. Probably because of these differences, immature hearts are more sensitive to calcium channel antagonists [36], and maximal contractility is more dependent on extracellular calcium [37] than in adults.

The relationship between arterial blood pressure (BP), cardiac output (CO), and systemic vascular resistance (SVR) remains the same throughout life:  $BP = CO \times SVR$ . That is, pressure and flow are not equal but are related via resistance. Thus, flow to an organ may increase, decrease or remain constant over a wide range of blood pressure, depending on changes in vascular resistance. Because of the unique physiology of the ELBW infant, measuring cardiac output and defining "normal" for parameters such as arterial blood pressure and heart rate are difficult. Marked variability in the quantity of blood flowing across the foramen ovale and ductus arteriosus adds to the complexity of monitoring the cardiovascular function of the premature infant. For example, defining hypotension is not simple [38,39]. Although the normal

**Figure 10.2** Predicted lower limit of mean blood pressure in newborns (initial 72 h of life). Reproduced from Engle [126] with permission from Elsevier.

ranges for blood pressure correlate with gestational age [40,41], the definition of hypotension remains elusive. One study noted that mean blood pressures that were below the gestational age in weeks were correlated with the 10th percentile for arterial blood pressure [42]. They recommended this criterion as a definition of hypotension (Fig. 10.2).

Nonetheless, the variability in "normal" arterial blood pressures and heart rates among infants of the same gestational and/or postnatal ages creates a dilemma in the clinical care setting, especially during the commonly unstable perioperative period. Recognizing that neither arterial blood pressure [43,44] nor capillary refill time [45] reliably correlates with left ventricular output in preterm infants, flow in the superior vena cava has been suggested to estimate systemic blood flow to the brain (and upper body). This eliminates the need for considering the influence of shunting through the ductus arteriosus or the foramen ovale on the accuracy of the measurement [46]. Of interest, neither dopamine nor dobutamine increased contractility when the drug was given to treat low superior vena cava blood flow [47]. Unfortunately, "functional echocardiography" requires sophisticated equipment and experience so that its use as a routine bedside monitor remains impractical.

Thus, until bedside monitoring allows direct measurement of flow, assessing acid–base status and intravascular volume of infants to define appropriate fluid administration requires integrating readily available cardiovascular parameters (e.g. arterial blood pressure, heart rate) with renal, hepatic, central nervous system, and respiratory function. For example, electrolyte concentrations, pH, pCO<sub>2</sub>, and urine output must be interpreted in the context of an infant's overall clinical condition (e.g. sepsis, bleeding, neurological status) as well as specific trends in arterial blood pressure, heart rate, and peripheral perfusion over multiple hours. Changes over time provide more useful information than isolated measurements.

# Central nervous system physiology: autoregulation of cerebral blood flow

Although cerebral vascular autoregulation is present in both preterm and term neonates after birth, the range of arterial blood pressures over which flow is regulated is narrower for preterm infants and seems to be easily disrupted [48,49]. In addition, the blood pressure of preterm infants is normally close to the lower autoregulatory limit, especially in the ELBW infant [49-52]. The upper range of autoregulation has not been clearly established in the newborn [49]. Of importance, autoregulation seems to be disturbed or disrupted by hypoxia, acidosis, seizures, and by the low diastolic blood pressures of patients with a patent ductus arteriosus [50,51]. Rapid increases in arterial blood pressure (e.g. from overly aggressive fluid administration) can rupture the fragile immature brain vessels, while hypotension and low cerebral perfusion pressures may produce cerebral ischemia. More than at any other developmental stage, the intravascular volume status of the neonate, especially preterm neonates, may have rapid and significant effects on the brain.

#### Hepatic physiology: glucose and coagulation

To discuss hepatic function from the perspective of neonatal fluids and electrolytes, two topics are most relevant: glucose homeostasis and coagulation of blood.

#### Glucose homeostasis

The transplacental supply of glucose to the fetus is abruptly interrupted at birth, which requires neonates to convert their liver glycogen stores to glucose by glycogenolysis or to produce glucose by gluconeogenesis. Compared to adults, the liver of term infants is larger and has a greater store of glycogen [53]. Thus, after the first day of life, most term infants can maintain a normal serum glucose concentration during a 10-12-h fast. Since glycogen storage and the capacity for its degradation mostly occur during the last trimester of pregnancy, infants born in the second or early third trimester often develop hypoglycemia, especially in the first 24-48h of life. The fetal liver apparently does not produce glucose by gluconeogenesis [54], but a variety of hepatic enzymes required for this process (e.g. glucose-6-phosphatase) develop rapidly after birth.

Glucose concentrations in the fetus remain constant (~50–55 mg/dL) during the third trimester of pregnancy if maternal carbohydrate metabolism is normal. In experimental animals, glucose utilization at midgestation is ~9.5 mg/kg/min and decreases to ~5 mg/kg/min at term [55]. These data provide estimates of normal serum glucose requirements for premature infants of similar gestation. Of note, the rates of glucose production

	Prothrombin time (sec) (range)	Partial thromboplastin time (sec) (range)	Thrombin time (sec) (range)
Adults	13.0 (11.2–14.5)	44.0 (36.8–50.0)	10 (9.0–11.1)
Term infants	13.6 (12.8–14.4)	65.2 (50.0–84.0)	12.5 (10.0–15.0)
ELBW infants	15.4 (14.6–16.9)	108 (80.0–168)	14.9 (11.0–17.8)

Table 10.2 Normal values of coagulation function in newborns compared with adults

From Barnard DR, Simmons MA, Hathaway WE. Coagulation studies in extremely premature infants. Pediat Res 1979; 13: 1330-5.

(7–10 mg/kg/min) by stable preterm infants who are receiving intravenous alimentation [56] are similar to those of fetal animals. The brain consumes ~4–5 mg/kg/min, protein synthesis ~2–3 mg/kg/min, and other organs (e.g. liver, heart, muscle) utilize the remaining glucose. A surge in the concentration of catecholamines, glucagon, and cortisol (e.g. during birth or stress) increases glycogenolysis and gluconeogenesis, often resulting in hyperglycemia. In high-risk newborns (e.g. large or small for gestational age, premature infants, asphyxiated infants), glucose concentrations must be monitored and infusion rates adjusted to maintain normoglycemia.

Initially, glucose should be infused at rates of ~5–6 mg/kg/min in NPO newborns (e.g. 10% dextrose, 4mL/kg/h = 6.6 mg/kg/min of glucose) and the rates adjusted to maintain serum glucose concentrations of 60–90 mg/dL. For infants who are stable on a well-established regimen, the glucose infusion rates in the operating room should mimic those used in the ICN and should be altered if hypo- or hypergylcemia develops. In many cases, especially in small infants, obtaining a blood sample may be difficult without an arterial or central venous catheter in place. Currently available devices allow glucose measurements on a single drop of blood, which can be obtained from a finger, toe or ear lobe.

Monitoring glucose intraoperatively is particularly relevant in critically ill newborns, because their symptoms of hypoglycemia are sometimes absent and often vague. The non-specific symptoms of hypoglycemia include irritability, jitteriness, and apnea in this age group, which are masked by general anesthesia. Hypoglycemia can have devastating effects on the central nervous system through effects on cerebral blood flow. Magnetic resonance imaging (MRI) of the brain of hypoglycemic newborns demonstrates white matter abnormalities, and clinical evaluation at 18 months of age revealed persistent central nervous system injury [57]. Older pediatric patients with abnormal glucose metabolism also have increased morbidity and mortality [58].

## Coagulation

Coagulation factors do not efficiently cross the placenta. Although these factors are produced by the fetus, their plasma concentrations and the laboratory tests used to monitor their function (prothrombin time (PT), activated partial thromboplastin time (APTT)) differ markedly in both normal term and preterm infants and adults (Table 10.2). Concentrations of vitamin K-dependent proteins (factors II, VII, IX, X), factors XI and XII, prekallikrein, and kininogen are about 50% those of adults. On the other hand, the levels of fibrinogen, factors V and VIII are similar to those of adults [59,60]. Coagulation disturbances associated with liver dysfunction are linked to decreased synthesis of clotting and fibrinolytic factors and with abnormal platelet function. PT correlates with availability of factor VII. APTT primarily reflects the amount of thrombin generated. The concentration of thrombin in newborns is about 50% that of adults.

In spite of the differences in liver function between newborns and adults, clinically significant bleeding is uncommon in normal neonates with adequate vitamin K levels. On the other hand, sepsis and/or asphyxia-induced disseminated intravascular coagulation (DIC) increase the risk for bleeding. Both asphyxia and sepsis deplete coagulation factors (e.g. fibrinogen, factors V and VIII, and platelets) and produce fibrin degradation products. To compensate for abnormal levels of coagulation factors, especially if accompanied by cardiovascular instability and ongoing blood loss, administering specific blood components not only improves clotting function but may also replete intravascular volume.

#### Hematological physiology

In otherwise normal appropriate for gestational age (AGA) fetuses, hemoglobin concentration varies with gestational age (14g/dL at 25 weeks' gestation, 16g/dL at 30 weeks, 17g/dL at 35 weeks, 18g/dL at term) [61] but not with gender. The higher concentration of hemoglobin of small for gestational age (SGA) infants at birth may compensate for intrauterine hypoxia and may represent a response to elevated concentrations of erythropoietin [62]. In contrast, compared to both SGA and AGA infants, preterm infants have lower concentrations of hemoglobin at birth. In addition, the normal postnatal decrease in hemoglobin occurs more rapidly in premature infants [63].

Indications for transfusion of red blood cells or other blood components pre-, intra- or postoperatively must be defined in the context of the patient's cardiorespiratory status, ongoing blood and fluid losses, and response to delivery of crystalloid and colloid.

# Neonatal perioperative fluids: general concepts

For the first 2–3h of life, the neonate's electrolyte concentrations reflect those of the mother and of perinatal events (e.g. asphyxia, placental or umbilical cord hemorrhage). Afterwards, the electrolyte concentrations reflect a balance between normal metabolism, cardiovascular, renal and hepatic function, and ongoing metabolic derangements (e.g. sepsis, congenital metabolic diseases, complex cyanotic congenital heart disease, etc.). Until adequate tissue perfusion is established and wash-out of accumulated acid and other metabolic byproducts of anaerobic metabolism occurs, metabolic acidosis may persist in depressed newborns, especially those who were severely asphyxiated and required resuscitation.

Sodium is seldom added to intravenous maintenance fluids of term and late preterm infants during the first 24h of life. During this time, urine output is usually low (see section on Renal physiology, above), despite the fact that 30 mL/kg of fluid must be mobilized from the lungs during and after birth [64]. On day 2 of life, sodium (2-6 meq/kg/day) is added to the intravenous fluids. In the ELBW infant, sodium-containing fluid is often required as early as 12-24h of life to maintain adequate intravascular volume, especially when there is evidence for excessive transcutaneous fluid losses (see section on Insensible water loss, above). After the first few days of life, adequate sodium intake is essential for infants of all gestational ages to sustain normal growth and weight gain. Poor skeletal and tissue growth, as well as adverse neurodevelopment, are associated with chronic sodium deficiency [26].

Ensuring normal fluid and electrolyte balance in the newborn in the presence of the high metabolic rate associated with growth, marked insensible water losses, and the limited ability to salvage and excrete water and solutes requires accurate monitoring of fluid loss (i.e. urine, gastrointestinal, cerebrospinal fluid, blood sampling) and electrolyte concentrations to guide the quantity and quality of replacement fluid. Frequent measurements of bodyweight will document excessive gain or loss and these data should be correlated with simultaneous trends in serum electrolyte concentrations (e.g. decrease or increase in sodium). Especially in the premature infant, surgery and anesthesia have dramatic effects on distribution of water and electrolytes and on organ function (e.g. cardiovascular, hepatic, renal). Based on the complex interactions between illness and immaturity, the anesthesiologist must consider the following when determining appropriate fluid and electrolyte management in the newborn (see Table 10.3).

- The normal postnatal diuresis contracts the extracellular space in all newborns, and to a greater degree in preterm infants. During the first few days after birth, negative fluid and electrolyte balance occurs normally in healthy term infants, but prematurity and/or hemodynamic instability may require aggressive intravascular fluid administration.
- Transepidermal fluid loss is inversely related to gestational age and can be as much as 60–100 mL/kg/ day in ELBW infants. During the first few postnatal days, naked preterm infants lose 15 times more water by evaporation than naked term infants [65].
- Providing a warm, humidified environment and/or the use of plastic shields reduces transepidermal fluid loss, especially in the ELBW infant. Shielding devices are difficult or impossible to use during surgery but should be used during transport of the patient to and from the operating room and in the operating room before and after surgery.
- The hypothesis that overhydration or hyper- or hyponatremia increases the incidence of patent ductus arteriosus, necrotizing enterocolitis, and chronic lung disease should be considered, but data documenting a strong correlation with these variables are inconsistent.
- An intravenous infusion of calcium is usually required in preterm, asphyxiated or large for gestational age (LGA) or small for gestational age (SGA) infants until they establish adequate enteral nutrition. Ideally, calcium is infused into a central venous catheter. Infiltration of calcium into subcutaneous tissue usually causes extensive tissue necrosis.

#### Preoperative evaluation of the neonate

The focus of any preoperative assessment includes identifying aspects of the patient's history and physical examination that are relevant to the surgery/procedure and anesthetic management. For example, in the case of newborns, this includes consulting with the staff in the intensive care nursery to identify the normal variability in the heart rate and blood pressure and the cardiovascular responses to interventions such as change in positioning, fluid administration or positive pressure ventilation. Details of labor and delivery are critical to analyze in the first 2–3 days of life, but they become less relevant as the baby gets older and recovers from her/his adaptation to the effects of *in utero* events. For example, the effects of a placental hemorrhage or severe asphyxia may have a dramatic impact on fluid management during the first day of life but will have less impact at 2 weeks of age. The 2

#### Table 10.3 Intraoperative fluids: newborn

Thirty-week gestation infant, 5 days old, 1.2 kg at birth, now 1.0 kg, with bowel perforation associated with necrotizing enterocolitis, is scheduled for open laparotomy. Her abdomen is distended, nasogastric tube in place. She requires ventilatory support (18/4, rate of 50,  $FIO_2 = 0.40$ ). Urine output has decreased from 2 mL/kg/h to 0.5 mL/kg/h. Two peripheral IVs and an umbilical artery catheter are in place. BP 50/24, heart rate 160 bpm, stable after multiple boluses of normal saline, platelets, fresh frozen plasma, fibrinogen. Dopamine infusing, 8 µg/kg/min. D10 with protein and electrolytes infusing at 5 mL/h.

- Arterial blood gas: pH 7.35; pO<sub>2</sub> 62; pCO<sub>2</sub> 37.
- Electrolytes: Na<sup>+</sup> 135; K<sup>+</sup> 4.6; Cl<sup>−</sup> 106; HCO<sub>3</sub><sup>−</sup> 18; Ca<sup>++</sup> 1.0; glucose 100 mg/dL.
- Renal function: BUN 32/creatinine 0.9.
- Hemoglobin 15; platelets 75,000; PT 18 sec; PTT 85 sec; fibrinogen 90.

Deficit	Maintenance	Ongoing losses
OmL	• 5 mL/h D10 infusing	<ul> <li>Blood products available in operating room: RBCs, fresh frozen plasma; platelets available</li> <li>Infuse crystalloid, 10–50 mL/kg/h or more; boluses to maintain hemodynamic instability</li> <li>RBCs for blood loss (1 mL for each 2–3 mL of blood loss). Fresh frozen plasma infusion/boluses in response to bleeding/laboratory values</li> <li>Monitor Hg, PT/PTT, platelets</li> </ul>

The same patient, now 2 months old, now dependent on total parenteral nutrition (TPN) secondary to "short gut" after surgery for necrotizing enterocolitis scheduled for hernia repair. No ventilatory support, no meds. No enteral intake; D15 with protein and electrolytes infusing at 25 mL/h; weight 4.2 kg; hemoglobin 10g/dL; glucose 90 mg/dL; open herniorrhaphy.

Deficit	Maintenance	Ongoing losses
0 mL	<ul> <li>According to "formula", 17 mL/h</li> <li>Tolerating 25 mL/h in ICN; continue 25 mL/h intraoperatively</li> </ul>	<ul> <li>Insignificant</li> <li>Bolus of crystalloid only in response to hemodynamic instability</li> <li>Transfusion unnecessary unless unexpected blood loss; postoperative apnea may prompt transfusion</li> </ul>

BUN, blood urea nitrogen; ICN, intensive care nursery; PT, prothrombin time; PTT, partial thromboplastin time; RBC, red blood cell.

week old may have residual but stable renal failure and neurological and hepatic insults, but it is likely he or she will have recovered from asphyxia-induced cardiac depression. Understanding how fluids and electrolytes were managed before surgery will help avoid dangerous and unnecessary alterations in therapy (e.g. rate of glucose delivery). Of course, intraoperative events, such as general anesthesia, blood loss, and increased insensible losses (e.g. open abdomen with exposed intestine), often require changes in the volume and type of fluid delivered. Developing an effective relationship with the intensive care nursery staff facilitates intraoperative consultation with the primary medical team, if necessary.

The following summarizes the most significant aspects of preoperative evaluation of the newborn.

**1.** Review of labor and delivery; documentation of appropriate fetal growth (AGA, LGA or SGA).

2. Review of systems.

• Trend in weight (daily or more frequent)

- Trend in intravenous and oral intake and urine output and specific gravity
- Trend in other output (gastrointestinal, cerebrospinal fluid, etc.)
- Composition of intravenous fluid (glucose, sodium, calcium) correlated with corresponding trends in plasma concentrations of these electrolytes
- Hemodynamic instability: trends in heart rate, arterial blood pressure, peripheral perfusion; presence and effect of patent ductus arteriosus or other cardiovascular dysfunction (e.g. tricuspid regurgitation after asphyxia)
- Current hemoglobin concentration and recent trend correlated with hemodynamic function; determine if this patient "requires" a minimum level of hemoglobin (e.g. increased heart rate or acidosis if the hemoglobin is <10g)</li>
- Central nervous system insult (presence of intraventricular hemorrhage)

- Current coagulation status, history of bleeding, and trends and requirements for blood components; availability of blood products.
- **3.** Adequacy of intravenous access and monitors (functioning arterial, venous or central venous catheters).
- 4. Estimate "allowable blood loss" as part of the preoperative evaluation. For example, blood volume in a 3-day-old, 1 kg infant is 100 mL/kg, or 100 mL. A loss of 20 mL of blood is 20% of the blood volume. Anticipating the need for transfusion depends on the current hemoglobin concentration and history of tolerance for decreasing blood volume and/or hemoglobin.

## Intraoperative fluid management

During transport from the ICN to the operating room, intravenous infusions, ventilatory support, body temperature, and monitoring of hemodynamic status/ oxygenation must be maintained. At a minimum, heart rate and oxygen saturation should be continuously monitored, and more invasive hemodynamic monitoring (e.g. arterial blood pressure) may be required depending on the clinical condition of the patient. The infant's head and body should be covered with semi-occlusive material and/or blankets to reduce evaporation and heat loss. Portable warming devices are often placed under the infant. Intravenous infusions that will be used in the operating room should be available and functioning before leaving the ICN. For example, the extensions on the intravenous and intra-arterial tubing should be long enough to allow their easy access with the surgical drapes in place.

Initially in the operating room, glucose infusion should continue at the same rate used in the intensive care nursery to maintain normoglycemia. Often, simply continuing the infusion of "maintenance" fluid or total parenteral nutrition is appropriate. In surgical procedures lasting longer than 1h, monitoring glucose concentrations is needed to ensure normoglycemia. In most cases, additional non-glucose containing fluid must be delivered to compensate for intraoperative events and losses of blood and fluid. To avoid hyperglycemia and its sideeffects (e.g. osmotic diuresis, central nervous system injury), glucose-containing solutions should never be used to replace volume losses. A variety of techniques allows the anesthesiologist to separate delivery of glucose (e.g. maintenance fluid) from intravenous crystalloid and/or colloid needed to replace intraoperative losses (e.g. multiple peripheral intravenous catheters or several access ports inserted into one peripheral or central line).

As always, anesthesia agents should be titrated to maintain appropriate hemodynamic status during induction of anesthesia. Newborns, especially premature newborns, vary enormously in their responses to anesthetic agents and are prone to hypotension. For example, an older infant or child may tolerate high concentrations of sevoflurane briefly for induction of anesthesia, but the same concentration of drug in a newborn often results in marked hemodynamic instability. Rapid delivery of intravenous agents to neonates may also cause significant cardiovascular instability. Often, dramatic hemodynamic responses to anesthetics (e.g. hypotension, tachycardia) require prompt rapid delivery of a bolus of normal saline or lactated Ringer's solution (5–10 mL/kg or more).

As surgery proceeds, blood loss and coagulation abnormalities often require the administration of various blood components to maintain intravascular volume and hemodynamic stability, and to restore the levels of coagulation factors to normal. Ideally, monitoring of the levels of coagulation factors (e.g. fibrinogen, platelets, prothrombin time, partial thromboplastin time), acid-base status (e.g. pH, pCO<sub>2</sub>), hemoglobin, and/or electrolytes will guide intravenous therapy. Monitoring blood loss requires meticulous observation of the surgical field, since small volumes of blood loss are difficult to track and are easily hidden in drapes and body cavities. Since the blood volume of a 1 kg infant is only 100 mL, a 10-20 mL blood loss can induce significant hemodynamic instability. Theoretically, urine output should be monitored but in the smallest of infants, measuring small urine volumes accurately often proves difficult or impossible. That is, placing a tube into the bladder and attaching the tube to a drainage system often requires the infant to produce more than 5mL of urine before the anesthesiologist can see any urine. In addition, the small catheter and drainage system are often soft and are easily compressed, kinked or occluded during positioning of the patient.

Inspired gases should be warmed and humidified to near body temperature. Overhead, servo-controlled warmers should be used during preoperative preparation (e.g. adjusting intravenous lines and ventilatory devices, preparation of the surgical site). The surgical bed should include a warming device (varies among institutions), and the room temperature should be adjusted to minimize the occurrence of hypothermia. Once the child is draped for surgery, the room temperature can be adjusted, depending on the response of the infant's body temperature to the surgery and to decreases in the environmental temperature. Intravenous fluids and blood products should be warmed, especially if large volumes of either are required.

The following summarizes the most significant aspects of intraoperative fluid management in the newborn (see case study, Table 10.3).

**1.** Ensure that the intravascular volume is adequate before induction of anesthesia.

- **2.** Determine the intraoperative need for blood products before the start of anesthesia/surgery. This process should begin in the intensive care nursery.
- **3.** In spite of normovolemia, the newborn may respond to judicious doses of either inhaled or intravenous anesthetic agents with dramatic changes in heart rate, arterial blood pressure, and peripheral perfusion. Fluid and/or colloid boluses or infusions may be required to maintain hemodynamic stability.
- 4. Glucose infusion should continue at the same rate used in the intensive care nursery to maintain normoglycemia. This can be considered the "maintenance" component of fluid administration. The infusion should be adjusted, based on intraoperative measurements of glucose.
- **5.** In most cases, delivering crystalloid compensates adequately for insensible losses, but the required rate of delivery depends on the type of surgery. For example, during a laparotomy to treat necrotizing enterocolitis, 10–50 mL/kg/h (or more) of non-glucose containing crystalloid may be required to compensate for insensible losses from inflamed, exposed bowel and peritoneum. During less invasive procedures (e.g. inguinal hernia repair), less crystalloid is required (0–5mL/kg/h). At some point after delivering large volumes of crystalloid (30–40mL/kg/h) for several hours (sometimes longer, sometimes shorter, depending on cardiovascular and clotting status), colloid may be a more appropriate intravenous therapy (see points 6 and 7).
- 6. Most critically ill newborns, especially those who are premature, seem to be more hemodynamically stable (e.g. less apnea and bradycardia) when their hematocrit is >40%. In those cases, frequent packed red blood cell transfusions (and/or erythropoietin) are required in the ICN. Infants who have been in the ICN for days to weeks and who are stable and undergoing elective surgery (e.g. inguinal hernia repair) often tolerate lower concentrations of hemoglobin. For example, an ex-26 week gestation infant undergoing an inguinal hernia repair at 10 weeks of age may have no cardiorespiratory problems (i.e. no apnea/bradycardia, tachycardia or hypotension) associated with a hematocrit of 30%. In contrast, a 5 day old who has a patent ductus arteriosus and necrotizing enterocolitis, and requires mechanical ventilatory support usually has improved perfusion and metabolic status with a hematocrit >40%. The hematocrit required by infants in the ICN provides the initial guideline for the appropriate perioperative level.
- Many newborns, especially critically ill newborns, respond more promptly to colloid delivery than to crystalloid after losing 10–20% of their blood volume. Colloid may include packed red blood cells, fresh

frozen plasma or fibrinogen, depending on the coagulation status and hemoglobin concentration.

- **8.** Monitoring urine output, arterial blood pressure and/ or central venous pressure guides intravenous fluid therapy.
- **9.** Heat and insensible fluid loss should be minimized during transport of the infant to and from the operating room.

# The older infant and child

#### Introduction

Unlike the newborn, older infants and children often present for elective surgery with a clearly defined medical and/or surgical history. That is, congenital anomalies and metabolic/genetic abnormalities have been identified and a specific, stable treatment plan has been established. Outside of trauma, accidents or development of an acute new illness (e.g. malignancy, gastrointestinal event, systemic or localized infection, etc.), emergent or urgent surgery is usually required to treat complications of a recognized anomaly or because diagnostic evaluations are needed to assess an underlying illness.

As in all age groups, preoperative evaluation of the fluid and electrolyte status of older infants and children requires assessing intravascular volume, reviewing cardiorespiratory/renal/hepatic/central nervous system status, and noting relevant laboratory studies. Finetuning fluid and electrolyte abnormalities must be balanced against the urgency of the surgery. When devising a rational plan for intraoperative fluid management, one must determine maintenance fluid requirements, replacement for ongoing losses, and the need to correct specific abnormalities (e.g. glucose, potassium, calcium, coagulation). In some cases, plans must be made for monitoring laboratory values (e.g. ensuring easy access to central venous, arterial or a large-bore peripheral intravenous catheter during surgery).

### Maintenance fluid: classic concepts

Maintenance fluids are defined as those containing appropriate amounts of water and electrolytes to replace urine, gastrointestinal, sweat, breathing, and skin evaporation losses. Oral, intravenous, and other routes can be used to supply maintenance fluid.

The contributions of Gamble [66] and Darrow [67] are often the starting point for understanding evidence-based fluid and electrolyte therapy. Gamble introduced the critical concept of the extracellular space and defined the role of the kidney in fluid maintenance by measuring loss of electrolytes during fasting and other stresses [66]. He emphasized the importance of maintaining the extracellular fluid space, especially in cases of excessive fluid

**Figure 10.3** Based on Holliday and Segar's data, energy expended (calories) is the approximately the same as requirement for fluid (mL). Although caloric expenditure varies (basal rate versus normal activity), three linear sections are easily identified (0–10 kg, 10–20 kg, >20 kg). Energy expended by hospitalized patients was estimated to be approximately between that for basal and normal activity. From the curve for the hospitalized patient, a 10 kg infant expends 1000 calories (requires 1000 mL/day, 100 mL/kg) and a 20 kg child, 1500 calories (requires 1500 mL/day, 100 mL/kg for 10 kg + 50 mL/kg for 10 kg). Reproduced from Holliday and Segar [68] with permission from American Academy of Pediatrics.

losses, such as with diarrhea. Darrow recognized the effects of potassium loss and developed regimens for replacing deficits of sodium, chloride and potassium in children with diarrhea [67]. He also estimated deficits in extra- and intracellular volume.

Finally, any discussion of "maintenance" fluids and electrolytes inevitably notices the report of Holliday and Segar: "The maintenance need for water in parenteral fluid therapy" [68]. These authors simplified the calculation of fluid requirements by correlating insensible loses to the metabolic rate of healthy children at rest and during activity (Fig. 10.3). They noted that the requirements for water paralleled those for energy, and that the metabolic rate correlated with weight: <10 kg, 100 kcal/kg; 10-20 kg, 1000 + 5 kcal/kg; > 20 kg, 1500 + 2 kcal/kg. For a 10 kg child, they calculated a net loss of ~34mL/kg/day of insensible loss (i.e. evaporative loss of water from the skin and respiratory tract) and ~66 mL/kg/day of urine, for a total of 100 mL/100 kcal/day (~4 mL/kg/h) of maintenance fluid for the  $\leq 10$  kg patient. In the normal, nonpremature infant, ~30% of insensible loss is via the lungs and 70% via skin. Based on curves generated from plots of weight versus estimated calories expended/day, the authors estimated that required maintenance fluid is100 mL/kg/day up to 10 kg, an additional 50 mL/kg/ day (~2mL/kg/h) for each kilogram between 10 and 20 kg, and 20 mL/kg/day (1 mL/kg/h) for each kilogram beyond 20kg. This is the basis for the "4-2-1" formula

Table 10.4 Calculating maintenance fluid: the "4-2-1 rule"

Weight (kg)	Hourly rate	Daily volume
<10	4 mL/kg	100 mL/kg
10–20	40 mL + 2 mL/kg (for each kg between 10–20)	1000 mL + 50 mL/kg (for each kg between 10–20)
≥20	60 mL + 1 mL/kg (for each kg >20)	1500 mL + 20 mL/kg (for each kg >20)

widely used to calculate the rates of hourly maintenance intravenous fluid requirement (Table 10.4).

Assuming that electrolytes in intravenous fluid should mimic those in breast milk, Holliday and Segar estimated the amount of sodium and potassium in 100 mL of human milk and used those concentrations of electrolytes to determine daily requirements based on the volume of maintenance fluid (i.e. ~3-4 meq/kg/day for sodium and ~2meq/kg/day for potassium). This led to the practice of adding 0.2% saline to 5% dextrose for routine intravenous fluid. However, clinicians should be mindful that Holliday and Segar's recommendations are estimates and intravenous fluid should be considered an "invasive therapy" or a "medication" rather than an exact replacement for breast milk, formula or other oral fluids. That is, patients who require intravenous fluid often have a significant illness, hormonal imbalance or physiological derangement (e.g. renal or hepatic disease, chronic lung disease) that complicates the maintenance of adequate intravascular volume and electrolyte balance. Therefore, a single "protocol" for delivering intravenous fluids/electrolytes is not appropriate for all patients or all clinical scenarios. Holliday reminds us, "When fluid therapy extends beyond the first day, monitoring is needed to adapt orders to special cases, avoiding the consequences of "one plan fits all" [69].

Although the principles proposed by Holliday and Segar for calculating routine intravenous fluid have been in place for over 60 years and are widely accepted, adhering to these formulas has been challenged recently (see section on Intravenous fluids and hyponatremia: current controversy, below). Clearly, variability of fluid and electrolyte needs from patient to patient requires the clinician to view the principles of Holliday and Segar as a starting point for "maintenance" [69]. The information gained by clinical assessment and monitoring of serum electrolytes often necessitates significant departures from the "4–2–1" formula. Furthermore, some authors have suggested that predicting fluid requirements (i.e. fluid losses) based on energy expenditure in hospitalized patients overestimates the need for maintenance fluid [70].

# Physiology of hyponatremia: clinically relevant concepts

Hyponatremia signifies an excess of water, with or without a deficit of sodium, in the presence of AVP. In most cases, hyponatremia is caused by water rather than sodium imbalance. Despite the fact that many clinical settings are associated with oversecretion of AVP (e.g. surgery, diuretic therapy, central nervous system abnormalities), hyponatremia is rare without an excess of water. Large volumes of hypotonic intravenous fluid are one obvious source of excess water. Moritz, on the other hand, claims that a neurological complication related to the use of 0.9% normal saline in a patient without underlying central nervous system disease has not been reported [71].

Sodium, more than any other molecule, establishes osmolality (normal, 280–290 mOsm/L) in the extracellular space (plasma osmolality =  $2 \times [Na^+] + [glucose]/$ 18 + [BUN]/2.8). Consequently, sodium contributes significantly to maintaining extracellular fluid volume, blood volume, and perfusion pressure. Through activation of mechanoreceptors in the left ventricle, carotid sinus, aortic arch, and renal afferent arterioles (see section on Renal physiology, above), hypovolemia stimulates the renin-angiotensin system (i.e. synthesis of renin and release of angiotensin II), non-osmotic (or osmotic) release of AVP, and thirst. Aldosterone increases sodium salvage and AVP decreases water excretion; both effects are primarily exerted in the renal tubules.

Sodium cannot freely move across cell membranes. Stable concentrations of sodium in the extracellular space depend on the energy-dependent activity of Na<sup>+</sup>-K<sup>+</sup>-ATPase (see section on Renal physiology, above). On the other hand, water freely passes through cell membranes in response to osmolar gradients (see section on General considerations, above). Thus, isotonic solutions do not change cell volume but intravenous hypotonic solutions can increase movement of water intracellularly and hypertonic solutions can increase movement of water extracellularly and alter cell volume, if compensatory physiological responses (e.g. changes in renal sodium and water excretion/reabsorption) are not prompt or are incomplete.

The etiology of hyponatremia (plasma Na<sup>+</sup><135 meq/L) may be multifactorial and complex. Hyponatremia may be isotonic (e.g. with bladder irrigation during laparoscopic surgery) or hypertonic (e.g. with hyperglycemia) but in most cases it is hypotonic. That is, hyponatremia decreases extracellular osmolality, permitting water to freely move from the extracellular to the intracellular space to maintain osmotic equilibrium. Although hypotonic hyponatremia is caused by myriad disorders (congestive heart failure, adrenal insufficiency, diuretics, cerebral salt wasting, etc.), the most relevant etiologies in the perioperative setting include excessive losses (e.g. vomiting, gastrointestinal (GI) suction) and "third-spacing" of fluids (e.g. peritonitis, burns).

Clinical symptoms of hyponatremia develop in proportion to the rapidity of its development. Mild hyponatremia is usually asymptomatic but severe, rapidly developing hyponatremia (Na<sup>+</sup> <120 meq/L) may produce lifethreatening cerebral edema and encephalopathy [72]. In some cases the morbid consequences are due to pontine and extrapontine myelinolysis [73]. Compared to acute hyponatremia (developing in less than 48h), chronic hyponatremia is often associated with fewer clinical symptoms because the brain has gradually accommodated to the changes in osmolality.

Complex regulatory systems in the brain, including glial cells, astrocytes/astrocyte foot processes, and aquaporin water channels interact to maintain normal water balance. Astrocytes protect neurons from a hyposmolar insult, in part because of their high number. Glia play a key role in the response to hyposmolality by actively transporting sodium from the intracellular to the extracellular space via Na<sup>+</sup>-K<sup>+</sup>-ATPase, allowing water to exit the cell. Swelling of cells induces a variety of other protective mechanisms, including potassium and anion channels, the Na<sup>+</sup>/Ca<sup>2+</sup> transporter, and Ca<sup>2+</sup>-ATPase.

Menstruant women seem to be predisposed to severe consequences of hyponatremia secondary to high concentrations of estrogen. Because the structure of estrogen resembles that of ouabain, an inhibitor of Na<sup>+</sup>-K<sup>+</sup>-ATPase, women have decreased capacity to adapt to hyponatremia. In addition, AVP vasoconstricts cerebral vessels of women more than it does in men. The resulting decreased availability of cerebral oxygen delivery impairs the energydependent mechanisms required to maintain intracellular volume [74]. AVP also directly promotes water entry into cells, especially in the brain, beyond its effects on hyponatremia alone [75].

Although no gender differences are apparent in children, prepubescent children also seem to be at high risk for hyponatremia-induced neurological complications for several reasons, including their high ratio of brain (fully grown by age 6) to cranium (not fully grown until adulthood), the higher intracellular concentration of sodium [76], and the lower activity of Na<sup>+</sup>-K<sup>+</sup>-ATPase [77]. During the first year of life, the open fontanelle may in part explain why infants have better neurological outcomes following hyponatremia [78].

# Intravenous fluids and hyponatremia: current controversy

Over the last two decades, reports of hyponatremiainduced morbidity and mortality have provoked heated debate about whether hypotonic or isotonic crystalloid should be used routinely as maintenance fluid, especially in the perioperative period. Non-osmotic stimuli for AVP secretion are commonly encountered perioperatively (e.g. pain, nausea and vomiting, narcotic administration, inhalation anesthetic agents, positive pressure ventilation), which increases the risk for hyponatremia. Some suggest that all surgical patients are at risk for hyponatremia, especially postoperatively [71,79], if there is central nervous system injury [80] or if the patient underwent scoliosis repair [81,82].

Burrows [81] noted that serum sodium concentration decreased postoperatively in patients who were given either hypotonic or isotonic fluids, but more so after hypotonic solutions. Arief and others described that hyponatremia for elective surgery resulted in respiratory arrest, seizures, and death or permanent brain injury in healthy women [83-85]. The same phenomenon has been noted in children, many of whom were postsurgical. Administering hypotonic intravenous fluid in the presence of AVP was hypothesized to precipitate hyponatremia and death or permanent brain injury in some children [86,87]. Because the incidence of hyponatremia in both adults (~1-2.5%) and children is high [88-91], awareness of this disorder is critical, especially in high-risk groups. Infants and children who are at high risk for hyponatremia include those with meningitis, encephalitis, head injury, bronchiolitis, chronic lung disease, and those who are postsurgery [92]. In addition, malignancies (lung, brain, leukemia, lymphoma, thymoma), various chemotherapeutic agents (vincristine, cyclophosphamide), and diuretics are also associated with hyponatremia. Finally, infants and children who require surgery are more likely to have significant medical illnesses that predispose them to AVP secretion (e.g. leukemia/chemotherapy, congenital heart disease/diuretic therapy, chronic lung disease/ ex-premature infant).

Holliday continues to suggest that rapidly restoring intravascular volume with a bolus of 20-40 mL/kg of normal saline, followed by oral rehydration therapy or maintenance fluid containing 0.25% normal saline, represents the most "physiological" approach to fluid and electrolyte therapy, including for patients who are dehydrated preoperatively [93,94]. However, several prospective randomized studies [95-97], as well as smaller observational reports [98] and a recent review [99], have noted that administering 0.9% sodium chloride postoperatively prevents significant hyponatremia, whereas administering hypotonic solutions may not. The rate of fluid delivery is apparently less important than the concentration of sodium delivered [96,97]. Hyponatremia developed even when hypotonic solutions were administered at one-half to two-thirds of the traditional maintenance rates; others report that administering excessive volumes of hypotonic intravenous fluid causes hyponatremia [98,100]. Hypernatremia did not develop even when 0.9% sodium chloride was delivered at rates as low as one-half standard maintenance [97]. Death or neurological injury was reported in 30% of severely hyponatremic children [100].

Based on these data, many suggest that isotonic solutions are appropriate for postoperative maintenance fluids with the proviso that serum electrolytes are monitored frequently and the rate and electrolyte composition of the intravenous fluid are adjusted as needed. As Bailey notes, "No single IV fluid can be used safely in all situations" [99]. Excessive delivery of any solution to patients with cardiovascular or renal failure could be disastrous. Finally, hypotonic intravenous solutions may be required to compensate for excessive free water loss (e.g. diabetes insipidus).

# Preoperative assessment and intraoperative fluid management in older infants and children

Whether to vigorously replace a preoperative fluid deficit induced by fasting, bleeding, excessive gastrointestinal losses, etc. depends on several factors, including the nature of the surgical procedure and its indications (e.g. acute trauma secondary to a gunshot wound versus elective craniotomy), current clinical status (e.g. hemodynamically stable), and co-existent medical problems (e.g. renal failure, chronic lung disease). In many cases, preoperative hypovolemia can be corrected by giving boluses of normal saline or lactated Ringer's (10-20 mL/ kg). In other cases (e.g. traumatic hemorrhage), fluid resuscitation initiated before surgery must be continued intraoperatively. Once hemodynamic stability has been achieved, intravenous fluid delivery should revert to maintenance fluids plus sufficient crystalloid/colloid to replace the ongoing fluid losses and to maintain hemodynamic stability. Intraoperatively, either normal saline or lactated Ringer's solution is routinely used for both maintenance fluids and replacement of volume deficits and ongoing fluid losses. Glucose, if needed, is given separately.

When prolonged preoperative fasting was in vogue, some experts recommended simply calculating the maintenance fluid for the number of hours the patient had been without oral intake [101] and delivering half that volume during the first hour of surgery and the other half over the subsequent 2h. Since clear liquids are now given orally up to 2h before the induction of anesthesia, children are seldom fasted preoperatively for more than 3–4h [102]. Thus, significant intravascular volume deficits due to prolonged fasting are uncommon, and any preoperative dehydration is more likely due to an underlying disease state. One must assess the current physical status of the patient rather than simply calculate the time of fasting before induction of anesthesia.

#### Table 10.5 Intraoperative fluids: beyond infancy

Three-year-old, previously healthy child is scheduled for excision of a Wilms' tumor. NPO  $\times$  3 h; weight 15 kg; hemoglobin 13 g/dL; open laparotomy.

Deficit	Maintenance	Ongoing losses
150 mL	50 mL/h	<ul> <li>10–20 mL/kg/h (or more) to compensate for insensible losses via exposed bowel</li> <li>Until transfusion, replace EBL with crystalloid (volume 2–3 times the EBL)</li> <li>Consider RBCs if Hgb &lt;8 g/dL and/or hemodynamic instability/or massive ongoing losses</li> </ul>

Six-year-old healthy boy hit by car while riding his bicycle. He is alert, oriented with an isolated fracture right femur. Past medical/surgical history is unremarkable. A 22g angiocath is infusing 0.9 normal saline. Weight 25kg; hemoglobin 12g/dL; no urine; scheduled for pinning of the fracture in the operating room under general anesthesia.

Deficit	Maintenance	Ongoing losses
<ul> <li>Full stomach</li> <li>Blood pressure 70/40, heart rate 150</li> <li>Deliver boluses of 0.9 normal saline, 10 mL/kg before induction</li> <li>Monitor hemoglobin, urine output</li> </ul>	70 mL/h	<ul> <li>Monitor Hgb, PT/PTT if bleeding persists</li> <li>Consider transfusion of packed RBCs if Hgb &lt;7 g/dL after crystalloid infusion to establish adequate intravascular volume or to replete ongoing blood loss and/or treat hemodynamic instability</li> </ul>

EBL, estimated blood loss; Hgb, hemoglobin; NPO, nil per os; RBC, red blood cell, PT, prothrombin time; PTT, partial thromboplastin time.

If preoperative assessment suggests hypovolemia or if hypotension develops during the induction of anesthesia, an intravenous bolus of lactated Ringer's solution or normal saline is appropriate initial treatment for patients of any age. After a 4–6h (or longer) fast, older infants or children without significant cardiorespiratory or renal disease usually have no evidence of intravascular compromise. If the preoperative fast was appropriate and/or there is no evidence for intravascular fluid deficit or hemodynamic response to induction of general anesthesia, administration of IV fluids beyond maintenance rates may be unnecessary or may be deliberately avoided (e.g. stable patient undergoing neurosurgery).

Rapidly administering intravenous fluids before, during or after the induction of anesthesia should be based on need and need alone. Both before and during surgery, the anesthesiologist must differentiate between fluids administered to treat hypovolemia and those administered for "maintenance" (e.g. to compensate for NPO status). Boluses of either lactated Ringer's solution or normal saline are appropriate for correction of hypovolemia (i.e. hemodynamic instability, poor perfusion).

In the perioperative period, one indication for giving hypotonic fluids is excessive loss of free water, which must be diagnosed and monitored by simultaneously determining serum and urine electrolyte concentrations. Meticulous monitoring of the patient's clinical status and serum electrolytes is essential to avoid perpetuating or inducing electrolyte abnormalities.

# Intraoperative glucose delivery in the older infant/child (see Table 10.5)

In the era of prolonged preoperative fasting, hypoglycemia was common [103,104]. Today, with more liberal NPO regimens, the incidence of hypoglycemia is 0–2.5% and occurs almost exclusively in patients who have been fasted for inappropriately long periods (8-19h) [105]. Nonetheless, in spite of its rare occurrence, the consequences of both hypo- (see section on Glucose homeostasis) and hyperglycemia can be catastrophic. For example, administering glucose-containing fluid at high rates during surgery often leads to hyperglycemia, glucosuria, and an osmotic diuresis. Of greater significance, hyperglycemia has been associated with increased mortality and infection in both adults and children in ICUs [106,107]. In the absence of an underlying metabolic derangement (e.g. diabetes, methylmalonic acidemia), intraoperative glucose administration is usually not necessary.

# The patient with diabetes: perioperative management

Although there are no controlled studies of perioperative management of pediatric patients with diabetes, the recommendations of an excellent recent review [108] were reaffirmed by the International Society for Pediatric and Adolescent Diabetes (ISPAD) in both its 2007 and 2009 consensus guidelines for both pediatric and adolescent patients [109]. The following discussion and recommendations are consistent with these reports.

The incidence of both type 1 and type 2 diabetes mellitus has increased in the pediatric population, both in the United States and worldwide [110,111]. Because of its common occurrence and the devastating multisystem complications of this disease, aggressive efforts have been undertaken to minimize morbidity. This includes maintaining tight glycemic control by continuous insulin infusion and administering long and rapidly acting insulin analogs. Tight glycemic control benefits both short-term surgical outcomes (wound healing, fluid and metabolic derangements) and long-term health [112-114]. On the other hand, tight glycemic control increases the risk for developing hypoglycemia. Anesthesiologists encounter diabetic patients frequently and must have knowledge of their increasingly complex treatment regimens.

Most pediatric patients with diabetes fall into one of two categories. Type 1 is usually caused by immunemediated pancreatic  $\beta$ -cell destruction that causes insulin deficiency. Type 2 is caused by a combination of insulin resistance and relative insulin deficiency [115]. Rarer forms of diabetes include genetic defects of  $\beta$ -cell function, genetic syndromes and systemic endocrine disorders, and those that develop secondary to other diseases or their treatment (e.g. cystic fibrosis, steroid administration, chemotherapy) [116].

The stress response caused by trauma and surgery elicits cortisol and catecholamine production and release, which increases blood glucose concentrations by catabolizing protein and fat. Patients with insulin deficiency are unable to increase insulin production sufficiently to counter the rise in glucose concentration; this causes profound hyperglycemia and ketoacidosis. Hyperglycemia impairs wound healing by hindering collagen production, decreasing the tensile strength of the wound, and adversely affecting neutrophil phagocytosis and bactericidal killing. Reducing sympathetic nervous stimulation is critical for preventing the release of catecholamines and their negative effects on glycemic control. A comprehensive flexible intra- and postoperative plan for pain control should be developed and understood by the nurses, anesthesiologists, and surgeons in order to reduce sympathetic activation.

In a study of perioperative infections that included ~23,000 adult patients, the rate of postoperative clean wound infections was 1.8% in patients without diabetes and 10.7% in those with diabetes [117]. However, this report failed to provide data on perioperative glucose control. A more recent study in adult vascular patients reported no difference in the risk for postoperative wound infection in diabetic and non-diabetic patients when the blood glucose was maintained between 122 and 168 mg/ dL [118]. In cardiac surgery patients, when the blood glucose levels were maintained below 200 mg/dL for 48h

postoperatively, the risk of sternal wound infection decreased [119]. In adult patients requiring intensive care, tight postoperative glycemic control (80–110 mg/dL) with an insulin infusion significantly decreased mortality and morbidity. However, 5.2% of the "tight control" group had hypoglycemic episodes (though none were severe) compared to 0.8% of controls [120].

For major surgery, the data in adults support tight perioperative control of glucose. A reasonable similar target in pediatric patients is a blood glucose concentration of <200 mg/dL. Because insulin therapy is often needed to achieve tight control, glucose concentrations must be monitored at least once an hour during surgery if patients are receiving insulin to ensure prompt detection and correction of hypoglycemia. General anesthesia masks the symptoms of hyperglycemia. Similarly, if the glucose concentration is maintained between 100 and 200 mg/dL, the risks associated with hyperglycemia (e.g. osmotic diuresis, dehydration, electrolyte imbalance, metabolic acidosis, and infection) are minimized. The data for brief and minor surgical procedures are less clear, but the goal of maintaining perioperative blood glucose levels below 200 mg/dL [109] seems appropriate.

Given the complexity and variability in treatment options, the need for tight glycemic control, and the variable effects of different surgeries and postoperative courses, a perioperative plan for every patient with diabetes should be devised in advance, ideally in consultation with an expert in diabetes management [108]. The perioperative approach should be based on two primary factors: the regimen followed by the patient chronically and the type of surgical procedure.

If a patient with diabetes must fast for any surgery or procedure, the following points should be borne in mind.

- Maintain the blood glucose concentration between 100-200 mg/dL. Preoperative monitoring should ensure stable glucose control for at least several weeks before surgery. Then a specific preoperative regimen can be developed for each patient that reflects her/his recent history of glycemic control. For example, patients who have stable insulin schedules and predictable glucose concentrations may only require a single preoperative determination of glucose concentration. Brittle diabetics with widely fluctuating glucose levels require more intense preoperative evaluation. It is important to remember that even a long-standing stable preoperative course may be disrupted by surgery and anesthesia. Establishing an approach to various intraoperative scenarios and having access to a diabetologist during surgery are essential components of preoperative planning.
- Children with diabetes should be admitted to hospital early on the morning of the procedure to measure their

blood glucose concentrations and to repeat them as needed. If necessary, an intravenous infusion is started. If the surgery is delayed for several hours, monitoring of blood glucose concentrations will help prevent both hypo- and hyperglycemia [108].

- If the blood glucose is >250 mg/dL, a conservative dose of regular (short-acting) insulin should be given to restore relative normoglycemia. This is best achieved by using the child's usual sliding insulin scale or a "correction factor." The insulin correction factor is the decrease in the blood glucose concentration expected after administering 1 U of short- or rapid-acting insulin. It is calculated by using the "1500 rule" (1500/child's usual total daily dose of insulin). For example, a child who typically takes 30 U of insulin daily would have a correction factor of 50 (1500 ÷ 30). Thus, giving 1 U of rapid-acting or short-acting insulin would be expected to decrease the blood glucose concentration by approximately 50 mg/dL [108].
- The treatment regimen of pediatric patients with type 2 diabetes may include insulin and/or one of several oral antihyperglycemic drugs. Metformin is commonly used and should be discontinued 24h before a procedure because its half-life is long and there is a remote risk of lactic acidosis in patients with renal or cardiac failure [121]. In fact, renal failure is a contraindication for the use of metformin.
- Other oral drugs, such as sulfonylureas and thiazolidinediones, may be discontinued on the morning of the procedure [122].

# For minor/short procedures

- Most pediatric patients with diabetes who are stable on a subcutaneous regimen of insulin can continue this mode of therapy.
- Since intermittent intravenous boluses of regular insulin seem to offer comparable effectiveness to continuous infusions in adults with type 2 diabetes, a similar approach is justified in pediatric patients. Patients with Type 2 diabetes can often be managed without continuously infusing insulin [123,124].
- During minor procedures that last <2h, patients typically continue to receive their usual basal rate of insulin for that time of day via their pump. However, when using this approach, the anesthesiologist must measure intraoperative glucose concentrations and be comfortable with using an insulin pump. Otherwise he/she must seek consultation with and have intraoperative access to a pediatric endocrinologist or other skilled personnel prior to inducing anesthesia.
- If the child can drink soon after a brief procedure, he/ she may not need an intravenous glucose infusion. If the fast is likely to be prolonged, an intravenous infusion should deliver glucose at a maintenance rate

(see section on Maintenance fluid: classic concepts, above).

• Patients with stable glucose and normal serum potassium concentrations have minimal risk for electrolyte imbalance (e.g. acidosis, hypokalemia).

### For longer/more complex procedures

- For procedures lasting more than 2h, patients with insulin pumps should receive intravenous insulin, either by the pump or by a separate infusion.
- Children with diabetes undergoing major surgical procedures should receive their usual insulin dose on the day prior to the procedure. On the morning of the procedure, an intravenous infusion of 5% or 10% dextrose (depending on a patient's relative risk for hyper- or hypoglycemia) in half-normal saline should be started at a maintenance rate (see section on Maintenance fluid: classic concepts, above). The rate of insulin infusion should be adequate to maintain blood glucose concentration between 100–200 mg/dL.
- Because prepubescent children are relatively more sensitive to insulin than pubertal adolescents [108], the insulin dose necessary for children varies with age. In prepubescent children with type 1 diabetes, the insulin requirement is typically 0.6–0.8 U/kg/d, compared to 1.0–1.5 U/kg/d for adolescents. Patients with type 2 diabetes often have higher insulin requirements because they have resistance to insulin. A suitable ratio of intravenous regular insulin to glucose for prepubescent children is 1U per 5g of intravenous glucose for adolescents (>12 years old) [108].
- Intraoperative maintenance fluids for children with diabetes should contain glucose if the case is long and/ or complex. However, intraoperative volume losses (e.g. blood, excessive insensible losses) should be replaced with non-glucose containing lactated Ringer's solution or normal saline. *To avoid hyperglycemia and its potentially disastrous consequences, glucose-containing solutions should not be used to replace intraoperative fluid losses*!
- Patients undergoing longer or emergency surgeries are at greater risk for metabolic decompensation. Their electrolytes should be assessed intraoperatively and corrected as needed. In all cases, blood glucose concentration should be measured hourly and, if abnormal, the amounts of insulin and glucose adjusted to maintain the blood glucose concentrations between 100–200 mg/dL [108].

As soon as the patient can resume normal oral intake after surgery, her/his usual diabetes regimen (insulin and/or oral drugs) should be reinstituted, and any glucose infusions discontinued. Normal renal function should be documented before restarting metformin. Patients who are unable to tolerate adequate oral intake require infusions of intravenous glucose, electrolytes, and regular insulin to maintain normal electrolytes and glucose concentrations of 100–200 mg/dL. Frequent monitoring of blood glucose and blood or urine ketone bodies is essential because the interplay of postsurgical events, including surgical trauma, inactivity, pain, nausea or vomiting, poor oral intake, and medications is complex. *Before* discharge, patients require appropriate teaching about how to contact experts if glucose and insulin therapy must be altered.

# Conclusion

Holliday's perspective on the contributions of Gamble, Darrow, Howland and others provides an exciting historical document [1]. He notes, "The development of body fluid physiology and fluid therapy in pediatrics has special importance in the history of medicine because this development introduced physiology into clinical practice" (and eventually enabled the explosion in surgical innovation). James Gamble and Dan Darrow were leaders in this enterprise. Holliday emphasizes, "Pediatrics, medicine, and surgery are all indebted to the research of each, which emphasized the value of basic physiology in clinical practice." Clearly, the foundation of current principles of fluid and electrolyte therapy is easily traced to these pioneers. However, these principles continue to evolve and should be revised when new evidence appears. Darrow advised in his address to the American Pediatric Society in 1957 that "research is the process by which teachers and students are forced to deal with the lively facts of medical science rather than rules of the trade" [1,125]. As we move forward in the era of clinical trials and evidence-based medicine, our practices for delivery of maintenance fluid, crystalloid for replacement of intraoperative fluid losses, and various synthetic colloids, as well as other practices, should be responsibly reviewed and revised based on rigorous investigation and data.

# Introduction

The hematological system is unique among all the systems in the body. It is composed of multiple components, each of which engages in a very specific and unique function that is critical for life. This chapter will focus on one of those functions: coagulation. New concepts describing the coagulation pathway, maturational factors affecting coagulation in neonates and infants, tests of and defects in the coagulation system, and principles of transfusion therapy and blood conservation will be discussed.

# The coagulation pathway

The coagulation system is a complex interplay of cellular elements and plasma proteins that functions to stop bleeding from an injured blood vessel and then to reestablish patency of that vessel. The process which stops bleeding is understood to occur in two phases. Primary hemostasis arrests bleeding by inducing vasoconstriction in the injured vessel and by causing the formation of a platelet plug. Secondary hemostasis then involves the circulating plasma coagulation factors and results in the formation of a fibrin clot at the site of blood vessel damage. While it is easy to think of these two phases as separate, distinct, and sequential, they are in fact highly co-ordinated, interdependent, and concurrent. In the end, the fibrinolytic system removes clot to re-establish blood flow and to allow wound healing [1].

Primary hemostasis is triggered by damage to a blood vessel wall. This disruption exposes subendothelial collagen to the bloodstream. Platelets become immediately involved and respond by adhesion to the wall of the damaged blood vessel, by activation, and by aggregation to each other. Platelet adhesion is mediated by von Willebrand factor (vWF). Circulating vWF binds to the exposed subendothelial collagen of the damaged blood vessel wall and then to the glycoprotein Ib receptor on platelet surfaces. This results in platelet adhesion to the blood vessel at the point of damage. Platelet activation then occurs, resulting in release of platelet agonists (adenosine diphosphate (ADP) and serotonin) and coagulation factors (vWF and factor V) from platelet storage granules and in changes in the shape and surface function of the platelets. Arachidonic acid from activated platelet membranes is converted into substances that cause vasoconstriction of the injured vessel by a series of enzymatic reactions involving cyclo-oxygenase. Changes in the shape of platelets allow the expression of glycoprotein

IIb/IIIa surface receptors. Platelet aggregation then occurs as fibrinogen binds these exposed receptors on adjacent platelets (Fig. 11.1). Finally, the phospholipid membrane of activated platelets provides the surface on which the process of secondary hemostasis occurs [2].

Secondary hemostasis involves the interaction of coagulation factors to form a fibrin clot. Roman numerals are used to designate most of these factors in order to provide an international code for clear communication [3] (Table 11.1). The clotting factors exist in inactive precursor forms before being converted to active enzymes upon initiation of secondary hemostasis [4]. Most coagulation factors (I (fibrinogen), II (prothrombin), V, VII, VIII, IX, X, and XI) and some anticoagulants (antithrombin and proteins C and S) are predominantly produced by the liver. Endothelial cells participate in the production of many anticoagulants (thrombomodulin, tissue factor pathway inhibitor, tissue plasminogen activator, heparan, nitric oxide, and cyclo-oxygenase) as well as some procoagulants (vWF, plasminogen activator inhibitor type 1, thromboxane, and possibly tissue factor) [1].

Our attempts at understanding secondary hemostasis began in the 1960s with a waterfall or cascade model of what came to be known as the "intrinsic" pathway of coagulation [4,5]. This pathway was described in vitro in cell-poor plasma and was termed "intrinsic" because all required factors existed in the plasma. An "extrinsic" pathway was subsequently described that involved tissue factor (TF), a protein in the blood vessel wall that is extrinsic to blood. Both of these pathways were determined to converge on a "common" pathway leading to thrombin generation and subsequent fibrin formation (Fig. 11.2). However, questions from several clinical and laboratory scenarios led to the recognition that the intrinsic and extrinsic coagulation pathways do not operate Table 11.1 Coagulation factor numbers and synonyms

Roman numeral	Synonyms
T	Fibrinogen
П	Prothrombin
Ш	Thromboplastin Tissue factor
IV	Calcium
V	Proaccelerin Labile factor
VII	Proconvertin Stable factor
VIII	Antihemophilic factor (AHF) Antihemophilic globulin (AHG) Antihemophilic factor A Factor VIII:C
IX	Plasma thromboplastin component Antihemophilic factor B Christmas factor
Х	Stuart factor Prower factor Stuart–Prower factor
XI	Plasma thromboplastin antecedent Antihemophilic factor C
XII	Hageman factor Contact factor Surface factor Glass factor
XIII	Fibrin stabilizing factor Laki–Lorand factor

independently in vivo. Additionally, even the early descriptions of coagulation recognized the significant role of phospholipid acting as a surface catalyst for coagulation and postulated that the phospholipid might be derived from platelets during the clotting process [5].

Subsequently, a cell-based model has been proposed to explain secondary hemostasis. This model emphasizes the importance of cell surfaces as the platform upon which the previously described extrinsic pathway initiates and then amplifies the beginning of secondary coagulation with subsequent fibrin formation by factors of the classic intrinsic pathway [6].

The cell-based model describes three overlapping phases of secondary coagulation: initiation of coagulation on TF-bearing cells, amplification of the procoagulant signal by thrombin generated on the TF-bearing cells, and propagation of thrombin generation on platelet surfaces.

Figure 11.2 Secondary hemostasis: the coagulation cascade.

Initiation of coagulation occurs when TF, a transmembrane protein that acts as a receptor and co-factor for activated factor (F) VII, is exposed on cells at the site of a blood vessel injury. FVIIa normally circulates in the blood in low concentrations, "patrolling" the circulation for damaged blood vessels with exposed TF. Once FVIIa and TF meet, the resulting FVIIa/TF complex catalyzes the activation of FX and FIX on the surface of the TF-bearing cells. FXa then interacts with FVa on the cell surface. This cell-bound FVa may come from the degranulation of nearby activated platelets or may originate from noncoagulation proteases. The Xa/Va interaction generates small amounts of thrombin (Fig. 11.3A). This thrombin is insufficient in quantity to lyse fibrinogen but it is sufficient to stimulate the second phase of the cell-based coagulation model. The FIXa formed by the FVIIa/TF complex diffuses from the TF-bearing cells to nearby activated platelets to play a later role in thrombin formation. However, the activity of FXa is restricted to the TF-bearing cell on which it was formed because tissue factor pathway inhibitor (TFPI) or antithrombin (AT) will inhibit any FXa that dissociates from the cell surface. This initiation phase of the cell-based coagulation model has been compared to the classically described extrinsic coagulation pathway (Fig. 11.4A).

In the subsequent amplification step, the initial thrombin produced on the TF-bearing cell surfaces activates more nearby platelets and FV, FVIII, and FXI. The activated platelets provide the phospholipid surfaces on which large amounts of thrombin are subsequently generated in phase three. The newly activated coagulation factors will become vital co-factors in this subsequent phase (Fig. 11.3B).

Figure 11.3 Secondary hemostasis: the cell-based model. Reproduced from Hoffman and Monroe [6] with permission from Elsevier.

**Figure 11.4** Comparison of the coagulation cascade and the cell-based model of secondary hemostasis. Reproduced from Hoffman and Monroe [6] with permission from Elsevier.

The third phase is propagation of thrombin generation on the surfaces of activated platelets. In this phase, FVIIIa from the amplification phase forms a complex with FIXa from the initiation phase on the surfaces of nearby activated platelets. FXIa from the second phase also binds to nearby platelets and can activate more circulating FIX to join surface-bound FVIIIa. The FVIIIa/IXa "tenase" complex then activates FX. The FXa joins with FVa from the second phase on activated platelet surfaces. This FXa/ Va "prothrombinase" complex finally catalyzes the largescale conversion of prothrombin into thrombin (Fig. 11.3C). These actions have been compared to those outlined in descriptions of the intrinsic coagulation pathway (Fig. 11.4B). Unlike the small quantity of thrombin produced by TF-bearing cells, the quantity of this plateletproduced thrombin is sufficient to cleave fibrinogen to fibrin. It also functions to stabilize the fibrin clot by activating FXIII to cross-link the fibrin monomers and to link thrombin-activatable fibrinolysis inhibitor (TAFI) and α2antiplasmin to the fibrin in order to inhibit the fibrinolytic process and thus prevent clot dissolution [6,7].

After clotting has occurred and bleeding has been stopped, activation of the fibrinolytic system allows patency of the involved blood vessel eventually to be restored so that wound healing can proceed. Tissue plasminogen activator (tPA) is released from endothelial cells in response to the presence of thrombin and venous occlusion. Both tPA and its substrate, plasminogen, bind to lysine residues on fibrin surfaces. Fibrin-bound tPA then converts this localized plasminogen to its active form, plasmin. Plasmin dissolves a fibrin clot by cleaving fibrin at specific lysine and arginine residues to eventually re-establish blood flow through the vessels [6,7].

The hematological system constantly balances the ability to keep blood flowing through undamaged vessels with the ability to stop bleeding from damaged blood vessels. Under normal circumstances, the luminal surface of undamaged blood vessels is non-thrombogenic because of the constitutive presence of thrombomodulin, AT, and heparan sulfate [8]. Thrombomodulin binds circulating thrombin, resulting in activation of protein C. Activated protein C, with its co-factor protein S, then attenuates thrombin production by inactivating FVa and FVIIIa. AT, catalyzed by endothelial cell-produced heparan sulfate, neutralizes circulating FIXa, FXa, FXIa, and thrombin to prevent fibrin formation [9]. Intact vessel walls also release nitric oxide and prostacyclin to inhibit platelet activity and release tPA to promote fibrinolysis [8]. Thus, undamaged blood vessels have protective mechanisms to prevent clot formation. Vascular damage not only exposes TF but also downregulates thrombomodulin and AT, thus creating an environment conducive to clot formation [8].

The hematological system is also constantly challenged to localize its coagulation process only to areas of blood vessel damage. Exposure of TF only on cells in areas of blood vessel damage and subsequent activation only of nearby platelets allows the coagulation process to stay localized to areas of blood vessel injury. Additionally, each activated coagulation factor that participates in the secondary hemostasis process is balanced by a naturally occurring anticoagulant in order to maintain control and to balance hemostasis: TFPI neutralizes the FVIIa/TF/Xa complex on TF-bearing cells; AT inhibits thrombin and circulating FIXa, FXa, and FXIa; and protein C, with its co-factor protein S, inhibits FVa and FVIIIa [1,7]. The fibrinolytic system is also balanced by inhibitors in order to control the extent of fibrinolysis. The activity of any circulating tPA is inhibited by plasminogen activator inhibitor (PAI) type 1. Ongoing formation of plasmin is prevented when TAFI cleaves the lysine residues from degrading fibrin to which tPA and plasminogen must bind in order to interact and form plasmin. Finally, circulating plasmin itself is inhibited by  $\alpha$ 2-antiplasmin [6–8]. In the end, under normal conditions, coagulation and fibrinolysis occur only where they are needed and are prevented from becoming pathological generalized problems by procoagulant and anticoagulant factors that delicately balance the system.

Figure 11.5 Coagulation factor levels in full-term infants and with age. HMWK, high molecular weight kininogen. Modified from Andrew et al [13].

# Maturation of the coagulation system

Coagulation proteins, platelets, and fibrinolytic proteins do not cross the placental barrier but their synthesis by the fetus begins at approximately 11 weeks of gestational age. During the remainder of fetal development, maturation of the coagulation and fibrinolytic systems parallel each other so that a delicate hemostatic balance is maintained [10,11]. However, despite this ongoing maturation, both quantitative and qualitative deficiencies exist in these systems at birth.

Plasma levels of coagulation factors and coagulation inhibitors have been documented in detail in both healthy premature infants (30–36 weeks' gestational age) and fullterm infants (>37 weeks' gestational age) from birth through 6 months of age [12,13]. Plasma levels of the vitamin K-dependent coagulation factors (II, VII, IX, and X) and the contact factors (XII, XI, high molecular weight kininogen (HMWK), and prekallikrein (PK)) at 1 day of age in the premature and full-term infants studied were all less than 70% of adult values. Additionally, levels of several of these factors (IX, XI, and XII) were significantly lower in the premature infants compared to the full-term infants. By 6 months of age, levels of all these coagulation factors in both premature and full-term infants had risen to within adult ranges (Fig. 11.5).

On the other hand, levels of fibrinogen, FV, FVIII, and FXIII, and vWF were all greater than 70% of adult values on the first day of life in both premature and full-term infants. Fibrinogen levels were lower in premature infants than in full-term infants while levels of FV were higher in premature infants than in full-term infants at 1 day of age. Levels of vWF on day 1 of life were higher than adult values in both groups of infants, dropping to adult range between 3 and 6 months of life [12,13] (Fig. 11.6). Finally, platelet counts in the neonatal period have been shown to be similar to those found in adults and not to differ between premature and full-term neonates [14].

**Figure 11.6** Coagulation factor levels in full-term infants. vWF, von Willebrand factor. Modified from Andrew et al [13].

The inhibitors of coagulation showed similar developmental patterns. At 1 day of age, plasma levels of AT, protein C, and protein S were lower in both groups of infants than levels in adults and levels of all three of these coagulation inhibitors were lower in premature infants than in full-term infants. In both groups at 6 months of age, levels of AT and protein S had risen to within adult ranges while protein C levels remained low [12,13] (Fig. 11.7).

In the fibrinolytic system, plasminogen levels were significantly lower on the first day of life in both premature and full-term infants than those seen in adults and were significantly lower in premature infants compared to fullterm infants. These values remained low during the first 6 months of life [12,13]. tPA levels in term newborns have also been found to be significantly lower than adult levels while PAI levels were similar to those measured in adults [15]. As these findings would predict, plasmin generation and fibrinolysis are suppressed in infancy. Thus, if thrombolytic therapy is needed in infants, higher doses of activator will need to be administered [15].

In addition to these quantitative issues in development of the hemostatic system, qualitative issues exist as well. The concept of a "fetal fibrinogen" has been proposed [16,17] and evidence of impaired fibrinogen function in infants has been postulated based on thromboelastography data [18] and on differences between measured activity and antigen levels of fibrinogen [19]. Comparison of the biological activity and the plasma levels of FXII, PK, protein C, and plasminogen has suggested that these factors may also exhibit qualitative deficiencies [10,20–22] but the data are not absolute [15,19]. Finally, impairment of platelet aggregation has been documented in neonates in the first 48h of life [23].

Coagulation tests have also been studied in infants. Activated partial thromboplastin time (aPTT) has been shown to be the most prolonged coagulation test in both premature and full-term infants on day 1 of life compared to adults, being 1.2-1.5 times longer in term infants and 1.4-2.4 times longer in preterm infants [12,13,24]. This prolongation has been attributed to the quantitative and qualitative deficiencies of contact factors described above. In full-term infants, aPTT values were similar to adult values by 3 months of age. In premature infants, this equalization occurred by 6 months of age. Values of prothrombin time (PT) are less prolonged, with reported values ranging from being not significantly different from adult values to being 1.15–1.3 times longer in term infants and 1.3 times longer in preterm infants [12,13,24]. Although FVII levels are low at birth, their levels are more preserved than those of other coagulation factors and may prevent excessive prolongation of the PT in early infancy. Thrombin times (TT) are approximately 1.16–1.4 times longer than adult values in term infants and 1.31-1.5 times longer in preterm infants [12,13,24]. The existence of dysfunctional fibrinogen may explain this prolongation. If prolonged at birth, PT and TT values reach adult ranges within several days of age [11–13].

Interpretation of these maturational issues of the hemostatic system is complex. There is no evidence that neonates, infants or children have an increased risk of bleeding spontaneously, after trauma or during surgery, compared to adults. In fact, thromboelastograms have shown intact coagulation systems even in neonates [25]. However, the alterations in coagulation factors and coagulation inhibitors in young infants result in a reduced ability to generate thrombin as well as a significant delay in thrombin generation once the coagulation system is triggered. On the other hand, deficiencies in the fibrinolytic system result in decreased plasmin generation and impairment of fibrinolysis [22,26]. Fortunately, maturation of coagulation and fibrinolysis proceeds in tandem and in accordance with gestational age, and the net effect apparently strikes the necessary balance to maintain a competent hemostatic picture. Nevertheless, while quantitative and qualitative immaturities resolve during the first year of life, normal values for plasma levels of most coagulation factors, coagulation inhibitors, and fibrinolytic proteins in young infants must be recognized to be different from those values considered normal for adults.

# **Evaluation of the coagulation system**

Anesthesiologists and surgeons usually employ laboratory tests of the coagulation system to screen patients preoperatively for inherited or acquired hemorrhagic disorders or to diagnose the cause(s) and monitor the treatment of intraoperative or postoperative bleeding [27]. None of the available tests is perfect because each either reports a quantitative count with no consideration of qualitative function or is performed *in vitro* in environments that are not equivalent to what actually occurs *in vivo*. This section will describe available laboratory tests and their indications and limitations.

### **Evaluation of primary hemostasis**

Evaluation of primary hemostasis includes quantitative and functional analysis of platelets and vWF. Platelet counts are measured by automated systems on wholeblood samples. The range of normal for platelet counts is typically 150,000–400,000/ $\mu$ L. Platelet counts, however, do not assess the functional capacity of the available platelets. The bleeding time (BT) and the closure time (CT) of the platelet function analyzer (PFA-100, Siemens Diagnostics, Marburg, Germany) have been developed for this purpose. The BT was described in 1910 as "a method for studying hemorrhage" [28] and attempted to assess primary hemostasis *in vivo*. The BT is performed by making a skin cut on the volar surface of the patient's forearm [29] and standardization is attempted by using commercially available spring-loaded devices to make the skin incision and by maintaining a constant forearm venous pressure of 40 mmHg using a sphygmomanometer cuff [30]. Typical reference ranges for BT are 6–11 min [30]. The BT is operator dependent [27], is not a useful predictor of hemorrhage risk with surgery in the absence of a bleeding history, and a normal value cannot exclude the possibility of excessive hemorrhage with invasive procedures [29]. Furthermore, the BT is a poor diagnostic and prognostic test for vWD [31] and does not reliably identify platelet dysfunction produced by aspirin or nonsteroidal anti-inflammatory drug (NSAID) use [29]. For these reasons, the BT has largely been replaced with *in vitro* tests such as the PFA.

In the PFA, whole blood is aspirated at high shear rates across an aperture cut in a membrane coated with collagen and either ADP or epinephrine. The collagen, along with the high shear rates employed and the patient's level of vWF, causes platelet adhesion to the membrane while the ADP or epinephrine stimulates platelet aggregation. Closure time, the amount of time required for a platelet plug to form and occlude the aperture in the membrane, is measured and is dependent on platelet number and function as well as on functional vWF. Thus, the PFA is a better screening test than the BT for vWD [32]. Normal CTs in children are  $91 \pm 13$  sec for ADP cartridges and  $117 \pm 23$  sec for epinephrine cartridges and these values are similar to those found in adults. Neonates have shorter CTs (56  $\pm$  6 sec for ADP cartridges and 81  $\pm$  17 sec for epinephrine cartridges), probably because of their elevated levels of vWF or presence of the larger, more hemostatically active multimers of vWF [32,33]. The CT is prolonged in patients with platelet counts below  $50,000/\mu$ L or hematocrits below 25% and in patients with severe platelet dysfunction (Bernard-Soulier syndrome (Gp Ib receptor defect) and Glanzmann thrombasthenia (Gp IIb/IIIa receptor defect)), and severe vWD (types 2 and 3). CT is also prolonged by aspirin, NSAID or Gp IIb/ IIIa inhibitor use [27,30,34]. The most reliable use of the PFA is in patients with severe bleeding where a normal CT excludes quantitative deficiencies of platelets or vWF, severe platelet function disorders, and severe vWD [30,35]. However, the PFA has a low sensitivity as a screening test for platelet function defects so its usefulness as a preoperative screening tool is questionable [35].

While abnormal results of BT or PFA-100 CT indicate a problem in primary hemostasis, definitive investigation and identification of the specific problem are accomplished by sophisticated tests such as platelet aggregometry, platelet secretion assays, and platelet flow cytometry. Platelet aggregometry is considered the gold standard for global platelet function testing. Platelet secretion assays use highly technical methodology to measure the release of substances from platelet granules. Platelet flow cytometry uses monoclonal antibodies to diagnose defects in platelet surface glycoproteins (Bernard–Soulier syndrome and Glanzmann thrombasthenia) [34]. Appropriate use of these tests requires extensive expertise in diagnosing hemostatic disorders and thus should be under the guidance of a hematologist.

Quantification of vWF levels (vWF:Ag) is obtained from plasma samples using an enzyme-linked immunosorbent assay (ELISA), a latex immunoassay or the Laurell immunoelectrophoretic assay [36,37]. The accepted standard for measuring functional vWF activity is the ristocetin co-factor assay (vWF:RCo). The antibiotic ristocetin induces the binding of vWF to the adhesive Gp Ib receptor on platelets. Therefore, addition of ristocetin to a mixture of patient plasma and formalin-fixed normal platelets should induce platelet agglutination that can be detected by aggregometry. The extent of platelet agglutination is proportional to the functional activity of vWF in the patient's plasma [37].

# **Evaluation of secondary hemostasis**

Evaluation of secondary hemostasis involves examining the steps in thrombin generation and fibrin formation. Available tests include quantitative measurements of coagulation factor levels and analyses of the interactions of these factors in the coagulation process.

Measurement of fibrinogen level is the most common quantitative test performed. In the most commonly used measurement method, the sample plasma is diluted 10fold and excess thrombin is added. Time to clot formation is then measured. The 10-fold plasma dilution ensures that the amount of fibrinogen remaining in the sample is the rate-limiting step in clotting. Time to clot formation is thus inversely related to fibrinogen concentration and, therefore, a fibrinogen level can be derived. Fibrin degradation products or other inhibitors of fibrin formation can cause artificially low results but, since excess thrombin is added to the test plasma, small amounts of heparin do not interfere with the results [38]. Normal values for fibrinogen level range between 150 and 400 mg/dL.

The interactions of coagulation factors are commonly measured with the PT, aPTT, and TT. The PT is classically used to examine the factors involved in the "extrinsic" and common pathways of coagulation and thus is sensitive to factors VII, X, V, II (thrombin), and I (fibrinogen) (Fig. 11.8). Thromboplastin, a mixture of TF, phospholipids, and calcium, is used to initiate coagulation. Changes in optical density of the plasma are then used to detect and time the formation of clot. The PT is expressed in seconds (usual range 10–14 sec) but the result will vary depending on the potency of the thromboplastin preparation used to initiate coagulation. Each batch of thromboplastin is assigned an International Sensitivity Index (ISI) value by its manufacturer which ranges from 1.0 to 2.0 based on comparison to an International Reference

**Figure 11.8** Portion of the coagulation cascade examined by the prothrombin time (PT). Reproduced from Bleyer et al [11] with permission from Elsevier.

Preparation. An international normalized ratio (INR) is then obtained by the following formula:  $INR = (PT_{test}/PT_{normal})^{ISI}$ . The INR thus allows a more accurate comparison of PT values [38]. Falsely prolonged PT values can be seen when too little sample is drawn or when too little plasma is available in a given sample (such as in polycythemic patients). The PT is useful in the detection of coagulation defects due to vitamin K deficiency, intestinal malabsorption, hepatic failure, dilutional or consumptive coagulopathies, and isolated deficiencies of the factors noted above, especially factor VII. Anticoagulation with oral vitamin K antagonists (warfarin) is monitored using the PT and INR [27].

The aPTT is described as a test to evaluate the "intrinsic" and common coagulation pathways (Fig. 11.9). Only the phospholipid part of thromboplastin is used to activate factor XII, hence the term "partial thromboplastin" time, and coagulation is accelerated for this test using an activator (celite, kaolin, silica or ellagic acid), hence the term "activated" PTT. The normal range for the aPTT is 21–35 sec but this range varies from laboratory to laboratory. The aPTT is prolonged by deficiencies of the contact coagulation factors (XII, XI, HMWK, and PK), factors VIII and IX, and factors of the common pathway (X, V, II (thrombin), and I (fibrinogen)). It is also prolonged in the presence of heparin, inadequate sample (or inadequate plasma), and lupus anticoagulants.

Lupus anticoagulants belong to the broad family of antiphospholipid antibodies and were initially thought to occur exclusively in patients with autoimmune disorders. However, they are now known to occur in up to 1% of the normal population. They inhibit the proper assembly

**Figure 11.9** Portion of the coagulation cascade examined by the activated partial thromboplastin time (aPTT). Reproduced from Bleyer et al [11] with permission from Elsevier.

of lipid-dependent coagulation complexes such as the factor VIIIa/IXa tenase complex and the factor Xa/Va prothrombinase complex. While their presence is probably the most common cause of a prolonged aPTT [39], they do not increase the risk of bleeding. In fact, their predominant clinical manifestation is the development of thrombosis secondary to their effect on plateletendothelial interactions and their interference with protein C and protein S activity. Initial differentiation of a prolonged aPTT may be made by using a 50:50 mixture of the plasma being tested and normal plasma. Subsequent correction of the aPTT indicates a factor deficiency whereas ongoing prolongation suggests the presence of an inhibitor such as heparin, lupus anticoagulants or a coagulation factor-specific inhibitor [27,38]. Immediate correction followed by prolongation at 1h may indicate a FVIII inhibitor. If heparin contamination is responsible for prolongation of the aPTT, treatment of the sample with hepzyme (an enzyme that neutralizes heparin) should correct the value.

Activity levels of most individual coagulation factors can be obtained by using the PT or aPTT to measure clotting in mixtures of patient plasma and commercially available plasma known to be deficient in the specific coagulation factor being assayed. The observed clotting times are proportional to the amount of the specific factor in the patient plasma and are then converted into units of factor activity using a reference curve constructed from the control plasma. PT-based assays are used to measure activity levels of factors II, V, VII, and X while aPTT-based assays are used for measurement of activity levels of factors VIII, IX, XI, and XII and of HMWK

**Figure 11.10** Portion of the coagulation cascade examined by the thrombin time (TT). Reproduced from Bleyer et al [11] with permission from Elsevier.

and PK. Factor antigen levels may be detected with immunological methods, including monoclonal antibodies. However, factor activity assays are typically most clinically relevant. FXIII function cannot be tested by the PT or aPTT but may be screened using 5M urea clot stability testing.

The TT is the time required for the conversion of fibrinogen to fibrin after a patient's plasma is exposed to exogenous thrombin (Fig. 11.10). The reference range for the TT is typically 10–15 sec. The TT is prolonged in the presence of heparin, antibodies to thrombin, hypofibrinogenemia, dysfibrinogenemia, fibrin degradation products, lupus anticoagulants, and amyloidosis [38]. In the presence of heparin, the TT can be modified to assess fibrin formation by using reptilase, a substance derived from snake venom. Reptilase, like thrombin, will stimulate the conversion of fibrinogen to fibrin but, unlike thrombin, it is not inhibited by heparin. The TT can also be prolonged by thrombolytic therapy since the action of these drugs decreases circulating levels of fibrinogen and fibrin.

#### **Evaluation of fibrinolysis**

The occurrence of fibrinolysis can be determined either by measuring the endproducts of fibrin degradation or by directly measuring clot lysis by viscoelastic tests [38]. When fibrinolysis occurs in response to the activation of the coagulation system, plasmin degrades the resulting fibrin clots into fibrin degradation products including D-dimers, a breakdown product composed of two of the "D" fragments of fibrin cross-linked together [40]. When plasmin is activated in the absence of coagulation activation, as may occur during liver transplantation or exogenous administration of tPA, fibrinogen is broken down into various fibrinogen degradation products (X, Y, D, and E fragments but mostly non-clotted X fragments) [38,41]. The presence of D-dimers thus specifically indicates the breakdown of FXIII cross-linked fibrin, as may be seen with disseminated intravascular coagulation (DIC), so the presence of D-dimers may indicate a pathological condition that can cause organ damage [42]. Assays for fibrin and fibrinogen degradation products and for D-dimers can be performed by automated methods, by ELISA or by mixing serial dilutions of the patient's plasma with antibody-coated latex beads and observing for the subsequent agglutination [39]. Assays for fibrin and fibrinogen degradation products are usually performed in reference laboratories while D-dimer assays can be performed in many hospital laboratories.

Viscoelastic tests assess hemostasis from clot formation to clot retraction and lysis [43]. These tests can identify both hypercoagulable and hypocoagulable scenarios as well as the occurrence of fibrinolysis. Thromboelastography (TEG®), rotational thromboelastography (ROTEM®), and Sonoclot® are the available viscoelastic tests. Some advantages of these tests are that they are performed on small samples of whole blood, not only making testing technically simpler but also allowing interactions between platelets, red blood cells, and coagulation factors to be taken into account. These tests can be performed in the operating room at the patient's bedside and, with the use of specific coagulation activators, can provide very rapid results that can be used to immediately influence patient care [44]. With the use of certain modifiers, the contributions of platelets and fibrinogen to the clotting process also can be assessed [45,46]. Additionally, the effects of coagulation product transfusions [25], recombinant factor VIIa [47,48], antifibrinolytics, antiplatelet therapies [49] and direct thrombin inhibitors [50] can all be monitored with modifications of these tests. These tests have proven very useful in managing the coagulation problems associated with liver transplantation and cardiac surgery [25,51,52] and have been used to develop algorithms to guide post-cardiopulmonary bypass (CBP) transfusion therapy [53,54]. Drawbacks to these tests include difficulty in standardization and the need for special training for clinicians to perform these tests and interpret their results. An additional concern is that the contribution of blood vessel endothelium is not considered by these tests because they are performed in an in vitro cuvette at low shear stresses [55].

#### Use of laboratory tests

Coagulation tests typically have been used to screen patients preoperatively in an attempt to predict perioperative bleeding problems. The rationale for obtaining preoperative coagulation tests in patients with significant systemic illnesses and in those undergoing procedures such as liver transplantation or cardiac surgery is straightforward and understandable. However, obtaining preoperative coagulation tests routinely on healthy patients who are undergoing routine procedures and have no history or physical signs to suggest an underlying bleeding diathesis is controversial. The main reason for obtaining screening tests in this population is to detect previously undiagnosed inherited bleeding disorders such as vWD or hemophilia [56]. However, because of the infrequent occurrence of these disorders [56,57], the routine use of coagulation tests for preoperative screening in the absence of a significant bleeding history seems unjustified from an economic standpoint [56]. Furthermore, the tests used for preoperative screening of patients (platelet count, BT, PFA, PT, aPTT) do not provide data that reliably predict perioperative bleeding [58]. Limitations of the platelet count, BT, and PFA in screening for defects of primary hemostasis have already been described. The PT screens only the "extrinsic" coagulation pathway and thus will not detect either type of hemophilia. Finally, the aPTT has not been found to predict postoperative bleeding in patients with no clinical indicators of bleeding problems [59].

The use of preoperative screening coagulation tests has been intensely scrutinized in children undergoing tonsillectomy and adenoidectomy (T&A). Approximately 2-4% of patients undergoing this surgery experience postoperative hemorrhagic complications [60,61]. These children are usually otherwise healthy and this surgery is often a child's first significant hemostatic challenge. Results from many studies have shown no ability of the PT or aPTT to predict which children will bleed postoperatively [56,60-62]. Additionally, there are a large number of initially abnormal routine tests that return to normal on retesting, thus causing unnecessary concern for parents, unnecessary delays in surgery, and increased costs [63,64]. Findings such as these have led some authors to state that in the absence of suspicions raised from a patient's history or physical exam, preoperative laboratory screening contributes little to patient care and should not be done [56,63,65–68]. Indeed, the practice advisory published by the American Society of Anesthesiologists on preanesthesia evaluation discourages the use of preoperative laboratory testing in asymptomatic patients unless indicated by findings on history or physical exam [69]. Additionally, the American Academy of Otolaryngology, Head and Neck Surgery recommends performing coagulation studies only in those patients undergoing T&A whose medical histories or physical exams may indicate coagulation problems [70].

Preoperative evaluation of the coagulation system should, therefore, start with a pertinent history and physical examination. A sample of questions to ask parents

#### Box 11.1 Questions regarding bleeding history

- Does your child have trouble with any of the following:
  - Easy bruising (larger than 2 inches)?
  - Gum bleeding with tooth brushing?
  - Frequent nose bleeds?
  - Oozing a long time from cuts or scrapes?
  - Abnormally heavy menstrual periods?
  - Bleeding into joints or muscles?
- Has your child had trouble with bleeding after:
  - Loss of teeth or dental extractions?
  - Previous surgery (including circumcision)?
  - Previous injuries?
  - When his/her umbilical cord came off?
- Is your child taking:
  - Antihistamines?
  - Aspirin?
  - Ibuprofen or other non-steroidal anti-inflammatory drugs?
  - Other over-the-counter medicines for headaches, colds or menstrual cramps?
- Does your child take any prescribed medicines or have any chronic medical problems requiring a doctor's ongoing care?
- Has your child ever received a blood transfusion?
- Is there a family history of easy bruising or unusual bleeding after surgeries, injuries or childbirth?
- Does anyone in your family have hemophilia, von Willebrand disease, low platelets or any other blood disorder?

and older children is outlined in Box 11.1 [56,71,72]. Pertinent findings on physical exam include petechiae, purpura, and ecchymoses with no antecedent injury [71,73]. Clinicians must always be aware, though, that the accuracy of histories and physical exams depends on the clinician performing them and the parent and/or child answering the questions. The ability of parents and children to understand and answer medically related questions appropriately may be lacking, memories and interpretations of previous events may not be perfect or accurate, family histories may be overinterpreted, knowledge of a child's personal or family history by foster or adoptive parents may be deficient, ingestion of medications may be forgotten, and exams may be incomplete [71,72]. Additionally, negative family histories may occur in up to 40% of cases of inheritable bleeding disorders because of spontaneous mutations or variable expression of the disorders in relatives. Also, young children may not have experienced an injury, undergone previous surgery or have had other experiences that would allow a bleeding problem to be revealed [64,71].

Currently, the opinion of most authorities remains that preoperative laboratory tests should only be obtained in the face of indicative histories and/or physical exams. However, one's clinical experience and judgment must be applied to the content and quality of the information obtained from the history and physical exam to make final decisions about obtaining preoperative laboratory tests.

In cases of active bleeding, quantitative assessments of platelet counts and fibrinogen levels and qualitative assessments of clotting with PT and aPTT have limitations. First, there are few agreed-upon absolute values at which transfusion of blood components is indicated. Second, these tests are usually done in a central lab with a relatively long turnaround time. Therefore, by the time results are obtained, the clinical picture may have changed. With advances in technology, point-of-care tests have been developed and allow results to be available to the bedside clinician significantly faster. Platelet counts, fibrinogen levels, PT, aPTT, and TT can all be obtained with this methodology but the accuracy and validation of these against conventional laboratory tests await confirmation [27]. The viscoelastic tests (TEG®, ROTEM®, and Sonoclot<sup>®</sup>) can also provide immediate data to clinicians and have been extensively studied as aids to manage post-CPB bleeding in children [25,74].

While the use of point-of-care tests ameliorates the timeliness problem, absolute trigger values that dictate intervention are still lacking. Therefore, transfusion decisions still are heavily influenced by the clinical situation and the appearance of the operative field (and the opinions of those observing it!) while coagulation tests are used to monitor trends in the coagulation status as therapy is administered.

# **Congenital hematological disorders**

Congenital disorders of hemostasis can present major perioperative management challenges to anesthesiologists that extend well beyond the time when the patient is anesthetized in the operating room. Knowledge of the more common of these disorders will allow intelligent conversations with hematologists and surgeons in preparing to provide appropriate care to affected children.

## Von Willebrand disease

Von Willebrand disease (vWD) is an inherited hemorrhagic disorder caused by quantitative or qualitative abnormalities in von Willebrand factor (vWF) [37,75,76]. It is the most common inherited bleeding problem, occurring in up to 2% of the population. However, its true incidence is difficult to establish because its highly heterogeneous nature and variable expression leave many cases undetected or undiagnosed. vWF serves two roles. It promotes the formation of a platelet plug during primary hemostasis by binding to components of exposed subendothelium and to platelet Gp Ib receptors, thus causing platelet adhesion to an injured blood vessel wall. It also acts as a carrier protein for coagulation factor VIII, thus preventing the rapid clearance of FVIII from the circulation. vWF is synthesized in endothelial cells and megakaryocytes in a precursor form that is cleaved into monomers which are then assembled into multimers through disulfide-linked bonds. The larger multimers are necessary to promote platelet adhesion to injured vessels. vWF is stored in the Weibel–Palade bodies of endothelial cells and in the  $\alpha$ -granules of platelets.

The inheritance of vWD follows an autosomal pattern, with the vWF gene located on chromosome 12. Three major types of vWD are generally identified. Type 1 is characterized by decreased amounts of vWF that otherwise is normal in structure and function. This type accounts for 70-80% of the cases of vWD and is inherited as an autosomal dominant trait. When interpreting vWF levels, however, it must be remembered that people with type O blood have mean vWF levels that are only approximately 75% of that seen in people with other blood types. Type 2 is caused by various qualitative defects in vWF, especially in the larger multimers, where there is failure of multimer assembly or increased proteolysis of mutant multimers (2A), increased binding of abnormal large multimers to the Gp Ib receptors of circulating platelets not actively involved in primary hemostasis (2B), decreased binding of vWF to platelets because of an abnormal vWF binding site for platelet Gp Ib receptors (2M), or an abnormal vWF binding site for FVIII leading to increased clearance of free FVIII with subsequent decreased plasma levels (2N). Type 3 is the most severe form of vWD and is characterized by a complete absence of vWF and an autosomal recessive or compound heterozygous inheritance. Finally, a "platelet-type" or "pseudo" vWD has been described where abnormal platelets demonstrate an enhanced affinity for normal vWF. This type of vWD, as well as type 2B, results in varying degrees of thrombocytopenia and the absence of large multimers of vWF in plasma due to spontaneous in vivo binding of vWF and platelets with subsequent consumption of the large multimers and platelets.

Clinical manifestations of types 1 and 2 vWD are typically relatively mild and are mostly those of mucous membrane bleeding: epistaxis, gingival bleeding, gastrointestinal bleeding, menorrhagia, excessive postpartum bleeding, cutaneous bleeding, easy bruising, and excessive bleeding after dental extractions, tonsillectomy and adenoidectomy, or minor surgeries or traumas. Type 3 vWD, however, can lead to the hemarthroses and muscular hematomas commonly seen with hemophilia and even to intracranial bleeding.

Screening tests for vWD, including aPTT, BT, and PFA, lack sensitivity and specificity so assays of vWF quantity, function, and structure are required for definitive diagnosis. Measurement of vWF:Ag determines vWF levels and

measurement of vWF:RCo assesses vWF function. The "ristocetin-induced platelet aggregation assay" (RIPA) uses lower doses of ristocetin than are used in the vWF:RCo assay to detect the hyper-responsive binding of vWF to platelets that is seen in type 2B and platelettype vWD. Electrophoresis is used to determine the structure of the vWF multimers present in a patient's plasma in order to help differentiate the subtypes of type 2 vWD. Finally, it may be useful to measure FVIII activity levels since significantly decreased levels are seen in types 2N and 3 vWD. Repeated testing may be required to establish the diagnosis of vWD because the results of these tests can vary considerably from time to time in individuals with vWD [77] and are influenced by factors such as stress (as may be induced while obtaining these tests in children!) and inflammation.

The goals of treatment of vWD are to restore the normal platelet adhesion of primary hemostasis and to increase abnormally low levels of FVIII. vWF:RCo and FVIII:C levels of 40-50% are considered sufficient for minor surgery or bleeding or for tooth extractions. Levels of 80-100% are desired for major surgery or life-threatening hemorrhage with maintenance of levels greater than 50% for at least 3 days for vWF:RCo and for 5-7 days for FVIII: C. DDAVP (desmopressin), a synthetic vasopressin analog, releases vWF from endothelial cells and platelets and increases plasma levels of vWF and FVIII. It is effective in treating patients with type 1 vWD. It will also restore plasma levels of FVIII and vWF in many patients with type 2 vWD but the vWF will still be qualitatively deficient so primary hemostasis may continue to be abnormal. However, DDAVP is contraindicated in type 2B and platelet-type vWD since the release of vWF will exacerbate the thrombocytopenia common to these conditions. DDAVP can be given intravenously at a dose of  $0.3 \mu g/kg$  bodyweight or intranasally at a dose of  $150 \mu g$ (one puff) for children weighing less than 50 kg and 300 µg (two puffs) for those weighing more than 50 kg. Problems with water retention may be encountered so fluid restriction is recommended for 24h following DDAVP dosing. Tachyphylaxis may also develop with repeat dosing. A trial dose of DDAVP with measurement of the subsequent vWF:RCo response is recommended before a child with vWD encounters a hemostatic challenge in order to guide its use. Replacement of vWF and FVIII may be required perioperatively in patients with type 3 vWD and in those with type 2 vWD who do not respond to DDAVP.

Several plasma-derived FVIII concentrates are commercially available and carry minimal risk of viral transmission. However, only one, Humate-P® (CSL Behring, Marburg, Germany), is licensed by the FDA for use in treating vWD since it is the only product that contains adequate amounts of the larger vWF multimers. Cryoprecipitate contains both vWF and FVIII so may be useful in instances where Humate-P is not available. Finally, antifibrinolytics can be used as an adjunct therapy, especially with bleeding from oral and nasal mucous membranes, to prevent clot lysis after hemostasis has been achieved by DDAVP, replacement therapy or local measures [37,75,76]. Antifibrinolytics are typically given for 3–7 days following surgical procedures in patients with vWD. It is obvious that the management of a child with vWD who is undergoing a surgical procedure must involve consultation with a hematologist, ideally at least a month prior to scheduled surgery, to allow time for appropriate testing and treatment planning.

### Hemophilia

Two types of hemophilia are typically discussed: hemophilia A (classic hemophilia) results from a deficiency of FVIII while hemophilia B (Christmas disease) results from a deficiency of FIX. Bleeding occurs in patients with either type of hemophilia because adequate amounts of thrombin cannot be generated since the factor VIIIa/IXa "tenase" complex cannot be formed on activated platelets. Both types of hemophilia usually are transmitted as X-linked recessive traits; therefore, most affected patients are males. However, approximately 30% of patients with hemophilia have negative family histories and appear to be affected by spontaneous mutations. Multiple gene mutations have been described as causing each of these diseases. Hemophilia A occurs more frequently than hemophilia B (1 in 10,000 versus 1 in 60,000 people). Classification of both types of hemophilia is based on levels of FVIII or FIX activity and is described as severe (levels < 1%), moderate (levels 1–5%) or mild (levels >5– 40%) [78,79].

The clinical manifestations of hemophilia are those of delayed bleeding that particularly involves joints and muscles or occurs with surgery or other injuries. This is in contrast to the immediate bleeding most commonly involving mucocutaneous surfaces seen in vWD. This difference is due to interference with primary hemostasis in vWD versus interference with secondary hemostasis in hemophilia. The severity of bleeding in hemophilia is determined by the severity of clotting factor deficiency and manifests as bleeding after surgery or trauma in mild and moderate disease and as spontaneous bleeding in severe disease. In neonates, bleeding occurs after heelsticks, injections, and circumcision. Therefore, boys born to mothers known to be carriers of hemophilia should not be circumcised until it has been determined that they do not have the disease.

As children grow older, excessive bruising, mouth bleeding after tooth loss, muscle hematomas, joint hemorrhages, and even intracranial bleeding may become evident. One of the more debilitating problems encountered by affected children is the development of a
progressive arthropathy in a "target joint." A target joint is one in which recurrent bleeding has occurred at least four times in 6 months or 20 total times. Iron from the blood extravasated into the joint accumulates in synovial cells, triggers inflammation, and results in the proliferation of friable synovial villi. This predisposes to further intra-articular bleeding and joint damage. In severe cases, these synovial villi may require arthroscopic removal or radio-active sclerosis.

The diagnosis of hemophilia is made by demonstrating low plasma activity levels of FVIII or FIX. Screening tests such as the aPTT are not consistent, sensitive or specific enough to be useful as diagnostic tools. Results of factor assays are expressed as "% activity" with one unit of factor per mL of plasma being equivalent to 1% activity. In families with a history of hemophilia, newborns can be diagnosed by testing plasma from cord blood, and fetal diagnosis can even be made as early as 20 weeks gestation.

Treatment of hemophilia focuses on factor replacement, typically with recombinant or plasma-derived FVIII or FIX. These products currently undergo multiple viral and pathogen inactivation steps, thus virtually eliminating infectious complications of HIV, hepatitis B or hepatitis C. Historically, cryoprecipitate was used to treat hemophilia A, with fresh frozen plasma used at times as well. However, large infusion volumes and infectious disease risks have made these therapies essentially obsolete in the United States.

Factor replacement therapy can be administered prophylactically or "on demand." Prophylactic therapy may be given 1-4 times per week to prevent bleeding. "Ondemand" therapy is used to treat acute bleeding episodes, with the desired plasma factor level depending on the location and severity of the bleeding. A minimum level of 40% should be targeted for minor oral, nasal or urinary tract bleeding and should be maintained for several days. For bleeding in more critical anatomical areas such as the brain, retropharynx or target joints and for severe bleeding in the gastrointestinal tract or muscle, levels of 80-100% should be achieved and then maintained for 3-14 days (depending on the severity of bleeding). When replacing FVIII, 1 unit/kg of replacement product will increase plasma levels of FVIII by 2%. The average halflife of the products is 12h. For FIX, 1 unit/kg of replacement product will increase plasma levels of FIX by 1% with an average half-life of 20–24 h.

A complication of treatment with factor replacement is the development of inhibitory antibodies to FVIII (or, more rarely, to FIX). Inhibitors develop in up to 20–30% of patients with hemophilia A and can make treatment quite complicated [79,80]. The titer of inhibitory antibodies is expressed in Bethesda units (BU), with one BU denoting the level of antibody that decreases the plasma factor level by 50%, and in logarithmic fashion. Elimination of these antibodies by immune tolerance induction therapy, where large and frequent (usually daily) doses of FVIII or FIX are administered with or without immunosuppressants, is successful in approximately 70% of these patients. Bleeding in the setting of high-titer inhibitors typically requires treatment with either high doses of recombinant FVIIa or with activated prothrombin complex concentrates [78,79,81].

Desmopressin may be useful in minor bleeding in patients with mild hemophilia A since it releases FVIII from endothelial cells and platelets. It will not be effective as a sole treatment with severe bleeding. As with vWD, the usefulness of DDAVP should be explored by documenting its effect on FVIII levels before depending on it to help treat bleeding. Antifibrinolytics may be helpful in preventing clot lysis after factor replacement has helped clotting to occur, especially after oral, intraocular or gastrointestinal bleeding. As is the case with managing a child with vWD, the expert help of a hematologist is crucial in providing the best perioperative care to children with hemophilia.

# **Thrombophilias**

The thrombophilias are coagulation abnormalities which predispose to the development of thromboembolic events [82]. Many thrombophilic abnormalities are inherited, including deficiencies of natural anticoagulants (AT, protein C, and protein S), factor V Leiden mutation, prothrombin G20210A mutation, and hyperhomocysteinemia. While inherited deficiencies of AT, protein C, and protein S are the least common of these abnormalities, they result in the highest potential for thrombosis since their absence leaves the stimulated coagulation system unregulated and unchecked. Factor V Leiden results from a mutation in the FV gene that makes the mutant FV resistant to inactivation by activated protein C, thus allowing its persistent activity and an increased risk for thrombosis. The prothrombin G20210A mutation results from a glutamine-to-arginine transition at position 20,210 of the 3' untranslated region of the prothrombin gene and leads to the production of increased levels of prothrombin with a subsequent increase in thrombin generation. Hyperhomocysteinemia results from a mutation in the gene coding for methylenetetrahydrofolate reductase which leads to an increased production of homocysteine with resultant endothelial cell damage [82-86].

Other thrombophilic abnormalities can be acquired, the most common of these being the presence of antiphospholipid antibodies such as anticardiolipin antibodies or the lupus anticoagulant. The lupus anticoagulant may be found in patients with autoimmune disorders such as systemic lupus erythematosus or in patients with malignancies or viral infections. The name is not accurate given that it is not exclusively associated with systemic lupus erythematosus nor is it truly an anticoagulant. Antiphospholipid antibodies may react with multiple components of the coagulation system and lead to alteration of platelet–endothelial interactions and inhibition of the protein C/protein S system that predispose patients to recurrent thrombotic events as well as recurrent fetal loss due to placental vascular insufficiency [82,86–88].

Although the presence of intrinsic prothrombotic abnormalities may set the stage for thrombosis, the imposition of additional clinical risk factors is usually necessary to cause thrombosis in children. The use of central venous lines is the most common thrombosis trigger in children with thrombophilia. Catheter-associated risk factors include the use of large-bore catheters, the use of percutaneously placed versus embedded catheters, location of the catheter tip in the right atrium, insertion in femoral or subclavian versus jugular veins, and the expertise of the physician placing the catheter. The use of heparin-coated catheters decreases thrombotic problems and the use of antibiotic-impregnated catheters decreases infective complications of thromboses. Other triggers include underlying medical conditions, most commonly systemic infection and cancer. Surgery, trauma, immobilization, autoimmune inflammatory diseases, congenital heart disease, vascular malformations, use of estrogencontaining oral contraceptives, and pregnancy may also play a similar role [83-86].

The frequent use of central venous catheters in neonates and infants, advances in medical care that allow the survival of children with chronic medical conditions, and improved diagnostic modalities for thrombosis are increasing the occurrence and recognition of thrombosis as well as the awareness of thrombophilia in children [84]. Peak incidences of thrombosis occur in neonates because of the use of central lines and the frequent existence of clinical risk factors and in adolescents with the onset of autoimmune inflammatory diseases and the use of oral contraceptives. Even in these two age groups, though, thrombosis still occurs significantly less frequently in thrombophilic children than in adults [82,84].

Non-invasive techniques used to diagnose thromboses include Doppler ultrasonography, echocardiography, computed tomography (CT) venography, and magnetic resonance (MR) venography. However, these techniques lack sensitivity and angiography of involved veins may be required for diagnosis. Treatment options for identified thrombi include observation without intervention, anticoagulation, thrombolytic therapy, and surgical thrombectomy, with ultimate decisions based on thrombus location, potential for future complications, and current clinical signs. Unfractionated heparin, low molecular weight heparin, warfarin, aspirin, and tPA are all available for use. While the optimal drug, dosage of that drug, and duration of therapy for children with thrombosis have not been definitively established, recommendations have been outlined by several authors [84,89]. Regardless of the therapy employed, close monitoring of the thrombus for extension or regression and the input of a knowledgeable hematologist to help diagnose and manage thrombophilic children after a thrombotic complication are important.

# Sickle cell disease

Hemoglobin molecules are composed of two pairs of globin chains, each possessing an Fe<sup>+2</sup>-containing heme group. Hemoglobin A, composed of two  $\alpha$  and two  $\beta$  chains, accounts for 95% of normal adult hemoglobin. Hemoglobin S contains abnormal  $\beta$  chains resulting from the substitution of the amino acid valine for glutamic acid in the sixth position of the 146-amino acid  $\beta$  chain. The alleles coding for the  $\beta$  chain are co-dominant so a person who is heterozygous for the normal and the sickle  $\beta$  chains produces both hemoglobins A and S. This predominantly benign carrier state, termed sickle cell trait (SCT), is found in more than 8% of African-Americans [90] and is felt to have persisted in this population because it offers protection from the fatal complications of *Plasmodium falciparum* malaria [91].

Homozygotes for the sickle  $\beta$  chain produce only hemoglobin S. This condition, termed hemoglobin SS disease, may be associated with significant clinical manifestations [92,93]. Hemoglobin S can also combine with hemoglobin C (Hb SC disease), abnormal  $\beta$  globin chains (HbS $\beta^0$  or HbS $\beta^+$  thalassemia) or other hemoglobin variants. The term sickle cell disease (SCD) encompasses all of these related abnormalities. HbS $\beta^0$  thalassemia is a disease similar to HbSS disease, while HbSC and HbS $\beta^+$ thalassemia typically are associated with milder disease. Hemoglobinopathies can be diagnosed by hemoglobin electrophoresis or high performance liquid chromatography. Patients with SCT as well as those with SCD will have a positive sickle dex screen. Currently, newborns in the United States are screened for SCD shortly after birth.

The pathophysiological consequences of hemoglobin S relate to it being less stable and less soluble than hemoglobin A as a result of altered electrical charge of the hemoglobin molecule. The decreased stability of hemoglobin S results in its accelerated denaturation and breakdown, leading to red blood cell (RBC) membrane damage and RBC rigidity. These rigid RBCs adhere to and damage endothelial cells, causing a chronic vascular inflammation. The decreased solubility of hemoglobin S leads to its rapid precipitation out of solution into long polymer strands when it is deoxygenated. This results in the characteristic deformation of RBCs into a sickled shape. Both vascular endothelial dysfunction and sickled RBCs play roles in the pathophysiology of SCD [93]. Intermittent painful vaso-occlusive crises are the clinical hallmark of SCD. Infection and surgical stress are frequent initiators although a triggering event is not found in over half of these crises. Activation of vascular endothelium and of inflammatory and coagulation systems leads to vaso-occlusion, trapping of RBCs, which subsequently deoxygenate and sickle, and ultimately ischemia, bone and organ infarctions, and pain. This often initially manifests in young children as dactylitis or painful swelling of the hands and feet. Management includes aggressive pain control with acetaminophen, NSAIDs, opioids, and possibly regional anesthetic techniques. Guidelines for pain management in children with SCD are available from the American Pain Society [94].

Acute chest syndrome (ACS) is another complication of SCD and is a leading cause of death. ACS is defined as a new pulmonary infiltrate in combination with fever, chest pain or respiratory symptoms. Etiologies include infections and fat emboli from necrotic bone marrow. Treatment includes the administration of a broad-spectrum antibiotic, the use of incentive spirometry, supplemental oxygen if hypoxia is present, and bronchodilators, adequate hydration and pain management, and transfusion if improvement is not achieved by initial interventions. Repeated episodes of ACS often lead to chronic lung injury.

Neurological complications, including transient ischemic attacks and stroke, are common with Hb SS disease. In instances of cerebral ischemic infarctions, emergency exchange transfusion to reduce the level of circulating hemoglobin S to less than 30% may be undertaken upon presentation. Chronic transfusion regimens are then useful to prevent recurrences.

Renal and genitourinary problems such as papillary necrosis, hyposthenuria, and enuresis can also occur in SCD. Priapism is a medical emergency and is treated with aggressive hydration, pain control, and possibly direct injection of  $\alpha$  agonists into the corpora cavernosa. Avascular necrosis of the femoral and humeral heads, retinopathy, and cholelithiasis/cholecystitis are other complications of SCD. Finally, while some degree of baseline anemia is present in all patients with SCD, acute decreases in hemoglobin levels can be caused by splenic sequestration or aplastic crises. Splenic sequestration may occur in association with a viral illness and may result in hypovolemia and even shock. Treatment involves fluid resuscitation, potentially including RBC transfusion. A splenectomy may be indicated for recurrent episodes. Aplastic crises are usually the result of a parvovirus infection and may also result in the need for RBC transfusion [92,93,95].

The complications of SCD may necessitate a variety of surgical interventions. Cholecystectomy is the most frequently performed procedure. Splenectomy and orthopedic, neurosurgical, cardiac, and obstetric procedures are also commonly undertaken. Preoperatively, identification of the current activity and level of severity of the patient's SCD is important. Manifestations of chronic organ system dysfunction and evidence of active infection should be sought. Useful preoperative laboratory tests include hemoglobin and hematocrit, blood urea nitrogen (BUN) and creatinine, and a chest x-ray (CXR) [93]. Prophylactic preoperative RBC transfusions have been shown to decrease the incidence of perioperative complications by diluting the abnormal RBCs with normal ones. Aggressive transfusion regimens aim to decrease the hemoglobin S concentration to less than 30% while conservative regimens aim to increase the hemoglobin level to 10g/dL without concern for hemoglobin S concentrations. The conservative regimen has been found to be as effective as the aggressive approach in preventing perioperative SCD-associated complications while significantly decreasing the number of RBC units transfused and the number of transfusion-associated complications [96]. This approach is currently recommended by the US National Institutes of Health [97]. Preoperative transfusion may be foregone in children undergoing minor superficial elective surgical procedures but is important prior to major surgical procedures (including thoracotomies, laparotomies, orthopedic procedures, and T&As) [98].

Red blood cells chosen for transfusion should be sickle negative and negative for all antigens against which the patient has pre-existing antibodies. Phenotypic matching of RBCs for C, E, and Kell antigens has been shown to decrease rates of RBC alloimmunization and ultimately to decrease rates of hemolytic transfusion reactions in patients with SCD [99]. Thus, RBCs chosen for transfusion should also ideally be phenotypically matched for these antigens. However, transfusing non-phenotypically matched RBCs (or RBCs from donors whose sickle status is not known) is acceptable in urgent situations.

Intraoperative anesthetic management includes exercising usual caution about adequate oxygenation, hydration, thermoregulation, and acid–base balance. No evidence exists to support the prolonged postoperative administration of supplemental oxygen in the absence of hypoxemia. However, pulse oximetry should be monitored and oxygen therapy should be used to maintain normal oxygen saturations.

Aggressive pulmonary toilet and early ambulation postoperatively may limit pulmonary complications. Adequate postoperative pain management is critical. Regional anesthetic techniques may be useful both intraoperatively as part of the anesthetic plan and postoperatively for pain control. Surgery on an outpatient basis is appropriate for superficial procedure on patients with stable disease [93]. The use of tourniquets for orthopedic procedures is controversial [100,101] but their uncomplicated use has been documented in patients after preoperative exchange transfusions [102]. Similarly, cardiac surgery involving CPB has been safely conducted after performing preoperative and intraoperative exchange transfusions [103,104]. No consensus exists on the appropriate body temperature to be maintained during CPB or on the use of cold cardioplegia, but the maintenance of normothermia seems intuitive.

# **Transfusion therapy**

Transfusion medicine has played a major role in allowing the medical and surgical advances that benefit children in the 21st century, and the administration of blood components is an integral part of the practice of anesthesiology. This section will describe the basic principles of transfusion therapy, the blood products available for transfusion, the logistics of transfusion, the indications and triggers for administering blood products, and the potential adverse effects that can accompany transfusion of these products.

# Principles of transfusion therapy ABO blood group system

Blood is classified into groups or types based on the presence or absence of specific inherited RBC surface antigens. The International Society of Blood Transfusion recognizes 30 major blood group systems, the most important of which is the ABO system. Dr Karl Landsteiner is credited with the discovery of the ABO system in 1900 and was subsequently awarded the Nobel Prize in 1930 for his work.

The ABO system defines an individual's "blood type" by the presence or absence of A and/or B antigens on RBC surfaces. These antigens are produced by the modification of a precursor called the H antigen through the enzymatic actions of co-dominant A and B alleles at the ABO locus on chromosome 9. A third allele, termed the O allele, exists but lacks enzymatic activity and, therefore, does not modify the H antigen or produce a RBC surface antigen. The homozygous presence of the A allele or the heterozygous presence of the A and O alleles thus results in only the A antigen being expressed on RBCs and an individual having "type A" blood. Similarly, the homozygous presence of the B allele or the heterozygous presence of the B and O alleles results in the production of only the B antigen, with subsequent "type B" blood. The homozygous presence of the O allele results in no RBC surface antigen production for this blood system and thus in "type O" blood. Finally, the heterozygous presence of A and B alleles results in production

Table	11.2	ABO	blood	group	system
-------	------	-----	-------	-------	--------

	ABO type					
	A	В	0	AB		
Allele combinations	AA AO	BB BO	00	AB		
ABO antigen present	А	В	None	A and B		
ABO antibody present	Anti-B	Anti-A	Anti-A Anti-B	None		

of both A and B antigens and "type AB" blood (Table 11.2). Ethnic and racial differences exist in the distribution of ABO blood groups across the world. In the United States, approximately 44% of the population has type O, 42% has type A, 10% has type B, and 4% has type AB blood [105].

Individuals develop antibodies against the ABO antigen(s) not present on their own RBCs. This occurs in the first years of life, even without exposure to blood transfusions, probably in response to exposure to antigens from bacteria, viruses or plants that are structurally very similar to the ABO antigens. Thus, those with type A blood develop anti-B antibodies (IgM type), those with type B blood develop anti-A (IgM type), those with type O blood develop both anti-A and anti-B (IgM and IgG types), and those with type AB blood develop no anti-ABO antibodies (see Table 11.2). IgG type anti-A and anti-B antibodies in type O mothers can cross the placenta and cause hemolysis in children with A or B antigens on their RBCs.

# Rh blood group system

The Rh blood group system is second in importance after the ABO group. A RBC antigen in the Rhesus macaque monkey, designated as "Rh factor," was reported by Drs Karl Landsteiner and Alexander Wiener in 1940 after finding that the serum of rabbits immunized with RBCs from this monkey agglutinated about 85% of human RBCs. A serologically similar antigen was also found in humans and retained the name "Rh factor." Two sets of nomenclatures have been used to describe the human Rh blood group system but the CDE nomenclature of the Fisher-Race system is most commonly used today. Although 50 antigens have been discovered in this group, the five most important ones are C, c, D, E, and e. There is no d antigen. These antigens are encoded by two adjacent gene loci, one for D and the other for C, c, E, and e, on chromosome 1. Of these five antigens, D is the most immunogenic and the Rh status of an individual is based

solely on its presence or absence. Inheritance of one D allele results in the production of the D antigen. The term "Rh positive" refers to the presence of the D antigen on the surface of RBCs whereas "Rh negative" indicates its absence. Approximately 85% of the United States population is Rh positive.

In contrast to the ABO blood group system, anti-Rh antibodies only develop in Rh-negative individuals after exposure to Rh-positive blood by a blood transfusion or by placental exposure during pregnancy. Once anti-Rh antibodies have developed, repeat exposure to Rhpositive RBCs can result in hemolysis. Since anti-Rh antibodies are of the IgG class, they can cross the placenta. This can be of grave importance to sensitized Rh-negative mothers carrying a Rh-positive child. These mothers may have been sensitized by the feto-maternal transfer of Rhpositive RBCs during a previous pregnancy with a Rhpositive child. Transplacental transfer of the sensitized mother's IgG anti-Rh antibodies to her second Rh-positive child can lead to hemolytic disease of the newborn (erythroblastosis fetalis) as the unborn child's Rh-positive RBCs are hemolyzed.

# Transfusion compatibility between recipients and donors

The presence of RBC surface antigens and circulating plasma antibodies to these antigens mandates immunological compatibility between recipients and donors of blood products. Since whole blood (WB) contains both ABO antigens and antibodies, it can be transfused only to ABO-identical recipients. Packed RBCs (PRBCs) contain RBC surface antigens but minimal amounts of antibodycontaining plasma so donors and recipients do not have to be ABO identical. However, patients can only receive PRBCs whose ABO surface antigens will not react with the patient's circulating anti-ABO antibodies. Type A patients with their anti-B antibodies can receive type A or type O PRBCs. Type B patients with their anti-A antibodies can receive type B or type O PRBCs. Type O patients with their anti-A and anti-B antibodies can receive only type O PRBCs. Finally, type AB patients with no anti-ABO antibodies can receive type AB, A, B or O PRBCs (Table 11.3). Therefore, when transfusing PRBCs, type O individuals are universal donors whereas type AB patients are universal recipients.

Conversely, plasma-containing products (including fresh frozen plasma and platelets) contain anti-ABO antibodies so patients can only receive plasma-containing products whose anti-ABO antibodies will not react with the patient's ABO surface antigens. Type A patients can receive type A or type AB plasma-containing products. Type B patients can receive type B or type AB plasmacontaining products. Type O patients can receive type O, A, B or AB plasma-containing products. Finally, type AB

#### Table 11.3 ABO compatibility

	Recipient ABO type				
	A	В	0	AB	
Compatible donor RBCs (contain antigens)	A O	B O	0	A B O AB	
Compatible donor plasma -containing products (contain antibodies)	A AB	B AB	O A B AB	AB	

patients can receive only type AB plasma-containing products (see Table 11.3). Therefore, when transfusing plasma-containing products, type AB individuals are universal donors whereas type O patients are universal recipients.

Rh factor status must also be considered when transfusing blood products. Rh-positive individuals may receive PRBCs from either Rh-positive or Rh-negative donors and plasma-containing products from donors without anti-Rh antibodies (either Rh-positive or previously untransfused Rh-negative donors).

Rh-negative individuals preferentially should receive Rh-negative PRBCs since exposure to Rh-positive RBCs invokes the production of anti-Rh antibodies in 30-80% of transfusion recipients. This is especially true if these recipients can be expected to receive further transfusions at future dates or if they are females who may bear children in the future. Although platelets contain ABO antigens, they do not contain Rh antigens. However, RBCs contaminate all platelet preparations to some extent. Thus, Rh-negative patients should preferentially receive Rh-negative platelets. If transfusion of Rh-positive platelets to Rh-negative recipients is necessary, Rho(D) immune globulin can be given within 72h to prevent the development of anti-Rh antibodies that may be induced by contaminating RBCs. Since fresh frozen plasma is devoid of Rh antigens, Rh-negative individuals can receive plasma from either Rh-positive or Rh-negative donors.

# Available blood products Collection techniques

A variety of blood products are available for transfusion and can be collected via two processes [106–108]. Whole blood can be collected from a single donor as a 450– 500 mL aliquot. While being collected, the blood is mixed with 70 mL of an anticoagulant/preservative solution. Basic "CPD" solutions contain citrate for anticoagulation, phosphate to buffer the acidosis that develops during storage, and dextrose to serve as a source of energy for the RBCs. These CPD anticoagulant/preservative solutions allow RBC-containing products to be stored for 21 days when kept at 1–6°C. The addition of adenine to the solution (CPDA-1) supports the synthesis of ATP by the RBCs and prolongs the shelf-life to 35 days. Newer adenine-saline additive solutions, such AS-1 (Adsol), AS-3 (Nutricel), and AS-5 (Optisol), add various additional amounts of phosphate, dextrose, adenine, mannitol, and saline and further extend the shelf-life to 42 days [107–109].

Most units of WB are subsequently separated into various components. This practice allows several patients to benefit from one blood donation, optimal storage of the different components, and focused administration of specifically indicated components [106]. Centrifugation of one unit of WB ultimately can provide one unit each of PRBCs, plasma, and platelets. In the majority of centers in North America, a unit of WB is separated initially into PRBCs and platelet-rich plasma. The platelet-rich plasma is then further separated into plasma and platelets. Cryoprecipitate can subsequently be obtained from plasma. Alternatively, individual components can be specifically collected from a donor by apheresis. In this process, blood from a donor is drawn into an external circuit, a specific component is separated by filtration or by centrifugation based on its specific gravity, and the remaining components are returned to the donor [106,107]. This process can be used to collect RBCs, platelets, plasma or granulocytes. Its use can minimize donor exposures for blood product recipients by providing larger quantities of a desired component from one donor than WB separation techniques can provide [107].

# Whole blood

Products containing red blood cells include WB and PRBCs. Whole blood is obtained from donors with a hematocrit of at least 38% [108] and is used not only to support hemoglobin levels but also to provide coagulation factors [110]. The ability of WB to raise hemoglobin levels, however, is limited by the hemoglobin level of the donor. Its use may be advantageous in neonatal exchange transfusions and in controlling bleeding after complex cardiac surgeries requiring cardiopulmonary bypass in children less than 2 years old and after massive blood loss and transfusion [107,111]. However, only relatively "fresh" WB (i.e. less than 24-48h old) is useful in correcting coagulopathic bleeding. During storage at 1-6°C, the activities of the temperature-sensitive labile coagulation factors, V and VIII, progressively diminish in WB [107]. Additionally, storage at this temperature rapidly and dramatically alters platelet survival. After 3h of storage at 4°C, platelet viability drops to 62% then to 12% after 24h and to 2% after 48h [112]. However, the logistics of timely acquiring, testing, and transporting WB so that it is available for use at many facilities within 24–48h of its collection pose major barriers to its regular availability. Because of these practical considerations as well as the previously mentioned benefits of separating WB into components, WB is rarely used today [106].

# Packed red blood cells

Packed red blood cells are the most common component used to raise hemoglobin levels and thus increase the oxygen-carrying capacity of blood [106,108,110]. They can be prepared by separation from WB or by apheresis. Like WB, PRBCs are stored at 1–6°C in an anticoagulant/ preservative solution. If CPDA-1 is the solution used, the hematocrit of the unit of PRBCs is 65–80%, the volume is approximately 250 mL, and the shelf-life is 35 days. If one of the additive solutions (AS-1, AS-3 or AS-5) is used, the volume of the unit is increased to approximately 350 mL, the hematocrit is decreased to 55–65%, and the shelf-life is extended to 42 days [106–108]. PRBCs can be further processed by freezing, washing, irradiation or leukocyte reduction.

Packed red blood cells with unique phenotypes or RBCs collected for autologous use that need to be stored for more than 42 days can be frozen for up to 10 years at -65°C or lower after adding glycerol as a cryoprotective agent. After thawing these frozen PRBCs for transfusion, the glycerol must be removed by washing the RBCs with progressively lower concentrations of sodium chloridecontaining solutions [106-108]. Washing RBC units also removes plasma proteins, inflammatory mediators such as cytokines, and other plasma contaminants. Washed RBCs are indicated to prevent severe recurrent allergic reactions caused by foreign plasma proteins, to remove excess potassium from older units of PRBCs or from those that have been irradiated, and to remove plasma IgA prior to transfusion to IgA-deficient patients who have developed anti-IgA antibodies. After washing, PRBC units must be used within 24 h if stored at 1-6°C or within 4h if stored at 20-24°C since the hermetic seal of the unit will have been broken [106–108].

Irradiation of PRBCs (or WB) with  $\gamma$ -irradiation using a cesium (<sup>137</sup>Cs) source or with x-rays using a linear accelerator is performed to inactivate viable lymphocytes, thus preventing transfusion-associated graft-versus-host disease. Irradiation is indicated when PRBC (or WB) recipients are immunocompromised, are first- or seconddegree blood relatives of the donor or are neonates. The shelf-life of PRBCs after irradiation is reduced to 28 days if the anticoagulant/preservative-dictated shelf-life still exceeds 28 days at the time of irradiation. Potassium and free hemoglobin leak from the RBCs into plasma after irradiation so washing of irradiated PRBCs may be considered when there is an extended length of time between irradiation and transfusion [106–108,113].

Leukocyte reduction of PRBCs is performed to decrease the incidence of febrile non-hemolytic transfusion reactions, to decrease the incidence of alloimmunization of recipients to HLA antigens, to reduce the risk of transmission of cytomegalovirus (CMV) and other infectious diseases transmitted by white blood cells (WBCs), and possibly to reduce the effects of transfusion-related immunomodulation [106-108,114]. Leukocyte reduction can be performed before storage at the time of collection of the blood or after storage in the laboratory or at the bedside. Post-storage leukocyte reduction has been reported to cause unexpected severe hypotension in some recipients (especially those taking angiotensin-converting enzyme (ACE) inhibitors) due to bradykinin activation [108]. Additionally, inflammatory mediators released by leukocytes during storage are not removed by poststorage leukoreduction. Given these considerations, more than 80% of RBCs transfused in the United States are leukoreduced before storage, with leukoreduction filters removing more than 99% of leukocytes [106,107].

### Plasma

Plasma is prepared by separation from the platelet-rich plasma component of WB or by apheresis. The volume of a unit of plasma derived from WB is 170–250 mL whereas a unit obtained by apheresis measures up to 500 mL. To be labeled as "fresh frozen plasma" (FFP), the plasma has to be stored at -18°C or colder within 8h of collection. This prevents the inactivation of the temperature-sensitive "labile" coagulation factors, V and VIII, and allows a shelf-life of 1 year [106,108]. If not frozen within 8h of collection, the activity of factors V and VIII will diminish but the plasma can still be frozen at or below -18°C within 24 h, labeled "plasma frozen within 24 hours", and stored for up to 1 year [107,108]. By definition, each mL of FFP contains one international unit (IU) of each coagulation factor [108]. FFP also contains 2-4mg of fibrinogen per mL [115]. No cryoprotectant is included in the unit and, therefore, the majority of leukocytes are killed or rendered non-functional. As a consequence, irradiation to prevent transfusion-associated graft-versus-host reaction and leukocyte reduction to prevent CMV infection are not necessary for FFP [107]. Prior to administration, FFP is thawed in a waterbath at 30-37°C for approximately 20-30 min. The unit should then be infused immediately or it may be stored at 1-6°C and transfused within 24h [107,108]. If it is not used within this 24-h window, it can be stored for an additional 4 days at 1–6°C but it must be relabeled as "thawed plasma" and it will have diminished, although still hemostatic, levels of factors V and VIII [106,108].

## Cryoprecipitate

Cryoprecipitated antihemophilic factor, or "cryoprecipitate," is the cold-insoluble white precipitate that forms when a unit of FFP is thawed only to 1–6°C. Once prepared from FFP, cryoprecipitate must be refrozen at –18°C or colder within 1 h and then has a shelf-life of 1 year. Each unit of cryoprecipitate contains concentrated amounts of fibrinogen (150–250 mg), factor VIII (80–150 IU), vWF (40–70% of original plasma concentration), factor XIII (30% of original plasma concentration), and fibronectin (30–60 mg) in approximately 5–15 mL of plasma. The plasma remaining after extraction of cryoprecipitate is relabeled as "cryoprecipitate-reduced plasma." Since this plasma is deficient in the abovementioned coagulation factors, it should not be used as a substitute for FFP.

Once thawed in preparation for transfusion, cryoprecipitate must be administered within 6h to prevent loss of factor VIII activity. If several cryoprecipitate units are pooled, transfusion must take place within 4h to minimize risks from potential contamination. Since cryoprecipitate is stored, like FFP, at temperatures below -18°C, irradiation and/or leukocyte reduction are not necessary before cryoprecipitate transfusions. Additionally, since cryoprecipitate contains no RBCs and only small amounts of plasma (thus, minimal amounts of anti-ABO antibodies), ABO and Rh compatibility are not required before its use in adults [106-108,115,116]. However, the small amount of plasma in cryoprecipitate units may be significant relative to the blood volume of infants and young children, so pediatric centers often administer cryoprecipitate whose plasma is ABO compatible with the recipient.

# Platelets

Platelets are prepared by separation from the platelet-rich plasma component or the buffy coat layer of WB or by apheresis. Platelet units prepared from WB are termed "random donor platelets" and contain a minimum of  $5 \times 10^{10}$  platelets in 50–70 mL of plasma. Platelet units obtained by apheresis are designated as "single donor platelets" and contain at least  $3.5 \times 10^{11}$  platelets in 200– 400 mL of plasma. One single donor apheresis platelet unit is equivalent to 6-8 units of random donor platelets. Apheresis platelet units have become the primary source of platelets for transfusion in the United States since their use minimizes donor exposures to recipients. Platelet units are stored at 20-24°C with continuous gentle agitation to prevent aggregation. Because of the risk of bacterial contamination at this temperature, platelet units in the United States currently have a shelf-life of only 5 days [106,107]. Since platelet units are not subjected to the extremely cold temperatures at which plasma and cryoprecipitate are stored, they (like WB and PRBCs) must be

irradiated to kill viable lymphocytes in clinical situations where transfusion-associated graft-versus-host disease is a concern and must be leukocyte reduced when transmission of CMV is a risk [106,108].

In adult centers, type compatibility may not be required between recipients and donors of platelet units for smallvolume transfusions. However, platelets express multiple surface antigens, including ABO and platelet-specific antigens, so ABO-identical platelets may be needed if survival of ABO-incompatible platelets is decreased. With the significant amount of plasma contained in platelet units, though, compatibility between donor plasma and recipient ABO type is generally recommended in infants and children. Additionally, since a small amount of RBCs remain in both random and single donor platelets, Rhnegative patients preferentially should be transfused with platelets from Rh-negative donors to prevent Rh alloimmunization, especially in females or in patients who may receive future transfusions [106,107,117].

## Logistics of transfusion

# Typing, screening, and cross-matching

Preparation for transfusion begins with determining the blood type and Rh status of the intended recipient and the prospective donor unit. ABO group is defined using forward and reverse typing. Forward typing tests patient RBCs against reagents containing anti-A and anti-B antibodies while reverse typing tests patient plasma against reagent cells that carry A or B surface antigens. Therefore, blood group is defined by identifying the ABO antigen(s) and anti-ABO antibody(ies) present. Neonates typically do not develop anti-ABO antibodies until 4–6 months of age; therefore, forward tying is primarily utilized to determine their blood type. Rh status is defined by testing RBCs for the presence of the D antigen using anti-D containing reagent [106].

The plasma of the intended recipient is then screened for the presence of unexpected antibodies to antigens of any of the other blood group systems that can be present on RBC surfaces. This is accomplished by incubating the recipient's plasma with screening RBC panels composed of three or four group O RBCs selected in such a way that most common non-ABO antigens capable of inducing the production of significant antibodies that could cause hemolysis are represented on at least one screening cell. Antihuman globulin is then added to agglutinate any RBCs to which an antibody has attached (indirect Coombs test). If an antibody is detected, the screen is considered positive and further investigation must be undertaken to identify the specific antibody present [106]. Antibody screening must be repeated if RBCs are ordered and 3 days have elapsed since the last antibody screen. An exception is in neonates where, due to the immaturity of their immune systems, an initial negative screen does not have to be repeated during the same hospitalization until after 4 months of age [107].

Cross-matching of recipient plasma and donor RBCs is the next step prior to PRBC transfusions. If the recipient has a negative antibody screen, only ABO compatibility between the recipient and the donor RBCs must be verified. This can be done with an immediate spin crossmatch to provide serological verification or with an electronic cross-match that uses a series of computer algorithms to select a suitable PRBC unit that is in stock in the blood bank. Either of these cross-matching techniques can be used to have PRBCs ready for transfusion in 5-10 min for recipients with negative antibody screens. However, if the recipient has a positive antibody screen, a more detailed serological cross-match, called an antihuman globulin (AHG) or "full Coombs" cross-match, must be performed to verify compatibility of the recipient's plasma against clinically significant non-ABO antigens that may be present on donor RBC surfaces. This process requires up to 45 min to perform, although identifying the recipient antibody and finding compatible donor RBCs may take considerably longer [106].

In contrast to PRBCs, cross-matching is not necessary prior to plasma, cryoprecipitate or platelet transfusions. For each of these products, units whose plasma is ABO compatible with the recipient's RBCs are administered. FFP and cryoprecipitate can be thawed and available for transfusion in approximately 20–30 min. Since platelets are stored at room temperature, they can be immediately available for transfusion when required.

## Administration of blood products

The process of transfusing blood products begins with the proper identification of the recipient, verification that the product to be transfused has been assigned to that recipient, and confirmation that the ABO type and Rh status of the blood product are appropriate for that recipient.

Red blood cell products transfused intraoperatively may need to be warmed since they will have been kept at 1-6°C in the blood bank or stored on ice in the operating room. This may be accomplished by warming the WB or PRBC unit in a temperature-controlled water bath or by warming the RBCs as they flow through the IV tubing by using circulating water, forced air or a heat exchanger. Warming these products prior to their administration attenuates not only the development of hypothermia but also any vasoconstriction and/or coagulopathy that may accompany hypothermia [118]. Care must be taken, however, to prevent excessive warming as this can lead to hemolysis [108]. FFP and cryoprecipitate will be warmed in the blood bank prior to their release and platelets are stored at room temperature so further warming is not usually necessary prior to their administration.

If PRBCs need to be diluted to expedite their flow through IV tubing, 0.9% NaCl (normal saline) should be used. Calcium-containing solutions such as Ringer's lactate must be avoided for this purpose because calcium in excess of the chelating ability of the citrate anticoagulant in the PRBC unit will cause the formation of small clots. Hypotonic solutions must also be avoided because they may cause hemolysis of the RBCs. No medicines or other IV solutions may be infused through the same IV tubing being used for any blood products [106,108].

Screening filters with pore sizes of  $170-200\,\mu$ m should be used in the transfusion of WB, PRBCs, FFP, cryoprecipitate, and platelets to remove clots and aggregates. These filters are incorporated into all standard blood administration sets. There are no firm indications for using microaggregate filters (pore size  $20-40\,\mu$ m) although these are commonly used when reinfusing blood processed through a cell saver device. Microaggregate filters will trap platelets so should definitely not be used when transfusing platelet units. Finally, once any blood product is accessed for transfusion, its administration should be completed within 4h to minimize the risk of bacterial contamination [106,108].

# Indications/triggers for blood product transfusion

Blood products are used for the correction of anemia to improve oxygen-carrying capacity and for the treatment of coagulopathies to attenuate bleeding. The administration of blood products, however, is accompanied by infectious, immunological, and non-immunological risks that must be weighed against the anticipated benefits of their use. Therefore, insightful thought processes should guide any decision to transfuse these products [110].

#### Packed red blood cells

There is no single minimum hemoglobin level that serves as a transfusion trigger for all patients in all clinical scenarios [106,110,115,119]. To complicate this problem for pediatric caretakers, there is a dearth of randomized controlled trials on RBC transfusion thresholds for neonates, infants, and children [107]. Surveys of pediatric intensive care units (PICUs) have shown significant variations in hemoglobin levels that trigger RBC transfusion [120] as well as a variety of clinical factors other than hemoglobin level than are used to help make this decision [121]. The "10/30" rule for transfusion that was introduced in the 1940s has fallen into disfavor based on risk: benefit analyses [110], and hemoglobin levels are currently allowed to fall to levels much lower than 10g/dL before PRBCs are administered in many clinical situations. Physiological signs such as tachycardia, hypotension and, if available, low mixed venous oxygen saturations or increased oxygen extractions ratios are useful in providing objective evidence of the need to correct a given level of anemia [106,110].

In addressing specific hemoglobin levels, data from adults have shown that at a hemoglobin level less than 6g/dL, coronary artery blood flow reserve may be exceeded and oxygen extraction may be compromised [110]. Studies in both adults and children in intensive care units using a restrictive transfusion strategy of only administering PRBCs when hemoglobin levels drop below 7g/dL have shown reductions in number of patients transfused and units given with unchanged or improved morbidity and mortality rates when compared to more liberal strategies of transfusing at hemoglobin levels of 9.5 or 10g/dL [122,123]. With these data in mind, recommendations to transfuse PRBCs for hemoglobin levels less than 7g/dL seem appropriate. Transfusion for levels greater than 10g/dL are probably unnecessary in the absence of ongoing blood loss or complicated clinical scenarios. Transfusions for hemoglobin levels between 7 and 10g/dL should be triggered by objective physiological signs of inadequate oxygen delivery to tissues [124]. These guidelines require modification for premature infants and for children with cyanotic congenital heart disease, congestive heart failure or significant co-morbidities. Indeed, although not without controversy [125], the use of a restrictive transfusion threshold in premature infants may be associated with an increase in neurological morbidities that have been postulated to result from decreased oxygen delivery to the brain [126]. Practice parameters for these infants and children are even less evidence based than those previously described.

It typically has been taught that transfusing 10–15mL of PRBCs per kg of bodyweight will raise the hemoglobin level by approximately 3g/dL or the hematocrit by 10% [106,107]. Formulas have been developed to add more precision to determinations of volume of PRBCs to be transfused. One such formula is:

Volume of PRBCs to be transfused = total blood volume × (desired hemoglobin – actual hemoglobin)/ hemoglobin of PRBC unit

Assumptions of total blood volume (TBV) are based on the age of the recipient: 90–100 mL/kg for preterm neonates, 80–90 mL/kg for full-term neonates, 80 mL/kg from 6 months to 2 years of age, and 70 mL/kg for children older than 2 years [127]. The hemoglobin of the PRBC unit depends on the anticoagulant/preservative solution used to store the unit [107]. The actual/predicted hemoglobin rise using this formula is 0.61–0.85 and is influenced by the TBV and PRBC hemoglobin values used. A new formula developed from a regression analysis of volume of PRBCs transfused versus bodyweight results in an actual/predicted hemoglobin rise of 0.95 that is valid across different age groups [128]:

Volume of PRBCs to be transfused

=  $4.8 \times \text{weight (kg)} \times \text{desired rise in hemoglobin (g/dL)}$ or =  $1.6 \times \text{weight (kg)} \times \text{desired rise in hematocrit (%)}$ 

Use of this formula may minimize the need for repeat transfusions.

# Plasma

Generally agreed upon indications for transfusing FFP include the treatment of active microvascular bleeding associated with an acquired coagulopathy (DIC, liver disease, massive transfusion, cardiac surgery or liver transplantation) in the presence of an INR >2.0 or an aPTT >1.5 times normal or when an INR and an aPTT cannot be obtained in a timely manner; replacement of rare congenital coagulation factor deficiencies (II, V, X, XI, XIII, protein C) when specific concentrates are not available; emergency reversal of the anticoagulant effects of warfarin; replacement of AT deficiency in patients with heparin resistance when AT concentrate is not available; and replacement of C1 esterase inhibitor in patients with hereditary angioedema [106,107,115,124,129]. FFP is not indicated for volume expansion, to augment albumin concentration or when specific factor concentrates are available to correct documented deficiencies [106,107,115,129]. "Cryoprecipitate-reduced plasma" is sometimes used in the management of thrombotic thrombocytopenic purpura (TTP), a condition where the breakdown of large multimers of vWF is inhibited, thus leading to microvascular thromboses and tissue infarctions. Transfusion of this plasma product, which is devoid of vWF, replenishes the deficient enzyme (ADAMTS13) responsible for cleaving vWF and ameliorates the complications of TTP [107,108,130].

Ten to 15 mL of FFP per kg of bodyweight is the conventional volume transfused for the above indications. This amount is reported to increase plasma levels of coagulation factors by 25–30% [106,115] and thus to exceed the factor level thresholds required for hemostasis (15% for factor V and 30% for all other factors) [131].

#### Cryoprecipitate

Transfusion of cryoprecipitate is indicated in the presence of microvascular bleeding when the fibrinogen level is <80–100 mg/dL or when the fibrinogen level cannot be measured in a timely fashion and in actively bleeding patients with congenital fibrinogen deficiencies. Cryoprecipitate is rarely indicated when the fibrinogen level exceeds 150 mg/dL but its use may be prudent with fibrinogen levels between 100 and 150 mg/dL when there is a risk of bleeding into a confined space such as the brain or the eye. Cryoprecipitate is not indicated as a first-line treatment for hemophilia A or B, factor XIII deficiency or vWD but may be used when purified or recombinant factor concentrates are not available or when vWD is unresponsive to the administration of DDAVP [106,107,115,124]. In small children, 1 unit of cryoprecipitate per 5 kg of bodyweight is estimated to raise the fibrinogen level by 100 mg/dL [107]. In older patients, one unit per 10 kg should increase the fibrinogen level by approximately 50–70 mg/dL [106].

## Platelets

Platelet transfusions may be required because of low platelet counts or because of abnormal platelet function regardless of the number of platelets present. Controlled trials are lacking, and only general guidelines are available to help guide platelet replacement therapy. In the face of active bleeding in the perioperative period, it is prudent to maintain platelet counts above 50,000/µL. When microvascular bleeding is present, this level should probably be raised to 100,000/µL. When active bleeding occurs in the setting of platelet dysfunction (uremia, thrombasthenias or ingestion of antiplatelet drugs), platelet transfusion will be required regardless of platelet counts. Even in the absence of bleeding, platelets are often transfused prophylactically when counts fall below  $50,000/\mu$ L in the setting of sepsis, antibiotic use or other coagulopathies or when counts fall below  $10,000/\mu$ L in patients who do not have these additional risk factors. Platelet counts greater than  $30,000/\mu$ L are felt to be a safe level for most neonatal ICU patients if they have no other risk factors or previous intraventricular hemorrhage.

Prior to invasive procedures such as surgery, central line placement, thoracentesis, endoscopy or lumbar puncture, platelet counts should be raised to greater than  $50,000/\mu$ L. For neurosurgical or ophthalmological procedures or if bleeding in the central nervous system has occurred, platelet counts above  $100,000/\mu$ L are preferred. Platelet transfusions are not typically indicated prior to bone marrow biopsies or in scenarios of increased platelet destruction (idiopathic thrombocytopenic purpura). Platelet administration will increase the risk of thrombosis in patients with TTP and heparin-induced thrombocytopenia [106,107,115,124,129].

When transfusing random donor platelets, 5–10 mL of platelets per kg of bodyweight in neonates and 0.1–0.2 units/kg in older infants and children should result in a platelet increment of  $50,000-100,000/\mu$ L. When single donor apheresis platelet units are being transfused, a general rule is to administer 10 mL/kg to neonates, <sup>1</sup>/<sub>4</sub> unit to children <15 kg, <sup>1</sup>/<sub>2</sub> unit to children between 15 and 30 kg, and a whole unit to children >30 kg. Response to these transfused volumes varies among patients and according

to the platelet content of the unit transfused. Failure to achieve expected platelet increments after transfusion should prompt a search for causes of platelet refractoriness and may require the use of phenotypically matched platelets for future transfusions [107].

### Massive transfusion

Trauma-induced injuries are the most common scenarios that result in massive hemorrhage. Indeed, hemorrhage accounts for 30-40% of all trauma-related deaths. One to three percent of civilian trauma patients will require massive transfusion [132]. Massive transfusion is defined in children as the transfusion of one blood volume of PRBCs in a 24-h period [133]. However, more dynamic definitions such as the transfusion of 50% of blood volume in a 3h period may be more relevant [134]. Since the use of PRBCs with minimum plasma replaced the use of WB in the late 1980s and early 1990s, dilution of coagulation factors with massive transfusion using PRBCs has become a significant problem [134,135]. The "lethal triad" of coagulopathy, hypothermia, and acidosis may accompany massive transfusion, with each component of this triad then exacerbating the other two components and exsanguination and death often resulting [132,136]. The aim of transfusion therapy in this situation is to restore blood volume, maintain tissue oxygenation, and achieve hemostasis to prevent or interrupt the development of this lethal triad [118].

Military and civilian adult studies have shown improved survival after transfusing FFP, platelets, and cryoprecipitate along with PRBCs during massive transfusion [132,137]. Some argue that blood component therapy during massive transfusion should be guided by laboratory tests; however, this is practically difficult because of slow turnaround times for these tests [138]. Therefore, massive transfusion protocols have been developed as part of "damage control resuscitation" using predetermined ratios of blood products to rapidly treat coagulopathies, decrease crystalloid infusions, and minimize delays in having blood products ready for use [133]. The goals of massive transfusion protocols are to provide plasma support to keep coagulation factor levels at least 40% of normal while not compromising delivery of RBCs and to transfuse enough platelets to maintain platelet counts well above 50,000/µL [139]. Several massive transfusion protocols advocate using a 1:1:1 ratio of PRBCs, FFP, and random donor platelets after identifying massive hemorrhage [139,140]. If using apheresis platelets, one unit is given after every 10-12 units each of PRBCs and FFP, as is 10 units of cryoprecipitate. Laboratory tests can later be used to refine therapy after bleeding has been controlled. Use of such a massive transfusion protocol has been shown to reduce coagulopathy development and mortality in adult civilian trauma patients [141].

# Potential adverse effects of transfusion

The transfusion of blood products is not without risks. Transmission of infectious diseases as well as non-infectious immune and non-immune mediated hazards of transfusion are sources of ongoing concern and investigation (Box 11.2). Advances in blood donor selection, infectious disease testing of donated blood products, use of leukoreduction filters, and irradiation of blood components in defined situations have made today's blood supply safer than ever [107,142,143]. Nevertheless, vigilance must be maintained to identify known risks and to anticipate emerging risks in today's blood supply.

#### Transmission of infectious diseases

While the public may be unaware of many of the risks of transfusion, the risk of contracting an infectious disease from a blood product transfusion has not escaped its attention. Potentially transmissible agents include viruses, bacteria, parasites, and prions (Box 11.3). Currently, donated blood products are regularly tested for human immunodeficiency virus (HIV), human T-lymphotrophic virus (HTLV), hepatitis B virus (HBV), hepatitis C virus (HCV), and *Treponema pallidum* [144] (Table 11.4).

Contraction of HIV or hepatitis is the major concern of patients (or parents of patients) when receiving blood component transfusions. Disease transmission by transfusions occurs primarily in the window period of a disease, i.e. the time after a blood donor has become infectious but before any donor screening tests are positive [114]. The advent of nucleic acid testing (NAT) in the last decade has shortened window periods and **Box 11.3** Infectious agents/diseases potentially transmissible by blood product transfusion

#### Viral

- Toxoplasmosis (Toxoplasma gondii)
- Leishmaniasis (Leishmania sp)

#### Prions

• Variant Creutzfeldt–Jakob disease

allowed earlier detection of several viruses than could be accomplished with serological tests [145]. As a result, transmission risks of these viruses have been decreased approximately 10,000-fold [146] and are so low that mathematical models are currently needed to estimate risks [114,147] (Table 11.5).

The first descriptions of transfusion-transmitted HIV infections occurred in late 1982 and early 1983. HIV antibody testing was begun in March 1985 with a resultant window period for HIV-1 of 22 days. HIV-2 testing of donor blood was implemented in 1992. Testing for the HIV p24 antigen was initiated in late 1995 and decreased the window period to 16 days. Currently, NAT for HIV RNA is performed on minipools of 16–24 donated units and has further reduced the window period to 11 days [114,148]. The current estimated residual risk for transfusion-associated transmission of HIV is 1 in 2.3 million [146].

The use of NAT has had an even more dramatic effect on decreasing transfusion-associated transmission of 
 Table 11.4 Infectious disease tests performed on donated blood components

Infectious agent	Tests
HIV	HIV nucleic acid amplification test Anti-HIV-1 Anti-HIV-2
HTLV	Anti HTLV-I/II
Hepatitis B virus	HBsAg Anti-HBc
Hepatitis C virus	HCV nucleic acid amplification test Anti-HCV
Treponema pallidum	Treponemal antibody test

HCV. A serological test for HCV antibody was developed in 1990 and thus identified the cause of most cases of non-A, non-B hepatitis [147]. This significantly reduced the incidence of post-transfusion HCV infection but left a window period of approximately 70 days. Institution of NAT for HCV RNA in 1999 decreased this window period to 8–10 days and reduced the residual risk of HCV infection to 1 in 1.8 million [114,146,148].

The risk for post-transfusion HBV infection is approximately 1 in 350,000 [142,146]. HBsAg and anti-HBc testing are currently performed on all donated blood in the United States. NAT testing for HBV DNA is not currently routinely performed in the United States since its use would reduce the window period by just 2–7 days compared to the most sensitive HBsAg screening tests [114,142].

West Nile virus first appeared in the US in 1999 with the peak number of cases reported in 2003. It was subsequently recognized that this virus could be transmitted through transfusion of leukoreduced and non-leukoreduced PRBCs or platelets and through transfusion

of FFP [149]. NAT methodology was quickly modified to test for this agent. NAT has been used in at-risk geographical regions since 2003 with subsequent dramatic reduction of transfusion-associated infection rates [147,150].

Hepatitis A virus is rarely transmitted by blood products since individuals are usually symptomatic when infected and thus excluded from donation, no chronic carrier state exists, and many people have developed antibodies either naturally from previous infection or by vaccination [106,114].

Cytomegalovirus is harbored in white blood cells and can be transmitted by transfusion of cellular products (WB, PRBCs, and platelets) that may contain functional white blood cells. Clinical disease after transmission is usually seen only in immunocompromised patients. The two approaches used in the United States to reduce the risk of CMV transmission in at-risk patients are the use of leukoreduced cellular blood products (termed "CMV safe") and the use of CMV-seronegative cellular blood products [106,114].

Donated blood products are routinely screened by serological tests for infection with *Treponema pallidum*, the causative agent of syphilis. In addition, this spirochete poorly survives storage in citrated blood at 4°C for longer than 72h so its transmission by transfusion is very infrequent [106,147].

A major concern is the transfusion-associated transmission of other infectious agents for which no screening tests are currently available. This includes human herpesvirus-8 (a causative agent of Kaposi sarcoma) and most of the parasitic diseases (malaria, babesiosis, Chagas disease, toxoplasmosis, and leishmaniasis) [115,142,143,151]. Fortunately, transmission of parasitic diseases is rare in developed countries. However, potential transmission of hepatitis G virus, other as yet unknown viruses, and the agent causing variant Creutzfeldt–Jakob disease is a significant concern [119,137].

Variant Creutzfeldt-Jakob disease is the human equivalent of bovine spongiform encephalopathy ("mad cow disease"). It is caused by a prion, an infectious agent composed mainly of protein that causes native proteins to refold and produce the clinical disease. The confirmed cases of transfusion-associated transmission have become evident 6-8 years after transfusion, with the donors not developing clinically apparent disease until 17-42 months after donation [142]. This long asymptomatic carrier state is of great concern since screening tests are not available [143]. Currently, potential blood donors who visited European countries affected by bovine spongiform encephalopathy between 1980 and 1996 are barred from donating [147]. New filtration processes to remove prions from donated blood products are being developed and offer hope for the future.

The risks of transfusion-associated transmission of infectious agents are not static because new agents continue to emerge and old agents change their properties and epidemiological patterns. New pathogen reduction technologies effective against most viruses, bacteria, and parasites are being developed to improve future safety, as are prion retention filters [147,151]. Nevertheless, currently used screening methods are effective enough that non-infectious hazards of transfusion have now emerged as the leading complication of transfusion therapy [114,146].

# Immune-mediated hazards of transfusion

Immune-mediated transfusion risks include hemolytic transfusion reactions, febrile non-hemolytic transfusion reactions, allergic reactions, transfusion-related acute lung injury, transfusion-associated graft-versus-host disease, post-transfusion purpura, transfusion-related immunomodulation, and alloimmunization [146].

#### Hemolytic transfusion reactions

Immune-mediated hemolytic transfusion reactions (HTRs) are caused by the transfusion of RBCs to patients with pre-existing antibodies to antigens on those RBCs. The most serious HTRs are caused by the transfusion of ABO-incompatible RBCs and result in acute intravascular hemolysis. Clerical error is the most common cause of this mishap and, therefore, most are preventable. Awake patients may manifest chills, fever, nausea, anxiety, and chest and flank pain but these may be masked in anesthetized patients. Tachycardia, hypotension, microv-ascular bleeding, and hemoglobinuria may be seen but need to be recognized as resulting from a HTR as opposed to myriad other potential causes in anesthetized patients.

Once an acute immune-mediated HTR is suspected, the transfusion should be immediately stopped, the unit of blood should be returned to the blood bank for investigation, and steps should be taken to prevent or ameliorate acute renal failure and coagulopathy.

Delayed immune-mediated HTRs result from the transfusion of RBCs containing a non-ABO antigen to which the recipient has developed an antibody because of a previous transfusion or pregnancy. The antibody is usually present in such low levels that it is undetected during the screening procedure. However, a rapid anamnestic response follows the transfusion. A delayed HTR presents 3–10 days after transfusion as a falling hemoglobin level. No treatment is usually indicated but recognition of the problem, identification of the recipient's antibody, and future transfusion of blood negative for the corresponding antigen are necessary [106,107,115,146,147].

## Febrile non-hemolytic transfusion reactions

A febrile non-hemolytic transfusion reaction (FNHTR) is defined as a 1°C increase in body temperature into the febrile range during or soon after a transfusion. These reactions are typically caused by leukocyte-derived cytokines that have been released into the blood product during storage or by the reaction of recipient antileukocyte antibodies (developed after previous transfusions or pregnancies) against donor leukocytes. They are most commonly seen in association with platelet transfusions but can also accompany RBC or plasma administration. FNHTR is a diagnosis of exclusion after other transfusionassociated causes of fever, such as acute HTRs, septic transfusion reactions or transfusion-related acute lung injury, have been ruled out. The use of prestorage leukocyte reduction has significantly reduced the occurrence of these reactions [106,107,146,147].

# Allergic reactions

Allergic reactions are the most common of all acute transfusion reactions and result from the reaction of an antibody in the recipient to a soluble plasma antigen in the donor. Leukocyte reduction of cellular blood products, therefore, does not decrease the occurrence of these reactions. However, pretransfusion washing of PRBCs or platelets removes plasma and associated antigens and thus does decrease the occurrence of allergic reactions. Treatment of allergic reactions involves stopping the transfusion and administering antihistamines. Some of these reactions are anaphylactic in nature and will require aggressive treatment, including steroids, and epinephrine. IgA deficiency of the recipient should be considered after a severe allergic transfusion reaction has occurred. IgA-deficient individuals can develop anti-IgA antibodies that react with donor IgA, resulting in an anaphylactic reaction. Use of IgA-deficient plasma or washed cellular products will be necessary for any future transfusions to recipients known to have IgA deficiency and anti-IgA antibodies [106,107,146].

#### Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI) has historically been a leading cause of transfusion-related deaths [146]. TRALI is defined as new acute lung injury occurring during or within 6h after a transfusion with a clear temporal relationship to the transfusion in patients with or without alternative risk factors for acute lung injury [152]. TRALI can occur after the administration of all types of blood components but is more likely after the transfusion of plasma-rich components such as FFP and apheresed platelets [153].

Two pathophysiological mechanisms have been proposed. In the "classic antibody-mediated" mechanism (approximately 85% of cases), donor antileukocyte antibodies react with recipient leukocytes, resulting in the release of inflammatory mediators that damage pulmonary alveolar epithelium and vascular endothelium leading to non-cardiogenic pulmonary edema. In approximately 15% of cases, no antibody can be detected. Systemic inflammatory conditions secondary to clinical scenarios such as major surgery, sepsis, trauma, aspiration or massive transfusion lead to activation of leukocytes and pulmonary endothelium with subsequent leukocyte sequestration in the lungs. "Bio-active factors" such as cytokines, interleukins or lipids in transfused products may then activate these sequestered leukocytes, leading to lung injury and non-cardiogenic pulmonary edema [106,153].

The clinical presentation of TRALI mirrors that of acute respiratory distress syndrome (ARDS). Treatment is primarily supportive with recovery usually occurring within 96h although the mortality rate is 5–10%. Diuresis does not improve symptoms and the role of steroids is unproven [106,115,153,154]. Plasma products from multiparous women have been implicated in the majority of cases of antibody-mediated TRALI because these donors may develop antileukocyte antibodies during pregnancy. Eliminating or minimizing the use of plasma products from these donors dramatically decreases the incidence of TRALI [107,153].

#### Transfusion-associated graft-versus-host disease

Transfusion-associated graft-versus-host disease (TA-GVHD) occurs when immunocompetent CD8+ lymphocytes in transfused cellular blood products (RBCs, platelets or granulocytes) engraft in a recipient, proliferate, and attack host tissues. This occurs when the recipient is immunocompromised and cannot eliminate the donor lymphocytes or when the recipient does not recognize the donor lymphocytes as foreign (biologically related donors or HLA-matched products) and thus does not eliminate them. Clinical manifestations include fever, rash, diarrhea, liver dysfunction, and pancytopenia and occur 1-6 weeks after transfusion. The diagnosis can be made by detecting donor DNA in a skin biopsy or in circulating lymphocytes taken from the recipient. Irradiating RBCs and platelets before their administration renders donor lymphocytes incapable of proliferating and thus eliminates the risk of the development of TA-GVHD. TA-GVHD is nearly uniformly fatal, with mortality rates approaching 90% [106,146,147].

#### Post-transfusion purpura

Post-transfusion purpura (PTP) is the development of severe thrombocytopenia after a transfusion in recipients who have developed antibodies against platelet-specific antigens as a result of previous transfusions or pregnancies. While PTP is a rare event, it can occur 5–10 days after the administration of RBCs, FFP or platelets. Both transfused and autologous platelets are destroyed in this process, thus severely decreasing the recipient's platelet count, even to below  $10,000/\mu$ L. Recovery is usually spontaneous although treatment with steroids and IV immune globulin is indicated, with plasmapheresis being a second-line intervention. Platelet transfusions are usually ineffective in raising the platelet count but, if felt necessary in the face of severe bleeding, may need to be administered in large doses since many of the transfused platelets also will be destroyed [106,146,155].

#### Transfusion-related immunomodulation

While the exact mechanism of transfusion-related immunomodulation (TRIM) has yet to be elucidated, modulation of the recipient's immune responses after transfusion may have both beneficial and harmful effects. Improved survival of transplanted kidneys has been documented in patients transfused before transplantation, as has survival of cardiac and liver transplant patients after pretransplant transfusion of donor-specific or HLA-DR shared RBCs. TRIM may also decrease the recurrence rate of Crohn disease and of miscarriages in women who share HLA antigens with their mates. Evidence linking increased incidences of postoperative infections and cancer recurrence with transfusions, however, is controversial and not definitely proven. Theories of the etiology of TRIM indict leukocytes as major participants so harmful effects of transfusion that are blamed on TRIM may be ameliorated by prestorage leukocyte reduction of blood products [119,146,156].

# Alloimmunization

Alloimmunization is the development of antibodies to minor RBC antigens or to platelet or leukocyte antigens after exposure by transfusion or pregnancy. Subsequent transfusion of blood products containing these antigens results in delayed HTRs or platelet refractoriness. Approximately two-thirds of clinically significant alloantibodies are directed toward Rh and Kell antigens on RBC surfaces. Up to 40% of children with sickle cell disease who are managed with chronic transfusion protocols develop alloantibodies. These children, therefore, should undergo extended RBC antigen phenotyping prior to the initiation of chronic transfusion therapy. Provision of PRBCs phenotypically matched for Rh and Kell antigens has been shown to decrease rates of alloimmunization from 3% per unit transfused to 0.5% per unit transfused [99]. Similarly, HLA-matched platelet units may be necessary for patients with platelet refractoriness and anti-HLA alloantibodies. These matched platelets, however, must be irradiated prior to transfusion to eliminate the risk of TA-GVHD due to the HLA similarity between donor and recipient [107,146,147].

# Non-immune mediated hazards of transfusion

Non-immune mediated hazards of transfusion include septic transfusion reactions, non-immune hemolysis, transfusion-associated circulatory overload, metabolic derangements, complications from red blood cell storage lesions, and mistransfusion [146].

# Septic transfusion reactions

Transfusion-associated bacterial sepsis is another potential cause of transfusion-related deaths. Platelet units are by far the most frequently contaminated blood product since they are stored at room temperature. *Staphylococcus* species are the most common contaminants of platelet units whereas gram-negative bacteria such as Yersinia enterocolitica that can replicate at cold temperatures are more commonly found as contaminants in PRBC units. The major sources of contamination are the donor's skin at the venipuncture collection site, donor bacteremia that is asymptomatic or undetected, unsterile collection packs, and violations of sterility during processing procedures. The institution in 2004 of mandatory testing of platelet units for bacterial contamination has resulted in a significant decrease in the incidence of post-transfusion sepsis. Ongoing improvements in blood component collection techniques as well as detection and treatment of bacterial contamination of blood components provide hope for further reduction of this transfusion-related risk [106,114,115,144,146].

#### Non-immune hemolysis

Non-immune hemolysis of RBCs can result from incorrect storage of the blood unit, inadequate deglycerolization of frozen RBCs, thermal injury to RBCs by malfunctioning blood warmers, exposure of RBCs to hypotonic or hypertonic IV solutions, rapid transfusion through small-bore IV catheters or processing techniques used during RBC salvage. This problem is usually preventable by strictly following established guidelines for storing, preparing, and transfusing RBCs [106,146].

#### Transfusion-associated circulatory overload

Transfusion-associated circulatory overload (TACO) is the development of cardiogenic pulmonary edema from volume overload during transfusion. Infants and patients with cardiopulmonary compromise and renal failure are particularly susceptible to this risk. Diuretic administration, as well as slowing the blood administration rate, may minimize TACO symptoms [146].

## Metabolic derangements

Hyperkalemia, hypocalcemia, and hypothermia can accompany the transfusion of blood products. Hyperkalemia is a potential problem with PRBC administration because RBCs leak potassium into their storage solution

over time. Potassium concentrations reach an average of 12mEq/L after 7 days of storage and 32mEq/L after 21 days of storage. Hyperkalemia can be a particular problem when transfusing neonates, when using unwashed previously irradiated PRBCs, or in instances of massive transfusion because of the relative volume of PRBCs administered. Hyperkalemia causes tall peaked T waves on an electrocardiogram and can lead to ventricular dysrhythmias and cardiac arrest. The use of fresher PRBCs (<14 days old), transfusion into IV lines further away from the right atrium, correction of acidosis, administration of calcium to stabilize the myocardium, and administration of glucose and insulin to lower potassium levels are helpful with prevention and treatment. After transfusion is completed, excess potassium is gradually taken back into RBCs and normal metabolic activity is restored [132,146,157].

Hypocalcemia from "citrate toxicity" may be a problem with administration of large volumes of plasma and platelets. These components have high citrate concentrations in their anticoagulant solutions. Citrate exerts its anticoagulant effect by binding ionized calcium. Neonates and infants are particularly prone to the development of hypocalcemia since their intracellular calcium reserves are limited. Hypocalcemia can produce tetany, prolonged QT interval on an electrocardiogram, and decreased myocardial function. Treatment consists of the administration of calcium and slowing the infusion rate of the blood products. Citrate undergoes rapid hepatic metabolism so hypocalcemia associated with transfusion is a transient problem [132,146,157].

Hypothermia is a complication of the rapid infusion of large amounts of inadequately warmed blood products. Hypothermia not only potentiates the cardiac toxicity of hyperkalemia and hypocalcemia but also is a component of the "lethal triad" of coagulopathy, hypothermia, and acidosis that can occur during massive hemorrhage and transfusion. Therefore, its occurrence should be aggressively prevented and/or treated [146].

#### Red blood cell storage lesions

The ability to store RBCs for up to 42 days gives blood distribution centers significant flexibility in managing the blood supply [143]. However, during this storage period, detrimental changes occur in RBCs themselves and in the RBC product as a unit. RBCs lose their deformability and increase their adhesiveness so that their passage through capillaries is impaired. Levels of 2,3-DPG fall so that the oxygen affinity of hemoglobin increases, while some hemoglobin molecules are converted to methemoglobin which is incapable of binding oxygen. Finally, concentrations of nitric oxide fall, possibly impairing vasodilation of blood vessels. Therefore, even though raising the hemoglobin level by transfusing RBCs allows more oxygen to be transported by blood, the sum of these effects may actually reduce the availability of this oxygen to tissues. These effects may be minimized by using PRBCs that are less than 14 days old [118,132,133,146,158].

## Mistransfusion

Mistransfusion is the transfusion of the incorrect blood product to the incorrect recipient. It is the most common non-infectious complication of blood product transfusion. Approximately 30% of the errors leading to mistransfusion occur in the blood bank while 50% occur in clinical areas. Meticulous attention to detail when labeling blood samples and identifying blood products and recipients is critical to avoid the occurrence of this preventable hazard of blood transfusion [114,146].

# **Blood conservation**

In light of the potential hazards posed by transfusing allogeneic blood products, efforts to minimize the necessity for transfusions should always be considered. These efforts may be especially important in patients who, for religious reasons (Jehovah's Witnesses), refuse blood product transfusion. Proactive blood conservation plans tailored to individual patients and their anticipated surgical procedures are essential for success but require significant forethought. Combining preoperative, intraoperative, and postoperative modalities will offer the best chance for a positive impact.

# **Preoperative modalities**

Personal and family histories of bleeding disorders should be sought and investigated prior to surgery. Indicated laboratory tests should be performed well enough in advance to allow preoperative action based on the results. Causes of anemia should be investigated. Anticoagulant and antiplatelet drugs should be discontinued, if feasible, for an appropriate interval before surgery.

Preoperative anemia is a major risk factor in determining the need for perioperative allogeneic blood transfusion [119,159]. This risk may be reduced by the preoperative administration of erythropoietin, a hormone produced by the kidneys that acts on erythroblast precursor cells in the bone marrow to accelerate the production of mature erythrocytes and thus increase hemoglobin levels [160]. Recombinant human erythropoietin has been shown to increase preoperative hemoglobin levels in infants and children prior to a variety of surgical procedures [160– 162]. However, it is expensive, it must be repeatedly injected intravenously or subcutaneously over a several week period preoperatively, and its use must be accompanied by iron supplementation. The most significant preoperative use of erythropoietin may be to increase hemoglobin levels in anticipation of preoperative autologous blood donation or intraoperative acute nor-movolemic hemodilution [162–165].

Preoperative autologous blood donation (PABD) is the preoperative collection of blood for transfusion back to the same donor in the perioperative period. PABD may be useful in children undergoing elective surgical procedures in which the likelihood of transfusion is substantial and in children who have rare blood groups or alloantibodies to high-incidence antigens. PABD decreases exposure to allogeneic blood products and has been used in a wide variety of surgical procedures in children [163,166-168]. As with erythropoietin, the use of PABD requires time and forethought. Depending on the size of the child and the anticipated surgical blood loss, several donations may be collected but the donations should be completed far enough in advance of surgery to allow the patient's hemoglobin level to recover prior to surgery. Estimations of the volume of blood to be collected at each donation have been based on a percentage (15%) of estimated blood volume (EBV), a defined amount (10mL) per kg bodyweight, a weight-corrected proportion of an adult unit of blood ([weight/50 kg]  $\times 450 \text{ mL}$ ), and on formulas to keep the child's postdonation hematocrit above 30%  $(EBV \times [initial hematocrit - 30]/average hematocrit with$ average hematocrit = (initial hematocrit -30)/2) [166]. PABD should not be used in children with active infections, anemia or limited cardiopulmonary reserves. Vascular access issues may limit the use of PABD in young infants [162,163]. This problem has been circumvented in some children prior to cardiac surgery by obtaining autologous blood from the large-bore vascular sheaths used during preoperative diagnostic cardiac catheterization [168]. The use of blood collected from PABD still carries risks from clerical errors and bacterial contamination, so appropriate indications should dictate its retransfusion while its automatic administration back to the donor without indications should be avoided [166].

#### Intraoperative modalities

Surgical technique obviously plays a role in limiting intraoperative blood loss and exposure to allogeneic blood transfusions. Direct control of bleeding vessels is essential and infiltration of local vasoconstrictors into surgical wound edges, use of tourniquets, patient positioning to elevate the surgical site, and use of topical clotting agents may all be important [159].

Anesthesiologists can also play helpful roles in minimizing perioperative exposure to allogeneic blood products. Maintenance of normothermia is important to prevent hypothermia-induced dysfunction of platelets and coagulation factors. Controlled hypotension techniques may help reduce intraoperative blood loss. Reinfusion of RBCs salvaged from the operative field may minimize effective blood loss but should not be used during cancer surgery, in patients with active infections or after application of topical clotting agents. Tolerating lower hemoglobin levels and basing decisions to initiate transfusion on indicators such as the development of lactic acidosis or hemodynamic lability may avoid transfusion in some cases. Administration of increased inspired oxygen concentrations will increase dissolved oxygen in blood and help maintain adequate oxygen delivery to tissues when lower hemoglobin levels are being allowed. The use of acute normovolemic hemodilution (ANH) or pharmacological interventions may also be considered [119].

Acute normovolemic hemodilution involves the intraoperative collection of blood for reinfusion at the end of surgery. Blood is withdrawn from a patient after anesthetic induction while isovolemia is maintained by infusing crystalloid (3:1 volume replacement) and/or colloid (1:1 volume replacement). Subsequently, blood with a lower hemoglobin level is lost intraoperatively and safe, fresh autologous blood with a higher hemoglobin level and functioning coagulation factors and platelets is available for reinfusion once blood loss is controlled. The amount of blood to be withdrawn can be calculated using the formula EBV × (initial hematocrit – target hematocrit)/average hematocrit where average hematocrit = (initial hematocrit - target hematocrit)/2 [169]. ANH may be considered when surgical blood loss is anticipated to exceed 15% of a child's EBV and the child has a baseline hematocrit exceeding 35% and adequate cardiopulmonary reserve to tolerate lowering of the hematocrit [166]. ANH has been used in children in surgeries ranging from posterior spinal fusions to abdominal surgery, cancer surgery, and bone marrow harvesting [166]. It offers advantages over PABD in that it may be performed on the day of surgery for both elective and emergency procedures after adequate vascular access has been obtained in an anesthetized child, and it is associated with lower administrative costs [170]. Blood withdrawn during ANH may be stored for up to 8h at room temperature and, if more than one bag of blood was withdrawn, should be reinfused in the reverse order of collection [169]. Therefore, blood with the highest hematocrit (the first unit collected) will be reinfused after bleeding has been controlled.

Pharmacological interventions include antifibrinolytic agents and recombinant factor VIIa. Antifibrinolytic agents include aprotinin and the lysine analogs, εaminocaproic acid (EACA) and tranexamic acid (TA). Although aprotinin is remarkably effective in reducing perioperative blood loss and transfusion exposure, its marketing was suspended in 2007 after concerns about adverse renal, cardiovascular, and cerebrovascular effects and increased postoperative mortality were raised in adults in whom it was administered during cardiac surgery [171–174]. While studies in neonates and children undergoing cardiac surgery have not documented similar concerns [175–178], aprotinin currently remains unavailable for clinical use.

Thus, EACA and TA are the two clinically available antifibrinolytic agents. Both of these agents exert their antifibrinolytic effect most importantly by binding with the lysine-binding sites of plasminogen and plasmin. This reversible binding alters plasminogen's conformation, precludes its association with fibrin, and prevents its conversion to its active form, plasmin, while also inhibiting the activity of plasmin on fibrin [179,180]. These drugs have been shown to decrease blood loss and allogeneic blood transfusion in cyanotic children undergoing cardiac surgery [181-183], in children undergoing repeat sternotomies for cardiac surgery [184], and in children undergoing posterior spinal fusion for idiopathic or secondary scoliosis [185-187]. They have also been shown to have beneficial effects in adults undergoing liver transplantation [188,189] and total knee replacement [190,191] and thus would probably be beneficial for similar types of surgeries in children. These drugs may also be helpful in preventing clot lysis in patients with vWD or hemophilia after hemostasis has been achieved with appropriate factor replacement therapy, especially with bleeding from mucous membranes [37,78]. Evidence points to TA being more effective than EACA in its hemostatic effects [192]. Appropriate dosing regimens remain an unresolved issue for both of these drugs. While no thrombotic complications have been reported with their use, an increased incidence of postoperative seizures has been reported with TA use in adults undergoing cardiac surgery [193,194].

Recombinant activated factor VII (rFVIIa) promotes clot formation by enhancing thrombin generation. A TFdependent mechanism involving saturation of exposed TF on injured blood vessels as well as a TF-independent mechanism involving direct interaction with activated platelets adherent to injured vessels may both be involved and confine the effects of rFVIIa to the injury site [195]. Resulting clot consists of a dense fibrin structure which is resistant to lysis because of concomitant increases in activation of the fibrin cross-linker, FXIII, and of TAFI [196]. rFVIIa is currently approved for use in patients with hemophilia A or B who have developed inhibitors to FVIII or FIX and in patients with acquired hemophilia to prevent or treat bleeding. It is also approved for the treatment of bleeding in patients with congenital FVII deficiency [197]. However, "off-label" applications are becoming increasingly frequent and include administration for reversal of warfarin-induced anticoagulation, management of inherited or acquired platelet function abnormalities, attenuation of hepatic dysfunctioninduced coagulopathies, and control of intracerebral and gastrointestinal hemorrhage [198,199]. rFVIIa has been found to be beneficial during liver transplantation [200], cardiac surgery [201,202], and trauma surgery [203,204]. Its role is mainly that of a "rescue" therapy but the optimal dosing regimen is unclear and randomized, blinded, controlled studies are needed to define the appropriate clinical scenarios for its use. The potential for systemic thrombotic complications ("black box warning" issued for increased risk of arterial thrombosis), the lack of a validated laboratory monitor, and the significant cost of rFVIIa all remain concerns [199,202].

# **Postoperative modalities**

Efforts to minimize exposure to allogeneic blood products should continue into the postoperative period. Useful strategies include limiting blood sampling to necessary tests and continued use of restrictive transfusion thresholds to trigger RBC transfusions. Reinstitution of postoperative anticoagulant or antiplatelet therapies should begin only after correction of coagulopathies acquired intraoperatively. Future considerations include development of appropriate coagulation test-based transfusion algorithms to guide blood component use and the development of safe artificial oxygen carriers to limit RBC transfusions.

# Introduction

Pediatric cardiac arrest is not a rare event. At least 16,000 American children (8–20/100,000 children/year) suffer a cardiopulmonary arrest each year [1–5]. More than half of these cardiac arrests probably occur in hospital [1,6]. With advances in resuscitation science and implementation techniques, survival from pediatric cardiac arrest has improved substantially over the past 25 years [7]. This chapter focuses on pediatric cardiac arrest, cardiopulmonary resuscitation, and other therapeutic interventions that have been specifically designed to improve outcomes from pediatric cardiac arrest.

# Epidemiology of pediatric cardiac arrest

Cardiovascular disease remains the most common cause of disease-related death in the United States, resulting in approximately 1 million deaths per year [8]. It is estimated that more than 400,000 Americans will suffer a cardiac arrest each year, nearly 90% in prehospital settings. While data regarding the incidence of childhood cardiopulmonary arrest are less robust, the best data suggest that ~16,000 American children suffer a cardiac arrest each year (annual incidence: 8–20/100,000 children per year) [1–5,9]. For in-hospital arrests specifically, it is estimated that approximately 2–6% of all children admitted to pediatric intensive care units [5,10,11] and approximately 4–6% of children admitted to cardiac units will suffer a cardiac arrest [12,13]. In short, pediatric cardiac arrest is a critical public health problem.

Outcomes from pediatric cardiac arrest have improved significantly over the past 20 years. For example, survival to discharge from pediatric in-hospital cardiac arrest has increased from <10% in the 1980s [14,15] to >25% in the 21st century. Of the pediatric patients who survive to hospital discharge, nearly three-quarters will have favorable neurological function defined by specific pediatric cerebral outcome measures and quality of life indicators (Table 12.1) [7,12,16,17]. Factors that influence outcome from pediatric cardiac arrest include:

- the pre-existing condition of the child
- the environment in which the arrest occurs

Table 12.1 Summary of representative studies of outcome following in-hospital pediatric cardiac arrest

CA, cardiac arrest; E-CPR, extracorporeal membrane oxygenation-assisted cardiopulmonary resuscitation; METS, medical emergency teams (rapid response teams); OOH, out-of-hospital; NICU, neonatal intensive care unit; PCPC, pediatric cerebral performance category; PICU, pediatric intensive care unit; ROSC, return of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia.

- the initial electrocardiographic (ECG) rhythm detected
- the duration of no-flow time (the time during an arrest without spontaneous circulation or cardiopulmonary resuscitation; CPR)
- the quality of the life-supporting therapies provided during the resuscitation
- the quality of life-supporting therapies administered after resuscitation.

Not surprisingly, outcomes after pediatric out-of-hospital arrests are much worse than those after in-hospital arrests (Table 12.2) [2–3,10,18–25]. This may be due to the fact

that there is a prolonged period of no flow in out-ofhospital arrests, where many of the pediatric cardiac arrests are not witnessed and only 30% of children are provided with bystander CPR. As a result of these factors, less than 10% of pediatric out-of-hospital cardiac arrests survive to hospital discharge, and among those who survive, severe neurological injury is common. These findings are especially troublesome given that bystander CPR more than doubles patient survival rates in adults [26].

An exciting prospective, nationwide, population-based cohort study from Japan similarly demonstrates more

OHCA, out-of-hospital cardiac arrest; ROSC, return of spontaneous circulation.

than doubling of survival rates for children who have out-of-hospital cardiac arrests and receive bystander CPR either with conventional CPR (with rescue breathing) or chest compression-only CPR compared to no bystander CPR [27]. The same study then further stratifies outcomes for out-of-hospital cardiac arrest into "cardiac" and "noncardiac" causes for arrest, and defines the relative value of rescue breathing during CPR by bystanders. Pediatric patients who have out-of-hospital cardiac arrests with non-cardiac causes and receive bystander conventional CPR (including rescue breathing) had an association with higher frequency of favorable neurological outcomes at 1 month after arrest compared to compression-only bystander CPR or no bystander CPR. For pediatric arrests defined as "cardiac" in nature, bystander CPR (conventional or compression only) was associated with a higher rate of favorable neurological outcomes 1 month after arrest compared to no bystander CPR. Interestingly, the two types of bystander CPR (conventional or compression only) seemed to be similarly effective for pediatric cardiac arrests with cardiac causes, consistent with animal and adult studies [27].

Survival outcomes after in-hospital cardiac arrest are higher in the pediatric population compared with adults; 27% of children survive to hospital discharge compared with only 17% of adults [7]. For both children and adults, outcomes are better after arrhythmogenic arrests, from ventricular fibrillation/ventricular tachycardia (VF/VT). Importantly, pediatric in-hospital arrests are less commonly caused by arrhythmias (10% of pediatric arrests versus 25% of adult arrests), and approximately one-third of children and adults with these arrhythmogenic arrests survive to hospital discharge. Interestingly, the superior pediatric survival rate following in-hospital cardiac arrest reflects a substantially higher survival rate among children with asystole or pulseless electrical activity (PEA) compared with adults (24% versus 11%). Further investigations have shown that the superior survival rate seen in children is mostly attributable to a much better survival rate among infants and preschool age children compared with older children [17]. Although speculative, the higher survival rates in children may be due to improved coronary and cerebral blood flow during CPR because of increased chest compliance in these younger arrest victims, with improved aortic diastolic pressure and venous return [28,29]. In addition, survival of pediatric patients from an in-hospital cardiac arrest is more likely in hospitals staffed with dedicated pediatric physicians [9].

# **Phases of resuscitation**

The four distinct phases of cardiac arrest and CPR interventions are: (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation/ arrest. Interventions to improve outcome of pediatric cardiac arrest should optimize therapies targeted to the time and phase of CPR, as suggested in Table 12.3.

Table 12.3 Phases of cardiac arrest and resuscitation	Table 12.3
---	------------

Phase	Interventions
Pre-arrest (Protect)	<ul> <li>Optimize community education regarding child safety</li> <li>Optimize patient monitoring and rapid emergency response</li> <li>Train in-hospital METs and rapid response teams</li> <li>Recognize and treat respiratory failure and/or shock to prevent cardiac arrest</li> <li>Transfer patients to skilled pediatric centers</li> </ul>
Arrest (no-flow) (Preserve)	<ul> <li>Minimize interval to BLS and ACLS (organized response)</li> <li>Minimize interval to defibrillation, when indicated</li> </ul>
Low-flow (CPR) (Resuscitate)	<ul> <li>Push hard, push fast</li> <li>Allow full chest recoil</li> <li>Minimize interruptions in compressions (15:2)</li> <li>Avoid overventilation</li> <li>Titrate CPR to optimize myocardial blood flow (coronary perfusion pressures and exhaled CO<sub>2</sub>)</li> <li>Consider E-CPR if standard CPR/ACLS not promptly successful (within 5 min), if available</li> </ul>
Post-resuscitation, short-term (Metabolic Delivery)	<ul> <li>Optimize cardiac output and cerebral perfusion</li> <li>Treat arrhythmias, if indicated</li> <li>Avoid hyperglycemia, hyperthermia, hyperventilation, hypoxemia, and hyperoxia</li> <li>Consider mild postresuscitation systemic hypothermia (34–36°C in centers with dedicated protocols and pediatric critical care medicine)</li> <li>Continual quality improvement for future responses to emergencies</li> </ul>
Postresuscitation phase, longer-term rehabilitation (Regenerate)	<ul> <li>Early intervention with physical medicine and rehabilitation</li> <li>Bio-engineering and technology interface</li> <li>Possible future role for stem cell transplantation</li> </ul>

ACLS, advanced cardiac life support; BLS, basic life support; E-CPR, extracorporeal membrane oxygenation-assisted cardiopulmonary resuscitation; METs, medical emergency teams.

# Prearrest

The prearrest phase refers to any relevant pre-existing conditions of the child (e.g. neurological, cardiac, respiratory or metabolic problems) and precipitating events (e.g. respiratory failure or shock) uncoupling metabolic delivery and metabolic demand. Pediatric patients who suffer an in-hospital cardiac arrest often have changes in their physiological status in the hours leading up to their arrest event [30,31]. Therefore, interventions during the prearrest phase focus on preventing the cardiac arrest, with special attention to early recognition and targeted treatment of respiratory failure and shock.

Early recognition plays a key role in identifying a pre arrest state in children, who, unlike adults, may be able to mount a prolonged physiological response to a worsening clinical picture. Medical emergency teams (METs) (also known as rapid response teams) are in-hospital emergency teams designed specifically for this purpose. Front-line providers, and even parents, are encouraged to initiate evaluation by METs based on physiological protocol-driven parameters or even intuition. Patients are assessed by the METs and those at high risk of clinical decompensation are transferred to a pediatric intensive care unit if necessary, with the goal of preventing progression to full cardiac arrest or decreasing the response time to initiation of advanced life support, thereby limiting the no-flow state. Implementation of METs decreases the frequency of cardiac arrests compared with retrospective control periods before MET initiation [32-34].

While early recognition protocols cannot identify all children at risk for cardiac arrest, it seems reasonable to assume that transferring critically ill children to an ICU early in their disease process for better monitoring and more aggressive interventions can improve resuscitative care and clinical outcomes. The caveat is that prearrest states must be identified to initiate monitoring and interventions that may inhibit the progression to an arrest. While a significant amount of research dollars and resources are spent on the other phases of cardiac arrest, particular focus on the prearrest state may yield the greatest improvement in survival and neurological outcomes.

#### No flow/low flow

In order to improve outcomes from pediatric cardiac arrest, it is imperative to shorten the no-flow phase of untreated cardiac arrest. To that end, it is important to monitor high-risk patients to allow early recognition of the cardiac arrest and prompt initiation of basic and advanced life support. Effective CPR optimizes coronary perfusion pressure (by elevating aortic diastolic pressure relative to right atrial pressure) and cardiac output to critical organs to support vital organ viability (by elevating mean aortic pressure) during the low flow phase. Important tenets of basic life support are: Push hard, push fast, allow full chest recoil between compressions, and minimize interruptions of chest compression.

The myocardium receives blood flow from the aortic root, mainly during diastole, via the coronary arteries. When the heart arrests and no blood flows through the aorta, coronary blood flow ceases. However, during chest compressions, aortic pressure rises at the same time as right atrial pressure and with the subsequent decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient that perfuses the heart with oxygenated blood. Therefore, full elastic recoil (release) is critical to create a pressure difference between the aortic root and the right atrium. A coronary perfusion pressure (CPP) below 15mmHg during CPR is a poor prognostic factor for return of spontaneous circulation (ROSC). Achieving optimal coronary perfusion pressure, exhaled carbon dioxide concentration, and cardiac output during the low-flow phase of CPR is consistently associated with an improved chance for ROSC and improved short- and long-term outcome in mature animal and human studies [35–42]. There is a critical need for research evaluating goal-directed CPR, in both immature animal models and pediatric patients.

Other measures essential for truncating the no-flow phase during ventricular fibrillation and pulseless ventricular tachycardia are rapid detection and prompt defibrillation. Clearly, CPR alone is inadequate for successful resuscitation from these arrhythmias. For cardiac arrests resulting from asphyxia and/or ischemia, adequate myocardial perfusion and myocardial oxygen delivery are the critical elements for return of spontaneous circulation.

## **Postarrest/resuscitation**

The postarrest/resuscitation phase includes co-ordinated, skilled management of the immediate postresuscitation stage, the next few hours to days, and long-term rehabilitation. The immediate postresuscitation stage is a highrisk period for ventricular arrhythmias and other reperfusion injuries. Goals of interventions implemented during the immediate postresuscitation stage and the next few days include adequate tissue oxygen delivery, treatment of postresuscitation myocardial dysfunction, and minimizing postresuscitation tissue injury (e.g. preventing postresuscitation hyperthermia and hypoglycemia and, perhaps, initiating postresuscitation therapeutic hypothermia, preventing hyperglycemia and avoiding hyperoxia). This postarrest/resuscitation phase may have the greatest potential for innovative advances in the understanding of cell injury (excitotoxicity, oxidative stress, metabolic stress) and cell death (apoptosis and necrosis), ultimately leading to novel molecular-targeted interventions. The rehabilitation stage concentrates on

salvage of injured cells, and support for re-engineering of reflex and voluntary communications of these cell and organ systems to improve long-term functional outcome.

The specific phase of resuscitation dictates the focus of care. Interventions that improve outcome during one phase may be deleterious during another. For instance, intense vasoconstriction during the low-flow phase of cardiac arrest improves CPP and the probability of ROSC. The same intense vasoconstriction during the postresuscitation phase increases left ventricular afterload and may worsen myocardial strain and dysfunction. Current understanding of the physiology of cardiac arrest and recovery allows us to only crudely manipulate blood pressure, oxygen delivery and consumption, body temperature, and other physiological parameters in our attempts to optimize outcome. Future strategies will likely take advantage of increasing knowledge of cellular injury, thrombosis, reperfusion, mediator cascades, cellular markers of injury and recovery, and transplantation technology, including stem cells.

# Interventions during the cardiac arrest (no-flow) and cardiopulmonary resuscitation (low-flow) phases

### Airway and breathing

Establishing an airway with effective gas exchange as soon as possible is critical for the success of resuscitation. Details of airway management are presented in Chapter 14. Establishing a patent airway with bag-valve-mask ventilation and 100% oxygen is an initial step in resuscitation, followed by endotracheal intubation as soon as possible, with minimal interruption in chest compressions. Colorimetric CO<sub>2</sub> detectors for exhaled gas are standard of care for pediatric CPR [43]. Absence of CO<sub>2</sub> in exhaled gas may mean the endotracheal tube is in the esophagus or that CPR is ineffective and there is no, or very low, pulmonary blood flow for gas exchange to occur. If CO<sub>2</sub> is absent, a direct laryngoscopy by an experienced clinician is performed immediately. If the tube is properly positioned in the trachea, attention is turned to effectiveness of chest compresions (see below). Persistence of adequate levels of end-tidal CO<sub>2</sub> during CPR is a favorable prognostic factor for ROSC [44,45].

During CPR, cardiac output and pulmonary blood flow are approximately 10–25% of those during normal sinus rhythm; therefore, a lower minute ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation. Animal and adult data indicate that hyperventilation ("overventilation" from exuberant rescue breathing) during CPR is common and can substantially compromise venous return and subsequently cardiac output [46–48]. These detrimental hemodynamic effects are compounded when one considers the effect of interruptions in CPR to provide airway management and rescue breathing and may contribute to worse survival outcomes [49–52].

While overventilation is problematic, in light of the fact that most pediatric arrests are asphyxial in nature (90% of arrests begin with respiratory insufficiency), immediate initiation of *adequate* ventilation is still important. The difference between arrhythmogenic and asphyxial arrests lies in the physiology. In animal models of sudden VF cardiac arrest, acceptable PaO<sub>2</sub> and PaCO<sub>2</sub> persist for 4–8 min during chest compressions without rescue breathing [53,54]. This is in part because aortic oxygen and carbon dioxide concentrations at the onset of the arrest do not vary much from the prearrest state with no blood flow and minimal aortic oxygen consumption. The lungs act as a reservoir of oxygen during the low-flow state of CPR; therefore, adequate oxygenation and ventilation can continue without rescue breathing.

Several retrospective studies of witnessed VF cardiac arrest in adults have also shown that outcomes are similar after bystander-initiated CPR with either chest compressions alone or chest compressions plus rescue breathing [5]. However, during asphyxial arrest peripheral and pulmonary blood flow continues during the prearrest state, resulting in significant arterial and venous oxygen desaturation, elevated lactate levels, and depletion of the pulmonary oxygen reserve. Therefore, at the onset of cardiopulmonary resuscitation, there is substantial arterial hypoxemia and resulting acidemia. In this circumstance, rescue breathing with controlled ventilation can be a life-saving maneuver. In contrast, the adverse hemodynamic effects from overventilation during CPR combined with possible interruptions in chest compressions to open the airway and deliver rescue breathing are a lethal combination in certain circumstances such as VT/VF arrests. In short, the resuscitation technique should be titrated to the physiology of the patient to optimize patient outcome, with rapid, efficient, skilled airway management with minimal interruption of chest compressions a cornerstone of success in pediatric resuscitation.

# Circulation

# Optimizing blood flow during low flow cardiopulmonary resuscitation

When the heart arrests, no blood flows to the aorta and coronary blood flow ceases immediately [55]. At that point, provision of high-quality CPR (*push hard, push fast*) is vital to re-establish coronary flow. The goal during CPR is to maximize the myocardial perfusion pressure (MPP). Related by the following equation: MPP = aortic diastolic

blood pressure (AoDP) - right atrial pressure (RAP), myocardial blood flow improves as the gradient between AoDP and RAP increases. During downward compression phase, aortic pressure rises at the same time as right atrial pressure with little change in the MPP. However, during the decompression phase of chest compressions, the right atrial pressure falls faster and lower than the aortic pressure, which generates a pressure gradient, perfusing the heart with oxygenated blood during this artificial period of "diastole." Several animal and human studies have demonstrated, in both VT/VF and asphyxial models, the importance of establishing MPP as a predictor for short-term survival outcome (ROSC) [41,56-59]. Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is also important to allow full chest recoil and to avoid overventilation (preventing adequate venous return because of increased intrathoracic pressure).

Based on the equation above, MPP can be improved by strategies that increase the pressure gradient between the aorta and the right atrium. As an example, the inspiratory impedance threshold device (ITD) is a small, disposable valve that can be connected directly to the tracheal tube or facemask to augment negative intrathoracic pressure during the inspiratory phase of spontaneous breathing and the decompression phase of CPR by impeding air flow into the lungs. Application in animal and adult human trials of CPR has established the ability of the ITD to improve vital organ perfusion pressures and myocardial blood flow [52,60-64]; however, in the only randomized trial during adult CPR, mortality benefit was limited to the subgroup of patients with PEA [62]. Additional evidence that augmentation of negative intrathoracic pressure can improve perfusion pressures during CPR comes from the active compressiondecompression device (ACD). The ACD is a hand-held device that is fixed to the anterior chest of the victim by means of suction similar to a household plunger that can be used to apply active decompression forces during the release phase, thereby creating a vacuum within the thorax. By actively pulling during the decompression phase, blood is drawn back into the heart by the negative pressure [65]. Animal and adult studies have demonstrated that the combination of ACD with ITD acts in concert to further improve perfusion pressures during CPR compared to ACD alone [62].

In the end, while novel interventions such as the ITD and ACD are promising adjuncts to improve blood flow during CPR, the basic tenets of *push hard*, *push fast*, *allow full chest wall release*, *minimize interruptions*, *and don't overventilate* are still the dominant factors to improve blood flow during CPR and chance of survival.

## Chest compression depth

The pediatric chest compression depth recommendation of at least one-third anterior-posterior (AP) chest depth (approximately 4cm in infants and 5cm in children) is based largely upon expert clinical consensus, using data extrapolated from animal, adult, and limited pediatric data. In a small study of six infants, chest compressions targeted to one-half AP chest depth resulted in improved systolic blood pressures compared to those targeted at one-third AP chest depth [66]. While only a small series with qualitatively estimated chest compression depths, this is the first study to collect actual data from children supporting the existing chest compression depth guidelines. In contrast, two recent studies using computed axial automated tomography (CT)[67,68] suggest that depth recommendations based on a relative percentage of AP chest compression depth are deeper than that recommended for adults, and that a depth of one-half AP chest depth will result in direct compression, to the point of fully emptying the heart and requisite shifting of heart because of inadequate AP diameter reserve in most children. Future studies that collect data from actual children and that associate quantitatively measured chest compression depths with short- and long-term clinical outcomes (arterial blood pressure, end-tidal carbon dioxide, return of spontaneous circulation, survival) are needed.

### **Compression/ventilation ratios**

The amount of ventilation provided during CPR should match, but not exceed, perfusion and should be titrated to the amount of circulation during the specific phase of resuscitation as well as the metabolic demand of the tissues. Therefore, during the low flow state of CPR when the amount of cardiac output is roughly 10-25% of normal, less ventilation is needed [69]. However, the best ratio of compressions to ventilations in pediatric patients is largely unknown and depends on many factors, including the compression rate, the tidal volume, the blood flow generated by compressions, and the time that compressions are interrupted to perform ventilation. Recent evidence demonstrates that a compression/ventilation ratio of 15:2 delivers the same minute ventilation and increases the number of delivered chest compressions by 48% compared to CPR at a compression/ventilation ratio of 5:1 in a simulated pediatric arrest model [70,71]. This is important because when chest compressions cease, the aortic pressure rapidly decreases and coronary perfusion pressure falls precipitously, thereby decreasing myocardial oxygen delivery [55]. Increasing the ratio of compressions to ventilations minimizes these interruptions, thus increasing coronary blood flow. The benefits of positive pressure ventilation (increased arterial content of oxygen and carbon dioxide elimination) must be balanced against the adverse consequence of decreased circulation. These

findings are in part the reason why the American Heart Association (AHA) now recommends a pediatric compression/ventilation ratio of 15:2 for two rescuers and 30:2 for a single rescuer.

# Duty cycle

In a model of human adult cardiac arrest, cardiac output and coronary blood flow are optimized when chest compressions last for 30% of the total cycle time (approximately 1:2 ratio of time in compression to time in relaxation) [72]. As the duration of CPR increases, the optimal duty cycle may increase to 50%. In a juvenile swine model, a relaxation period of 250–300 msec (duty cycle of 40–50% at a compression rate of 120 per min) correlates with improved cerebral perfusion pressures compared with shorter duty cycles of 30% [73].

## Circumferential versus focal sternal compressions

In adult and animal models of cardiac arrest, circumferential (vest) CPR has been demonstrated to dramatically improve CPR hemodynamics [74]. In smaller infants, it is often possible to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (thoracic squeeze). In an infant animal model of CPR, this "two-thumb" method of compression with thoracic squeeze resulted in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum [75]. Although not rigorously studied, our clinical experience indicates that it is very difficult to attain adequate chest compression force and adequate aortic pressures with the two-finger technique, so we fully support the AHA guidelines for healthcare providers to perform CPR on infants with the two thumbs plus encircling hands technique [76].

#### **Open-chest cardiopulmonary resuscitation**

In animal models, high-quality standard, closed-chest CPR generates myocardial blood flow that is >50% of normal, cerebral blood flow that is approximately 50% of normal, and cardiac output ~10-25% of normal [55,57,77,78]. By contrast, open-chest CPR can generate myocardial and cerebral blood flow that approaches normal. Although open-chest massage improves CPP and increases the chance of successful defibrillation in animals and humans [79-81], performing a thoracotomy to allow open-chest CPR is impractical in many situations. A retrospective review of 27 cases of CPR following pediatric blunt trauma (15 with open-chest CPR and 12 with closedchest CPR) demonstrated that open-chest CPR increased hospital cost without altering rates of ROSC or survival to discharge. However, survival in both groups was 0%, indicating that the population may have been too severely injured or too late in the process to benefit from this aggressive therapy [82]. Open-chest CPR is often provided to children after open-heart cardiac surgery and sternotomy. Earlier institution of open-chest CPR may warrant reconsideration in selected special resuscitation circumstances.

# Vascular access

Obtaining vascular access is obviously crucial to the success of resuscitation. Standard peripheral venous access is the first technique to consider. Details and techniques of peripheral venous access are presented in Chapter 17. Infants and children, especially hospitalized children and those with multiple previous medical interventions, often have poor peripheral venous access and it is not uncommon, even with in-hospital arrest, to encounter a patient without venous access. In this situation intraosseous (IO) infusion has become the recommended practice, supported by decades of animal study and clinical use [43,83]. Fourteen, 16, and 18 gauge specially made styletted intraosseous needles should be kept on all CPR carts, and the flat surface of the proximal tibia is utilized. The needle is placed perpendicular to the bone and inserted with a twisting, "boring" motion until loss of resistance heralding perforation of the bony cortex into cancellous bone. In infants and young children, active bone marrow hematopoiesis is occurring, and removal of the IO needle stylet and aspiration of bone marrow signifies successful placement. After rapid flush of 5-10mL normal saline, resuscitation drugs and fluids can be administered IO, all followed by rapid flush with saline. These drugs include epinephrine, atropine, antiarrhythmic agents, naloxone, and dextrose. Fluids and blood can also be administered and blood samples can be obtained for laboratory studies. Caution must be exercised to detect extravasation of fluid into surrounding tissues. Standard venous access must be obtained as soon as possible. Central venous access is often difficult to obtain during resuscitation, and IO access is preferred. Venous access attempts should not interfere with chest compressions.

## Medications used to treat cardiac arrest

While animal studies have indicated that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, there are no prospective studies to support the use of epinephrine or any other medication to improve survival outcome from pediatric cardiac arrest. A variety of medications are used during pediatric resuscitation attempts, including vasopressors (epinephrine and vasopressin), antiarrhythmics (amiodarone and lidocaine), and other drugs such as calcium chloride and sodium bicarbonate. Each will be discussed separately below. Epinephrine (adrenaline) is an endogenous catecholamine with potent  $\alpha$ - and  $\beta$ -adrenergic stimulating properties. The  $\alpha$ -adrenergic action (vasoconstriction) increases systemic and pulmonary vascular resistance. The resultant higher aortic diastolic blood pressure improves coronary perfusion pressure and myocardial blood flow even though it reduces global cardiac output during CPR, and as noted above, adequacy of myocardial blood flow is a critical determinant of ROSC. Epinephrine also increases cerebral blood flow during good-quality CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation [84-86]. However, recent evidence suggests that epinephrine can decrease local cerebral microcirculatory blood flow at a time when global cerebral flow is increased [87]. The  $\beta$ -adrenergic effect increases myocardial contractility and heart rate, and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi; however, the  $\beta$ -adrenergic effects are not observed in the peripheral vascular beds secondary to the high dose used in cardiac arrest.

Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation. High-dose epinephrine (0.05-0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01-0.02 mg/kg) in animal models of cardiac arrest and may increase the incidence of initial ROSC [88,89]. However, prospective and retrospective studies have indicated that the use of high-dose epinephrine in adults or children does not improve survival and may be associated with worse neurological outcome [90,91]. A randomized, blinded, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine after failed initial standard-dose epinephrine in pediatric in-hospital cardiac arrest demonstrated a worse 24-h survival in the high-dose epinephrine group (one of 34 survived with high dose, versus 7 of 34 with standard dose, p = 0.05) [92]. Based on these clinical studies, high-dose epinephrine cannot be recommended routinely for either initial or rescue therapy. Importantly, these studies indicate that high-dose epinephrine can worsen a patient's postresuscitation hemodynamic condition and likelihood of survival.

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction ( $V_1$  receptor) and reabsorption of water in the renal tubule ( $V_2$  receptor). Vasoconstrictive properties are most intense in the skeletal muscle and skin vascular beds. Unlike epinephrine, vasopressin is not a pulmonary vasoconstrictor. In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine. However, it can decrease splanchnic blood flow during and following CPR and can increase afterload in the postresuscitation period, placing further strain on the left ventricle [77,93–96]. Adult randomized, controlled trials suggest that outcomes are similar after use of vasopressin or epinephrine during CPR [97,98]. A case series of four children who received vasopressin during six prolonged cardiac arrest events suggested that the use of bolus vasopressin may result in ROSC when standard medications have failed [99]. However, a more recent retrospective study of 1293 consecutive pediatric arrests from the National Registry of CPR (NPCRP) found that vasopressin use, while infrequent (administered in only 5% of events), was associated with a lower likelihood of ROSC.

Therefore, it is unlikely that vasopressin will replace epinephrine as a first-line agent in pediatric cardiac arrest. However, the available data suggest that its use in conjunction with epinephrine may deserve further investigation, especially in prolonged arrest unresponsive to initial epinephrine resuscitation.

#### Antiarrhythmic medications

See the section on ventricular fibrillation in children.

# Calcium

Calcium is used frequently in cases of pediatric cardiac arrest, despite the lack of evidence for efficacy. In the absence of a documented clinical indication (i.e. hypocalcemia, calcium channel blocker overdose, hypermagnesemia or hyperkalemia), administration of calcium does not improve outcomes from cardiac arrest [100–108]. On the contrary, three pediatric studies have suggested a potential for harm, as routine calcium administration was associated with decreased survival rates and/or worse neurological outcomes [100–108]. Despite limited clinical data to support the use of calcium during CPR, it is reasonable to consider calcium administration during CPR for cardiac arrest patients at high risk of hypocalcemia (e.g. renal failure, shock associated with massive transfusion).

#### **Buffer solutions**

There are no randomized controlled studies in children examining the use of sodium bicarbonate for management of pediatric cardiac arrest. Two randomized controlled studies have examined the value of sodium bicarbonate in the management of adult cardiac arrest [109] and in neonates with respiratory arrest in the delivery room [110]. Neither study was associated with improved survival. In fact, one multicenter retrospective in-hospital pediatric study found that sodium bicarbonate administered during cardiac arrest was associated with decreased survival, even after controlling for age, gender and first documented cardiac rhythm [107]. Therefore, during pediatric cardiac arrest resuscitation, the routine use of

sodium bicarbonate is not recommended. Clinical trials involving critically ill adults with severe metabolic acidosis do not demonstrate a beneficial effect of sodium bicarbonate on hemodynamics despite correction of acidosis [111,112]. This is somewhat surprising in light of data that severe acidosis may depress the action of catecholamines and worsen myocardial function [113,114]. Nevertheless, the common use of sodium bicarbonate during CPR is not supported by clinical data. Pediatric patients with implanted cardiac pacemakers may have an increased threshold for myocardial electrical stimulation when acidotic [115]; therefore, administration of bicarbonate or another buffer is appropriate for management of severe documented acidosis in these children. Administration of sodium bicarbonate also is indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia or sodium channel blocker poisoning.

The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. Carbon dioxide must be cleared through adequate minute ventilation; thus, if ventilation is impaired during sodium bicarbonate administration, carbon dioxide build-up may negate the buffering effect of bicarbonate. Because carbon dioxide readily penetrates cell membranes, intracellular acidosis may paradoxically increase after sodium bicarbonate administration without adequate ventilation. Therefore, bicarbonate should not be used for management of respiratory acidosis.

Unlike sodium bicarbonate, tris-hydroxymethyl aminomethane (THAM) buffers excess protons without generating carbon dioxide; in fact, carbon dioxide is consumed following THAM administration. In a patient with impaired minute ventilation, THAM may be preferable when buffering is necessary to mitigate severe acidosis. THAM undergoes renal elimination, and renal insufficiency may be a relative contraindication to its use. Carbicarb, an equimolar combination of sodium bicarbonate and sodium carbonate, is another buffering solution that generates less carbon dioxide than sodium bicarbonate. In a canine model of cardiac arrest comparing animals given normal saline, sodium bicarbonate, THAM or Carbicarb, the animals given any buffer solution had a higher rate of ROSC than the animals given normal saline. In the animals given sodium bicarbonate or Carbicarb, the interval to ROSC was significantly shorter than in animals given normal saline. However, at the end of the 6-h study period, all resuscitated animals were in a deep coma, so no inferences regarding meaningful survival can be drawn [116]. It is premature to recommend either THAM or Carbicarb during CPR at this time.

Table 12.4 summarizes the recommendations for medication administration during pediatric CPR [43].

# **Postresuscitation interventions**

# **Temperature management**

Mild induced hypothermia is the most clinically promising recent goal-directed postresuscitation therapy for adults. Two seminal articles [117,118] have established that induced hypothermia (32-34°C) could improve outcome for comatose adults after resuscitation from VF cardiac arrest. In both randomized, controlled trials, the inclusion criteria were patients older than 18 years who were persistently comatose after successful resuscitation from non-traumatic VF [119,120]. Interpretation and extrapolation of these studies to children are difficult; however, fever within the first 48h following cardiac arrest, brain trauma, stroke, and ischemia is associated with poor neurological outcome. Emerging neonatal trials of selective brain cooling and systemic cooling show promise in neonatal hypoxic-ischemic encephalopathy (HIE), suggesting that induced hypothermia may improve outcomes [121,122].

The efficacy of therapeutic hypothermia following pediatric cardiac arrest is being evaluated in a randomized controlled trial (clinicaltrials.gov identifier NCT00880087); THAPCA: Therapeutic Hypothermia After Pediatric Cardiac Arrest (www.thapca.org). At a minimum, it is advisable to avoid hyperthermia in children following CPR. Using an approach of "therapeutic normothermia" with scheduled administration of antipyretic medications and the use of external cooling devices, while monitoring core temperature, may be necessary to prevent hyperthermia in this population. Notably, preventing hyperthermia is not easy. Many children become hyperthermic post arrest despite the intention to prevent hyperthermia [118].

#### Glucose control

Both hyperglycemia and hypoglycemia following cardiac arrest are associated with worse neurological outcome [123–126]. While it seems intuitive that hypoglycemia would be associated with worse neurological outcome, whether hyperglycemia *per se* is harmful or is simply a marker of the severity of the stress hormone response from prolonged ischemia is not clear. In critically ill adult patients, tight glucose control using an insulin infusion was associated with improved survival [127,128]. However, subsequent studies of non-surgical adult populations and neonatal/pediatric trials have demonstrated no survival benefit and the potential for harm from attempts at tight glucose control because of high rates of inadvertent hypoglycemia [123,129–135].

In summary, there is insufficient evidence to formulate a strong recommendation on the management of hyperglycemia in children with ROSC following cardiac arrest. If hyperglycemia is treated following ROSC in pediatric

Medication	Dose	Remarks
Adenosine	0.1 mg/kg (maximum 6 mg) Repeat: 0.2 mg/kg (maximum 12 mg)	Monitor ECG Rapid IV/IO bolus
Amiodarone	5 mg/kg IV/IO; repeat up to 15 mg/kg (maximum: 300 mg)	Monitor ECG and blood pressure Adjust administration rate to urgency (give more slowly when perfusing rhythm present) Use caution when administering with other drugs that prolong QT (consider expert consultation)
Atropine	0.02 mg/kg IV/IO 0.03 mg/kg ET <sup>a</sup> Repeat once if needed Minimum dose: 0.1 mg Maximum single dose: Child 0.5 mg Adolescent 1 mg	Higher does may be used with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg)	Slowly Adult dose: 5–10 mL
Epinephrine	0.01 mg/kg (0.1 mL/kg 1:10 000) IV/lO 0.1 mg/kg (0.1 mL/kg 1:1000) ETª Maximum dose: 1 mg/IV/lO; 10 mg ET	May repeat every 3–5 min
Glucose	0.5–1 mg/kg IV/IO	D <sub>10</sub> W: 5–10mL/kg D <sub>25</sub> W: 2–4mL/kg D <sub>50</sub> W: 1–2mL/kg
Lidocaine	Bolus: 1 mg/kg IV/IO Maximum dose: 100 mg Infusion: 20–50 µg/kg per min ETª: 2–3 mg/kg	
Magnesium sulfate	25–50 mg/kg IV/IO over 10–20 min; faster in torsades Maximum dose: 2 g	
Naloxone	<5 y or ≤20 kg: 0.1 mg/kg IV/IO/ETª ≥5 y or >20 kg: 2 mg IV/IO/ET	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1–15µg/kg)
Procainamide	15 mg/kg IV/IO over 30–60 min Adult dose: 20 mg/min IV infusion up to total maximum dose 17 mg/kg	Monitor ECG and blood pressure Use caution when administering with other drugs that prolong QT (consider expert consultation)
Sodium bicarbonate	1 mEq/kg per dose IV/IO slowly	After adequate ventilation

Table 1	12.4	Medications	for	pediatric	resuscitation	and	arrhy	/thmias
---------	------	-------------	-----	-----------	---------------	-----	-------	---------

<sup>a</sup>Flush with 5 mL of normal saline and follow with 5 ventilations. ET indicates via endotracheal tube.

ET, endotracheal; IO, intraosseous. Reproduced from Atkins et al [43] with permission from American Heart Association.

patients, blood glucose concentrations should be carefully monitored to avoid hypoglycemia.

## **Blood pressure management**

A patient with ROSC may have substantial variability in blood pressure following cardiac arrest. Postarrest/ resuscitation myocardial dysfunction is very common and is often associated with hypotension (see below) [119,120,136–145]. In addition, hypertension may occur,

especially if the patient receives vasoactive infusions for postarrest myocardial dysfunction. Optimization of blood pressure post arrest is critical to maintain adequate perfusion pressure to vital organs that may have already been injured from the "no-flow" and "low-flow" states during initial cardiac arrest and CPR.

Cerebral blood flow in healthy patients is tightly controlled over a wide range of mean arterial blood pressure via the cerebral neurovascular bundle (autoregulation); however, adults resuscitated from cardiac arrest have demonstrated impaired autoregulation of cerebral blood flow and this may also be the case in children [146]. Dysautoregulation of the cerebral neurovascular bundle following cardiac arrest may limit the brain's ability to regulate excessive blood flow and microvascular perfusion pressure, thereby leading to reperfusion injury during systemic hypertension. However, in animal models, brief induced hypertension following resuscitation results in improved neurological outcome compared with normotensive reperfusion [147,148]. Conversely, systemic hypotension may perpetuate neurological metabolic crisis following ischemic injury by uncoupling bio-energetic demand and delivery. Therefore, a practical approach to blood pressure management following cardiac arrest is to attempt to minimize blood pressure variability in this high-risk period following resuscitation.

# Postresuscitation myocardial dysfunction

Postarrest myocardial stunning and arterial hypotension occur commonly after successful resuscitation in both animals and humans [119,120,136–145]. Animal studies demonstrate that postarrest myocardial stunning is a global phenomenon with biventricular systolic and diastolic dysfunction. Postarrest myocardial stunning is pathophysiologically and physiologically similar to sepsis-related myocardial dysfunction and postcardiopulmonary bypass myocardial dysfunction, including increases in inflammatory mediators and nitric oxide production [139,142,143,145].

Because cardiac function is essential to reperfusion following cardiac arrest, management of postarrest myocardial dysfunction may be important to improving survival. The classes of agents used to maintain circulatory function (i.e. inotropes, vasopressors, and vasodilators) must be carefully titrated during the postresuscitation phase to the patient's cardiovascular physiology. Although the optimal management of postcardiac arrest hypotension and myocardial dysfunction has not been established, data suggest that aggressive hemodynamic support may improve outcomes. Controlled trials in animal models have shown that dobutamine, milrinone and levosimendan can effectively ameliorate postcardiac arrest myocardial dysfunction [136,137,149,150]. In clinical observational studies, fluid resuscitation has been provided for patients with hypotension and concomitant low central venous pressure, and various vasoactive infusions, including epinephrine, dobutamine, and dopamine, have been used to treat the myocardial dysfunction syndrome [110–120,140–144]. In the end, optimal use of these agents involves close goal-directed titration, and the use of invasive hemodynamic monitoring may be appropriate.

General critical care principles suggest that appropriate therapeutic goals are adequate blood pressures and adequate oxygen delivery. However, the definition of "adequate" is elusive. Reasonable interventions for vasodilatory shock with low central venous pressure include fluid resuscitation and vasoactive drug infusions. Appropriate considerations for left ventricular myocardial dysfunction include euvolemia, inotropic infusions, and afterload reduction.

# Neuromonitoring

Continuous neuromonitoring and goal-directed intervention following cardiac arrest is an exciting frontier with great promise for improving neurological outcomes post cardiac arrest [151]. Continuous EEG (cEEG) monitoring is an increasingly instituted modality for neuromonitoring of critically ill patients, especially to diagnose nonconvulsive seizures (NCS) and seizures in patients receiving muscle relaxants. cEEG monitoring is noninvasive, performed at the bedside, and permits continuous assessment of cortical function. Interpretation of cEEG is usually performed by a neurologist from a remote location, and not bedside critical care physicians. However, advances in quantitative EEG tools may allow bedside caregivers to identify important electrographic events, such as seizures or abrupt background changes, to potentially permit real-time analysis and intervention [152]. In a prospective study of cEEG in children, nonconvulsive seizures were detected in 39% (12 of 31) of children following cardiac arrest [153]. In a partially overlapping cohort of 19 children, NCS were common in children undergoing therapeutic hypothermia after cardiac arrest [153]. NCS seem to be a common occurrence following cardiac arrests in children.

Although the relationship of NCS to worse outcomes has not been established in pediatric patients following cardiac arrest, it has been associated with worse outcomes among critically ill adults and neonates [154–160]. We believe that cEEG should be considered for children post cardiac arrest and that patients with NCS (especially status epilepticus with NCS) should be treated with anticonvulsant medication. Further study is warranted to better establish frequency of NCS and potential benefit in outcomes with anticonvulsant therapy.

Oxidative injury may be greatest in the early phases of postresuscitation therapy following cardiac arrest [161]. Interestingly, the use of 100% oxygen (compared to room air) during and immediately following resuscitation in animal models may potentiate oxidative injury to key mitochondrial enzymes (pyruvate dehydrogenase or manganese superoxide) or mitochondrial lipids (cardiolipin) and is associated with worse neurological outcomes [162–165]. Experimental protocols in large animals using peripheral pulse oximetry to titrate oxygenation in the postresuscitation phase can reduce postresuscitation hyperoxia and significantly improve neuropathology and neurobehavioral outcomes [166]. Consistent with these experimental findings, arterial hyperoxia ( $PaO_2 \ge$ 300 mmHg) was independently associated with inhospital mortality compared with either hypoxia or normoxia in an observational study among critically ill adult patients admitted to the ICU within 24h of a cardiac arrest [167]. We believe it is prudent to titrate oxygenation during and following pediatric cardiac arrest. Although the optimal SpO<sub>2</sub> is not known, we recommend titration of FiO<sub>2</sub> to the lowest amount necessary to assure SpO<sub>2</sub> > 94%.

Perhaps the future of postarrest care will include more aggressive neurocritical care monitoring, such as near infrared spectroscopy, cerebral microdialysis, brain tissue oxygen saturation (PbtO<sub>2</sub>), cerebral blood flow, and even bedside analysis of mitochondrial dysfunction.

# **Other considerations**

# Quality of cardiopulmonary resuscitation

Despite evidence-based guidelines, extensive provider training, and provider credentialing in resuscitation medicine, the quality of CPR is typically poor. CPR guidelines recommend target values for selected CPR parameters related to rate and depth of chest compressions and ventilations, avoidance of CPR-free intervals, and complete release of sternal pressure between compressions [168]. Slow compression rates, inadequate depth of compression, and substantial pauses are the norm. An approach to "push hard, push fast, minimize interruptions, allow full chest recoil and don't overventilate" can markedly improve myocardial, cerebral, and systemic perfusion, and will likely improve outcomes [51]. Quality of postresuscitative management has also been demonstrated to be critically important to improving resuscitation survival outcomes [140]. Measuring the quality of CPR and avoiding overventilation during cardiac arrest resuscitation have recently been re-emphasized by consensus of the International Liaison Committee on Resuscitation and the American Heart Association [169]. Although the correct amount, timing, intensity, and duration of ventilation required during CPR are controversial, there is no controversy that measurement and titration of the amount of ventilation to the amount of blood perfusion are desirable. Thus, additional technology that is safe, accurate, and practical would improve detection and feedback of the "quality of CPR."

Recent technology has been developed that monitors quality of CPR by force sensors and accelerometers and can provide verbal feedback to the CPR administrator regarding the frequency and depth of chest compressions and the volume of ventilations. Recent pediatric data illustrate that intensive training and real-time corrective feedback can help chest compression quality approach age-specific AHA CPR guideline targets [170–172]. Moreover, improvements in postresuscitation care can improve resuscitation survival outcomes [140].

# Extracorporeal membrane oxygenationcardiopulmonary resuscitation

Extracorporeal cardiopulmonary resuscitation (E-CPR) has been reported to improve short-term and long-term survival outcomes following in-hospital and out-of-hospital cardiac arrest refractory to conventional therapy in observational studies [173-177]. Such studies are provocative and hypothesis generating, but can be criticized for small numbers, selection bias, and the lack of randomization to control for confounding by indication [178]. It is unlikely that there will ever be a randomized controlled trial (RCT) investigating the treatment effect of E-CPR for in-hospital cardiac arrest, because of the need for a large sample size, complexity of methodology, lack of blinding, and lack of equipoise among providers. Devoid of a RCT, E-CPR observational studies in children clearly suggest favorable early survival outcomes in children with primary cardiac disease when E-CPR protocols were in place at the time of the arrest [30,161–171]. For pediatric patients without primary cardiac disease, the data are less clear. Impressively, these studies consistently show that >1/3 of children provided with E-CPR survive to hospital discharge despite median durations of CPR of approximately 50 min prior to extracorporeal membrane oxygenation (ECMO) implementation. Importantly, 64% of patients who survived to discharge after E-CPR had favorable neurological outcomes [178].

Current guidelines recommend that extracorporeal CPR (E-CPR or rescue ECMO) should be considered in pediatric patients with in-hospital cardiac arrest that is refractory to initial resuscitation efforts when the cause of the arrest is believed to be reversible or amenable to heart transplantation [43]. Timely, quality E-CPR may be an exciting adjuvant to conventional CPR for pediatric patients. Future frontiers will define patient populations and optimize the clinical approach to extracorporeal support; however, clinicians providing CPR should consider E-CPR early in the course of a resuscitation not responding to conventional CPR. Perhaps after failure to attain ROSC within 5min, clinicians should ask themselves: (1) Does the patient have a potentially reversible process? (2) Would ECMO be a "bridge" to a potentially good outcome? (3) Do we have the personnel and resources to provide EMCO promptly? If the answer to all three is "yes," prompt implementation of E-CPR should be considered.

# Ventricular fibrillation and ventricular tachycardia in children

Pediatric VF or VT has been an underappreciated pediatric problem. Recent studies indicate that VF and VT (i.e. shockable rhythms) occur in 27% of in-hospital cardiac arrests at some time during the resuscitation [179]. In a population of pediatric cardiac intensive care unit patients, as many as 41% of arrests were associated with VF or VT [13]. According to the National Registry of Cardiopulmonary Resuscitation (NRCPR) database (www.nrcpr.org), 10% of children with in-hospital cardiac arrest had an initial rhythm of VF/VT. In all, 27% of the children had VF/VT at some time during the resuscitation [179]. The incidence of VF varies by setting and age [180]. In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, post cardiac surgery, and prolonged QT syndromes, VF and pulseless VT are more likely.

The treatment of choice for short-duration VF is prompt defibrillation. In general, the mortality rate increases by 7-10% per minute of delay to defibrillation. Because VF must be considered before defibrillation can be provided, early determination of the rhythm by electrocardiography is critical. An attitude that VF is rare in children can be a self-fulfilling prophecy with a uniformly fatal outcome. The recommended defibrillation dose is 2 J/kg, but the data supporting this recommendation are not optimal and are based on old monophasic defibrillators. In the mid-1970s, authoritative sources recommended starting doses of 60-200 J for all children. Because of concerns about myocardial damage and animal data suggesting that shock doses ranging from 0.5 to 1 J/kg were adequate for defibrillation in a variety of species, Gutgesell et al evaluated the efficacy of their strategy to defibrillate with 2 J/kg monophasic shocks. Seventy-one transthoracic defibrillations in 27 children were evaluated. Shocks within 10 min of 2 J/kg resulted in successful defibrillation (i.e. termination of fibrillation) in 91% of defibrillation attempts [181]. More recent data demonstrate that an initial shock dose of 2 J/kg terminates fibrillation in <60% of children, suggesting that a higher dose may be needed [22,182,183]. Despite five decades of clinical experience with pediatric defibrillation, the optimal dose remains unknown.

# Antiarrhythmic medications: lidocaine and amiodarone

Administration of antiarrhythmic medications should never delay administration of shocks to a patient with VF. However, after an unsuccessful attempt at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. Epinephrine is the current first-line medication for both pediatric and adult patients in VF. If epinephrine and a subsequent repeat attempt to defibrillate are unsuccessful, lidocaine or amiodarone should be considered.

Lidocaine traditionally has been recommended for shock-resistant VF in adults and children. However, only amiodarone improved survival to hospital admission in the setting of shock-resistant VF compared with placebo [184]. In another study of shock-resistant out-ofhospital VF, patients receiving amiodarone had a higher rate of survival to hospital admission than patients receiving lidocaine [185]. Neither study included children. Because there is moderate experience with amiodarone use as an antiarrhythmic agent in children and because of the adult studies, it is rational to use amiodarone similarly in children with shock-resistant VF/VT. The recommended dosage is 5mg/kg by rapid intravenous bolus. There are no published comparisons of antiarrhythmic medications for pediatric refractory VF. Although extrapolation of adult data and electrophysiological mechanistic information suggest that amiodarone may be preferable for pediatric shock-resistant VF, the optimal choice is not clear.

## Pediatric automated external defibrillators

Automated external defibrillators (AEDs) have improved adult survival from VF [186,187]. AEDs are recommended for use in children 8 years or older with cardiac arrest [76,188]. The available data suggest that some AEDs can accurately diagnose VF in children of all ages, but many AEDs are limited because the defibrillation pads and energy dosage are geared for adults. Adapters with smaller defibrillation pads that dampen the amount of energy delivered have been developed as attachments to adult AEDs, allowing their use in children. However, it is important that the AED diagnostic algorithm is sensitive and specific for pediatric VF and VT. The diagnostic algorithms from several AED manufacturers have been tested for such sensitivity and specificity and therefore can be reasonably used in younger children.

# Simulation and pediatric cardiopulmonary resuscitation

Simulation has achieved an increasingly important place in medical education and training in pediatric anesthesiology and critical care, with resuscitation scenarios among the most frequent programs provided by pediatric simulation centers [189]. Simulation scenarios can reveal gaps in knowledge and technique for physicians. In a study of 20 anesthesia residents in a scenario of hyperkalemic cardiac arrest during anesthesia for a craniotomy for tumor incision in a 1-year-old patient weighing 10kg resulting in pulseless electrical activity, only one-third of the residents performed chest compressions properly, and administered the correct dose of epinephrine. Only one-fourth of the residents considered hyperkalemia as a cause of the arrest, and none asked for dosing aids [190]. In a study of *in situ* simulation training for effective chest compressions in a pediatric ICU, healthcare providers with more frequent exposure to these sessions correctly demonstrated proper chest compressions in significantly less time than those with less frequent exposure to these sessions [172]. See Chapter 42 for a thorough discussion of simulation in pediatric anesthesia.

# Intraoperative cardiac arrest

See Chapter 40 for a detailed discussion of the causes of intraoperative cardiac arrest.

# When should cardiopulmonary resuscitation be discontinued?

Several factors determine the likelihood of survival after cardiac arrest, including the mechanism of the arrest (e.g. traumatic, asphyxial, progression from circulatory shock), location (e.g. in-hospital or out-of-hospital), response (i.e. witnessed or unwitnessed, with or without bystander CPR), underlying pathophysiology (i.e. cardiomyopathy, congenital defect, drug toxicity or metabolic derangement), and the potential reversibility of underlying diseases. These factors should all be considered before deciding to terminate resuscitative efforts. Continuation of CPR has been traditionally considered futile beyond 15min of CPR or when more than two doses of epinephrine are needed [191]. Presumably in part because of improvements in CPR quality and postresuscitation care, improved outcomes from in-hospital CPR efforts beyond 15min or two doses of epinephrine are increasingly the norm [7,16]. The potential for excellent outcomes despite prolonged CPR has been highlighted by the E-CPR data noted above [192-197]. Conversely, the decision to discontinue CPR prematurely is final and cannot be rescinded. In the first decade of the 21st century, there is no simple answer to the important clinical question: when should CPR be discontinued?

# Updated recommendations for pediatric CPR

In late 2010 the latest recommendations from the American Heart Association, European Resuscitation Council, and International Liaison Committee on Resuscitation were published [204]. The major changes from the previous recommendations published in 2005 are:

**1.** Additional evidence shows that healthcare providers do not reliably determine the presence or absence of a pulse in infants or children.

- **2.** New evidence documents the important role of ventilations in CPR for infants and children. However, rescuers who are unable or unwilling to provide ventilations should be encouraged to perform compression-only CPR.
- **3.** To achieve effective chest compressions, rescuers should compress at least one third the anterior-posterior dimension of the chest. This corresponds to approximately 1.5 inches (4 cm) in most infants and 2 inches (5 cm) in most children.
- **4.** When shocks are indicated for ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) in infants and children, an initial energy dose of 2 to 4 J/kg is reasonable; doses higher than 4 J/kg, especially if delivered with a biphasic defibrillator, may be safe and effective.
- **5.** More data support the safety and effectiveness of cuffed tracheal tubes in infants and young children, and the formula for selecting the appropriately sized cuffed tube was updated.
- **6.** The safety and value of using cricoid pressure during emergency intubation are not clear. Therefore, the application of cricoid pressure should be modified or discontinued if it impedes ventilation or the speed or ease of intubation.
- 7. Monitoring capnography/capnometry is recommended to confirm proper endotracheal tube position.
- **8.** Monitoring capnography/capnometry may be helpful during CPR to help assess and optimize quality of chest compressions.
- **9.** On the basis of increasing evidence of potential harm from exposure to high-concentration oxygen after cardiac arrest, once spontaneous circulation is restored, inspired oxygen concentration should be titrated to limit the risk of hyperoxemia.
- **10.** Use of a rapid response system in a pediatric inpatient setting may be beneficial to reduce rates of cardiac and respiratory arrest and in-hospital mortality.
- **11.** Use of a bundled approach to management of pediatric septic shock is recommended.
- **12.** The young victim of a sudden, unexpected cardiac arrest should have an unrestricted, complete autopsy, if possible, with special attention to the possibility of an underlying condition that predisposes to a fatal arrhythmia. Appropriate preservation and genetic analysis of tissue should be considered; detailed testing may reveal an inherited "channelopathy" that may also be present in surviving family members

The reader is advised that new guidelines are published every few years, and the most recent guidelines should be sought out and followed.

# **Summary**

Outcomes from pediatric cardiac arrest and CPR appear to be improving. Perhaps the evolving understanding of pathophysiological events during and after pediatric cardiac arrest and the developing fields of pediatric critical care and pediatric emergency medicine have contributed to these apparent improvements. In addition, exciting breakthroughs in basic and applied science laboratories are on the immediate horizon for study in specific subpopulations of cardiac arrest victims. By strategically focusing therapies to specific phases of cardiac arrest, there is great promise that critical care interventions will lead the way to more successful cardiopulmonary and cerebral resuscitation in children.

# CASE STUDY

A 5-year-old girl was found floating at the bottom of a swimming pool after not being seen by her parents for approximately 10min. She was pulled from the water by a lifeguard. He noted that she was apneic and had no signs of life. Rescue breaths were given and chest compressions were initiated. The lifeguard gave rescue breaths co-ordinated with chest compressions at a cycle of 15:2 while the emergency medical services (EMS) were called. Upon arrival of the EMS, an endotracheal tube was placed while in-line neck stabilization was provided. Following intubation, the girl was hand ventilated at a rate of 10-12 breaths per min and received compressions at a rate of 100 per min simultaneously. An AED was placed and did not advise shocking. The EMS providers placed a cervical collar, and inserted an intraosseous needle in her proximal right tibia. They infused an intraosseous bolus of 2mL epinephrine 1:10,000 (0.1mL/kg based on a presumed weight of 20 kg) every  $3 \text{min} \times 3$ . She was transported to an outside hospital emergency department (ED), and return of spontaneous circulation was noted on arrival.

In the ED she had a rectal temperature of 36°C, a heart rate of 170 beats per min, a blood pressure of 120/60 and  $SpO_2$  of 100% with FiO2 1.0. Her end-tidal  $CO_2$  was 65mmHg. Her pupils were 4mm bilaterally and reactive and she had intermittent extensor posturing with stimulation, but no purposeful movement. Two peripheral intravenous lines were placed. Her initial venous blood gas revealed a pH 6.9, PCO<sub>2</sub> 65 mmHg, PaO<sub>2</sub> 25 mmHg, bicarbonate 12meq/L, a base deficit of -22meq/L and an ionized calcium of 1.02 mmol/L. A complete blood count had a white blood cell count of 15,000/mm<sup>3</sup>, hemoglobin of 12g/dL, and a platelet count of 242,000/mm<sup>3</sup>. A chemistry panel showed a sodium of 138 meq/L, potassium 7 meq/L, chloride of 103 meq/L, BUN of 15 mg/dL and a creatinine of 0.3 mg/dL. The glucose was 345 mg/dL. The initial chest x-ray showed an endotracheal tube in the mid trachea with bilateral hazy infiltrates. Secondary to hyperkalemia in the face of a severe metabolic and mild respiratory acidosis, the patient was hyperventilated

at a rate of 22 breaths per min. She received 2 meq/kg of sodium bicarbonate as well as 50 mg/kg of calcium gluconate intravenously. She also received 20 mL/kg of normal saline,  $20 \mu \text{g}$  of fentanyl, and 1 mg of midazolam for posturing and twitching, with resolution of her twitching. The head computed tomography scan showed no intracranial injury. She was then transferred to the ICU for further management.

On arrival in the ICU, her vital signs were rectal temperature of 35.5°C, a heart rate of 150 beats per min, a blood pressure of 90/40 and a SpO<sub>2</sub> of 100% on FiO<sub>2</sub> 1.0 with hand ventilation. She had an end-tidal CO<sub>2</sub> of 50 mmHg. She was placed on initial ventilator settings of tidal volume 160 mL, a positive end expiratory pressure of 10 cmH<sub>2</sub>O and a rate of 22 breaths per min with FiO<sub>2</sub> 1.0. To avoid hyperoxia, her supplemental oxygen was weaned to maintain her SpO<sub>2</sub> >94%. Her ventilation rate was titrated to maintain normocarbia.

Simultaneously she had an esophageal and bladder temperature probe placed for core temperature monitoring. The esophageal probe was placed through the mouth and measured to terminate at the distal end of the esophagus. The temperature-sensing Foley catheter was placed for both urinary output monitoring as well as continuous core temperature monitoring. A 5 French, 12cm triplelumen right subclavian catheter was placed under sterile conditions. This was placed both for continuous medication administration as well as co-oximetry and central venous pressure monitoring. A repeat chest x-ray was obtained which showed the catheter terminating at the right atrial-superior vena caval junction. There was no evidence of pneumothorax and the esophageal probe terminated at the distal esophagus. She also had a right radial arterial line placed under sterile conditions for continuous arterial blood pressure monitoring and frequent lab sampling.

Following these procedures, the patient remained tachycardic with a heart rate of 140 bpm, and became hypotensive with a blood pressure of 70/40. Her central venous pressure was  $2 \text{ cmH}_2\text{O}$ , and her repeat venous blood gas was pH 7.13/PCO<sub>2</sub> 45/PO<sub>2</sub> 38/base deficit -12/lactate 6. She received another 20 mL/kg of normal saline × 2 with improvement in her central venous pressure to 6, but despite fluid boluses she remained persistently hypotensive at 80/40. At that time, the intensivist decided to initiate vasopressor therapy to improve her cerebral perfusion pressure. Dopamine was infused at 5µg/kg/min, resulting in a blood pressure of 102/55 mmHg and a urine output of approximately 5mL/kg/h.

Labs were sent to further evaluate end-organ perfusion. Her troponin was  $1.5 \mu g/L$ , creatine kinase (CK) was 2023 units/L and her CK-myocardial band percentage was 7%. Her amylase, lipase, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were within normal limits. Her glucose was 327 mg/dL. She remained comatose with a Glasgow Coma Score of 6 Total (Eye opening 1, Verbal response 0 (intubated), Motor response 5).

At that time the clinical team placed her on a cooling blanket with the goal of maintaining her temperature between 36 and 37°C to avoid hyperthermia. She was initiated on maintenance fluids without dextrose due to hyperglycemia. An insulin infusion was ordered to start at 0.01 units/kg/h to maintain her glucose <180 and prevent excessive urine output from osmotic diuresis. Because of hypotension and the known risk of postcardiac arrest myocardial depression, an echocardiogram was obtained at the bedside, which showed a shortening fraction of 40% and a hyperdynamic myocardium. Because of intermittent posturing and tachycardia, which resolved after IV midazolam treatment, a continuous electroencephalogram was performed to monitor for postcardiac arrest seizure activity. The neurologist noted non-convulsive seizure activity on the electroencephalogram, and the patient was loaded with 20 mg/kg of intravenous fosphenytoin. She was sedated with fentanyl and midazolam infusions to decrease metabolic demand immediately post arrest.

During the 3 days following her cardiac arrest, her temperature was maintained between 36 and 37°C, her blood pressure was maintained within normal limits or age and she was weaned off dopamine, her PaCO<sub>2</sub> was maintained in the 40s and her SpO<sub>2</sub> was maintained at >95%. Within 36h post arrest, trophic feeds were initiated and slowly titrated to goal caloric needs via a nasoduodenal feeding tube. On postcardiac arrest day 3, her neurological exam revealed bilateral reactive pupils, a cough and gag, spontaneous respiratory effort, and she was localizing to noxious stimuli. Her seizures were controlled with phenytoin and EEG monitoring was discontinued at 72h with no new seizures evident. On day 4 post arrest, her temperaturesensing Foley and esophageal probes were removed so that she could go to MRI for evaluation of her brain and cervical spine. Her cervical spine showed no evidence of bony or ligamentous injury and her cervical collar was removed by trauma surgery. Her brain MRI showed evidence of subtle acute hypoxic ischemic injury in the cerebral cortex bilaterally. On day 5 her sedation infusions were discontinued and she was extubated. On day 6 her central line and arterial line were discontinued and she was transferred to inpatient rehab for intensive therapies.

Three months following her cardiac arrest, she was verbal and interactive. She was able to ambulate with assistance. She had had no seizures and was maintained on phenytoin with plans to wean it off at 6 months post arrest if there was no new seizure activity.

## **Key points**

- **1.** The chain of survival includes early, good-quality CPR, early defibrillation if appropriate, aggressive postresuscitative care and rehabilitation services.
- **2.** Prompt bystander CPR was provided with chest compressions and rescue breathing.
- **3.** Postresuscitative care requires a multidisciplinary approach and focus on details of avoiding secondary injuries from hyperoxia, hyperthermia, hypotension and acidosis.
- 4. Post cardiac arrest, patients often exhibit intravascular volume depletion, and have a systemic inflammatory response syndrome (SIRS) and myocardial depression. Therefore, close hemodynamic monitoring and cardiovascular supportive care are necessary for optimal postresuscitative care.

# **Preoperative evaluation**

Quality perioperative care begins with a comprehensive preanesthetic evaluation and preparation of the child and family. Healthcare providers should aspire to deliver healthcare that is safe, effective, patient centered, efficient, and equitable [1]. These principles should guide not just the preoperative evaluation but the entire perioperative process.

While the majority of children presenting for surgery are in excellent general health, many will have complex medical and/or psychological issues requiring careful assessment and planning. Pediatric co-morbid diseases are predominantly genetic, congenital or developmental. This contrasts to the largely acquired and degenerative diseases more common in adulthood. Accordingly, while the guiding principles are the same, the focus and approach of the preoperative evaluation for children and adults are often different. This section outlines the rationale for and organizational aspects of the preoperative evaluation, key issues in history taking, physical examination and ordering investigations, and a review of current fasting guidelines and medical conditions commonly encountered in pediatric patients.

## **Goals of preoperative evaluation** Achieve optimal medical outcomes and minimize risk

The primary role of the preoperative evaluation is to identify the presence and severity of both known and previously undiagnosed conditions [2]. Untreated or poorly managed diseases can frequently be optimized prior to surgery. Of particular interest are conditions that complicate the provision of anesthesia and/or increase perioperative risk. Understanding perioperative risk is essential for developing an appropriate management plan aimed at achieving optimal outcomes and for providing

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

appropriate preoperative counseling to the patient and family.

Neonates, infants, and young children are at increased risk of anesthesia-related morbidity and mortality compared to older children and adults [3–7]. Young age is associated with an increased incidence of both respiratory [8–10] and cardiac complications [11]. Age-independent risk factors for adverse outcomes include the presence of multiple co-morbidities and American Society of Anesthesiologists (ASA) physical status classification of III or more [5,11,12]. However, the ASA classification should be used with caution as a predictive tool, as it was not designed for use in children or as a predictor of their perioperative outcome and there is poor inter-rater reliability in the pediatric setting [13].

Respiratory complications predominate in children and include events such as laryngospasm, bronchospasm, hypoxia and postextubation stridor. Specific risk factors for respiratory complications include current or recent upper respiratory tract infection [8,10,14,15], asthma [16], obstructive sleep apnea [17], bronchopulmonary dysplasia, obesity [18–20], passive smoking [15,21], positive family history of asthma or atopy (in at least two members) [22] and specific conditions (e.g. Down syndrome) [23]. The preoperative evaluation should aim to identify these risk factors.

#### Identification of psychological issues

The perioperative period can be a stressful time for the child and family. Anxiety and behavioral stress are very common in children, and have been associated with adverse postoperative outcomes such as emergence delirium, increased pain, increased analgesia use, anxiety, and sleep problems [24,25].

The preoperative consultation provides an excellent opportunity to establish rapport with the child, identify high-risk patients, and develop a plan aimed at minimizing anxiety and distress. Effective preparation of the child for surgery is guided by the child's age and developmental level, and may include elements such as education, hospital tours, play therapy, hypnosis, relaxation techniques, and sedative/anxiolytic premedication. These will be discussed at greater length later in the chapter.

### Education

It has been shown that children and parents want detailed information regarding the perioperative period [26–28]. While younger children may be more interested in the physical appearance of the operating room, older children may be concerned about the anesthetic technique, procedures, pain and potential complications [26].

Comprehensive information is also required for ethical and legal purposes in order for parents to make informed decisions about their child's care. The information should cover key topics such as the rationale for fasting, details of the anesthetic plan and the role of the anesthesiologist. Unfortunately, parental knowledge in these areas has frequently been shown to be lacking [29]. There may be a perception by some anesthesiologists that the provision of detailed information may increase parental anxiety but this has been shown not to be the case and may have the opposite effect of reducing anxiety levels [27,30,31].

Information can be communicated in a number of ways. Verbal information given during the preoperative evaluation can be effectively supplemented with written and audiovisual matter [30,31]. While formal parental education programs are known to improve knowledge and reduce anxiety in parents [32], educational programs for children may not provide a similar benefit [33]. Translation services must be available as appropriate for parents whose primary language is not English, and are not able to fully understand the perioperative information.

#### Perioperative planning

A comprehensive perioperative plan is essential for quality patient care. The complexity of planning is proportional to the patient and family's particular needs. Key considerations in the perioperative planning process include:

- 1. identifying an appropriate surgical setting
  - hospital type: tertiary pediatric versus peripheral hospital
  - operating theater location: "main" operating theater versus day unit
  - admission type: inpatient versus out
- 2. arranging appropriately skilled practitioners
  - a specialist pediatric anesthesiologist should ideally care for all children, particularly those at greater risk of adverse outcomes. The absence of a specialist pediatric anesthesiologist is an established risk factor for adverse perioperative outcomes [9,22]
  - some diseases warrant care from a subspecialized pediatric anesthesiologist, such as a cardiac anesthesiologist for children with complex cardiac issues
- 3. formulation of specific anesthesia plan
  - preparation and premedication
  - fasting prescription
  - induction: mode of induction, parental presence
  - intraoperative management: monitoring, analgesia
  - postoperative management: destination and special monitoring/observation requirements

4. identify special needs or equipment.

#### Hospital efficiency and economics

Thorough and timely preoperative evaluation and planning can reduce the incidence of day-of-surgery cancellations and delayed start times [34]. Reduced cancellations mean less wasted operating theater time and greater utilization of healthcare resources.

# Organizational aspects of the preoperative evaluation

Organizational frameworks for preoperative assessment differ between institutions. High day-of-surgery admission rates necessitate the implementation of effective systems to process and evaluate patients in the preoperative period [35]. All children scheduled for surgery should be screened for significant issues, using either a written questionnaire or telephone interview [36]. This process identifies children who will benefit from further outpatient evaluation. Additionally, a phone call on the day prior to surgery confirms planned patient attendance and understanding of fasting policies, and identifies any new issues (e.g. upper respiratory tract infection).

Outpatient assessment clinics play an important role in the preoperative process and have been shown in adults to improve patient satisfaction and reduce the rate of cancellations, length of stay, patient anxiety, inappropriate referrals, and unnecessary investigations [34,37–41]. Most healthy pediatric patients do not, however, require outpatient evaluation and can be safely assessed on the day of surgery [42,43].

Outpatient preassessment clinics frequently adopt a multidisciplinary approach, with team members consisting of anesthesiologists, nurse practitioners, nurses, physiotherapists and child life specialists. Nurse practitioner-assisted models of preoperative evaluation have been successfully introduced in some institutions, allowing anesthesiologists more time in the operating theater [42,44]. Regardless of which professional evaluates the child, the ultimate responsibility for declaring "fitness for surgery" rests firmly with the anesthesiologist performing the case.

#### History

The preoperative evaluation should incorporate a thorough exploration of the patient's medical history. Information can be obtained from a variety of sources, including an interview with the patient and his/her parents; a review of medical records with an emphasis on previous anesthetic charts; and a discussion with the child's regular physician(s) and the proceduralist performing the scheduled surgery.

During interactions with patients and their parents, medical professionals often spend the majority of time interacting with parents and focus predominantly on medical talk [45]. It is important to involve the child in the discussion and to utilize the opportunity to build rapport and establish the confidence of the child.

The nature of the presenting condition and the details of the planned procedure should be established first. Knowledge of the presenting problem immediately identifies potential anesthetic issues, e.g. the child with obstructive sleep apnea presenting for adenotonsillectomy is at risk of airway complications and increased apnea incidence postoperatively. Understanding the surgeon's specific plans and potential concerns is crucial to planning safe anesthesia.

Background history should begin with a review of relevant obstetric and perinatal issues. Points of interest include the gestational age at birth and problems of prematurity, in particular the requirement for and duration of respiratory support and incidence of apnea. Growth and developmental history should then be assessed. Failure to reach or loss of developmental milestones should initiate diagnostic work to investigate the possibility of unrecognized neuromuscular conditions, many of which have profound anesthetic implications (e.g. Duchenne muscular dystrophy). Congenital and acquired medical conditions should also be reviewed with a focus on disease duration; severity; course and stability; current disease activity; past and current treatment (medical and surgical); complications of therapy; and long-term prognosis.

Family history is important in identifying the presence of genetic conditions of anesthetic interest. Important inherited conditions include malignant hyperthermia; pseudocholinesterase deficiency; muscular dystrophies; disorders of coagulation (e.g. hemophilia, von Willebrand disease); primary electrical diseases of the heart (e.g. Wolff–Parkinson–White syndrome, prolonged QT syndrome, Brugada syndrome and catecholaminergic polymorphic ventricular tachycardia) [46]; and metabolic conditions (e.g. porphyria).

Past surgical procedures should be investigated, with a particular focus on the anesthetic experience. Useful information includes the mode and success of previous anesthetic induction, the need for sedative premedication, anesthesia drugs and techniques employed, and complications. Anesthetic plans should be modified accordingly when adverse episodes in past experience have been identified, such as induction distress, emergence agitation or delirium, airway difficulties, awareness, adverse drug reactions (e.g. malignant hyperthermia, anaphylaxis), requirement for postoperative ventilation and severe postoperative nausea and vomiting (PONV). Risk factors for postoperative vomiting (PV) in children include age greater than 3 years, surgical duration of greater than 30 min, strabismus surgery and positive history of PV for the child or PV/PONV in first-degree relatives [47,48].

An appraisal of past pain experiences is critical, particularly in the setting of a complex medical history or multiple past procedures. Important aspects of the pain history include previous difficulties with pain management (e.g. uncontrolled pain or unacceptable adverse effects from analgesic medications), past or current chronic pain, and current analgesic requirements. A systematic review searching for organ-specific conditions should be conducted, with a particular emphasis on the known associations of identified syndromes (e.g. congenital heart disease with Down syndrome) (Table 13.1). Chapter 38 outlines commonly encountered syndromes.

All current and recent medications should be identified, including prescription, "over-the-counter," herbal, and natural medications. Drug and environmental sensitivities and the nature of the adverse reaction are important in developing an appropriate treatment plan. Latex allergy is discussed in Chapter 40. Enquiry about recent immunizations is recommended. Although the interaction between anesthesia, surgery and vaccination is unclear, a delay between immunization and surgery of at least 2–3 days following an inactivated vaccine or 14–21 days following a live attenuated vaccine is recommended [49,50]. This practice avoids coinciding the time of peak incidence for systemic vaccine reactions with the perioperative period, minimizing confusion with postoperative complications [49].

#### **Physical examination**

The approach to clinical examination is tailored to the individual needs of the patient. Physical examination should be thorough, while minimizing patient exposure (for both modesty and thermoregulation) and distress. The primary focus is the airway, heart, and lungs.

Much valuable information can be obtained by direct observation of the child's physical appearance and behavior during the interview process. The quality of the child's interactions and level of co-operation with the examiner will shape the anesthesiologist's plans for anesthesia induction, including an assessment of the likely benefit of parental presence. Physical characteristics or signs that may be readily apparent during general observation include cyanosis, pallor, jaundice, nutritional state, work of breathing, oxygen requirement, conscious state, dysmorphic features (including specific syndromes), deformity (e.g. scoliosis), abnormal posture, movement disorders, and gross developmental level.

Baseline clinical observations should be recorded, including height, weight, heart rate, blood pressure, respiratory rate, oxygen saturation and temperature. Current bodyweight is essential for calculating appropriate drug doses. Weight-based dosing is simple and commonly used, despite the recognized non-linear relationship between weight and dose [51]. Calculation based on body surface area (BSA) is an alternative approach that may result in more accurate drug prescription [52]. Body Mass Index (BMI, weight [kg]/[height [m]<sup>2</sup>) is used to define overweight and obesity [53]. Childhood obesity is increasingly common and can lead to important pharmacokinetic changes, which further complicates accurate drug dose determination [54]. Co-operation during formal airway examination (as is conducted in adults) is unlikely to be forthcoming in small children. Furthermore, the parameters and scoring systems (e.g. Mallampati score) used in adult practice have not been validated in the pediatric setting. Assessment should seek to identify potential predictors of difficult intubation and/or ventilation such as limited mouth opening, stridor, obligate mouth breathing (suggesting adenoidal hypertrophy), loose teeth (risk of displacing into airway), mandibular hypoplasia/ retrognathia, macroglossia, cleft or high-arched palate, tonsillar hypertrophy, restricted cervical spine movement and scars from previous neck surgery, radiotherapy or tracheotomy.

Cardiovascular signs of interest include presence of peripheral pulses (bilateral brachial and femoral), cardiac murmurs and evidence of cardiac failure (cyanosis, tachypnea, gallop rhythm, pulmonary rales and hepatomegaly). Respiratory examination should include an assessment of respiratory effort; presence of coryza (volume, purulence); the upper airway (see above); tracheal position; chest wall deformities (e.g. scoliosis, pectus excavatum) that can be associated with restrictive lung defects; and auscultation of the lungs to detect wheeze or crackles.

Preoperative evaluation should include an evaluation of peripheral veins and nomination of sites for application of topical local anesthetic cream. Indwelling vascular access devices (e.g. Portacath, Permacath) and surgically created arteriovenous fistulas (for hemodialysis or repeat infusions, e.g. hemophilia) are located and examined for patency and signs of infection. Caution is needed to prevent compression of fistulas with either blood pressure or pneumatic tourniquet cuffs. Other implanted devices that should be identified preoperatively include feeding tubes (e.g. percutaneous gastrostomy tubes) and electronic devices such as pacemakers, automatic implantable cardiac defibrillators (AICD), deep brain and vagus nerve stimulators. Electronic devices can malfunction in the setting of surgical electrocautery or strong magnetic fields (e.g. magnetic resonance imaging (MRI)), and may require reprogramming or modification of surgical plans.

Spinal anatomy should be examined if neuraxial techniques are planned. Evidence of spinal malformation, deformity, prior surgery or local skin infection may preclude such techniques. Any pre-existing neurological deficit should be documented prior to neuraxial or regional techniques. Where relevant, the operative site is examined in order to understand the nature of the surgical pathology and extent of the planned procedure.

#### **Preoperative investigations**

Routine preoperative blood screening of healthy children has long been abandoned from practice

System	Preoperative considerations, associated disease and/or anesthetic implications
Cardiovascular	
Murmur Congenital heart disease	Clinical assessment, ECG, echocardiography, cardiology consultation Circulatory physiology (repaired, unrepaired, palliated), functional status, risk of endocarditis, anticoagulation, consultation with cardiologist
Pacemaker/AICD	Indication, mode, underlying rhythm/pacemaker dependence, date of last device check, risk of electrocautery interference, consider reprogramming to asynchronous mode and inactivate AICD for surgery
Respiratory	
Obstructive sleep apnea	Severity (polysomnography), cardiovascular complications, risk factors (young age, syndromal, airway surgery, opioid use), arrange postoperative monitoring
Prematurity	Respiratory (apnea, BPD, subglottic stenosis), cardiovascular (PDA, heart failure related to BPD), retinopathy of prematurity (caution with high inspired oxygen), see Chapters 20 and 21
Asthma	Severity and current control, recent URTI, consider short preoperative course of oral corticosteroids
Cystic fibrosis	Respiratory assessment (sputum, reactive airways, hospitalizations, exercise tolerance, pulmonary hypertension, right heart failure), nasal polyps, diabetes mellitus, malabsorption (pancreatic insufficiency), liver disease
Central nervous system	
Epilepsy	Seizure pattern and control, give regular medications, ketogenic diet (avoid glucose, potential metabolic acidosis), drug interactions, altered seizure threshold (surgery, stress, drugs, e.g. tramadol, meperidine)
Cerebral palsy	Seizures, communication difficulty, muscle spasm/contractures, poor swallowing, gastro-esophageal reflux, respiratory issues (recurrent pneumonia, poor cough, scoliosis with restrictive lung deficit)
Tumor	Raised intracranial pressure (altered conscious level, vomiting/aspiration risk), localized neurological signs (e.g. bulbar dysfunction secondary to posterior fossa mass)
Neuromuscular disease	
Muscular dystrophy	Respiratory function, cardiomyopathy, hyperkalemia with succinylcholine, volatile anesthetic-associated rhabdomyolysis
Gastrointestinal tract	
Chronic liver disease	Portal hypertension (splenomegaly, ascites, varices), coagulopathy, anemia, thrombocytopenia, hepatopulmonary syndrome, renal failure, encephalopathy, altered pharmacokinetics of anesthetic drugs
Endocrine & metabolic	
Chronic corticosteroids	Immunosuppression, hypertension, diabetes mellitus, obesity, adrenocortical suppression and potential for perioperative adrenal crisis
Diabetes mellitus	Define type of diabetes, control, complications, and treatment regime Potential problems: hypoglycemia, hyperglycemia (wound infection, osmotic diuresis, electrolyte imbalance), ketoacidosis
Obesity	Asthma, URTI, diabetes mellitus (type II), OSA, drug dosing
Renal	
Chronic renal failure	Define etiology, mode/frequency of dialysis and systemic complications (anemia, platelet dysfunction, fluid and electrolyte imbalance, metabolic acidosis, cardiovascular disease)
Hematological	
Anemia	Consider and investigate cause, severity dictates management (i.e. transfusion)
Coagulopathy	Increased bleeding risk. Replace platelets/factors in consultation with hematologist
Sickle cell disease	Anemia, vaso-occlusive disease (hyposplenism, pulmonary infarcts, stroke), cardiomegaly, renal and hepatic dysfunction. Role of perioperative transfusion unclear
Reproductive	
Possible pregnancy	Unknown risk of anesthesia in early pregnancy, consider pregnancy testing when pregnancy a possibility (follow local hospital protocol)

## Table 13.1 Review of common conditions by organ system

AICD, automatic implantable cardiac defibrillators; BPD, bronchopulmonary dysplasia; GER, gastro-esophageal reflux; OSA, obstructive sleep apnea; PDA, persistent ductus arteriosus; URTI, upper respiratory tract infection.

recommendations on the grounds that it provides little benefit to patients, has several potential disadvantages and rarely leads to alterations in patient management [55–61]. Thorough clinical assessment should instead lead to selective and targeted investigations that answer specific clinical questions. Indications for ordering investigations include diagnosing previously unrecognized conditions that may be suspected from the clinical assessment; assessing severity of known conditions; and establishing a "baseline" for parameters that may change during the treatment.

Every preoperative investigation should be carefully considered, and potential benefits balanced against inherent risk. Inappropriate testing causes unnecessary patient discomfort, wastes time and money, potentially delays surgery, can lead to additional invasive investigations in the event of false-positive results, and can have adverse medico-legal outcomes (routine tests are frequently not followed up appropriately) [62].

#### Hemoglobin

Asymptomatic anemia in the pediatric population is common yet difficult to detect clinically [57,63]. Mild-tomoderate anemia is of minimal consequence to healthy children having minor surgery and does not alter anesthetic management [64–66]. Routine testing is therefore not recommended. Severe anemia reduces oxygencarrying capacity and can impair tissue oxygen supply. A safe lower limit for hemoglobin concentration in children undergoing surgery is unclear. Preoperative management of severe anemia is dictated by the urgency of the planned surgery.

Measuring preoperative hemoglobin should be considered in certain settings, including:

- severe anemia suspected from clinical assessment
- increased baseline risk of anemia (age <1 year, chronic disease, ethnicity)
- former preterm infants, whereby anemia increases the incidence of postoperative apnea [67,68]
- to establish a baseline before surgery with potential for major blood loss.

#### Sickle cell disease

Sickle cell disease is a relatively common hematological condition, particularly in children originating from central Africa, southern Italy, northern Greece, Turkey, Saudi Arabia, and central India [69]. Sickle cell disease has significant implications for the perioperative period and unless previously tested, children at high risk should be considered for preoperative screening (hemoglobin electrophoresis) [70–72]. It is noted that detection rates for sickle cell disease during preoperative screening are very low. A Canadian study that screened 1906 children diag-

nosed 4.1% (79 children) with the sickle cell trait and 0.16% (three children) with sickle cell disease [73]. Two of the three patients who tested positive had a known family history, emphasizing the importance of thorough clinical assessment.

Patients with known sickle cell disease require preoperative hemoglobin assessment to guide perioperative management. Preoperative transfusion is recommended prior to major surgery, aiming for Hb 8–10 g/dL and HbS <30% [74,75].

#### Blood group

Blood group and antibody screening are performed when the potential for perioperative blood transfusion is significant. To minimize patient distress, specimen collection and subsequent testing can be completed following anesthetic induction. In the patient with non-ABO red cell antibodies or a history of multiple transfusions, testing is performed in advance of surgery allowing time for antibody assessment and sourcing of blood products. In sickle cell disease, extended cross-matching should include Rhesus and Kell subgroups [76].

#### **Coagulation studies**

Concern commonly exists regarding the potential for undiagnosed bleeding disorders in patients presenting for major surgery or neuraxial blockade, particularly in younger children in whom significant haemostatic challenges may not have occurred previously [77,78]. There is no evidence, however, to support routine preoperative coagulation studies (activated partial thromboplastin time (APTT), prothrombin time (PT)) in low risk patients [59,77-81]. Coagulation tests have low sensitivity and positive predictive value, and neither exclude an underlying haemostatic disorder nor predict increased bleeding risk [77-79]. A study of children with prolonged APTT attending a hematology outpatient clinic found that in 65% of cases, the initial abnormality was attributable to a sampling or processing error and that only 2.4% of initially abnormal results were due to an underlying coagulopathy [79].

Recommendations regarding preoperative coagulation testing support a targeted approach aimed at those patients deemed to be at increased risk for an underlying bleeding disorder [82]. Despite the lack of evidence to support routine testing, isolated case reports of serious coagulation disorders detected by routine testing have prompted authors to advise caution in abandoning the practice [83]. Triggers for preoperative coagulation testing include:

- family history of bleeding disorders
- a personal history of easy bruising, bleeding after minor trauma and/or recurrent epistaxis

- an underlying condition associated with coagulopathy (e.g. liver disease, malabsorption, malnutrition)
- potentially as a "baseline" prior to major surgery with a large expected transfusion requirement likely to result in acquired coagulopathy.

Standard testing with APTT, PT and a platelet count will not reliably diagnose all underlying haemostatic disorders. Conditions such as factor XIII deficiency, some forms of von Willebrand disease, and disorders of platelet function may be missed [77]. Where there is concern regarding an undiagnosed bleeding disorder, consultation with a hematologist is useful and should result in a more comprehensive battery of tests, including platelet function, specific factor assays and assessment for von Willebrand disease [79].

#### Urea, electrolytes, and creatinine

Assessment of electrolytes and renal function will be dictated by the clinical history (e.g. pre-existing renal impairment, diabetes insipidus). A recent study examining electrolyte levels in children with cardiac disease and taking cardiac medications found a low overall incidence of abnormalities requiring treatment and recommended against routine screening in this group [84].

#### Chest radiography

Routine screening chest x-ray has no role in pediatric practice [85-87]. Chest x-ray should be considered for children with cardiac, respiratory and malignant diseases. In particular, children with suspected lymphoma require a chest x-ray to exclude a mediastinal mass. The presence of a mediastinal mass is associated with significant anesthetic morbidity, including complete airway obstruction and cardiovascular collapse, and warrants careful preoperative planning. Additional imaging such as computed tomography and echocardiography is recommended to assess for compression of the trachea, bronchi, heart or great vessels, all of which are associated with increased anesthetic morbidity [88]. Furthermore, respiratory function testing with flow-volume loops may be predictive of airway obstruction during anesthesia [89].

## **Fasting guidelines**

Preoperative fasting aims to reduce the risk of gastric regurgitation and pulmonary aspiration by minimizing the volume of fluid and particulate matter in the stomach. While pulmonary aspiration is uncommon, when it does occur it can result in serious morbidity and rarely mortality [90]. Modern fasting guidelines (Table 13.2) are more liberal than previous recommendations, 
 Table 13.2
 American Society of Anesthesiologists fasting recommendations

Ingested material	Minimum fasting period (hours)
Clear fluids	2
Breast milk	4
Infant formula	6
Non-human milk	6
Light meal	6

reflecting an increased understanding of both the potential adverse effects of prolonged fasting (e.g. dehydration, hypoglycemia, patient discomfort) and the differential rate of gastric emptying of various substrates (where clear liquids are emptied at a quicker rate than solids). With fasting, neonates and young infants may be more at risk of hypoglycemia compared to older children.

Clear fluids can be safely given until 2h preoperatively with no increase in the gastric volume or reduction in pH [91]. Children allowed clear fluids are less likely to be dehydrated, less thirsty and hungry, more comfortable, and better behaved than children fasted for 6h [91,92].

Breast milk clearance from the stomach is slower than clear fluids but faster than various formula preparations [93,94]. Mean gastric emptying time for breast milk in one study was 2.43h (range 2–2.75) [95]. Despite the ASA recommendation of a 4-h fast for breast milk, some institutions have adopted a 3-h limit with no adverse clinical outcome [96].

Infants can safely consume formula until 4h preoperatively with no increase in gastric fluid volume [97]. Fasting times for formula feeds in infants varies between institutions, ranging from 4 to 6h [96,98,99]. The ASA recommends a 6-h fasting interval for formula [100]. The specific composition of the formula is also important, with factors such as osmolality, protein content, energy density, and pH all altering the rate of gastric emptying [101]. For example, whey-predominant formula empties more rapidly than casein-predominant formula [94].

Cow's milk separates into a liquid phase and a solid curd phase after mixing with acidic gastric fluid [97]. The high lipid content results in slow gastric emptying. Cow's milk is therefore treated in the same way as solid food, and a 6-h fast is recommended [100].

Fasting guidelines apply to healthy children undergoing elective surgery. The presence of factors known to delay gastric emptying should be considered when assessing aspiration risk. Gastric emptying may be reduced by trauma, pain, bowel obstruction, ileus and opioids [96,102]. Fasting recommendations vary between institutions and anesthesiologists need to be aware of local policies.

### Specific conditions requiring careful preoperative evaluation

There are a number of common scenarios or conditions that merit particular attention in the preoperative evaluation. Cerebral palsy, congenital heart disease and the ex-premature infant are covered elsewhere.

### Asthma

Asthma is a chronic inflammatory disorder of the airways characterized by recurrent episodes of bronchospasm and airflow obstruction, with symptoms of wheeze, breathlessness, and cough. The incidence of serious respiratory morbidity in asthmatic patients is reportedly low [103] but when bronchospasm does occur, it can be lifethreatening [104]. Laryngoscopy and endotracheal intubation are potent airway irritants that can precipitate bronchospasm. Intraoperative complications are associated with recent asthma symptoms, recent need for bronchodilator use and recent hospitalization for asthma symptoms [103]. Acute or poorly controlled asthma delay elective surgery. Bronchial hypershould responsiveness persists following an acute exacerbation and the risk of intraoperative airway events remains increased several weeks following resolution of symptoms [105,106].

History taking should focus on current and recent symptom control, nocturnal symptoms, bronchodilator requirements (including increasing use), recent hospitalizations, recent respiratory tract infection and prior mechanical ventilation for acute asthma (indicating severity of disease). Auscultation should ideally reveal no evidence of wheeze. If the child routinely monitors peak expiratory flow, then repeating this measurement is useful to assess current status.

A short course of corticosteroids reduces the incidence of perioperative bronchospasm [107] with no increased risk of wound infection or breakdown [108,109]. A suggested regime is oral methylprednisolone 1 mg/kg daily, commencing at least 48 h prior to surgery [110]. Administration of inhaled  $\beta$ 2-agonists prior to induction also reduces the incidence of bronchospasm in both adults and children [111–113]. Regular bronchodilators are continued on the day of surgery and an additional dose of  $\beta$ 2-agonist immediately before induction is prudent.

## **Diabetes mellitus**

Diabetes mellitus is a metabolic disorder of multiple etiologies characterized by chronic hyperglycemia with disturbances of carbohydrate, fat and protein metabolism. Diabetes is classified into type 1 (insulin dependent, prone to ketosis); type 2 (non-insulin dependent, variable insulin resistance); gestational diabetes: and "other specific types" [114]. "Other specific types" include monogenic diabetes (formerly maturity-onset diabetes of the young (MODY)); genetic defects of insulin action; disease of exocrine pancreas (e.g. cystic fibrosis); endocrinopathies (e.g. acromegaly); drug induced (e.g. corticosteroids); and associated with genetic syndromes (e.g. Prader–Willi, Down syndromes) [114].

The neuroendocrine response to surgery releases counter-regulatory hormones (e.g. cortisol, catecholamines) that result in hyperglycemia, and potentially ketoacidosis in type 1 diabetics. Fasting and the requisite reduction or omission of regular medications further compounds the situation. Perioperative hyperglycemia increases the risk of wound infection [115].

Evaluation and planning are best conducted in advance of surgery with endocrinology consultation. Assessment defines the type of diabetes, current treatment regime, quality of current control (including HbA<sub>1c</sub>), presence of complications, planned surgery, and anticipated postoperative course.

Regular medications are administered on the day before surgery with the exception of metformin, which is withheld for 24h. Where possible, surgery is scheduled for the first case of the day, minimizing fasting time (usual fasting guidelines) and facilitating planning. The aims of management are to avoid hypoglycemia, hyperglycemia (target blood glucose 90-180 mg/dL), fluid and electrolyte imbalance, and ketosis. Management of antidiabetes medication on the day of surgery is determined by the duration of surgery, usual treatment regime and local hospital protocols. A review by Rhodes et al outlines the algorithms used at the Children's Hospital Boston [116]. Regardless of the regimen (subcutaneous injection or insulin infusion), patients with type 1 diabetes must not have insulin withheld on the day of surgery. Intravenous dextrose infusion will reduce the risk of hypoglycemia. Regular glucose monitoring is mandatory in all patients throughout the perioperative period. An anesthetic that facilitates early oral intake postoperatively (e.g. regional analgesia) aids in re-establishing the usual treatment regime.

#### Epilepsy

Seizure disorders are common in children, particularly in those with abnormal brain structure and/or developmental delay (e.g. cerebral palsy). The incidence of perioperative seizures can be increased by surgical stress, fasting, interruption of usual medication regime and the administration of drugs that may alter the seizure threshold (e.g. tramadol, pethidine).

During the preoperative evaluation, it is important to establish the type and frequency of seizures, specific triggers and the quality of seizure control. Associated disease states may have particular anesthetic significance; for example, up to 50% of children with tuberous sclerosis have intracardiac rhabdomyomas, which can cause outflow obstruction or arrhythmias [117]. The patient's current treatment regime should be reviewed and may include pharmacological therapies, a ketogenic diet, vagal nerve stimulation and past surgical interventions. Chronic administration of anti-seizure medications, such as carbamazepine and phenytoin, has been associated with resistance to opioids and muscle relaxants [118–120]. Solutions containing glucose (e.g. sugary premedications) should not be administered to children who are treated with a ketogenic diet, as this may lower ketone levels and reduce the seizure threshold [121]. Vagal nerve stimulation is sometimes used to treat intractable epilepsy. Vagal nerve stimulators do not need to be reprogrammed or turned off preoperatively, but standard precautions with electrocautery should be adopted (as for permanent pacemakers) and the device's function should be checked postoperatively [122]. All regular medications should be administered on the day of surgery.

#### Heart murmur

The discovery of an undiagnosed cardiac murmur during the preoperative evaluation presents a common dilemma for anesthesiologists. Innocent cardiac murmurs are audible at some period of their life in up to 70% of children [123]. Innocent murmurs are those not associated with underlying structural or physiological abnormalities, and are therefore asymptomatic. On auscultation, they are predominantly systolic (Still's vibratory and pulmonary flow murmurs), but occasionally continuous (venous hum) [124]. While the overall incidence of structural heart defects is low, a murmur could still indicate underlying pathology with significant perioperative implications.

A pathological murmur is more likely in the presence of a positive family history (hypertrophic obstructive cardiomyopathy (HOCM), congenital heart disease); maternal diabetes, infection or drug ingestion; prematurity; chromosomal abnormality; and in the presence of symptoms such as poor feeding, failure to thrive, breathlessness, recurrent respiratory tract infections and reduced exercise tolerance [125]. General examination findings suggesting a pathological cause include low oxygen saturation/cyanosis, increased work of breathing, absent pulses and hepatomegaly. Innocent murmurs occur during early or mid systole, are usually soft (<grade III) and are associated with normal splitting of the second heart sound. They are not associated with an ejection click or palpable thrill. Typically innocent murmurs disappear or diminish with standing and increase with squatting [123]. Pansystolic or diastolic murmurs raise suspicion of underlying pathology. A normal 12-lead ECG is reassuring, while evidence of left axis deviation or left ventricular hypertrophy is cause for suspicion [126].

Differentiating innocent from pathological murmurs can be difficult, particularly when faced with an uncooperative, moving and/or crying child. Where doubt exists, surgery should be delayed and the child referred to a pediatric cardiologist [126]. If the decision is made to proceed with surgery, appropriate cardiology follow-up should occur postoperatively. Antibiotic prophylaxis is recommended only for children with unrepaired cyanotic congenital heart disease and various repaired defects [127]. Therefore very few children with a previously undiagnosed murmur who proceed with planned surgery will require antibiotic prophylaxis (i.e. cyanosis mandates further assessment).

#### **Obstructive sleep apnea**

Patients with obstructive sleep apnea (OSA) have episodes of partial and/or complete upper airway obstruction during sleep that can result in hypoxemia, hypercapnia, abnormal sleep patterns, and, if left untreated, pulmonary hypertension. OSA is common, especially in the setting of obesity, certain syndromes (e.g. Down syndrome) and in children with adenotonsillar hypertrophy.

The risk of perioperative respiratory complications is increased in OSA [17]. Preoperative assessment aims to detect OSA (although clinical diagnosis is unreliable), define disease severity and identify complications [128]. History taking should focus on identifying symptoms such as snoring, apnea, restless sleeping and behavioral problems. Physical examination of the upper airway and cardiorespiratory system should be performed. Overnight polysomnography is best practice for the diagnosis and classification of severity of OSA [129]. Echocardiography is recommended preoperatively for children with severe (SpO<sub>2</sub> <70%) or frequent desaturation events, systemic hypertension and/or evidence of right ventricular failure [129]. Children with severe OSA may benefit from preoperative continuous positive airway pressure (CPAP) [129].

During the preoperative phase, a plan should be made regarding postoperative destination (general ward versus intensive care unit) and monitoring requirements.

#### **Oncology patient**

Children with cancer require anesthesia for a variety of interventions, including the initial diagnostic evaluation (imaging, biopsies), long-term central venous access device insertion, tumor resection, radiotherapy, and intrathecal chemotherapy. Preanesthesia evaluation should identify pathophysiological manifestations of the malignancy, adverse effects of medical treatment and behavioral or psychological issues. Potential organspecific effects to consider include airway compromise (tumor, post radiotherapy); respiratory involvement (mediastinal mass, pulmonary toxicity and radiotherapy changes); cardiac toxicity (e.g. anthracycline-related cardiomyopathy); bone marrow suppression (anemia, thrombocytopenia and neutropenia); immunosuppression; and gastrointestinal disease (mucositis, vomiting and aspiration risk). Children (and their parents) requiring repeated anesthesia often develop preferences regarding elements of the anesthetic technique such as the use of sedative premedication, the mode of induction (intravenous versus inhalational), use of antiemetics and techniques for avoiding emergence agitation. Preoperative evaluation should therefore focus on exploring prior anesthetic experience and seek to identify patient preferences.

A recent series of review articles by Latham et al is recommended for a comprehensive oncology overview [130–132].

#### Upper respiratory tract infection

The incidence of upper respiratory tract infection (URTI) in children presenting for surgery is high [133]. Anesthesiologists commonly face the difficult dilemma of deciding whether the proposed surgery should proceed or not. Active or recent URTI is a well-defined risk factor for perioperative respiratory complications [7,8,22,134], including laryngospasm [7,10,14,135], bronchospasm [136,137], desaturation [136,138,139], severe coughing and airway obstruction [22]. However, most of these events are manageable, and the likelihood of long-term sequelae is minimal [15,136,140].

Every patient with URTI symptoms should be assessed on their individual merits before a decision is made to proceed with surgery. Important principles for the clinician to consider in the decision-making process are outlined below.

- Severity of symptoms. Evidence of severe URTI or potential lower respiratory tract infection typically warrants postponing surgery [133]. Standard criteria for cancellation are:
  - fever >38 or 38.5°C
  - purulent nasal discharge
  - productive cough
  - systemically unwell (e.g. poor appetite, myalgia, lethargy, "not usual self" or "too unwell to go to school")
  - lower respiratory tract signs (wheeze, crepitations).
- Duration and course of URTI symptoms. Recent onset (24–48h) of URTI symptoms may herald the onset of a serious illness that has not yet revealed its full extent. A significant condition evolving in the perioperative period increases patient discomfort and risk. Conversely, an established URTI that is improving suggests a benign course.

- Differential diagnoses. While the majority of URTI-like symptoms are due to viral URTIs (i.e. the common cold), potential differential diagnoses to consider are:
  - non-infectious rhinitis (allergic or vasomotor)
  - viral infections such as influenza, laryngotracheobronchitis (croup), bronchiolitis, measles and varicella
  - bacterial infections such as epiglottitis, tonsillitis, pneumonia and meningitis [133,141].
- Presence of the specific risk factors for adverse outcomes in the setting of URTI. These include:
  - age <1 year old [141]</li>
  - history of prematurity (<37 weeks old) [15]
  - asthma [15]
  - parental smoking [15,22,134]
  - children with congenital heart disease presenting for cardiac surgery (URTI increases respiratory complications, bacterial infections and length of ICU admission) [142].
- Clinical urgency of the planned surgical procedure. Emergency surgery proceeds regardless of an URTI because the benefits outweigh risk. For elective surgery (i.e. not time critical), the risk–benefit equation may favor cancellation.
- Type of surgery. Ear, nose and throat (ENT) and airway procedures (e.g. bronchoscopy) carry a higher risk of respiratory complications in children with and without a URTI [9,15,143]. Duration of anesthesia does not seem to be important [15].
- Anticipated plan for airway management. Facemask anesthesia is associated with the lowest risk of respiratory complications but its use is limited to certain cases [134]. Endotracheal intubation increases the risk of respiratory complications by up to 11 times [7,15]. Studies comparing endotracheal (ETT) intubation with laryngeal mask use have demonstrated an increase in the total number of respiratory complications in the ETT group [22,144]. If airway manipulation is unavoidable, some anesthesiologists may elect to defer surgery.
- Social and logistic considerations. Frequently families have made major commitments (e.g. time off work/ school, interstate travel) to attend hospital for the scheduled surgery. While the child should not be put at risk to avoid inconvenience, in borderline cases this may be an important consideration. Cancellation has a significant social, emotional and economic impact on patients and their families [145].

An informed discussion involving the anesthesiologist, parent(s) and surgeon is essential. The potential risks and benefits of proceeding versus cancellation need to be well communicated, and all parties involved in reaching a decision. Cancellation is prudent if either the surgeon or family expresses significant concern. Details of any discussion should be clearly documented in the medical record.

In the case of procedure deferment, the optimal time to reschedule must be determined. It is established that bronchial hyper-responsiveness (BHR) persists beyond the duration of URTI symptoms, returning to baseline by 6 weeks [146,147]. A prospective study of 1078 children found an increased risk for 4 weeks following URTI [15], while a recent prospective cohort study of 9297 children found risk was increased for the first 2 weeks but lowered between 2 and 4 weeks post URTI [22]. No consensus exists regarding optimal timing for surgery after simple URTI but a delay of 2–4 weeks following resolution of symptoms seems reasonable.

Preoperative bronchodilators may be effective in reducing respiratory complications, although the evidence is unclear. A study by Elwood found no benefit in the administration of preoperative bronchodilators (albuterol or ipratropium) in a select population of children having non-airway, non-cavity surgery [148]. Importantly, the rate of respiratory complications in control and URTI groups was identical. A recent study demonstrated a 50% reduction in the rate of perioperative bronchospasm and severe cough in children with recent URTI who were given salbutamol 10–30 min before surgery [149].

Intraoperative management of the child with a URTI is discussed in Chapter 15.

# Preoperative anxiety and psychological preparation of the child

Surgery and anesthesia can be frightening and stressful experiences for a child. Many children cry, scream, verbally express fear or sadness, protest, attempt to escape the procedure and/or physically or verbally resist mask placement for anesthesia [150]. Up to 40-50% of children experience high levels of anxiety in the preoperative period [150,151], which peaks during mask placement and may delay the induction process [150]. In cases of extreme distress and anxiety, it is not uncommon for children to be physically restrained during induction [152], which can be emotionally traumatic for children, parents, and medical staff and lead to dissatisfaction with the anesthetic experience [153]. Preoperative anxiety has implications for postoperative recovery, with research suggesting that high levels of preoperative anxiety are associated with increased pain, longer times to discharge, higher rates of emergence delirium and increased behavioral problems in the days and weeks following surgery [154–156]. Of particular concern, the nature of children's early experiences with anesthesia and surgery (whether positive or negative) may predispose them to better or worse reactions to future surgical experiences [156,157]. Therefore it is critically important that we aim to minimize children's anxiety and distress during this vulnerable period in order to lessen adverse psychological reactions and increase children's and their parents' overall satisfaction with the experience.

#### **Risk factors**

The experience of having general anesthesia and surgery alone does not determine the amount of anxiety and distress children experience. Factors which influence distress include the child's age and developmental stage, individual temperament traits, coping style, parental anxiety, and previous medical experiences [151].

Research has shown that younger children (7 years or less) are particularly vulnerable to anxiety and distress during the preoperative period [150,151]. Young children find it hard to understand why they must have surgery. Some young children may believe that surgery, illness and hospitalization are punishments for being naughty or the result of a deliberate desire of the clinician to hurt them [158]. Further, young children tend to worry about separation from their parents and fear strangers. With advancing age, children are able to invoke some type of coping strategy and seek more information about their procedure. However, although high levels of anxiety are more common among younger children, up to 30% of school-aged children also show extreme levels of anxiety and distress during the preoperative period [150]. Older children may regress to a more basic level of reasoning when faced with the prospect of surgery and may be more upset with dealing with the medical practitioners themselves. Adolescents may fear health and body integrity.

Individual temperament traits and coping styles have also been suggested as placing a child at risk of anxiety during the preoperative period [154]. Specifically, research suggests that children with a "shy-inhibited" temperament are more likely to be highly anxious during this period [154,159]. Children with these temperament traits are predisposed to be more fearful of others and highly aroused and emotional in unfamiliar situations [160]. In addition, children who use avoidance behaviors as a way of coping with stress have also been found to be more likely to show higher levels of preoperative anxiety [161]. These children attempt to ignore the situation, withdraw, avoid information and use wishful thinking ("I wish I wasn't sick") as their primary means to cope with their stress. In contrast, children who engage in approach behaviors, such as information seeking, non-procedural talk, coping statements and humor, have been found to show less distress upon induction to anesthesia[150].

Multiple previous hospital admissions and surgeries have also been linked with high preoperative anxiety [154]. Research suggests that children do not necessarily habituate to repeated procedures and past aversive experiences may increase the negative emotions associated with surgery and may thereby interfere with coping [154,162]. In comparison, for children with good-quality past surgery experiences, repeated experience may facilitate the development of adaptive skills and may lessen levels of preoperative anxiety. Therefore, what appears to be important is the quality of children's past medical experiences rather than just having a previous experience per se. Other factors, such as parental anxiety, have been shown to influence the relationship between multiple surgeries and anxiety. For example, Kain et al [163] found that on average, children's anxiety did not differ at their second surgery compared with their first, but at the second surgery parental anxiety was significantly lower.

Parental behavior and level of anxiety during the preoperative period have been found to have a strong influence on children's anxiety levels [154]. Anxious parents tend to elicit agitation and anxiety by their presence and this is especially the case when a parent is so distressed that they cannot assist their child to cope. In addition, parents who use emotion-focused behaviors (reassurance, apologies, empathy, and empathetic touch) are also more likely to elicit distress from their child [164]. This type of response or conversation tends to draw children's attention to the surgery and conveys the message that the surgery is something to worry about and be frightened of. In comparison, parents who use distracting behaviors (non-procedure related conversation and humor) or encourage the use of coping skills (e.g. "You're helping your whole body feel better by doing your breathing") are more likely to promote their child's ability to cope with the stress of surgery. This is because these behaviors convey the message that surgery and anesthesia are manageable.

#### Assessment of anxiety

Methods for assessing preoperative anxiety and distress have primarily relied on observational ratings of children's overt behaviors, such as facial expressions, crying, torso movements, kicking, verbal protest, and need for restraint. The most frequently used measures are the Yale Preoperative Anxiety Scale [165] (designed for use during induction of anesthesia) and the modified Yale Preoperative Anxiety Scale (Box 13.1) [166] (designed for use during the induction phase and in the preoperative holding area). On both versions of this scale, items fall into one of five categories of behavior (activity, emotional expressivity, use of parents, state of arousal and vocalization) and clinicians rate the behaviors they observe. The benefits of Yale scales are that they can be used with children as young as 2 years of age and are quick and easy to administer.

**Box 13.1** Modified Yale Preoperative Anxiety Scale (m-YPAS). The child is scored for each domain and scores are then added giving a total score from 5 to 22 with a higher score representing more distress [166]

#### Activity

- The child is looking around curiously, playing with toys, reading (or other age-appropriate behavior); moves around the holding area/ treatment room to get toys or to go to parent; may move toward operating room.
- Not exploring or playing, may look down, fidget with hands or suck thumb (blanket); may sit close to parent while waiting, or play has a definite manic quality.
- Moving from toy to parent in unfocused manner, non-activity derived movements; frenetic/frenzied movement or play; squirming, moving on table; may push mask away or cling to parent.
- Actively trying to get away, pushes with feet and arms, may move whole body; in waiting room, running around unfocused, not looking at toys, will not separate from parent, desperate clinging.

#### Vocalizations

- Reading (non-vocalizing appropriate to activity), asking questions, making comments, babbling, laughing, readily answers questions but may be generally quiet; child too young to talk in social situations or too engrossed in play to respond.
- 2. Responding to adults but whispers, "baby talk," only head nodding.
- 3. Quiet, no sounds or responses to adults.
- 4. Whimpering, moaning, groaning, silently crying.
- 5. Crying or may be screaming "no."
- 6. Crying, screaming loudly, sustained (audible through mask).

#### **Emotional expressivity**

- 1. Manifestly happy, smiling or concentrating on play.
- 2. Neutral, no visible expression on face.
- 3. Worried (sad) to frightened, sad, worried or tearful eyes.
- 4. Distressed, crying, extreme upset may have wide eyes.

#### State of apparent arousal

- Alert, looks around occasionally, notices or watches what anesthesiologist does (could be relaxed).
- 2. Withdrawn, sitting still and quiet, may be sucking on thumb or have face turned into adult.
- **3.** Vigilant, looking quickly all around, may startle to sounds, eyes wide, body tense.
- Panicked whimpering, may be crying or pushing others away, turns away.

#### Use of parents

- Busy playing, sitting idle or engaged in age-appropriate behavior and doesn't need parent; may interact with parent if parent initiates the interaction.
- Reaches out to parent (approaches parent and speaks to otherwise silent parent), seeks and accepts comfort, may lean against parent.
- **3.** Looks to parent quietly, apparently watches actions, doesn't seek contact or comfort, accepts it if offered or clings to parent.
- Keeps parent at distance or may actively withdraw from parent, may push parent away or desperately clinging to parent and not let parent go.

Tab	le	13.3	Inductior	ı Comp	liance	Checklist	[167]
-----	----	------	-----------	--------	--------	-----------	-------

Checklist	Score
Perfect induction (does not exhibit negative behaviors, fear or anxiety)	
Crying, tears in eyes	
Turns head away from mask	
Verbal refusal, says "no"	
Verbalization indicating fear or worry, "where's Mommy?" or "will it hurt?"	
Pushes mask away with hands, pushes nurse/anesthetist with hands/feet	
Covers mouth/nose with hands/arms or buries face	
Hysterical crying, may scream	
Kicks/flails legs/arms, arches back, and/or general struggling	
Requires physical restraint	
Complete passivity, either rigid or limp	
Total score (number of categories checked, perfect score = 0)	

Figure 13.1 Generic visual analog scale used to assess the child's perception of their anxiety levels.

Observational methods of children's co-operation during induction have also been frequently used as a proxy measure of children's distress levels. The most commonly used is the Induction Compliance Checklist (Table 13.3) [167], which contains 10 possible negative or uncooperative behavioral responses to induction (such as crying, turning head away from mask, verbal refusal, verbalization of fear, physically resists mask, kicking and thrashing about, requires restraint, passive). The higher the number of negative behavior responses, the lower the rate of compliance, with a score of 0 representing a perfect induction.

Other less frequently used measures include self-report measures, such as a visual analog scale (VAS) [168], whereby children rate their anxiety on a scale from 0–100 (Fig. 13.1). As anxiety and distress are subjective experiences, self-reported measures are perhaps the most valid way to assess anxiety. However, for children undergoing induction of anesthesia, it is often not practical to obtain these ratings and self-report measures are also not suitable for very young children.

Physiological measures of anxiety and stress, such as levels of serum cortisol (a steroid hormone released in response to stress), have also been used in a small number of studies [169]. Serum cortisol levels are obtained immediately after induction of anesthesia via a blood sample. Ideally a baseline level of cortisol is needed to make sense of these findings, but it is not practical to sample children's blood prior to surgery. Other physiological indicators of anxiety such as heart rate and blood pressure are not suitable for this setting as they may be influenced by a range of other factors. These physiological indices are neither sensitive nor specific indictors of anxiety.

# Non-pharmacological preparation programs

Knowledge of the growing literature for assisting children and their families facing surgical experiences is important for any anesthesiologist embarking on doing work with children. A number of different nonpharmacological interventions designed to reduce preoperative anxiety and increase compliance during induction have been described in the literature. Interventions have been targeted at the child, parent or both and include:

- cognitive or behavioral interventions, such as teaching coping skills, distraction, hypnosis, modeling and rehearsal, and shaping and exposure
- parenting interventions, such as acupuncture, psychoeducation and instruction on reinforcing children's coping behaviors during the procedure
- contextual interventions: parental presence, low sensory environment, use of induction room, patient retains own clothing, disguised anesthesia delivery systems.

With the exception of parental presence, the majority of evidence for specific non-pharmacological interventions is based on one or two single studies. Furthermore, published intervention trials often differ in terms of sample selection, blinding procedures and outcomes measures and often use a combination of interventions (e.g. parental presence and premedication). Such methodological differences have made it difficult to compare results across studies. Another limitation of current research is that few trials have stratified for age or examined adolescents. This is problematic given that past research has indicated that younger children are most at risk of preoperative anxiety [151], although even older children

report high levels of anxiety during this stressful period [150]. Children with chronic illness, developmental delay, behavioral problems and previous surgical or hospitalization experiences have also been excluded from the majority of intervention trials. Given that these children may benefit most from interventions to reduce anxiety and increase co-operation and that these are the groups of children who present most often for surgery, exclusion of these children from studies represents a significant gap in the literature. With these limitations in mind, Yip et al [170] recently conducted a Cochrane Database review examining non-pharmacological interventions for assisting the induction of anesthesia in children. Their review included 17 trials involving 1796 children, their parents or both. Eight trials assessed parental presence and the remaining trials examined a range of different nonpharmacological interventions, directed at either children or parents. No evidence was found to support parental presence during induction or education of parents (i.e. in the form of pamphlets or videos) in reducing anxiety or improving co-operation of children. In comparison, based on single studies, promising evidence was found for acupuncture for parents, clown doctors, a quiet environment, video games and computer packages. The authors concluded that large randomized controlled trials are needed to determine the efficacy of these promising interventions.

Despite promising evidence to support a range of non-pharmacological interventions to reduce anxiety and increase co-operation in children, the translation of this research into practice has been limited. For example, in a study by O'Byrne et al [171] which surveyed a large sample of psychological experts, the majority rated coping skills, relaxation, and film as the most effective preparation procedures. Hospital tours, printed materials and narrative preparation were rated as the least effective. However, in a subsequent study surveying hospital staff, it was found that the least effective methods are actually the most frequently used in the "real world." They concluded that this is likely due to their ease of administration and cost-effectiveness whereas largescale psychological interventions are often time consuming, expensive and not universally effective. Thus, the challenge is to find low-cost, easy-to-administer interventions and to target children who will most benefit from these types of non-pharmacological methods (rather than provide interventions to all children universally).

The finding that non-pharmacological interventions are not necessarily helpful for all children experiencing preoperative anxiety means that it is important that interventions are tailored to the individual child. Factors such as age, developmental level and past medical experiences have all been shown to affect the effectiveness of interventions aimed at reducing anxiety in children [162]. For example, Kain et al [162] found that the optimal timing of preparation depends on the age of the child. In their study, children aged 6 years or older were less anxious if prepared 5-7 days prior to surgery, and most anxious if presented with information within 24h of surgery. In comparison, children aged 3-6 years may benefit from preparatory information closer to the time of surgery. Children with past surgical experiences may not need the same level of preparation as those without past surgical experiences, as these children are likely to know what to expect. Research suggests that these children may benefit less from information-based preparatory programs and more from programs that focus on facilitating coping skills [162]. Further, the quality of children's past surgical experiences (whether positive or negative) needs to be taken into account when designing these programs [172].

Below we have briefly reviewed a number of nonpharmacological interventions.

#### Distraction

Distraction is a simple cognitive behavioral strategy that helps reduce children's distress. The goal is to focus the child's attention away from the upsetting aspects of the procedure and towards relatively more pleasant alternative stimuli. While a variety of distraction techniques exists, to be effective, the distraction technique must be age appropriate, and it must be appealing to the recipient.

Given their broad appeal, video games have been used in a variety of healthcare settings to distract children [173,174]. The benefit of video games is that they require active participation (as opposed to a passive activity such as watching television) and therefore are thought to engage sufficient attention resources of the child in order to distract them. To date, one study has utilized video games as a means of distraction during induction of anesthesia [175]. These authors found that children aged 4-12 years who played with a hand-held video game had less anxiety at induction compared with children who only had their parent present. No difference was seen in anxiety levels between children who played a video game children who received premedication with and midazolam.

Music therapy has been shown to achieve a significant reduction in preoperative anxiety at separation of parents and entry into the operating theater but not during induction of anesthesia [176]. Anxiety has been found to be at its highest during mask placement and it is possible that passive activities are not sufficient to engage children's attention during periods of extreme stress. Similarly, other more passive methods of distraction, such as use of novel toys, books and blowing bubbles, have not been found to reduce anxiety during induction compared with parental presence alone [177].

The presence of clown doctors during the induction of anesthesia has been shown to be an effective intervention for reducing anxiety for children in the preoperative waiting area in two studies [178,179]. However, the presence of clowns does not necessarily reduce anxiety during induction of anesthesia, with one study showing that anxiety in children accompanied by clowns actually peaks during this period and is greater than the anxiety found in children receiving midazolam or no intervention [179]. While further studies investigating the efficacy of this intervention are needed, it is interesting to note that Vagnoli et al found much resistance from staff regarding the use of clown doctors [178]. They found that while the majority of staff acknowledged the effectiveness of this technique, many were not in favor of utilizing clown doctors as it was believed that they would interfere with the operating room routine. This finding highlights the importance of considering the practicality of certain interventions.

#### Parental presence

Having a parent present during induction is thought to reduce the child's anxiety by providing comfort and eliminating separation anxiety [180]. As noted previously, parental presence during the induction of anesthesia has been the most extensively studied non-pharmacological intervention aimed at reducing anxiety and increasing co-operation in children. Most children prefer a parent to be with them and most parents prefer to be present during induction [181,182]. Further, an overwhelming proportion of parents believe that they were of some help to their child and the anesthesiologist during induction [169,181,183]. However, well-controlled randomized control trials have not shown this intervention to be effective for the reduction of children's preoperative anxiety or increase in children's compliance [170]. The reasons for this are not well understood, but some recent research has suggested that it may be what parents actually do and say during induction that is more critical to the reduction of children's anxiety than their mere presence. For example, parental behaviors such as criticism, excessive reassurance and commands have been associated with increased anxiety levels in children, whereas parenting behaviors aimed at distracting children or prompting coping skills have been associated with reduction in children's anxiety and distress [164]. Some research suggests that parents take their cues from anesthesiologists and nurses about how to behave during induction. When anesthesiologists use more non-procedural talk and humor, so do parents [164]. Thus, training medical staff may directly affect parents' behavior by engaging in higher rates of desirable behaviors themselves [150].

#### Hypnosis

Hypnosis uses relaxation, focused guided imagery, suggestions and therapeutic metaphors to build self-control over physical and emotional symptoms. Use of hypnosis is not recommended without appropriate training. Professionals using hypnosis as part of their treatment should have appropriate credentials from a recognized hypnotherapy association. In Australia, this association is known as the Australian Society of Hypnosis. To date, one study has evaluated the efficacy of hypnosis on anxiety versus midazolam [184]. It found that compared with midazolam, fewer children were anxious during induction in the hypnosis group compared to the midazolam group.

#### Acupuncture

Acupuncture is part of traditional Chinese medicine and involves inserting fine needles into specific points on the skin or applying various other techniques to the acupuncture points to bring about healing or relief from pain. One study has evaluated the efficacy of acupuncture in alleviating anxiety in parents of children undergoing surgery [185]. They found that children of parents who had anxiety reduction acupuncture prior to induction were less anxious and more co-operative during induction than children whose parents who received sham acupuncture. Parents' subjective ratings of anxiety were also less in the group who had anxiety reduction acupuncture rather than sham acupuncture.

#### **Environmental modifications**

The equipment, bright lights, the number of medical staff interacting with the child and high noise levels of the induction room are all believed to contribute to children's increased anxiety during induction of anesthesia. Few studies, however, have investigated the impact simple modifications to the environment may have on children's levels of anxiety and co-operation during induction. In one study, a low sensory input group (dimmed OR lights, only one person (the anesthesiologist) interacting with the child and soft classical music played in the background) was compared to a control group (usual practice) [186]. The authors found that children in the low sensory input group were less anxious and more co-operative during induction. However, it is unclear which aspect was most effective.

#### **Educational programs**

Preoperative education programs take various forms, including information leaflets and tours of the theater environment, videos depicting children going to theater, role play or psychological preparation. Educational programs may target parents or children or both. In studies investigating the effect of educational programs on parental anxiety, there has been some evidence to suggest that parents who participate in a preparation program or who view a preoperative video regarding anesthesia demonstrate reduced anxiety on the day of surgery [30,162]. Others, however, have found that this reduction in anxiety does not extend to the important and most stressful time of anesthetic induction [187].

Evidence for the efficacy of information-based programs designed for children to reduce their levels of preoperative anxiety has been mixed. Some studies have shown that information-based preparations (including tour of OR, watching a video showing a child from surgery to discharge and medical play with dolls for 30min) are successful at reducing anxiety in the preoperative holding area. However, this reduction in anxiety is temporary and does not extend to after separation from parents or induction of anesthesia. Others, however, have failed to find evidence for the efficacy of information-based programs for either the preoperative holding area or anesthesia induction. In a more recent study, an interactive computer program was used to prepare children for dental surgery and compared to a cartoon strip or no preparations [188]. Preparation with interactive computer packages (in addition to parental presence) was more effective in making children more co-operative during induction compared to parental presence alone.

# Pharmacological interventions for reducing anxiety

## Goals of premedication

There is no doubt that pharmacological premedication is an important, and often the best strategy to reduce anxiety in children. As stated in an early editorial, "if anxiolysis is the objective, premedication is the treatment" [189]. Other non-pharmacological strategies do not always provide a reliable and constant effect on preoperative level of anxiety. The aim of sedative premedication is to decrease the preoperative level of anxiety in children, facilitate parental separation, enhance the child's collaboration at induction of anesthesia, and improve recovery and postoperative outcome.

The decision to premedicate a child should not be based on set recipes or routine prescriptions for all children, but should be integrated within a global assessment of the child's needs and be part of the overall preoperative preparation for anesthesia. Medication should not be the rescue solution to a lack of proper preoperative assessment and interaction with the child and family. Premedication should be a supplemental strategy to reduce the child's anxiety and facilitate parental separation.

#### Pros and cons of premedication

There is controversy over the use of premedication, particularly over its routine use, for every child [190]. The arguments in favor of administering premedication stem from concern that preoperative anxiety and stress lead to negative postoperative outcomes such as emergence delirium, negative postoperative behavior changes, and increased postoperative pain [25,154,190]. Moreover, preoperative anxiety enhances neurohumoral response to stress, which further contributes to adverse postoperative outcomes [191]. Those who support systematic premedication highlight the impact of preoperative anxiety on these adverse outcomes and thus the potential benefit of an anxiolytic and sedative agent such as midazolam [192]. There is no doubt that many randomized controlled trials have highlighted the beneficial effect of midazolam in reducing preoperative anxiety and improving coping capabilities during induction of anesthesia [167,193]. Furthermore, the use of premedication is associated with reduced anxiety and improved satisfaction with the anesthesia management in the parents[167].

A reduction in postoperative behavior disorders (POBD) is one aim of premedication but there are conflicting data in the literature regarding the real benefit of this premedication in preventing the occurrence of negative postoperative behavior. While some authors have shown a higher incidence of arousal distress [194] and POBD after midazolam premedication [184,195], others have demonstrated no effects [155] or a slight decrease and limited in time [196]. More strikingly, preparing children with a non-pharmacological hypnotic strategy led to a significantly lower incidence of POBD than those who received midazolam [184]. The reason for this discrepancy may be due to a negative effect of the anterograde amnesia induced by midazolam in children [197,198]. Midazolam exerts a dissociative effect on memory by inhibiting explicit memory while implicit memory is preserved [199]. As implicit memory is involved in behavior, midazolam may potentiate POBD by not protecting the child from unconscious memory of preoperative events with a negative and emotional content. The child may be unable to report these memories consciously in the postoperative phase but rather express them postoperatively with negative behavior. The potentially negative effect of midazolam on memory and the recent development of successful cognitive behavioral therapies to reduce preoperative anxiety reinforced the arguments against the use of systematic premedication in children.

The development of a specific child-friendly environment [190], specific preoperative programs based on a multimodal information strategy [33,190,200], and extending the indications for parental presence at induction [169,190,201] have contributed to a reduction in preoperative anxiety and hence reduced the need to rely solely on pharmacological approaches. However, one should keep in mind that there will still be some children (especially preschool children) who may need a sedative premedication despite the application of all other strategies described. Sedative premedication should be given selectively and at the discretion of the anesthesiologist.

#### Most commonly used drugs

The sedative premedications used vary from one country to another but midazolam and clonidine are the most popular and most studied drugs with midazolam being the most widely and frequently administered sedative agent in children. The intravenous solution of midazolam allows administration by different routes (intranasally at 0.3 mg/kg, orally 0.25-0.5 mg/kg, rectally 0.5 mg/kg, and sublingually 0.3 mg/kg) and, being highly lipophilic in physiological pH, midazolam provides beneficial pharmacokinetic properties with rapid onset of action. In recent studies, the level of sedation and anxiolysis was considered as satisfactory in more than 75% of children after  $7.7 \pm 2.4 \text{ min}$ ,  $12.5 \pm 4.9 \text{ min}$  and  $16.3 \pm 4.2 \text{ min}$ respectively following intranasal, oral or rectal administration [202,203].

The oral route is the most popular and recommended administration mode. The nasal route is uncomfortable and seems to be associated with a potentially higher risk for paradoxical reactions [204,205]. The rectal route has also been largely abandoned since the absorption and concentration levels are unpredictable.

The half-life of midazolam can be very variable since the drug is essentially metabolized by the liver by the CYP450 enzyme system, particularly the subtypes 3A3 and 3A4 which have been found to be very variable between patients [206,207]. Moreover, many drugs can affect the CYP450 activity and contribute to the prolongation of the half-life.

Despite a relatively high safety profile, there are clinical situations where midazolam should be administered with caution because of the risk for airway obstruction, such as in children with large tonsils [208] and/or with obstructive sleep apnea. In addition, it has been recently demonstrated in children that midazolam induces a decrease in functional residual capacity, which may affect gas exchange in those with cardiopulmonary disease [209].

Clonidine, an  $\alpha$ 2-adrenoceptor agonist, is nowadays the best alternative agent to midazolam [210]. It provides anxiolysis and sedation [211] without affecting cognitive function or memory [212]. In addition, its analgesic properties can be beneficial in children [213]. Furthermore, studies have demonstrated the beneficial effect of clonidine premedication in preventing agitation at induction of anesthesia with sevoflurane [214], and a decrease in the incidence of emergence delirium [215]. Clonidine can be administered by the intravenous, intramuscular, transdermal, oral and rectal routes [216]. It is mostly administered via the oral route at a dose of 4µg/kg. Pharmacokinetic studies in children confirm that following oral administration, the bio-availability is relatively low (55%) and the maximum concentration level is obtained after 1h [217]. Clonidine should be administered at least 60 min prior to induction to be effective. The elimination half-life of clonidine in children is similar to that observed in adults, at around 9h [216]. This explains the longer sedative effect seen in children premeditated with clonidine. This prolonged sedation may be seen as a benefit or a problem postoperatively, with children better sedated and calmer but slower to leave the postanesthesia care unit (PACU). The sedative-anxiolytic effect of clonidine is mediated by the hyperpolarization of the ascending noradrenergic neurons in the locus ceruleus consequent on the inhibition of calcium entry into calcium channels in nerve terminals and change in membrane ion conductance [218].

Clonidine has a good therapeutic profile with very few contraindications to its administration. While the best indication could be children with obstructive sleep apnea syndrome, clonidine should be used with caution in children treated on a long-term basis with methylphenidate (Ritalin®) since this latter may also blunt sympathetic response and an association with clonidine may lead to a bradycardia and cardiovascular collapse at induction of anesthesia [219].

Ketamine is also used occasionally for premedication. It needs to be administered at a high dosage (5-10 mg/kg intrarectally or orally) to be effective and thus may induce a greater incidence of adverse events [220] and prolong postoperative sedation [221]. Intramuscular administration of ketamine (4mg/kg) provides a dissociative sedation within 5–20 min but may have a higher incidence of respiratory adverse events and laryngospasm and should be performed under close monitoring [222]. Some authors have suggested adding midazolam 0.5 mg/kg to ketamine at 3mg/kg orally to decrease the incidence of adverse events, shorten the onset time and decrease the recovery time [223]. In spite of the above concerns, there is still a place for ketamine, particularly intramuscular ketamine, in extremely anxious and unco-operative children who refuse to take premedication orally and in those who are unwilling to have any contact with health providers who are not part of their usual environment, such

as autistic [223] or hyperactive children treated by methylphenidate (Ritalin®).

Recently, new interest has been focused on melatonin but there are conflicting data in the literature regarding the anxiolytic effect of this agent [224,225]. Studies have demonstrated that oral melatonin at a dose of 0.2–0.4 mg/ kg reduces the incidence of emergence delirium [225] and may prevent the occurrence of sleep disturbance at week 2 postoperatively [224].

Finally, one should not forget premedication with nonsedative drugs such as paracetamol to initiate pain treatment [226], salbutamol in children with bronchial hyper-responsiveness [149], and antibiotics as recommended by the American Heart Association [127].

In summary, it is important to reduce preoperative anxiety in children. Pharmacological premedication is one aspect of the multimodal approach that includes nonpharmacological interventions such as behavioral preparation programs, parental presence at induction, and distraction techniques. There is no single medication that fits all children of all ages and pharmacological premedication should be administered according to the interaction between the child, the parents and the anesthesiologist during the preoperative assessment.

# Awareness and recall in pediatric anestheisa

Recently awareness has become a topic of major interest to the pediatric anesthesiologist. This is largely because of several studies which have shown a relatively high rate of awareness in children compared to adults [227–231]. Although the data are scarce, these studies may also suggest that the causes and consequences of awareness may be different in children.

#### What is awareness?

The usual definition of awareness is the explicit recall of an event that occurred during anesthesia. However, it is also possible to be awake during anesthesia without recall, and it is also possible to form implicit memory during anesthesia. Explicit recall is memory which is consciously recalled. Implicit memory is memory which leads to alterations in behavior with no conscious recollection.

#### The maturation of memory processes

Before discussing awareness in children, it is useful to have a brief understanding of what memory and consciousness are, and how they develop.

#### Consciousness

The study of consciousness is a controversial topic. From a philosophical perspective, being conscious involves having your own private world of sensations which are linked in a single being and which connect with other past experiences beyond the immediate physical sensation [232,233]. Anesthesiologists tend to take a more practical view of consciousness. Being conscious is being aware of the environment, and is often measured by seeking evidence of cognition or a coherent response to command. Being awake during an anesthetic is being conscious during the anesthetic.

#### Memory

Memory is divided into short-term (working) memory and long-term memory. Long-term memory is further classified as implicit or explicit. Explicit memory may contain semantic knowledge (facts) or episodic knowledge (what you remember doing). There are four basic steps to memory: encoding, consolidation, storage and retrieval. Encoding is the process of attending to information and associating it meaningfully and systematically with established memory. Memory is more easily encoded if it "fits in" easily and if there is a stronger motivation for encoding. Consolidation is the process of shaping the new information to enable long-term storage. Retrieval is the process of bringing memory back into working or short-term memory. Retrieval is most effective when the cues or context for retrieval closely resemble those present at encoding.

#### Implicit memory

Implicit memory is memory that unconsciously alters behavior. It does not require conscious processing for encoding or retrieval. Types of implicit memory include non-associative habituation or sensitization, and associative learning such as classic or operative conditioning.

#### Development of memory and consciousness

The point at which a human becomes conscious is controversial but certainly relevant to pediatric anesthesiologists. Evidence for consciousness can be assumed if there is evidence of thought or of a sense of self. Infants do show signs of thinking. If you show an infant an attractive object and suddenly plunge them into darkness, they will still search for the object [234]. Similarly, an infant will show greater attention to situations inconsistent with previous knowledge, such as objects that when released seem to defy gravity. Evidence for self is harder to determine but in the toddler clear evidence of self can be seen in the use of the pronouns such as "I" and "we." While all agree that infants are indeed conscious, it is hard to find good measures for precisely when an infant or toddler is conscious or unconscious from an anesthesiologist's perspective. Loss of response to command is used as a standard measure of consciousness in adult anesthesia. This requires language, understanding and motivation – all of which may not be possible in small children.

If we look back from adulthood, we cannot remember much about what happened before we were 3 years of age. This is known as "infantile amnesia." This, along with poorly developed language, makes the assessment of memory difficult in young children. There is, however, good evidence of memory from an early age. Implicit memory develops before explicit memory. Non-associative memory has been demonstrated in the fetus. A newborn will respond to their mother's voice, which they have heard during the last weeks of pregnancy, but not their father's [235,236]. Associative memory can be demonstrated in a neonate's response to painful stimuli such as heelprick [237].

The development of explicit memory is probably linked to the development of language. Good evidence for explicit memory can be found from around 3 years of age [238] and continues to develop throughout childhood. With increasing age, children can store increasing numbers of items in their working memory, and encoding, consolidation and retrieval are faster and more accurate as the child has a better understanding of events and increasing depth of experience. These factors must be borne in mind when considering how we assess explicit recall and awareness under anesthesia in children.

#### Measuring awareness in children

The measurement of awareness is inherently imprecise and subjective; it is even more so in children. If we simply ask a child if they remembered anything during the anesthesia, then they may not be able to differentiate between memories formed during anesthesia and those formed in the PACU. Similarly, they may report dreams or other forms of inaccurate or false memories. In adult awareness studies, researchers have sought to standardize studies by using an interview similar to that originally described by Brice [239]. However, its structure is unsuitable for children [228]. Children have poorer memory encoding, consolidation and retrieval strategies. Without carefully building context during questioning, children may not retrieve an awareness memory. Open-ended or temporally inconsistent questions such as used in the Brice interview could lead to an underestimate of awareness in children. Awareness may also be underestimated as confirmation of awareness relies on the richness of the memory. Children's memory may contain errors which make such confirmation more fraught with difficulties.

Children also have poorer source monitoring; they are more likely to confuse the origin or place of a memory. This is particularly likely if leading or repeated questions are used, which may implant memory. This may overestimate the incidence of awareness in children. Thus poor interview techniques can result in awareness being either under- or over-reported in children [240].

#### Children being awake during anesthesia

The isolated forearm technique involves inflating a tourniquet around the arm of a patient, before any neuromuscular blocking agents are given, and then repeatedly asking the patient to squeeze the researcher's hand. Isolated forearm technique studies in the adult population have demonstrated that patients may be awake and paralyzed during routine anesthesia with few clinical signs of being awake [241]. Typically, few of these patients have any explicit recall of being awake. Byers and Muir also used an isolated forearm technique during induction of anesthesia in children and found that many children responded to commands, though none had subsequent explicit recall [242]. Andrade et al performed a similar study during anesthesia but found that very few children responded to command [243].

#### Awareness in adults

Before looking more closely at awareness in children, it is useful to quickly recap what we know about awareness in adults. In adults, most studies find an incidence of awareness during routine anesthesia of roughly 1:2000 cases [244-247]. Lower or higher incidences may be due to different populations or ways in which awareness is assessed [248,249]. Risk factors include presence of paralysis or significant cardiovascular compromise, anesthesia for trauma, bronchoscopy, obstetrics and cardiac surgery, and a family history of awareness [246,248,250-257]. It is unclear if total intravenous anesthesia is also a risk factor [258-260]. Awareness is often not volunteered unprompted and there may be some delay in reporting [246]. In adults, awareness is usually auditory but may also include pain or feelings of paralysis. Awareness may be associated with tachycardia or hypertension but these signs are often present without awareness [261]. In adults, awareness is most commonly due to inadvertent light anesthesia after mishap or misjudgment [248,262]. Awareness under light anesthesia may also occur where the patient cannot tolerate larger doses of anesthesia (such as trauma or caesarean section).

Most adults who are aware do not enjoy the experience [263]. Many show anxiety postoperatively, some may avoid future anesthesia and some may develop posttraumatic stress disorder (PTSD) and other significant and persistent psychological disturbances [264–269]. In adults, principles of prevention are paying attention to good technique and reducing risk of error. Bispectral Index (BIS) monitoring has been shown to be superior to standard practice in reducing awareness in high-risk adults [250].

#### Frequency of awareness in children

A survey of the pediatric anesthesia community found that 27% of respondents had at least one case of pediatric awareness in their practice [270]. There are three old [271–273] and five newer cohort studies [227–231] designed to determine the incidence of awareness in children. Some other studies primarily designed to test for wakefulness or implicit memory formation also made some measure of explicit recall [242,243,274–277]. There are also three case series describing consequences of awareness which include some adults who would have been children when the awareness occurred [267–269]. A recent case report also describes two clear cases of awareness in children [278].

In 1973, McKie and Thorp interviewed 202 children aged 7–14 years and found 10 cases of definite awareness (5%) [272]. In 1988, O'Sullivan et al reported the effect of pretreatment with tubocurarine on the incidence of dreaming in 144 children aged 5–14 years who received succinylcholine [273]. There were no cases of awareness. The same investigators later published a prospective study of dreaming and awareness in 120 day-case children aged 5–17 years [271]. Again there were no cases of awareness. These studies used a very limited assessment for awareness.

More recently, a cohort study in 864 children aged 5–12 years found seven cases of awareness (0.8%) [227]. In this study the anesthesiologists were unaware which children were being studied. Postoperatively, the children were interviewed three times (for two of these, the interview was a proxy interview by the parents) and where awareness was suspected, the child's verbatim responses were then sent to four independent pediatric anesthesiologists who judged each report as "no awareness," "possible" or "awareness". Awareness was judged to have occurred if all agreed it was "awareness." More recently, the same group published another cohort study in 500 children [230]. This used Brice's idea of increasing the specificity of assessment by playing particular noises to the subjects during anesthesia [239]. In this cohort, using the same system of adjudication as used above, only one child was classified as being aware (0.2%). Importantly, some children reported hearing sounds during the anesthetic that had been played to them before anesthesia, thus clearly demonstrating errors of source monitoring.

In 2007, Lopez et al reported a cohort study assessing awareness in 410 children aged 6–16 years and found five

children (1.2%) to be aware [228]. The children were interviewed by trained psychologists within 36 h and 1 month after the procedure. In this study, the interview was carefully tailored to the cognitive ability of children. The reports were tape recorded and then reviewed by three independent adjudicators who classified the transcript as "awareness," "possible awareness" or "not awareness." Children were classified as aware if at least two adjudicators judged the case as 'awareness."

A cohort study from The Netherlands with 928 children aged 5–18 years found six awareness cases (0.6%) [229]. Similarly, a multicenter cohort study in the United States reported an awareness incidence of 0.8% in children aged 5–15 (14 of 1784 interviewed children) [231].

Lastly, there are three small studies assessing implicit memory formation in children which incidentally found no evidence for explicit memory [274–276]. Similarly, in two studies designed to detect wakefulness using the isolated forearm technique, evidence for wakefulness was found in both cases but there was no explicit recall [242,243].

The earlier studies reported wide ranges in incidence. The high rates may be due to outdated anesthesia practice and the low incidences may be due to poor interview techniques. The recent large cohort studies all report incidences just below 1% – an incidence appreciably higher than in adults. The reason for the higher incidence remains unclear.

#### Characteristics of awareness in children

While many of the characteristics of awareness in children are similar to those in adults, there are some differences. Any comparison, however, must be tempered by the fact that there are very few studies and reports on which to base these comparisons. As in adults, in children awareness is often not volunteered to hospital staff (though some reports found that children told their siblings) and may only be detected at the second or third interview. In adults, awareness is often auditory and may be accompanied by pain and intense fear. Although some children do describe experiences like this, children report more tactile experiences, less pain and the experience may be less distressing. The memories are often fragmentary and less detailed. This is consistent with the developmental aspects of memory described previously.

#### Causes of awareness in children

In the pediatric studies reported so far, repeated airway manipulation was the only factor found to be associated with awareness [228]. There are no other obvious causes for awareness and awareness occurred in what would be considered as low-risk groups. It remains unclear why awareness is more common in children compared to adults.

There are three possible explanations for the high incidence of awareness. First, the finding may be due to measurement error and implanted memory or false recall due to errors in source monitoring. This is indeed a possibility though there are equally strong arguments to suggest that measurement error could underestimate the incidence of awareness. It is, however, pertinent to note that in one study, children reported hearing a stimulus that was given in the preoperative holding area – clear evidence that error in source monitoring does occur [230].

The second possibility is that pediatric anesthesiologists use techniques that increase the risk of awareness. The use of induction rooms has been suggested to increase the risk of awareness [279]. Induction rooms are used widely in Europe and Australia to enable induction to occur in a quieter, friendlier environment where parents can accompany their child without having to enter the main operating room itself. If induction rooms are used, the child is disconnected from the circuit for transfer to the operating room. In theory, this may allow breathing room air, lightening of anesthesia and hence increase risk of awareness - particularly if the circuit in the operating room is not primed. While pediatric anesthesiologists who use induction rooms should always be aware of this risk, it is unlikely to be the main cause of awareness in children as induction rooms were not used in two of the studies [228,231]. Another possibility is that pediatric anesthesiologists just accept periods of lighter anesthesia in children. There is no evidence to support this suggestion, but it is interesting to note that when comparing the two studies done by Davidson et al [227,230] the incidence was lower in the study where the anesthesiologists knew an awareness study was being performed; thus it is possible that awareness is reduced simply by anesthesiologists being more careful to avoid it.

The third possible cause could be simple and fundamental differences in the pharmacology of anesthetics in children. Children do have a higher minimum alveolar concentration (MAC). MAC peaks in infancy then declines with increasing age [280,281]. The MAC-awake is the concentration at which 50% return to consciousness [282]. When considering awareness, MAC-awake may be the more relevant measure of potency of anesthesia. Like MAC, MAC-awake is higher in children and declines with age [283-286]. Thus children do need more anesthetic to ensure unconsciousness. It is possible that awareness is more common in children simply because anesthesiologists do not give enough anesthetic or allow enough time for effect site concentrations to become adequate. Interestingly, the degree to which the EEG is suppressed at 1 MAC does vary with age [287–290]. The significance of this for awareness risk is unclear.

Lastly, some children might be at risk for awareness for exactly the same reasons as adults. Errors in drug delivery due to miscalculation or equipment failure or syringe swap are just as likely to occur in children. Similarly, some children who are extremely unwell may not be able to tolerate large doses of anesthetic and children having cardiac surgery will have cardiovascular signs of inadequate anesthesia ablated – just as in adults. These may be the causes of awareness seen in some children but in the recent cohort studies, aware children were not in these high-risk groups and as far as can be determined, errors were not the cause.

#### **Consequences of awareness in children**

In adults, the consequences of awareness vary. In prospective cohort studies in adults, the incidence of severe psychological disturbance has been described as 0%, 2%, 9% and 44% [264–269]. Severe disturbance may only be apparent some time after the event. Awareness in the setting of paralysis is associated with greater anxiety and risk of significant persistent psychological disturbance. In children, data are scarcer.

Three studies interviewed adults about their experiences of awareness. Some of these studies included adults who would have experienced the awareness when they were children. Samuelsson et al found 46 cases of awareness and of these, five were children at the time of the previous surgery (aged 7-12 years) [267]. Of the 46 cases, 15 had psychological symptoms but only one of the children. Schwender et al interviewed 45 people and eight would have been under the age of 18 years at the time of awareness [268]. Twelve of the 37 adults developed psychological symptoms while only one of the eight children did. Osterman et al interviewed 16 adults all of who had diagnostic criteria for post-traumatic stress disorder (PTSD) [269]. Three would have been children at the time of awareness. These studies confirm that there are still some children who can have significantly disturbing awareness.

Although some children do develop substantial anxiety and significant delayed psychological disturbance, the children described in the recent large cohort studies do not appear as distressed as adults. In one, there was no evidence for behavioral disturbance 1 month after the event and at later follow-up none had signs of PTSD [227,291]. Another study found no evidence for PTSD 1 year after the event [292].

#### **Prevention and management**

Without understanding the causes of awareness in children, it is difficult to know how to prevent it.

Obviously it would be prudent to apply many of the recommendations made in adult anesthesia to reduce risk of error. This includes labeling syringes carefully, checking anesthesia machines and in particular that vaporizers are well fitted and full. As mentioned before, care should be taken to ensure that anesthetic levels in children are not light during transfer and most importantly, it must always be remembered that children have fundamentally higher anesthesia requirements – give more and wait longer for adequate effect site concentration to be achieved. In particular, remember that there is a substantial delay between end-tidal concentration of a volatile anesthetic and brain concentration.

The role of depth of anesthesia monitors and awareness in children is unclear. Most EEG-derived depth monitors have been validated to some extent in children. The numbers tend to go up and down with loss and regaining consciousness and there is some rough correlation with anesthetic concentration. There are theoretical reasons why they may have poorer performance due to EEG maturation but apart from infants, their performance seems similar to that in adults. However, the proof of their utility lies in properly conducted trials. There are no trials assessing the use of EEGderived depth monitors in preventing awareness in children and because of differences in awareness characteristics and possibly causes, adult studies cannot be extrapolated to children.

The management of awareness is supportive. Children who report being aware should be listened to and the anesthesiologist should be sympathetic. The child and family should be provided with a clear explanation of anything that may have contributed to awareness and while persistent psychological disturbance may be rare, further psychological counseling should be offered. Particular care should be taken to follow up children who report painful experiences while being paralyzed. It should also be remembered that PTSD may develop some months after the event.

# Implicit memory in children during anesthesia

In adults, implicit memory can be detected for events that occur during anesthesia [293]. Unlike explicit memory, there is some weak evidence that implicit memory can be formed without periods of consciousness or wakefulness [294]. The relevance of implicit memory formation during anesthesia is uncertain. In awake subjects, implicit memory can result in reinforcement of an existing desire [293]. For example, subliminal priming with pictures of food will increase an existing hunger. It is thus often considered that negative conversation about a patient during anesthesia or negative experiences during anesthesia may increase a patient's existing perioperative anxiety which can be manifest as increased stress or maladaptive behavior postoperatively. While fine in theory, this is hard to prove or detect in practice. Similarly, therapeutic suggestions may also improve postoperative state but once again this is hard to prove clinically.

It has been suggested that children have a high incidence of postoperative maladaptive behavior and that this may be partly due to implicit memory formation. It is known that implicit memory matures earlier than explicit memory but as in adults, the actual relevance of implicit memory for events during anesthesia is uncertain in children. Several studies have found no evidence for implicit memory for events during anesthesia in children [240,243,274–276,295].

#### Awareness in the very young

Awareness requires explicit memory and children begin to develop some form of explicit memory at around the age of 3 years. However, younger children could still form implicit memory or have periods of consciousness during anesthesia. There is very little research or discussion examining the effect of periods of consciousness or implicit memory formation during anesthesia in this age group.

There is, however, increasing evidence that untreated pain is detrimental to infants, resulting in morphological change in the spinal cord, persisting changes in behavior and worse clinical outcomes. Similarly, several landmark studies have suggested that providing adequate analgesia and anesthesia in neonates undergoing surgery reduces stress markers and improves clinical outcomes [296–298]. Thus at the very least, the very young should not be left to suffer pain, regardless of any discussion about implicit memory or consciousness.

It would also seem reasonable and humane to reduce any obvious signs of distress caused by surgery. This could involve regional anesthetic, sedation or rendering the child unresponsive (general anesthesia). Unfortunately, assessing whether or not an infant is unconscious can be difficult (especially if the infant is paralyzed). Similarly, we have no easy direct way to determine if they are forming implicit memory. This makes the titration of anesthesia particularly difficult in this age group.

#### Conclusion

Awareness can certainly occur in children and there is substantial evidence to suggest that it may be more common than in adults. The reasons for this are unclear. While awareness is often not distressing in children, there are well-documented cases where it has resulted in significant psychological disturbance. It is difficult to know how to prevent awareness in children until we know more about why it occurs in children.

# **Postoperative behavior disorders**

There is increasing awareness of the potential lasting negative psychological impact of hospitalization, anesthesia and surgery in children. These are events that may be stressful for both children and parents. Three clinical phenomena have been associated with this psychological stress: preoperative anxiety, emergence delirium in the very early postoperative period, and negative postoperative behavior changes after discharge from hospital [299,300]. While postoperative behavior disturbance was first described as early as 1945 [301], there is still no clear definition of the concept of negative postoperative behavior change. Further, knowledge about this has been limited as its detection has tended to rely on just one questionnaire that presents several limitations [302]. It is probable that various postoperative psychological disturbances occur after a distressing hospitalization. Thus, rather than speaking of just negative behavior change as defined by the questionnaire most widely used, it may be more useful to consider a wider concept of postoperative behavior disorders.

## **Negative postoperative behavior changes** Measuring postoperative behavior changes

In the past decade, concerns have been expressed about the high incidence of negative postoperative behavior changes in the pediatric population [154,156,196,303]. In spite of such concern, only one tool is used in nearly all the medical literature for the measurement of these negative changes: the Post Hospitalization Behavior Questionnaire (PHBQ) [302]. This questionnaire was developed in 1966 by Vernon et al [302] and was designed to measure children's behavior after discharge from hospital. It is composed of 27 items that evaluate six categories of anxiety: general anxiety, separation anxiety, eating disturbances, sleeping disturbances, aggression toward authority, and apathy/withdrawal. For each item, parents have to compare the actual (posthospitalization) behavior of their child with the child's typical behavior before hospital admission on a 1-5 scale (much less than before scored 1; less than before - scored 2; same as before - scored 3; more than before - scored 4 and much more than before - scored 5). High scores indicate negative behavior change and low scores suggest positive behavior change. In the original PHBQ study [302], the questionnaire was sent to parents 6 days after discharge and a total score was obtained by adding the scores of each item.

#### Psychometric properties of the PHBQ

As this tool is the one used in most studies, it is important to understand its limitations before reviewing the literature. The value of a psychometric tool can be considered in terms of validity and reliability.

**Validity.** The validity of the construct was evaluated by comparing the total score achieved from the PHBQ with psychiatric interviews of 20 children aged between 2 and 10.5 years who underwent tonsillectomy. There was a moderate correlation (r = 0.47) [302]. It should be noted, however, that the sample used to evaluate the validity of construct was very small and not representative of all age groups [302]. Moreover, most of the questions of the PHBQ were more suited to the behavior of the young child and could not be applied to older children. This issue is of great importance since postoperative behavior in children may differ considerably with age. Consistent with this, recently researchers found moderate correlations between the PHBQ and the Child Behavior Checklist (a well-validated tool that is used extensively in children for the assessment of behavioral and emotional problems [304,305]) in the 2-4 and 4-7-year age groups [306], but no correlation at all in children above 7 years of age.

**Reliability.** Two classes of reliability of the PHBQ were tested: the test–retest reliability and the internal consistency. The first one was tested by Cassell et al in 37 children undergoing cardiac catheterization, ranging in age from 3 to 11 years [307]. The second class of reliability, the internal consistency, was evaluated in the original PHBQ study of Vernon et al [302]. In this study, 387 children aged from 1 month to 16 years (mean age  $5.68 \pm 4.33$  years of age) and having various type of surgery were recruited. The internal consistency (Cronbach's alpha) for the six factors varied between 0.46 (Eating disturbances) and 0.73 (General anxiety), and was 0.82 for the total score [302]. However, the internal consistency for the six categories of anxiety (Cronbach's alpha) was lower than the value recommended in the literature [308].

Thus, in summary, the validity and reliability of the PHBQ have only been partly established, especially in older children.

Despite all the limitations highlighted in the last paragraph, the PHBQ is still considered as the "gold standard" tool for assessing postoperative behavior changes [302,309]. Another issue is that, this questionnaire has been often modified and various versions have been used in the literature with alterations in the number of items, mode of collection (the absolute versus the relative form) and the timing of application in the postoperative period. None of these modified questionnaires has been validated.

The mode of collection of the PHBQ is the most obvious variant. Two different versions can be identified:

• the *original, relative form* developed by Vernon et al [302] in which the parent is asked to compare the

postoperative behavior with the preoperative behavior of their child

the *absolute form*, in which the parent is asked to complete the questionnaire twice, before and after the operation. In this form, each item is rated on a four-point Likert scale from "never" to "always" and changes in behavior are determined for each item by comparing the postoperative score with the preoperative score. Thus, each item can indicate a positive or a negative change, or no modification.

While the relative form has been reported to be more sensitive than the absolute form, it is also possible that the absolute form is less subject to response bias and thus could be more appropriate [309].

Finally, in the original formulation, no cut-off score was determined to identify clinically significant negative postoperative behavior changes [302]. There is great variability in the literature with regard to the scoring system and the presence or not of a cut-off score for the confirmation of the presence of negative postoperative behavior changes. While the total PHBQ score and subscales (obtained respectively by summing the scores of all the items and by summing the items belonging to the subscale) were reported in the original publication by Vernon et al [302], recent studies used only the total score [309] or reported only the percentage of any negative behavior change [154]. Thus, the definition of "negative postoperative behavior changes" may differ between studies and is arbitrary given the fact that no investigations were conducted to specify this aspect [155,299]. For instance, Stargatt et al used a cut-off score of 7 to consider deterioration in behavior as significant [155], whereas other authors used no cut-off score and reported percentage of any negative change [154].

Also there usually is no reporting of how behaviors improve. In most studies, only negative behavior is considered, with no description of how this might be balanced by behaviors actually improving. A child may have a net improvement in behavior while the analysis only highlights the negative changes. This tends to overemphasize negative behavior change.

A final criticism of the PHBQ is that it is a crude score which gives little indication of the type of symptoms presented by the children, their severity and their consequences for the children's life and development. Thus, it is probable that this concept as determined by the PHBQ regroups symptoms of different severity, integrating benign symptoms, which reflect "a normal reaction" to a stressful event, and more severe symptoms, which could be more incapacitating for children and their families. Lastly, the PHBQ can only reveal the symptoms related to some aspects of behavior, namely anxiety.

In summary, the absence of standardization of the PHBQ makes comparisons between studies hazardous. If

we also consider the lack of validation and reliability of this questionnaire, and the limited scope of the tool, then the concept of "negative postoperative behavior changes" as detected by the mean of the PHBQ might be questionable. Given all these remarks, the results in the literature should be considered with caution.

# Incidence and duration of negative postoperative behavior changes

The incidence of POBD varies considerably between studies, from no change [310] to almost 80% of children presenting some negative behavior changes [311,312]. As discussed above, this variability can be attributed to the various methodologies applied in the different studies, and also to the small samples selected and to their characteristics, such as the medical condition and the cultural differences of the children. Nevertheless, the most frequently reported incidence of significant negative behavior changes is between 15% and 40% of children [153,155,156,313,314].

Despite the high incidence of negative behavior changes, it is important to note that most negative behavior changes are generally limited in duration. A metaanalysis including 26 studies using the PHBQ revealed that negative behavioral changes diminished with time and largely disappeared 2 weeks postoperatively [309].

There is little evidence for the persistence of negative postoperative behavior changes beyond 2 weeks. Most studies that addressed this issue were either retrospective [315] or were performed more than 30 years ago and have potentially significant limitations [316,317]. For instance, it is striking to note that Douglas (1975) showed in a follow-up that children with repeated admissions to hospital before the age of 5 years were "more likely to be delinquent and more likely to show unstable job patterns" than those who had not been admitted to the hospital during this period of age [316]. This early finding has been challenged by a more recent longitudinal study performed on 1048 children, which did not show any significant correlation between hospitalization during the preschool years and the evaluation of the child's behavior at the age of 6 years old if social factors and life events were taken into account [318].

# Risk factors for negative postoperative behavior changes

Younger children, and in particular preschool children, are at increased risk for experiencing negative behavioral changes following anesthesia [300]. Other risk factors such as the child's preoperative anxiety, temperament and history as well as parental anxiety were also found to correlate highly with the occurrence of emergence delirium and/or negative behavioral changes [300,303,319]. It has also been demonstrated that emergence delirium and

negative behavioral changes may be linked with children being agitated on recovery being more prone to develop negative behavior postoperatively [300].

Pain is also a risk factor for negative postoperative behavioral changes. Children with pain have almost a 10 times higher risk for having negative behavioral changes following tonsillectomy [156,300,320]; and if an aggressive pain treatment is established, more positive than negative behavioral changes are observed in children undergoing adenoidectomy [321]. Typically, behavioral changes associated with acute postoperative pain peak within 24h and wane progressively thereafter.

In addition to these factors, there are still unanswered questions regarding the role of intraoperative awareness as a trigger for negative postoperative behavioral changes. Changes in behavior could also be due to episodes of intraoperative implicit memory of events. While recent studies failed to demonstrate any evidence for the persistence of implicit memory during general anesthesia, it is important to point out that such assessment can be difficult to achieve and is based on complex psychological tests that may not be adapted to the child's cognitive development [240,243]. The role of midazolam as a risk factor for negative postoperative behavioral changes is unclear [198]. While some authors demonstrated the usefulness of midazolam in reducing negative postoperative behavior changes consequent upon a reduction in preoperative anxiety [167,322], others failed to show any benefit [155] or even demonstrated a higher incidence of negative changes following midazolam premedication [195].

Finally, a recent study using the Child Behavior Check List to assess negative postoperative behavior changes demonstrated a higher incidence of negative behavioral changes when urological surgery is performed at an age less than 24 months [323].

These findings confirm the complexity of the negative postoperative behavioral changes, which are of multifactorial origin with a potential interaction between preoperative (child's and parental anxiety, temperament, culture, preparation for surgery, etc.), intraoperative and postoperative (agitation on recovery, pain, family environment, etc.) factors.

#### Summary and suggestions

Despite all the limitations highlighted above (the lack of consensus on the terminology, the evaluation, the incidence and the severity of negative postoperative behavior changes) one should still bear in mind that important psychological manifestations may occur postoperatively in children. Therefore, preoperative assessment and preparation for anesthesia should focus on the parental and child's anxiety in order to prevent possible psychological symptoms that could be generated by hospitalization, anesthesia and surgery. Parents should be warned that some children may have behavior change and told that it is usually self-limiting. Parents should be encouraged to contact the anesthesia team in the presence of persistent negative changes after approximately 2 weeks postoperatively. In this case, it would be worth organizing a psychological assessment in order to better specify the symptoms and to offer the child psychological support.

#### Post-traumatic stress disorder

Post-traumatic stress disorder is a psychiatric disorder generally diagnosed by means of DSM-IV. To meet the DSM-IV criteria, a person must have been exposed to an "extreme" stressor, usually involving a threat to life or physical integrity. The response to that stressful event must include a specific number of symptoms from each of three broad categories:

- at least one re-experiencing symptom (the traumatic event can be re-experienced in various ways such as recurrent and intrusive memories, flashbacks and nightmares)
- three avoidance behaviors toward trauma-related stimuli (for example, hospital and doctors)
- two hyperarousal symptoms (such as irritability and hypervigilance).

Symptoms must be present for more than 1 month and must cause clinically significant distress or impairment in social and/or academic functioning or other important areas of functioning [324].

Since hospitalization can be a stressful experience, the potential development of PTSD is of great concern in the pediatric population. Two specific experiences, namely intraoperative awareness and a stay in the intensive care unit, have been associated with the development of PTSD. While this disorder has been largely investigated in adults, there is still a lack of knowledge on the incidence of PTSD following hospitalization in children.

# Post-traumatic stress disorder following admission to a pediatric intensive care unit

The criteria for admission to the PICU are various and include respiratory distress, deterioration in neurological condition, traumatic injuries, acute illness, and postoperative care. These experiences can be very stressful due to the medical condition itself as well as the requisite ICU treatment, which may include invasive and/or painful procedures (intubation, catheterization, etc.). For these reasons, the potential development of PTSD is of great concern in this specific population.

In adults, various studies have been performed in order to investigate the long-term psychological outcomes of ICU-treated patients. Results showed that the prevalence of PTSD is high (approximately 20%) [325] and the symptoms seem to persist over time and may negatively affect quality of life. Various risk factors for the development of post-ICU PTSD have been identified. Studies have highlighted potential factors such as an excessive administration in ICU of benzodiazepines, post-ICU memories of terrifying and/or psychotic experiences occurring during their stay in ICU and the presence of a prior psychopathology. However, the severity of illness does not seem to be a significant predictor for the occurrence of PTSD.

Although many studies in the last two decades have focused on the experience of pediatric illness, these studies were mainly looking at the impact on the parents. Thus, there is still a lack of knowledge about the longterm psychological impact of the PICU stay on the children themselves and the nature of their recall. The literature looking at the incidence of PTSD in children is scarce [326–330], but authors report a similarly high proportion of post-traumatic stress symptoms to that reported in adults, even several months following discharge from an ICU [327,330]. However, little is known about the mechanisms underlying the development and maintenance of PTSD in the pediatric population. Accordingly, there is no clear information about the involvement of factors related to the children's stay in the ICU (such as length of admission, severity of illness, degree of pain, number of invasive procedures and various medications) in the development of PTSD. In addition, it is unknown whether factors related to the hospital stay are better predictors than other variables, such as cognitive factors (i.e. subjective appraisals of the trauma and nature of memories of the PICU stay). In fact, only one study tried to examine the relationship between the nature of the PICU memory and the symptoms of PTSD. The results showed a significant relationship between memory for delusional events (such as hallucinations) and PTSD symptoms, and in particular intrusive thoughts [327].

The studies with an interest in this subject have several methodological limitations, such as small sample size (≤60 children) [328–330], the use of screening questionnaires to evaluate PTSD rather than applying semistructured interviews [327,329,330], and the lack of reference to the influential cognitive theories of PTSD, which would help to identify the risk factors [327–330].

Post-traumatic stress disorder has significant consequences for children's lives as it can interfere with normal childhood development, including learning capacity and the acquisition of socially appropriate behavior. Furthermore, if PTSD is left untreated, it may last for at least 5 years in more than one-third of the children [331]. Given the possibly high incidence of PTSD, any child admitted to the PICU should be followed, ideally with a 1-month follow-up becoming a standard of practice in order to detect any symptoms and to offer psychological support to both the child and parents if necessary. In contrast to the uncertainty about the concept of negative postoperative behavioral changes, PTSD is clearly defined in the literature with well-validated tools for the detection of its occurrence.

Post-traumatic stress disorder following hospitalization in children is still underinvestigated and underappreciated, and deserves both attention and further research.

# CASE STUDY

A 5-year-old child arrives at the preoperative assessment clinic 2 days prior to a scheduled outpatient adenotonsillectomy. The family and child are nervous. The parents report that 1 year ago, the child had had ear tubes inserted and on that occasion had needed to be held down for an inhalational induction, and had been very unsettled in the PACU. On discharge, the child had shown some regressive behavior for a week.

Today the child appears reluctant to be examined and very shy, hiding behind his mother. He also has a cough and purulent runny nose.

Reviewing the record, it is noted that the child has "mild obstructive sleep apnea." The parents say a sleep study has been performed but the results are not in the child's notes.

On examination, the child has a fever of 38.5°C. The lungs are clear on auscultation but a soft systolic murmur is heard. No other abnormalities are found. The child has

normal oxygen saturation and pulses. You think the child probably has a normal second heart sound.

Lastly, the mother reports that she is terrified of anesthesia as she clearly recalls being wide awake and paralyzed during a laparoscopic cholecystectomy performed 10 years earlier.

#### Notes

After discussion with the family, it is decided to delay the case for 3 weeks to allow the upper respiratory tract infection to clear and to give time for more evaluation and preparation. In the meantime, you organize a cardiac review and request the missing sleep study report. You also suggest the family comes back a week prior to the planned surgery to discuss anesthesia options and in particular to introduce the family to coping strategies to reduce anxiety at induction. Before they leave, you discuss the risk of awareness in children.

# Introduction

Expertise in airway management in infants and young children is the cornerstone upon which every subspecialist in pediatric anesthesia is based. This expertise consists of two major facets: a comprehensive knowledge and understanding of the developmental anatomy and physiology of the human upper airway from birth through adolescence, and the physical skills of airway management which occur only by experience over time. This chapter will provide the basis upon which knowledge of pediatric airway management is gained. The chapter is divided into three major sections: (1) Developmental anatomy and physiology of the upper airway; (2) Procedures and techniques for management of the normal pediatric airway; and (3) Specialized techniques with which to manage the child with an abnormal upper airway that presents challenges in ventilation or tracheal intubation.

The human upper airway is loosely defined as the airconducting passages from the nose to the carina [1]. Anatomically, the upper airway of the developing fetus, infant, and child is a moving target. Its developmental course during fetal life is relatively less known compared with other organ systems, since much of this understanding is gained from descriptive animal and

human postmortem studies. The structures of the upper airway continue to change shape and properties until the latter part of the first decade of life. Furthermore, up to 3% of children may have congenital or acquired upper airway abnormalities [1].

From an evolutionary perspective, the human upper airway is relatively smaller than other related species, and is oriented in a more vertical position in the body. In humans, the facial bones and accompanying oral airway structures assume a more vertical position beneath the cranium (this mirrors the changes seen during human growth; see below). These changes were likely due to the acquisition of language for survival [2,3]. Diamond called this adaptation "the great leap forward" and postulated that it occurred approximately 40,000 years ago [4].

Many other species are able to produce sounds that are analogous to vowels, but only humans are able to produce consonants, the basis of the spoken language. The ability to form consonants, according to Shprintzen, is the result of the relatively smaller supralaryngeal tract that evolved in humans. This adaptation included the ability of humans to close off and separate the communication between the nasal and oral pharynx to facilitate speech of consonants. The unique human property of having large adenoid tissue facilitates this separation. It is notable that the peak age of adenoidal growth (3–5 years) is the same approximate age of the refinement of consonant sounds [3].

This anatomical adaptation necessarily confers a disadvantageous human property: the predisposition to upper airway collapse during sleep (i.e. obstructive sleep apnea syndrome; OSAS) or during artificially induced unconsciousness (i.e. sedation or general anesthesia). Other than brachycephalic dogs, such as the English bulldog [5], OSAS appears to only occur in humans.

## **Developmental anatomy**

In embryological life, the upper airway develops within the structural framework of the cranium and the most cephalad ends of the digestive and respiratory systems. The following description of the embryological development of the human is based on writings and descriptions from a number of references [6–10]. On the lateral surface of the 5 week-old, 4.0mm embryo, one can observe five or six pairs of narrow masses called branchial arches (Fig. 14.1). Each branchial arch contains characteristic types of ectoderm and mesoderm, the primordial precursors of epithelial (e.g. skin) and mesothelial structures (e.g. muscle, bone), respectively. The areas between the arches are called branchial clefts. The tissue underlying the branchial clefts contains outpouchings of the foregut region, the pharyngeal pouches. These consist of endoderm and will develop into corresponding endothelial structures of the upper digestive and respiratory systems. The developing structures of each branchial arch receive motor or sensory innervation from an adjacent cranial nerve. Regardless of where the primordial muscle cell migrates to, it will retain its original embryonic innervation.

#### **Branchial arches**

The first branchial arch will ultimately develop into the ramus of the mandible and the muscles of mastication. It

Figure 14.1 On the lateral surface of the 5-week-old, 4.0 mm embryo, one can observe five or six pairs of narrow masses called branchial arches.

also contributes to development of the middle ear bones and muscles between the ear and mandible, such as the tensor tympani, tensor veli palatini, and anterior belly of the digastric muscle. Motor and sensory innervation to the structures derived from the first arch is supplied by the trigeminal nerve.

The second branchial arch forms bony and muscular structures from the ear (proximally) to the hyoid bone (distally), including the muscles of facial expression that are innervated by the facial nerve (cranial nerve (CN) VII). In the developed human, the path of second branchial arch development can be traced from the styloid process, to the stylohyoid ligament, to the lesser cornu of the hyoid bone. Embryological abnormalities in the growth of the first and second branchial arches result in any one of a number of congenital airway syndromes involving the ear and jaw, such as Goldenhar syndrome.

The third branchial arch develops into the body and greater cornu of the hyoid bone and the stylopharyngeus muscle, which aids in elevating the pharynx during swallowing, and is innervated by the glossopharyngeal nerve (CN IX).

The fourth through sixth branchial arches contribute to the formation of the thyroid, cricoid, arytenoid, corniculate, and cuneiform laryngeal cartilages, as well as the muscles that form the pharynx, larynx, and upper half of the esophagus. These structures are innervated by the vagus (CN X) and accessory (CN XI) nerves. The earliest appearance of the future larynx is seen as a bud growing out from the ventral part of the foregut at approximately 4 weeks' gestation. The laryngeal and esophageal tracts are initially seen as one common tube that eventually separates into two adjacent, functionally different conduits. By 16 weeks' gestation, the larynx contains all its definitive elements in their proper proportions. During fetal and postnatal [11] growth, the development of the size of the larynx closely parallels the size of the surrounding bony and cartilaginous structures.

#### **Pharyngeal pouches**

The pharyngeal pouches are outpouchings of the lateral wall of the foregut that develop into the pharyngeal structures. Each pouch, at its lateral-most aspect, contacts the ectodermal epithelium of a branchial cleft. The first branchial cleft becomes part of the external auditory canal, but the remaining branchial clefts are remodeled and do not correspond to recognizable structures in the mature human. Nevertheless, abnormal formation of this area can lead to cysts or more significant malformations.

The first pharyngeal pouch becomes incorporated into the future temporal bone and forms the epithelial lining of the middle ear and the tympanic membrane. Adjacent to the first pharyngeal pouch, the first branchial cleft develops into the external auditory canal. The second pharyngeal pouch develops into the tonsil. The superior portion of the third pharyngeal pouch differentiates into the inferior parathyroid and the inferior portion migrates caudad to become the thymus. The fourth pharyngeal pouch forms the superior parathyroid gland. The area roughly corresponding to the fifth and sixth pharyngeal pouches is incorporated into the thyroid gland.

# Anatomical structures of the upper airway and their relation to the practice of pediatric anesthesia

The approach to airway management of infants and young children is influenced by developmental differences in head and neck anatomy. These differences are modified by two major growth spurts during childhood, the first at the time of the acquisition of permanent dentition (age 7–10 years), and the second during puberty in the teenage years, both of which contribute to the vertical growth of the facial structures. Thus, it is no coincidence that these two general age ranges are the approximate points in life in which certain persons without obvious anatomical deformities will become difficult to intubate.

#### Skull

When compared to the older child, the infant's skull (especially the occipital region) is relatively larger, such that neck flexion may not be required to attain the classic "sniffing" position that optimizes visualization of the glottic structures during laryngoscopy. At birth, the neurocranium to face size ratio is 8:1, and declines to 6:1 at 2 years of age, 4:1 at 5 years, and approximately 2:1 by adulthood [12,13]. The growth of the lower facial bones is proportionately linear from ages 1 to 11 years [11].

The mandibular arch of the infant is U-shaped and becomes more V-shaped during childhood until adolescence, when it is completely developed. The angle between the ramus and the body of the mandible is more obtuse in infants than in adults. This largely accounts for the relatively low incidence of difficult intubations in infants and young children compared with adults.

#### Nose

Overall, the most important difference in nasal anatomy between young children and adults is merely the smaller size. Small nasal passages are more likely to become obstructed with blood or secretions as a result of manipulations during general anesthesia. Young children are less likely to have occult nasal polyps or septal deviations when compared with adults [14]. The anatomical dimensions of the nasopharynx increase linearly between 1 and 11 years of age [11]. In the past, small infants were considered to be obligate nasal breathers and therefore predisposed to breathing difficulties during periods of nasal obstruction. However, this has largely been disproven [15] although infants with choanal atresia will often develop upper airway obstruction that results in varying degrees of hypoxemia [16].

#### **Oral cavity**

The infant tongue is relatively larger in proportion to the oral cavity when compared with the adult. Tongue volume increases linearly between 1 and 11 years [11]. Magnetic resonance imaging (MRI) studies of the upper airway during general anesthesia have demonstrated that, as in adults [17], upper airway obstruction occurs primarily at the levels of the soft palate and epiglottis, and not at the level of the tongue [18].

The 20 primary teeth are identified by a lettering system (Fig. 14.2A). They begin to erupt during the first year of life, and are shed at between 6 and 12 years of age. The 32 permanent teeth begin to appear at the same time as the primary teeth are shed and are identified by a numbering system (Fig. 14.2B).

#### Oropharynx

In newborns, the uvula and epiglottis are in close proximity, which makes possible the simultaneous acts of nasal breathing and oral ingestion of liquids. This anatomical relationship is maintained throughout most of the first year of life but during the second year, the larynx begins to descend as it adapts to its greater role in phonation.

Although mechanisms have not been elucidated, the pharynx of premature newborns is susceptible to passive collapse, especially during apnea, but may also collapse as a result of cervical flexion or nasal obstruction [19]. These effects are exacerbated by the administration of general anesthesia or sedatives, which decrease pharyngeal muscle tone. Furthermore, pharyngeal collapse often occurs in premature infants during application of cricoid pressure.

Of interest, the upper airway of a normal infant is smaller in both inspiration and expiration at 6 weeks of age compared to the neonatal period. This relative narrowing may be caused by postnatal growth of adenoid tissue or thickening of the mucous membrane lining in response to infection or second-hand smoke exposure. The linear dimensions of the soft palate and oropharynx increase linearly between 1 and 11 years of age [11,20].

Adenoidal and tonsillar tissue is minimal at birth, and then grows rapidly between 4 and 7 years of age. The growth of airway lymphoid tissue parallels the growth of the facial and cervical bony structures [11]. Hypertrophied tonsil and adenoid tissue is likely the most common cause of upper airway obstruction after administration of general anesthesia in children in this age group.

**Figure 14.2** (A) Primary teeth (baby teeth). The picture is viewed as if the patient is facing the examiner with their mouth open. The 20 primary teeth are lettered A through T, beginning with the right upper molar and ending at the right lower molar. (B) Secondary teeth. The 32 permanent adult teeth are identified by a numbering system that begins at the right upper third molar and ends at the right lower third molar. Reproduced from [365] with permission from the American Dental Association.

The epiglottis of infants is relatively narrow and short, and angled into the lumen of the airway. The lower portion of the oropharynx at the level of the epiglottis is particularly compliant and prone to collapse during anesthetic or sedative-induced upper airway obstruction [21]. Therefore, obstruction at the epiglottic level can be significantly lessened by placing the patient in the lateral position [21].

The effect of gender on oropharyngeal length has been studied, with particular reference to an association between relatively longer airway length and the predisposition to obstructive sleep apnea [22]. Prior to the onset of puberty, boys and girls have relatively similar oropharyngeal length but after the onset of puberty, the oropharyngeal lengths in boys are greater than those of girls, even after correcting for height and weight (Fig. 14.3). The relatively longer upper airway length in males has been

**Figure 14.3** Prior to the onset of puberty, boys and girls have relatively similar oropharyngeal lengths but after the onset of puberty, the oropharyngeal lengths in boys are greater than those of girls, even after correcting for height and weight. Reproduced from Ronen et al [22] with permission from the American Academy of Pediatrics.

implicated as a possible etiological factor in the greater disposition in males toward OSAS [23]. Thus, postpubertal boys may have a greater disposition toward upper airway collapse in response to administration of pharmacological agents that depress consciousness.

#### Larynx

During infancy, the relative position of the larynx is slightly higher in the neck than in older children and adults. Although its position relative to the cervical spine is complete by the age of 3 years (it descends from C2-C3 to C4-C5), it continues to descend relative to other facial structures such as the mandible [24]. The tip of the epiglottis proceeds in a gradual and linear descent from C2 to C3 from birth to 18 years of age [25]. This relative movement is unique to humans because of the shifting functionality from sucking and swallowing while breathing to the development of speech later in life. Early in life, a relatively high larynx facilitates simultaneous sucking and respiration due to the apposition of the epiglottis (as high as C1) and the soft palate. Additional differences in early life that protect against aspiration during feeding include relatively thicker aryepiglottic folds and larger arytenoids.

The chest wall of neonates and small infants is highly compliant and tends to collapse inward, thus reducing functional residual capacity (FRC) and promotion of atelectasis. To preserve FRC, the adductor muscles of the larynx act as an expiratory "valve" and restrict exhalation in order to maintain positive end-expiratory pressure. This is referred to as "laryngeal braking" [26,27].

The higher position of the larynx during infancy influences airway management to the extent that the glottic

**Figure 14.4** Distance between vocal cords and carina as a function of weight in pounds and age in years. Reproduced from Butz [30] with permission from the American Academy of Pediatrics.

opening is more easily visualized using a straight, rather than a curved laryngoscope, and in infants less than 1 year of age, elevation of the base of the skull is usually not necessary [28].

In children with pharmacologically induced neuromuscular blockade, the cricoid cartilage is the narrowest portion of the upper airway because of its inability to distend in a similar manner to the vocal cords [29-31]. A tracheal tube that easily passes through the relatively compliant vocal cords may compress surface mucosa at the level of the cricoid cartilage and predispose to inflammation, edema, and subsequent scarring and stenosis [32–34]. Tracheal edema is more likely to increase airway resistance in smaller diameter airways since the resistance to flow through a tube is related to the fifth power of the radius of the tube (since this flow is largely turbulent). In non-intubated, sedated children without neuromuscular blockade, the adductor muscles of the vocal cords are active, and are the basis for the narrowest portion of the upper airway to occur at this level [35-37].

The relationship between the sizes of the structures along the upper airway remains relatively stable throughout growth and development [37]. Therefore, there appears to be no specific age during childhood at which the form or structure of the most appropriate tracheal tube (i.e. cuffed versus uncuffed) would require a change for the benefit of the child.

Some congenital conditions, notably trisomy 21, are associated with smaller than normal subglottic and tracheal diameters [38–42]. Therefore, appropriate tracheal tube sizes may be smaller than usual for age in these patients. Ultrasound examination of the subglottic region may be used to guide tracheal tube size selection [43].

Tracheal lengths (distance between glottis and carina) increase linearly during childhood [30,44]. A familiarity with these distances in infants will facilitate proper placement of the tracheal tube midway between the glottis and carina (Fig. 14.4). A shortened tracheal length (i.e. higher bifurcation) caused by a reduced number of tracheal

cartilage rings is noted in certain conditions such as trisomy 21 [40] and myelomeningocele [39,45]. Therefore, in these patients, special attention is warranted to ensure proper tracheal tube position and avoidance of right bronchial intubation.

# Developmental physiology of the upper airway

The human upper airway serves a concomitant function as a conduit for breathing and for the passage of food. This property, which is only found in higher evolved species, presents a unique problem, the basis of which is that the upper airway is integrally involved in the processes of breathing, speech, and eating, without the benefit of rigid cartilaginous support. In the conscious state, this requires rigorous neurological co-ordination between competing structures. Although relatively little is known about the development of neural control in the upper airway [1], it is this characteristic that renders the upper airway vulnerable to collapse during administration of sedatives or anesthetics.

The pharyngeal and laryngeal muscles that normally contract to maintain upper airway patency are activated in parallel with the diaphragm. Activation of pharyngeal abductor muscles prevents upper airway collapse in response to the brief challenge of negative pressure created by diaphragmatic contraction. Contraction of pharyngeal adductor muscles maintains lung volume during the exhalation portion of a breath [46].

# Development of airway protective mechanisms

The term "airway protective mechanisms" encompasses two separate but inter-related functions of the upper airway: protection against aspiration of foreign material into the respiratory tree, and protection against airway collapse during sleep or states of pharmacologically impaired consciousness.

The mechanisms that protect against pulmonary aspiration of liquid or solid contents into the respiratory tree include a series of unconsciously controlled reflexes that include swallowing and cough (to transport substances away from the laryngeal inlet), and apnea and airway obstruction, which are attempts to prevent substances entering the respiratory tree [47]. Additional reflexes consist of laryngospasm and arousal [48]. Collectively, these have been termed the laryngeal chemoreflexes (LCR), and they mature throughout development [49]. The perinatal period represents a time of relatively high vulnerability to aspiration, as is clinically seen in the meconium aspiration syndrome, which occurs in 4% of all livebirths [50].

In the newborn, introduction of water into the larynx results in a characteristic set of responses that include swallowing, apnea, bradycardia, and peripheral vasoconstriction with shunting to the central vascular bed. These adaptive responses are prominent in preterm infants and lessen with advanced gestational age [47,51-56]. The apneic reflexes have been implicated in the etiology of sudden infant death syndrome (SIDS) [57]. Administration of sedatives and anesthetic agents is associated with prolongation of the apneic reflex [58-60]. The apneic reflex is also prolonged (and bradycardia worsened) during baseline hypoxemia [61,62], anemia [63] and respiratory syncytial virus (RSV) infection [64,65]. Conversely, the apneic reflex is shortened by administration of central stimulants such as theophylline [59]. Soon after the newborn period, the apneic portion of the LCR response disappears [66]. Cough is more prominent, and continues for the remainder of life when foreign substances enter the laryngeal area.

The effect of anesthetics and sedatives on the efficacy and potency of airway protective reflexes is clinically important to establish the safety of pharmacological agents administered to non-tracheally intubated children. The body of knowledge concerning these effects is beginning to develop. At predefined depths of general anesthesia, propofol appears to be a more potent inhibitor of the laryngospasm reflex than sevoflurane [67] and fentanyl does not appear to reduce the propensity toward laryngospasm in sevoflurane-anesthetized children [68]. Data are also emerging on the effects of anesthetics on upper airway patency. In adults, at similar depths of sedation or general anesthesia, propofol appears equal to isoflurane in promoting upper airway collapse [69,70] and both are more potent than equivalent levels of deep sedation attained with midazolam [71]. In children, the addition of 50% nitrous oxide promotes upper airway closure in those with enlarged tonsils who received oral midazolam [72] and halothane appears to preserve upper airway patency better than equipotent levels of sevoflurane [73].

# Management of the normal pediatric airway

#### **Preoperative airway assessment**

Preoperative airway assessment will identify nearly all children who, when anesthetized, are likely to develop difficult mask ventilation or difficult tracheal intubation. Information gained from the preoperative history and physical examination will determine the method of anesthetic induction and the approach for maintaining a patent upper airway following loss of consciousness. Similarly, risk factors for postoperative respiratory complications are identified at this time, allowing for appropriate preparation or delay of anesthesia and surgery when appropriate. Common airway assessment techniques used in adults have not been validated for use in infants and children; however, modifications of these methods may yield valuable information.

#### History

In almost all cases, a review of the child's previous anesthetic records as well as discussion with parents will reveal potential airway management problems. A history of previous uneventful anesthetics is encouraging, but changes in growth and development may affect airway anatomy. A reliable history of unobstructed breathing during sleep, especially while supine, often predicts the ability to mask ventilate without difficulty. Conversely, loud snoring and/or obstructive apnea are excellent predictors of upper airway obstruction following anestheticor sedative-induced unconsciousness.

During the preoperative interview, children and parents should be asked about the presence of loose deciduous teeth. Chipped or missing teeth should be documented. Very loose teeth should be electively removed after induction of general anesthesia to avoid accidental dislodgment (and pulmonary aspiration) during airway manipulations. A loose tooth is removed by grasping it with a dry piece of gauze and pulling while rocking the tooth gently back and forth. Some bleeding is expected. This is performed immediately following induction of anesthesia or after tracheal intubation, depending on the location of the tooth and risk of dislodgment during direct laryngoscopy. If elective tooth removal is contemplated, it should be discussed with parents and caregivers during the preoperative visit to avoid an unpleasant surprise when they are reunited with their child in the recovery room.

Children with non-permanent orthodontic hardware that may be dislodged during airway management should have such devices removed whenever possible. Occasionally, preoperative orthodontic consultation may be required.

#### Co-existing diseases and airway management

A number of co-existing diseases may influence airway management. For example, children with tumors of the head or neck may have distorted airway anatomy. Previous radiation therapy which results in scarring of the tongue and submandibular tissues is often associated with difficult tracheal intubation secondary to poor mandibular soft tissue compliance. Radiation therapy may also cause mucosal tissues to be friable and prone to bleeding.

If a child presents with an unfamiliar syndrome or diagnosis, the anesthesiologist should obtain a comprehensive understanding of the condition as it relates to airway management. The anesthetic implications of a number of common congenital syndromes and conditions are presented in Chapter 38.

The presence, type, and severity of pulmonary disease affect the advantages and disadvantages of different airway management techniques. For example, the child with limited pulmonary reserve may not tolerate anesthetic-induced hypoventilation and may require tracheal intubation and controlled ventilation for a procedure that would be performed with spontaneous ventilation and a natural airway in an otherwise healthy child. On the other hand, the child with highly reactive lower airways may benefit from a technique that is less stimulating to the airway.

In children with asthma, the severity, triggers, and current medication status should be assessed. Medical management should be optimized prior to surgery. This may include inhaled  $\beta$ -agonist therapy, inhaled corticosteroids or a course of systemic corticosteroids, depending on the severity of disease and the procedure being performed. Adequate preoperative preparation of asthmatic children results in decreased intraoperative bronchospasm [74]. Uncontrolled asthma may warrant postponement of elective surgery. Some children may have persistent lower airway obstruction despite maximal medical management. In such cases, the anesthetic plan should include provisions for limiting triggers that exacerbate bronchoconstriction.

Bronchopulmonary dysplasia is a chronic lung disease associated with prematurity. Currently, most cases occur in infants born at less than 30 weeks' gestational age and weighing less than 1200g at birth [75]. Various factors contribute to the genesis of bronchopulmonary dysplasia, including mechanical ventilation-induced barotrauma and volutrauma, hyperoxia, infection, and genetic factors [75,76]. Although one study did not demonstrate an increased risk of postoperative respiratory complications [77], former preterm infants with pulmonary sequelae of prematurity may have a reduced tolerance of apnea and heightened airway reactivity, which can manifest as bronchospasm, oxyhemoglobin desaturation or laryngospasm.

Children with significant pulmonary disease may benefit from preoperative consultation with a pulmonologist. Conditions meriting such consultation include cystic fibrosis, severe asthma or pulmonary hypoplasia associated with congenital conditions such as congenital diaphragmatic hernia. Preoperative optimization of medical management and development of a postoperative care plan may decrease the incidence of postoperative complications.

#### Preoperative fasting and risk of aspiration

The adequacy of preoperative fasting and the risk of pulmonary aspiration of gastric contents should be assessed in every child. Current guidelines and recommendations for preoperative fasting in children are presented in Chapter 15. Children with high intestinal obstruction ideally should have gastric decompression prior to a rapid-sequence induction of general anesthesia. A history of gastroesophageal reflux disease warrants an assessment of its severity and response to therapy. Children with mild reflux disease or disease that has been effectively treated are candidates for inhaled induction of anesthesia. Children with esophageal motility disorders such as achalasia should be regarded as being at risk for pulmonary aspiration and managed accordingly.

#### **Physical examination**

Preoperative airway examination focuses on identification of physical features that suggest a difficult facemask ventilation or tracheal intubation. In adults, there are validated assessments that identify predictors of airway management difficulty [78-82]. Although seemingly useful (Fig. 14.5), similar validated assessments have not been published for infants and young children. Nonetheless, there are certain anatomical features that are consistently associated with airway difficulty in the pediatric population. These include limited mouth opening, limited neck mobility, maxillary hypoplasia, mandibular hypoplasia, and diseases associated with decreased compliance of the submandibular space. School-aged children and adolescents will co-operate with physical examination maneuvers to assess the airway but in toddlers and infants, the airway exam is limited to an assessment of external physical features. In infants, neck mobility can be assessed by watching the infant track a colorful object, and mouth opening is assessed during crying.

**Figure 14.5** Although visualization of pharyngeal structures correlates with ease of intubation in adults, similar validation studies in pediatric patients have not been performed.

#### Routine airway management

#### Preoperative preparation of airway equipment

Airway-related equipment that should be prepared in the operating room prior to the arrival of the patient includes the appropriate sized facemask, laryngoscope handle and blade, tracheal tube, oral airway, laryngeal mask airway, and working suction catheter. If use of a laryngeal mask is planned, it should be prepared with lubricant and ready for insertion (see below).

A syringe of succinylcholine, 4–5 mg/kg, for intramuscular injection should be within reach in case laryngospasm or other type of upper airway obstruction occurs and immediate paralysis is required when intravenous access is absent. This dose should be calculated prior to the induction of general anesthesia.

#### Facemask ventilation

Proper positioning of the child during induction of general anesthesia is important in promoting upper airway patency and facilitating facemask ventilation and direct laryngoscopy. Because of the wide range of patient sizes encountered in pediatric practice, the adequacy of mask size and fit should be assessed prior to anesthetic induction. A properly fitting mask will cover the nose and mouth without covering the eyes or extending beyond the chin. A common mistake among trainees is to press the cephalad end of the mask onto the middle of the nose and unknowingly obstruct the airway. The cephalad end of the mask should be properly positioned on the bridge of the nose without pressing into the orbits. Introducing the mask to the child before it is connected to the anesthesia circuit provides a non-threatening opportunity for the child to acclimatize to it while giving the anesthesiologist an opportunity to assess fit.

Various types of pediatric facemasks are commercially available. While some have been designed to minimize dead space (attractive in the smallest patients), there are no data supporting the superiority of one mask type over another. Reusable black facemasks have largely been supplanted by transparent disposable facemasks. These disposable masks are advantageous in that the anesthesiologist can look through them during ventilation and assess the position of an oral or nasopharyngeal airway or identify regurgitated fluid or vomitus. Application of a fruit- or candy-scented lip balm to the interior of the unscented mask may improve the child's acceptance.

During inhaled induction of general anesthesia, the facemask is initially applied gently to the face. The hand holding the mask should be held in such a way that the child's field of view is not obstructed. The other hand may be placed on the child's head and kept ready to hold the head still during the excitement stage of anesthetic induction. As consciousness is lost, the position of the hand holding the mask is adjusted so that the third and
possibly the fourth and fifth fingers are over the bony mandible. Special care must be taken in smaller children not to exert pressure on the submandibular tissues, which can create upper airway obstruction by posterior displacement of the tongue. Following loss of consciousness, 5–10 cmH<sub>2</sub>O of continuous positive airway pressure (CPAP) is applied by partial closure of the adjustable pressure limiting (APL) valve, and a head tilt or chin lift maneuver is performed with the left hand holding the mask while the right hand holds the breathing bag to assess breath-to-breath adequacy of air movement. Adequacy of ventilation is also continuously assessed by visual inspection of chest rise and breathing bag movement, auscultation with a precordial stethoscope, and the presence of a capnographic waveform.

# Chin lift, jaw thrust, and continuous positive airway pressure

Simple maneuvers such as performing a chin lift or mandibular protrusion (jaw thrust) can restore upper airway patency and relieve obstruction by increasing pharyngeal diameter at several levels [83-87]. The combination of either of these two techniques with the application of approximately 10 cmH<sub>2</sub>O of CPAP is the initial treatment of airway obstruction in the spontaneously breathing child [88]. These combined maneuvers (jaw thrust with CPAP or chin lift with CPAP) increase the diameter and patency of the upper airway as well as that of the glottic opening [84]. While chin lift and jaw thrust have effects on tongue and epiglottis position, CPAP acts as a pneumatic splint to increase airway dimensions. Because jaw thrust combined with CPAP has not been shown to be superior to chin lift combined with CPAP, it has been suggested that chin lift with CPAP is preferable to a forceful jaw thrust, since this can result in postoperative discomfort [86]. In children with suspected cervical spine injuries, neck extension should be avoided; jaw thrust may be preferable in these cases.

#### Oral airway

After optimization of positioning, facemask application, and application of CPAP, the oral airway is usually the next intervention to restore patency of an obstructed upper airway in the anesthetized child. A variety of oral airways for pediatric patients with subtle differences in design are commercially available, with no literature supporting the superiority of one type or brand over another. However, those with hollow channels offer the advantage of being able to insert a suction catheter into the oropharynx with the oral airway inserted.

When inserting an oral airway, care must be taken to select the appropriate size. A properly sized airway should have its pharyngeal tip projecting just beyond the angle of the mandible when held next to the child's head

Figure 14.6 Sizing the oral airway, showing the pharyngeal tip projecting just beyond the angle of the mandible.

with the opposite end at the mouth (Fig. 14.6). Insertion of an undersized airway can push the tongue posteriorly and worsen obstruction, while an oversized airway can impinge on the epiglottis or glottis and worsen obstruction or trigger coughing and laryngospasm.

Oral airways are generally reserved for use in anesthetized children and are poorly tolerated by awake or lightly anesthetized children as they can stimulate gagging, coughing or laryngospasm. However, as a child emerges from anesthesia, it is best to leave an oral airway in place to prevent the child from biting on the tracheal tube and to maintain airway patency following extubation. Children will typically expel the device as they regain full consciousness.

#### Nasopharyngeal airway

A nasopharyngeal airway may be inserted to restore patency of the obstructed upper airway when the obstruction is suspected to be at the level of the upper pharynx or higher. Unlike an oral airway, a nasopharyngeal airway can be tolerated in the sedated or lightly anesthetized child and can be left in place postoperatively to maintain airway patency in selected circumstances such as following tonsillectomy for obstructive sleep apnea.

A disadvantage of nasopharyngeal airway insertion is occurrence of epistaxis, especially if the adenoid has been removed. This can be minimized by using a soft airway and adequate lubrication. If time allows, topical administration of a vasoconstrictor to the nasal mucosa is helpful. Hypertrophic adenoid tissue can impede passage and may result in bleeding. The proper size nasopharyngeal airway can be selected by holding it next to the face before insertion. With the flared external end at the position of the nasal opening, a properly sized airway will have the pharyngeal tip extending a finger breadth beyond the space between the angle of the mandible and the tragus (Fig. 14.7). A nasopharyngeal airway that is too

**Figure 14.7** Sizing the nasopharyngeal airway, showing the pharyngeal tip projecting just beyond the space between the angle of the mandible and the tragus.

Figure 14.8 Two-handed mask technique.

short may not bypass upper airway obstruction, while one that is too long can impinge on the epiglottis and trigger coughing or laryngospasm.

## Two-person, two-handed mask ventilation

When it is difficult to maintain a patent airway with the above techniques, having one provider apply the facemask using two hands and simultaneously perform a chin lift and jaw thrust while another provider delivers breaths with the breathing bag is more effective than a single-handed mask ventilation technique (Fig. 14.8). Patients requiring a two-person technique should be considered difficult to ventilate by facemask [89,90].

#### Modified oral or nasal airway

The functionality of a standard oral or nasopharyngeal airway can be increased by inserting a 15 mm tracheal tube adaptor into the opening of the oral airway or the flared end of a nasopharyngeal airway (Fig. 14.9). The resulting modified airway can then be connected to the anesthesia circuit, and positive pressure can be delivered if the leaks around the airway are manually sealed. Positive pressure ventilation can be delivered by holding the mouth and opposite nasal passage closed [91]. This assembly with a nasopharyngeal airway is particularly useful in patients with limited mouth opening in whom oral airway or laryngeal mask insertion is not possible. The modified nasal airway is also a valuable adjunct to pediatric difficult airway management as a means of providing oxygen and inhaled anesthetic during oral

**Figure 14.9** Oral and nasopharyngeal airways can be attached to a 15 mm tracheal tube adaptor to provide easy connection with an anesthesia machine circuit.

intubation while maintaining spontaneous respiration [92]. Similarly, a cut tracheal tube can also be used for the same purposes [93] but since it is made of stiffer material, it is more likely to cause trauma and bleeding during insertion.

# Airway management with a facemask or natural airway

Maintenance of general anesthesia with a facemask is possible if a patent airway is easily achieved with or without an oral or nasal airway. Generally, use of a facemask is preferred for cases of shorter duration, and when the head of the operating room table is not turned away from the anesthesia machine. A natural airway that does not require the assistance of the anesthesiologist for patency is often used in conjunction with nasal cannula for supplemental oxygen administration, and the use of intravenous general anesthesia, such as propofol. Special cannulas designed to monitor exhaled carbon dioxide are commercially available or a standard cannula can be modified for this purpose. This technique is commonly used during total intravenous anesthesia for radiological or gastrointestinal endoscopy procedures.

## Laryngeal masks and supraglottic devices

The introduction of the laryngeal mask airway (laryngeal mask) into clinical practice marked the beginning of a new era of anesthesia care for adults [94] and children [95]. Since that time, the laryngeal mask has functioned as an alternative to the facemask or the tracheal tube, depending on the clinical situation. Of equal importance is its use as an airway rescue device in patients with life-threatening upper airway obstruction, or as an aid to difficult tracheal intubation.

The laryngeal mask consists of an airway tube with an elliptically shaped cuff at the distal end that is inflated after insertion. When properly positioned, its distal aperture lies opposite the laryngeal inlet while the tip of the cuff rests in the proximal esophagus. The inflated cuff creates a seal with the lateral walls of the hypopharynx, the esophageal inlet, and the tongue base.

The classic sniffing position is used for routine laryngeal mask insertion. The deflated or partially inflated laryngeal mask is held in the dominant hand like a pencil, with the tip of the index finger at the junction of the cuff and the airway tube on the side of the laryngeal aperture. The mouth is opened and the tip of the device is pressed cephalad along the hard palate and into the oropharynx until a resistance is felt as the tip engages the esophageal opening. Because of anatomical differences in children (e.g. large tongue, cephalad larynx, tonsillar hypertrophy), this technique may result in a lower success rate than in adults. Therefore, alternative approaches have been devised (i.e. lateral and rotational insertion techniques) which may be more successful in children [96-101]. These studies were performed using the classic laryngeal mask; therefore it is unknown whether these results can be extended to other commercially available laryngeal masks and supraglottic airways that have alternate designs.

Airway management with the laryngeal mask is advantageous in a number of ways. Insertion of the device is simple and easily learned, and there is a high success rate with insertion even by inexperienced operators. Laryngeal mask insertion does not require muscle relaxation, can be performed at a lighter level of anesthesia compared to tracheal intubation, and is associated with fewer hemodynamic changes when compared to tracheal intubation [102,103]. However, when compared to adults, optimal positioning of the laryngeal mask becomes progressively more difficult in direct relation to the decreasing size of the child. Incorrect positioning of the laryngeal mask may lead to inadequate ventilation, airway trauma, mask dislodgment, and gastric insufflation. Fiberoptic assessment of laryngeal mask position is often useful to ascertain that the mask is properly positioned. A jaw thrust maneuver while inserting the smaller sized larvngeal masks may facilitate optimal positioning by lifting the epiglottis off the posterior pharyngeal wall and allowing the mask tip to slide into the upper esophageal sphincter without causing downfolding of the epiglottis.

The laryngeal mask is not usually associated with mechanical trauma to the tracheal mucosa and vocal cords. This is particularly relevant in children undergoing multiple anesthetics over a relatively short time interval (e.g. daily radiation treatment). Interestingly, the incidence of postoperative sore throat is equally as common compared with a tracheal tube [104]. The occurrence of postoperative sore throat in children appears to be correlated with laryngeal mask intracuff pressures above 40 cmH<sub>2</sub>O [105]. The incidence of other less commonly reported complications from laryngeal mask use, such as lingual, hypoglossal or recurrent laryngeal nerve injury [106–109], may also be decreased by routine monitoring of laryngeal mask cuff pressures.

In the years following the introduction of the laryngeal mask, a variety of supraglottic airway devices have become available for use in children. The Cobra perilaryngeal airway (CobraPLA, Engineered Medical Systems, Indianapolis, IN) has a pharyngeal cuff rather than a laryngeal bowl and a leaf-shaped head with a slotted grill through which ventilation occurs. The CobraPLA has been demonstrated to perform as well as the Unique disposable laryngeal mask (Laryngeal Mask North America, San Diego, CA) in infants and children in terms of ease of insertion, airway sealing pressure, amount of gastric insufflation, and complications following removal. There is some evidence that its laryngeal positioning may not be optimal in infants less than 10kg [110]. The i-Gel (Intersurgical Ltd, Berkshire, UK) has a non-inflatable bowl made of a heat-sensitive elastomeric gel whose shape conforms to fit the supraglottic airway. Although there exists a body of evidence supporting the efficacy and safety of the classic laryngeal mask and the ProSeal laryngeal mask in pediatrics, there are fewer data showing similar efficacy and safety of the similar supraglottic devices that are now available.

Like an oral airway, laryngeal masks and other supraglottic airways are poorly tolerated in awake or lightly anesthetized patients. Insertion at an inadequate plane of anesthesia can result in coughing, laryngospasm, gagging, and emesis. A number of studies have been conducted to determine optimal drug dosages to achieve adequate conditions for laryngeal mask insertion. Sevoflurane alone can be used to facilitate laryngeal mask insertion in children [111]; an effective concentration of 2.2 vol% provides satisfactory conditions in 95% of patients when 10min are allowed to elapse for equilibration of brain and alveolar sevoflurane concentrations prior to insertion [102].

At approximately equipotent dose levels, propofol is a more potent suppressor of upper airway reflexes compared to thiopental [112] and is a superior induction agent for laryngeal mask insertion in terms of adverse respiratory events such as coughing or laryngospasm [113]. Propofol alone can be administered to facilitate laryngeal mask insertion. Doses exceeding 5mg/kg are required to achieve satisfactory conditions in 90% of unpremedicated children [114]; however, such doses may result in undesirable hemodynamic effects and apnea. The combination of propofol with other drugs to facilitate laryngeal mask insertion is advantageous. For example, co-administration of lidocaine will result in less pain on injection of propofol [115–117] and may contribute to decreasing airway reflexes [118]. Opioids, such as fentanyl [119], alfentanil [115], and remifentanil [120] may also aid laryngeal mask insertion when co-administered with propofol.

In adults, the laryngeal mask was originally designed for removal as the patient awakens [94]. In children, there has been controversy over whether it is better to remove the laryngeal mask under deep general anesthesia or after awakening. Some studies show a higher incidence of respiratory complications (coughing, laryngospasm or oxyhemoglobin desaturation) when the laryngeal mask is removed when the child has largely regained consciousness [121,122] but others found a decreased incidence of such complications with awake removal [123,124] and some report no difference in complications based on removal technique [125,126]. One of the principal advantages of laryngeal mask removal under deep anesthesia is time efficiency - following laryngeal mask removal and assurance of a patent airway, the child can be transferred to the recovery room and allowed to emerge from anesthesia. If laryngeal mask removal under deep anesthesia is planned, the end-tidal sevoflurane concentration at which this can be safely performed in 95% of children without coughing, movement, laryngospasm or other airway complication is 2.2 vol% [127,128].

Laryngeal mask insertion may be tolerated in conscious newborns with severe upper airway obstruction, as occurs with the Pierre Robin sequence, Treacher Collins syndrome or Goldenhar syndrome [129–132]. The ProSeal laryngeal mask (Laryngeal Mask North America) is similar to a classic laryngeal mask with the addition of a channel through which a gastric drainage tube can be passed. The ProSeal mask is available in sizes appropriate for use in infants and children. Some practitioners avoid positive pressure ventilation with laryngeal mask use because of the possibility of gastric insufflation. Thus, the ProSeal mask may be preferred in patients who require positive pressure ventilation [133,134].

Pressure support ventilation decreases the work of breathing in spontaneously breathing children [135]. The advent of anesthesia machines with more sophisticated ventilators that can deliver pressure support ventilation has also made use of laryngeal masks more feasible as an alternative to tracheal intubation [136]. While work of breathing is improved with the application of CPAP [137], work of breathing is less and respiratory rate and endtidal carbon dioxide are lower with pressure support ventilation compared to CPAP in children breathing with a laryngeal mask [138].

## Laryngeal Tube

The Laryngeal Tube (VBM Medizintechnik, Sulz, Germany) is an extraglottic device that is inserted blindly in a manner similar to the laryngeal mask. When inserted, the distal end is positioned in the proximal esophageal opening. The device has an interconnected distal esophageal cuff and a proximal pharyngeal cuff, which results in equilibration of pressures between the two cuffs. Ventilation is delivered through numerous holes in the section of the tube between the esophageal and pharyngeal cuffs. This device is available in single-lumen and dual-lumen versions. The dual-lumen Laryngeal Tube has a channel that terminates in the esophageal end of the device. A catheter can be passed blindly through this lumen for gastric decompression. Indications for use of the laryngeal tube are similar to those for the laryngeal mask. However, unlike the laryngeal mask, this device cannot be readily used as a conduit for tracheal intubation.

# **Tracheal intubation**

Indications for tracheal intubation are determined by the surgical procedure and the potential risk of aspiration of gastric contents. As a general rule, tracheal intubation is indicated for open cavity procedures of the abdomen or chest, intracranial procedures, and in cases where control of arterial  $PCO_2$  is required. It is also indicated in cases where the anesthesiologist has limited access to the airway, such as procedures involving the head and neck or patients in the prone or lateral position.

# Positioning for mask ventilation and tracheal intubation

In adults, the "sniffing position" (neck flexion and head extension) is classically described as the optimal head and neck position to facilitate direct laryngoscopy and tracheal intubation. The recommendation of this position is based on texts published between 1852 and 1944 [139]. Recently, a number of publications have suggested that the sniffing position in adults may offer no advantage over simple extension of the head for successful direct laryngoscopy [140–142]. Vialet et al compared the alignment of the oral, pharyngeal, and tracheal axes in children anesthetized for MRI scans of the head and neck, and found that there was better alignment achieved with simple extension of the head as compared to the sniffing position [143]. However, comparative trials examining the optimal position for laryngoscopy and intubation in children have not been done. The large occiput of an infant, when placed on a pillow, can flex the head and result in airway obstruction. Eliminating the pillow or placing a soft roll beneath the shoulders may improve upper airway patency.

# **Direct laryngoscopy**

Direct laryngoscopy remains the most common method of tracheal intubation in children. Direct laryngoscopy using a straight Miller blade has traditionally been emphasized in infants and young children. This practice is largely based on anatomical studies [28] but comparative studies have not been performed [139,144,145]. The straight Miller blade may allow for greater control and displacement of the base of the tongue. The smaller size and lower profile of the straight blade may give the operator more room to pass the tracheal tube through the mouth and pharynx. When laryngoscopy is performed using a straight blade, the blade is advanced and used to directly lift the epiglottis to expose the larynx. The straight blade can also be directed into the vallecula and used to indirectly lift the epiglottis as is done with the standard curved blade. Miller's 1946 original description of the infant version of the blade states "... the epiglottis is visualized and raised slightly to expose the cords or, if the operator desires, the tip of the blade may be placed in front of the epiglottis and raised sufficiently to visualize the cords after the method of Macintosh" [146]. While direct laryngoscopy with the Miller blade may be more difficult to learn [147], there is evidence in adults that a superior view of the larynx can be achieved compared to the Macintosh blade [147,148].

If, during direct laryngoscopy, the visualization of the glottis is suboptimal, the laryngoscopist can optimize the glottic position by external manipulation of the thyroid cartilage. This practice was described by Benumof as optimal external laryngeal manipulation (OELM) [149].

**Figure 14.10** The glottis can be externally manipulated by using the fifth finger of the left hand that holds the laryngoscope.

The application of backward, upward, and rightward pressure on the thyroid cartilage (known as the BURP maneuver) [150] is an example of a specific type of OELM that many laryngoscopists employ as a first-line attempt at achieving optimal glottic exposure. In newborns and small infants, OELM can be performed using the fifth finger of the left hand (Fig. 14.10).

# Hemodynamic response to laryngoscopy and tracheal intubation

Tracheal intubation in infants and children is an intensely stimulating procedure and can provoke tachycardia, hypertension, increased intracranial pressure, and bradycardia [151–155]. Tracheal intubation with flexible bronchoscopy does not result in a decreased pressor response compared to direct laryngoscopy [151]. Performance of intubation under deep anesthesia attenuates the pressor response to intubation; however, many of the agents used to achieve this can cause cardiovascular depression. The opiates fentanyl, remifentanil, and sufentanil have all been used for this purpose with success [156–158] while lidocaine does not appear to be effective [159].

# Movement of the tracheal tube tip with neck movement

Flexion or extension of the neck results in predictable changes in location of the tracheal tube tip. In children, with both orotracheal and nasotracheal tubes, neck flexion results in caudad migration of the tube tip, while extension causes cephalad migration of the tube tip [160–162]. Therefore, bronchial intubation or extubation may result with neck movement after securing the tracheal tube.

# Tracheal intubation without neuromuscular blockade

With the introduction into clinical practice of sevoflurane, propofol, and remifentanil, there has been increased interest in achieving tracheal intubation without neuromuscular blockade. Successful intubation can be accomplished with sevoflurane alone [163] although other drugs are commonly co-administered. Intubating conditions can be improved when sevoflurane is combined with propofol [164,165], lidocaine [118] and remifentanil [166,167].

## "Awake" tracheal intubation

In select circumstances outside the obstetric delivery room, tracheal intubation may be performed in unpremedicated newborn infants who might not tolerate the cardiovascular depressant effects of anesthetic or sedative drugs. However, infants and neonates do experience the pain and discomfort from laryngoscopy; its performance without sedative premedication or general anesthesia has untoward cardiovascular (and behavioral) effects and should be avoided whenever possible. Furthermore, the administration of anesthetic, sedative, and neuromuscular blocking drugs improves conditions for intubation and decreases the likelihood of airway trauma [168-171]. A consensus statement published by the International Evidence Based Group for Neonatal Pain states "tracheal intubation without the use of analgesia or sedation should be performed only for urgent resuscitations in the delivery room or for life-threatening situations associated with the unavailability of intravenous access" [172].

# **Nasotracheal intubation**

Before the advent of muscle relaxants, nasotracheal intubation was the preferred route for tracheal intubation; the technique was perfected by pioneering anesthesiologists such as Dr Ivan Magill (now memorialized for the forceps used for this purpose that bear his name) [173]. Following the introduction of muscle relaxants into anesthesia practice, orotracheal intubation became the favored technique. In current anesthesia practice, nasotracheal intubation is required for certain procedures (e.g. Lefort I osteotomy), while it is preferable for other procedures but not essential (e.g. oral rehabilitation). In other situations, such as in infants in the prone position, many anesthesiologists prefer a nasotracheal tube because of the possibility that it is more stable and secure than an oral tube. For children undergoing cardiac surgery, a nasotracheal tube may leave more room in the mouth for transesophageal echocardiography probe insertion. Nasotracheal intubation may be more comfortable than orotracheal intubation if postoperative tracheal intubation is expected.

Nasotracheal intubation is more challenging to perform than orotracheal intubation. The most common complication is epistaxis, especially in children with adenoidal hypertrophy. Other less common complications include retropharyngeal perforation [174,175], sinusitis [176], bacteremia [177-179] and turbinate avulsion [180,181]. Nasotracheal intubation is contraindicated in the setting of facial or skull fractures; intracranial tube placement has been reported following attempted nasotracheal intubation in this setting [182]. Oxymetazoline 0.05% can be applied to the nasal mucosa for vasoconstriction and to decrease the risk and severity of epistaxis. Cocaine (4-10%) and lidocaine with epinephrine have also been used for this purpose. Oxymetazoline is as effective as 10% cocaine and more effective than lidocaine with epinephrine for the prevention of epistaxis from nasotracheal intubation [183]. In a related study assessing vasoconstriction for endoscopic sinus surgery, oxymetazoline was preferable over both 0.25% phenylephrine and 4% cocaine [184]. To avoid triggering laryngospasm, topical vasoconstrictors should be sprayed after a deep plane of anesthesia has been reached or following administration of a neuromuscular blocking drug.

Topical vasoconstrictors used for nasal mucosal vasoconstriction are potent  $\alpha$ -agonists that can be absorbed and exert systemic effects; these agents should be used judiciously. Life-threatening hypertension and pulmonary edema following the use of topical 0.5% phenylephrine have been described [184–186]. Severe hypertension and reflex bradycardia progressing to sinus arrest have also been reported following oxymetazoline administration [187,188].

The occurrence of nasal bleeding may also be reduced by softening the tracheal tube, which is achieved by soaking the tip in warm water or saline [189]. However, the use of a red rubber catheter to guide the tracheal tube through the nose into the pharynx is a more effective method of decreasing epistaxis compared to softening the tube tip in warm water [190–192].

Once inserted through the nose, the tube should be advanced so that its tip lies in the pharynx. Direct laryngoscopy is then performed, and the tip of the tracheal tube located in the pharynx. Once laryngeal exposure is optimized, the tube is gently grasped and guided into the trachea using Magill forceps as the tube is advanced. Care must be taken not to damage the cuff of a cuffed tube with the forceps.

Occasionally, it is difficult to advance the nasotracheal tube into the trachea despite an excellent view of the glottic inlet. This may occur because the natural curvature of the nasotracheal tube directs the tip anteriorly as it is advanced rather than in a direction parallel to the long axis of the trachea. Techniques to overcome this problem include neck flexion, directing the tube posteriorly with

Figure 14.11 Proper taping of the nasal RAE tracheal tube to avoid pressure on the skin of the nasal alae.

the Magill forceps, rotating the tube so the narrowest part of the beveled tip is aligned parallel with the glottic opening, turning the head to the side, and rotation of the tube 180° as it is advanced to direct the natural curvature of the tube more posteriorly.

When securing a nasotracheal tube, it is important to tape the tube in a way that avoids excess pressure between the tube and the ala, as this can result in ischemia and subsequent ulceration (Fig. 14.11).

# **Tracheal tube selection**

A variety of methods exist for determining the expected tracheal tube size in children, including formulas based on age, height–length ratio, ultrasound measurement [43] and qualitative methods such as comparison of tube size with the size of the fifth finger nail [193]. Although height is often used in the emergency department setting [194,195], age-based formulas are more commonly used by anesthesiologists. Uncuffed tube size is often determined by a modified Cole's formula: internal tube diameter (mm) = 4 + age/4 [193,196,197]. If a cuffed tube is to be used, a one-size smaller diameter tube should be selected to account for the small increase in external diameter created by the deflated cuff: internal tube diameter (mm) = 3 + age/4 [196].

# **RAE tubes**

Oral and nasal tracheal tubes with a preformed bend (RAE tubes, named from the initials of the inventors Ring, Adair, and Elwyn) may be desirable in surgical procedures involving the eyes, oral cavity or face [198]. These tubes allow the anesthesia circuit to be directed away from the surgical field without kinking. The length of the preformed bend is fixed and varies with tube size. Sometimes the RAE tube that is the proper size for the child's tracheal diameter is too short or too long due to the fixed location of the bend. In cases where it is too long, a smaller size cuffed RAE can be used. In cases where it is too short, a standard straight tube may need to be substituted. For oral and nasal RAE tubes, a useful way of choosing the proper size based on length is to hold the tube next to the child's face and assess the location of the cuff or tube tip. In cuffed tubes, the cuff should lie at the level of the suprasternal notch; the tip of an uncuffed tube should lie at the level of the sternoclavicular junction.

# Cuffed versus uncuffed tracheal tubes

Historically, uncuffed tracheal tubes were preferred in children up to the approximate age of 8–10 years. The lack of a cuff allowed for a greater internal diameter, which translated into lower resistance and decreased work of breathing during spontaneous ventilation, and greater ease of suctioning secretions. There was also concern that the use of cuffed tubes may be associated with a higher risk of subglottic injury. However, the use of modern tracheal tubes with high-volume, low-pressure cuffs has not been associated with an increased incidence of subglottic airway injury or of postextubation croup following their use in anesthetized children [199].

In 1951, Eckenhoff published a seminal article describing the anatomy of the infant and pediatric larynx [29]. The widespread teaching based on this article was that the infant larynx is funnel shaped with the widest portion at the glottic inlet and the narrowest portion at the cricoid ring. This has been disproven in a purely static anatomical measurement model using magnetic resonance imaging [35,37]; however, the cricoid ring remains *functionally* the narrowest portion of the airway because it is a complete ring and is non-distensible. These latter studies found the pediatric larynx to be slightly elliptical in cross-section, with a smaller transverse diameter and a larger anteroposterior diameter. Given this elliptical shape, an uncuffed tube of a size that effectively ablates an air leak would be expected to exert more pressure on the lateral walls of the larynx and trachea [200]. The cuff of a properly sized cuffed tracheal tube would conform to the shape of the trachea as it is inflated and pressure would be evenly distributed. The use of cuffed tubes in children is associated with a decreased incidence of post intubation stridor [201]. In addition to the anatomical factors described above, this may also be related to decreased need for repeat laryngoscopy and tube changes in cases where an uncuffed tube that is too small or too large is initially inserted.

Cuffed tracheal tubes provide a better seal to protect the trachea from macroaspiration, while simultaneously allowing for lower fresh gas flows (with associated economic advantages) and decreased operating room pollution. In cases such as tonsillectomy, use of a cuffed tube can limit escape of oxygen-enriched inspired gases and decrease the risk of intraoperative fires, although this does not obviate the importance of limiting inspired oxygen concentration in these cases. However, there is some evidence that the presence of a cuff may contribute to bronchoscopically proven airway injury [202].

In our clinical practice, uncuffed tracheal tubes are rarely used. However, they remain useful in certain situations where maximizing the internal diameter of the tube is important. Because resistance to airflow is inversely proportional to the fourth power of the radius of the tube (or fifth power with turbulent flow), the ability to ventilate can be impaired by selecting a cuffed tube that is a size smaller than the appropriate uncuffed tube. This effect is most clinically significant with smaller tube sizes used in preterm and very low-birthweight infants. Moreover, suctioning and pulmonary toilet are more difficult with the smallest tubes. An uncuffed tube is advantageous to achieve single lung ventilation by advancing and lodging it into the ventilated main bronchus. A separate bronchial blocker may be placed alongside the tube or within it, and because the bronchial blocker occupies a portion of the lumen, a larger lumen will help limit resultant increased resistance to airflow through the tube.

# Determining proper endotracheal tube length

Like tracheal tube diameter selection, a variety of formulas have been created to predict the proper depth of orotracheal tube insertion. In infants and neonates, a commonly used rule of thumb is the "1234-78910 rule," where a 1kg infant will have the tube taped at 7 cm at the maxillary alveolar ridge, a 2 kg infant taped at 8 cm, a 3 kg infant taped at 9cm, and a 4kg infant taped at 10cm. In infants, when an uncuffed tracheal tube is used, it is common practice to advance the tube to achieve a deliberate right main bronchial intubation while auscultating the left chest. The centimeter depth at which breath sounds disappear (or become greatly decreased) is identified as the carina. The tube is then withdrawn midway between the carina and the vocal cords. Prior to performing this maneuver, it is useful to identify the centimeter marking relative to the gum or incisors following intubation and advancement of the cuff just beyond the vocal cords (or with an uncuffed tube, 1–2 cm beyond the vocal cords). Knowing the centimeter marking with this depth of insertion as well as the depth of the carina gives the anesthesiologist an idea of how much cephalad or caudad tube displacement can safely occur.

In older children, a good rule of thumb that is used to estimate the proper orotracheal tube depth in centimeters is to multiply the appropriate tube internal diameter (in millimeters) by 3. For nasotracheal intubation, multiplying the appropriate tube internal diameter by 4 is an effective method. When a cuffed tube is used, the ballotte technique can be used to place the cuff in its proper position at the level of the suprasternal notch. Identification of the depth of the tube relative to the maxillary alveolar ridge or maxillary incisors gives a more precise depth marking than identification relative to the lip.

# Assessing tube size following endotracheal intubation

The appropriateness of the tracheal tube size selected must be verified in every child. A tube that is too large may exert excessive pressure on the tracheal mucosa, resulting in mucosal ischemia. In the short term, this can lead to mucosal edema and stridor following extubation, while in the long term it may contribute to the development of subglottic stenosis.

In some children, an oversized tube is identified by an inability to advance the tube into the trachea during the intubation attempt. The most common method to assess tube size after placement of the tube is the air leak test. After midtracheal positioning of the tube tip, the APL valve is closed and the circuit pressure is allowed to increase while a stethoscope is placed over the thyroid cartilage. The leak pressure occurs when air is heard escaping around the tube. The ideal leak pressure is between 20 and 30 cmH<sub>2</sub>O. It is important to avoid a slow and prolonged leak test as this will have the hemodynamic consequences of a prolonged Valsalva maneuver. When a cuffed tube is used, the cuff inflation volume can be adjusted to achieve the desired leak pressure. For short cases, if the initial leak test is above 40 cmH<sub>2</sub>O, some anesthesiologists will not exchange the tube for a smaller one in the interest of avoiding the trauma of repeated laryngoscopy. For longer cases, if the leak pressure is greater than 30–35 cmH<sub>2</sub>O, exchange with a smaller tracheal tube may be preferred.

# Rapid-sequence induction and intubation in pediatric patients

Rapid-sequence induction and intubation (RSII) is used to minimize the time from anesthetic-induced loss of consciousness and endotracheal intubation, to decrease the risk of pulmonary aspiration of gastric contents. RSII is often more challenging in pediatric patients when compared to adults because infants and small children have relatively higher oxygen consumption rates, reduced functional residual capacity (FRC), and elevated closing volumes and thus will develop oxyhemoglobin desaturation more quickly during periods of apnea. Because of this propensity toward hypoxemia during RSII in children, and the lack of any feasible period of preoxygenation, many pediatric anesthesiologists perform a "modified" rapid-sequence induction [203]. In this modified technique, gentle facemask ventilation is performed using low inflation pressures (<10–15 cmH<sub>2</sub>O) while cricoid pressure is applied until enough time has elapsed for complete neuromuscular blockade to be established. In support of this practice, appropriately applied cricoid pressure has been shown to be effective in preventing gastric inflation during gentle bag-mask ventilation in anesthetized infants and children [204,205]. In older children and adolescents who can co-operate with adequate preoxygenation, a classic RSII may be preferred. If the initial attempt at intubation fails, gentle facemask ventilation through cricoid pressure should be performed. If ventilation is difficult with cricoid pressure despite the use of adjunctive devices (e.g. oral or nasopharyngeal airway, laryngeal mask), cricoid pressure should be lessened or released [206,207].

Cricoid pressure is contraindicated in the presence of active vomiting, suspected laryngeal or tracheal injury, and unstable cervical spine injuries [206,208]. In children, cricoid pressure applied below the cricoid ring can result in significant distortion of the larynx and trachea and increase the difficulty of ventilation or intubation [209]. A recent report of the complications of RSII in a large children's hospital population revealed an incidence of difficult intubation of 1.7%; however, it is unclear if these difficulties were related to presence of cricoid pressure [210].

# Postoperative airway management

The first priority in the postoperative care of the child is ensuring a patent airway. Assessment should focus on residual effects of anesthetic agents, opioids, and sedatives in the context of the preoperative condition of the child, the course of intraoperative airway management, the surgical procedure, anticipated fluid shifts, and the expected postoperative course. During recovery, proper head and neck positioning promotes airway patency. In the supine position, a soft roll placed under the shoulders will extend the head and neck and help open the upper airway. Placing the child in the "recovery (lateral) position" increases upper airway size [21] and allows secretions to drain out of the mouth rather than backward into the pharynx. If airway obstruction fails to improve with positioning, and the child is semi-conscious, a soft nasopharyngeal airway can be inserted; if the child is still anesthetized, an oral airway may be preferred. If airway obstruction is incompletely relieved with a nasopharyngeal airway, a 15mm tracheal tube adaptor can be placed into the external flared end of a nasopharyngeal airway for the delivery of CPAP [91]. If one suspects that postoperative upper airway obstruction is caused by the residual effect of opioids, naloxone can be cautiously administered to test and treat this possibility. Incremental doses of  $0.5-1\mu g/kg$  can be carefully titrated to reverse respiratory depressant effects without reversal of analgesic effects. Children who fail these measures to restore airway patency may require tracheal reintubation.

## Non-invasive respiratory support

In selected cases, non-invasive ventilatory support, such as CPAP or bi-level positive airway pressure (BiPAP), may be a useful option and can allow some patients to avoid tracheal intubation and mechanical ventilation in the postoperative period. Non-invasive support in older children is most often delivered by facemask or nasal mask, while nasal prongs are used in neonates and infants. Children and adolescents who use such devices preoperatively should receive respiratory support from these devices in the postoperative period. CPAP delivered by nasal prongs to neonates and infants is an effective way to improve respiratory function and prevent reintubation following extubation in the neonatal intensive care unit [211], as well as for treatment of apnea of prematurity [212,213].

#### Postoperative mechanical ventilation

If postoperative mechanical ventilation is required, a plan must be developed for transfer of the child's care from the operating room to the intensive care unit. Clear communication regarding the course of airway management should include discussion of the ease of facemask ventilation and direct laryngoscopy, tracheal tube size and insertion depth, current ventilator settings, and the reason why postoperative mechanical ventilation is necessary. The child will need to be transitioned from general anesthesia to an appropriate sedation regimen. If airway management was difficult, a plan should be in place in the event of accidental extubation. Keeping an appropriately sized laryngeal mask at the bedside is essential in such cases. If an oral RAE tube was used, this should be changed to a standard tracheal tube as protrusion of the tongue can easily result in extubation, and pulmonary toilet is more difficult with RAE tubes.

# Upper airway complications and management

#### Laryngospasm

Laryngospasm is a prolonged glottic closure maintained beyond the initiating stimulus and is a protective reflex that causes complete closure of the vocal cords to protect the trachea from aspiration of foreign material [214]. Prolonged laryngospasm can result in hypoxemia, bradycardia, postobstructive negative pressure pulmonary edema, regurgitation and aspiration of gastric contents, and cardiac arrest. Laryngospasm is more common in children than adults; it has been estimated to occur at a frequency from 1 per 1000 anesthetics to 17 per 1000 anesthetics [215–217]. While one belief has been that hypoxemia itself will result in abolition of this reflex, data from the Pediatric Perioperative Cardiac Arrest Registry reveal that laryngospasm continues to be a cause of cardiac arrest in children [218]. The incidence of laryngospasm appears to be increased in children with a history of active or recent upper respiratory tract infection [217,219–221].

Initial treatment of laryngospasm consists of CPAP delivered by facemask with 100% oxygen. Deepening the anesthetic may relieve the obstruction and can be achieved with intravenous propofol. If hypoxemia is occurring, the treatment of choice is immediate neuromuscular blockade with succinylcholine. In adults, low-dose succinylcholine (e.g. 0.1 mg/kg) is effective in treating laryngospasm [222]. However, larger doses may be preferred if reintubation is planned. When administering succinylcholine in children, some pediatric anesthesiologists prefer to co-administer an anticholinergic agent (i.e. atropine or glycopyrrolate) to prevent succinylcholine-induced bradycardia.

If laryngospasm develops prior to establishment of intravenous access, succinylcholine (4-5mg/kg) may be administered via the intramuscular route [223]. Maximal twitch depression at the abductor pollicis following intramuscular injection of succinylcholine will develop in 3-4min; however, clinical relief of airway obstruction occurs much sooner [224,225]. Succinylcholineinduced bradycardia is less likely with intramuscular administration [223,226]. Intralingual or submental administration of succinylcholine has been recommended because of its rapid onset of action [227,228]; however, many avoid this route because of concerns about intraoral bleeding. Intramuscular administration of 4-5mg/kg of succinylcholine may result in a phase II block, and more than 20 min may elapse before neuromuscular blockade resolves [223].

Additional treatments for laryngospasm, such as pressure in the "laryngospasm notch" [229], digital elevation of the tongue [230], nitroglycerine [231] and doxapram[232] have been proposed but their efficacy in children has not been evaluated.

Laryngospasm accompanied by a strong inspiratory effort and hypoxemia may lead to negative pressure pulmonary edema with or without pulmonary hemorrhage [233–236]. The treatment depends on the severity of symptoms, and includes supplemental oxygen, furosemide, and positive pressure respiratory support.

# **Pulmonary aspiration of gastric contents**

Pulmonary aspiration of gastric contents is a relatively uncommon event, although its incidence in children appears equal to or higher than that in adults [237–239]. The incidence in the pediatric population ranges from 1 in 2632 anesthetics [238] to 1 in 1000 anesthetics [239]. Death from anesthetic-related pulmonary aspiration is exceedingly rare. Children with clinically apparent pulmonary aspiration who did not develop symptoms within 2h are unlikely to develop subsequent respiratory complications [238].

Factors associated with increased risk of pulmonary aspiration include emergency surgery, presence of bowel obstruction or ileus, younger age, and ASA physical status 3 or 4 [238,239]. Obesity is not associated with an increased gastric fluid volume or increased risk of pulmonary aspiration [240].

# **Postintubation croup**

Postintubation croup presents as inspiratory stridor, hoarseness, a "barky" cough and, in severe cases, intercostal retractions and respiratory distress. Postintubation croup is thought to result from airflow restriction due to tracheal edema from mechanical trauma or mucosal ischemia related to endotracheal intubation. The site of greatest restriction is at the level of the cricoid ring. The incidence in children was reported to be 1% in 1977 [241]; however, more recent data suggest a lower incidence [242]. Postintubation stridor may develop shortly following tracheal extubation or several hours later. Upper airway obstruction from other causes must be investigated before the diagnosis is made. Treatment is initially supportive and is not unlike the treatment of infectious croup, which also results from subglottic edema. Delivery of humidified mist is first-line therapy. Physical exam findings determine the need for additional treatment. Nasal flaring, subcostal or intercostal retractions, or other features indicative of increased work of breathing are indications for pharmacological therapy. Dexamethasone, 0.5 mg/kg up to 10 mg, is an effective second-line treatment. Nebulized racemic epinephrine can also be administered but should be reserved for severe cases. Because of the potential for rebound edema after the racemic epinephrine has worn off, children should be observed to ensure that symptoms do not recur.

# Airway management for tracheostomy insertion

Infants and children who require chronic ventilatory therapy will likely benefit from insertion of a tracheostomy tube. Diagnoses associated with the need for

tracheostomy include neuromuscular impairment, chronic lung disease, trauma, upper airway anomalies, congenital heart disease, and prematurity [243]. Infants who have had long-term tracheal intubation and mechanical ventilation may develop subglottic stenosis and require tracheostomy to provide long-term ventilatory support. The in-hospital mortality in pediatric patients who undergo tracheostomy during their hospitalization is as high as 8.5% [243]. Most of these children present to the operating room with a secured airway (tracheal tube). In these cases the ease of previous mask ventilation and tracheal intubation must be determined preoperatively. Those children in whom direct laryngoscopy was difficult should have a plan developed in case accidental extubation occurs before tracheostomy completion. Such a plan might include leaving an airway exchange catheter in the trachea during completion of the tracheostomy or withdrawal of the tracheal tube to a position just above the tracheostomy incision, with the tip still between the vocal cords so that it can be easily advanced for reintubation should this be required. These cases require close vigilance and communication with the surgeon throughout the procedure. The risk of a surgical fire can be reduced by minimizing the inspired oxygen concentration and avoiding the use of nitrous oxide. The surgical team should avoid the use of cautery to enter the airway.

The choice of tracheostomy tube size and length depends on the indications for tracheostomy. Patients requiring chronic mechanical ventilation often benefit from low-pressure, high-volume cuffed tubes, often made with silicone or other soft material to minimize airway trauma. Patients with upper airway obstruction without significant lung disease often benefit from small uncuffed tracheostomy tubes, which are large enough to provide a patent airway, yet allow sufficient air leak to support vocalization. Consultation with the surgeon and pulmonologist is important to understand all the goals of the procedure and select the correct tracheostomy tube.

Certain children with upper airway congenital anomalies may not have an existing tracheal tube immediately prior to surgical tracheostomy. Airway management for tracheostomy may entail tracheal intubation with subsequent management as described above. Alternatively, a laryngeal mask may be used as an anesthetic airway conduit during tracheostomy insertion.

A newly placed tracheostomy requires 7–10 days for the stoma to be well formed; prior to this period, if a tube change is needed, it should be performed by an otolaryngologist. After healing, tracheostomy tubes should be changed every 1–2 weeks to reduce the formation of granulation tissue or mucus plugging of the tube. A tracheostomy bypasses the humidification and warming function of the nose and upper airway so an artificial humidification device is necessary. Heat and moisture exchangers (HMEs) are generally used to facilitate this function. They should be selected to minimize resistance to airflow, and minimize work of breathing [244].

# Management of the child with a preexisting tracheostomy

Tracheostomized children presenting for general anesthesia and surgery require a different approach to airway management. During the preoperative visit, the anesthesiologist should determine the type, size, and presence of a cuff on the tracheostomy tube. Parents and caregivers should be asked about the frequency of suctioning, as well as the suction catheter size and the depth it is inserted. The presence or absence of a leak around the tracheostomy tube as well as the amount of ventilator support the child requires should also be determined during the preoperative assessment. These children should come with emergency replacement supplies for their tracheostomy, which should be kept with them throughout their perioperative course.

Inhaled anesthetic induction is the most common induction technique in these children. It is often necessary to connect a flexible "accordion" extension from the end of the anesthetic circuit to the tracheostomy tube to increase the limited clearance between the clavicles and mandible, especially in infants. In those with a significant leak around the tracheostomy tube, inhaled induction may be prolonged due to mixing of air inspired from the upper airway with gases inspired through the tracheostomy tube. Following the loss of consciousness, holding the mouth and nose closed or applying a sealed facemask will help decrease mixing and facilitate ventilation through the tracheostomy.

For short procedures, it is often unnecessary to change the tracheostomy tube. For intracavitary or long procedures, if there is a significant leak around the tracheostomy tube, a standard cuffed tracheal tube will enable effective positive pressure ventilation. This can be achieved by exchange of the existing tracheostomy tube with the same-sized cuffed tracheal tube. With an established tracheal stoma, this is easily accomplished; however, consultation with an otolaryngologist may be useful in selecting the most appropriate tube and for performing the exchange, if necessary. Another option is replacement of the tracheostomy tube with a wirereinforced tube. This lower profile alternative can be useful in cases where a standard tracheostomy tube would encroach on the surgical field. This tube can be secured to the chest with tape or sutured in place in selected circumstances. In cases where the tracheostomy site encroaches on the surgical field, the child's airway can be secured with an oral or nasal tracheal tube, and the tracheostomy site can be sealed with gauze and nonocclusive tape and dressing.

Tracheostomy tubes are available in a variety of sizes and lengths for pediatric use. They can be constructed from metal or plastic. Plastic tubes are most frequently used and are made from silicone or polyvinyl chloride. Some tracheostomy tubes are supplied with a tracheostomy disconnection wedge, which facilitates separation of connections to the tracheostomy. The internal and external diameters are usually marked on the flange of the tracheostomy tube. Several manufactured tubes have wire-reinforced designs, allowing flexibility without kinking, and some have long flexible proximal ends (e.g. FlexTend<sup>TM</sup>), which place connections to the tube away from the child's neck, thus reducing the chance of tube obstruction in small patients.

Tracheostomy tubes are available in cuffed and uncuffed versions [245]. The cuff helps to protect the airway from secretions and facilitates positive pressure ventilation in children with poor lung compliance. Cuffed tracheostomy tubes have a high-volume, low-pressure cuff, a low-volume, high-pressure cuff, or a foam cuff, which is useful in patients with chronic aspiration. The Tight-To-Shaft tube (TTS<sup>TM</sup>) has a low-volume, high-pressure cuff used for patients who need intermittent inflation such as during meals and at night. When deflated, the cuff assumes the profile of the tube and enables phonation and use of the upper airway. The cuff should be inflated with sterile water because it is gas permeable and will slowly deflate over time.

The Montgomery tube is a T-shaped silicone tube that has a short lumen projecting from its side at a 75° or 90° angle. It is typically used after tracheal reconstruction to stent the airway and can be left in place for months. The upper limb extends above the glottis and the short limb is brought out through the tracheostomy stoma.

# The difficult pediatric airway

There are two broad categories of pediatric patients with a "difficult" airway: those who are difficult to mask ventilate, and those who are difficult to tracheally intubate by an experienced practitioner using standard direct laryngoscopy. Definitions for each of these categories have been proposed but are inconsistent throughout the literature. Therefore, in this chapter we focus on airway management techniques once a practitioner is faced with the expected or unexpected situation of inability to adequately perform mask ventilation or tracheal intubation despite the use of standard equipment, as described above in the section on management of normal pediatric airways.

There have been no systematic and validated studies that define predictors of difficult mask ventilation or tracheal intubation in the pediatric population. In adults, limited head extension, reduced mandibular space, and large tongue are predictive of difficult intubation [246]. These are also features in children with difficult intubations [247]. The mandibular space represents the area available to displace the tongue and soft tissue. Adequate mandibular size is necessary for an easy direct laryngoscopic view of the glottis. Reduction of this space by anatomical anomalies (e.g. micrognathia) often makes laryngoscopy difficult. The mentum–hyoid distance provides an estimate of the mandibular space. In infants, the minimum mentum–hyoid distance for a "normal" airway should be 1.5 cm [247].

The diversity and complexity of craniofacial anomalies in children are vast; thus, an exhaustive review is not possible here. Nevertheless, children with craniofacial anomalies can be defined according to the anatomical compartment that relates to the airway difficulty. Craniofacial dysmorphisms may be defined as primary abnormalities of the maxilla, abnormalities of mandibular size, abnormalities of mandibular hinge and sliding function, and anatomical anomalies of the tongue and cervical spine. Classifying patients in this manner allows selection of the most appropriate equipment for addressing the airway anomaly (Table 14.1).

There is no device that represents a panacea for airway management and each device has unique strengths and weaknesses that need to be matched with the patient's condition and anatomical details. For example, a patient with limited mouth opening would be best managed with a flexible bronchoscope or optical/lighted stylet rather than a rigid video laryngoscope, whereas a patient with Robin sequence who presents with a potentially difficult mask ventilation may be best managed with a laryngeal mask followed by tracheal intubation through the mask, thus permitting ventilation during intubation. We use a simple acronym (AVAD: Anesthesia, Ventilation, Adjuncts, Devices) to guide the approach to airway management in known difficult airway patients (Fig. 14.12). Thinking about the patient in terms of these components facilitates the formulation of a primary and secondary plan, and dictates the necessary equipment for the chosen approach. The care provider should select an approach and device for each of the four components of the acronym.

As an example, let us consider a neonate with Pierre Robin sequence. The Anesthesia plan may include deep sedation with a secondary plan for general anesthesia. The Ventilation plan may be spontaneous ventilation and the Adjunct a modified nasal airway, with a secondary plan of controlled ventilation using a laryngeal mask. The Device may be a video laryngoscope with the fiberoptic bronchoscope as a back-up device. The chart helps to ensure that all the critical aspects of the care plan are addressed, and horizontally represents increasing anesthetic and technical complexity. Nevertheless, practitioners should adopt a standard and consistent set of airway-related equipment and drugs for all anticipated difficult airway patients (Fig. 14.13).

When approaching the child with a known cause for a difficult airway, one of the first *a priori* decisions

Primary anatomical area of abnormality	Maxilla	Mandible size	Tongue & soft tissue	Cervical spine	Larynx	Mandible sliding and hinge function

to be made is the anticipated level of consciousness during the airway management process. This largely depends on the anesthesiologist's confidence in their ability to avoid life-threatening hypoxemia in an anesthetized or sedated child using a facemask or a laryngeal mask.

# "Awake" intubation

Tracheal intubation of an unco-operative child at a nearly conscious level is difficult and associated with complications [155,248]. Since the advent of the laryngeal mask, this approach has been largely abandoned for sedated or anesthetized techniques, with rare exceptions. For

**Figure 14.13** One example of a standard equipment and medication set-up for anticipated pediatric difficult airway. *From left to right*: atropine, succinylcholine, propofol, 2% lidocaine with mucosal atomizer attachment, vecuronium, lighted stylet, laryngeal mask, and oral airway.

example, neonates with Robin sequence (see below) are expected to have difficulty with mask ventilation; therefore, awake insertion of a laryngeal mask and confirmation of adequate ventilation can precede induction of general anesthesia [129,131].

# **Sedated intubation**

Many children with anticipated difficult airways can be sedated to provide comfort and amnesia, yet retain spontaneous ventilation and upper airway patency during tracheal intubation attempts. A sedated technique is useful when life-threatening upper airway obstruction during induction of general anesthesia is anticipated, such as may be seen in children with a large cystic hygroma [249]. Although light sedation has been described for tracheal intubation in infants using opioids, amnestic agents, and incremental doses of induction agents, most children will require deeper levels of sedation to ensure optimal intubating conditions. This may also be accomplished using dexmedetomidine, as a sole agent or in combination with other agents [250]. Dexmedetomidine allows arousal with strong stimulation and maintenance of spontaneous ventilation, using a bolus dose of up to  $2-4\mu g/kg$  over 10min followed by a continuous infusion of 0.7µg/kg/h. Dexmedetomidine can be combined with incremental doses of ketamine (0.25 mg/kg) or midazolam (up to 0.1 mg/kg) to facilitate intubation without clinically significant respiratory depression [251,252]. There is little evidence for which to base the selection of drugs for sedated approaches to

intubation. Further studies are necessary to determine the optimal methods for preserving airway patency while minimizing reactivity during tracheal intubation.

# Intubation under general anesthesia

The majority of children with a known or expected difficult intubation can receive general anesthesia during the intubation process. Many pediatric anesthesiologists will require an indwelling intravenous catheter prior to administration of general anesthesia but this is practitioner dependent. Upper airway patency may be facilitated by insertion of an oral or nasal airway. A nasal airway may be attached to a 15 mm tracheal tube adaptor, which allows connection to the anesthesia circuit for provision of anesthesia and oxygen, during intubation attempts (see Fig. 14.9) [92].

# Ventilation of the patient with a difficult airway

The ultimate goal of any airway management strategy is to maintain adequate oxygenation and avoid lifethreatening hypoxemia. It is critical that this overarching principle is not lost during attempts to secure the airway.

Facemask ventilation represents the first step in maintaining oxygenation between intubation attempts. The optimal ventilation strategy for the management of the difficult pediatric airway remains unknown. Traditional teaching advocates the maintenance of spontaneous ventilation during airway management because of the fear of loss of the ability to ventilate with multiple traumatic attempts and to preserve the ability to quickly awaken the patient if necessary. In children this concern is weighed against the possibility of coughing, and other movements if the level of anesthetic is too light. There is no plausible research that can examine this issue directly; much of the rationale for this strategy comes from case reports and clinical observations. Maintenance of spontaneous ventilation is it facilitates oxygenation during airway manipulation [253], it provides clues to the glottic location by way of the bubbling of secretions that can be observed breathing, and provides the anesthesiologist with increased uninterrupted time to accomplish the intubation. In addition, there may be greater upper airway patency and better visualization resulting from less soft tissue collapse when airway tone is preserved [254]. Although maintenance of spontaneous ventilation is preferred, some practitioners will attempt positive pressure ventilation and, if successful, will administer neuromuscular blockade to facilitate the intubation process. Although neuromuscular blockade often facilitates ventilation and intubation, there are reports in adults where the addition of neuromuscular blockade in itself has been reported to change the anatomical characteristics of the upper airway, and worsen ventilation or intubation conditions [255,256].

Topical anesthesia should be applied to the glottic structures to minimize airway reactivity and should be performed when an adequate depth of anesthesia is confirmed. An increase in heart rate, respiratory rate or physical movement when a 5 second jaw thrust is applied is usually a good indicator of adequate anesthetic depth for airway manipulation.

A total intravenous technique during intubation attempts will minimize operating room pollution from anesthetic gases. Various combinations of easily titratable intravenous agents (e.g. propofol, remifentanil) can be used for this purpose [257,258].

Impossible mask ventilation is unusual in the pediatric population. It is difficult to determine the true incidence because children suspected of impossible mask ventilation due to altered anatomy will undergo tracheal intubation using deep sedation and spontaneous ventilation. In an observational review of 22,000 adult anesthetics, the reported incidence of impossible mask ventilation was one in every 690 cases [259]. One-quarter of these patients were also difficult to intubate. Neck radiation was found to be the most significant predictor of impossible ventilation.

# Indirect methods of tracheal intubation

There are many approaches to tracheal intubation in the child with a known or suspected difficult airway. In certain circumstances it may be appropriate to attempt direct laryngoscopy, if a reasonably long amount of time has passed since the previous intubation attempt and the anesthesiologist feels that the growth of the child has altered their airway anatomy in a favorable direction. If a direct method is deemed impossible, a variety of options exist for indirect tracheal intubation.

# **Fiberoptic bronchoscopy** (see Video clips 14.1–14.4)

The first article describing the use of flexible fiberoptic bronchoscopy in children appeared in 1978 [260] and despite many modifications in design, it remains the "gold standard" for accomplishing tracheal intubation in the difficult pediatric airway [92,248,252,253,261-291]. Limitations of fiberoptic intubation in children include the significant time necessary for skill acquisition, the processing and preparation time of the equipment, the fragility of the bronchoscope, and the high purchase and repair costs. Despite these limitations, the skill necessary to consistently perform a smooth fiberoptic intubation can be acquired during routine cases in children with normal airways. The introduction of the 2.2mm and 2.7mm ultrathin bronchoscopes allowed fiberoptic intubation of neonates and small children with tracheal tubes as small as 2.5mm [292,293]. These ultrathin bronchoscopes did not have a working channel and so functionality was limited in the presence of copious secretions; however, modern versions are available with functional working channels. Many larger bronchoscopes now incorporate a charge coupled device camera (CCD), which transmits the image from the tip of the scope to a screen, and replaces the fiberoptic bundles present in traditional scopes. This provides a high-clarity image without the honeycombing typically seen with standard fiberoptic bronchoscopes.

Fiberoptic intubation in children is performed in a similar fashion to adults but may be more challenging because of the small size of the scopes used, the short apnea time and the small size of the airway. The child is placed in a neutral position and the tongue elevated from the posterior pharyngeal wall by an assistant using a suction tubing or a gauze. The endoscopist places the scope in the midline in the pharynx and advances the scope in a deliberate manner following the tongue base and successively visualizing the uvula, palate, epiglottis and the vocal cords. A jaw thrust helps to elevate the epiglottis and allow for smooth passage of the scope. The thumb lever on the scope should be manipulated very slowly to allow for control of the scope position and adequate visualization of the airway structures. The scope should not be advanced if embedded in soft tissue as evidenced by a characteristic pink hue of the airway mucosa on the screen. After the scope is placed into the trachea, the tube is advanced along the scope into the trachea with the Murphy eye positioned anteriorly, this minimizes the incidence of hang up of the tracheal tube at the glottic opening by positioning the leading edge of the tube away from the right arytenoid, the most common location for hanging up of the tube.

Adult bronchoscopes can facilitate fiberoptic intubation in children. One method requires two providers. One places the bronchoscope at the glottic opening, while the other manipulates the tracheal tube independently into the trachea. This technique has the advantage over standard fiberoptic intubation of visualizing the passage of the tracheal tube through the vocal cords. A stylet in the tracheal tube will assist in directing the tube into the trachea [277]. A second technique involves the placement of a guidewire (e.g. 0.0035 in cardiac catheter guidewire, Mallinckrodt, St Louis, MO, USA) or tracheal tube exchanger into the trachea via the working channel of the bronchoscope. The bronchoscope is then removed and the tracheal tube advanced over the guidewire into the trachea [262,294–296].

In small children, the nasal route provides the most direct approach to the glottic opening with the flexible bronchoscope. This advantage has to be weighed against surgical considerations and the risk of nasal bleeding. Application of a vasoconstrictor such as oxymetazoline decreases this risk and visualizing the nasal passage prior to placing the tube may provide information as to the presence of polyps, adenoid tissue or narrowing that may impede advancement of the tracheal tube. The tracheal tube size should be matched closely to the fiberoptic bronchoscope size to reduce the incidence of impingement of the tracheal tube on glottic structures. Rotation of the tracheal tube 90° counterclockwise will orient the Murphy eye anteriorly, and may enhance placement through the glottic opening [297].

During fiberoptic intubation, ventilation can be enhanced using the Frei endoscopy mask, which incorporates a perforated silicone membrane that allows passage of the bronchoscope [298]. Alternatively, one may use the "mask mouth technique" in which the facemask is applied only to the mouth and one nare is occluded while the bronchoscope is advanced through the opposite nasal passage [299].

The laryngeal mask can serve as a conduit for intubation and an adjunct for ventilation in children with difficult airways. There are several manufactured designs and shapes but ideally the mask should provide full glottic exposure without encroachment of the epiglottis into the mask bowl. Prior to using a laryngeal mask as a conduit for intubation, it is critical to confirm that all components of the selected tracheal tube easily pass through the selected mask. Some masks will not accommodate the pilot balloon, particularly in smaller sizes [300,301].

To facilitate bronchoscopy through the laryngeal mask, a bronchoscope adaptor is placed on the 15 mm connector of the tracheal tube; the tracheal tube is then placed in the airway tube of the laryngeal mask and the cuff inflated. The anesthesia circuit is then attached to the tracheal tube and ventilation is established. An occlusive adhesive (e.g. Tegaderm<sup>™</sup>) can be applied to the bronchoscope adaptor to maintain a seal around the bronchoscope. Fiberoptic bronchoscopy is then carried out through the tracheal tube. When the trachea is entered, the tracheal tube cuff is deflated and the entire tube-bronchoscope adaptor unit is advanced into the trachea (Fig. 14.14) [302]. Removal of the laryngeal mask is challenging in children because the length of the tracheal tube is often similar to the length of the laryngeal mask tube. Techniques that may assist in laryngeal mask removal include using two tubes joined together to extend the working length, using a long pair of laryngeal forceps or using a tube stabilizer or exchanger.

# Modified optical laryngoscopes

A variety of modified optical laryngoscopes have been developed to aid with direct visualization of the glottis in difficult airway pediatric patients. At the time of writing, there is not a sufficient body of knowledge with which to judge the comparative efficacy and complications of each of the devices. However, a number of case reports and case series have been published to date.

The Bullard laryngoscope (Circon ACMI, Stamford, CT) represents one of the earliest designs of optical laryngoscope. It consists of a curved metal blade with an integrated fiberoptic light source attached to an eyepiece. It provides an indirect view of the glottic opening and requires minimal mouth opening (0.64 cm) for insertion. Like many optical laryngoscopes, visualization may be limited by secretions. In a series of 93 children aged 1 day to 10 years, intubation was successful in 90 patients (97%). Two failures were attributed to excess secretions [303].

The Airtraq<sup>®</sup> (King Systems, Noblesville, IN) is an intubating device that consists of a curved blade with two adjacent channels. It is designed to provide glottic exposure without alignment of the oral, pharyngeal or laryngeal axes. One channel houses the optical system containing a series of prisms and lenses which end in a viewfinder (Fig. 14.15), while the second channel acts as a holder for the tracheal tube and a guide for advancing the tube into the trachea [304]. The infant Airtraq accepts tracheal tubes of internal diameter 2.5–3.5 mm, while the pediatric version accepts tubes of internal diameter 3.5–5.5 mm. The device is also available with the posterior surface removed to facilitate nasal

**Figure 14.14** A bronchoscope adaptor is placed on the 15 mm connector of the tracheal tube, which is then placed in the airway tube of the laryngeal mask. This facilitates air exchange during bronchoscopic intubation.

Figure 14.15 Pediatric Airtrag<sup>®</sup> intubating device.

intubation. After lubrication of the Airtrag channel and blade surface, the Airtrag is inserted in the midline of the pharynx and the tip placed in the vallecula. The device is adjusted so that the glottis is located in the center of the viewfinder, after which the tracheal tube is advanced into the trachea. After confirmation of successful tracheal intubation, the tracheal tube is moved laterally away from the Airtraq and the device slowly withdrawn. The Airtrag has been used successfully in patients with difficult direct laryngoscopy due to craniofacial anomalies such as Treacher Collins syndrome and Robin sequence [305]. In a series of 20 children managed with the Airtrag for elective surgery, one patient required the use of a malleable stylet to facilitate intubation because of difficulty aligning the glottis in the center of the view, and a second patient required two attempts to achieve successful intubation [306]. Other methods have been described to facilitate tracheal intubation with an Airtrag. These include the use of a gum elastic bougie, a flexible or malleable tracheal tube, and utilizing a fiberoptic bronchoscope [307,308]. Like many indirect devices for tracheal intubation, difficulty with tube passage is more common in infants and small children. This problem is also common with the non-channeled video and optical devices, and underscores the fact that the infant and neonatal airways are different from those of toddlers and older children [309].

The Truview EVO2 (Truphatek International, Netanya, Israel) is an indirect rigid laryngoscope with an angulated blade tip. The laryngoscope incorporates an optical lens that ends in an evepiece that allows the operator to "see around the corner" and obtain an improved glottic view. It has an integrated oxygen port that allows oxygen administration during intubation. Tracheal intubation is achieved by placing the blade in the midline in the pharynx and following the curve of the tongue to the glottic opening. Once the glottis is visualized, the tracheal tube is advanced into the trachea. In a prospective comparison of intubation conditions between the Truview and the Miller laryngoscope in 60 neonates and infants, the Truview provided a statistically significant improvement in view with comparable intubation times [310]. In addition, since the Truview does not require neck extension for visualization and tracheal intubation, it can be used in patients with immobile cervical spines [311].

# Video laryngoscopes

The miniaturization of video technology has fueled a revolution in laryngoscope design. There is a rapidly growing selection of video laryngoscopes available for pediatric use, such as the Glidescope<sup>®</sup>, the Storz Video Laryngoscope, the McGrath Scope, and the Pentax Airway Scope. This section will focus on devices with specific pediatric designs.

Figure 14.16 Glidescope® Cobalt and disposable plastic blade.

# **Glidescope**<sup>®</sup> (see Video clip 14.5)

The Glidescope® (Verathon Medical, Bothell, WA) is a curved laryngoscope with an integrated miniature camera and a heated lens to minimize fogging during laryngoscopy. The device has evolved over the years from a bulky unit to a slim design (Glidescope<sup>®</sup> Cobalt, Fig. 14.16). The Cobalt consists of a camera stick that is inserted into a disposable plastic sheath. A high-resolution image is displayed on a small portable video screen. The blade of the device is placed in the midline of the pharynx and the tip placed in the vallecula. A styletted tracheal tube is usually necessary, and although the manufacturer recommends a 50–60° angulation of the tube, others report higher success in placing the tube with a 90° hockey-stick configuration [312]. Passage of the tracheal tube should be directly visualized during placement prior to its appearance on the video monitor to avoid injury to pharyngeal structures [313–319]. The Cobalt is available with a variety of blade sizes. When compared with direct laryngoscopy in difficult airway patients, it has been shown to improve the glottic view [319-321].

There remains a population of patients in whom significant difficulty is encountered with tracheal tube placement despite an adequate glottic view with the Glidescope. These difficulties can arise from a number of factors including the limited ability to manipulate the tube within the smaller pediatric pharynx, the acute angulation of the tracheal tube causing impingement on the anterior commissure or anterior trachea, and difficulty locating the tube in the pharynx after inserting the blade [322]. Some practitioners advocate placing the tracheal tube and Glidescope simultaneously as a single unit or placing the tracheal tube in the pharynx under direct vision prior to placing the Glidescope. If the tracheal tube impinges on the anterior trachea or anterior commissure, the Glidescope should be withdrawn slightly to decrease

**Figure 14.17** The tracheal tube on the left is "reverse loaded" by rotating the Murphy eye anteriorly on the stylet.

the anterior displacement of the glottis, allowing the axis of the tube and the trachea to become better aligned, and rotating the tube so that its concavity is oriented more posteriorly ("reverse loading", Fig. 14.17). The gum elastic bougie has also been utilized as a guide for tracheal intubation in children using the Glidescope [323].

There will always be certain patients in whom the Glidescope and other video laryngoscopes will fail so alternatives need to be readily available for difficult airway patients.

#### Storz video laryngoscope

The Storz video laryngoscope (SVL; Karl Storz Company, Tuttingen, Germany) incorporates a camera into various standard blades. The Storz DCI video laryngoscope is a rigid blade that integrates fiberoptics and a lens into the light source of Miller- and Macintosh-type blades [324]. The blades connect to a device-specific camera that transmits the image to a video monitor. The use of the SVL is similar to other video laryngoscopes in that the blade is placed in the midline followed by insertion of the tracheal tube. Advancing the tracheal tube along the shaft of the blade rather than from the right side of the pharynx as in traditional laryngoscopy facilitates quick visualization on the video monitor and avoids injury to the palatoglossal structures. The SVL has been successfully employed in intubating the trachea of patients with normal airways and has been reported to be more efficacious in pediatric difficult airway patients when compared to direct laryngoscopy. A one grade improvement in view (Cormack and Lehane) can be expected compared to Miller blade laryngoscopy [324–330]. Use of the SVL requires adequate mouth opening and practiced hand-eye co-ordination. The view through the SVL may be limited by fogging, which can be decreased by use of an anti-fog solution or prewarming the device.

#### **Optical stylets**

Optical stylets were first introduced into clinical practice in the 1970s and remain useful adjuncts in the management of the pediatric difficult airway. The optical stylet consists of a fiberoptic bundle within a rigid or malleable J-shaped stylet that ends in an eyepiece. They can displace pharyngeal soft tissue because of their rigid form and are more easily maneuvered than flexible scopes. They often incorporate a port for insufflating oxygen to minimize secretions and fogging. However, we do not recommend oxygen insufflation even at low flow rates as pneumothorax and subcutaneous emphysema remain ever-present risks in infants [331–333]. Optical stylets are simple to assemble and their use involves a short learning curve. Furthermore, they are inexpensive when compared to fiberoptic bronchoscopes and video or optical laryngoscopes. The optical stylet allows visualization of the tracheal tube as it passes through the vocal cords because the stylet is recessed within the tracheal tube during intubation. However, their may be compromised by secretions or fogging.

## **Bonfils fiberscope**

The Bonfils fiberscope (Karl Storz Company, Tuttingen, Germany) is a rigid fiberoptic stylet with a J-shaped 45° anterior-angulated tip. It provides a 90° angle of view and is available in all pediatric sizes. It is designed to be used via the retromolar approach, which brings the glottis into view rapidly and avoids negotiating the stylet around the bulk of the tongue. Once at the glottic opening, the preloaded tracheal tube is advanced through the vocal cords under direct vision. Some practitioners recommend the use of a rigid laryngoscope to create space for placement of the scope; however, some authors recommend against the use of this device in neonates [308,334-337]. The small optic aperture and significant 40-fold magnification render the visualization vulnerable to secretions [335]. In a simulated difficult pediatric airway, the Bonfils was easier to use and associated with better views of the larynx than direct laryngoscopy; however, intubation success rate and intubation times were similar [338].

#### Shikani Optical Stylet

The Shikani Optical Stylet (SOS; Clarus Medical, Minneapolis, MN) is a malleable, stainless steel J-shaped stylet with an enclosed fiberoptic bundle [339]. The pediatric SOS is 27 cm long and can accommodate tracheal tubes as small as 2.5mm internal diameter. The SOS has been successfully used to intubate neonates and older children with a difficult airway. Extension of the head and application of jaw thrust facilitates elevation of the epiglottis off the posterior pharyngeal wall, which facilitates passage of the stylet [250,340-344]. The SOS is useful in patients who require maintenance of a neutral cervical spine during tracheal intubation [345]. Like the Bonfils, tracheal intubation can be accomplished efficiently and effectively with the assistance of the direct laryngoscope [346]. Use of the SOS is associated with minimal airway stimulation, permitting intubation in sedated children [131]. The SOS is lightweight, easily prepared and cleaned, and useful in managing the difficult airway in size ranges.

## Lighted stylet

The lighted stylet allows tracheal intubation by observation of a transilluminated light in the neck. This often requires a darkened operating room to allow optimal visualization of the light. After loading the tracheal tube onto the lighted stylet, it is inserted orally in the midline of the pharynx while performing jaw thrust and the transilluminated light is located as a cone of light in the neck just above the suprasternal notch. It is critical that the light is located in the midline of the neck, as any deviation from the midline will direct the tube towards the esophagus. The centrally located light is then observed as the stylet is advanced caudally. Once the glottis is entered, the operator feels the stylet moving past the cords and observes an intensification of the light in the neck. Sometimes light is conducted down the trachea, creating a characteristic "cone of light" effect. The tracheal tube is then advanced off the stylet and tracheal placement confirmed by the usual means. Resistance during advancement of the stylet towards the glottis may suggest that the device is off midline or the tip may be entrapped in the vallecula or on the aryepiglottic fold. This requires retraction of the device and reinsertion while improving jaw thrust to elevate the epiglottis off the posterior pharyngeal wall [347].

Lighted stylet-guided intubation utilizes tactile and visual cues to successfully place the tracheal tube, it is a low-cost technique that is easily learned and remains useful in cases where visualization of the glottis is difficult or impossible. It can be employed in awake patients with difficult airways and can be successfully utilized via the nasal route [348–355]. In a cohort of patients with normal airways, the lighted stylet was as efficacious for tracheal intubation as the Airtraq<sup>®</sup> [356].

In 1957, Sir Robert Macintosh was the first to describe the use of a lighted stylet to facilitate intubation [357]. Since the advent of his 18-inch illuminated tracheal tube introducer, there have been many stylet designs. The fiberoptic lighted intubation stylet (Anesthesia Medical Specialties, Santa Fe, CA) is available in pediatric sizes, accommodating tracheal tubes as small as 3.5 mm internal diameter. Lighted stylets for use with tube diameters less than 3.5 mm can be fashioned by inserting a single fiberoptic light pipe adjacent to an appropriately sized stylet for the selected tracheal tube. The light pipe is illuminated by a fiberoptic light source and in this manner a lightwand can be created for any sized patient (Fig. 14.18).

## **Digital intubation**

Digital intubation is a rarely taught technique that should be learned by pediatric anesthesiologists [358]. It predates direct laryngoscopy and may have been performed as early as the 1500s. It can be performed rapidly in patients

**Figure 14.18** Lighted stylets for use with tube diameters less than 3.5 mm can be fashioned by inserting a single fiberoptic light pipe adjacent to an appropriately sized stylet for the selected tracheal tube. (A) Narrow gauge single fiberoptic light pipe. (B) Final assembly of fiberoptic light pipe, stylet, and endotracheal tube. See text for further explanation.

who may be difficult to intubate by direct laryngoscopy or who may be in a position that does not allow easy access to the airway (e.g. extubation in the prone position). To perform a digital intubation, the anesthesiologist stands at the side of the patient facing the head of the operating room table. The gloved non-dominant index finger is placed along the surface of the tongue in the midline and is advanced to feel the epiglottis, and then the finger is advanced further until the aryepiglottic folds are located. The dominant hand holds a styletted tracheal tube in a C-shaped configuration like a pencil and slides the tube alongside the non-dominant finger. The tip of the tracheal tube is directed through the glottis by the nondominant finger and tracheal intubation is confirmed by the usual means. In a report of 39 digital intubations in 37 neonates, the mean time to intubation was 7 sec. All the patients were successfully intubated; one patient required two attempts [359].

# Extubation of the difficult airway

Extubation of the difficult airway can occasionally be more challenging than the intubation and requires careful planning and preparation to avoid complications. The operating room should be prepared in a similar fashion to the set-up for intubation and the device successfully utilized in securing the airway should be available in the operating room. In selected cases, the use of an airway exchange catheter (Cook, Bloomington, IN) may be beneficial in the extubation of children with difficult airways. The Cook catheter is placed through the lumen of the tracheal tube into the trachea and is left in place after extubation. The catheter allows the administration of supplemental oxygen through a central hollow core. In a series of 20 pediatric difficult airway patients with an exchange catheter in place, five underwent successful reintubation over the catheter. No sedatives were required with the exchange catheter in place [360].

# **Surgical airway**

On extremely rare occasions, the anesthesiologist may encounter a dire "can't ventilate/can't intubate" situation associated with prolonged hypoxemia which, if left untreated, would likely result in patient mortality. Therefore, every pediatric anesthesiologist should have a reasonable approach to obtaining a surgical airway should this rare event occur. Cricothyroidotomy was first described in 1969 [361]. There are three methods of achieving oxygenation via the cricothyroid membrane: the small cannula (often an intravenous angiocatheter) approach, the commercially available large cannula approach using the Seldinger technique, and the open surgical technique in which a tracheostomy tube is inserted. The techniques of choice for anesthesiologists and others not trained in open surgical tracheostomy are the needle cricothyroidotomy and Seldinger guided placement techniques.

# Angiocatheter technique

The angiocatheter technique is probably the most plausible in pediatric patients requiring emergency surgical airway access. A needle cricothyroidotomy can be achieved using a 14, 16 or 18 gauge angiocatheter that is placed through the cricothyroid membrane. While extending the cervical spine, the angiocatheter connected to a syringe of saline is introduced in the midline in the lower half of the cricothyroid membrane at a 45° angle in an inferior and posterior direction [362]. The syringe attached to the angiocatheter is gently aspirated during insertion, and return of air confirms tracheal entry. The catheter is then advanced off the needle into the trachea. A highpressure oxygen source (such as a wall oxygen supply or jet ventilator) is needed to overcome the resistance of the catheter in order to deliver effective oxygenation (ventilation is not readily achieved). The oxygen source can be connected to the catheter by a 3mL syringe with the plunger removed and attached to a 15mm tracheal tube adaptor. Barotrauma is a risk of ventilation through the angiocatheter, particularly in situations where exhalation is not possible because of upper airway obstruction. Structures at risk during the puncture are the superior thyroid artery along the lateral border of the membrane, the cricothyroid arteries, and the pyramidal lobe of the thyroid. The posterior tracheal wall could also be injured during the puncture attempt; thus, confirmation of correct placement is critically important as insufflation of highpressure gas outside the trachea can cause life-threatening tension pneumomediastinum and tension pneumothorax. Even after correct placement, reassessment of positioning should occur frequently as children have little margin for error and a correctly placed catheter can become dislodged with minimal movement [363].

# Large catheter Seldinger approach kits

Cricothyroidotomy kits based on the use of the Seldinger technique are now available for pediatric use. There are several manufactured kits that share common steps. A limited skin incision is made after identifying anatomical landmarks, a needle is inserted through the incision and cricothyroid membrane into the trachea, a guidewire is placed through the catheter and the catheter is removed leaving the guidewire in place. A dilator airway catheter assembly is advanced over the wire into the trachea and the guidewire and dilator are removed [364]. Ideally, pediatric anesthesiologists should develop expertise with this approach using an animal model or a specially designed patient simulator.

# CASE STUDY

A 2-month-old, male former 31-week premature infant with Robin sequence presented for repair of bilateral large inguinal hernias, and open gastrostomy tube. Birthweight was 1600g and it was evident after birth that the patient had significant micrognathia, with cleft palate. The patient had no other congenital anomalies, including no cardiac disease. He had moderate upper airway obstruction in the supine position without airway support. His airway had *Continued*  been maintained with nasal CPAP of 5-7 cm H<sub>2</sub>O, with FiO<sub>2</sub> 0.21-0.30 and flows of 1-2L/min. In addition, he was nursed in the lateral or prone positions. He had no major apnea/desaturation events, had grown slowly with nasogastric tube feeds and now weighed 1950 g. The multidisciplinary team of neonatologists, otolaryngologists, pulmonologists, and craniofacial anomaly specialists was considering tracheostomy to maintain airway patency. However, they were undecided at this point and wanted to address the hernias and a long-term feeding solution before attemping to wean the patient from CPAP and commiting him to a tracheostomy. The patient's trachea had never been intubated, and he had not had previous surgery or imaging procedures. Medications were multivitamins and iron, and he had no drug allergies. On physical examination, the patient had obvious significant micrognathia, normal cervical range of motion, and very mild retractions with no obvious upper airway obstruction on nasal CPAP of 5 cmH<sub>2</sub>O, FiO<sub>2</sub> 0.21. There was a small 6 Fr nasogastric tube in the right nare. The lungs were clear to auscultation bilaterally, there was no cardiac murmur, and a 2 Fr percutaneously inserted central catheter (PICC) was present in the right arm. SpO<sub>2</sub> was 96%, chest radiograph revealed clear lung fields, normal heart size and configuration, and the PICC was present in the midsuperior vena cava. Preoperative laboratory studies included hemoglobin concentration of 10.1 g/dL, a capillary blood gas of pH 7.36, PaCO<sub>2</sub> 44 mmHg, PaO<sub>2</sub> 44 mmHg, and calculated base excess of +3 meq/L. After a discussion with the parents about the risks of difficult airway management and possible postoperative mechanical ventilation had occurred the day before, consent for anesthesia was obtained and the patient transported to the operating room.

The following equipment had been assembled in the OR: standard Miller 0 and 1 laryngoscope blades; styletted uncuffed endotracheal tubes of 2.5 and 3.0 mm sizes; oral airways size 000, 00, and 0; disposable straight laryngeal mask airways (LMA) size 1 and 1.5; Glidescope Cobalt® video laryngoscope with the small video baton and size 1 plastic laryngeal blade, and neonatal Magill forceps. Succinylcholine, 4mg, and propofol, 6mg were drawn up in syringes. After discussion with the pediatric anesthesia fellow, it was decided to use the LMA as a conduit for fiberoptic intubation. A second attending anesthesiologist was present for induction of anesthesia and tracheal intubation, and the patient's otolaryngologist, who was operating with a series of short cases in the adjacent OR, was alerted that the case was to start and was available for emergency back-up.

Standard monitors were placed, glycopyrrolate 0.02 mg was administered IV, the patient was preoxygenated with a facemask and FiO<sub>2</sub> 1.0 for 3 min, and a #1 LMA, lubricated with 2% lidocaine gel, was inserted gently with the cuff

deflated and the patient awake. He tolerated this well, the cuff was inflated with 3 cc air, and the airway was patent with audible crying. After gentle awake assisted ventilation demonstrated good chest excursion, inhalation induction with sevoflurane, 2% inspired, and 5L/min oxygen flow, was begun. Inspired sevoflurane was increased slowly to 4%, the patient had a patent airway throughout, and passed through stage II of general anesthesia without incident, and with manually assisted ventilation and end-tidal sevoflurane of 3% had SpO<sub>2</sub> 99%, heart rate (HR) 135, and blood pressure (BP) 60/35. End-tidal carbon dioxide (ETCO<sub>2</sub>) was 24 mmHg.

An extended 3.0mm uncuffed ETT had been fashioned beforehand, made up of a standard 3.0 ETT with connector removed and the upper half of a second ETT taped with a single layer of clear plastic tape with the connector removed. The extended ETT was loaded onto a 2.2mm pediatric fiberoptic bronchoscope (FOB), pushed up to the proximal end of the scope. The video image was displayed on three large screens in the OR. The FOB was lubricated, had antifog solution applied to the tip, and was inserted into the end of the LMA with a standard FOB elbow adaptor, and advanced easily down the shaft of the LMA, with the second anesthesiologist gently assisting ventilation and stabilizing the LMA. When the aperture of the bowl of the LMA was reached, the glottis was in clear view, with the epiglottis stented up by the LMA. Slight vocal cord abduction was observed with inspiration. Propofol 2mg was administered to deepen anesthesia and produce apnea, and the FOB was advanced carefully, always with the airway lumen in view, until the vocal cords had been passed, and the cartilaginous tracheal rings and pars membranosa were clearly in view. The scope was advanced further to just above the carina, to avoid carinal stimulation. Then, the ETT was advanced down the scope, through the LMA, and very gently through the glottic opening, rotating the ETT so the beveled tip would be parallel to the vocal cord alignment. After passage of the ETT below the vocal cords, FOB position was checked and was still just above carina. The FOB was withdrawn slowly, and the ETT tip could be seen in mid trachea. The ETT connector was placed on the end of the extended ETT, and manual ventilation produced excellent chest rise, equal bilateral breath sounds, and persistent ETCO<sub>2</sub> of 45–50 mmHg. SpO<sub>2</sub> had decreased to 91% but quickly recovered to 99% after 30 sec of manual ventilation. HR was 120, BP slightly lower at 52/30, but with reduction in sevoflurane concentration to 2% and 10mL lactated Ringer's solution bolus, returned within 2min to 65/35. There was a leak around the ETT at  $20 \text{ cmH}_2\text{O}$ .

While grasping the ETT in the back of the oropharynx with the Magill forceps, the LMA cuff was deflated and the LMA removed gently over the extended ETT after the connector had been removed. The tape was removed from the extended ETT, producing a standard 3.0 ETT, the connector replaced, correct ETT placement and ventilation again verified, and the ETT secured in standard fashion. After the ETT was secured, a direct laryngoscopy was performed and a Grade IV Cormack and Lehane view was evident, even with external laryngeal manipulation. All airway procedures were detailed in the electronic anesthesia record, and a patient alert for difficult airway clearly noted. A caudal anesthetic and rectal acetaminophen were used for intra- and postoperative analgesia.

The case proceeded uneventfully and it was decided to transport the patient back to the neonatal intensive care unit (NICU) with the endotracheal tube in place. Analgesia was provided with morphine and the patient received 48h of mechanical ventilation, with good pain control. Extubation occurred in the NICU, with the patient awake, the anesthesiologist present at the bedside with LMA and fiberscope, and nasal CPAP ready to apply immediately after extubation. The patient was successfully extubated to nasal CPAP, spent another month in the NICU and was weaned from CPAP, with improved upper airway obstruction and good somatic growth, and was discharged home with pulse oximetery and apnea monitoring, without tracheostomy, at age 3 months. The parents were well aware of the difficulty with tracheal intubation.

#### Conclusions

This case illustrates the principles outlined in this chapter, including thorough discussion and preparation for the difficult airway, assembling all airway equipment and drugs beforehand, choosing one primary method of intubation with at least one back-up method available, having expert assistance immediately available, and planning for the difficult extubation. In addition, communication with other providers and parents, and documentation of airway procedures, are very important in the care of the patient with a difficult airway.

# **Evaluation of preoperative data**

The preoperative assessment of a child for general anesthesia requires a focused and systematic review of the history and organ systems. The assessment should include details of the past medical history, current and recent medications, allergies, family history, nil per os (NPO) status, physical examination, and necessary ancillary testing.

Before beginning a detailed medical history, it is important to document a review of the child's vital signs, fasting status, and weight. A discussion of the fasting guidelines before surgery is found below. The child's weight should be assessed to determine whether he/she is normal weight, overweight or obese. An estimation of the child's ideal bodyweight may be calculated using the formulas:

> For children  $\leq 8$  years of age: weight (kg) =  $2 \times age (years) + 9$ For children > 8 years of age: weight (kg) =  $3 \times age (years)$ .

An estimate of the obese child's bodyweight for drug and fluid management should be based on the child's ideal bodyweight for age plus one-third the difference between the actual weight and the ideal weight.

The identity and legal status of the parent, guardian or person accompanying the child must be established preoperatively to ensure the consent for anesthesia and surgery is legal and appropriate medical information is available and accurate. If the patient is >18 years of age, he/she may consent for surgery. However, if the patient is cognitively challenged, a health proxy (i.e. legal guardian) is required to consent for surgery irrespective of the patient's age.

Family history of inheritable disorders or serious reactions that were potentially fatal under anesthesia should be solicited. Specific mention should be made of malignant hyperthermia and muscle wasting diseases, which are discussed below.

In reviewing the past medical history, the child's gestational age at birth is important, as infants who were born prematurely (i.e. <37 weeks' gestational age) may

*Gregory's Pediatric Anesthesia*, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos. © 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

require overnight observation for perioperative apnea (see Premature Infant below) if their postconceptual age is currently <60 weeks. Furthermore, full-term neonates up to 4 weeks' postnatal age should not undergo general anesthesia on an ambulatory basis; they too should be admitted and monitored overnight.

A complete review of systems should be done during the assessment, including the cardiac, respiratory, gastrointestinal, genitourinary and renal organs, central nervous system, endocrine, and musculoskeletal systems.

Children with congenital heart disease, or their parents or guardians, should be questioned regarding the nature and status of the heart defect; whether the defect resolved spontaneously or required surgery; if surgery was performed; the nature and date of the surgery; recent admissions or physician visits related to following up the cardiac defect; and cardiac medications prescribed. In most instances, a recent cardiology evaluation should be available, including an updated echocardiogram to provide evidence of the heart's function and the need for antibiotic prophylaxis for subacute bacterial endocarditis. If the child's feeding, activity, color or vital signs have changed substantially since the last cardiac evaluation, consideration should be given to delaying the surgery for further cardiac evaluation.

If a murmur is detected during preoperative assessment, it is important to establish whether the murmur is new or old and whether its nature has changed. If there are no signs or symptoms of growth or activity delays, shortness of breath, blue spells, syncope or feeding problems, then a consultation with a cardiologist may be required based on the quality and duration of the murmur, whether and where it radiates, the presence of a diastolic murmur, and whether there is evidence of heart failure. If there is any uncertainty about the pathological nature of the murmur, a cardiologist should be consulted.

Illnesses affecting the respiratory system range from minor to life threatening. Discussions of the child with an upper respiratory tract infection (URTI) and respiratory compromise follow. Apart from congenital anomalies that may present in the perinatal period (such as congenital diaphragmatic hernia or congenital lobar emphysema), it should be determined whether the child has recently had serious croup or respiratory syncytial virus and whether the child was admitted to hospital for other respiratory ailments.

Children who present for tonsillectomy and adenoidectomy have either chronic infectious tonsillitis or obstructive sleep apnea (OSA). For the latter, most children have a clinical diagnosis based on the otolaryngologist's assessment of the severity of the symptoms. There are no clinical criteria that are diagnostic for OSA in children; thus the diagnosis of OSA can only be made by polysomnography [1]. Children with OSA are usually normal in weight but snore loudly at night. They may stop breathing during their sleep and may arouse without actual awakening. They are often fatigued in the morning, despite having slept a full night. Many of them experience nocturnal enuresis and have attention deficit disorder and/or exhibit behavioral and learning difficulties at school. It is important to determine whether a polysomnogram was performed and if so, the oxygen saturation nadir during sleep. Children whose nadir is <85% show greater sensitivity to respiratory depression (apnea) with standard doses of opioids. If a polysomnogram was not done, opioid sensitivity can be evaluated during anesthesia by observing the child's respiratory responses to small doses of opioids while he/she breathes spontaneously. If apnea occurs in response to opioids, reduced doses must be administered cautiously during anesthesia and postoperatively to minimize the risk of perioperative adverse airway events.

Gastroesophageal reflux disease (GERD) is a national pandemic in children. Many children are diagnosed with reflux and treated with antireflux medication, even though they have no symptoms. Although most children undergo inhalational induction of anesthesia, including those with documented gastroesophageal reflux who undergo upper endoscopy, GERD does not appear to increase the risk for regurgitation and aspiration during anesthesia. Accordingly, we proceed with our usual anesthetic technique in children with gastroesophageal reflux.

Children with renal insufficiency or failure require a complete blood count and electrolyte panel preoperatively. If the child has renal failure, the type of dialysis and the timing of the last dialysis treatment, as well as how much fluid was removed, should be documented.

Children with Down syndrome present interesting challenges from a variety of perspectives. They range in cognitive function from very difficult behavioral problems to high-functioning, very pleasant children. It is important to obtain a complete cardiac history in these children because congenital heart disease (e.g. ventricular septal defect and endocardial cushion defect) is common. These children frequently have asymptomatic subglottic narrowing and require a tracheal tube sizes 0.5 to 1 mm ID smaller than expected for age. Much has been written about the instability of the cervical spine in these children despite the fact that there are only isolated reports of neurological sequelae associated with general anesthesia and surgery [2]. Evidence of a pre-existing neurological complaint, that the child suddenly favors one hand or foot over the other or has had a change in gait, complains of pain in the neck, is unable to turn the head to one side or the other, or complains of dizziness or fainting should be noted and are reason for concern regarding the integrity of the cervical spine. In such cases, a neurological investigation should be sought before proceeding with

anesthesia. Although the American Academy of Pediatrics recommends cervical spine imaging in all 3–5-year-old children with Down syndrome, there is no evidence that these investigations are predictive of adverse neurological outcomes in the perioperative period. During anesthesia and tracheal intubation, the necks of these children should be maintained in a neutral position at all times.

Children with diabetes mellitus present a number of challenges in the perioperative period [3]. Those whose diabetes is controlled with diet or oral medications should have their morning blood sugar checked. These children do not usually require additional care and can resume their diet and medications postoperatively. Insulindependent diabetes presents a more complex management problem. A thorough history should detail their diabetes control, whether they experience hypo- or hyperglycemia, their typical HbA<sub>1c</sub> concentration (typically <9%), the type and frequency of insulin, and whether they use an insulin pump. In many instances, the endocrinologist responsible for managing their diabetes provides a protocol to the patient and staff that recommends management of the diabetes in the perioperative period. Children who are prone to hypoglycemia should have a glucose infusion and measurement of periodic blood sugar concentrations (or finger pricks) during surgery and anesthesia. If the preoperative blood sugar is >250 mg%, a sliding scale of insulin should be started to reduce the blood sugar. Children who have insulin pumps should also have a fasting glucose measured and their pump set to basal rate during surgery; if the pump alarms with high or low blood sugars during surgery, a blood glucose should be determined to validate the alarm and appropriate action should be taken based on the result.

Children with muscle disorders, specifically malignant hyperthermia and the dystrophies and myopathies, are discussed below.

In adolescents, it is important to establish their use of tobacco and illicit drugs, which may not be possible until the child is separated from the parents. If there is any suspicion that illicit drugs, such as cocaine, crack or other cardiac and neurotoxins have been consumed recently, a toxicology screen should be obtained.

A list of medications, the frequency of their use, and when they were last taken should be compiled. Liquid medications may be taken on the morning of surgery. Children who take medication in pill form will often only take it when it is mixed with food. These medications, often antiepileptic drugs, should not be taken before surgery.  $\beta$ -Blockers and  $\alpha$ 2-agonists should be continued in the perioperative period, as suddenly stopping them may cause rebound effects. Since angiotensin-converting enzyme (ACE) inhibitors have been reported to cause severe hypotension in adults when taken on the day of surgery [4], their ingestion should be suspended for that day. Herbal medications, particularly St John's wort and most medications that begin with the letter "g" (e.g. garlic, gingko biloba), should be stopped at least 1 week before anesthesia [5,6].

Allergies present a very serious conundrum for anesthesiologists. Any drug reaction that a parent or child reports as abnormal is listed as an allergy in the chart. The reactions may be recognized effects of the drug (i.e. a flat skin rash after amoxicillin). Once a medication is listed as an allergy on a patient's chart, it is often difficult, if not impossible, to expunge it from the list. Examples of "allergic reactions" that are not allergic reactions that were reported to the authors while preparing this chapter include allergy to epinephrine because it causes headaches, a diaper rash from oral sulfonamide antibiotic, and a penicillin rash that occurred in the parent but was listed on the child's chart. Most allergies listed in the patients' charts have no immunological basis. Flat skin rashes produced by oral liquid antibiotics are almost certainly non-immunological in origin and warrant re-exposing the child to the antibiotic (if needed) if there was no re-exposure for 5 years. Egg allergy is not a contraindication to propofol [7]; soy and peanut allergies are contraindications only to propofol manufactured in Europe. Latex is commonly cited as an allergy. Skin (and hand) latex reactions are generally cited but are generally are non-immunological and do not proceed to systemic anaphylactic reactions. With the removal of latex from most medical products, children with spina bifida and congenital urological abnormalities are no longer exposed to latex products repeatedly and do not develop latex allergy [8]. These children are not born with a latex allergy, although one parent indicated that she was informed of such a predisposition in a spina bifida clinic. The most important question to ask regarding latex susceptibility is whether the child develops any reaction when he/ she touches a toy balloon to her/his lips or the dentist inserts a rubber dam in the mouth. If the lips or tongue swell, then it is highly probable the child is immunologically allergic to latex. A latex-free environment in the operating room ensures safe care of children who are latex allergic.

Before any child is anesthetized, physical examination of the head and neck, chest, and heart must be performed. Physical examination of the head and neck includes the extent of mouth opening, ability to extend the tongue and neck and the state of the dentition, including loose teeth and any detachable plates or oral appliances. The latter must be removed before surgery. All metal piercings and objects must be removed to prevent aspiration (if they are within the oropharynx) or a skin burn if electrocautery is used [9].

Auscultation of the heart and lungs should be performed and recorded on the preoperative record. Any abnormal findings should be recorded and if necessary evaluated preoperatively.

Routine laboratory testing, such as complete blood counts, chemistry profiles, and urinalysis examination, is not indicated for most elective pediatric surgical procedures. However, if large blood loss is expected, a preoperative complete blood count and blood for type and screen or cross-match should be performed. In some children, it may be necessary to wait until they are anesthetized and intravenous access is established before sufficient blood can be obtained for the required tests.

The most recent recommendations by the ASA Task Force on Preanesthesia Evaluation state that "the literature is insufficient to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management" [10]. We require a preoperative pregnancy test for all menarchal females who require anesthesia at our institution. If the test is positive, we inform the patient of the result and work towards a decision on whether to proceed with surgery and anesthesia. If we proceed with anesthesia, the optimal anesthetic technique for the mother and fetus must be reached by consensus with the pregnant mother.

The clinical value of a chest radiograph in a child about to undergo surgery is typically less than that of an oxygen saturation determination. An oxygen saturation reading of <95% is abnormal and may suggest deterioration of the child's pulmonary or cardiac status. This warrants further investigation.

Specialized tests such as electrocardiography and echocardiography can be invaluable clinical tools in a child with known congenital heart disease or myocardial dysfunction. These tests help to evaluate the cardiac anatomy, intracardiac shunting, ventricular function, right-sided heart pressures, valvular function, and the presence of pleural or pericardial effusions.

Radiological investigations, such as computed tomography (CT) or magnetic resonance imaging (MRI), may be useful not only to the surgical team but also to an anesthetist when evaluating the scope of the disease process, especially those involving airway anatomy.

Once all of the relevant preoperative data have been compiled, an assessment of the "ASA physical status" of the child should be performed. This metric is an assessment of the child's pre-existing diseases, but it is not intended as a measure of perioperative risk (Box 15.1).

# Medical conditions

# Malignant hyperthermia

Preparation of the anesthetic machine for an elective case of malignant hyperthermia (MH) begins with scheduling the child as the first case of the day as the concentra-

#### Box 15.1 ASA physical status classification system

#### P1. A normal healthy patient

- **P2.** A patient with mild systemic disease

tion of inhaled anesthetics in the operating room is at its nadir if the room was unused overnight [11]. The vaporizers should be removed from the machine, the anesthetic circuit flushed, and the carbon dioxide canisters replaced with new ones to reduce the concentration of anesthetics in the machine to  $\leq 10$  ppm. Removing the vaporizers from the machine ensures that they cannot be inadvertently turned on during the anesthetic and that anesthetic cannot leak into the circuit. The anesthetic circuit should be purged of all residual inhalational anesthetic by flushing the machine with a fresh gas flow of 10 L/min (air/oxygen mixture) while the ventilator is operating.

Although the threshold concentration of vapor above which MH occurs is unknown, most studies suggest that the inhaled agent concentration in the machine should be reduced to  $\leq 10$  ppm. For Ohmeda Excel machines, a 10– 15-min flush at 10 Lpm air/oxygen achieves this. For the newer anesthetic workstations from Siemens (Kion) and Drager (Primus and Fabius), a 75-min flush may be required to achieve  $\leq 10$  ppm of anesthetic. To reduce the flush times of the latter three machines to <10 min, one may replace the integrated breathing circuit with autoclaved circuit components or insert charcoal absorbent in the inspiratory and expiratory limbs of the breathing circuit [12]. Data for the wash-out of anesthetics from the new Ohmeda-GE machines are pending.

Once the breathing circuit has been flushed, a trigger-free anesthetic that includes propofol, opioids, non-depolarizing muscle relaxants, nitrous oxide, benzodiazepines, and regional anesthesia (all local anesthetics) may be used [11]. Monitoring must include end-tidal CO<sub>2</sub> (the earliest sign of a MH reaction) and temperature. IV dantrolene should be available in sufficient quantity to treat a reaction should it occur (2.4 mg/kg IV to stop most reactions, but 10 mg/kg may be necessary). The elimination half-life of intravenous dantrolene is 10h; recrudescence may occur after 6h when the blood concentration of dantrolene falls below the 3µg/mL threshold [13]. Redosing half the original dose of dantrolene at this time will prevent recrudescence. New, rapidly soluble formulations of dantrolene are currently under investigation [13]. There is no longer any role for prophylactic preoperative dantrolene in children with MH.

## **Myopathies**

The anesthetic management of children with the common myopathies, including Duchenne muscular dystrophy (DMD), Becker muscular dystrophy, and Emery-Dreifuss syndrome, should be tailored to avoid medications that are known to induce rhabdomyolysis, hyperkalemia, and myoglobinuria. In children <8 years of age, DMD is associated with unstable muscular membranes because they lack dystrophin. The administration of an inhalational anesthetic (halothane >> sevoflurane) with or without succinylcholine destabilizes the muscle membrane and releases the cellular contents, including myoglobin and potassium [14]. As the children reach adolescence, the muscle wasting in DMD abates and the predominant anesthetic concern is a progressive cardiomyopathy. In the case of Emery-Dreifuss, heart block may be the complicating presentation. Hence, preoperative echocardiogram and electrocardiogram are warranted before anesthetizing adolescents with DMD or Emery-Dreifuss syndrome.

The interaction between anesthetics and mitochondrial myopathies is far less clear [15]. Some children with myocardial myopathy develop lactic acidosis during infancy. Children with myopathies should receive normal saline for their intravenous solution as lactated Ringer's solution will increase lactate concentrations. Although MH is only associated with King-Denborough and central core diseases, rhabdomyolysis may theoretically occur in children with mitochondrial myopathies who receive an inhalational anesthetic. Hence, it is reasonable to flush the anesthetic machine before the child is anesthetized as if preparing for an MH patient. Even though many such children have been anesthetized with inhalational anesthetics without complications, it seems reasonable to recommend alternative anesthetics whenever possible, i.e. total intravenous anesthesia (TIVA).

# Nil per os

All children scheduled for elective surgery should be fasted according to the ASA guidelines (Box 15.2) [16]. Note the fasting intervals are not age adjusted. Children who chew gum must expectorate the gum before induction of anesthesia. Although gum increases gastric fluid volume, the risk of regurgitation and aspiration pneumo-

Box 15.2 Fasting intervals before elective surgery

Clear fluids	2 h
• Breast milk	4 h
Infant formula	6 h
Solids	8h

nia is not increased by chewing gum, therefore surgery need not be delayed [17].

The bowels of patients requiring emergency surgery cease peristaltic action as soon as the injury occurs. Peristalsis may further be impaired by the administration of opioids. Hence, all foods present in the stomach at the time of injury likely remain there until peristalsis resumes. The time until peristalsis resumes after an injury and after opioid administration is unpredictable. The only time interval that correlates inversely with the risk of aspiration pneumonitis (i.e. gastric fluid pH <2.5 and gastric volume >0.4 mL/kg) is the last oral intake-to-injury interval [18]. Bowel sounds alone do not confirm the resumption of intestinal peristalsis and gastric emptying, although passing of gas almost certainly indicates that peristalsis has resumed. We consider all children who undergo emergency surgery to be at risk for regurgitation and aspiration of gastric contents and take appropriate airway precautions.

## Upper respiratory tract infection

Children who have had a recent upper respiratory tract infection (URTI) should not undergo non-emergency anesthesia for 4–6 weeks after the infection to ensure resolution of the pathological effects in the small airways. Because young children have 6–7 URTIs per year, most clinicians proceed with anesthesia 2–4 weeks after the original infection. When children present for elective surgery with a URTI, we recommend canceling the anesthetic if any one of the criteria in Box 15.3 is present[19] as each increases the risk of perioperative airway events.

Children with clear rhinorrhea, whether due to a mild URTI or allergic rhinitis, should receive 1–2 drops of oxymetazoline or neosynephrine (0.25%) per nostril to reduce nasopharyngeal secretions during anesthesia. We prefer to manage these children with a facemask to reduce the risk of airway reflex responses but if the airway must be manipulated, a supraglottic airway may trigger fewer airway reflex responses than a tracheal tube.

# Asthma

Up to 20% of children have asthma or an asthmatic history, but many fewer present with severe asthma that may complicate anesthesia [20]. Children with a history of asthma must be in optimal pulmonary condition and

**Box 15.3** Criteria for canceling elective surgery in a child with a URTI

1. Fever >38.5°C

2. Behavioral and eating changes

3. Mucopurulent secretions

**4.** Lower respiratory tract wheezing or rhonchi that do not clear with deep coughing

without a recent exacerbation or recent hospitalization with asthma to proceed with elective anesthesia and surgery [21]. The preoperative assessment should determine the age at onset of asthma, number of and date of the most recent hospital admissions for asthma, treatment ( $\beta$ 2-agonists or steroids by inhalation), and current state of the asthma. Most children with asthma have never stayed overnight in hospital. If they have, the asthma is severe and should be carefully assessed. If oral steroids have been prescribed recently for an acute exacerbation of asthma, careful preoperative examination of the chest must be performed to ensure that there is no lingering reactive airway component.

On the morning of surgery, the child's lungs should be examined to check for wheezing. Preoperative bronchodilator therapy should be administered to non-wheezing children with mild-to-moderate asthma, as this reduces airway resistance during sevoflurane anesthesia and tracheal intubation by about 25% [22]. If wheezing is present, the child should be instructed to cough deeply to clear any airway secretions present, and bronchodilator therapy should then be administered. If the wheezing persists, the child should be referred to their pulmonologist for reassessment and the anesthetic deferred.

Preoperative bronchodilator therapy should be administered to children who are wheezing and present for emergency or urgent non-airway surgery. If tracheal intubation can be avoided, a facemask or laryngeal mask airway (LMA) should be used. An inadequate depth of anesthesia can cause laryngospasm when an LMA is in place. Equipment should be prepared to administer intraoperative bronchodilator therapy should the need arise (see Bronchospasm below).

#### **Ex-premature infants**

Infants who were born prematurely (<37 weeks' gestational age) and are <60 weeks' postconceptual age (defined as the sum of the gestational and postnatal ages) require 12–24h of postanesthesia monitoring for apnea, irrespective of the surgery [23]. Factors that increase the risk of perioperative apnea in ex-premature infants include age (<60 weeks' postconceptual age), anemia (<12 g% Hb) and secondary diagnoses (e.g. intraventricular hemorrhage) [23,24]. Caffeine 10 mg/kg IV may be administered intraoperatively to reduce the frequency of perioperative apneas, but this may not completely eliminate apnea. Once the infant has been 12 h apnea free, he/ she may be discharged home.

In contrast to general anesthesia, regional anesthesia does not appear to increase the risk of perioperative apnea and does not require perioperative monitoring, unless the infant was also sedated, has multisystem disease or a history of perioperative apneas [25]. Spinal or caudal anesthesia should provide sufficient anesthesia to perform hernia surgery, the most common procedure in ex-premature infants [26]. If the infant is >44 weeks' postconceptual age, he/she may be discharged home from the postanesthesia care unit (PACU). If the parents have an apnea monitor at home and have been trained to manage apnea, the child may be discharged home in the parent's care.

# Sickle cell disease

Sickle cell disease (SCD) or sickle cell anemia occurs primarily in children of sub-Saharan descent, with a frequency in North America of 1:5000. A point genetic mutation results in the replacement of the Hb AA with Hb SS in every red blood cell. Thus, 100% of the cells in children with SCD are at risk for sickling; these children have chronic low hemoglobin concentrations (6-8g%), may have had acute vaso-occlusive crises, and may have received multiple red cell transfusions in the past. Vasoocclusive crises involve a number of organs including bone, chest, and brain. They occur in some children and never in others, are unrelated to the presence of hypoxia, hypovolemia or hypothermia, and may be fatal [27]. Evidence now suggests that those with sickle cell disease and vaso-occlusive crises have markers of a systemic inflammatory response to the disease that upregulates endogenous factors, including an adhesive factor that traps sickle red cells in arterioles and precipitates occlusive crises [28]. Whether the traditional factors of hypoxia, hypovolemia, and hypothermia exacerbate the initial process or compound the inflammatory process has not been clearly established.

Sickle cell may also present in a heterozygote form, Hb AS, known as sickle trait. This disorder presents few problems during anesthesia and surgery provided extreme conditions, such as hypothermia, are not employed. Children with Hb AS have normal hemoglobin concentrations. Two additional hemoglobinopathies, Hb SC and Hb SD, occur less frequently than Hb SS but are equally likely to sickle. The hemoglobin concentrations are normal in children with Hb SC and SD.

The sickledex test determines whether the red cells can sickle. This test can be performed rapidly, inexpensively, and reliably in infants >6 months of age. In infants <6 months of age, the presence of Hb F interferes with sickling and renders the sickledex test non-confirmatory. In fact, infants <6 months of age rarely sickle because Hb F is present.

The definitive diagnostic test for SCD is the hemoglobin electrophoresis or high-performance liquid chromatography. These tests identify the specific normal and abnormal hemoglobins present in blood of infants and children of any age.

To attenuate the risk of a perioperative sickle crisis during elective surgery in children with SCD, some hematologists recommend transfusing packed red cells to increase the total hemoglobin to 10 g% [29]. This practice reduces the frequency of acute vaso-occlusive crises in children with SCD. Others disagree with both the practice of prophylactic blood transfusions and the need for transfusions in children undergoing *minor* surgery. The disadvantages of frequent transfusions in children who are at risk for sickle crises include sensitizing the recipient to minor antibodies (i.e. Kell and Duffy), iron overload, and transfusion reactions. It is important to consult local hematologists regarding the institutional management of children with SCD before the day of surgery to avoid surgical delays.

## **Anterior mediastinal mass**

Children with anterior mediastinal mass (AMM) have a life-threatening risk for anesthesia when they present for a tissue (lymph node) biopsy, CT scan for diagnosis or indwelling central line for chemotherapy [30]. These tumors grow (on occasion very rapidly) in the small and confined space of the anterior mediastinum. Growing anterior mediastinal tumors can press on the tracheobronchial tree and/or right side of the heart (superior vena cava, right atrium or pulmonary artery). Four tissues can be found in AMMs in children: lymphomas, teratomas, thymomas, and thyroid. The most rapidly growing tumor in the anterior mediastinum is the lymphoblastic lymphoma, a non-Hodgkin lymphoma which has a doubling time of only 12-24h. These children may present with minor findings (e.g. night sweats) that rapidly progress over 1-2 days to life-threatening problems (e.g. orthopnea, superior vena cava syndrome). In children, investigating the effects of the tumor on the mediastinal structures, as well as acquiring tissue for the cell type, often requires anesthesia. The decision to proceed with local or general anesthesia depends on the age and level of co-operation of the child, the extent of mediastinal organ compromise, and the accessibility of the node or tumor being biopsied. A multidisciplinary team that includes the surgeon, anesthesiologist, and oncologist should review all radiological and preoperative data before embarking on the surgery.

In children who can tolerate local anesthesia and sedation, proceeding with the surgery is moot. However, for children who cannot tolerate local anesthesia with sedation and who have tumors that severely compromise the airway and/or pulmonary artery, a 12–24-h course of steroids should be considered to shrink the tumor (usually a lymphoblastic lymphoma). The risks associated with administering steroids include tissue necrosis, that may render diagnosis of the tumor cell type difficult, and cause tumor lysis syndrome. Some oncologists are reluctant to treat these children with steroids because of the potential difficulty of establishing the tissue diagnosis should tumor necrosis occur. Establishing the tumor type is critical for determining which lymphoma regimen the child is to receive; the goal is to provide the most effective treatment with minimal treatment complications.

For most children who require radiological investigation, tumor biopsy or chemotherapy access, general anesthesia with spontaneous respiration is ideal. If the child cannot lie flat, anesthesia can be induced and the trachea intubated while the child is in the left lateral decubitus or sitting position. We intubate the trachea at induction of anesthesia to ensure a viable airway should it become necessary to turn the child prone because cardiovascular collapse occurs. Tracheal intubation is performed without muscle relaxation so spontaneous respiration can be maintained. It is important to recognize that the capnogram may be very helpful when establishing whether pulmonary circulation (and cardiac output) is present; sudden compression of the pulmonary artery will eliminate or markedly reduce the capnogram before systemic cardiovascular manifestations are present.

#### **Endocarditis prophylaxis**

The American Heart Association significantly revised the indications for bacterial endocarditis prophylaxis in 2007 [31]. The new recommendations were crafted for dental procedures and adopted by the dental societies. The American Heart Association no longer recommends endocarditis prophylaxis for children undergoing gastrointestinal, urological and genitourinary surgeries. However, many specialists in these areas continue to request endocarditis prophylaxis. Accordingly, it is incumbent upon the anesthesiologist to inquire of the specific specialist whether endocarditis prophylaxis should be administered.

For dental procedures, the only indications for subacute bacterial endocarditis (SBE) prophylaxis are those in Box 15.4. The antibiotic regimen for endocarditis prophylaxis has not changed since previously published [31].

## Full stomach and rapid-sequence induction

The term "full stomach" refers to the presence of residual solid or liquid foods in the stomach at induction of

Box 15.4 Endocarditis prophylaxis

- 1. Prosthetic cardiac valve
- 2. Previous infective endocarditis
- 3. Cardiac transplantation children who develop a valvulopathy
- 4. Congenital heart disease (CHD)
  - (i) Unrepaired cyanotic heart disease (incl. palliative procedures)
  - (ii) Repaired CHD with prosthetic material or device during the first6 months after procedure
  - (iii) Repaired CHD with residual lead at or adjacent to prosthetic patch or device

anesthesia and is usually associated with hypokinetic or akinetic intestinal peristalsis. In such cases, the child is at risk for regurgitation and possibly aspiration of residual gastric contents into the lungs during anesthesia, a potentially fatal perioperative complication. A full stomach occurs most often in patients requiring emergency surgery, but also in children with gastric dysmotility syndromes and diabetes. In most cases of emergency surgery, the time interval between ingestion of food and induction of general anesthesia is too brief to ensure complete evacuation of the gastric contents. A full stomach due to the "trauma," pain, and stress of the injury is exacerbated by the administration of opioids, which increase gastric and intestinal paresis and further delay emptying of food from the stomach.

There are three important principles to remember in such cases.

- There is no safe time interval after an injury that guarantees that the stomach is empty of food.
- There is no safe time interval after an injury that guarantees that there is no risk of regurgitation of gastric contents.
- All children (even those treated with prokinetic motility medications) are at risk for regurgitation and aspiration during induction of, maintenance of, and emergence from anesthesia.

The interval between food ingestion and injury is the only variable that has been associated with an increased gastric fluid volume and decreased pH; the shorter the interval, the greater the risk that a larger gastric volume and lower pH is present. For example, if >8h have passed between the last food ingested and the injury, the gastric fluid volume should be less and pH greater than if only 2h had passed [18]. However, the risk in either case is not zero.

To protect the airways of children who are at risk for regurgitation and aspiration during induction of anesthesia, a rapid-sequence induction (RSI) of anesthesia secures the airway quickly and safely. Although there is no evidence that a RSI is the best strategy to use, it seems reasonable to induce anesthesia quickly and insert a tracheal tube into the larynx as quickly as possible. To perform a RSI, the appropriate equipment must be prepared (see Box 15.5).

In most institutions, a RSI is performed using intravenous anesthesia. Propofol is the most common induction agent (2–4mg/kg), although ketamine (1–2mg/kg) and etomidate (0.2–0.3mg/kg) may be used for hemodynamically unstable children. We recommend succinylcholine 2mg/kg for paralysis, although rocuronium 0.8–1mg/kg has also been used. (NB: Recent concern regarding unexpected hyperkalemia and ventricular tachycardia in male children with undiagnosed muscle (wasting) diseases who received succinylcholine led the FDA to issue a black

#### Box 15.5 Rapid sequence induction for children

#### Preinduction

- Laryngoscope handle/blades sized for age
- Tracheal tubes appropriate for the age of the child, with a stylet
- Active Yankauer suction
- Preparation of induction agents and muscle relaxants in weightappropriate doses
- Preoxygenation through a tight-fitting mask and breathing circuit (as tolerated)
- Position the head and neck optimally
- Suction and remove existing nasogastric tube

#### Induction

- Rapid intravenous induction of anesthesia using predetermined doses
  of drugs
- Maintain facemask with 100% oxygen; ventilation is usually avoided
- Once fasciculations are seen after succinylcholine or depression of the twitch response after a non-depolarizing relaxant, laryngoscopy and tracheal intubation are performed rapidly
- Insert a predetermined size tracheal tube
- If a cuffed tracheal tube is used, the cuff is inflated before the lungs are auscultated. Adjust cuff pressure once auscultation is performed

box warning of this complication. If succinylcholine is used, intravenous calcium chloride (10 mg/kg IV, repeat as necessary) must be immediately available to restore normal sinus rhythm. If the child has a muscle wasting disorder, rocuronium should be used if paralysis is required to secure the airway.) However, if the airway appears to be difficult or precarious, then alternative strategies to secure the airway should be considered, including an inhalational anesthetic or topical local anesthetic and TIVA sedation. If an inhalational induction is performed, the child may require emergency turning to the left lateral decubitus position if regurgitation occurs. It may be necessary to topicalize the airway during TIVA while maintaining spontaneous respiration to prevent coughing.

There is much debate regarding the importance and relevance of cricoid pressure in a RSI [32]. Currently, there is no evidence to support or refute the use of cricoid pressure for this purpose. However, there are some concerns regarding the application of cricoid pressure in infants. In both infants and children, the cricoid ring and trachea are mobile and deformable, and only 10 N of force are required to compress the airway by 50%. This is one-third the force recommended for cricoid pressure [33]. Cricoid pressure may also increase the level of difficulty of tracheal intubation by distorting tracheal anatomy or compressing the cricoid ring. Very few assistants are trained properly in the location of the cricoid ring and in the magnitude of the force required to occlude the esophagus. It remains our view that there is insufficient evidence for or against the use of cricoid pressure during RSI in children; the clinician should use their own best judgment in planning the optimal strategy to secure the airway rapidly and safely [32].

# Preparation of operating room, equipment, monitors

# Anesthetic machine

A complete machine check must be concluded before anesthesia commences. Modern anesthetic machines provide complete start-up checks that, for the most part, are completely automated. These will be machine specific, must be performed unless there is insufficient time to do so due to a pending emergency, and are not discussed further. Refer to the operations manual for the specific machine to conduct the machine check.

Before embarking on an anesthetic, the pressures in the emergency gas cylinders on the machine must be checked. An emergency oxygen cylinder is required on all machines to provide administration of oxygen if the line oxygen supply fails. Because oxygen is completely gaseous in these pressurized cylinders, the pressure in the tank decreases linearly as the tank is emptied. The volume (in liters) of oxygen present in the emergency E cylinder is the product of the ratio of the pressure within the tank to 2200 pounds per square inch (psi) (the pressure of a full cylinder of oxygen), and the number of liters of oxygen in a full cylinder (618L). Thus, it is easy to calculate how many minutes of oxygen are available in the E cylinder for a given flow rate should the wall oxygen source fail. A source of air should also be available so that less than 30% oxygen can be delivered to infants at risk for oxygen toxicity and for those with congenital heart disease in whom excess oxygen may cause excess pulmonary blood flow. This is usually provided from a wall source, although an emergency air cylinder should be available. Supplementary nitrous oxide cylinders are not essential to maintain anesthesia if the wall source of N2O fails. These tanks can be a source of operating room pollution and are costly to replace. Nitrous oxide in E cylinders contains both liquid and gaseous nitrous oxide at 750 mmHg pressure. The pressure within the cylinder remains constant until all the liquid nitrous oxide has evaporated. Up to that point, the content of nitrous oxide tanks can only be determined by weight. When the pressure gauge on the cylinder indicates that the pressure is decreasing, the cylinder is nearing empty and must be replaced quickly.

#### Box 15.6 SALTED mnemonic

- S Suction, stylet and solution (IV fluids RL or normal saline)
- A Airways oral and nasal different sizes
- L Laryngoscope Miller blades from sizes 0–3; MAC 2 or 3
- T Tubes tracheal tubes of appropriate sizes, tape
- E Equipment anesthesia machine with breathing circuit, McGill forceps, facemasks, back-up self-inflating AMBU bag, fluid warmer, venous cannulation kit, and standard monitors
- **D** Drugs (anesthesia and resuscitation drugs)

## **Anesthetic equipment**

To ensure that the anesthetizing location is properly and completely prepared, it is useful to refer to a checklist such as the one shown in Box 15.6.

Appropriately sized equipment should be available for each child. A range of facemask sizes, oral airways, laryngoscope blades, tracheal tubes, and laryngeal mask airways should be present. We prefer cushioned clear facemasks that fit the contour of the child's face and permit rapid identification of either fluid or solid material within the mask. The importance of oral airways in establishing a patent upper airway in children has been supplanted in our practice with the jaw thrust maneuver (see below). We advocate the use of Miller and Wisconsin straight blades for tracheal intubation in infants and children because they align the axes of the mouth, pharynx, and larynx. A range of sizes of laryngoscope blades should be available in every anesthetizing location (Table 15.1). We advise against placing a roll under the shoulder of neonates and infants during laryngoscopy unless the laryngoscopist is seated; the shoulder roll raises the larynx, which is already anterior and cephalad in the neonate compared with older children, making it more difficult to align the axes while the laryngoscopist is standing. In neonates with limited oxygen reserve or when performing an awake tracheal intubation, the Oxyscope<sup>™</sup>, a straight blade fitted with a source of oxygen at the tip of the blade, may prevent oxygen desaturation during laryngoscopy. Macintosh blades are best suited for use in adolescents.

The classic laryngeal mask airway (cLMA) was introduced to replace facemasks in adults and has subsequently proven to be a versatile and useful airway device in children as well [34]. To fit pediatric airways, the dimensions of the adult cLMA were scaled down in size, although the mask was otherwise unmodified and made no compensation for the difference in laryngeal anatomy. The cLMA has proven to be effective in circumstances other than elective anesthesia, including neonatal resuscitation and fiberoptic intubation. A range of sizes of the cLMA should be available (see Table 15.1). Although effective, the cLMA does not "protect" the airway from

Laryngoscope blade size					
Age (years)	Miller blade size				
0–0.5 years	Miller 0				
0.5–2 or 3 years	Miller 1				
2–4 years	Miller 1.5				
3–8 years	Miller 2				
Classic LMA size					
Weight (kg)	LMA size	Max. ETT size			
0–5 kg	#1	3.5 mm ID			
5–10kg	11/2	4.0			
10–20 kg	2	4.5			
20–30 kg	21/2	5.0			
30–50 kg	3	6.0			

Table 15.1 Airway equipment

ETT, endotracheal tube; ID, internal diameter; LMA, laryngeal mask airway.

regurgitation and laryngospasm. Since the tone of the gastroesophageal sphincter is reduced in children compared with adults, children may be at greater risk for regurgitation in the presence of a full stomach or positive pressure ventilation. Hence, it is best to avoid LMAs in these clinical situations. Modifications of the cLMA to include a vent for regurgitant gas or liquid from the esophagus, as in the ProSeal supraglottic airway, may better protect the airway against aspiration.

Complications of the cLMA in children include gastric inflation, aspiration, airway obstruction, and laryngospasm. The frequency of complications with the cLMA in infants <1 year of age is greater than that in older children. Fiberoptic studies have demonstrated that the epiglottis folds down into the bowl of the cLMA in about 50% of children when the LMA is otherwise properly functioning; the relevance of this finding remains unclear.

A range of diameters of tracheal tubes appropriate for the child's age, as well as tubes 0.5 mm internal diameter smaller and larger, should always be available. The appropriate size uncuffed tracheal tube is based on the internal diameter (ID) of the tube. Guidelines for tracheal tube sizes in infants and children are: infant's weight (<1500 g, 2.5 mm ID; 1500 g–full-term gestation, 3.0 mm ID), neonate to 6 months postnatal age, 3.5 mm ID and 0.5–1.5 year, 4.0 mm ID. For children >2 years of age, the size of uncuffed tubes may be estimated using the formula: age (in years) /4 + 4 (or 4.5) mm ID. The size of cuffed tubes (mm ID) may be estimated using the formula: age (in years)/4 + 3(for children <2 years) or +3.5 (for those >2 years).

The length of a tube from the lips to midtrachea in infants <1000 g in weight is 6 cm, 1000–2500 gm is 7–9 cm,

in term neonates 10 cm, and for infants and children, 10 + age (years) mm.

In the past, uncuffed tracheal tubes were used to secure the airway of children <8 years of age. The circular shape of the tracheal tube was similar to the shape of the lumen within the cricoid ring, which allowed for a good seal to form without the need for a cuff on the tube. Cuffs were avoided in children out of the concern that the loosely adherent pseudostratified columnar epithelium within the cricoid ring, the only solid cartilaginous ring in the upper airway, would swell and further encroach on this narrowest portion of the upper airway and cause stridor. Because airflow within the upper airway is turbulent, a 50% reduction in the radius of the airway would increase the resistance to airflow by the fifth power of the radius or 32-fold. This increase in resistance would rapidly lead to respiratory distress, fatigue, and ultimately respiratory failure in young infants and children, particularly if they were also septic. To preclude this potentially serious airway problem in the perioperative period, in addition to avoiding cuffed tubes, we carefully selected the tracheal tube in children so that it either passed through the cricoid ring without resistance or it did so with an audible leak at a peak inspiratory pressure of about 20 cmH<sub>2</sub>O. If an audible leak were present at a peak airway pressure  $\leq 10 \text{ cmH}_2\text{O}$ , then the tracheal tube was changed to a half-size larger, otherwise ventilation may prove to be inadequate during the surgery. Before proceeding, the peak inspiratory pressure at which there was an audible leak would be retested. This process would be repeated until a satisfactory sized tube was present.

Recently, there has been a shift from uncuffed to cuffed tracheal tubes in children. This shift in practice has in no small part been facilitated by the introduction of the soft, high-compliance cuffed Microcuff® tube (Microcuff GMbH, Weinheim, Germany) [35]. These tubes have no Murphy eye, the cuff is positioned very close to the tip of the tube, the cuff material is polyurethane, and the shape is cylindrical (rather than spherical as in low-compliance cuffed tubes), mimicking the shape of the larynx. Several relatively small size studies have reported similar incidence of complications in children with high-compliance cuffed and uncuffed tubes. Microcuff<sup>™</sup> tubes confer several additional advantages over traditional uncuffed tubes, including less contamination of the OR with anesthetic gases, fewer laryngoscopies and reintubations, and more consistent tidal volumes (as chest wall and abdominal compliance change during surgery) [36]. Overall, these factors substantially reduce the number of manipulations of the airway in children, OR costs, and OR pollution.

A functioning wall suction with suction tubing (that is long enough to reach the OR table) and a plastic Yankauer suction tip are mandatory. Yankauer suctions can cause trauma to oropharyngeal tissues that must be avoided. This is achieved in young children whose molar teeth have not come in by inserting the Yankauer between the cheek and the teeth and passing it behind the premolars to reach the hypopharynx. With this approach, the child cannot damage their central incisors by biting down on the suction while it is in the mouth. In addition, the suction should not remain in one position within the hypopharynx to avoid applying prolonged negative pressure to tissues (such as the uvula) and causing edema and bleeding. We prefer to use a Yankauer suction rather than a suction catheter in the OR because the former is capable of suctioning large volumes of blood, secretions, and/or vomitus expeditiously should the need arise; the latter is often difficult to pass into the hypopharynx.

The optimal ventilation strategy for infants and children during surgery has been the subject of much interest [37]. For many years, volume-controlled pressure-limited ventilators were used to ventilate the lungs of infants and children during surgery. However, these ventilators could not account for either the circuit compliance or the variable leak around the tracheal tube. There was additional concern regarding the shape of the inspiratory pressure tracing and the risk of delivering high pressures. Pressurecontrolled ventilation has been used successfully in neonatal intensive care units (NICU) for many years, in part because it limits the peak pressure and decreases barotrauma with its constant inspiratory pressure pattern. It also provides a more even distribution of inspiratory gas in the lungs, reducing ventilation/perfusion (V/Q)mismatch.

Despite the advantages of pressure-controlled ventilators, many anesthesia ventilators were simply unable to compensate for decreases in abdominal and chest wall compliance caused by the surgeons or their instruments or by peritoneal insufflation of the abdomen or chest during laparoscopy. When this occurs, it is difficult to ensure reliable tidal volume ventilation. A new generation of anesthetic machines offers markedly improved ventilators and ventilation strategies that are hybrids of the best aspects of both volume- and pressureregulated ventilation. These new ventilators may prove to be ideal for both preterm and term neonates. The hybrid pressure-regulated volume-controlled mode, which maintains a fixed tidal volume by taking into account the compressible volume of the breathing circuit, is used during controlled ventilation, and a pressure support mode is used once spontaneous respiration commences. It is essential to avoid causing barotrauma in small neonates by presetting weight-appropriate respiratory parameters on the ventilator before commencing ventilation.

**Box 15.7** Basic mandatory monitoring for anesthesia and other monitors

- Electrocardiogram
- Arterial blood pressure
- Pulse oximetry
- End-tidal CO<sub>2</sub>
- Temperature
- Secondary optional monitors
  - anesthetic depth monitoring
  - cerebral oxygenation monitoring
  - invasive monitors

## **Emergency drugs**

Emergency drugs should always be available before inducing anesthesia. Syringes with a small-gauge (23 or 25 G) needle that contain weight-appropriate doses of atropine and succinylcholine should be immediately available to facilitate intramuscular or sublingual drug injection in an emergency. A syringe of propofol (1–2 mg/ kg) should always be available to facilitate tracheal intubation or LMA insertion, as well as to break laryngospasm and increase the depth of anesthesia quickly [38]. Inotropic drugs are not routinely prepared for healthy children undergoing elective surgery.

#### Monitors

The ASA mandates basic patient monitoring during all anesthetics (Box 15.7). Monitoring children during anesthesia must include the standard five monitors: electrocardiogram, arterial blood pressure, oxygen saturation, capnogram, and temperature, as well as any additional monitors specific for the child's medical or anesthetic condition, e.g. depth of anesthesia monitor. Many infants and preschool age children fight the application of monitors while awake. Although induction of anesthesia is usually well tolerated and safe in expert hands, every effort should be made to apply at least a pulse oximeter before inducing anesthesia. The remaining monitors should be applied as soon as the child loses consciousness.

#### Electrocardiogram

A standard three- or five-lead electrocardiogram should be used in every anesthetic to detect arrhythmias (bradycardia) and peaked T waves or ST segment changes. The most common rhythm disturbance in healthy children is bradycardia that is usually caused by hypoxemia or vagal reflex stimulation (Box 15.8). Ventricular arrhythmias are exceedingly uncommon during sevoflurane anesthesia. The most common causes of ventricular arrhythmias in children are hyperkalemia and intravascular injection of amide local anesthetic.

#### Box 15.8 Causes of bradycardia

- 1. Hypoxia
- 2. Vagal reflex response (e.g. prolonged laryngoscopy, traction on the extraocular muscles)
- 3. Medication (e.g. succinylcholine)
- Congenital heart defect, cardiac conduction defect, heart failure and cardiomyopathy
- 5. Raised intracranial pressure
- 6. Electrolyte imbalance (hyperkalemia, hypocalcemia)
- 7. Massive air embolism
- 8. Tension pneumothorax

#### Arterial blood pressure

Arterial blood pressure is usually measured noninvasively every 5min with an automated Doppler technique during elective surgery. The cuff should cover approximately two-thirds the length of the humerus. In children, systolic pressure is used primarily as a measure of volume status and secondly as a measure of cardiac function. Diastolic pressure is not as closely regarded because peripheral vascular resistance is low in infants and children. Invasive pressures are usually reserved for prolonged surgeries, especially those associated with large blood loss, congenital heart disease or when sick children require inotropic support or repeated blood gas measurements.

#### **Pulse oximetry**

Pulse oximetry is used to determine the hemoglobin oxygen saturation (SaO<sub>2</sub>) by measuring transmittance of two wavelengths of red light, 660 and 940 nM, through the blood in arterioles. The probe is commonly affixed to a digit but may also be applied to the earlobe, the hypothenar eminence or lateral aspect of the foot in infants. In addition to a visual display of SaO<sub>2</sub>, current pulse oximeters have an audible tone whose pitch decreases when saturation decreases. Most oximeters use motion-artifact compensation software that enables them to measure the oxygen saturation even when the child is moving, e.g. during induction or emergence from anesthesia. Pulse oximetry accurately measures oxygen saturations between values of 70% and 100%. Most nail polishes do not interfere with the accuracy of oximeter readings, although we prefer to apply the oximeter to an unpainted surface. Pulse oximeters may fail to detect a pulse in the presence of a low cardiac output, low arterial blood pressure, hypothermia or vasculopathy. It should be noted that carbon monoxide is neither sensed nor measured by pulse oximeters in current use.

# Capnography

Infrared analysis of the end-tidal carbon dioxide tension in the breathing circuit has been used to estimate the partial pressure of carbon dioxide in blood. Two distinct techniques are available to display end-tidal carbon dioxide tension. One continuously aspirates gas from the breathing circuit and determines the carbon dioxide tension in a remote sensor, known as side-stream capnography. The other analyzes the carbon dioxide tension directly in the breathing circuit and is known as mainstream capnography. The accuracy of side-stream capnometry improved dramatically when circle system breathing circuits replaced t-piece circuits because there is less dilution of expiratory gas. Side-stream capnometry using gas obtained from the elbow of the circle breathing circuit provides accurate data, even in neonates without cyanotic heart disease who have small tidal volumes. Mainstream capnography, on the other hand, is unpopular, particularly for infants and neonates, because it increases the dead space of the circuit and the sensors are bulky and heavy and may kink small tracheal tubes.

Recently, small dead-space, light mainstream capnography sensors have been developed for use with an oxygen facemask in children (personal communication, K. Miyasaka, Japan) although additional studies are required before they are available for clinical use. Capnography using gases obtained from the elbow of a circle circuit may also be accurately monitored while sedated children breathe through a facemask or through baffled nasal prongs.

#### Temperature

With induction of anesthesia, children undergo peripheral vasodilation and redistribute heat from their core to their periphery. In children, heat is lost from the body by four routes: 39% by radiation, 34% by convection, 24% by evaporation, and 3% by conduction [39]. The following strategies reduce/prevent substantial heat loss.

The temperature of the operating room should be increased to about 28°C (80°F) before non-febrile infants and young children enter the room. It is important to increase the room temperature as soon as the case is booked or the previous patient vacates the operating room because it may take more than an hour to sufficiently increase the room temperature. Increasing the temperature in the operating room raises the temperature of both the walls and ceiling and the air within the room, thereby reducing radiation and convection heat loss [39]. Forced air warmers are the single most effective strategy available to minimize heat loss by patients who undergo surgery lasting 1 h or more [40]. Although it is comforting to prewarm the air mattress before the child enters the operating room, doing so before the child is anesthetized does not alter the child's temperature at the end of surgery. Furthermore, it may predispose to airborne contamination and possible surgical infection [41]. Until further evidence is forthcoming, forced air warmers should not be used until the skin is prepped and draped for surgery.

Supplemental warming devices, such as warming blankets, overhead heat lamps, and fluid warmers, should also be used to maintain normothermia in neonates if the need arises.

The temperature of all children who receive anesthesia or sedation should be monitored continuously during the procedure and in the PACU. Core temperature is ideally measured in the midesophagus, immediately retrocardiac. The optimal location of the probe can be confirmed when using a combination esophageal stethoscope and thermistor, by inserting the stethoscope until the heart sounds are maximal. Alternative sites to measure core temperature include the rectum, nasopharynx, bladder and axilla, although each site has its limitations. Rectal temperature probes may yield inaccurate temperatures if the probe exits the rectum or is immersed in stool. Nasopharyngeal temperature may underestimate the core temperature if the probe is cooled by gas passing through the ventilation circuit. Axillary temperature may under- or overestimate core temperature because of IV fluid infused through the ipsilateral arm, because the probe is not positioned against the axillary blood vessels or because it is adjacent to the forced air warmer.

# Anesthetic depth monitoring

Recently attention has been focused on reports of awareness, which occurs in about 1% in children who undergo elective surgery [42,43]. Most consider that this incidence of awareness is much greater than their experience, although postanesthesia interviews to determine the incidence of recall are not routine. Because children rarely self-declare their awareness, it is equally likely that our experience underestimates the true incidence of awareness.

Analysis of the reports of awareness in children suggests that many awareness episodes are attributable to local practices that expose children to low concentrations of anesthesia during periods of stimulation. In some cases, awareness occurred during the transport of children from the anesthesia induction room to the operating room [42], whereas in others the anesthesiologists deliberately decreased the anesthetic concentrations immediately after loss of eyelash reflex to reduce the risk of seizures [43]. These practices contrast with most of our practices where the anesthetic concentrations of sevoflurane are neither interrupted nor dramatically decreased until an adequate depth of anesthesia is achieved. We believe that the incidence of awareness during pediatric anesthesia is far less frequent than reported, that most instances are explicable by local practices, and do not justify routine depth of anesthesia monitoring in children.

The Bispectral Index (BIS) is the most widely studied anesthetic depth monitor in children in North America, although other monitors such as the Cerebral State Index and Spectral Entropy monitor are approved for clinical use. The BIS is purported to measure anesthetic depth continuously using a scale from 0 to 100; readings between 40 and 60 are considered adequate for general anesthesia. Thirty to 60 sec are required to display an index value. The probability that recall will occur is significantly increased if the BIS is >60 for more than 30 sec. A number of factors may influence BIS readings. First, BIS measurements vary with the anesthetic administered [44], For example, at comparable surgical depth, the BIS measurements during halothane anesthesia are 50% greater than those using sevoflurane. The difference may be explained in part by the very different EEG patterns of the two anesthetics. The EEG pattern associated with sevoflurane anesthesia consists of more slow waves and less fastrhythm activity than halothane. Although the BIS measurements correlate generally with the sevoflurane concentration, the accuracy of the measurement is poor. BIS readings with nitrous oxide and ketamine do not reliably estimate the depth of anesthesia. Second, age affects the BIS readings [45,46] which in children <5 years of age are less reliable than those in children >5 years of age. The most likely explanation for this effect is related to maturation of the EEG from birth to school age. Third, the depth of anesthesia measurement is substantially affected by the extent of muscle relaxation. Recovery of the twitch response increases BIS readings, while paralysis decreases them. This effect complicates interpretation of the BIS reading. In non-paralyzed patients, the EMG component from spontaneous respiration may erroneously increase the BIS reading. Fourth, position may affect the BIS reading. Placing the patient in the Trendelenburg position  $(30^{\circ} \text{ head down})$  increases the BIS by 20% [47].

There are few indications for the routine use of the BIS monitor in children, except for those who cannot tolerate general anesthesia because of hemodynamic instability, those in whom nitrous oxide is not used, and those anesthetized with total intravenous anesthesia (TIVA).

# Methods for inducing anesthesia

## Anxiolysis

A number of strategies may be used to allay anxiety in children before induction of anesthesia. These are summarized below.

## Parental presence at induction of anesthesia

Two systematic reviews have summarized the published evidence on parental presence at induction of anesthesia (PPIA) and determined that PPIA reduced the anxiety of

parents but not of children [48,49]. The popularity of PPIA has been facilitated in part by the use of induction rooms; parents accompany their children for induction of anesthesia in a non-sterile environment. Use of these rooms improves the efficiency of room changeover. Parents who are most insistent on being with their children during induction of anesthesia are often the most disruptive, least likely to calm their child, and actually provoke further non-compliant behavior in their child. Children 1-6 years of age are those for whom PPIA may be most beneficial. Separation anxiety rarely occurs before 8 months of age. Above all, parents should never be invited by healthcare personnel to accompany their child for a procedure lest both the hospital and the medical personnel be held responsible for any untoward outcomes to the parent. Rather, the parent should be told that they might be accommodated if they choose to accompany their child for the induction of anesthesia. Before a parent does this, everyone on the OR team must agree and understand that a parent will be present at induction, understand their role while the parent is present, and ensure that the parent understands that he or she must leave when asked to do so. Parents must be educated regarding the normal behavior of children during induction of anesthesia. They should be told that their child might cry, resist application of the mask (inhalation induction), experience noisy (and at times irregular) breathing, and demonstrate involuntary movements of the arms and/or legs, body twisting or frank lifelessness as anesthesia is induced. If the parent appears to be too emotional to cope with this situation, he/she should not be allowed to accompany the child to the induction. We believe that a blanket policy that all parents may accompany their child for induction of anesthesia should not be the standard for any anesthetic department. Rather, selection of parents to accompany their child for induction of anesthesia should be made carefully and on a case-bycase basis by the anesthesiologist only after determining that it is in the child's best interest for the parent/guardian to be present.

In cases of cognitively challenged adolescents and children, it may be difficult, if not impossible, to transfer the child to the operating room voluntarily without a parent. In such cases, it is imperative to ask the parents whether the child will come to the operating room unaccompanied. If not, then a parent must accompany the child. In children who are physically abusive and resistant to transfer to the operating room, intramuscular premedication can be used (see below).

#### **Distraction techniques**

There are a number of distraction and educational techniques that may be effective in reducing a child's anxiety. Preoperative coloring books, stories, videos, and websites have been developed to educate children of all ages about the appearance of the operating room, the equipment that will be used, and how they will be anesthetized. Operating room tours, usually on weekends, are popular in many children's hospitals. A staff representative dresses the family members and children in OR attire, they visit an operating room, and the child plays with anesthesia breathing circuits and facemasks. On the morning of surgery, child life providers may orient children who may be at risk for emotional instability and anxiety at the time of separation from parents and induction of anesthesia to the anesthesia mask. They may mark the inside of the mask with flavored lip balm before applying the mask to the child's face. Distraction techniques including video games, earphones, and portable internet devices all reduce preoperative anxiety [50]. To complement the above strategies, the circulating nurses and/or anesthesiologist should be skilled and trained to facilitate smooth and rapid separation of the child from the parents and then distract the child by pointing out wall designs, pictures, and other features as they travel to the operating room. Once the child enters the operating room, the anesthesiologist should establish rapport by telling a story, engaging them in conversation about a recent birthday, holiday or vacation, or by singing as they prepare for induction of anesthesia.

#### Pharmacological sedation

For some children, premedication is required to facilitate smooth separation from their parents. For some parents this is the first time the child and they have been separated, which can be extremely traumatic if the children and parents have been inadequately prepared.

Midazolam is the most widely used premedication for children in North America because it can be given orally, nasally, rectally, intramuscularly or intravenously to calm the child before induction of anesthesia. Whichever route of administration is used, midazolam premedication may depress respiration enough to cause apnea during induction of anesthesia with 8% sevoflurane.

The dose of oral midazolam increases with decreasing age [51]. We routinely give a maximum dose of 1.0 mg/kg (maximum dose 15–20 mg) to children 2–3 years of age to ensure a >95% success rate of sedating children in 10–15 min and administer a decreasing dose with increasing age and give 0.3–0.4 mg/kg for children  $\geq$ 6 years of age [52,53]. This medication is an excellent anxiolytic and produces a smooth parent–child separation within 10–15 min of oral administration. However, even the commercial strawberry-flavored midazolam leaves a bitter aftertaste that adolescents complain about. To minimize the impact of the aftertaste, oral midazolam is best administered as a single swallow. We wash away the aftertaste by offering them a swallow or two of water. For younger
children, midazolam should be instilled into the lateral gutters of the mouth via a needleless syringe. For older children, midazolam may be administered in a small medicine cup and followed by a sip of water. Obstructive sleep apnea is one of the few cautions regarding oral midazolam. About 3% of children with sleep apnea experience transient hemoglobin desaturation [54].

Alternative oral premedications include oral ketamine (5–6mg/kg), although it offers few advantages over midazolam and may cause more postoperative vomiting [55]. Postoperative hallucinations and nightmares are extremely rare after oral ketamine. Some have combined oral midazolam and ketamine in a 50:50 mixture with good success. Other oral premedications include clonidine (2 $\mu$ g/kg) [56] and dexmedetomidine (2 $\mu$ g/kg) [57]. Although these  $\alpha$ 2-agonists provide effective premedication, they require 60–90 min for the onset of effect and may produce bradycardia and sedation that persist beyond the duration of the anesthetic. This onset time for sedation often exceeds the time the child is in the ambulatory unit. As a result, there is little role for these premedications in most ambulatory pediatric surgical practices.

Intranasal premedication is of limited interest in children because they dislike nasal administration of medications. Intranasal midazolam 0.1-0.2 mg/kg causes effective premedication, but the bitter burning aftertaste persists in the nasopharynx long after recovering from the anesthetic [58]. Intranasal sufentanil  $2-4 \mu \text{g/kg}$  is also effective, although sufentanil is infrequently used in children. Its use may precipitate chest wall rigidity and necessitate succinylcholine administration. Most recently, intranasal dexmedetomidine ( $0.5-1 \mu \text{g/kg}$ ) has been used for premedication [59] despite the fact that its onset of action is delayed and the sedation it causes may extend into the recovery period.

## Intramuscular ketamine

For children who are cognitively challenged and have behavior problems, transfer to the operating room may be the greatest obstacle to completing the surgery. Even the parents may be unable to coax the child to participate and to facilitate the transfer. The typical child who presents in this manner is a muscular 75kg or larger, autistic or Down syndrome child. He or she refuses to ingest or accept any premedication. If the child refuses transfer to the operating room under any conditions, the choice is either to cancel the surgery or premedicate the child with an intramuscular injection. In anticipation of the latter, the parent/caregiver and the child should be seated on a stretcher. Intramuscular ketamine 3-5mg/kg (concentration 100 mg/mL) should be administered via a small-gauge needle into either the bare deltoid region of an arm or through the clothing in the same region [60,61]. The latter is not ideal, but in some instances it is our only choice for achieving sedation. Once the ketamine is administered, it may take up to 5 min for the child to relax and stop resisting our efforts. This premedication is usually metabolized before the anesthesia and surgery are completed.

#### Induction techniques

Induction of anesthesia is defined as the transition from awake to anesthetized states. Anesthesia may be induced by one of several techniques, including inhalation, intravenous, intramuscular or rectal routes. The choice of technique depends on several factors, including the age of the child, the child's level of co-operation, clinical condition, and preoperative status. For some techniques, such as intravenous induction or single-breath induction, a qualified assistant is required.

#### Inhalational induction

The most common method of inducing anesthesia in children for elective surgery in North America is by inhalation. All infants and children, including those who are crying and upset, can undergo a smooth inhalational anesthesia induction if the atmosphere and attitude of the staff are appropriate. On many occasions we have engaged upset children in the operating room in a warm and reassuring manner and successfully induced anesthesia by mask. It is our belief that using "brutane" to hold children down and force a mask on their face has no place in pediatric anesthesia and may psychologically scar the child for life. We comfort children and achieve a successful induction of anesthesia by using this approach, even in children who have many emotional concerns and fears.

The greatest challenges at induction of anesthesia often occur in preschool-age children. In this age group, distraction techniques and premedication are key strategies for minimizing anxiety and distress during separation from parents and induction of anesthesia. Our induction strategy is designed to empower children during the induction and maximize their participation. Upon arrival in the operating room, we apply as many monitors as the child tolerates. The child chooses their favorite flavor from two or three choices of lip balm and then colors the inside of the mask with it, or if the child is too young (<3 years of age), we flavor the facemask for the child. With the child seated on the operating table with their back to our chest (or in our lap if a diaper is worn), we gradually and gently bring the facemask to the nose and mouth while flowing 5-7 L/min of 70% nitrous oxide in oxygen in the breathing circuit. We employ a 1 L reservoir bag in the pediatric breathing circuit to reduce the time required to wash in anesthetic into the circuit. It is critically important to ensure the adjustable pressure limiting (APL) valve is wide open so the child does not feel that they are unable to exhale as a tight-fitting facemask is applied.

During this time, we distract the child by singing a song or by telling a joke or a story until the end-tidal and inspired N<sub>2</sub>O concentrations equilibrate or the child ceases to respond to verbal stimulation. At this time, the child has sufficient anesthesia that they cannot recall any malodorous gas, which allows us to increase the sevoflurane concentration to 8% in one stepwise move and reduce the total fresh gas flow to 3–4 L/min.

Once the child begins to lose consciousness (and their neck becomes too supple to hold up their head), we place them supine on the operating table while they continue to breathe 8% sevoflurane in 70% nitrous oxide. The remaining monitors are then applied. During this early period of the induction, we maintain silence in the operating room and the surgeons are not allowed to stimulate or manipulate the child. If the child becomes apneic during this period (as is often the case after premedication), ventilation should be assisted manually and gently. To reduce the risk of awareness, the concentrations of sevoflurane and nitrous oxide are maintained until intravenous access is established. Once IV access is established, an IV dose of propofol (1-2 mg/kg) is administered, the nitrous oxide is discontinued, and the laryngeal mask airway or tracheal tube is inserted [62]. Anesthesia is continued with 8% sevoflurane in 100% oxygen until we verify bilateral air entry in the chest. If apnea occurs after the airway is secured, the inspired concentration of sevoflurane is reduced by 25-35% or more until spontaneous ventilation resumes. If nitrous oxide is not contraindicated, it may be reintroduced at this time, along with an appropriate concentration of inhalational anesthetic. Only after the airway is secured should the surgeon examine the child.

Several alternative strategies may be used to achieve a deep level of anesthesia with sevoflurane, including increasing the inspired concentration of sevoflurane in a stepwise manner (2% per minute). Although this approach provides the same final outcome, its disadvantages are that it results in a longer induction time and excitement period.

Another distraction strategy that may be used is known as troposmia. Troposmia is a distorted perception of an odor that, in this case, can be attributed to the presence of inhalational anesthetics. The anesthesiologist asks the child their favorite flavor after applying a standard (e.g. strawberry) lip balm to the facemask. The child is then told that as they are anesthetized, the anesthetic will magically change the strawberry flavor to the child's favorite flavor. In one study, 80% of the children confirmed that they smelled their favorite flavor when they breathed the anesthetic gas [63].

The child with mask phobia poses a real challenge for those attempting to induce anesthesia by inhalation [64]. Besides refusing a mask, these frightened children often steadfastly refuse needles (and therefore an intravenous induction), leaving clinicians few options for inducing anesthesia. Several different solutions have been devised to address this problem, ranging from removing the mask from the breathing circuit to forcing the mask on the child's face (also known as "brutane") with 8% sevoflurane in the breathing circuit. We believe that induction of anesthesia with the former strategy is the preferred approach whereas induction with the latter approach is potentially traumatic and psychologically harmful, and it is not recommended.

There are many reasons why children may be fearful of facemasks, including the unappealing odor of 8% sevoflurane administered to an unpremedicated child, endexpiratory pressure that prevents the child from completely exhaling, and claustrophobia. Irrespective of the reason for the mask phobia, we hold to the philosophy that if the mask is the focal point of the fear, it should be eliminated from the induction. To induce anesthesia without a facemask, we interlace our fingers, with the breathing circuit elbow positioned between our fingers and deliver 70% nitrous oxide in oxygen. We cup our hands under the child's chin and gradually bring them closer and closer until they cover the child's mouth. Since nitrous oxide is heavier than air, our hands act as a reservoir for the nitrous oxide. Although this approach can be criticized for increasing operating room pollution, we believe this is the optimal approach for management of children with mask and needle phobias. Once the hands are tight over the mouth, we add 8% sevoflurane into the fresh gas flow. When the child is adequately anesthetized, we insert the elbow of the breathing circuit into the facemask and continue the anesthetic. When interviewing these children during the recovery period, they are thrilled that they avoided the "feared" mask.

Another way to deliver anesthesia by mask if the anesthesiologist insists on administering sevoflurane from the outset (i.e. without first using premedication or nitrous oxide) is to rotate the facemask 90° and use the balloon of the cuff to occlude the nares as anesthesia is induced. This eliminates/decreases the smell of sevoflurane and allows anesthesia to be induced smoothly.

Children who are older (usually >6 years of age) and understand how to hold their breath can perform a singlebreath induction of anesthesia [65,66]. This is done by first priming the circuit with 8% sevoflurane (with or without 70% nitrous oxide) by flushing the circuit and reservoir bag 3–4 times. A 2L reservoir bag is preferred because it limits the circuit volume and provides a sufficient reservoir in the event the child takes an additional breath. Before taking a single breath through the breathing circuit, the child practices vital capacity breathing, i.e. inhaling through their mouth and exhaling to residual volume through the mouth (by instructing the child to exhale until there is no air left in their lungs). Once the child has mastered the breathing maneuvers, they exhale to residual volume, at which point the facemask is applied tightly to the face. The child is instructed to take a single vital capacity breath through the mouth and hold it for as long as they can. While the child is holding their breath, the anesthesiologist counts aloud slowly. In general, the child loses consciousness before the count reaches 20 (sec), the head and neck are supported and the child placed in the supine position.

#### Intravenous induction

Most children eschew intravenous inductions because they fear the pain associated with establishing intravenous access. For children without intravenous access, anesthetic cream can be applied topically to the skin to obviate pain caused by the needle puncture. Several such creams are available, including the eutectic mixture of local anesthetics (EMLA®) cream (AstraZeneca, Wilmington, Delaware), which requires a 45–60-min application time to produce topical anesthesia, and Ametop® (Smith and New, Canada) and Synera® (Zars Pharma Inc, Salt Lake City, Utah) which require a 30-min application time and do not cause blanching of the skin or venoconstriction.

Once intravenous access has been established, intravenous anesthesia can be induced. Currently, the only induction agents routinely available in the US are propofol, ketamine, and etomidate; sodium thiopental is no longer available.

Propofol is the most widely available induction agent. It is available as Diprivan in a 1% solution that includes Intralipid (long-chain triglycerides from soy oil), EDTA, egg lecithin, and pH adjustment. Since propofol is a phenol derivative, it causes pain when injected into the small peripheral veins of children. Numerous strategies have been devised to attenuate or prevent this pain but two techniques appear to be the most effective: pretreatment with 70% nitrous oxide in oxygen by inhalation or a modified Bier block using 0.5–1 mg/kg of 1% lidocaine injected into a vein and occluding the vein for 30–45 sec [67].

Propofol is a very safe induction agent for children. When it was originally released, propofol was contraindicated in children with egg allergy. Egg lecithin is a phospholipid derived from egg yolk, a product to which children are not known to be allergic [7]. A second concern relates to children with soy allergy who may develop anaphylaxis to propofol. This theoretical concern has not been reported to occur in the literature, in part because all soy proteins are removed in the manufacturing of propofol, according to Astra Zeneca, North America. However, non-North American manufacturers caution against the use of propofol in children with soy and peanut allergy, as children with soy allergy share epitopes with peanuts and develop peanut allergy [68]. Fortunately, >80% of children who claim to have peanut allergy are actually hypersensitive to peanuts, not immunologically allergic [69]. If children with "peanut allergy" have not been tested immunologically, then the clinician may either avoid propofol or administer a small aliquot of propofol to assess their allergic sensitivity to the drug.

Ketamine may be used for induction of anesthesia, although the concern of postoperative nightmares has relegated it to a second-tier anesthetic that is given for specific indications such as sepsis or cyanotic heart disease.

Etomidate has been neither studied in children nor approved for use in this age group. Its primary indication is for patients in septic shock. In adults, etomidate (0.3 mg/kg) suppresses adrenal function when administered as a continuous infusion, but comparable studies with etomidate have not been conducted in children to determine if they also develop adrenal suppression. Moreover, no dose–response relationship has been determined for etomidate and anesthesia in children. Etomidate may cause myoclonic jerking and pain upon intravenous injection. The latter may be prevented by pretreatment with intravenous lidocaine.

Sodium thiopental has been used for almost half a century as an intravenous induction agent, but in the past two decades it has been supplanted by propofol. Thiopental induces anesthesia very rapidly, and its effects are terminated equally rapidly, primarily by redistribution of the drug. Only 10% of thiopental is metabolized per hour, which delays emergence from anesthesia, particularly if supplemental doses are administered. Hence, this anesthetic is not suitable for continuous intravenous infusion. Most recently, thiopental has been in short supply and unavailable for clinical use.

#### Intramuscular induction

Intramuscular inductions of anesthesia are uncommon in children because they are painful and because the induction of anesthesia is delayed. The only anesthetic currently used for intramuscular injections is 3–5 mg/kg of ketamine (see above), and this is usually reserved for adolescent children who are cognitively impaired and unco-operative. The preferable location for an IM injection is the deltoid or triceps muscle, in part because there is little fat in the subcutaneous tissue, which causes a greater likelihood that the drug will be deposited into muscle rather than fat. The onset of sedation is approximately 3–5min and the duration of action is approximately 30–45min.

Rarely do children who require emergency securing of their airways present without intravenous access. When this does occur, any one of several approaches may be undertaken. Intravenous access may be established before induction of anesthesia, after anesthesia is induced with an inhalational agent or after IM injection of ketamine (3-5 mg/kg), atropine (0.02 mg/kg) and succinylcholine (4 mg/kg).

### **Rectal induction**

Rectal induction of anesthesia was popular in young children (<5 years of age) in the past, particularly for those who were unwilling to take oral premedication or who were very frightened. Several regimens have been used for rectal induction: methohexital 15-25 mg/kg, midazolam 1.0 mg/kg, ketamine 5 mg/kg, or thiopental 30-40 mg/kg [70-72]. A number of problems were identified with rectal anesthesia inductions, including poor bioavailability of the induction agent (due to unpredictable rectal venous absorption or evacuation of the drug from the rectum), risk of laryngospasm (with methohexital), and possible delayed recovery from anesthesia. In immunocompromised patients, rectal administration of drugs may lead to sepsis. Today, rectal inductions are rarely employed. Most anesthetists prefer to involve the parents in managing the child's behavior at induction of anesthesia rather than administer a rectal medication.

# Problems during induction of anesthesia

## **Oxygen desaturation**

Healthy children breathing room air should have a SaO<sub>2</sub> >95% before induction of anesthesia, and this level of saturation should be maintained after induction of anesthesia and airway instrumentation, particularly with a FiO<sub>2</sub>  $\ge$  0.33. However some children decrease their SaO<sub>2</sub> to <94% in the early anesthesia period and do not increase it substantially, despite an increase in the FiO<sub>2</sub>. In the presence of a normal capnogram, the foremost diagnosis is an endobronchial intubation, followed by asthma, mucus plug, and atelectasis. Once bilateral air entry is confirmed, no wheezing is detected, and suctioning the tracheal tube fails to produce purulent secretions, the next most probable diagnosis is segmental atelectasis. The mechanism for the atelectasis is the decrease in lung volumes and chest compliance that occur with induction of anesthesia plus reduced tidal volumes and respiratory effort. In this situation most of the pulmonary blood perfuses the basal segments of the lungs, whereas the upper lung segments receive most of the ventilation. This V/Q mismatching is relatively unaffected by increasing the FiO<sub>2</sub> from 0.30 to 1.00 because of the sigmoidal shape of the oxyhemoglobin dissociation curve.

To restore the SaO<sub>2</sub> to >94%, the atelectatic alveoli must be reopened (or recruited) [73]. This is accomplished by manually inflating the lungs to 20–30 cmH<sub>2</sub>O pressure for 20–30 sec (known as an alveolar recruitment maneuver). This maneuver should be applied cautiously if the child's circulation is unstable. The maneuver shifts ventilation up the pressure–volume curve where right-to-left shunting is minimal. The fresh gas used during this inspiratory pause may include any concentration of oxygen (including up to 70% nitrous oxide) as well as inhaled anesthetic to maintain general anesthesia. Once the inspiratory pause is completed, a physiological positive end-expiratory pressure (up to  $10 \text{ cmH}_2\text{O}$ ) is applied and spontaneous respiration is allowed to resume.

## **Bronchospasm**

Bronchospasm occurs infrequently in children during induction of anesthesia with sevoflurane and halothane [74] but is more common during induction with isoflurane and desflurane [75] and following tracheal intubation. Bronchospasm is defined as a sudden constriction of the airways. Wheezing, on the other hand, which literally means "hissing," is whistling (high- or low-pitched) noises in the airways. To keep these two terms distinct, remember the expression: "all that wheezes is not bronchospasm." Bronchospasm occurs more commonly in children with asthma, pulmonary infections, and anaphylaxis. Wheezing can occur at multiple airway levels, including the larynx (e.g. stridor), and can be intrinsic to the airway (e.g. asthma) or extrinsic to the airway (e.g. pneumothorax).

The factors that predispose to bronchospasm during anesthesia include a recent upper respiratory tract infection, asthma, foreign body in the airway (e.g. peanut or tracheal tube), first- and second-hand smoking, and GERD. Preoperatively, the chest is auscultated to detect wheezing. If new-onset wheezing is detected, elective surgery should be canceled and the child should be referred to the pediatrician or pulmonologist for further evaluation and treatment. Elective surgery should be canceled because wheezing is a sign of unstable pulmonary disease and increases the perioperative risks of general anesthesia. If the surgery is urgent/emergency, bronchodilator therapy should be instituted preoperatively, airway management should be directed towards avoiding a tracheal tube, and equipment should be prepared to provide intraoperative bronchodilator therapy (see below). If the child wheezes chronically despite maximum pulmonary therapy and there is no acute exacerbation of the disease, a dose of bronchodilator should be administered preoperatively and if possible, avoid using a tracheal tube.

If bronchospasm occurs after tracheal intubation, the cause should be determined and treated immediately. For

the new onset of bronchospasm following induction of anesthesia and tracheal intubation, one should first rule out an endobronchial intubation by auscultating both lungs and verifying the depth of the tracheal tube tip in the airway. The tracheal tube should be suctioned to remove mucus plugs from the airways. Although passing a suction catheter down the tracheal tube does not rule out the presence of mucus or a defective ET tube cuff, it reduces the probability that either is present. If the bronchospasm is not resolved with either of these maneuvers, then albuterol should be administered via the tracheal tube. To deliver an aerosol of albuterol, the albuterol canister should be inserted into the barrel of a 30 mL syringe in the inverted position (after removing the syringe plunger) and the plunger should be reinserted on top of the canister and the syringe attached to the elbow of the breathing circuit. Pushing on the syringe plunger delivers albuterol into the circuit. Three to 12% of the aerosolized drug reaches the tip of the tracheal tube, depending on the internal diameter of the tracheal tube (from 3 to 6 mm ID) [76]. Hence, 5-10 activations may be required to deliver enough albuterol to alter bronchial tone. If these maneuvers fail and bronchospasm continues,  $1-2\mu g/kg$ epinephrine may be administered IV. If bronchospasm persists despite these treatments, then an extrinsic cause for the bronchospasm (e.g. pneumothorax) should be sought, investigated, and treated.

## Laryngospasm

Laryngospasm is an infrequent but potentially lifethreatening emergency in unintubated patients that most commonly occurs during induction or emergence from anesthesia. The frequency of laryngospasm in children varies dramatically from 0.4% to 10% among studies, the study populations, and predisposing factors [77–79]. Factors that increase the risk of laryngospasm in children are shown in Box 15.9 [79,80].

Laryngospasm is defined as reflex closure of the false and true vocal cords, although the precise pathogenesis

**Box 15.9** Factors that increase the frequency of laryngospasm

- Young age (infants and young children)
- History of reactive airways disease
- Recent URTI (<2 wk)
- Exposure to second-hand smoke
- Airway anomalies
- Airway surgery
- Airway devices (tracheal tubes, possibly LMA)
- Stimulating the glottis during a light plane of anesthesia
- Secretions in the oropharynx (e.g. blood, excess saliva, gastric juice)
- Inhaled anesthesia (vs intravenous anesthesia)
- Inexperienced anesthesiologist

of this reflex remains unclear. Complete laryngospasm is defined as closure of the false vocal cords and apposition of the laryngeal surface of the epiglottis and interarytenoids. This results in complete cessation of air movement or noisy breathing, lack of movement of the reservoir bag, and an absent capnogram. In contrast, incomplete (or partial) laryngospasm is defined as incomplete apposition of the vocal cords that leaves a small gap posteriorly that is sufficient to permit a persistent inspiratory stridor, limited movement of the reservoir bag, and progressively increasing respiratory effort. Some assert that incomplete laryngospasm is not laryngospasm at all, but for treatment purposes this is a moot point.

Laryngospasm begins as faint inspiratory stridor during induction of or emergence from anesthesia and is associated with suprasternal and supraclavicular indrawing due to increased inspiratory effort, increased diaphragmatic excursions, and flailing of the lower ribs. As greater inspiratory effort is expended, the intensity and volume of the stridor increase and the chest wall movement resembles that of a "rocking horse." As laryngospasm progresses, air movement through the almost closed glottis ceases and the inspiratory effort becomes completely silent. This is an ominous sign. If progression of the laryngospasm is not stopped, the limited reserve of oxygen in the lungs will be exhausted and oxygen desaturation will ensue. This will be followed immediately by a decrease in heart rate. This downward spiral must be interrupted as described below.

Management of laryngospasm requires a multifaceted and immediate response (Fig. 15.1) [78]. As soon as the diagnosis is suspected, a tight-fitting facemask should be applied to the child's face and 100% oxygen delivered with positive end-expiratory pressure (maximum 15–  $20 \text{ cmH}_2\text{O}$  to limit gastric inflation). If the triggering event is blood, secretions or foreign material in the airway, these should be removed to take away the source of glottic stimulation.

As soon as the offending agent (if one is present) has been removed, a jaw thrust maneuver should be applied. The jaw thrust maneuver requires familiarity with the anatomy of the retromandibular notch, an area subtended by the condylar process of the ascending ramus of the mandible anteriorly, the mastoid process posteriorly, and the external auditory canal superiorly [81]. Bilateral digital pressure is applied to the most cephalad point on the posterior edge of the condylar process of the ascending ramus of the mandible, and the pressure is directed towards the frontal hairline. Pressure on the edge of the condylar process should be applied for 3-5 sec at a time and then released, all the while sealing the facemask tightly against the child's face. By applying and releasing pressure on the condylar processes, the repeated painful stimuli may cause sufficient pain to induce the child to

Figure 15.1 Algorithm for diagnosing and managing laryngospasm in children. Reproduced from Hampson-Evans [78] with permission from Elsevier.

cry. If the child cries, the vocal cords must open, which terminates the laryngospasm. In addition to delivering 100% oxygen and positive end-expiratory pressure to the upper airway, this maneuver confers the additional benefit of pain and the "flight and fright" response, which stimulates the respiratory effort and vocalization, possibly breaking the laryngospasm. Remember, laryngospasm cannot develop or persist if the vocal cords are moving and the child is vocalizing or crying.

If positive end-expiratory pressure, 100% oxygen, and the jaw thrust maneuver fail to quickly break the laryngospasm, further intervention should be undertaken before desaturation and bradycardia develop. Appropriate treatment at this stage includes IV atropine (0.02 mg/kg) and IV propofol (<1 mg/kg) [38,82,83]. If the laryngospasm breaks, then ventilation should be assisted with 100% oxygen and an inhalational anesthetic. However, if the laryngospasm does not abate and the heart rate and oxygen saturation continue their downward courses, succinylcholine (1–2 mg/kg IV or 4–5 mg/kg IM) should be administered and the trachea intubated.

An interesting report suggests that gentle chest compressions effectively break laryngospasm in children [84]. Adding chest compressions to the management of laryngospasm requires a pair of free hands to perform the compressions. If no free hands are available, do not abandon the maneuvers described above. A free pair of hands may not be readily available but if they are, chest compression is worthy of consideration. The risks associated with performing chest compressions include sternal or rib fractures, which must be explained to the parents if they occur. Currently, it is our opinion that there is insufficient evidence to recommend routine use of chest compressions to relieve laryngospasm in children.

#### Bradycardia

Bradycardia is a slowing of the heart rate below agedefined limits. For infants (<1 year of age) this is 100 beats/minute (bpm), for young children 1–5 years of age, 80 bpm, and for children >5 years of age, 60 bpm. Since cardiac output of infants and children is heart rate dependent, a slow heart rate means a reduced cardiac output. If the heart rate decreases below these limits, corrective action should be taken to restore the heart rate, and if necessary cardiopulmonary resuscitation should be initiated.

Although hypoxia is the foremost cause of bradycardia in children, drug-associated causes include halothane and succinylcholine. Since sevoflurane has replaced halothane in developed countries, this cause of bradycardia has all but disappeared [74]. This is not the case in many developing countries. A single dose of succinylcholine remains a common cause of bradycardia in children but occurs much less commonly today because succinylcholine is not routinely used in children for tracheal intubation. Recently, it was reported that the incidence of bradycardia during the first 6 min of sevoflurane anesthesia in children with Down syndrome was fivefold greater than in matched controls [85]. Children who are rate dependent for cardiac output and develop bradycardia may require treatment with atropine or isoproterenol.

The causes of bradycardia in healthy children are listed in Box 15.8. To stop progressive slowing of the heart rate, the underlying cause of the bradycardia should be corrected (e.g. correct hypoxia when present and administer atropine 0.02 mg/kg). Atropine is only effective when myocardial electrical activity is present and the bradycardia is of vagal origin. If asystole occurs, however, atropine does not restore the heart rhythm, and the only definitive treatment is epinephrine ( $10 \mu \text{g/kg}$ ). Secondary treatment should include isoproterenol.

## **Hypotension**

The incidence of hypotension during induction of anesthesia in children is small. During minimum alveolar concentration (MAC) studies, we defined hypotension as a >30% decrease in systolic blood pressure from baseline and at 1 MAC, the decrease in systolic blood pressure was <30% in both neonates and infants 1–6 months of age anesthetized with halothane [86] and in all children through adolescents who were anesthetized with sevoflurane or desflurane [87,88]. The decrease in systolic and mean arterial blood pressures in healthy children at >1 MAC sevoflurane and halothane was neither remarkable nor required intervention [65,66,89]. Induction of anesthesia with sevoflurane plus an intravenous bolus of propofol is a popular method of securing the airway of children. Recently, we determined that an intravenous bolus of 0–3 mg/kg of propofol given to 120 children anesthetized with 8% sevoflurane was associated with systolic blood pressures that were within the normal range [62].

In children, in addition to the effects of induction agents on blood pressure (BP), direct and indirect factors may cause hypotension during induction of anesthesia. Direct causes include a prolonged preoperative fast, bleeding, chronic vomiting or diarrhea, and anaphylaxis. Indirect causes of hypovolemia include coning of the brainstem, septic shock, cardiac tamponade, tension pneumothorax, major vascular compression (pulmonary arterial compression from an anterior mediastinal mass) and, rarely, hypothyroidism.

If hypovolemia is suspected, the initial treatment of hypotension is to restore euvolemia, rather than administer vasopressors. Balanced salt solutions, such as lactated Ringer's solution, should be administered in repeated 10–20 mL/kg boluses while reducing the inspired concentration of inhalational anesthetic.

# **Maintenance of anesthesia**

## Methods

The anesthetic management of infants and children during maintenance of anesthesia is most commonly accomplished with inhalational anesthetics. Over the past 150 years, the molecular structure of inhalational anesthetics has been refined to the point that today these anesthetics are effective, reliable, easy to deliver, offer favorable pharmacokinetics, and are safe. The vast majority of anesthetics in children are based on an inhalational anesthetic with intravenous supplementation of analgesics and antiemetics. One key advantage that distinguishes inhalational anesthetics from intravenous drugs is the ability to continuously measure end-tidal anesthetic concentrations of inhaled agents. This measurement provides invaluable knowledge regarding the accuracy of our delivery system and the patient's responses to the anesthetic.

Currently, three inhalational anesthetics are used to maintain anesthesia: isoflurane, sevoflurane, and desflurane. Although a discussion of the pharmacology of inhaled anesthetics is beyond the scope of this chapter (see Chapter 9), several key principles are summarized. All three anesthetics preserve cardiorespiratory homeostasis in healthy children. However, the use of desflurane in severe asthmatics and children exposed to secondhand smoke may be associated with more adverse respiratory events that are due to changes in pulmonary resistance during and after desflurane [90]. In addition, if desflurane is used for maintenance of anesthesia through an LMA, we remove the LMA when the child is awake to reduce the risk of adverse respiratory events [91].

The speed of emergence from isoflurane and sevoflurane anesthesia is similar when the anesthetic concentration is tapered during the maintenance phase. The speed of emergence after desflurane is more rapid than both isoflurane and sevoflurane, particularly if desflurane was the sole anesthetic used during the maintenance period, it was supplemented with short-acting opioids or nonopioid analgesics, and if the surgery was prolonged [92]. Alternatively, if large doses of opioids were used for analgesia, the sedative effects of the opioids may result in similar emergence times for all anesthetics.

Nitrous oxide is the oldest anesthetic still in use in developed countries and is commonly used during maintenance of anesthesia in children. Although it has several disadvantages, we believe none of them warrants its withdrawal from practice. However, there are several clinical scenarios (bowel obstruction, middle ear surgery, spine surgery with motor evoked potential and cardiopulmonary bypass) in which nitrous oxide is contraindicated. In other situations it has provided a background of anesthesia, sedation, and analgesia during painful procedures for decades. A meta-analysis of postoperative nausea and vomiting after anesthesia revealed that omission of nitrous oxide surprisingly yielded a 2% incidence of awareness [93]. Side-effects from nitrous oxide are common and include perioperative nausea and vomiting, expansion of air-filled cavities in the body, depression of methionine synthetase, and atmospheric pollution.

The environmental concern regarding nitrous oxide relates to its effects on depletion of the ozone layer and global warming. With an estimated life in the troposphere of 110 years [94], nitrous oxide is not environmentally green; however, <5% of the nitrous oxide released into the atmosphere originates from medicinal use. Fertilizers, fossil fuel combustion, and synthetic material manufacturing (nylon) are the top three anthropogenic sources of N<sub>2</sub>O [94]. Anesthesia is not listed as a source of nitrous oxide in global environmental textbooks [94]. Methods to reduce the medical fingerprint on the troposphere include combining desflurane with nitrous oxide, reducing the use of desflurane, using sevoflurane or isoflurane with an oxygen/air fresh gas flow, and improved carbon dioxide absorbents [95].

Total intravenous anesthesia is used as a primary means of providing anesthesia for children with malignant hyperthermia, for those undergoing spine surgery requiring motor evoked potential monitoring, and for those with a history of severe perioperative nausea and vomiting. Propofol and ketamine are the primary general anesthetics used for TIVA. Propofol has few side-effects beyond pain on injection and a lack of analgesic properties. Pain on injection can be obviated by pretreatment with 70% nitrous oxide or by applying a modified Bier block for 30-45 sec with IV lidocaine (0.5-0.75 mg/kg) [67,96]. Propofol has anti-nausea effects that have been exploited in children with histories of nausea and vomiting. However, its major liability remains propofol infusion syndrome (PRIS), which in some jurisdictions has resulted in the anesthetic being proscribed for use as a sedative [97]. Propofol has caused PRIS in children sedated with >5 mg/kg/h of propofol for  $\geq 48 \text{h}$  [97]. Between 1989 and 2004, more than 33 cases of PRIS were described in children during propofol sedation/ anesthesia, as evidenced by an evolving lactic acidosis (for no apparent clinical reason) that reverted to a normal pH once the propofol infusion was discontinued or sudden death occurred [97-100]. Currently, continuous propofol infusions are used in North America to sedate children for medical and surgical procedures, but not in intensive care units when multiple days of sedation are required. Frequent blood gas determinations are prudent in all children who are sedated with propofol for prolonged periods. If an inexplicable lactic acidosis develops, propofol should be discontinued and appropriate resuscitation measures instituted.

Propofol infusion rates to prevent movement during MRI or surgery range from 200 to 400µg/kg/min (12-24mg/kg/h) in infants and children [101,102]. For surgery, supplemental medications, including opioids, muscle relaxants, and sedatives, are usually required. We have also noted that younger infants and those who are cognitively challenged require much greater propofol infusion rates to prevent movement during MRI than older children without cognitive impairment. A word of caution when using propofol infusions for infants <1 year of age: clearance of propofol is least in neonates and increases from neonates to infants 1 year of age. Thereafter, clearance remains unchanged into adulthood [103]. Thus, after the initial loading dose of propofol, the reduced drug clearance in young infants may necessitate lower infusion rates or recovery will be delayed.

To account for the differing pharmacokinetics of propofol (and other medications) over time and in children with differing physiology, target-controlled infusions were developed [104]. These infusion pumps incorporate software that automatically adjusts the infusion rate to the child's characteristics and to the desired blood concentration of propofol in that age group. To date, these infusion pumps have been modestly successful but are not widely available and are not expected to be available for use in humans in North America in the near future.

Supplemental analgesics are also used during both inhalational and intravenous anesthesia to prevent physiological responses and movement to pain. Remifentanil (with a zero context-sensitive half-life)  $0.05-0.1 \mu g/kg/min$  can be administered as an infusion, whereas other opioids (fentanyl and morphine) are more often administered by intravenous boluses. Fentanyl  $(1-2\mu g/kg)$  or morphine (0.05-0.1 mg/kg) can be administered intravenously; the dose is adjusted up or down depending on the child's exposure to opioids, the severity of the pain, and concomitantly administered analgesics.

### Age versus minimal alveolar concentration

Minimal alveolar concentration (MAC) is defined as the minimum alveolar or end-tidal concentration of inhalational anesthetic at which 50% of subjects move in response to a noxious stimulus, usually a skin incision in humans. In children, the MAC values for most inhalational anesthetics increase with decreasing age, reaching a peak value during infancy. For example, the MAC of halothane and isoflurane increases with increasing gestational age and through early infancy, reaching its zenith in infants 1–6 months old. It then decreases with increasing age (Fig. 15.2) [105]. The MAC for desflurane, on the other hand, also increases during infancy but reaches its zenith later (6–12 months of age), and then decreases with increasing age [88]. In the case of sevoflurane, the rela-

**Figure 15.2** Age and the MAC of isoflurane from premature infants to adults. Reproduced from LeDez and Lerman [105] with permission from Lippincott Williams & Wilkins.

tionship between MAC and age differs substantially from the aforementioned inhaled anesthetics [87]. The MAC of sevoflurane, interestingly, is constant at 3.2% in neonates and infants 1–6 months of age. It then decreases abruptly to 2.5% in late infancy to adolescence. The neurobiological reason(s) why MAC changes with age in childhood and why the relationships differ among the different anesthetics have not been explained, although several theories have been proposed, including differences in central nervous system development and neurohumoral factors.

The MAC concept includes the notion that all concurrently administered inhaled anesthetics contribute to the total MAC. Thus, 60% nitrous oxide with 1% isoflurane is equivalent to 0.6 + 1.0 or 1.6 MAC of inhalational anesthesia. This notion applies to isoflurane and halothane in children, as well as to all the inhalational anesthetics in adults. However, when the MAC of sevoflurane and desflurane was determined in children in combination with nitrous oxide, the MAC contribution of 60% nitrous oxide was only 20%, two-thirds less than the effect of nitrous oxide in the presence of isoflurane and halothane [87,106]. The reason for this substantially diminished effect of nitrous oxide with these two relatively insoluble anesthetics has not been explained.

A number of factors have been shown to influence the MAC of inhalational anesthetics. Approximately 90% of adults who are homozygous or heterozygous for the melanocortin-1 receptor gene (i.e. red heads) require 20% more anesthesia than those without this mutation [107]. Children with cerebral palsy and severe mental retardation require 25% less halothane than healthy children [108]. Chronic anticonvulsant therapy also reduces MAC.

In addition to the traditional nociceptive stimulus of skin incision, the MAC responses to other stimuli, including tracheal intubation and extubation, LMA insertion and removal, tracheal intubation/skin incision ratio, and wakefulness have been reported in children [109]. The tracheal intubation to skin incision ratio in children is about 1.33 for halothane and sevoflurane. MAC awake for sevoflurane in children 2–5 years of age is approximately 0.66% and is almost 50% greater than that in 5–12-year-old children, 0.44% [110].

# Fluid management General principles

Intravenous fluid administration sets should be prepared before the child arrives in the operating room. For young children, a 500 mL bag of lactated Ringer's solution with a buretrol is appropriate; for infants (<1 year) a 250 mL bag with a buretrol is preferable. All pediatric IV sets should include a manual controller, a one-way valve (to prevent medications from passing retrograde up the IV tubing), and needleless ports and/or three-way stopcocks for medication administration. For children >8 years of age, the IV infusion set may be prepared with a macro- or micro-drip without a buretrol and a 1000 mL bag of balanced salt solution.

For neonates and preterm infants from the NICU, we continue the clear maintenance infusion fluids from the NICU, i.e. 10% glucose and supplemental calcium. The infusion rate used in the NICU should be continued during surgery, since suddenly reducing this hyperglycemic infusion may cause hypoglycemia. If sequential blood glucose concentrations can be measured during surgery, the glucose infusion should be adjusted to maintain normoglycemia. Intralipid infusions from total parenteral nutrition are best discontinued before transfer to the OR to reduce the risk of contaminating the Intralipid and central venous access line by repeated line accessing.

Most IV fluids administered to healthy children during elective surgery now consist of a non-glucose containing isotonic salt solution, commonly lactated Ringer's solution in North America. These solutions replaced glucosecontaining hypotonic solutions after reports of seizures, aspiration, and brain damage. Worldwide, the shift to isotonic solutions for intraoperative fluid maintenance in children has occurred more slowly [111]. Lactated Ringer's solution is slightly hypotonic (280 mOsm/L) and contains small concentrations of potassium and lactate. Normal saline (0.9% NaCl) is isotonic (308 mOsm/L) and contains no additional ionic moieties but has a pH of 5.0. It is not routinely used as the primary maintenance solution, since large volumes may lead to a hyperchloremic metabolic acidosis (non-anion gap type). We advocate glucosecontaining solutions, such as 1% or 2.5% glucose in lactated Ringer's (LR) solution as a maintenance solution for full-term neonates and infants <6 months of age, and for young children who are cachectic, chronically malnourished, tolerate fasting poorly (maple sugar disease), and suffer from debilitating disease who may be at risk for hypoglycemia [112,113]. These solutions should not lead to intraoperative hyperglycemia or hyponatremia. Although the incidence of hyponatremia has been dramatically reduced with the shift to isotonic salt solutions, some specific surgeries may require intraoperative monitoring of serum electrolytes [114].

Children with specific medical conditions should have tailored intravenous solutions. For children in renal failure or renal insufficiency, normal saline is the preferred balanced salt solution because it contains no potassium. Children with a mitochondrial myopathy and who had lactic acidosis during infancy should be fasted for only brief periods (to avoid acidosis and hypoglycemia) and should receive only normal saline with glucose supplementation as needed. Infants and children <2 years of age who may be hypovolemic should be assessed preoperatively to determine the magnitude of their fluid deficit: mild, moderate or severe [115]. The signs of mild dehydration (5% bodyweight loss – approximately 50 mL/kg deficit) include poor skin turgor and dry mouth. The signs of moderate fluid dehydration (10% of bodyweight loss – 100 mL/kg deficit) include sunken fontanelle, tachycardia and oliguria in addition to the signs of mild dehydration. The signs of severe fluid dehydration (15% of bodyweight loss – 150 mL/kg deficit) include sunken eyeballs, hypotension, and anuria plus the signs of moderate dehydration.

Correction of hypovolemia requires a staged infusion of fluids. Approximately 50% of the deficit should be replaced in the first hour, 25% in the second, and 25% in the third hour. A balanced salt solution should be used to restore euvolemia.

#### **Elective surgery**

For minor elective surgery, the traditional calculation for the hourly fluid infusion rate has been based on replacing the triad of fluid deficit during fasting, ongoing maintenance, and blood and third space losses. In children, the calculation was predicated on the 4–2–1mL/kg/h where 4mL/kg is for the first 10kg, 2mL/kg is for the second 10kg and 1mL/kg is for the third 10kg and any additional bodyweight thereafter hourly [116]. Initial blood loss may be replaced with balanced salt solution at a rate of 3mL of solution for every 1mL of blood loss. For third space losses, the replacement volume is based on the severity of the losses: 1–2mL/kg/h for minor surgery, 2–5mL/kg/h for moderate surgery, and 6–10mL/kg/h for major surgery and large third space losses.

In a reappraisal of their 1957 4-2-1 fluid recommendations for children in the perioperative period, Holliday and Segar reviewed a series of reports of hyponatremia in children who had received hypotonic glucosecontaining solution and evaluated the risks of using a balanced salt solution for maintenance fluids [117]. They determined that their original formula could lead not only to hyponatremia if excessive volumes were rapidly infused in young children, but to fluid and sodium overload in some children if the formula was used with a balanced salt solution. This was of particular concern in the postoperative period because pain and medications may lead to the syndrome of inappropriate antidiuretic hormone where an excess infusion of balanced salt solution might place some children at risk for congestive heart failure. They concluded that their previous 4-2-1 fluid formula used with hypotonic glucose-containing solutions should be replaced with a 2-1-0.5 formula for fluid management in children with balanced salt solutions. In this case, they recommended intraoperative

rehydration with 20–30 mL/kg balanced salt solution in all children and postoperative maintenance using half their original formula or 2–1–0.5 mL/kg [117].

Although most pediatric surgeons are careful to minimize bleeding during surgery, it is important to remain vigilant to blood loss throughout the procedure. For procedures that are likely to result in significant tissue trauma or blood loss, appropriate size IV access must be provided for transfusion of the blood and blood products needed for volume replacement. Packed red cells cannot be rapidly infused through either #24 gauge intravenous catheters or peripherally inserted central catheters (PICC). A #22 gauge catheter is the smallest intravenous cannula through which blood can be infused rapidly. Every effort should be made to insert the largest intravenous catheter that the child's veins will accommodate. Initial blood loss is replaced with a balanced salt solution in a ratio of 3 mL of salt solution for every mL of blood loss. This replacement, together with the maintenance requirement, should be logged on the anesthetic record. As the combined volume of balanced salt solution approaches 75–100 mL/kg, it is important to consider the possibility of dilutional thrombocytopenia and dilution of coagulation factors; coagulation indices should be measured at this time.

The threshold for initiating packed red blood cell (RBC) transfusions in children has undergone a renaissance in the past decade as evidence is mounting that the outcome and complications associated with transfusion at 7 g% hemoglobin are similar to that with transfusion at 9 g% [118,119]. The estimated blood volume in children decreases with increasing age from 95–100 mL/kg in premature infants to 70 mL/kg in adults [120]. Note that the estimated blood volume of obese children is reduced 10% from that of non-obese children of similar age [120]. To estimate the allowable blood loss during surgery, the following equation based on hematocrit (Hct), may be used [120]:

Maximum allowable blood loss

= (starting Hct – target Hct)/(starting Hct) × Estimated blood volume (Equation 1)

Some use a modified version of equation 1 and replace the "starting Hct" in the denominator with the "average Hct." This increases the allowable blood loss before transfusion. Irrespective of which equation is used, the actual Hct should be determined before initiating blood transfusion to ensure that the Hct has actually decreased to the desired level. When initiating a blood transfusion in a child, two formulas provide rough estimates of the amount of blood required to increase the hemoglobin concentration 1g%: 4mL/kg packed cells and 6mL/kg whole blood.

### **Postoperative vomiting**

The incidence of postoperative vomiting (POV) in children depends on a number of factors that relate to the child (motion sickness history, age), the anesthetic (inhaled anesthetics, nitrous oxide, opioids, preoperative fluid administration, postoperative fluid ingestion), and the surgery (inguinal/orchidopexy, tonsillectomy and adenoidectomy, strabismus, and middle ear surgery). To predict the probability of POV in children, a validated score has been developed [121]. The risk of POV increases with the number of the risk factors present: age  $\geq$ 3 years, duration of surgery  $\geq$ 30 min, strabismus surgery, and a history of POV in the proband or immediate family [121,122].

Children should be fasted preoperatively for brief periods and not forced to drink oral fluids postoperatively until they request them [123]. Intraoperatively, the child should be hydrated with IV fluids and provided with regional anesthesia and non-steroidal antiinflammatory agents instead of opioids when possible. If the child is scheduled for emetogenic surgery and has a history of POV, the optimal anesthetic regimen may include propofol oxygen/air and two antiemetics, although conflicting evidence exists regarding the role of substituting propofol and nitrous oxide in POV [124,125].

The optimal prophylactic antiemetic strategy to administer to children during anesthesia is dexamethasone and a serotonin receptor antagonist, such as ondansetron [126,127]. A dose of dexamethasone between 0.0625 and 1 mg/kg (maximum 24 mg) has been shown to be equally effective, although we limit our maximum dose to 10 mg [128]. One report suggested that dexamethasone is associated with an increased incidence of postoperative tonsil bleeding [129] but we question the validity of those data and continue to use dexamethasone routinely in tonsil surgery without complications. The dose of ondansetron we use for prophylaxis in children is 0.05–0.15 mg/kg.

# Emergence and recovery from anesthesia

As surgery concludes, the inspired concentration of inhalational anesthetics or infusion rates of intravenous drugs should be reduced. Neuromuscular blockade should be antagonized and function of the neuromuscular junction assessed before extubation. Equipment should be available to manage the airway (facemask, 100% oxygen) as well as complications from the extubation (suction).

The primary focus of the entire anesthesia team at this time is to assess the child's airway, their ability to breathe, and their ability to protect their airway should bleeding or vomiting occur following extubation. It is our practice to remove the tracheal tube or LMA when the child has fully recovered airway reflexes and is awake. There are very few surgical or medical indications to remove the airway during deep levels of anesthesia and little evidence that this practice results in a better outcome. The greatest concern regarding deep extubations is that a child who is deeply anesthetized and transported with an unsecured airway relies totally on extremely high-quality nursing in the recovery room to manage the airway until emergence. In most instances, the anesthesiologist returns to the operating room and does not remain at the child's side during recovery in the PACU.

The evidence is mixed regarding the frequency of adverse airway events following deep tracheal extubation or awake extubation [130,131]. We transfer children to the PACU awake, with an intact airway rather than anesthetized with a potentially compromised airway. This approach ensures that the child's airway is protected, independent of the skill level of the PACU nurses. However, transferring children deeply anesthetized may be safe if the skill set of the nurses in PACU includes managing anesthetized children.

In our experience, children who have an LMA in their airway are at increased risk for developing progressive airway obstruction several minutes after emergence from anesthesia and removal of the device. Accordingly, we remove all LMAs in the operating room before transferring the child to PACU. In the case of desflurane, we found a substantially greater frequency of adverse airway reflex responses compared to isoflurane when the LMA was removed during a deep level of anesthesia than when it was removed awake [91]. We remove all LMAs when the child is awake, especially if desflurane has been administered.

The timing of tracheal extubation is critical for minimizing the risk of adverse airway events during emergence from anesthesia. The optimal time for extubation requires that children have sufficiently emerged from anesthesia and can support their own airway and that adverse airway events are unlikely to occur after extubation. Recognizing the optimal time for extubation requires that we appreciate the three phases of emergence from inhalational anesthesia in children: early, middle and late. Each of these phases may last for several minutes, depending on the anesthetic administered and the age of the child. During the early phase of emergence, the child first coughs intermittently, gags, struggles, and moves nonpurposefully. This phase passes relatively quickly as the child enters the middle or quiescent phase. During this phase, the child may adopt one or more of several appearances, including deeply anesthetized, apneic or "agitated" and may breath-hold, strain, and/or have oxygen desaturation, the latter necessitating manual ventilation of the lungs to restore the  $SaO_2$  to >95%. As the child resumes quiet, spontaneous respiration, they enter the third phase of emergence, which is characterized by purposeful movement, flexing the hips and coughing and gagging on the tracheal tube, all of which increase in intensity until the child grimaces and opens the eyes spontaneously. Removing the tracheal tube during either the early or middle phase markedly increases the risk of triggering an adverse airway event. It is only during this third phase of emergence that we are least likely to trigger adverse airway reflex responses when the tracheal tube is removed. Our residents are taught that if you think it is the correct time to remove the tube, don't! Leave the tube *in situ* for another minute (or two) until the child is definitely in the late or third phase of emergence, when the tracheal tube may be removed safely.

While children emerge from anesthesia, the practitioner can follow one of two strategies: either no-touch or stimulation. With the former technique, the child breathes 100% oxygen undisturbed and unstimulated while we await the third phase of emergence (as described above). When the end-tidal anesthetic concentration decreases to a level consistent with wakefulness (sevoflurane concentration <0.6%) [110], the eyes will open spontaneously, the child will reach for the airway, gag, and grimace, all of which indicate that it is time to remove the airway. With the latter technique, the initial recovery is the same as that with the no-touch technique; however, we speed the transition through the second and third phases by applying digital pressure to the posterior ramus of the condylar process, the most cephalad portion of the ascending ramus of the mandible, for 3-5 sec while directing the force toward the hairline [81]. This is done when the endtidal anesthetic concentration of isoflurane is <0.25% or sevoflurane <0.6%. The child becomes highly aroused, gags on the tracheal tube, reaches for and removes the tube, and opens their eyes. Both strategies provide similar outcomes with safe and protected airways.

In the vast majority of children, emergence from anesthesia progresses smoothly as described above; there is increasing arousal, gagging, and rejection of the presence of the tracheal tube. However, in rare instances, this sequence of events fails to progress at all, or if it progresses, it is not smooth. Children who fail to emerge from anesthesia must be assessed for a variety of potential problems (Box 15.10). The most common causes of delayed emergence are drug overdose or failure to taper or reduce the dose of inhalational or intravenous anesthetic or the presence of hypothermia. However, rare but potentially catastrophic events such as unexpected hypoglycemia or intracranial bleeding may complicate the anesthesia and surgery and lead to prolonged coma. Laboratory tests may be required to diagnose the cause of the coma. Definitive treatment should be administered once the diagnosis is confirmed.

Box 15.10 Causes of delayed emergence from anesthesia

- Residual drug effects: inhalational anesthetics, opioids, propofol
- Non-anesthesia medications: recreational drug use (cocaine, crack), herbal medicines (valerian, St John's wort)
- Depressed neuromuscular junction: residual neuromuscular blockade or pseudocholinesterase deficiency
- Hypothermia
- Hypo- or hyperglycemia
- Electrolyte imbalance: hyper- or hyponatremia
- Acid–base disturbance
- Hypercapnia
- Cerebrovascular accident/hypoxia: check pupil size and responsiveness to light bilaterally, presence of a gag reflex, symmetrical limb reflexes

#### **Complications during recovery**

Approximately 5% of patients have complications in the PACU [132]. Of these, 77% are from vomiting and 22% from respiratory causes. The remaining 1% or less are due to cardiac problems. The age distribution of the complications is important: vomiting occurred more than twice as frequently in children >8 years of age, whereas respiratory complications occurred twice as frequently in infants <1 year of age.

### Vomiting

The frequency of vomiting in the PACU has decreased dramatically following the introduction of prophylactic antiemetics for children at risk for postoperative nausea and vomiting (PONV). Routine use of dexamethasone and ondansetron reduces the perioperative incidence of vomiting by up to 80% or more [126]. Our experience is that few children vomit in the PACU; most children who vomit do so after ingesting their first fluids, in the car on the way home or at home. Hence, we encourage oral ingestion of liquids after surgery only when the child asks to drink [123]. If the child continues to vomit, there are few effective interventions that have been shown stop the vomiting. Oral fluids should be withheld. If the child is an ultra-rapid metabolizer of ondansetron, the antiemetic effect of this drug may be short-lived. CYP450 2D6 and CYP450 3A4 are responsible for degradation of 5-HT3 receptor antagonists such as ondansetron [133]. Single nucleotide polymorphisms of CYP450 2D6 have been reported to cause rapid metabolism of these drugs. A second dose of ondansetron may be given if at least 2 h have passed since the first dose.

#### Emergence agitation

The introduction of sevoflurane into pediatric anesthesia caused a recrudescence of emergence agitation (also known as emergence delirium, ED). Emergence delirium has been recognized as a sequela after anesthesia for several decades; the frequency increased every time a new, less soluble inhalational anesthetic was introduced. ED has a peak incidence in children (of both sexes) at 2–6 years of age, is more common after some anesthetics (sevoflurane > desflurane > isoflurane >> TIVA), lasts 10–15 min, and is terminated either spontaneously or following a single IV dose of propofol, midazolam, clonidine, dexmedetomidine, ketamine or opioids [134–137].

The challenge is to differentiate ED from pain in children in the PACU after surgery. To that end, ED was assessed in children undergoing MRI with either sevoflurane or halothane [138]. Since none of the children experienced pain after the MRI, any delirium must have resulted from the anesthetic. The authors found a fivefold greater incidence of ED after sevoflurane than after halothane.

A host of studies continued to report ED after a variety of surgeries using non-validated delirium scales, with and without adequate analgesia. This led to much confusion regarding the nature, cause, and treatment of ED. To clarify much of the confusion, the Pediatric Anesthesia Emergence Delirium (PAED) score was developed and validated as an objective measure of ED; a score >10 is indicative of the presence of ED but some have suggested that a score >12 may be more specific [139,140].

# Laryngospasm, postoperative stridor, and negative pressure pulmonary edema

Laryngospasm, postoperative stridor, and negative pressure pulmonary edema occur both during induction of anesthesia and during or after emergence from anesthesia. Pulmonary edema, on the other hand, is more common after tracheal extubation than during induction of anesthesia. Factors that increase the risk of laryngospasm include removing the tracheal tube from the larynx prematurely, the presence of blood, secretions or foreign material within the pharynx, second-hand smoke, and a recent history of upper respiratory tract infection (see Box 15.9). For a full discussion of laryngospasm, please refer to the section on induction of anesthesia above.

Postextubation stridor may also occur upon tracheal extubation. Stridor occurs because the epithelium within the cricoid ring swells after the tracheal tube is removed, thus reducing the cross-sectional diameter of the airway. Because airflow in the upper airway is turbulent, the resistance to airflow increases as the fifth power of the radius decreases. That is, if the radius of the airway within the cricoid ring decreases by 50%, the resistance to airflow increases 32-fold. In infants with increased oxygen requirements and metabolic rates, residual opioids, muscle weakness, and anesthesia may further compromise their ability to maintain an increased work of breathing during stridor, which could hasten fatigue and

respiratory failure. Children with Down syndrome have a greater risk of postextubation stridor [141]. Treatment of stridor includes humidified oxygen, dexamethasone (1 mg/kg IV) and nebulized racemic epinephrine (0.5 mL epinephrine in 2 mL saline). Rarely is it necessary to reintubate the trachea for persistent and severe stridor in the PACU. If hypoxemia or respiratory failure occurs, the trachea should be reintubated with a smaller size tube than the one originally used. To avoid further irritating the epithelium, an audible leak should be present after intubation. If a racemic epinephrine treatment is repeated more than twice, the child should be observed for rebound edema in either the PACU or a monitored unit.

Negative pressure pulmonary edema or postextubation pulmonary edema is an infrequent complication that usually occurs immediately or within several minutes after tracheal extubation in healthy, muscular adolescents and young adults, although it has been reported in infants [142–145]. Once the trachea is extubated, as the airway appears increasingly obstructed, the child appears somnolent and unresponsive. A cascade of events then rapidly occurs. Laryngospasm is present and may range in severity from very mild (i.e. hiccups) to severe. Contemporaneously, the oxygen saturation decreases, almost out of proportion to the severity of the airway obstruction. Ventilation by mask with 100% oxygen is usually insufficient and tracheal reintubation is required to restore the SaO<sub>2</sub> to normal values. Reintubation of the trachea is accomplished by using a muscle relaxant, propofol or both. Upon reintubation, pink frothy pulmonary edema fluid is suctioned from the tracheal tube. Positive pressure ventilation with a positive end-expiratory pressure and sufficient oxygen to restore the oxygen saturation to >94% should be maintained until oxygen and ventilation are no longer needed. Tracheal intubation is usually the only measure needed to treat the pulmonary edema. Sedation should be provided until the pulmonary edema resolves (usually 12-24h or more), after which time the trachea can be extubated.

The mechanism of the pulmonary edema postextubation is believed to be the result of extremely negative intrathoracic pressures generated against an obstructed airway (i.e. laryngospasm) and a marked increase in venous return. This excess fluid overloads the left ventricle and causes pulmonary edema.

#### **Oxygen desaturation**

Failure to maintain adequate oxygen saturation in the recovery room is a common problem. Evidence suggests that a single alveolar recruitment maneuver reduces the risk of post-extubation desaturation [146]. Unrecognized hypoxia may lead to deterioration in the child's clinical status and to sudden bradycardia and cardiac arrest. Continuous monitoring of the child's

oxygen saturation is essential in the PACU to provide an early indication of this complication. The minimum acceptable oxygen saturation in the PACU is 94%. Administration of oxygen by facemask may be required to maintain the oxygen saturation, particularly if residual anesthesia or opioids are present, a craniofacial or muscular abnormality is present, or the child is obese or fluid overloaded. In healthy children, oxygen desaturation is generally indicative of hypoventilation and/or airway obstruction. Because there is no means of assessing ventilation in children in the PACU who do not have artificial airways, we rely on clinical signs to expeditiously diagnose and treat airway obstruction and hypoventilation.

Children should be weaned from oxygen dependency (assuming they did not require supplemental oxygen preoperatively) before they are discharged to the floor or the step-down unit. Some children remove their face-masks themselves when they awaken from anesthesia; if their oxygen saturation is >94% while breathing room air, then no additional oxygen is required. If the child requires supplemental oxygen by facemask, oxygen administration should be changed to nasal prongs. The prongs should subsequently be removed and the adequacy of SaO<sub>2</sub> in room air determined. If the child cannot maintain oxygen saturation after attempts to wean them from the oxygen, further investigation may be required (such as a chest x-ray) to rule out aspiration, pneumonia or pneumothorax.

# Transport to the postanesthesia care unit and intensive care unit

Transferring children from the operating room to either the postanesthesia care unit (PACU) or the intensive care unit (ICU) has inherent risks that must be anticipated and assessed continuously.

Before commencing transport to the PACU, the child must have a stable airway, be able to maintain adequate oxygenation and ventilation, have stable heart rate and blood pressure measurements, and have adequate pain control. A vigilant expert who is trained to manage potential postoperative problems should accompany the child.

During transport to the PACU, most children breathe spontaneously without an oral airway in place. The optimal position for transfer of a child, particularly after airway surgery, is the lateral decubitus position, known as the "recovery position" [146]. In this position, the upper leg is flexed at the hip and the upper knee is resting on the bed in front of the lower leg. The child's upper hand should be placed under their lower cheek. This position facilitates drainage of secretions, blood or vomitus out of the mouth rather than onto the larynx, and the tongue falls to the lower cheek or out of the mouth rather than posteriorly onto the larynx. This position permits direct airway intervention should the need arise.

Supplemental oxygen may be administered during transport by nasal prongs or facemask; if the child is monitored with pulse oximetry, oxygen desaturation may not occur if the child hypoventilates. Some advocate pulling up the chin to feel air movement on their palms during transport. We do not encourage maneuvers that close the child's mouth because doing so often obstructs the airway. Instead, we recommend extending the child's neck with the base of the hand (thenar and hypothenar eminences) and holding the fingertips over the mouth/ nose to sense expiration.

Others transport the child to the PACU in the supine position. This position undermines all of the advantages outlined for the decubitus position and facilitates posterior displacement of the tongue, which may obstruct the airway [147]. Opioids have been shown to depress hypoglossal motor nuclei centrally, which relaxes the genioglossus muscle [148]. If the child is positioned supine, relaxation of the genioglossus muscle may cause the tongue to obstruct the laryngeal inlet. When opioids are co-administered with inhalational anesthetics, the motor tone of the genioglossus muscle decreases, allowing the tongue to fall back and obstruct the airway. Thus, children who receive opioids and inhalational anesthetics should be transported in the lateral decubitus position to reduce the risk of airway obstruction during recovery.

Children who have recovered from anesthesia and who have normal heart and lungs generally do not have oxygen desaturation when breathing room air, unless their airway becomes obstructed. Administering oxygen en route to the PACU came into vogue about two decades ago at the same time as portable pulse oximetry became available for transport. Studies at that time demonstrated that children desaturate en route to the PACU. However, in most instances, the desaturation resulted from airway obstruction, not from desaturation during tidal respiration. Rather than administering oxygen during transport, the child should be positioned in the recovery position with the neck extended with the anesthesiologist's thenar and hypothenar eminences and should be carefully observed for evidence of upper airway obstruction. In this position, the anesthesiologist's fingertips are positioned over the child's mouth and nose to sense the warm air of expiration. If a facemask is used to deliver oxygen, observing moisture on the mask is the usual means of detecting respiration.

If the patient is scheduled for transport to the intensive care unit, additional planning is required before transfer. The medical and nursing staff in the intensive care unit must be given a verbal summary of the child's condition as it relates to anesthetic/drug infusions, cardiorespiratory status, and ventilation requirements before transport so they can prepare the appropriate equipment. The decision to transport the child with or without a tracheal tube should be made in conjunction with the intensive care team with a view to the child's longer-term management. Depending on the reason for admission to the ICU, the child should be transferred with appropriate monitoring, emergency drugs, and equipment to maintain cardiorespiratory stability, including equipment to re-establish the airway should it be lost during transport. Specifically, propofol, succinylcholine and atropine (and inotropes, depending on the child's needs) should be immediately available as well as a bag, facemask, second tracheal tube and a functioning laryngoscope.

In the case of neonates, particularly preterm infants, the distance between the operating room and the neonatal ICU is usually substantial and over several floors. Given the precarious nature of the neonate's airway and the need for adequate analgesia, it seems prudent to transfer these small infants with their airways secured with a tracheal tube and once in the NICU, a dialog should take place between the anesthesiologist and the neonatologist regarding the timing of tracheal extubation.

# CASE STUDY

A 3-year-old child with loud snoring, brief periods of apnea during sleep, fatigue upon arousal in the morning, and attention deficit disorder presented to the otolaryngology service for possible ambulatory tonsillectomy. The child was small for his age, weighed 13kg, and was otherwise healthy. The review of systems was unremarkable. He had an uneventful bilateral tympanostomy as an infant under general anesthesia. The child had no history of allergies to medications and was taking no medications. There was no family history of anesthesia-related complications or muscle diseases, although both parents had type II diabetes.

The child was appropriately fasted for surgery. To smooth separation from his parents, 10 mg oral midazolam was administered in a medicine cup and followed with a swallow of water. The nurse accompanied the child to the operating room where monitors were applied.

He chose a flavor of lip balm that we applied to color the inside of the clear facemask. The mask was then gently

applied to his face while administering 70% nitrous oxide in oxygen. When he stopped responding to our conversation, 8% sevoflurane was added to the fresh gas. After intravenous access was established, a dose of propofol (1.5 mg/kg) was administered, and the trachea was intubated with an uncuffed RAE tube. After the mouth gag was inserted, the child spontaneously breathed a gas mixture of 70% nitrous oxide and 1% isoflurane. Dexamethasone (2mg) and ondansetron (1mg) were administered intravenously. Without a polysomnogram, it was unclear whether this child had oxygen desaturation at night and would be hypersensitive to opioids. To determine his sensitivity to opioids, we administered  $20 \mu g/kg$ morphine. After a single intravenous dose, the child stopped breathing, his respiratory rate slowed from 35 to 18/min and his heart rate decreased from 125 to 96 beats per minute. A second dose of morphine was administered for a total of  $40 \mu g/kg$ . At the conclusion of the anesthetic, the child breathed spontaneously but made no effort to reject the tracheal tube.

When the end-tidal isoflurane concentration had decreased to 0.2% and the child had not aroused, we became concerned. The doses of the propofol and opioids were rechecked to verify that an accidental overdose had not occurred. The ampoules for the dexamethasone and ondansetron were similarly rechecked. A venous blood sample was sent for blood gases, pH, electrolytes, and glucose concentration. All of the laboratory results were within normal limits. His vital signs were within normal

limits. Help was summoned and a differential diagnosis of possible causes was explored. The parents were asked again about recent prescription or non-prescription (including herbal) medications that the child may have taken, but there were none.

No obvious cause for the comatose state was forthcoming until one of the anesthesiologists removed the tape from the child's eyes. Lifting the eyelid revealed a shocking finding. The child's left pupil was fixed and dilated and unresponsive to light.

The trachea remained intubated, and he was taken for an emergency computed axial tomography (CAT) scan that showed an intraventricular bleed, hydrocephalus, and a midline shift. Neurosurgery was consulted and they scheduled the child for insertion of a ventriculo-peritoneal shunt. Cerebral angiogram later demonstrated an arteriovenous malformation that was coiled by the interventional radiologist. The child made a slow but steady recovery after this completely unexpected and unpredictable neurological catastrophe.

## Conclusions

This case shows how unexpected changes can occur during anesthesia without the usual changes in heart rate, arterial blood pressure, blood gases, and pH. It also demonstrates that anesthesiologists must look beyond the expected causes of a problem, here possible drug effects in a child who possibly had sleep apnea.

# Introduction

The importance of the postoperative care unit in the safe, successful management of a child who has undergone anesthesia cannot be overstated. This phase immediately following surgery is beset with potential pitfalls and complications that require rapid assessment and treatment. Not only are there the basic needs that exist of a patient wakening from anesthesia, but in children there are additional unique aspects of postanesthesia care. Particularly in infants, perioperative anesthetic morbidity is higher than other age groups, which further underscores the importance of the dedicated pediatric postanesthesia care unit (PACU) [1]. The Pediatric Perioperative Cardiac Arrest (POCA) registry supports the importance of proper management in the postoperative period [2]. The increased incidence of adverse events mandates care and consideration of the design and staffing of a pediatric PACU in addition to the essential appropriate postoperative management of potential issues and complications.

# Essentials of the postanesthesia care unit

#### Design

When determining the design of a recovery area, the ideal location of any PACU is adjacent to the operating rooms to minimize transfer time and distance for safety reasons. The floor plan or design of a pediatric PACU need not differ from any other PACU environment. Typically, a PACU will have an open plan to permit optimum visibility, although this may not be ideal for all recovering children. Not only can the audible distress of another patient be disruptive, but chatter and discourse of the medical staff have been noted as an unwanted feature of postoperative recovery [3]. The importance of lowering environmental stresses such as excessive noise is now being recognized in modern designs [3]. The presence of curtains between each bed space allows some visible privacy, but does nothing to change the noise pollution. Separate rooms would allow for a better sound barrier but they may be undesirable, as they do not allow for vigilant

**Figure 16.1** A modern pediatric postanesthesia care unit with open design, immediate adjacency to operating rooms, parents present, and ample staffing with experienced pediatric PACU nurses, and prompt availability of anesthesia providers to respond to emergencies.

monitoring by a nurse who is covering several patients and may also be more difficult to navigate in an emergency situation. A possible compromise occurs with rooms that have sliding glass dividers and curtains between them that allow flexibility between rooms but the ability to separate the rooms as needed. With any plan, separate isolation rooms are needed either for barrier purposes or reverse isolation. The number of beds in the PACU should reflect the surgical volume with a ratio of 2.5 beds to each operating room according to current perioperative environment design models (Fig. 16.1).

# Equipment

The equipment in the pediatric PACU needs to have the ability to cover patients of all sizes. The American Academy of Pediatrics proposed guidelines for the pediatric perioperative anesthesia environment [4]. The essential components were identified to promote the safety and well-being of infants and children by reducing the risk of adverse events. In particular, all pediatric anesthesia equipment and drugs that are required in the operating room should be available for patients in the PACU. Every child admitted to the PACU must have their vital signs monitored which mandates monitoring equipment that is appropriate for all ages and sizes. Suction apparatus and oxygen delivery, via a flow meter to allow titration of inspired oxygen as required, must be available at each bedside. Equipment for intravenous fluid administration must allow for microadjustments of volume delivery. Particularly in the smallest children, placing the intravenous fluids on a pump to deliver set volumes on arrival to the PACU is advisable. Due to the increased risk of heat loss in children in the operating room, devices for the

**Figure 16.2** A standard emergency cart centrally located within the PACU with age-specific airway supplies and defibrillator on top.

maintenance of normothermia must be available and utilized.

The pediatric PACU should also have a focal, easily accessed location for the placement of portable emergency equipment. To prepare for the unexpected, a resuscitation cart with equipment appropriate for pediatric patients of all ages, including pediatric defibrillator paddles, must be immediately available. Specialized equipment for management of the difficult pediatric airway by a variety of techniques for airway control, intubation and ventilation, including emergency cricothyrotomy, is desirable. A dedicated airway bag that contains packets of age/weight-specific airway supplies should be a part of the resuscitation cart apparatus (Fig. 16.2). To simplify procedure in the event of an emergency, written pediatric doses for resuscitation drugs, and potentially pediatric advanced life support (PALS) algorithms, should be visible or immediately available. All emergency equipment must be frequently checked and regularly maintained with a checklist system.

## Staffing

Staffing of the pediatric PACU is an important component for the success of the environment. For most patients, recovery from anesthesia is uneventful, but it is also a time when catastrophic events can occur. Pediatrictrained medical and nursing staff are required to be vigilant, caring and knowledgeable. In 1999 the American Society of Anesthesiologists assembled a task force to provide recommendations specifically for a pediatric PACU [4]. This task force recommended that in order to apply specific expertise in the provision of pediatric anesthesia services, an anesthesiologist or other physician trained and experienced in pediatric perioperative care, including the management of postoperative complications and pediatric cardiopulmonary resuscitation, must be immediately available to evaluate and treat any child in distress.

The intensity of nursing care is typically greater in a pediatric PACU than on the floor with assignments based on acuity. The requirements of PACU nursing will be institution dependent. Prior pediatric experience and PALS training would clearly be advantageous and is recommended. Mock codes, possibly to include scenarios using simulation, should be routinely performed with anesthesia and nursing staff so that the care is seamless in a true emergency. Although not stated by the task force, nursing staff should be pediatric trained, and ideally, with a background in pediatric intensive care. This would suggest confidence in the care of the unconscious child, ability to recognize a child in distress, ability to recognize a lost airway and having expertise in the safe administration of potent analgesics. To recognize the subspecialty expertise, pediatric PACU nurses are to be engaged as part of the perioperative team and be members of pediatric perioperative team meetings that include surgeons, anesthesiologists and nursing staff. This builds a cohesive group for the good of the pediatric perioperative environment.

#### Transport

Any hospital patient transport presents a period of significant risk of morbidity and mortality [5,6]. The transport of a child from the operating room (OR) to the PACU should not be considered routine. Apnea, loss of a patent airway, vomiting and emergence agitation are just a few of the potential problems encountered during transfer. To be prepared for these events, it is advisable for the anesthesia provider to have resuscitation drugs and airway equipment that are individualized for the patient or surgery that was performed. Children should be transferred on a bed or crib with guardrails. The lateral recovery position is often used because it facilitates a patent airway with gravity opening the airway and draining oral secretions and blood (Fig. 16.3). Oxygen must always be available along with a suitable delivery device such as nasal cannula, facemask or anesthesia circuit with mask. The use of a monitoring device depends on the status of the patient and distance to the recovery area.

Figure 16.3 Lateral recovery position with airway open to encourage forward drainage of secretions. (Bed rail left down only for purpose of photo.)

## **Handover and assessment**

The universal criteria by which patients are deemed suitable for the pediatric PACU are variable and dependent on many factors, including staffing and acuity. Some patients are easily considered candidates for PACU, including healthy outpatients for minor procedures, and others are clearly not suitable, such as the potentially hemodynamically unstable patient with cardiac disease. Other cases fall into a gray area that requires thought about the ultimate location for recovery. Skills and comfort level of the individual PACU and relationship with the floor or intensive care units may affect the decision of disposition post surgery. For example, following a repair of cleft palate, some centers will recover a patient in the PACU while other centers will prefer direct admission to the step-down or intensive care unit. Similarly, some PACUs may be comfortable with an intubated patient and the subsequent extubation procedure, while others may not [7,8]. Therefore, when determining admission parameters, it is important that there is a clear understanding by the surgical and anesthesia personnel about what location is suitable for the recovery of the individual child.

After the decision is made to admit to the PACU, it is important that there be good communication to the PACU from the operating room. Advance communication from the OR at the very least should include a phone call as the case nears completion. The call alerts the PACU to the new admission and should include details regarding the age, weight, stability of the patient, any intraoperative complications that would affect postoperative care, and any special needs. This initial call allows the nurses to target care, prepare medication and reorganize staff assignments as necessary. Once the patient arrives, the admitting staff should perform an 'initial assessment' prior to the handover from the anesthesia staff. This assessment must quickly determine airway patency, oxygen saturation, heart rate and rhythm, temperature and blood pressure. If all is well, it is then possible to proceed to the medical handover.

With regard to the communication between the anesthesia provider and PACU nurse, and in every aspect of medicine, the handover of patient care is critical. Patient safety is especially vulnerable when crossing professional boundaries. Misunderstanding can occur simply due to differences in culture, training, norms, attitudes, perspectives, goals, expectations, status, gender and socioeconomic status. Indeed, communication breakdowns are a leading cause of medical errors. In 2005, a US Joint Commission on Accreditation of Healthcare Organizations (JCAHO) analysis found that 70% of sentinel events were caused by communication breakdowns, half of those occurring during handovers [9]. To address the problem, the Joint Commission instituted a National Patient Safety Goal in 2006, calling on hospitals to implement a standardized approach to patient handovers. See Chapter 45 for more detail.

In order to improve the handover, it is important to recognize the process, a novel example of which was described at Great Ormond Street Hospital for Children in London [10]. The handover of patient and information from the operating room to the cardiac intensive care unit was actually reviewed by motor racing teams that likened the handover to a racing pit stop. Their recommendations and involvement resulted in standardized handovers, thereby eliminating variation and resulting in clear and concise instructions to ensure that even if team personnel changes, all members are absolutely clear about their responsibilities. Communication was noted as a critical factor in success. The same principles must be applied the handover of a patient from the OR to the PACU.

It has been advocated that training be instituted using interactive simulation-based sessions of standardized patients, clinicians, and manikin simulators with facilitated video debriefing to stimulate thought and reinforce positive behavior. Also, the introduction of mnemonics is useful to ensure timely, accurate and complete information about a patient's care plan, treatment, current condition and any recent or anticipated changes. Examples of these techniques include the "Five Ps" (patient name, problem list, plan of care, purpose of plan, precautions), as well as "I-SBAR" and the "I PASS the BATON" which are shown in Boxes 16.1 and 16.2. The hope is that the use of any of these measures will facilitate a consistent process, thereby improving patient safety.

## Monitoring and patient safety

The American Society of Anesthesiologists has published standards for postanesthesia care, most recently updated in 2009 [11]. These standards are minimum requirements, and specify only that "The patient shall be observed and **Box 16.1** Examples of communication tools that use mnemonics for ease and consistency: I-SBAR communication tool

Т	Introduction	Identify yourself and the patient
S	Situation	Patient age Gender Preop diagnosis Procedure Mental status preprocedure Patient stable/unstable

monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation, such as pulse oximetry, shall be employed in the initial phase of recovery." Pulse oximetry is certainly used universally in pediatric anesthesia during the early phases of recovery but electrocardiographic (ECG) monitoring is not always used, with heart rate source being taken from the pulse oximeter or manual counting. An advantage of ECG monitoring is the ability to have a monitor of circulation when the pulse oximeter does not function due to patient movement or poor perfusion.

**Box 16.2** Examples of communication tools that use mnemonics for ease and consistency: I PASS the BATON communication tool

Т	Introduction	Introduce yourself		
Р	Patient	Name: identifiers, age, sex, location		
Α	Assessment	"The problem," procedure, etc.		
S	Situation	Current status/circumstances, uncertainty, recent changes

т	Timing	Level of urgency, explicit timing, prioritization of actions		
0	Ownership	Who is responsible (person/team) including patient/family?		
N	Next	What happens next? Anticipated changes? Contingencies?		

Additional benefits are the ability to diagnose non-sinus rhythms and to measure respiratory rate using impedence plethysmography. In addition, although the utility of capnography via a nasal cannula in non-intubated patients undergoing procedural sedation is well established, newer data suggest it may also be useful in some patient populations in the PACU, and this type of monitoring could become more frequent in the future [12].

Detailed nursing standards for postanesthesia care have also been published and are regularly updated [13]. Although the exact details of monitoring and assessment will be governed by regulatory agencies and local institutional policies and procedures, in general, a pediatric patient recovering from general anesthesia should have 1:1 nursing care for the initial recovery period, along with frequent monitoring of vital signs, i.e. every 5–15 min during the early recovery phases.

Regardless of the policies and guidelines in place, there is no substitute for well-trained PACU nurses with expertise and experience in pediatric anesthesia, who can recognize problems, institute treatment and call for help from their anesthesia and nursing colleagues. The anesthesiologist also must be mindful of the setting, i.e. busy children's hospital PACU with multiple available anesthesiologists and nurses available to address patient problems, versus a free-standing surgicenter with one or two operating rooms, PACU nurses with limited pediatric experience, and no readily available anesthesia providers for PACU problems because all are caring for patients in the operating rooms. The setting often determines the preferred treatment strategy, i.e. deep versus awake tracheal extubation, or the type or age of patient treated.

## **Parental presence**

As previously stated, the primary goal of the pediatric PACU is to provide a safe environment for patients to return to their preanesthetic state. However, there is evidence that children may suffer negative behavioral changes following hospitalization for surgical procedures [14]. Although it is difficult to predict which child will do poorly, a 2006 cohort study revealed that particular individual, familial and procedural variables were able to identify the children at greatest risk of significant negative behavior change [15]. In particular, a factor that predicted negative behavior was increased parental anxiety. Other factors included younger age, overnight admission, lower birth order, and, surprisingly, having a discussion with the anesthetist preoperatively [15].

As part of the child's stress due to hospitalization and procedures, it would seem intuitive that separation from a parent may compound the problem. For this reason, many parents request to be present as their child recovers from anesthesia [16,17]. The policy of allowing parents into the PACU, however, is uniquely institutional and varies both culturally and nationally. It is not universally adopted, in part because there is little evidence that having a parent present during recovery from anesthesia results in a positive outcome, and as previously mentioned, parental anxiety may be counterproductive. However, in a recent randomized prospective study from Canada, a benefit of parental presence in the PACU for healthy children undergoing outpatient surgery was a decrease in negative behavior change at 2 weeks postoperatively [18]. There was no difference in acute distress (measured by "crying episodes") in the PACU between the group with a parent present and the group where no parent was present.

Despite these findings, parents may be successful with the non-pharmacological measures to relieve pain and distress. The non-pharmacological methods, that involve imagery, relaxation, breathing techniques and massage, may make pain more tolerable and give children a sense of control without the administration of drugs [19]. A qualitative interview study of children and parents following tonsillectomy noted that children have their own coping strategies. These included distraction, such as watching TV, thinking of something else, talking and reading, relaxing, eating ice cream, and simply having someone present [20].

The debate as to the value and appropriateness of parents in the PACU will continue. Most

anesthesiologists have an anecdotal experience that colors their perspective on the matter. However, the emergence from anesthesia is obviously a potentially stressful time for the child. The sensation of pain, nausea and vomiting and waking in a strange and foreign environment are all contributors to this stress. The idealized benefit of a familiar and recognized caregiver is compelling although the actual evidence for such an advantage is poor. There are a significant number of studies on the effects of parental presence in the preoperative period and during induction of anesthesia, but the practice that includes presence of parents in the postoperative period and the PACU environment remains in need of additional study.

# **Discharge criteria**

Discharge criteria have been created to permit an objective evaluation of children leaving the recovery unit. The criteria will depend upon the patient age, surgery performed and the subsequent destination (home versus floor versus intensive care). The two commonly used and cited scores in the literature are the Modified Aldrete score for inpatient care [21] and the postanesthetic discharge scoring systems (PADSS) for patients being discharged home [22]. Both scores use a selection of physiological variables to form an objective measure for discharge eligibility (Tables 16.1, 16.2). Whether the anesthesiologist must personally reassess the patient before discharge, or rely on a protocol with a physician order to discharge the patient when criteria are met, is

Table	16.1	Discharge criteria using scoring systems. Modified Aldrete
Score.	Nine	or more points are required for recovery to be confirmed

Category	Score = 2	Score = 1	Score = 0
Respiration	Breathes, coughs freely	Dyspnea, shallow or limited breathing	Apnea
$O_2$ saturation	SpO <sub>2</sub> > 92% in room air	Supplemental $O_2$ to maintain SpO <sub>2</sub> > 92%	SpO <sub>2</sub> < 92% with oxygen
Circulation	BP within 20 mmHg of preop	BP within 20–50 mmHg of preop	BP within 50 mmHg of preop
Consciousness	Awake and orientated	Wakes with stimulation	Non- responsive
Movement: voluntarily or on command	Four extremities	Two extremities	No extremities

governed by both regulatory agencies and local institutional policy and procedures.

The key components of scores like these include the following parameters: hemodynamic stability, respiratory sufficiency, neurological baseline, ability to maintain and protect the airway, absence of excessive bleeding, normo-thermia, minimal pain (patients should be observed for at least 30min after the last dose of opioid), ability to ambulate if appropriate, and absence of excessive vomiting. The ability to drink clear liquids prior to discharge is not a discharge criterion, and forced ingestion of liquids is actually associated with a higher incidence of postoperative nausea and vomiting (PONV) [23].

Patient age is also a critical factor. Although actively debated, it is suggested that preterm infants should reach a minimum number of weeks postconceptual age (PCA) to be considered for outpatient surgery due to risks of postoperative apnea. Most institutions use conservative

 Table 16.2
 Post Anesthetic Discharge Scoring System (PADSS). At least nine points are required to be eligible for discharge

Category	Description of status	PADSS score
Vital signs	Within 20% range of preop	2
	Within 20–40% range of preop	1
	>40% range of preop	0
Ambulation	Steady gait/no dizziness	2
	Ambulates with assistance	1
	Not ambulating/dizziness	0
Nausea and vomiting	Minimal, treated with oral meds	2
	Moderate, treated with parenteral meds	1
	Continues after repeated treatments	0
Pain	Acceptable to patient	2
	Pain somewhat acceptable	1
	Pain not acceptable to patient	0
Surgical bleeding	Minimal: no dressing changes required	2
	Moderate bleeding: dressing change	1
	Severe bleeding: intervention required	0

criteria close to 50 weeks' PCA or a very conservative 60 weeks. However, 44 weeks can generally be considered the absolute minimum PCA for outpatient surgery based on when the true risk of apnea is considerable. Even in those infants who reach the minimum age criteria for discharge, an extended recovery time with observation during feeding and sleeping may be warranted [24]. Risk factors associated with apnea of prematurity are anemia, PCA and gestational age [24]. A separate entity known as apnea of infancy can occur in term infants but because of its rarity, term infants are not subject to the same postoperative monitored care unless other factors warrant it [25]. It is recommended that term infants, on the other hand, should be a minimum of 4 weeks of age to be eligible for same-day discharge. Although the risk of apnea in a fullterm infant is extremely low, case reports suggest that it is not zero [26-28].

In addition to overall discharge criteria from anesthesia, there are also procedure-specific issues that may affect the time to discharge. For example, a child who receives a spinal anesthetic should show signs of resolution of both sensory and motor blockade prior to disundergoing charge. Children adenotonsillectomy typically would stay in PACU for 2h and show an ability to take fluids. In a recent study to determine the factors that may delay discharge in children undergoing tonsillectomies, it was found that PONV and oxygen desaturation were the two major factors contributing to prolonged length of stay (LOS) [29]. The authors noted that the overall risk of prolonged LOS decreased with increasing age. Interestingly, LOS was not affected by the presence of an upper respiratory tract infection (URTI), leading the authors to suggest that patients with a URTI could be eligible for day case surgery.

Finally, handover of care for inpatients being discharged from the PACU to the floor or ICU needs to be as rigorous as with arrival. Full handover should include not only the intraoperative report but also the medications given and any PACU issues or special instructions. Prior to the final handover of the child to the accepting team, it should be confirmed that the intravenous infusions are placed on mechanized infusion pumps rather than free-flowing drips, a final examination of wound sites should be done, and an appropriate escort (nurse or doctor) who can give an accurate report to the accepting team needs to accompany the child for transport.

# Potential postanesthesia problems and complications

## Respiratory

Children are more likely to have airway-related problems rather than cardiovascular problems in the immediate postoperative period. Next to episodes of nausea and vomiting, the most frequent complications in the PACU are those that require airway support [30]. Maintenance of the airway following general anesthesia and sedation presents challenges due to the negative factors that occur during the perioperative period. Not only are the children still under the sedative influences of the anesthesia, but there are also risks of inadequate reversal of neuromuscular blockade, as well as diffusion hypoxia and the consequences of additional analgesic medications being administered in the PACU that can result in additional altered respiratory drive. The normal anatomy of a neonate or infant can render the airway vulnerable, and when side-effects of surgery are added, particularly surgery involving the airway, it is clear that a specialist's care and attention to detail may be required.

Although tracheal extubation occurs in the operating room in the vast majority of pediatric anesthesia programs and cases, the benefits and risks of extubation while deeply anesthetized versus "awake" continue to be debated [31]. The patient whose trachea has been extubated while deeply anesthetized will often be at increased risk of airway obstruction from airway muscle laxity, or emerging from anesthesia with increased risk for laryngospasm, during the early period after admission to the PACU, and so extra vigilance is required in this situation. In a minority of pediatric anesthesia programs, the patient is taken to the PACU with the endotracheal tube in place, in order to increase operating room efficiency. The trachea is extubated on the physician's order by protocol so that the PACU nurse can perform the extubation when criteria are met [7].

Hypoxemia is not uncommon in the pediatric patient who is recovering from anesthesia and surgery. In addition to mechanical issues that involve the airway, there are other intrinsic pulmonary events that lead to hypoxemia. The combination of higher oxygen consumption in the presence of a relatively reduced functional residual capacity and higher closing capacity puts the younger child at greater risk of oxygen desaturation. For all these reasons, postoperative patients should receive supplemental oxygen either by mask or by blow-by devices, and children are no exception. Children can be reluctant to accept any device to provide oxygen, but purposeful removal of the mask or blow-by device is often a good sign that it is no longer required. As oxygen is being delivered, the basics of airway support must still continue to be employed, including ensuring the airway is patent, there are clear breath sounds on auscultation with good chest excursion, no signs of respiratory distress (stridor, nasal flaring), no wheezing and a normal respiratory pattern devoid of apneic episodes.

A child may be best managed by placing them in the lateral recovery position and employing jaw thrust and mouth opening when airway obstruction is evident. Compared to the supine position, the lateral position will increase total airway volume by 45% in children who have been sedated for MRI, with the greatest change seen in the region between the epiglottis and vocal cords [32]. One must remember that neonates are obligate nasal breathers and the occlusion of the nares with assorted tubing or incorrect mask placement can lead to a compromised airway.

## **Residual neuromuscular blockade**

Residual neuromuscular blockade has significant clinical implications for the patient in the PACU. These implications are due to changes in pharyngeal function with increased risk of aspiration, airway muscle weakness that can lead to airway obstruction, and attenuation of the hypoxic ventilatory response. In adults, there is evidence that up to 40% of patients exhibit a train of four ratio of <0.9 in the recovery area [33,34]. Although evidence would suggest that children have a more complete response to neuromuscular reversal and respond to lower doses of neostigmine significantly better than adults, the complications that can result from incomplete reversal can be devastating in a very young child [35,36]. When a child is admitted to the recovery area and exhibits the typical signs of incomplete reversal such as weakness or floppiness with the "fish out of water" appearance, this must be considered a cause and treated promptly before respiratory decompensation ensues. Administering additional neuromuscular blocking reversal is not necessarily the treatment of choice and should only be used if the maximum dose of neostigmine (0.07 mg/kg) has not already been administered as that dose should not be exceeded. Larger doses of neostigmine will lead to further muscular weakness and possible cholinergic crisis. Instead, care should be supportive, including reintubation if respiratory compromise is significant. The patient may then be sedated and ventilated until the neuromuscular blockade has subsided and extubation criteria are met.

#### Postextubation stridor or croup

One complication that is typically not seen until the PACU course is postextubation stridor (also known as postintubation croup). In 1977, the incidence of postextubation croup after anesthesia was reported at 1.6–6% [37]. Although these data are old, there is little evidence that the incidence has changed despite trends towards the use of cuffed endotracheal tubes. An editorial on the subject outlined the changes that have occurred over the last several decades based on recent literature, and how these changes have supported the use of cuffed endotracheal tubes in children [38]. It remains unclear what the overall outcome will be with changes in practice, and whether

eventually there will be a significant difference in the incidence of stridor in the PACU based on preference of endotracheal tube.

Postextubation stridor often may not need immediate treatment beyond humidified oxygen. However, if there are any sign of respiratory distress, nebulized racemic epinephrine (0.5mL of 2.25% solution in 3mL normal saline, for children over 6 months of age, 0.25 mL if less than 6 months) provides a rapid response. The mechanism of action of racemic epinephrine is through its stimulation of  $\alpha$ -receptors resulting in vasoconstriction and secondary reduction in mucosal and submucosal edema. Due to the rebound effect of racemic epinephrine that may occur up until 2h after administration, a child must remain in the PACU or in a monitored setting until this risk is no longer present as readministration may be necessary. Although it may take at least an hour to see results, a single dose of dexamethasone (0.15–0.6 mg/kg) can be administered for reduction of airway edema and the duration significantly outlasts racemic epinephrine with a half-life of over 30h [39-41]. Despite the long half-life, dexamethasone dosing should be repeated every 6-12h until resolution. In cases of significant respiratory distress, the child should be admitted to a monitored setting where heliox (60-80% helium:20-40% oxygen mixture) can be delivered [42]. Although heliox has no antiinflammatory or bronchodilatory properties, its low density allows improved oxygen delivery and carbon dioxide elimination. In extreme cases, reintubation with an endotracheal tube at least 0.5–1 mm smaller than the original tube may be needed.

#### Laryngospasm

Laryngospasm, an event typically associated with intraoperative care, remains a potential complication in the PACU. Laryngospasm may occur due to irritation of the vocal cords, commonly from either saliva or blood, or simply from the child still being at risk while emerging from anesthesia with stage II being exhibited. Laryngospasm is the forceful closure of the vocal cords, resulting in total obstruction of the airway, and if untreated can be catastrophic. The first step must be the administration of oxygen by positive pressure mask with jaw thrust. In addition to simple jaw thrust, pressure applied to the "laryngospasm notch," located behind the lobule of the pinna of each ear, is anecdotally effective [43]. If the patient exhibits full airway obstruction without evidence of air movement, or if significant desaturations or bradycardia occur, succinylcholine is to be administered (or another rapid-acting muscle relaxant if succinylcholine is contraindicated). When laryngospasm occurs in the PACU, intubation is typically not necessary, and all that is needed for relaxation of the vocal cords is a small dose of intravenous succinylcholine (0.1-0.5 mg/kg). Small

doses of propofol have also been reported for the treatment of laryngospasm in children [44]. The child will require bag/mask ventilation until good spontaneous respirations are restored. Atropine should be available in case either the succinylcholine or episode of hypoxia during the laryngospasm causes bradycardia.

#### Apnea

Although apnea may occur for many reasons in the PACU, apnea in the ex-premature infant requires careful consideration preoperatively during the work-up to guarantee that the appropriate postoperative destination is secured. With better survival of prematurely born infants, an increasing number of these patients appear on the operating schedule and so require care in the PACU. Typically, if the child is still in the intensive care nursery, then postoperative care will continue on the neonatal intensive care unit. However, if the child is on the ward or is an outpatient, individual consideration for the unique pathophysiology of a premature infant must be made to determine the postoperative disposition and level of monitoring.

Apnea is defined as a cessation of airflow for more than 20 sec, or the cessation of breathing for less than 20 sec if it is accompanied by bradycardia or oxygen ( $O_2$ ) desaturation [45]. The frequency is inversely related to gestational age and the actual cause of apnea of prematurity is unknown, although it is likely to be multifactorial [46]. Depression or immaturity of the respiratory central generator located in the brainstem is most likely in addition to vulnerability to inhibitory influences such as hypoxia and temperature changes [47].

Beyond considerations that exist for infants with apnea of prematurity, the presence of obstructive sleep apnea (OSA) in any child presents significant risk in the postoperative period and is responsible for considerable morbidity, with a complication rate of up to 27% [48]. In fact, in 60% of children with severe OSA, nursing intervention in the postoperative period was required to treat complications that included desaturation to SpO<sub>2</sub> <90% [49]. The children also demonstrated signs of increased work of breathing and/or new radiographic findings of pulmonary edema, effusion, infiltrate, pneumothorax or pneumomediastinum.

Because of the potential complications that exist in this population, the American Society of Anesthesiologists in 2006 published practice guidelines for perioperative management that suggested that children with a history of OSA having adenotonsillectomy should be admitted for overnight stay if they are less than 3 years of age or if they have contributing medical conditions such as obesity [50]. If an otherwise well child greater than 3 years of age has mild-to-moderate OSA with an apnea-hypopnea index <10, same-day discharge may be considered. If the decision is made to discharge the child the same day as the procedure, it is best if the case is performed earlier in the day after a minimum PACU stay of 2h [51].

Due to the chronic hypoxemia exhibited by children with OSA and its effects on respiratory drive, it is important to be cautious when ordering pain medication postoperatively. Children with a history of OSA have a higher incidence of apnea after administration of a typical  $0.5 \mu g/kg$  dose of fentanyl when compared to children without OSA [52]. As a reference, children with sleep apnea who demonstrated an oxygen saturation <85% on polysomnography require only half the morphine dose to have the same analgesic effect as a child who did not have the same degree of desaturation [53].

When an infant or child is showing signs of OSA in the PACU, immediate maneuvers to stimulate the patient and open the airway are to be performed. These maneuvers include repositioning with a shoulder roll or to lateral position, performance of jaw thrust or insertion of a nasal or oral airway, and occasionally the administration of positive pressure by mask. If these measures are unsuccessful, the child may require tracheal intubation until they are fully recovered and able to maintain their own airway. In addition, the child who requires nasal continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP) by mask at home during sleep may benefit from its application in the PACU.

## **Pulmonary edema**

Pulmonary edema is rarely seen in children, but must be considered as a cause in the postoperative differential diagnosis of hypoxemia with desaturations in the PACU. Causes of pulmonary edema may be related simply to the delivery of a large volume of fluid or blood products in the operating room with or without significant fluid shifts, or to negative pressure pulmonary edema (NPPE). Clinical presentation is the same between these, but history will help delineate the cause. A history of forceful respirations against a closed airway such as laryngospasm, biting on the endotracheal tube or even longstanding history of upper airway obstruction from enlarged tonsils or epiglottis that has now been relieved with surgery, can lead to NPPE. The pathogenesis of NPPE from negative intrathoracic pressure causes decreased pulmonary capillary perivascular pressure, favoring hydrostatic transudation of fluid into the interstitial tissue. Although normal pleural inspiratory pressures are -2 to  $-5 \text{ cmH}_2\text{O}$ , negative pressures from -50 to -100 cmH<sub>2</sub>O are possible, particularly with young muscular males [54]. After the obstruction is relieved, there is a sudden increase in venous return and a redistribution of blood volume from peripheral to central circulation with a resulting increase in pulmonary hydrostatic pressure that is compounded by capillary leak.

In any of these scenarios, if significant pulmonary edema is present, the child will exhibit lower pulse oximetry readings, tachycardia, and tachypnea. Rales will be heard on chest auscultation and occasionally the child may exhibit pink frothy sputum. If otherwise stable and saturations are kept within normal range with supplemental oxygen, this may be all that is required. However, depending on the degree of pulmonary edema and respiratory distress, intubation with delivery of positive endexpiratory pressure (PEEP) may be necessary along with diuresis (furosemide 0.1 mg/kg with a maximum of 5 mg) to assist with the shift of fluid out of the lungs. In the case of NPPE, the use of PEEP is supported, but whether the delivery of diuretics is of benefit remains unclear [55].

## **Pulmonary aspiration**

The risk of pulmonary aspiration in the perioperative period in children is low at approximately 0.1%, but it is not negligible and is at least two times higher than the risk in adults [56]. Particularly after airway surgery, the increased amount of secretions and blood puts the child at risk for aspirating these fluids during recovery from the sedative effects of anesthesia or pain medications. If aspiration is suspected, examination of the lungs may help to determine the diagnosis if significant rhonchi or coarse breath sounds are heard unilaterally, particularly on the right side. Treatment is supportive as sequelae are typically mild, although incidence and severity may correlate with the underlying medical condition of the child [56]. Pharmacological intervention with steroids or antibiotics for presumed aspiration is unwarranted.

#### Pneumothorax

Another cause of hypoxemia in the PACU is pneumothorax. Many surgical procedures, such as central line placement, ventriculoperitoneal shunts and any thoracic procedure, put the child at risk for intraoperative pneumothorax that may not manifest until the postoperative period. A thorough exam and chest radiograph will help determine the diagnosis. If the pneumothorax is significant and causing respiratory compromise, a chest tube will need to be inserted and the child sent to the appropriate postoperative setting. Lesser degrees of pneumothorax may be treated with 100% oxygen by non-rebreathing facemask, to hasten resolution by displacing nitrogen and allowing for faster resorption of the pneumothorax.

# **Cardiovascular factors**

Although respiratory complications far outweigh hemodynamic issues in the typical recovering pediatric patient, children can decompensate rapidly and cardiovascular depression is a late and ominous sign.

## **Hypotension**

Hypotension in the PACU, particularly in the presence of tachycardia, narrow pulse pressure, poor capillary refill (>3 sec) and low urine output (<0.5 mL/kg/h), is typically the result of hypovolemia. Depending on the nature of the procedure, the cause of the hypovolemia needs to be quickly determined in order to know whether to administer fluid or blood products. Attention to any blood accumulation in surgical drains allows for a rapid assessment. Isotoninc crystalloid fluid boluses (normal saline, lactated Ringer's solution or Plasmalyte®) should be administered in 5–10 mL/kg increments, depending on the degree of hypotension and ongoing losses with critical assessment in changes in blood pressure and heart rate in response to the fluid challenge. If there is any question as to the nature of the hypotension, blood should be drawn to check the acid-base status and base deficit as well as hemoglobin and/or hematocrit. If replacing blood loss, 10-15mL/kg of packed red blood cells will raise the hemoglobin by 2-3g/dL if no ongoing blood loss is occurring.

Other causes of hypotension that would be extremely uncommon in the PACU would be anaphylaxis from either latex exposure or delivery of postoperative drug, early signs of perioperative sepsis, or mechanical reasons such as pneumothorax or pericardial tamponade. Sympathetic block from central neuraxial anesthesia typically does not exist in a child below the age of 5 years due to lack of a significant peripheral vasodilation or venous pooling, and rarely would cause hypotension in a child older than 5 years with the typical low concentrations of local anesthetic that are used for postoperative infusions.

#### Hypertension

The presentation of hypertension in the postoperative period is typically the consequence of pain and is therefore usually associated with tachycardia and other outward signs of discomfort. If pain is suspected, appropriate treatment is necessary to alleviate the physiological responses in a rapid, safe manner. If not due to pain, the most common cause of hypertension may actually be the result of inaccurate readings due to a small blood pressure cuff, so this cause must be ruled out early on. Hypertension is rarely due to volume overload but some children are more susceptible than others to excessive intraoperative volume resuscitation, so the possibility does exist. Hypertension may also be the result of emergence agitation or bladder distension or, in patients with renal failure, rebound hypertension can occur because they are not taking their regular antihypertensive agent due to NPO status. In a child with moderate-to-severe hypertension in the PACU that is not attributable to pain, treatment may consist of intravenous agents such as

hydralazine (0.25–0.5 mg/kg), labetalol (0.2 mg/kg), nitroprusside infusion (1–10 $\mu$ g/kg/min) or nicardipine infusion (0.5–5 $\mu$ g/kg/min). Close hemodynamic monitoring needs to occur if delivering any of these agents.

## Tachycardia

Tachycardia is very non-specific in the PACU. As previously mentioned, when accompanied by hypotension, the combination suggests hypovolemia that needs to be promptly managed. Tachycardia and hypertension together suggest pain, anxiety or both. Tachycardia can also be secondary to drugs administered in the operating room such as atropine or glycopyrrolate and when no other factors are present, these causes should be considered and no further treatment is necessary. Rarely, tachycardia may be due to an underlying conduction abnormality, particularly in a child with a cardiac history, and these children will require a cardiology consult and/ or admission to the ward to determine the significance. If an arrhythmia, i.e. supraventricular tachycardia, is suspected, it is crucial to record the abnormal rhythm, either by printout or electronically with as many leads as possible, and to record a standard 12-lead ECG, so that the consultant physicians will have adequate information.

# Bradycardia

Bradycardia is often a more ominous sign than tachycardia and is often consequent to hypoxia. Indeed, the heart rate of a preterm infant will begin to fall within 30 sec of onset of apnea [57]. Therefore attention should be directed toward airway management and ensuring adequate oxygenation in the face of sudden, unexpected bradycardia. Having corrected hypoxia as a cause of bradycardia, other causes such as increased intracranial pressure or simple vagal response to airway maneuvers can be entertained. If bradycardia persists and is accompanied by low cardiac output or hypotension, atropine (0.02 mg/kg) should be administered. If unsuccessful and the patient remains in a low-output state, resuscitation efforts should then proceed with intravenous epinephrine and standard cardiopulmonary resuscitation (CPR) per pediatric advanced life support (PALS) protocol.

Other than tachy- or bradyarrhythmias, other arrhythmias are extremely rare in the PACU. With the reduction in the use of arrhythmogenic inhalational agents such as halothane, nodal or junctional arrhythmias are less frequent. However, a greater number of patients with congenital heart disease are surviving and requiring surgeries unrelated to the heart. These patients may have underlying defects in their conduction pathways that may become obvious in the PACU. A rhythm strip should be run in any child who has an unexpected change in heart rate to help determine any cardiac etiologies, and a cardiologist should be consulted prior to discharge from the PACU, if concern remains about significant cardiac pathology as a cause of the arrhythmia. Additionally, any hemodynamically significant arrhythmia requires basic resuscitation protocol.

# Hypothermia and hyperthermia

# Hypothermia

Hypothermia is defined as a core temperature of less than 36°C [58]. It is well documented that children lose heat more readily than their adult counterparts and anesthesia can further disrupt the patient's ability to thermoregulate [59]. Neonates and infants are at particular risk of developing hypothermia even during transport from the OR to the PACU. A working group established by the American Society of Anesthesiologists (ASA)/Physician Consortium for Performance Improvement noted that anestheticinduced impairment of thermoregulatory control is the primary cause of perioperative hypothermia [60]. Even mild hypothermia (1-2°C below normal) has been associated in randomized trials with a number of adverse consequences, including increased susceptibility to infection, impaired coagulation and increased transfusion requirements, cardiovascular stress and cardiac complications, and postanesthetic shivering and thermal discomfort [61]. In addition, neonates are at risk of apnea and bradycardia when hypothermic.

Beyond the physiological issues, hypothermia also has an impact on efficiency of a PACU and is associated with an increased length of stay which has logistical and financial implications for a successful surgical unit [61].

It is therefore not surprising that perioperative temperature management is one of the five quality incentives established by the ASA as the Pay-for-Performance and Anesthesiology Quality Incentive [60]. The goal is to have measured at least one body temperature that is equal to or greater than 36°C (or 96.8°F) within the 30 min immediately before or the 30 min immediately after anesthesia end time, with some exceptions.

Temperature is to be measured as part of the initial assessment upon a child's arrival in the PACU. Measurements from different sites may not correlate particularly well because of compensatory mechanisms such as vasoconstriction that can change the relationship between the central and peripheral temperature. Core temperature must be estimated from peripheral sites and taken rectally, axillary, orally or via tympanic membrane. All of these sites have issues related to reliability, accuracy and flaws in measurement technique. Axillary temperatures in neonates and infants do correlate well with rectal temperature and thus remain the preferred method in many PACUs [62,63].

Acknowledging the importance of avoiding hypothermia has lead to the practice of prewarming of patients in the operating room [64,65]. When this has not occurred and the patient arrives hypothermic to the PACU, a number of measures are often employed. Simple and standard measures such as fluid warmers, warm blankets and infrared heat lamps are first line but may not be completely effective in treating hypothermia [66]. Only active warming devices such as convection or forced air warming devices have consistently been proven effective at treating hypothermia and are therefore recommended by the ASA for these circumstances [67].

## Hyperthermia

Hyperthermia in the PACU is a very different entity. The typical cause of hyperthermia would be aggressive warming in the operating room. Although extremely rare, one must still have a high index of suspicion for a late presentation of malignant hyperthermia (MH) in a hyper-thermic child, particularly if any other associated signs are present such as muscle rigidity, hyperventilation, and tachycardia. Aggressive diagnosis and treatment (see Chapter 40) should then ensue if a true case is suspected.

A more common concern would be how to recover the patient who may be MH susceptible but who has received a non-triggering anesthetic. Despite the seriousness of an episode of MH, it is reasonable for a patient who is at risk for MH to be admitted to the PACU and still be able to be discharged the same day as the procedure when they have not been exposed to potent inhaled anesthetics or succinylcholine [68]. In fact, there is no advantage to keeping a patient who is MH susceptible in the PACU for a prolonged period of time if there are no other complicating factors [69]. Based on a review of over 250 MH-susceptible patients, and per the Malignant Hyperthermia Association of the United States (MHAUS) website, a 1h stay in the primary PACU with an additional 1–1.5h in a step-down PACU, if indicated, is recommended [70].

# **Emergence agitation or delirium**

It is not uncommon for children to emerge from anesthesia disoriented and frightened, resulting in negative behavior of restlessness, anxiety and inconsolability. As part of the assessment of this behavior, careful consideration must be given to an organic cause must be made. For example, hypoxemia, hypercarbia, hypotension, hypoglycemia, raised intracranial pressure or untreated pain should all be ruled out. Only after this has occurred can the phenomenon of emergence delirium (ED), also referred to as emergence agitation (EA), be considered. In the modern era of the pediatric PACU, the issue of emergence delirium has become a popular topic of discussion. For example, a well-referenced analysis of perioperative morbidity published in 2004 failed to include ED as an adverse event as it seemingly was not considered a major issue at that time [1]. Defined as "a disturbance in a child's awareness of and attention to his/her environment with disorientation and perceptual alterations including hypersensitivity to stimuli and hyperactive motor behavior in the immediate postanesthesia period," ED can be stressful for the child, parents and caretakers [71].

There is a range of behavioral responses following anesthesia, from crying uncontrollably after emergence for more than 3min (mild) to uncontrollable behavior requiring physical restraint for more than 3min (major) [71]. With such a range of presentation, it is difficult to describe a precise incidence of ED as it may be as high as 80%, depending on how it is defined. The spectrum of clinical presentation has therefore lead to the creation of behavioral scales such as the Pediatric Anesthesia Emergence Delirium (PAED) scale (Table 16.3). When tested in 50 children for validity, the PAED scale revealed consistency and reliability [71].

The issue of emergence agitation/delirium was not truly evident until the practice of using sevoflurane started replacing the use of halothane. This suspicion that sevoflurane resulted in more frequent episodes of emergence delirium was reviewed in a meta-analysis which confirmed that sevoflurane was associated with a consistently higher incidence of agitation when compared to halothane [72]. In fact, ED is associated with both of the newer inhalational agents, desflurane and sevoflurane [73,74]. Because desflurane and sevoflurane have a greater incidence of emergence delirium compared to isoflurane

Table 16.3 Pediatric Anesthesia Emergence Delirium Scale (PAED)

Category	Score 4	Score 3	Score 2	Score 1	Score 0
Child makes eye contact	Not at all	Just a little	Quite a bit	Very much	Extremely
Child's actions are purposeful	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is aware of surroundings	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is restless	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is inconsolable	Extremely	Very much	Quite a bit	Just a little	Not at all

or halothane, this results in the possible conundrum of the supposed benefit of shorter acting agents in promoting a quicker recovery and shorter discharge times possibly being negated by the increased incidence of ED from a rapid emergence. This concern was demonstrated to be valid in a study comparing recovery and discharge criteria between halothane and sevoflurane in children undergoing myringotomy tube placement. Emergence agitation was significantly higher in the sevoflurane group versus halothane group (57% versus 27%, respectively), and discharge times were similarly prolonged with the sevoflurane group [75].

However, it is simply not the fact that rapid emergence is responsible for ED. Delayed emergence by gradually decreasing the inhaled agent has no effect on the incidence of ED [76] and comparative anesthetics that offer quick emergence, such as propofol, still demonstrate that inhaled agents are associated with a greater incidence of ED [77]. This was shown in a randomized cross-over study where propofol was noted to have a zero prevalence of ED compared to sevoflurane as a maintenance agent [78]. The propofol group did have a longer recovery stay, but the parental satisfaction was higher with the propofol group than with the sevoflurane group.

In order to prevent emergence agitation or delirium, it is important to know the factors that predict its occurrence. First, ED may be associated with the type of surgery. An increased incidence is found after otorhinolaryngological and ophthalmological surgeries, at 26% and 28% respectively, when compared to other types of procedures [79]. In addition, there are patient factors that predict postoperative ED such as age less than 5 years, increased preoperative anxiety, and a temperament that is more emotional, more impulsive, less social, and less adaptable [80]. Clearly, these factors cannot necessarily be controlled preoperatively. There are also anesthesia factors, over and above what agent is used to induce and maintain anesthesia. For example, the smoothness of the induction is a predictor of emergence. Weldon et al studied 80 children less than 6 years of age receiving either sevoflurane or halothane [81]. All the children were premedicated with midazolam and received caudal regional anesthesia after their inhaled induction so that postoperative pain would not be a factor in their EA. Although the study was designed to compare the inhaled agents, and showed that children who received sevoflurane had a significantly higher incidence of EA than halothane at arrival to PACU (26% vs 6%), it also showed that the incidence of emergence agitation was higher in the children who had increased anxiety preoperatively per the Yale Preoperative Anxiety Scale [82,83]. In addition to an increased incidence of agitation on admission and more episodes of severe agitation, these same children also had a greater incidence of difficult mask inductions.

Early thoughts as to the cause of emergence delirium/ agitation included the presence of pain. Although pain may be a contributing factor to an unsatisfactory emergence period, it has not been shown to be the cause of ED. In fact, ED has been shown to have a similar incidence after non-painful procedures such as MRI [75]. In children who have undergone sevoflurane anesthesia without surgical intervention, a small dose of fentanyl at  $1\mu g/kg$ 10min prior to emergence reduced emergence agitation from 56% to 12% with no increase in time to discharge [83]. Studies using caudal block in order to take the pain issue out of the equation of postoperative ED have shown inconsistent results as to the effectiveness of regional anesthesia in addition to sevoflurane for avoidance of agitation [81,84].

In addition to avoiding the agents that are commonly associated with emergence delirium such as sevoflurane and desflurane, other agents have been studied to determine if using them prophylactically will reduce the incidence of ED. In a recent meta-analysis, midazolam and 5-hydroxytryptamine-3 receptor (5HT3) inhibitors such as ondansetron were not found to have a protective effect against ED, whereas propofol, ketamine, fentanyl and  $\alpha$ 2-adrenoceptor agonists were all found to have a preventive effect [85].

The  $\alpha$ 2-adrenoceptor agonists are an emerging group of drugs used in the management of postoperative agitation. Clonidine causes sedation, analgesia and reduction in sympathetic tone and can be administered through many routes. An intravenous dose of 2µg/kg after anesthetic induction has been demonstrated to significantly reduce the incidence and severity of emergence agitation in boys undergoing circumcision with penile blocks under sevoflurane anesthesia [86]. This efficacy in the management of ED with clonidine has not been consistent at a dose of  $1.5 \mu g/kg$  when compared to the more efficacious tropisetron [87]. Dexmedetomidine, another α2agonist, has both prophylactic and treatment potential for ED. When using dexmedetomidine as a single bolus dose immediately after inhalation induction, the incidence of emergence agitation in children who received sevoflurane with caudal block was significantly lower in a dosedependent manner. The incidence of agitation in the group who did not receive dexmedetomidine was 37% whereas the group receiving  $0.15 \mu g/kg$  had an incidence of EA at 17% and a group who received 0.3µg/kg was 10% with no differences in time to discharge. Alternatively, infusion of dexmedetomidine at a rate of 0.2µg/kg/h infusion after induction and continuing 15 min into PACU is effective in reducing the incidence of ED [88,89]. The incidence of emergence agitation in the children who received dexmedetomidine infusion was 26% compared to 60.8% in the sevoflurane group with no differences in time to extubation or discharge from PACU.

In addition to the expected preventive measures and agents, melatonin, a hormone secreted by the pineal gland, when administered preoperatively has been demonstrated to be efficacious in the management of ED in a dose-dependent manner of up to 0.4 mg/kg (maximum 20 mg) when compared to midazolam [90]. Although doses of melatonin at 0.05 mg/kg and 0.2 mg/ kg decreased ED, a dose of 0.4 mg/kg was the most efficacious and reduced the incidence of emergence delirium to 5.4%.

Beyond pharmacological intervention, parental presence has been evaluated in terms of its effect on emergence delirium. Although there was no measurable improvement on the incidence or duration of ED, the parents themselves had greater satisfaction with being present during the recovery phase [91].

Emergence agitation continues to be addressed, and additional work needs to be done to determine not only how to prevent its occurrence, but to improve the process by which it is diagnosed and treated when it occurs. These goals are necessary in order to make an otherwise uneventful perioperative course more pleasant for the child, family, and providers.

# Seizures and myoclonus

Postoperative seizures are an uncommon event in the PACU but can be indicative of a more serious underlying problem. Regardless of the etiology of the seizure, supportive measures should be immediate and include the delivery of oxygen with airway maintenance and special efforts to avoid self-harm in the child. Depending on the severity and duration of the seizure, oxygen may be delivered by facemask or positive pressure ventilation, or require endotracheal intubation. A physician should be in attendance and determine the need for immediate pharmacological intervention, also depending on the severity or duration of the epileptic activity.

Causes of postoperative seizures are numerous, with significant consequences. Hypoxemia may be rapidly ruled in or out and treated as necessary with appropriate oxygenation and ventilation. If this is clearly not the cause, state laboratory tests should be obtained to rule out hypoglycemia and electrolyte disturbances such as hyponatremia and hypocalcemia must be sent, then rapidly interpreted and treated. A rare but potentially fatal cause of postoperative seizures is local anesthetic toxicity and the seizures may actually be a prelude to cardiovascular collapse. A thorough history of local anesthetic delivery should be assessed that includes last dose and total dosing if there is any suspicion of local anesthetic toxicity. If this is determined to be the cause, in addition to supportive measures, intravenous lipid emulsion should be delivered if cardiovascular arrest ensues [92]. PACU providers should be made aware of this possibility and be informed as to the location and delivery of lipid emulsion. See Chapter 40 for further discussion of this problem.

Beyond seizure activity, myoclonus may be observed in the PACU. Myoclonus is defined as the involuntary contraction of a muscle or muscle groups and has a variety of causes, including some anesthetic agents such as etomidate or as a prodrome to seizure activity. After other causes of myoclonus are ruled out, the possibility of central anticholinergic syndrome (CAS) should be entertained. CAS is secondary to the central antagonism of muscarinic cholingeric receptors and may be caused by medications that cross the blood–brain barrier, such as atropine or scopolamine [93]. The symptoms vary from agitation to actual coma, with myoclonus as a presenting sign. Slow delivery of physostigmine  $(10–30\,\mu g/kg$  with maximum of 3 mg) is the treatment of choice.

# Pain

Pain management does not begin in the PACU, but needs to be managed for the entire perioperative period and is the responsibility of every anesthesiologist. In the PACU, the recognition of postoperative pain becomes the duty of a recovery nurse as intraoperative analgesic medications wear off and the pain becomes more intense as the patient recovers. Although a complete discussion of pain is beyond the scope of this chapter and is presented elsewhere in this book (see Chapter 33), in the PACU environment it is important to consider how to assess the pain, what analgesics are appropriate, and what potential pitfalls and complications exist.

The assessment of pain in children remains a challenge in part because of the diversity of age range. No single assessment tool or score can possibly be applied equally to the newborn and the adolescent. Although of little benefit to children who are pre- and non-verbal, developmentally delayed or cognitively impaired, self-reporting is probably the most important single reliable indicator of pain. Children as young as 3 years of age can reliably score their own pain [94] provided that they are trained to use the chosen score prior to surgery. There are many validated pain intensity scales including visual analogs, faces scales, and numeric ratings, which are presented elsewhere. The OUCHER score utilizes photographs of a child's face exhibiting varying expressions of pain intensity alongside a numerical rating scale and allows the young child to self-report. Different ethnic versions are available and it has been validated in the 3-12-yearold age group, specifically in the PACU setting [95] (Fig. 16.4).

**Figure 16.4** OUCHER pediatric pain scale for children age 3–12 years. (A) African-American version. (B) Hispanic version. Reproduced from Beyer and Knott [95] with permission from Elsevier.

Categories Scoring 0 1 2 No Face Occasional Frequent to particular grimace of frown, constant expression withdrawn, quivering chin, or smile disinterested clenched jaw Uneasy, restless, Kicking, or legs Legs Normal position or tense drawn up relaxed Arched, rigid or Activity Lying Squirming, quietly, shifting back and jerking normal forth, tense position, moves easily Cry No cry Moans or Crying steadily, (awake or whimpers; screams or asleep) occasional sobs, frequent complaints complaint Consolability Difficult to Content, Reassured by relaxed occasional console or touching, hugging comfort or being talked to, distractable

Each of the five categories (F) Face: (L) Legs; (A) Activity; (C) Cry; (C) Consolability is scored from 0-2, which results in a total score between zero and ten. Reproduced from Willis [97] with permission from Jannetti Publications.

In those children unable to provide a self report (age 3 years or less, or developmentally delayed), behavioral observational scales assist the caregiver in determining a level or degree of pain. The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) [96], the Face, Leg, Activity, Cry, Consolability Scale (FLACC) [97] (Table 16.4) and Preverbal, Early Verbal Pediatric Pain Scale (PEVPPS)[98] are all valuable tools but limited in that behavior varies significantly between individuals. These scales are not perfect as a paucity of abnormal behavior does not mean an absence of pain, and negative behavior does not necessarily indicate pain.

Finally, physiological signs, such as tachycardia, tachypnea, and hypertension, can be used as an indicator of pain but are the least sensitive and least specific markers [99]. Particularly in a child, these physiological signs can be present due to other stresses including anxiety or fearfulness, and need to be combined with other evidence that suggests pain as a cause. With all the different types of scales available, each institution needs to determine the ones that work best for their environment for the different age groups and keep it consistent for reliability across providers.

In the clinical setting, proving the existence of pain through a validated pain score is less important than actually understanding the potential degree of pain with knowledge of the surgery and actively managing symptoms and signs of distress. The PACU nursing staff have many pain management strategies available to them, both pharmacological and non-pharmacological, to ease pain and distress postoperatively [100]. Multimodal approaches are often the most effective and take advantage of nonopioid and opioid agents as well as other measures for comprehensive pain management.

Non-opioid pharmacological agents offer pain relief without some of the unfavorable side-effects such as nausea and vomiting and respiratory depression, and are therefore useful adjuncts to the postoperative pain management plan. Simple analgesics that require oral administration such as *acetaminophen* require patient

 Table 16.4
 Faces, Legs, Activity, Cry, Consolability (FLACC) Scale [97]

co-operation and the absence of nausea and vomiting. Its mode of action is predominantly central by modulating dynorphin release through inhibition of cyclo-oxygenase (COX) [101] and recent findings suggest that it is highly selective for COX-2 [102]. Oral dosing is 10-15 mg/kg. Rectal administration of acetaminophen at 30-40 mg/kg is associated with a delayed (between 1 and 3 h) and varied uptake but offers an alternative route of administration in a child who must remain NPO or an unco-operative or nauseated child [103]. Daily cumulative dosing should be carefully monitored with previously administered doses and prescribed dosing clearly stated during handovers. Although oral dosing may be prescribed every 4h, rectal dosing requires an every 6h dosing scheme due to the delayed and unpredictable absorption. Maximum oral daily dosing limits are 100 mg/kg per day for children, 75 mg/kg for infants, 60 mg/kg for term and preterm neonates beyond 32 weeks of postconceptual age, and 40 mg/kg for preterm neonates from 28 to 32 weeks postconceptual age [104]. Injectable or intravenous acetaminophen (paracetamol) is now available in many countries and is undergoing clinical trials in children for perioperative use. In a prospective, placebo-controlled, doubleblind study versus its older prodrug, proparacetamol, in 183 patients aged 1-12 years undergoing inguinal hernia repair, IV paracetamol was as effective as the older drug at relieving pain, with less injection site pain [105].

Other non-opioid agents such as the non-steroidal antiinflammatory drugs (NSAIDs) can be delivered orally or intravenously. *Ibuprofen* at 10 mg/kg is given orally every 6h and can be alternated with acetaminophen throughout the postoperative period. Another NSAID option is intravenous ketorolac at 0.2–0.5 mg/kg every 6h with a single maximum dose of 15 mg and a maximum daily dosage of 90 mg [106]. Little difference in efficacy has been noted between the NSAIDs, and the mode of action is again by COX inhibition, similar to acetaminophen but predominantly peripherally in this case [107]. NSAIDs are invaluable in the successful management of pain and have been demonstrated to have a significant opioid-sparing effect of up to 46% [108,109]. Although widely used, caution should be exercised in children due to potential sideeffects. Use in neonates and infants is not currently indicated due to the risk to the developing kidneys. There also remains controversial use in children due to the risk of bleeding from platelet dysfunction as well as the question of bone healing for certain orthopedic procedures [110,111]. Aspirin and other salicyclates can cause Reve syndrome in children and are therefore rarely recommended in this population of patients except for specific indications that do not include postoperative pain management [112].

Opioids continue to represent the mainstay of analgesia in the PACU. The popularity of these drugs stems from their efficacy, speed of onset and titratability. When nonopioid agents are ineffective by themselves for pain management, the addition of an opioid analgesic is required. Often fentanyl is the opioid intravenous analgesic of choice for the initial PACU period and for outpatients. Intravenous *fentanyl* 0.5–1.0µg/kg every 3–5min or *morphine* 0.05–0.1 mg/kg every 10–15min have been extensively used and studied, but caution needs to be exercised as these medications have significant adverse potential, especially in children. In particular, neonates are prone to ventilatory depression, having immature and poorly developed responses to airway obstruction, hypercapnia and hypoxemia [113]. *Hydromorphone* at 10µg/kg every 10–15min may also be used for severe pain in the PACU setting.

Although typically administered intravenously, opioids have good bio-availability by other routes. For example, fentanyl can be given intranasally at  $2\mu g/kg$  without an increase in vomiting, hypoxemia or discharge times [114]. Short procedures such as myringotomy, when an intravenous line is not inserted, are ideally suited to this route of administration.

Opioids can also be administered through infusion devices, and patient-controlled analgesia (PCA) can be used for children typically 6 years and older [115]. Background or basal infusions should be used with caution and will require ongoing monitoring not only in the PACU but on the ward [116]. If a child is to receive PCA, it is advantageous to have this mode of analgesia started in the PACU with instructions so that it is fine-tuned and the child's pain is well under control prior to discharge to the ward.

For children who are going home from the recovery room, providing them with an oral dose of their prescribed medication prior to discharge will help the transition process from hospital to home. This allows the family additional time to get prescriptions filled and provides for a more comfortable ride home for the child. Before giving an oral medication, however, it needs to be clear that the child is alert enough to take the medication, able to maintain their own airway easily, and be free of nausea or vomiting prior to discharge. In addition, any oral medication that is made of a combination of the opioid with either acetaminophen or ibuprofen must be started only after the appropriate time interval has passed to keep those agents on an every 4 or every 6h schedule.

Non-pharmacological analgesic remedies may include physical contact through cuddling, stroking, massage, holding and rocking. In addition, newborn infants can often be comforted with concentrated sugar water (24% dextrose 0.1–0.2 mL instilled intraorally or applied to a pacifier), perhaps due to the sucrose's release of endogenous opioids [117]. Older children may require more sophisticated methods using cognitive interventions along the lines of distraction, guided imagery and simple delivery of information. In addition, behavioral interventions such as biofeedback, positive reinforcement and relaxation exercises with controlled breathing can help alleviate pain in the postoperative period.

# Postoperative nausea and vomiting

Postoperative nausea and vomiting (PONV) is a major cause of patient dissatisfaction in adults following anesthesia and surgery. Children have an even higher incidence of postoperative vomiting than adults [118] and nausea, which is difficult to diagnose in younger patients, is most likely under-reported. Effective management is important not simply for the humanitarian aspect but because length of stay (LOS) in the PACU is largely determined by PONV. Each episode of vomiting can result in a 28-min delay in children after adenotonsillectomy [23] and can be a major cause of unanticipated admission after outpatient surgery [119].

In 2003, the consensus guidelines for the management of PONV were developed as an evidence-based tool for clinicians [120]. In 2006, a multidisciplinary panel made further modifications, with attention to children due to their nearly doubled risk of postoperative vomiting (POV). The consensus guidelines focused on risk factors for PONV/POV, recommendations for prophylaxis, and the most effective treatment regimes.

Prophylactic management of pediatric POV typically requires drug intervention that may be costly or associated with unwanted side-effects [121]. It is therefore ideal to target those children at particular risk of POV. Risk factors for children are similar to those for adults, with a few differences. POV is rare under the age of 2 years but it increases with age until puberty, after which it decreases. A study in children under 14 years of age noted a sharp increase in PONV at age 3 years with a 0.2-0.8% increase per year [122]. There appears to be no gender difference in preadolescent patients, and a history of PONV or motion sickness in a child's parent or sibling may be a risk factor. Certain surgical procedures are associated with a higher incidence of POV in children such as adenotonsillectomy, orchidopexy, penile surgery, hernia repair, and especially strabismus repair [123].

The revised PONV consensus guidelines included a simplified risk score to determine the degree of POV risk in children. The degree of risk is based on the number of risk factors that are present from the following: duration of surgery  $\geq$ 30 min; age  $\geq$ 3 years; strabismus surgery; and history of POV or PONV among relatives. Risk of POV is elevated as the number of risk factors increase, with one

risk factor representing a 10% risk and four risk factors representing a 70% risk for POV [122]. Of interest, this risk assessment analysis does not include tonsillectomy (with or without adenoidectomy) as a dominant risk factor for POV, when it is described by many as a significant cause of morbidity [124].

Having determined the children who represent a risk of POV, the next step is to address factors for reducing baseline risks such as promoting the use of propofol for total IV anesthesia (TIVA). Although not yet validated in pediatrics, in adults the avoidance of inhalation agents and use of straight regional techniques is recommended in those patients with a high risk for PONV. This is rarely applicable to children, but the use of regional anesthesia in addition to general anesthesia to minimize opiate requirement may reduce the incidence of pediatric POV [125]. In addition, although considerable hydration has been shown to reduce the frequency of PONV [126], insisting that children drink prior to discharge may actually increase the incidence.

Prophylactic drug therapies can either be monotherapy or a combination of medications. The prophylactic antiemetics recommended for pediatric patients include the 5HT3 antagonists ondansetron, dolasetron, granisetron, and tropisetron. Since the publication of the first guidelines, ondansetron (0.05–0.1 mg/kg up to 4 mg) was approved for use in children as young as 1 month of age and granisetron ( $40 \mu g/kg$ ) and tropisetron (0.1 mg/kg) were added as therapeutic options [127]. Because the 5HT3 antagonists as a group have greater efficacy in the prevention of vomiting than nausea, these drugs are the first-line choice for prophylaxis in children.

Other therapies to prevent POV include dexamethasone (0.15 mg/kg), droperidol (0.05–0.075 mg/kg up to 1.25 mg), dimenhydrinate (0.5 mg/kg), and perphenazine (0.07 mg/kg). The revised guidelines specify a revised upper limit for the dose range of dexamethasone, reduced from 8 mg to 5 mg to address concerns over unwanted side-effects such as hypoglycemia, delayed wound healing and wound infection [128]. The timing of drug administration may also be a key factor in successful prophylaxis. For example, dexamethasone should be administered early in the anesthetic [128], while ondansetron has been shown to be more effective when given preoperatively [127].

The 2006 consensus guidelines recommend that children who are at moderate or high risk for POV should receive combination therapy with two or three prophylactic drugs from different classes. This differs from the recommendations for adults, where combination therapy should be reserved for "high risk" only. The combinations recommended in the revised consensus guidelines for children are ondansetron (0.05 mg/kg) with dexamethasone (0.15 mg/kg), ondansetron (0.1 mg/kg) with droperidol (0.015 mg/kg), or tropisetron (0.1 mg/kg) with dexamethasone (0.5 mg/kg). All of these combinations require intraoperative administration, and the particular drugs, doses and timing need to be conveyed during handover so that any breakthrough PONV/POV may be managed with that knowledge available.

The recommendations for treatment of PONV/POV when it occurs in the PACU, or when prophylaxis fails, include the use of an antiemetic chosen from a different therapeutic class than the agents used for prophylaxis. Droperidol can be used for pediatric patients who have failed all other therapies and are being admitted to hospital, although the potential for extrapyramidal sideeffects exists. The United States Food and Drug Administration issued a "black box" warning on droperidol in 2001 for its association with QT prolongation. However, in the doses prescribed in the United States, the risk of cardiac effects from droperidol is no higher than other available antiemetics, but this possibility may still significantly reduce the willingness of physicians to prescribe it [129].

Non-pharmacological therapies have undergone some investigation in pediatrics. Acupuncture has been successfully used for POV prophylaxis in children undergoing strabismus repair, dental surgery and tonsillectomy [130]. Success using this technique in children has not been consistent [124].

With the options available and the fact that the incidence of POV is undoubtedly higher in children than in adults, a greater need for a better understanding and ageappropriate management of POV in children is necessary to reduce this unwanted side-effect in the perioperative period.

# **Medication errors**

Medication errors in the PACU are a frequent occurrence, maybe possibly as high as 5% of all orders, and have significant potential to cause harm [131]. Medication errors may occur at any point from prescription to administration, and are the result of breakdowns in communication, calculation errors, decimal point errors, the use of a leading/trailing zero and/or knowledge deficit on the part of the health professional.

Children are at increased risk because almost all medications are prescribed on a weight basis and therefore require a calculation step. In fact, error rates for children have been found to be inversely related to the weight of the patient, with the greatest errors occurring in the smallest children [132]. Analgesic medications in particular are commonly involved in medication errors because of widespread use, split dosing and weight-based dosing regimen. Although medication errors may occur at any time and for any of the previously stated reasons, most errors occur at the ordering stage in children often simply due to a result of poor handwriting [132–134]. For this reason, electronic prescribing systems are becoming increasingly frequent in the PACU and offer the clinician and patient the promise of safer prescribing. The American Academy of Pediatrics has recognized that within the hospital, computerized physician order entry (CPOE) can prevent medication errors, and this success is gaining increasing support in the literature [135,136]. Particularly in children, this additional safeguard may be an extra layer that will prevent potentially catastrophic events in the postoperative period.

# **Urinary retention**

Urinary retention is often difficult to assess in the pediatric patient due to a child's inability to communicate the issue clearly, and it therefore may be underdiagnosed. In the adult population, urinary retention occurs at approximately 16% incidence and is associated with the amount of intraoperative intravenous fluid delivery and bladder volume on admission to the PACU as well as advancing age [137]. This would suggest that straight catheterization or bladder emptying prior to emergence in the operating room should occur in patients who have received a considerable amount of IV fluid in the operating room without a urinary catheter present. There is no association of urinary retention in the PACU with such factors as gender, urinary symptoms, type of surgery or anesthesia, intraoperative administration of anticholinergics or morphine. Postoperative urinary retention is not a significant factor after caudal anesthesia when compared to ilioinguinal/iliohypogastric block and does not delay recovery [138]. However, Metzelder et al demonstrated that children who undergo distal hypospadias repair and receive penile block are significantly less likely to exhibit postoperative urinary retention when compared to patients who receive caudal anesthesia (5/33 versus 15/27, respectively) [139].

Urinary retention, often forgotten as a possibility in children in the PACU, should be considered in any child who has otherwise unexplained tachycardia or signs of discomfort that cannot be attributed to the procedure.

# Conclusion

The pediatric PACU requires careful planning and ongoing maintenance in order to provide a safe, efficient environment for the recovering pediatric patient. Despite widespread knowledge of the basic principles of postanesthetic recovery and the publication of general national standards, as this chapter indicates, specific practices are dictated by institutional experience and preference. Basic tasks such as recognizing and managing potential peri-

CASE STUDY

The nursing staff in the pediatric PACU are notified by telephone from the operating room that a 4-year-old boy has just undergone a tonsillectomy and adenoidectomy and is ready for transfer to the PACU. The operating room nurse, using a checklist to ensure that all the important information is conveyed, gives the patient name, age and weight, identifies the surgeon responsible and gives a brief description of the operation. She also confirms with the anesthesia provider that there are no additional concerns or issues to be conveyed at the time of initial report. A pediatric-trained PACU nurse then prepares for the admission by establishing that the allocated bed space directly adjacent to her other patient is clean, that the monitoring is complete and working, and that there is an Ambu® bag and functioning suction.

The patient arrives in the PACU escorted by the anesthesia team and surgical resident. The patient is in the left lateral recovery position and has an oxygen mask applied that is connected to a full tank. On arrival, a rapid assessment is made by the PACU nurse which reveals a sleeping child with pink lips and patent airway. Monitors are placed and show an oxygen saturation of 100%, pulse (P) of 100 and blood pressure of 100/60. Temperature is 37°C.

Using the I-SBAR method, the nurse anesthetist introduces herself and the patient's identity is confirmed by name band with the PACU nurse. The remainder of the handover is as follows: the patient is a 4-year-old male weighing 20 kg with a history only significant for obstructive sleep apnea who underwent adenotonsillectomy and is currently stable. He has no known drug allergies and receives no current medications. The family are in the surgical waiting room and have spoken to the surgeon. The patient has undergone general anesthesia, with an inhalational induction of anesthesia, intravenous line placement and the insertion of a 4.5 cuffed RAE endotracheal tube. He received fentanyl 20µg and no muscle relaxants. For antiemetic prophylaxis, he was given dexamethasone 2 mg and ondansetron 2mg, as well as rectal acetaminophen 650 mg suppository. Fluid given was 400 mL of lactated Ringer's solution. The surgery took longer than anticipated due to excessive intraoperative bleeding. A deep extubation of the trachea was performed at the end of the case to avoid coughing and rebleeding. There were no drains and no labs were pending. Vital signs remained stable throughout the case with the exception of tachycardia that peroperative complications are compounded by the nuances of taking care of pediatric patients of all ages and understanding the differences across these ages while also incorporating the parents into the experience.

sisted throughout at a rate of 100–130 beats per minute. The patient's risk factors are his sleep apnea and risk of postoperative obstruction, and the nurse anesthetist states that she is also concerned about the risk of bleeding in the PACU in addition to the sleep apnea.

The nurse anesthetist has no additional specific care requirements to report, but the anesthesiologist has written postoperative orders including pain medication at a reduced dose, due to the apnea history. The IV is to be put on a pump and the family informed of the patient's arrival to the PACU.

Within 10 min after arrival in the PACU, the child wakes up crying and coughing. His parents are invited into the PACU to help pacify him and aid in the assessment of anxiety versus pain. The parents are immediately concerned over the amount of blood in the saliva and ask the PACU nurse if this is normal. The PACU nurse reassesses the patient and notes that there are indeed copious bloodfilled secretions from the airway which require suctioning. The vital signs are measured and noted to be as follows: SpO<sub>2</sub> 98%, P 140, and BP 90/60. The anesthesiologist is called with a brief report of the concerns and he comes immediately to the bedside to assess.

At this time the patient vomits what appears to be a large volume of blood. The anesthesiologist immediately determines the possibility of an ongoing tonsillar bleed and so instructs the PACU nurse to administer 10mL/kg bolus fluid and to arrange for blood products to be delivered. The child is kept in head-down position to the side and frequent vital signs are measured. The anesthesiologist communicates his concerns to the surgeon in the operating room with an updated assessment of the current situation and a rapid plan of action is established.

During this time, other members of the PACU team bring the centrally located emergency cart with airway equipment to the bedside, along with emergency drugs for the induction of anesthesia. A second fluid bolus of 10 mL/kg is administered and a stat hemoglobin level sent for analysis, prompting the procurement of blood from the blood bank. The child is no longer vomiting and vital signs improve after the second delivery of volume, as noted by an increased blood pressure and reduced heart rate.

Resuscitation is deemed adequate and the patient is electively transported back to the operating room for reexploration of the tonsillar bleed. The parents remain in the *Continued*
PACU during this time and are informed of the events as they occur. The child undergoes a successful cauterization of the tonsillar bleed and makes an uneventful recovery.

### Key points

This case illustrates several basic points.

- 1. Proper handover and communication in the PACU environment are essential. The Joint Commission has recently made the process of handover a key element of its assessment of a medical center or unit and evidence shows that good communication reduces the incidence of adverse events.
- **2.** The PACU is an environment of constant vigilance and attention to detail. Regular patient assessment and attention to changes in condition require rapid manage-

ment. Fully functioning monitoring with frequent measurements is imperative.

- **3.** There must be a central core of emergency equipment supply and drugs and all team members should be familiar with what is present and available in the PACU. The ability of the PACU team to recognize the potential need for emergency airway care or volume resuscitation requires appropriate equipment and supplies that are readily available.
- **4.** Even without issues such as pain, severe nausea and vomiting or emergence agitation, the PACU is an environment where a seemingly stable patient can become unstable and all team members need to act swiftly and appropriately.

## Introduction

Vascular access and monitoring of circulation, respiration, the central nervous system, and other end organs is a central task for the pediatric anesthesiologist. The vast majority of cases will require simple peripheral venous access and standard non-invasive monitors. Extensive surgery or significant underlying disease may necessitate invasive cardiovascular monitoring, and procedures where the brain is at risk may require central nervous system monitoring. This chapter will address peripheral venous access and then invasive vascular access and monitoring, followed by monitoring of respiration, temperature, neuromuscular blockade and renal monitoring. Finally, central nervous system monitoring will be reviewed.

## Venous access

## **Peripheral veins**

Any visible peripheral vein, and many that are not visible, may be utilized for peripheral venous access. One strategy in pediatric patients is to cannulate a small superficial vein on the hand or foot with a small catheter (24 or 22 gauge) before induction or during inhalation induction of anesthesia to facilitate the early administration of intravenous agents and provide expeditious airway management. Later, with the airway secure and with an immobile patient, larger bore peripheral venous access can be achieved. Simple surgeries without blood loss require smaller catheters, but if significant fluid or blood administration is anticipated, larger catheter sizes should be utilized. Recommended sizes for major surgery are 22 or

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

24 ga 1" catheters for infants newborn through 6 months, 22 ga 1" or 20 ga 1.25" catheters for 6 months to 3 years, 20–22 ga or 18 ga 1.5" for 3–12 years, and 16 or 14 ga 2" catheters for teenage or adult patients. Resistance to fluid flow predicted by Poiseuille's Law is proportional to the length of the catheter and the viscosity of the fluid, and inversely proportional to the fourth power of the catheter radius. When rapidly infusing the more viscous colloids or packed red blood cells, it is important to use a large-bore, short catheter in a large peripheral vein.

The saphenous vein at the ankle is large and in a constant anatomical position in patients of all ages. It can usually be cannulated even if it cannot be seen or palpated. A recommended technique is to apply a tourniquet below the knee, prepare the site antiseptically, and extend the ankle at the medial malleolus with one hand while puncturing the skin at a shallow angle of 10–30° with an angiocatheter 0.5-1 cm anterior and 1 cm inferior to the medial malleolus. Advance the catheter slowly in the groove between the malleolus and the tibialis tendon until blood return through the needle is established. Advance the needle and catheter together several millimeters, then advance the catheter over the needle into the vein with the index finger of the same hand that made the skin puncture, while maintaining extension of the ankle so that the saphenous vein is tethered straight in its course, to minimize the possibility of puncturing the posterior wall due to kinking of the vein. If the vein can be entered but the catheter will not advance its full length into the vein, a small flexible guidewire of 0.015" or 0.018" may be used to assist in cannulation of the saphenous or any other peripheral vein [1]. Other large peripheral veins may be found in infants and children on the dorsum of the hand, at the wrist superficial to the radial head, as branches of the cephalic or brachial venous system in the antecubital fossa or on the dorsolateral aspect of the foot. The latter site is especially prominent in many newborns.

The external jugular vein is often visible in infants and children undergoing anesthesia and surgery. This site can be used in cases of difficult access. A recommended technique is to choose the larger external jugular vein, put a small rolled towel under the shoulders and place the patient in 30° Trendelenburg position, prepare the site antiseptically, and have an assistant compress the vein gently with pressure just above the clavicle to further distend it. Rotation of the head 45-90° away from the side of cannulation and slight extension of the neck and traction of the skin over the vein with one hand will tether the vein into a straighter course to facilitate successful cannulation. The vein is punctured high in its visible course with an angiocatheter attached to a syringe filled with heparinized saline, and with the needle bent upwards 10–20° to facilitate the very flat, superficial angle of incidence necessary to cannulate the vein without puncturing its back wall. With constant, gentle aspiration of the syringe, the vein is entered and catheter advanced into the vein. Short peripheral catheters of the same size as recommended above should be used. A catheter advanced too far into the venous plexus beneath the clavicle will often exhibit resistance to the free, gravity-driven flow of fluid, and traction or withdrawal of the catheter a few millimeters may be necessary. External jugular catheters are often difficult to secure to the skin on the neck, and suturing them in place is recommended. This will enhance stability postoperatively as the patient begins moving. One advantage of using the external jugular vein for a peripheral venous catheter is that it is easily accessible under the surgical drapes, and can be frequently monitored for extravasation or kinking of the catheter, which is more common with this site than with the other commonly used peripheral veins.

### **Umbilical vein**

The umbilical vein in the fetus is a conduit for carrying oxygenated and detoxified blood from the placenta, through the abdominal wall, the liver and patent ductus venosus to the inferior vena cava (IVC) and the right atrium [2] (Fig. 17.1). This vessel can usually be cannulated at the umbilical stump for the first 3-5 days of postnatal life. Passage into the IVC depends on the patency of the ductus venosus, which often exists for the first few days, just as the ductus arteriosus. Sterile technique without a guidewire is used to pass the catheter blindly a premeasured distance. If no resistance to passage is met and free blood return is achieved, the catheter tip is usually in the high IVC or right atrium, and functions as a central venous catheter. Catheter tip position must be determined by radiography as soon as possible to determine if it is through the ductus venosus into the IVC or the right atrium. Often, the ductus venosus is not patent, and the catheter tip passes into branches of the hepatic veins, and is visible in the liver radiographically. In this location, the catheter must not be used except for emergencies. Central venous pressure monitoring is inaccurate in this position, and portal vein thrombosis, liver and intestinal necrosis can occur with the infusion of hyperosmolar or vasoactive drugs such as sodium bicarbonate and dopamine. An alternative site for central access must be chosen.

### Percutaneous central venous access

Percutaneous central venous access can be utilized for several indications:

- difficult peripheral venous access or need for prolonged vascular access
- need to monitor central venous pressure, i.e. large fluid shifts or blood loss, or cardiovascular surgery
- need for vasoactive infusions [3].

**Figure 17.1** The fetal circulation. A catheter placed in the umbilical vein should have its tip through the ductus venosus into the inferior vena cava at or near its junction with the right atrium. The tip of an umbilical artery catheter should lie at the level of the third lumbar vertebral body, between the origin of the renal arteries and the bifurcation of the aorta. Reproduced from Parellada and Guest [2] with permission from Lippincott Williams & Wilkins.

Precise indications will vary according to the practitioner. A double-lumen central catheter of the smallest acceptable size is recommended for percutaneous central venous catheter placement. For all sites, either audio Doppler or two-dimensional ultrasound can be used to facilitate insertion. The larger distal lumen is used for central venous pressure monitoring and drug injection, and the smaller proximal lumen for vasoactive and other infusions. The smallest available double-lumen catheter is currently 4 Fr in size. Superior vena cava (SVC) catheters should be used with caution or not at all in patients weighing less than 4kg because of the increased risk of thrombosis (see Complications). Recommended sizes and lengths are shown in Table 17.1.

Sterile technique using gown and wide draping leads to a "cleaner" insertion technique with fewer infectious complications [4]. In cardiac patients, the left side SVC lines should generally be avoided. The risk of erosion/ perforation is greater, and 5–15% of patients with congenital cardiac disease have a persistent left SVC, which

 Table 17.1 Recommended central venous catheter sizes and lengths according to weight

Patient weight	IJ/subclavian vein	Femoral vein
<10 kg	4 Fr, 2 lumen, 8 cm	4 Fr, 2 lumen, 12 cm
10–30 kg	4 Fr, 2 lumen, 12 cm	4 Fr, 2 lumen, 12–15 cm
30–50 kg	5 Fr, 2 lumen, 12–15 cm	5 Fr, 2 lumen, 15 cm
50–70 kg	7 Fr, 2 lumen, 15 cm	7 Fr, 2 lumen, 20 cm
>70 kg	8 Fr, 2 lumen, 16 cm	8 Fr, 2 lumen 20cm

most often drains either to the coronary sinus or the left atrium, neither of which is a desirable location for a catheter tip. So, if left-sided line placement is contemplated, ascertain by echo/cath report the presence of the left SVC. If this is not known in a patient with congenital heart disease, choose an alternative site, i.e. femoral venous.

The following general discussion of the Seldinger technique in pediatric patients can be applied to all percutaneous vascular access sites, either venous or arterial. The Seldinger technique is used for all percutaneous central venous cannulations. A central line insertion and maintenance "bundle" will reduce infection rates and should be used, including a checklist to ensure all steps are followed [5] (Box 17.1). After wide sterile skin preparation with iodine or chlorhexidine-based solution, wide draping is carried out, preferably with a clear, fluid impermeable adhesive aperture drape so that the underlying anatomy is clearly visible. Slow, controlled, careful needle manipulation, especially in small infants, must be emphasized. The slight movement in or out of only 1 mm or less may be enough to prevent passage of the guidewire. It is very important to have the guidewire prepared to insert and immediately accessible when the vein is entered, so the anesthesiologist does not have to look away from the puncture site to reach for the wire on a distant tray, often resulting in enough movement of the needle to prevent successful guidewire passage.

After the desired vein is entered, the needle position is fixed by stabilizing it against the patient's body with the heel of non-dominant hand, and the guidewire is carefully advanced into the right atrium. The resistance to wire passage should be minimal. Experienced operators learn to recognize the "feel" of a guidewire passing successfully. If any resistance is encountered, the wire must be carefully withdrawn, and another approach made if the needle is still in the vessel, ascertained by free aspiration of blood. Forcing a guidewire in the face of resistance can lead to significant complications.

The electrocardiogram should be carefully observed as the guidewire is slowly advanced. Premature atrial contractions (PAC) are usually observed as the first guidewireinduced dysrhythmia, signifying atrial location. If no PACs are observed, the operator should suspect that the guidewire is not in the atrium. If ventricular extrasystoles are the first observed dysrhythmia, especially if they are multifocal in nature, the wire is very likely in an artery, and the left ventricle has been entered retrograde.

After guidewire passage, a very small skin incision with a #11 scalpel is made. Finally, careful dilation and catheter passage follow. The dilators in the pre-packaged central venous catheter kits are often one size larger than the catheter, i.e. 5 Fr dilator for 4 Fr catheter. This may be undesirable for small infants, and either passage of the catheter without dilation or use of a dilator the same size as the catheter is preferable to make the smallest possible hole in the vein to minimize bleeding and trauma to the vessel wall, both of which may lead to an increased incidence of thrombosis or vascular insufficiency.

Meticulous attention must be paid to blood loss in small infants during catheterization procedures, with

#### Box 17.1 Central line catheter care bundles

#### Insertion bundle

- Wash hands before the procedure
- For all children aged ≥2 mo, use chlorhexidine gluconate to scrub the insertion site for 30s for all areas except the groin, which should be scrubbed for 2 min. Scrubbing should be followed by 30 to 60s of air drying
- No iodine skin prep or ointment is used at the insertion site
- Use a sterilized prepackaged tray with catheter that contains all necessary equipment and supplies including full sterile barriers
- Create an insertion checklist, which empowers staff to stop a nonemergent procedure if it does not follow sterile insertion practices
- Use only polyurethane or Teflon catheters<sup>a</sup>
- Conduct insertion training for all care providers, including sides and video

#### Maintenance bundle

- Assess daily whether catheter is needed
- Catheter-site care
- No iodine ointment
- Use a chlorhexidine gluconate scrub to sites for dressing changes (30-s scrub, 30-s air-dry)
- Change gauze dressings every 2 d unless they are soiled, dampened, or loosened<sup>a</sup>
- Change clear dressings every 7 d unless they are soiled, dampened, or loosened<sup>a</sup>
- Use a prepackaged dressing-change kit or supply area
- Catheter hub, cap, and tubing care
  - Replace administration sets, including add-on devices, no more frequently than every 72 h unless they are soiled or suspected to be infected
  - Replace tubing that is used to administer blood, blood products, or lipids within 24 h of initiating infusion<sup>a</sup>
  - Change caps no more often then 72 h (or according to manufacturer recommendations); however, caps should be replaced when the administration set is changed<sup>a</sup>
  - The prepackaged cap-change kit, or supply area elements to be designated by the local institution

<sup>a</sup>These procedures are according to the CDC recommendations.

direct compression of bleeding puncture sites using the heel of the non-dominant hand, while threading dilators, catheters, etc. Use of an assistant may be necessary in difficult catheterizations. After passage of the catheter to the desired depth, it is secured with sutures and a dressing. If more than 1 cm of catheter is outside the patient, additional suturing or catheter holding devices are necessary.

### Internal jugular vein

The right internal jugular (IJ) vein is the most common site chosen for central venous access in pediatric cardiac

surgery, and is often an excellent choice for other major surgery. It is large, and runs in close proximity superficial to the carotid artery along most of its length. The primary advantage of using the IJ vein is that it provides a direct route to the right atrium, and thus a high rate of optimal catheter positioning if the vessel can be cannulated. Various studies report only a 0-2% incidence of catheter tip outside the thorax, in contrast to 5-10% for the subclavian route [6,7]. The primary disadvantage comes from difficulty in cannulation in small infants, who have large heads and short necks, and thus difficulty in obtaining the shallow angle of approach necessary to access the vessel. Also some series report a 10-15% incidence of carotid artery puncture in infants and ultrasound studies of neck vessel anatomy reveal the partial or complete overlap of the IJ vein anterior to the carotid artery [7]. This site is also not comfortable for some awake infants, and tip migration may be significant with turning the head or flexion/extension of the neck [8]. All insertion techniques involve placing a small roll under the shoulders, using steep Trendelenburg position, and rotating the head no more than 45° to the left. Greater rotation will produce more overlap of the IJ vein and carotid artery, and increase the risk of carotid puncture [9]. Recent studies have demonstrated that liver compression and simulated Valsalva maneuver also increase the diameter of the IJ vein, possibly increasing the success rate of cannulation [10].

There are numerous approaches to the IJ vein, some of which are described here (Fig. 17.2).

- Muscular "triangle" method: puncture at the top of the junction where the sternal and clavicular heads of the sternomastoid muscle meet, lateral to the carotid impulse, directing the needle at the ipsilateral nipple. These landmarks are often not well defined in infants.
- Puncture exactly halfway along a line between the mastoid process and the sternal notch, just lateral to the carotid impulse.
- Use the cricoid ring as a landmark, and puncture just lateral to the carotid impulse.
- Jugular notch technique: puncture just lateral to the carotid impulse, just above the jugular notch on the medial clavicle a low approach.

An ultrasound technique (see below) should be used to clearly identify the course of the vessel and to detect any significant overlap with the carotid artery. There is no need to use a finder needle for small catheters, where access needle is 20ga or smaller. Surface landmarks are often inaccurate for estimating the correct depth of insertion for SVC lines, i.e. locating the tip midway between the sternal notch and nipple. See discussion below for a method of ascertaining the correct placement for all sites.

**Figure 17.2** Sites for central venous cannulation of the superior vena cava. 1: high approach, midway between mastoid process and sternal notch; 2,3: middle approach using apex of muscular triangle or cricoid cartilage; 4: low approach using jugular notch; 5: lateral approach to subclavian venepuncture. Reproduced from Andropoulos et al [31] with permission from Lippincott Williams & Wilkins.

## Subclavian vein

The subclavian vein is positioned immediately behind the medial third of the clavicle [11,12]. Advantages of this route include the subclavian vein's relatively constant position in all ages in reference to surface landmarks, stability and less tip migration with patient movement, and comfort for the awake patient [13,14]. Disadvantages include an incidence of pneumothorax, especially with an inexperienced operator, and an occasional inability to dilate the space between the clavicle and first rib. Also in 5–20% of patients, subclavian catheters will enter the contralateral brachiocephalic vein or ipsilateral internal jugular vein, instead of the SVC [15].

### Technique (see Video clip 17.1)

A small rolled towel is positioned vertically between the scapulae, steep Trendelenburg position is used, and the arms are restrained in neutral position at the patient's sides. This position maximizes the length of subclavian vein overlapping the clavicle and moves the vein anterior, bringing it in close proximity to the posterior surface of the clavicle [11]. The right subclavian vein should always be the first choice (see below). Turn the head toward the side being punctured (i.e. toward right for right-sided line). This position will compress the internal jugular vein on that side and prevent the guidewire from entering it, especially in infants [16], which may lead to complications such as dural sinus thrombosis [17]. It will not,

however, prevent the guidewire from crossing the midline and entering the contralateral brachiocephalic vein [16]. The needle is bent upwards in midshaft at a 10–20° angle to insure a very shallow course. In our experience the puncture site that is most successful is 1–2 cm lateral to the midpoint of the clavicle [11], directly lateral from the sternal notch, with the needle directed at the sternal notch.

Contact the clavicle first to insure a shallow angle of incidence to minimize the risk of pneumothorax. Then, the needle is "walked" carefully underneath the clavicle and advanced slowly with constant aspiration until blood return is achieved. Advancing the needle only during expiration is recommended to minimize the risk of pneumothorax. Having an assistant manually ventilate the patient will facilitate this process. If not successful, the needle is withdrawn slowly with gentle aspiration, because about 50% of infant subclavian veins are cannulated during withdrawal due to compression or kinking of the vein during needle advancement. Slow, controlled, careful needle manipulation, especially in small infants, must be emphasized. After the vein is entered, advance the guidewire; there should be no resistance. Look for premature atrial contractions, sometimes only one or two, as a sign that the wire is in the heart. If no dysrhythmias are seen, withdraw the wire, rotate it 90° clockwise, and advance it again until PACs are seen. Use a dilator (be very careful not to advance it too far – only far enough to expand the space between the clavicle and first rib) and pass the catheter to the desired depth using one of the guidelines noted below.

Complications during subclavian catheterization occur when a needle angle of incidence is too cephalad, resulting in arterial puncture, or too posterior, resulting in pneumothorax. If the needle course remains shallow, just underneath the clavicle, and directed straight horizontally at the sternal notch, complications are rare. Advancing the needle too far in infants may result in puncture of the trachea.

### External jugular vein

Advantages of this approach are its superficial location and thus low risk of arterial puncture. A disadvantage is that the younger the patient, the less likely it is that the guidewire will pass into the atrium; the success rate is less than 50% if the patient is less than 1 year old and only 59% in patients less than 5 years [18,19]. Positioning is the same as the internal jugular approach – the vein is punctured high in its course and the guidewire is passed. Often it can be observed turning medially toward the SVC. If no resistance is felt and PACs are seen, or the guidewire is visualized on the transesophageal echocardiogram (TEE), then passage has been successful. Because of the low success rate of central cannulation from the external jugular vein approach, our practice is to use the internal jugular vein first in all patients.

## Femoral vein (see Video clip 17.2)

The femoral vein has long been used for central venous catheterization in pediatric patients, with no greater infection or other complication rate compared to other sites [20,21].

### Technique

The patient is positioned with a rolled towel under the hips for moderate extension. The puncture site should be 1–2 cm inferior to the inguinal ligament (line from the anterior superior iliac spine to the symphysis pubis) and 0.5–1 cm medial to the femoral artery impulse, with the needle directed at the umbilicus. Ultrasound guidance (see below) is important for the greatest chance for first-pass, atraumatic placement. The guidewire is passed, ensuring no resistance. A vessel dilator is used and then the catheter is passed all the way to the hub to position the tip in the mid inferior vena cava (IVC). It is important to puncture the vessel well below the inguinal ligament, to minimize the risk of unrecognized retroperitoneal bleeding. Bleeding below the inguinal ligament is easily recognized and treated with direct pressure.

Several studies have conclusively demonstrated that in the absence of increased intra-abdominal pressure or IVC obstruction, mean central venous pressure as measured in the IVC below the diaphragm is identical to that measured in the right atrium in patients with and without congenital heart disease [22–26]. The only caveat is in the patient with interrupted IVC with azygous vein continuation into the SVC, a condition commonly encountered in patients with the heterotaxy syndromes. The equivalence of IVC and right atrial pressures under these conditions has not been evaluated, but the catheter can be used as any other central line for infusion of drugs and fluids.

## Ascertainment of correct position of central venous catheters

Correct placement of central venous catheters (CVC) is essential to prevent complications (see below), and to give accurate intravascular pressure information. The tip of a central venous catheter should lie in the SVC, parallel to the vein wall, to minimize the perforation risk. Many authorities recommend placement in the upper half of the SVC, where the tip will be above the pericardial reflection in most patients, thus minimizing the risk of tamponade if perforation occurs [27]. In small patients the SVC is often short, i.e. 4–5 cm total length, and the pericardium is usually opened during cardiac surgery in these patients, providing drainage in case of perforation. In addition, the risk of arrhythmias is present with a catheter positioned

**Figure 17.3** (A) Postoperative chest radiograph with the tip of a right internal jugular vein catheter in proper position in the mid-superior vena cava. (B) Tip of catheter malpositioned, deep in the right atrium.

**Figure 17.4** Transesophageal echocardiographic image of the superior vena cava (SVC)–right atrial (RA) junction in sagittal plane in an infant. The tip of the right internal jugular catheter is in the SVC, 6 mm above the RA. Reproduced from Andropoulos et al [15] with permission from Lippincott Williams & Wilkins.

in the right atrium. Various methods to determine correct placement are discussed below.

### Radiography and echocardiography

The chest radiograph is considered the gold standard for correct placement, but obtaining and processing a chest radiograph is time consuming, costly and usually not necessary in the operating room. A chest radiograph should be obtained immediately postoperatively (Fig. 17.3), position of intravascular catheters ascertained and adjustments made by the anesthesiologist if necessary. It is important to note that an anteroposterior radiograph may miss malposition in one of several ways. The most common is for an SVC catheter to be directed posteriorly down the azygous vein, which may not be detected by anteroposterior radiograph alone. Ideally, the tip of the catheter should be parallel to the SVC wall, in the mid-SVC, but in any case it should be above the SVC–right atrium (RA) junction. The position of the pericardial reflection is variable in infants and young children, and radiographic landmarks such as the carina above the pericardial reflection are not reliable to ascertain tip placement [28].

If TEE is utilized for cardiac surgery, the tip of the central catheter can usually be visualized in the region of the SVC–RA junction; this is easily done before surgery starts and is a very accurate method of ascertaining correct position [15] (Fig. 17.4).

## Electrocardiographically guided placement

The intravascular electrocardiogram (ECG) may be used in children to guide correct CVC placement [29,30]. Either a 0.9% or 3% saline-filled lumen with special ECG adaptor or a guidewire within the lumen attached to a sterile alligator clip and leadwire substituted for the right arm surface ECG lead may be used. Entry of the catheter tip into the right atrium is signified by the sudden appearance of a P atriale, an exaggerated, large, upright P wave. The catheter tip is then pulled back 1–2 cm into the desired position in the SVC. Success rate for proper placement in the reported studies has been 80–90%, but there have been no controlled studies in children comparing this to other methods. This method also requires special equipment which is not always available.

### Height- and weight-based formula

A large study of CVC placement in infants and children undergoing congenital heart surgery developed formulas for correct insertion depth based on height and weight [31] (Table 17.2). CVC were inserted in the right internal jugular or subclavian vein and the postoperative radiograph studies were used to determine the tip position in reference to the SVC–RA junction. The length of catheter inside the patient was added to this distance to determine the position of the SVC–RA junction, and formulas developed that would predict placement above the RA, in the SVC 97.5% of the time (95% confidence interval 96–99%). All catheter tips predicted to be in the atrium using these data would be high in the RA within 1 cm of the SVC–RA 
 Table 17.2 Recommended length of superior vena cava central venous catheter (CVC) insertion in pediatric patients based on weight: right internal jugular or subclavian veins

Patient weight (kg)	Length of CVC insertion (cm)
2–2.9	4
3–4.9	5
5–6.9	6
7–9.9	7
10–12.9	8
13–19.9	9
20–29.9	10
30–39.9	11
40-49.9	12
50–59.9	13
60–69.9	14
70–79.9	15
80 and above	16

junction, minimizing any perforation risk. The formulas are simple and easily implemented because weight and height can be easily measured on all patients undergoing surgery.

For patients with height less than 100 cm:

 $(\text{Height} \div 10) - 1 \text{ cm}$ 

is the correct insertion distance, i.e. a 75cm patient would have the catheter secured at 6.5cm for either the right internal jugular or the subclavian route.

For patients with height 100 cm or greater:

$$(\text{Height} \div 10) - 2 \text{ cm}$$

is the correct distance. The caveats to this seemingly useful technique are that for the internal jugular vein, the puncture site is high, exactly midway between the mastoid process and the sternal notch, and for the subclavian, puncture site is 1–2 cm lateral to the midpoint of the clavicle. If different puncture sites are utilized, the operator must adjust the formulas accordingly. Also, the formulas have not yet been evaluated for accuracy in a prospective fashion.

## Percutaneously inserted central catheters

Percutaneously inserted central catheters (PICC) have been utilized in the neonatal nursery for more than a decade, and have become standard practice for ill newborns expected to require prolonged venous access. The complication rate for these catheters is very low, and they are usually relatively easy to insert into the central circulation via the antecubital, saphenous, scalp, hand, axillary or wrist veins, when placed by experienced, skilled personnel. Such personnel include nurses [32] or physicians placing them at the bedside, or in the interventional radiology suite [33] with ultrasound and fluoroscopic guidance. The key to successful placement is early access, before all large visible superficial veins are injured from attempts at peripheral intravenous placements. For this reason, the PICC line is optimally placed in the critically ill newborn in the first 12–24h after admission. Like all central venous catheters, they occasionally cause complications such as perforation of the atrium or embolization of a portion of the catheter [34]. The infection rate is very low.

### Technique

A suitable vein should be identified. The branches of the basilic vein on the medial half of the antecubital fossa offer the highest success rate because of the large size and direct continuation with the axillary and subclavian veins. The cephalic vein tributaries can also be used, but are less likely to pass into the axillary vein. Other sites, e.g. the saphenous, hand, and scalp veins, are cannulated as for a peripheral intravenous catheter. The site is prepared and draped, and appropriate local anesthesia and/ or intravenous analgesia are administered. The vein is entered using a large break-away needle or angiocatheter, and a 2 Fr non-styleted silicone catheter flushed with heparinized saline is passed with forceps a distance measured from the entry site to the SVC-RA junction. Continued easy passage without resistance and continuous ability to aspirate blood signify proper placement. A radiograph, with injection of diluted contrast if needed, should be obtained prior to use. Proper catheter tip position is in the SVC or IVC, not in the right atrium.

Occasionally the PICC line will not pass centrally, i.e. into the intrathoracic portion of the subclavian vein or further, or into the IVC. In this case it should be considered no differently from a peripheral venous line. For central PICC lines, any centrally delivered medication or fluid may be used, i.e. parenteral nutrition, dopamine, CaCl, etc. The 2 Fr PICC lines are too small for rapid fluid boluses or blood products, therefore inadequate as the sole prebypass access for cardiac surgery or for other major surgery. Recently, 3.5-4 Fr soft polyurethane double-lumen PICC lines, with two 22 ga lumens, have become available, which can be placed using modified Seldinger technique, with a central vein placement rate of 66% [35]. Alternatively, 3 Fr PICC lines, placed with the aid of ultrasound and fluoroscopic guidance with a guidewire in the interventional radiology suite, may be used in newborns with caution, especially in the SVC position, because of the risk of thrombosis [36]. In older infants and children, these larger catheters are preferred. Tan et al [37] reported a series of 124 such catheters in cardiac surgical neonates, noting a low thrombosis rate of 1.6% and a low infection rate of 3.6 per 1000 catheter days,

with a median onset of 37 days; thus these catheters can be extremely useful in this population.

## **Arterial access**

Tables 17.3 and 17.4 display recommended catheter sizes for arterial access based on site and patient weight.

### **Radial artery**

This is the preferred location in the newborn if an umbilical artery line is not possible or needs to be replaced, and in virtually all other patients. Placement on the same side as an existing or planned systemic to pulmonary artery shunt is avoided, e.g. a right-sided modified Blalock– Taussig shunt.

### Technique (see Video clip 17.3)

The wrist is extended slightly with rolled gauze, the fingers taped loosely to an armboard, with the thumb taped separately in extension to tether skin surface over the radial artery (Fig. 17.5). An angiocatheter flushed with heparinized saline is used as a "liquid stylet" to increase the rapidity of flashback of blood into the hub of the needle after aseptic preparation. The skin is punctured at a 15–20° angle at the proximal wrist crease at the point of maximal impulse of the artery. Palpation is the usual method of identifying the artery, but audio Doppler localization can be helpful if the pulse is weak. Lighter planes of anesthesia provide stronger pulses and increase the success rate of cannulation.

The first attempt, before any hematoma formation or partial dissection of the artery, always yields the greatest chance for success, so the operator should optimize conditions, e.g. positioning, lighting, and identification of the vessel. Puncture of the artery with the needle is signified by brisk flashback. The needle and catheter are then advanced 1–2 mm into the artery and an attempt is made to thread the catheter primarily over the needle its full length into the artery. Threading should have minimal resistance and is signified by the continuing flow of blood

Table 17.3 Recommended arterial catheter sizes: radial, dorsalis pedis, posterior tibial, brachial arteries

Weight	Radial/DP/PT arteries	Brachial artery
<2 kg	24 g	Not recommended
2–5 kg	22 g	24 g
5–30 kg	22 g	22 g
>30 kg	20 g	22 g

DP, dorsalis pedis; PT, posterior tibial.

Table 17.4 Recommended arterial catheter sizes: femoral, axillary arteries

Weight	Femoral/axillary arteries
<10kg	2.5 Fr, 5 cm long
10–50 kg	3 Fr, 8 cm long
>50 kg	4 Fr, 12 cm long

**Figure 17.5** Insertion of a radial arterial catheter in an infant. (A) Radial artery is approached with a saline-filled angiocatheter, at the proximal wrist crease. (B) Rapid flashback of arterial blood (*arrow*) is noted with arterial puncture using liquid stylet technique. (C) A 0.015" guidewire is inserted and threaded into the artery. (D) The angiocatheter is threaded over the guidewire.

into hub of needle. If threading is not successful, the needle is replaced carefully in the angiocatheter, and the needle and catheter can be passed through the back wall of artery. Then the needle is removed, and a 0.015" guidewire with flexible tip can be used to assist threading of catheter. The catheter is pulled back very slowly and when vigorous arterial backflow occurs, the guidewire is passed and the catheter threaded over the guidewire into the artery [38]. Minimal resistance signifies successful threading. If unsuccessful, further attempts may be made at the same site or at slightly more proximal sites to avoid areas of arterial spasm, thrombosis or dissection.

The circulation distal to the catheter should be assessed by inspection of color and capillary refill time of fingertips and nailbeds, and quality of signal from a pulse oximeter probe. A recommended technique for securing the catheter is with a clear adhesive dressing and transparent tape so that the insertion site and hub of the catheter are visible at all times.

### **Femoral artery**

The superficial femoral artery is a large vessel that is easily accessible in almost all patients [39] and is a logical second choice for cardiac surgery when radial arterial access is not available. In infants, especially patients with trisomy 21, transient arterial insufficiency develops in up to 25% of patients after arterial catheterization when 20 ga (3 Fr) catheters are used [39]. For this reason, in the author's institution the smallest commercially available catheter, 2.5 Fr (equal to 21 ga), is used in patients weighing less than 10 kg (see Table 17.4).

### Technique

A small towel is placed under the patient's hips to extend the leg slightly to neutral position. Slight external rotation, with the knees restrained by taping to the operating room bed, fixes adequate position. After sterile prep and drape, the course of the superficial femoral artery is palpated and punctured 1–2 cm inferior to the inguinal ligament, to avoid puncturing the artery above the pelvic rim, where a retroperitoneal hematoma could develop. If the pulse is weak, as in the case of aortic arch obstruction, use of audio Doppler effectively identifies the course of the vessel.

The puncture technique varies and may include direct puncture with an angiocatheter or Seldinger technique using the needle in the commercially supplied kit, or a 21 ga butterfly needle with the extension tubing removed. All of the above are flushed with heparinized normal saline to increase the rapidity of flashback. A small flexible guidewire, 0.015" or 0.018", is used. It is normally possible to thread a polyethylene catheter over the guidewire without making a skin incision, and under no circumstances is dilating the tract and artery with a dilator recommended, which could cause arterial spasm, dissection or bleeding around the catheter if the puncture site is large. The catheter is secured by suturing around the entry site of catheter and wings around the hub. Distal perfusion is immediately assessed, and a pulse oximeter probe is placed on the foot for continuous monitoring and early warning of arterial perfusion problems.

## **Brachial artery**

The brachial artery has been successfully used for monitoring for cardiac surgery in children, but using this site for arterial monitoring should generally be avoided because it has poor collateral circulation compared to the radial, femoral, and axillary arteries. Theoretically, there should be a higher incidence of arterial insufficiency with this site, but a study by Schindler et al, of 386 brachial artery catheters in infants and children undergoing cardiac surgery, documented no permanent ischemic damage, and only three temporary arterial occlusions, when 22 and 24 ga catheters were used [40]. It should only be used in situations when other options are limited, e.g. a right upper extremity arterial line is required to monitor pressure during cross-clamping for repair of coarctation of the aorta, or during bypass for aortic arch hypoplasia or interruption.

### Technique

A 24ga catheter should be used in patients under 5kg. The arm is restrained in neutral position on an armboard and the arterial impulse is palpated above the elbow crease, well above the bifurcation into radial and ulnar arteries. Cannulation proceeds as for the radial artery. Meticulous attention must be paid to distal perfusion at all times, and the catheter removed for any signs of ischemia. Pulse oximeter monitoring of distal pulses will provide early detection of perfusion problems. The catheter should be removed or replaced with a catheter in a site with better collateral circulation as soon as possible after the repair.

### **Axillary artery**

The axillary artery is large and well collateralized, and several series in critically ill children have demonstrated this to be a viable option with a low complication rate when other sites are not accessible [41,42]. However, given the potential morbidity of an ischemic arm and hand, and the theoretical problem of intrathoracic bleeding, this puncture site should be considered a last resort when there are limited options.

### Technique

The arm is abducted 90° and extended slightly at the shoulder to expose the artery. The artery is palpated high

Formula	Normal values			
	Adult	Infant	Child	
$CI = \frac{CO}{BSA}$	2.8-4.2 L/min/m <sup>2</sup>	2–4	3–4	
$SVI = \frac{SV}{BSA}$	30–65 mL/beat/m <sup>2</sup>	40–75	40–70	
$LVSWI = \frac{1.36 \cdot (MAP - PCWP) \cdot SVI}{100}$	$45-60 g \cdot m/m^2$	2–40	30–50	
$RVSWI = \frac{1.36 \cdot (PAP - CVP) \cdot SI}{100}$	$5-10 g \cdot m/m^2$	5–11	5–10	
$SVRI = \frac{(MAP - CVP) \cdot 80}{CI}$	1500–2400 dyne $\cdot$ sec $\cdot$ cm <sup>-5</sup> $\cdot$ m <sup>2</sup>	900–1200	1300–1800	
$PVRI = \frac{(PAP - PCWP) \cdot 80}{CI}$	250–400 dyne $\cdot$ sec $\cdot$ cm <sup>-5</sup> $\cdot$ m <sup>2</sup>	<200	<200	

#### Table 17.5 Derived hemodynamic parameters

BSA, body surface area; CI, cardiac index; CO, thermodilution cardiac output; LVSWI, left ventricular stroke work index; PVRI, pulmonary vascular resistance index; RVSWI, right ventricular stroke work index; SVRI, systemic vascular resistance index; SV, stroke volume; SVI, stroke volume index.

in the axilla and punctured using an angiocatheter, then exchanged over a guidewire for a longer catheter or by primary Seldinger technique. A catheter that is too short (e.g. 22 ga 1" long) will often be pulled out of the vessel with shoulder extension. Therefore, the shortest recommended catheter is 5cm long (see Table 17.5). Careful attention must be paid to distal perfusion, as with the brachial artery. Tip position should be ascertained by chest radiograph, and should not lie deeper than the first rib. The proximity to the brachiocephalic vessels makes it imperative that the catheter be flushed very gently by hand after blood draws, and that no air bubbles or clots ever be introduced, because of the risk of retrograde cerebral embolization.

### **Umbilical artery**

The umbilical artery is accessible for the first few days of life and is the site of choice for newborns requiring surgery in the first week of life (see Fig. 17.1). The complication rate is lower with the catheter tip placed in the high position, i.e. above the diaphragm, versus low tip position, i.e. at the level of the third lumbar vertebra [43]. The catheter can be left in place for 7-10 days. A relationship to intestinal ischemia and necrotizing colitis has been demonstrated [44] and enteral feeding with a umbilical arterial catheter (UAC) in place is controversial [45]. Umbilical catheters are most commonly inserted by the neonatal staff in the delivery room or neonatal ICU shortly after birth. Technique involves cutting off the umbilical stump with an umbilical tape encircling the base to provide hemostasis, dilating the umbilical artery, and blindly passing a 3.5 Fr catheter a distance based on weight, then assessing position as soon as possible radiographically. Lower extremity emboli, vascular insufficiency, and renal artery thrombosis have all been described [46]; however, the overall risk is low and this site is highly desirable because it is a large central artery yielding accurate pressure monitoring [47] during all phases of neonatal surgery, and preserves access for future interventions.

### **Temporal artery**

The superficial temporal artery at the level just above the zygomatic arch is large and easily accessible in newborns, particularly the premature infant. It was widely used in the 1970s in neonatal nurseries [48] but rapidly fell out of favor with the realization that significant complications, e.g. retrograde cerebral emboli, were disturbingly common [49,50]. It should only be used when a brachiocephalic pressure must be measured for surgery in the face of an aberrant subclavian artery, so that the only way to measure pressure during cross-clamping or on bypass is via direct aortic pressure or temporal artery pressure. Examples are coarctation of the aorta, aortic arch interruption or hypoplasia, with aberrant right subclavian artery that arises distal to the area of aortic obstruction [51]. The catheter must be used only during the case, blood drawing and flushing should be minimized, and it must be removed as soon as possible after the repair.

### Technique

A 24ga catheter is used for newborns. The artery is palpated just anterosuperior to the tragus of the ear, just superior to the zygomatic arch. A very superficial angle of approach, i.e. 10–15°, is used and the artery is cannulated as described for the radial artery.

## **Dorsalis pedis/posterior tibial arteries**

These arteries are often easily cannulated and quite useful for monitoring and blood sampling during surgery when radial arteries are not available. Superficial foot arteries should not be used for cardiopulmonary bypass cases, because of the well-known peripheral vasoconstriction and vasomotor instability in the early postbypass period, which is more pronounced with these arteries than with the radial artery.

### Technique

*Dorsalis pedis*: the foot is plantarflexed slightly to straighten the course of the artery, which is palpated between the second and third metatarsal. A superficial course is taken and the artery cannulated. *Posterior tibial*: the foot is dorsiflexed to expose the artery between the medial malleolus and the Achilles tendon. The artery is often deep to the puncture site, so a steeper angle of incidence is required.

## **Ulnar artery**

The ulnar artery should only be used as a last resort when other options are not available, because its use is only considered when radial artery attempts have been unsuccessful or thrombosed by past interventions. There is a high risk of ischemia of the hand if both the radial and ulnar artery perfusion is significantly compromised. Despite this, one series of 18 ulnar artery catheters in critically ill infants and children had an ischemia rate not different from radial and femoral artery catheters, of 5.6% [52].

## **Arterial cutdown**

Cutdown of the radial artery is a reliable and often efficient method for establishing access for congenital heart surgery, and other major surgery when other arterial access has failed or is not available. Despite the speed and ease of access for a cutdown, available literature indicates a higher rate of bleeding at the site, infection, failure, distal ischemia, and long-term vessel occlusion compared to percutaneous techniques [53,54].

### Technique

The arm is positioned as for percutaneous radial catheterization. After surgical preparation and draping, an incision is made at the proximal wrist crease between the styloid process and the flexor carpi radialis tendon, either parallel or perpendicular to the artery. Sharp and blunt dissection is carried out until the artery is identified, and it is isolated with a heavy silk suture, vessel loop or right angle forceps. It is no longer considered necessary to ligate the artery distally to prevent bleeding, and in fact the artery may remain patent after a cutdown if not ligated distally. The simplest and very effective technique is to cannulate the exposed artery directly with an angiocatheter, in the same manner as for percutaneous radial artery catheter placement. The catheter is then sutured to the skin at its hub and the incision closed with nylon sutures on either side of the catheter. Removal entails cutting the suture at the hub of the catheter, removing the catheter, and applying pressure for a few minutes until any bleeding stops. The remaining skin sutures can be removed at a later date.

## Percutaneous pulmonary artery catheterization

Percutaneous pulmonary artery (PA) catheterization has a limited role in pediatric anesthesia for several reasons. The small size of many patients precludes placement of adequate sized sheaths and catheters, and many patients in whom PA catheter monitoring would be desirable have intracardiac shunting, invalidating results of standard thermodilution cardiac output measurements and confusing mixed venous oxygen saturation (SvO<sub>2</sub>) measurements. In addition, frequent need for right-sided intracardiac surgery makes PA catheterization undesirable. Thus, when pulmonary artery pressure or SvO<sub>2</sub> monitoring is indicated, transthoracic PA lines are the most common method in congenital heart surgery. The availability of continuous central venous oxygen saturation catheters (see below) and the perception that the risk:benefit ratio for PA catheter placement is most often unfavorable limit the indications for this technique.

The most common indications for percutaneous PA catheterization in pediatric anesthesia are in patients over 6 months of age able to accept a 5 or 6 Fr introducer sheath in the femoral or internal jugular vein. Patients having surgery on left heart structures who do not have intracardiac shunting, who are at risk for left ventricular dysfunction or pulmonary hypertension may benefit from the information available. Examples include aortic surgery, aortic valve repair or replacement, subaortic resection or myomectomy for hypertrophic cardiomyopathy, mitral valve repair or replacement. In addition, major surgery, i.e. liver transplant in larger patients, may be an indication for percutaneous PA catheterization.

### Technique [55]

An oximetric catheter is recommended. Commercially available models are 5.5 Fr or 8.5 Fr, and thus require a 6 Fr or 9 Fr sheath, respectively. The 5.5 Fr catheter should be used in patients under 50 kg and the 8.5 Fr in patients over 50 kg. The sheath is placed into the internal jugular, femoral or subclavian veins as described above. The preferred sites of insertion are right internal jugular, left subclavian, femoral vein because of the direct path and curvature of the catheter. If an oximetric catheter is used, it is calibrated prior to insertion. The balloon integrity should be tested before insertion by inflating the recommended volume of air or CO<sub>2</sub>, and the sterility sleeve is inserted before placement.

The PA and central venous pressure (CVP) ports are connected, flushed, and calibrated before insertion. The PA catheter is inserted 10–15 cm with the balloon deflated, depending on patient size. The balloon is inflated and the catheter advanced slowly toward the tricuspid valve, whose position is indicated by enlarging V waves on the CVP trace. The catheter is advanced through the tricuspid valve by advancing during diastole until the characteristic right ventricular trace is visible, with no dichrotic notch and a diastolic pressure of 0-5mmHg. Then, the catheter is advanced carefully through the pulmonary valve during systole, until the characteristic PA tracing is visible, with a dichrotic notch and higher diastolic pressure. The catheter is then advanced gently until the pulmonary capillary wedge pressure tracing is obtained, at which time the balloon is deflated so the PA tracing rapidly returns. Difficulty with advancing through the pulmonary valve may be assisted by counterclockwise rotation of the catheter while advancing, positioning the patient right side down and giving a fluid bolus, or by using TEE to visualize the tip and guide subsequent attempts [56]. The catheter must not be left in the wedge position except during brief periods because of the risk of pulmonary artery rupture and lung ischemia distal to the catheter. During bypass, the catheter can be pulled back several centimeters to reduce the risk of perforation on bypass.

## Information obtainable with a pulmonary artery catheter

Right atrium, PA, and pulmonary capillary wedge (PCWP) pressures. In the absence of mitral valve stenosis or pulmonary venous or arterial hypertension, PA diastolic ~ PCWP ~ LAP ~ left ventricular end-diastolic pressure, which is proportional to left ventricular end-diastolic volume, the classic measure of preload [57]. Despite the presence of pulmonary hypertension or residual mitral stenosis (diagnosed with postoperative TEE), information from the PA catheter can still be used to direct therapy.

Cardiac index may be measured by standard thermodilution methods, with care taken to input the correct calculation constant into the monitor software according to the catheter size and length, and volume and temperature of injectate. The average of three consecutive injections made in rapid succession at the same point in the respiratory cycle, i.e. expiration, will optimize conditions to achieve an accurate measurement during steady-state conditions. Vascular resistances and stroke volume can also be calculated, using the formulas in Table 17.5 [57,58].

Hemodynamic data represent only half the information available from an oximetric PA catheter. The other half consists of oxygen delivery and consumption measurements and calculations, which may also be used to

Tab	le	17.6	Derived	oxygen	delivery/	consumption	parameters
-----	----	------	---------	--------	-----------	-------------	------------

Formula	Normal values		
	Adult	Infant	Child
Arterial O <sub>2</sub> content CaO <sub>2</sub> = $(1.39 \cdot Hb \cdot SaO_2) + (0.0031 \cdot PaO_2)$	18–20 mL/dL	15–18	16–18
Mixed venous O <sub>2</sub> content $CvO_2 = 1.39 \cdot Hb \cdot SvO_2 + 0.0031 \cdot PvO_2$	13–16 mL/dL	11–14	12–14
Arteriovenous $O_2$ content difference avDO <sub>2</sub> = CaO <sub>2</sub> - CvO <sub>2</sub>	4–5.5 mL/dL	4–7	4–6

$O_2$ delivery index $DO_2I = 10 \cdot CO \cdot CaO_2/BSA$	450–640 mL/min/m <sup>2</sup>	450–750	450–700
$O_2$ consumption index $VO_2I = 10 \cdot CO \cdot (CaO_2 - CvO_2)$	85–170 mL/min/m <sup>2</sup>	150–200	140–190

Hb, hemoglobin; PaO<sub>2</sub>, partial pressure of oxygen in arterial blood; PvO<sub>2</sub>, partial pressure of oxygen in mixed venous blood; PcO<sub>2</sub>, partial pressure of oxygen in pulmonary capillary blood; Qs, pulmonary shunt blood flow; Qt, total pulmonary blood flow; SaO<sub>2</sub>, measured arterial oxygen saturation; ScO<sub>2</sub>, measured pulmonary capillary oxygen saturation; SvO<sub>2</sub>, measured mixed venous oxygen saturation.

guide therapy in the critically ill patient with low cardiac output syndrome [57,58] (Table 17.6). Oxygen consumption/delivery data require either measurement of mixed venous and systemic arterial saturations from blood samples from the tip of the PA catheter and arterial line (measured by co-oximetry, not calculated) or substitution of these values with  $SvO_2$  from the oximetric catheter (a valid assumption if properly calibrated), and pulse oximeter value instead of measured systemic saturation. There are data from the adult and pediatric critical care literature suggesting that the ability to increase and maximize both oxygen delivery and consumption may improve outcome, and is a predictor of survival from critical illness, including postoperative cardiac surgery [59–62].

# Ultrasound guidance for vascular access

Numerous studies demonstrate that ultrasound guidance, either two-dimensional visual ultrasound [63] or audio Doppler ultrasound, improves the outcome of central venous cannulation, in both children and adults [64,65]. Use of these methods leads to fewer attempts, decreased insertion time, fewer unintended arterial punctures, and fewer unintended arterial catheter placements. The consensus of many experts in the field of vascular access is that use of these guidance techniques should be considered standard of care.

A 9.2MHz pencil-thin audio Doppler probe can be gas sterilized and reused. The probe is applied to the site, and the course of the artery and vein is ascertained by their characteristic audio profiles – high-pitched, intermittent, systolic flow for the artery, and a low-pitched, continuous venous hum for the vein. The probe is centered over the loudest signal, perpendicular to the skin surface, and the vessel is punctured exactly in the axis of the center of the probe. A "pop" followed by the continuous sound of blood aspiration can often be heard when the vessel is entered. The guidewire, dilator, and catheter are then passed as above. A variation of the audio Doppler technique is a device with the Doppler probe within the needle [66]. However, these needles are expensive, direct comparison has not shown them to be superior to visual ultrasound for cannulation, and because the lumen of the needle is partially occluded with the Doppler probe, flashback of blood is slow and unreliable.

Two-dimensional echocardiography, in the form of either commercially available devices for CVC cannulation only (Sonosite®) or surface probes on standard echocardiography machines, can be used to image large vessels (Fig. 17.6A). The color Doppler feature on the latter may be particularly useful to identify desired vessels during difficult vascular access. The internal jugular vein (IJV) is the vessel most frequently accessed with ultrasound, and it is visualized superficial to and lateral to the carotid artery. The IJV is also easily compressible with the probe and is gently pulsatile, while the carotid artery is round, difficult to compress with probe pressure, and very pulsatile (Fig. 17.6B). The probe is held directly over the desired vessel, with the goal of puncturing it exactly in the midline. The needle can be seen indenting and then puncturing the vessel during correct placement (Fig. 17.6C).

Visual ultrasound is particularly useful to clarify the anatomy after several previous attempts have been made. One can identify the vessel in the midst of a hematoma that has formed or recognize overlap of the artery and vein. Once the vessel has been punctured and the guidewire passed, the ultrasound can be used to visualize the guidewire in the lumen of the vessel by scanning closer to the heart. Ultrasound methods are described most often for the IJV but are also useful for the

**Figure 17.6** (A) Ultrasound-guided puncture of the internal jugular vein in an infant. Arrow denotes 13 MHz pediatric probe. (B) Two-dimensional ultrasound view of the right internal jugular vein and carotid artery in an infant. femoral and subclavian veins. It should also be noted that real-time ultrasonographic visualization of needle insertion, vessel puncture, and guidewire passage of the internal jugular vein in infants results in fewer attempts and faster cannulation than merely marking the skin after ultrasound visualization followed by blind puncture of the vessel [67].

Audio Doppler can be used to assist in the cannulation of any artery, and is particularly useful when pulses are diminished from previous attempts, hypotension or vasospasm. Visual ultrasound can also be used to cannulate radial arteries, and Schwemmer et al found that this technique resulted in a 100% success rate, versus 80% for the traditional palpation method, and also resulted in higher success rate on the first attempt and lower number of attempts [68].

## Interpretation of intravascular pressure waveforms

The normal systemic arterial pressure waveform changes with progression distally from the central arterial circulation, e.g. ascending aorta, distally to the abdominal aorta and femoral arteries, and then to the peripheral arteries, such as the radial and dorsalis pedis/posterior tibial arteries [57] (Fig. 17.7). In general, the more central sites

**Figure 17.7** Progression of the arterial pressure tracing from the root of the aorta to more peripheral arteries. Pulse wave amplification produces a higher systolic peak and slightly lower diastolic pressure in the smaller distal arteries, especially the dorsalis pedis. Reproduced from Reich et al [57] with permission from Elsevier.

will produce less peaked systolic pressure waves with slightly lower systolic pressure readings. The dicrotic notch is pronounced in the central arteries. With distal progression, pulse wave amplification will produce a higher peaked systolic pressure wave with a slightly higher systolic pressure. This is most pronounced in the arteries of the foot, where the systolic pressure may be 5–15 mmHg higher than the ascending aorta. The mean and diastolic pressures change very little with progression. This concept is very important in interpreting arterial pressure tracings. The postbypass arterial tracing is frequently dampened with catheters in small distal arteries, e.g. radial or foot arteries [69]. This usually resolves within a few minutes after bypass. For particularly long and difficult operations with long bypass and cross-clamp times, or in major non-cardiac cases with substantial blood loss and hemodynamic instability, it may be useful to place catheters in larger arteries, e.g. femoral or umbilical, or to measure the pressure directly in the aortic root immediately after bypass to ascertain an accurate arterial pressure.

The arterial pressure tracing can yield more information than simply the systolic and diastolic blood pressures [70,71]. The slope of the upstroke of the pressure wave may be an indicator of systemic ventricular contractility, i.e. the steeper the upslope, the better the contractility. Significant reductions in contractility flatten the upslope. The position of the dicrotic notch may give an indication of peripheral vascular resistance. In infants, the normal dicrotic notch is in the upper half of the pressure wave. With low peripheral resistance, as in arterial run-off through a patent ductus arteriosus, the dicrotic notch is lower on the descending limb of the waveform, due to diastolic run-off into the pulmonary artery, resulting in a relatively longer period of ventricular systole. The area under the curve of the systolic portion of the arterial tracing increases with increased stroke volume. Finally, a hypovolemic patient will often exhibit more pronounced respiratory variation during positive pressure ventilation, as the stroke volume decreases when positive pressure impedes an already limited venous return (Fig. 17.8). Computerized pulse-contour analysis of the arterial pressure waveform has been used to measure stroke volume (see below under New Techniques in Pediatric Intravascular Monitoring).

Mechanical and electronic components of the intravascular pressure measurement system are important considerations when interpreting waveforms [57]. The shortest possible large-bore, stiff plastic tubing should be used. Minimizing the number of stopcocks and connections will also improve the fidelity of the transmitted pressure wave. Thorough flushing before use to produce a bubble- and clot-free fluid path is critical. Periodic recalibration at the right atrial level is important to account for "drift" in the transducer setting. When ringing or overdamping is recognized, some monitor models offer adjustment of electronic filter frequency. The routine setting should be 12Hz. If the arterial tracing is underdamped, e.g. overshoot producing an artificially high spike as the systolic pressure, filter frequency may be decreased as low as 3Hz to compensate. Conversely, if overdamped, the filter frequency may be increased to as high as 40Hz. Mechanical devices (ROSE®, Accudynamic®) may also be inserted to change the resonance frequency and/or damping factor of the system.

**Figure 17.8** (*Top panel*) The arterial pressure tracing with depressed (A) and normal (B) myocardial contractility. (*Middle panel*) Low (A) and normal (B) systemic vascular resistance. (*Lower panel*) Hypovolemia (A) and normovolemia (B) – arrows represent positive pressure ventilations. Reproduced from Gregory [70] with permission from Elsevier.

Under no circumstances should a bubble be intentionally introduced into the system to produce increased damping effect. Appropriateness of resonance frequency may be tested by flushing the system from a pressurized bag of heparinized saline, stopping suddenly, and observing the number and amplitude of oscillations required to return to baseline waveform. Proper damping is signified by one oscillation below and one above the mean before return to normal waveform [72,73].

Failure of arterial pressure monitoring systems is always possible during surgery, due to mechanical problems such as kinking or clotting of the catheter. Spasm of the artery is more common than in adults, and the artery may be compressed, such as aberrant right subclavian compression from a TEE probe or compression of an axillary artery from a sternal retractor. A back-up oscillometric blood pressure cuff should always be present, preferably placed on a different extremity than the arterial catheter.

## Central venous, right and left atrial waveforms

Normal atrial (i.e. central venous) pressure waveforms consist of the A, C, and V waves corresponding to atrial contraction, closure of the tricuspid or mitral valves, and ventricular contraction. Normal right atrial A wave pressure is lower than V wave pressure, which is usually less than 10 mmHg. Changes from the normal tracing can give important information about the hemodynamic status and cardiac rhythm of the patient. For example, when atrioventricular synchrony is lost, as in junctional ectopic tachycardia or supraventricular tachycardia, the A wave disappears and the V wave enlarges considerably, reflecting backward transmission of ventricular pressure through an ineffectively emptied atrium (Fig. 17.9). Determining the cardiac rhythm from the ECG is often difficult at rapid heart rates because the P wave of the ECG is indiscernible. The left or right atrial waveform can give crucial added information in this situation, clearly retaining the A wave in cases of sinus tachycardia. Competency of the AV valves can also be assessed from

**Figure 17.9** ECG demonstrating normal sinus rhythm in the first third of the panel, with onset of supraventricular tachycardia. Note the arterial pressure tracing with a 12–15 torr decrease in systolic pressure, and the loss of the A wave on the central venous pressure tracing, with the appearance of large V waves with a systolic pressure increase from 10 to 16 mmHg.

the atrial tracing. Mitral or tricuspid regurgitation will produce a large V wave on the left atrial tracing. It is often very useful to record the vascular pressure tracings in sinus rhythm at baseline for later comparison.

## New techniques in pediatric intravascular monitoring

### **Cardiac output monitoring**

Because traditional percutaneous, balloon-tipped pulmonary artery catheterization is limited in small children and those with intracardiac shunting, several other methods to measure cardiac output and oxygen delivery in patients with congenital heart disease have recently been applied. Lithium dilution cardiac output (LiDCO) uses a standard central line in the SVC or even a peripheral IV catheter, and a special femoral artery catheter equipped with a lithium-detecting electrode. A dilute solution of lithium chloride is injected into the vein and arterial blood is withdrawn into the lithium electrode. The cardiac index is related to the area under the curve of the change of lithium concentration. This method has been demonstrated to have reasonable correlation with thermodilution cardiac output in children after congenital heart surgery. In a study of 48 measurements in 17 patients 2.6-34 kg, correlation between LiDCO and thermodilution cardiac output was good ( $r^2 = 0.96$ , mean bias  $-0.1 \pm 0.31 \,\text{L/min}$  [74].

Transpulmonary thermodilution cardiac output uses a similar principle to LiDCO, with temperature as the indicator instead of lithium concentration. Cold saline is injected into a central venous catheter and, via a thermistor placed in a femoral artery, a time temperature curve is derived, which correlates reasonably well with standard thermodilution cardiac output as measured by a standard pulmonary artery catheter [75]. Both lithium and any thermodilution method are limited to patients without any intracardiac shunting, significantly restricting their use in congenital heart disease.

Yet another newer method is pulse-contour analysis of the arterial waveform (PiCCO), which relates the contour and area under the curve to the stroke volume, and thus the cardiac output. This continuous method is periodically calibrated using the transpulmonary thermodilution cardiac output as described above (again making the method invalid with intracardiac shunting), and demonstrated good correlation with transpulmonary thermodilution in a recent study of 24 pediatric patients after cardiac surgery ( $r^2 = 0.86$ , mean bias  $0.05 \pm 0.4 \text{ L/min/m}^2$ ) [76].

## Central venous oxygen saturation monitoring

Monitoring of intravascular oxyhemoglobin saturation using reflectance catheters has been used in the umbilical artery, pulmonary artery, and adult-sized central venous catheters for a number of years, but only recently have standard pediatric sized 4 and 5 Fr, double- and triplelumen CVCs become available for routine use to measure central venous oxygen saturation (ScvO<sub>2</sub>) in pediatric patients. In 16 pediatric patients undergoing cardiac surgery, Liakopoulos et al demonstrated good correlation between ScvO<sub>2</sub> as measured with the catheter, versus blood co-oximetry ( $r^2 = 0.88$ , bias  $-0.03 \pm 4.72\%$ ) [77] (Fig. 17.10).The advantage of this method is that it is an

**Figure 17.10** Central venous oxyhemoglobin saturation ( $ScvO_2$ ) in the superior vena cava, comparing blood co-oximetry to fiberoptic reflectance spectroscopy. (A) Correlation between catheter ( $ScvO_2$ -cath %) and blood co-oximetry ( $ScvO_2$ -blood %). (B) Bland–Altman plot of bias and precision between the two methods. Reproduced from Liakopoulos et al [77] with permission from Lippincott Williams & Wilkins.

accurate measure of oxygen delivery that is independent of intracardiac shunting, and thus may have better utility in the congenital heart disease patient. More outcome data are needed for this technique but it may prove to be a useful adjunct for continuous monitoring of oxygen delivery in major cases.

### **Emergency vascular access**

Intraosseous access to the venous circulation has been described for use during a crisis when no other venous access is available, e.g. during cardiopulmonary resuscitation or shock [78]. Rarely, it may be required for emergency resuscitation in the operating room or intensive care unit, and therefore it is necessary for the pediatric anesthesiologist to be familiar with the technique. Normally this procedure is used only in small children, and the flat surface of the proximal tibia is used. Commercially available 14 or 16 ga intraosseous needles or 16 ga bone marrow aspiration needles may be used. The site is aseptically prepared, the skin is punctured and the outer bony cortex is contacted. With a boring motion, the needle is advanced through the outer cortex into the marrow space, heralded by a sudden loss of resistance. Infants have active marrow production in long bones and when the stylet is removed and the needle aspirated, bone marrow should appear in the hub. Rapid infusion of 10 mL normal saline without extravasation confirms proper placement, and emergency drugs and fluids may be administered. They reach the central circulation via the bone marrow sinusoids, which connect to the emissary veins from the bony cortex and then to the larger veins draining into the central circulation. Drugs injected intraosseously, e.g. epinephrine, reach the heart slightly more slowly than when injected into a central vein, but the peak drug levels are not different [78]. Intraosseous needles should be available for the rare crisis in the operating room or intensive care unit. They should be replaced as soon as possible with conventional peripheral or central venous access.

## **Complications of vascular access**

## Thrombosis

Thrombosis is the single most frequent complication, especially among infants. Central venous thrombosis secondary to vascular access develops in 5.8% of neonatal patients, which is ten times that of older patients, and accounts for 40–50% of central venous thromboses after congenital heart surgery [79]. The frequency significantly decreases in patients over 6 months of age. Factors that contribute to the risk of thrombosis include:

- large-bore catheters in small vessels, i.e. larger than 4 Fr in small infants
- duration of cannulation exceeding 7 days

- venous stasis due to extreme fluid restriction or low cardiac output
- infusion of high osmolarity fluids, i.e. concentrated dextrose in parenteral nutrition fluids
- hypercoagulable states [80].

Other risk factors for thrombosis include protein C resistance due to factor V Leiden mutation, prothrombin mutations, and methylenetetrahydrofolate reductase mutations [81], elevated preoperative C-reactive protein [82] and arterial catheterization with the use of vasoconstrictors such as norepinephrine, vasopressin or terlipressin [83]. Immediate consequences of SVC thrombosis include SVC syndrome [84] with increased intracranial pressure, and chylothorax from ineffective drainage of the thoracic duct into the SVC. IVC thrombus leads to ascites, renal and intestinal dysfunction, and edema of the lower abdomen and extremities. The patient must be assessed carefully for signs of thrombosis, and suspicion of thrombosis should be evaluated by ultrasound examination.

Treatment modalities include removing the catheter, heparinization, thrombolytic agents such as tissue plasminogen activator and urokinase [85-87], antithrombin III replacement [88] and surgical thrombectomy. Mortality from SVC thrombosis is reported to be as high as 33% and therefore it is critical to try to prevent this complication, preferably by avoiding SVC catheters in patients under 4kg. Thrombosis also leads to a higher rate of infection [89,90]. Heparin-bonded catheters may decrease the rate of thrombosis and do not increase risk of bleeding [89,91]. They may also lead to a lower rate of catheter colonization and infection [92]. However, it is currently not possible to bond both heparin and antibiotics to the same catheter. In patients with occlusion of central veins from previous catheters, magnetic resonance venography may be useful in identifying patent veins for future interventions [93].

Thrombosis or dissection of an artery is a serious complication that must be treated immediately. Immediately after arterial catheter placement, it is important to inspect the distal extremity, comparing it to the other extremity, and palpate distal pulses. Placement of a pulse oximeter probe distal to the catheter serves as a continuous monitor and early warning of vascular insufficiency. Transient compromise to perfusion immediately after catheter placement due to arterial spasm or during low output states may be observed. However, when extremity perfusion is significantly compromised, treatment by removal of the catheter, use of vasodilators, warming the extremity, heparin, thrombolytics, surgical consultation for thrombectomy or surgical reconstruction is indicated [94].

### **Malposition/perforation**

Central venous catheter tips should not lie in the right atrium. Adult and pediatric studies have consistently

demonstrated a higher rate of heart and great vessel perforation with associated cardiac tamponade when catheter tips are in the atrium [27,95–99]. Perforation is also less common with right-sided lines, e.g. right IJ or subclavian, because the catheter tip is parallel to the vein wall. The catheter tips of left-sided lines are frequently at a 45-90° angle of incidence to the SVC or atrium, and mechanical models demonstrate that this position is more likely to lead to great vessel perforation [100]. Finally, 5-10% of patients with congenital heart disease have a left SVC [99] which most often drains into the coronary sinus or left atrium and both of these sites are undesirable locations for a catheter tip [101]. Thus the ideal position of a CVC is in the mid SVC with the tip parallel to the vein wall (see Fig. 17.3). Soft polyurethane or silicone catheters are also much less likely to perforate than stiffer polyethylene catheters [100].

Perforation is recognized by inability to consistently aspirate blood, an abnormal waveform, and signs and symptoms of pericardial tamponade or hemothorax. Treatment involves aspiration of all the blood possible through the catheter and establishing alternative access, intravascular volume replacement, and drainage of the pericardial or pleural blood, by needle, tube or surgical exploration.

Many authorities recommend positioning the tip of the catheter in the superior half of the SVC, above the pericardial reflection. This recommendation is based on the theoretical concept that if there is a perforation, cardiac tamponade will not be produced, and also the catheter tip will be above the SVC bypass cannula and thus yield accurate CVP measurements on cardiopulmonary bypass [102]. There are several problems with this approach in pediatric anesthesia and surgery, particularly in small patients. First, the SVC is often only 4-5 cm long, leaving little room for error in placement. It is preferable to have the catheter slightly too deep in the SVC, because this will lead to accurate pressure measurements and proper infusions of drugs and fluids. When a multilumen catheter is positioned too high, a proximal port may not be intravascular, leading to extravasation of important or caustic drugs and fluids [103]. In addition, the pericardium is usually opened in congenital heart surgery and drained postoperatively, rendering placement above the pericardial reflection unnecessary. Many series of catheter placements in children document that the IJ route results in tip placement in the SVC or RA 98-100% of the time, whereas the subclavian route has a 5-15% incidence of catheter malposition, i.e. across the midline in the contralateral brachiocephalic vein or up the ipsilateral internal jugular vein.

Despite numerous previous reports of cardiac perforation by central venous catheters, and the publication of studies documenting height- and weight-based formulas for depth of insertion of SVC catheters in infants [31], reports of cardiac perforation resulting in death or necessitating surgical exploration by sternotomy continue to occur [104].

When IVC catheters are used, accurate CVP measurements are obtained whether above or below the diaphragm usually. Umbilical venous catheters (UVC) should be above the level of the diaphragm at the IVC RA junction, but not in the RA [105] to ensure passage through the ductus venosus and parallel position to the IVC wall [106]. In a series of 128 portal vein thromboses in neonates, 73% of them had a UVC and in half of these the UVC was malpositioned; this constituted a major risk factor for poor outcome [107].

A recently described complication of femoral venous catheters is inadvertent placement in the lumbar venous plexus, which may result in paraplegia from epidural hematoma or infusion of vasoconstrictive substances [108,109]. Catheterization of the lumbar venous plexus usually occurs when there is partial or total occlusion of the IVC from previous interventions, and the guidewire passes posteriorly through collateral circulation into the lumbar plexus. This malposition may be suspected during insertion when resistance to catheter passage is encountered or the catheter will not thread its entire length. An anteroposterior radiograph reveals an abnormal catheter course, often appearing to be more lateral than normal. A lateral radiograph will definitely diagnose such malposition where the catheter tip passes posterior to the vertebral bodies. The catheter must be removed immediately and the patient assessed for neurological deficit if this malposition is discovered. Retroperitoneal hematoma from perforation of the femoroiliac vessels from catheter or guidewire can also occur [110].

Inadvertent arterial puncture can nearly always be prevented by the use of an ultrasound guidance system for central venous catheter placement (see above). However, if this complication occurs, the following general principles are useful. After needle puncture, if there is any question about whether the vessel is an artery, remove the needle immediately, elevate the area, and hold firm pressure for 5-10 min. A small-bore needle puncture of the carotid or femoral artery, e.g. 20ga or smaller, is not usually an indication to cancel surgery. If a larger hole is created in the artery, i.e. a dilator and the catheter have been placed, pressure transduction can be used to confirm location. In this case, a discussion with the surgeon must ensue. Normally, the catheter can be removed, and pressure held without consequences unless a very large catheter was used, e.g. introducer sheath or large-bore CVP catheter, in which case surgical exploration and repair should be undertaken. In most cases of elective cardiac surgery, it is prudent to postpone the case if a large hole has been made in the artery. The case can usually be safely

performed 24 h later if no bleeding has occurred. In emergency or urgent cases which must proceed despite a large hole in the artery, the neck or groin should be prepped into the field for exploration if excessive bleeding or hematoma formation occur.

## Pneumothorax

This complication is most frequent with the subclavian approach, but also may occur with the internal jugular approach, especially with the low puncture sites, e.g. jugular notch approach. To avoid this complication with the subclavian approach, it is important to advance the needle only during expiration. A very shallow approach with the needle directed just posterior to the clavicle and at the sternal notch is also important. For the IJV, a higher puncture site and limiting the caudad advancement of the needle to stop above the clavicle will usually prevent this complication [111].

Continuous aspiration should be performed as the needle is advanced using a saline-filled syringe. If air is aspirated as the needle advances, attempts at venipuncture should stop immediately and careful monitoring for compromise of ventilation and hemodymanics should ensue. A chest radiograph should be obtained if the start of surgery is not imminent to make the diagnosis, and pleural drainage by needle, catheter or tube should be undertaken if indicated. After sternotomy, the pleura can be opened on that side during sternotomy if pneumothorax is diagnosed or suspected.

### Infection

Catheter-related sepsis results in significant morbidity, some mortality, prolongation of ICU stay, and increased expense. The incidence of arterial catheter related infection is low. A study of 340 arterial catheters in children revealed a 2.3% incidence of local site infection and 0.6% catheter sepsis [112]. However, central venous catheterassociated bloodstream infection is a major problem. There is strong evidence that several strategies may be employed to reduce this complication [113]. The first is the use of full barrier precautions, e.g. sterile gown, mask, gloves, and careful septic technique during insertion [5]. Second, chlorhexidine has been shown to be superior to other antiseptic solutions. Finally, antibiotic bonding to the resin of the catheter will reduce infection [114]. This can be done in several ways, i.e. antibiotics already embedded in the resin (minocycline/rifampin or chlorhexidine/silver sulfadiazine) or applied at the time of insertion by soaking the outer and inner surfaces of the catheter in a negatively charged antibiotic at 100 mg/mL concentration such as vancomycin, cefazolin or other cephalosporins. Antibiotic is slowly released from the catheter, delaying and reducing colonization and reducing the incidence of catheter sepsis. The increased cost per

catheter is about \$20 but one episode of catheter sepsis is estimated to cost \$14,000 in 1995 dollars [114]. In a study of antibiotic-impregnated catheters in 225 critically ill children, minocyline/rifampin-coated catheters delayed the onset of infection in those patients who were infected to 18 days, from 5 days in non-antibiotic catheters [115]. Central venous catheters indwelling more than 5–7 days have an increased incidence of colonization and sepsis [116] as well as vessel thrombosis.

Suspicion of catheter sepsis should be followed by peripheral blood culture, and blood culture from the central line. The catheter should be removed when possible and the tip cultured. Institute antibiotic therapy empirically tailored to the most common institutionspecific pathogens, and provide coverage for *Staph. epidermidis*, which continues to be a common pathogen in catheter-related sepsis. A comprehensive, systematic intervention program to prevent central line-associated bloodstream infections in a very busy cardiac ICU, including insertion, access, and maintenance protocols, and a protocol for timely removal of central lines, reduced the infection rate from 7.8 infections per 1000 catheter days to 2.3 infections per 1000 catheter days [117]. A recommended central line insertion bundle is displayed in Table 17.2.

### Arrhythmias

Other complications associated with vascular access procedures include arrhythmias. Ectopic atrial tachycardia, in particular, has been associated with a catheter tip in the right atrium [118,119]. Atrial fibrillation has also been associated with CVC placement [120]. More commonly, arrhythmias occur with the passage of the guidewire [121] and include isolated premature atrial contractions, supraventricular tachycardia and, if the guidewire is advanced into the right ventricle, premature ventricular contractions and even ventricular tachycardia or fibrillation. Complete heart block has also been described during guidewire passage in small infants [122]. Great care must be taken when passing the guidewire to stop advancing it when significant arrhythmias are encountered, and when advancing the catheter over the wire, to retract the wire as the catheter is advanced. Patients particularly at risk for significant arrhythmia are those with known history of arrhythmia and also those with significant right ventricular hypertrophy.

### Systemic air embolus

Systemic air embolus is a constant threat for patients with central or peripheral venous catheters and intracardiac shunting [123], particularly two-ventricle patients with right-to-left shunting and single-ventricle patients in infancy who have obligate mixing of systemic and pulmonary venous return in the systemic ventricle. Air may lodge in the coronary arteries (especially the right), pul-

monary artery or cerebral vessels, leading to potentially serious complications. Observation of the TEE or transcranial Doppler ultrasound as used for neurological monitoring reveals rapid passage of any introduced systemic venous air into the aorta and cerebral circulation. For this reason, meticulous attention must be paid to prevent introduction of air into the systemic venous circulation as much as possible. Precautions include thorough de-airing of all intravenous infusions before connection to the patient, de-airing of continuous flush central venous lines, air filters on continuous infusions, and careful technique when injecting drugs and fluids. The latter involves holding any syringe upright, flushing fluid from the proximal intravenous tubing into it, and aspirating and tapping the syringe first before injecting so that any air is trapped at the superior aspect of the syringe. Constant vigilance of all infusions, and use of TEE as a monitor for intracardiac air and the transcranial Doppler for systemic arterial air, may reduce the risk of significant air embolus.

### Other complications

Thoracic duct injury, chylothorax [124], brachial plexus injury, cervical dural puncture [125], phrenic nerve injury [126], vertebral arteriovenous fistula [127], Horner syndrome [128], and tracheal puncture have also been described. These complications can essentially be eliminated with skilled personnel using ultrasound-guided techniques to accurately identify the location of the vessel.

Finally, embolization of catheter or guidewire fragments sheared off during difficult insertion procedures occurs occasionally [17]. Never withdraw a guidewire or catheter through a needle if any resistance is encountered. If resistance is encountered, the guidewire and needle, or catheter and needle, must be withdrawn completely from the vessel together as a unit.

## **Respiratory monitoring**

The continuous monitoring of ventilation in the anesthetized patient is the standard of care for pediatric anesthesia [129]. Inadequate ventilation is one of the most frequent causes of patient injury in the American Society of Anesthesiologists' Closed Claims database [130], including in pediatric patients. This section will review methods of respiratory monitoring, including inspection and auscultation, pulse oximetry, capnography and anesthetic gas monitoring, and the monitoring of ventilation volumes and pressures.

### Inspection and auscultation

Although not often emphasized due to the proliferation of technology to monitor ventilation, inspection of the patient for adequate and symmetrical chest rise, lack of signs of inspiratory or expiratory obstruction, and lack of cyanosis or pallor representing inadequate oxygenation are important monitoring techniques for every anesthetized patient. The precordial or esophageal stethoscope, although used less frequently in recent years [131], still is very useful for continuous auscultatory monitoring of respiration and heart tones, and serves as an adjunct to the electronic devices used for every case. A standard stethoscope is essential equipment to have available at all times to assess ventilation, as equipment failures do occur.

### **Pulse oximetry**

Pulse oximetry uses the unique light absorption characteristics of oxy- and deoxyhemoglobin to estimate the arterial oxygen saturation (SpO<sub>2</sub>). In standard pulse oximetry, two wavelengths of 660 and 930nm are used, transmitted through tissue to a detector that uses an algorithm to measure only the pulsating, arterial portion of oxyhemoglobin and filters out absorption due to nonpulsating capillaries, veins, bone and soft tissue [132]. The widespread clinical availability of pulse oximetry since the mid-1980s has done more to change anesthetic and critical care practice in the past two decades than any other single monitor. Despite the obvious intuitive value of measuring SpO<sub>2</sub> to prevent arterial desaturation episodes, to date there are only four published large controlled trials of pulse oximetry and outcome, all in adults, and although these trials demonstrated reduced incidence of perioperative hypoxemia, they did not demonstrate a difference in outcomes [133].

The utility of pulse oximetry in pediatric anesthesia was conclusively shown by Coté et al in two studies [134,135]. The first was a single-blind study of 152 patients where all had pulse oximetry but in half the data were not available to practitioners, whereas in the other half the monitor and alarms were available. Major desaturation (<85% for >30 sec) occurred more frequently in the blinded group (35 versus 11, p = 0.021). The pulse oximeter diagnosed hypoxemia before cyanosis and bradycardia were evident. In a second single-blind study of pulse oximetry and capnography in 402 patients, 260 ventilation problems were detected in 153 patients; blinding the oximeter data increased the number of patients experiencing major desaturation events (31 versus 12, p = 0.003), blinding the capnograph data had less effect, with only five of 59 major desaturation events first diagnosed by the capnograph, versus 41 by the oximeter and 13 by the anesthesiologist. These studies firmly established the utility of the pulse oximeter in preventing and diagnosing major desaturation events, and were the cornerstone of the current requirement for pulse oximetry in all pediatric anesthetic and sedation cases.

### Pitfalls, problems, and artifacts of pulse oximetry

There are a variety of manufacturers of pulse oximeters, and the instructions for each should be followed carefully, particularly the proper disposable or reusable probe size for each patient. In small infants less than 3 kg, it is often desirable to wrap the disposable probe around the hand or foot, as these will allow light transmission but are often more secure than their tiny digits. Bright ambient light should be shielded by covering the probe. Despite the ubiquitous use of pulse oximetry, it should be remembered that there are myriad manufacturers and proprietary algorithms for signal acquisition and averaging, and that in the normal arterial oxygen saturation ranges >90%, pulse oximetry is accurate to  $\pm 2\%$ , with potentially less accuracy at SpO<sub>2</sub> <90% [132].

Cyanotic congenital heart disease (CHD) is common in pediatric anesthesia, and several studies have compared SpO<sub>2</sub> to measured blood arterial oxyhemoglobin saturations in cyanotic CHD using co-oximetry. Schmitt et al [136] studied 56 children with cyanotic CHD undergoing cardiac surgery with two simultaneous steady-state measurements comparing SpO<sub>2</sub> to co-oximeter measured arterial blood oxygen saturation (SaO<sub>2</sub>) in each patient. The linear regression between  $SpO_2$  and  $SaO_2$  was 0.91; however, using Bland-Altman analysis, the bias and precision between the two methods were very close when  $SpO_2$  was >80%, but much worse when  $SpO_2$  was <80%, with the pulse oximeter overestimating the measured arterial saturation by 5.8%, and two standard deviations of precision being only 10%. In a more recent study using two modern generation pulse oximeters (see below), Torres et al [137] made 122 paired observations in 46 children with acyanotic and cyanotic CHD after cardiopulmonary bypass, and found that in patients with SpO<sub>2</sub> <90%, the bias was 3-6%, with the oximeter reading higher than the measured blood saturation, with precision 5–6%. Thus, although the pulse oximeter is an excellent trend monitor in cyanotic CHD, it will consistently overestimate the true arterial saturation, especially with SpO<sub>2</sub> <80%.

Poor peripheral perfusion states are common in pediatric anesthesia due to hypothermia, hypovolemia, cardiogenic shock, and many other etiologies. Since pulse oximetry relies on adequate perfusion of the digits so the device can detect oxyhemoglobin saturation in pulsating tissue, vasoconstriction that accompanies the conditions noted above can prevent detection of minimal levels of arterial pulsation and prevent the pulse oximeter from functioning. Villaneuva et al [138] studied 19 children 2–60 kg requiring arterial catheters for surgery, and measured the performance of two older generation pulse oximeters for accuracy and functioning in response to low perfusion states induced by both inflation of a blood pressure cuff and by clinical conditions, using seven perfusion variables (age, weight, core and skin temperature, hemoglobin, pulse pressure, and laser Doppler blood flow). They compared bias in 94 paired measurements between  $SpO_2$  and measured arterial hemoglobin saturation. Overall, bias was within  $\pm$  2%. Factors increasing bias included decreased weight, decreased pulse pressure, decreased core temperature, and decreased laser Doppler flow. The strongest predictor of inaccurate readings was skin temperature <30°C. In the six instances of oximeter failure to function, low skin temperature was present in all. Pulse oximetry can also serve as a perfusion monitor in an extremity or digit distal to an arterial catheter, i.e. radial or femoral; if an adequate pulse oximeter plethysmograph signal is present, it is a sign of adequate perfusion.

Intravascular dyes which absorb light in the same range as hemoglobin predictably will affect SpO<sub>2</sub>. Among the commonly used dyes, methylene blue produces a significant, short-lived, artifactual desaturation. Indocyanine green produces a less profound desaturation effect, and indigo carmine's effect is even less profound [139]. Although bilirubin light absorption spectrum has some overlap with hemoglobin, hyperbilirubinemia has been shown to have little effect on the accuracy of pulse oximetry [140]. Fetal hemoglobin also has little effect on the accuracy of pulse oximetry [141].

The usual sites for pulse oximetry on the extremities may be unavailable due to burns, trauma, surgery on the extremities or congenital malformations. In these cases, conventional pulse oximeter probes have been placed on the earlobe, bridge of nose, buccal mucosa, tongue, and penis [142–144]. More central locations (buccal mucosa, tongue, nose) will experience desaturation and resaturation changes significantly earlier than the distal sites on the hand or foot [145]. In cases where major vascular structures may be occluded during surgery or where access to the extremities is limited (cardiac surgery), it is often helpful to place two or more pulse oximeter probes on both upper and lower extremities, in case of failure of one site to function.

### Newer developments in pulse oximetry

Newer generation pulse oximeters developed over the past 5–10 years (Masimo Signal Extraction and Rainbow Technologies, Masimo Corporation, Mission Viejo, CA, and Nellcor N-395 and N-595, Nellcor-Puritan Bennett Corporation, Pleasanton, CA) have been designed to address some of the limitations of the older technology, and to extend the capabilities of pulse oximetry to measure new parameters, such as total hemoglobin and perfusion by quantifying the plethysmographic signal. The new technologies incorporate more sensitive electronic filtering designed to detect true arterial pulsation during motion or poor peripheral perfusion. In a study of 75

children monitored in the postanesthesia care unit where motion artifact is a frequent problem, Malviya et al [146] compared the new with the old technology and determined that the new technology correctly determined the 27 true desaturation events of SpO<sub>2</sub> <90% 100% of the time, whereas the older technology was successful only 59% of the time. In addition, false alarms were reduced by 50% with the new technology.

The newer technologies use up to eight wavelengths of light and are capable of determining accurate  $\text{SpO}_2$  in the presence of abnormal hemoglobins, including carboxyhemoglobin and methemoglobin [147]. With increasing concentrations of either of these abnormal hemoglobins, conventional two-wavelength pulse oximetry reads an  $\text{SpO}_2$  that converges toward 85%, the isosbestic point for normal hemoglobin. However, because both of these substances have higher affinity for hemoglobin than oxygen, the true oxygen saturation is significantly lower. The additional wavelengths will detect these abnormal hemoglobins and also measure a true  $\text{SpO}_2$ , and thus are important additions if the patient is at risk for these conditions.

Despite this technological advance, unless the patient is at risk for CO inhalation, such as after a burn injury, or methemoglobinemia, such as with high-concentration NO inhalation, its utility in routine pediatric anesthesia is limited. Another novel use of the new technology is to measure total hemoglobin; this is proportional to the total absorption of light in the light path, but depends on a constant SpO<sub>2</sub> and blood volume, i.e. changes in the amount of hemoglobin in the light path due to changes in intravascular volume can be confused with changes in absolute hemoglobin concentration. With these caveats, this non-invasive estimation of hemoglobin concentration has reasonable accuracy, and could find clinical utility as a trend monitor [147].

Finally, despite these advances in technology, Robertson & Hoffman [148] found that two different late-generation pulse oximeters performed significantly differently under adverse clinical conditions in terms of rejection of data, and that as  $SpO_2$  decreased, particularly to <70%, there was significant disagreement, with a bias of 3–7% at these low saturations.

Pulse oximetry can serve as a more objective index of peripheral perfusion by converting the pulsatile component of the light absorption signal into an electric signal that represents the plethysmograph at that particular location. Displaying this signal continuously can serve as a useful estimate of tissue perfusion in that location, i.e. a strong beat-to-beat signal variation represents adequate tissue perfusion. In addition, the degree of respiratory variation of arterial pulse pressure with positive pressure variation can be an important measure of fluid status, i.e. the greater the respiratory variation in the pulse pressure, the more the relative hypovolemia; intravascular fluid administration will often reduce this respiratory variation [149]. Because the plethysmograph derived from pulse oximetry is derived from arterial pulsations, it is now being used as a non-invasive monitor of volume status. The variation in the plethysomographic waveform amplitude of the pulse oximeter has been shown to correlate well with variation in arterial pulse pressure intraoperatively and in the intensive care unit; future study will be required to determine whether this modality could be used clinically.

All of the above cited data suggest that pulse oximeter values, particularly under challenging clinical conditions, should always be interpreted in light of the clinical condition of the patient and other respiratory and circulatory parameters.

### Capnography

Monitoring of end-tidal carbon dioxide (CO<sub>2</sub>) is a requirement for all general anesthetics, both to confirm the initial correct placement of endotracheal tubes and other airway devices, and also to continuously monitor adequacy of ventilation [129]. Most capnographs utilize infrared light to quantify CO<sub>2</sub> in the exhaled gas, and there are two major configurations: mainstream and sidestream. Mainstream capnography uses an in-line detector in the breathing circuit near the connector of the endotracheal tube. It requires disposable cuvettes and frequent calibration. Advantages are rapid response time and no aspiration of gas from the breathing circuit. Disadvantages include a bulky apparatus that may place tension on the endotracheal tube. Sidestream capnographs aspirate gas from the breathing circuit at the elbow distal to the Y-piece. Advantages include lightweight small-bore tubing for aspiration and automatic calibration. Disadvantages include a relatively slower response time, and potential for aspiration of large volumes of gas up to 200 mL/min, which may be problematic with small infants and low fresh gas flows. Microstream capnography uses lower gas aspiration volumes of 50 mL/min or less [150].

After direct laryngoscopy to visualize an endotracheal tube through the vocal cords into the trachea, capnography is the gold standard to confirm correct placement of the endotracheal tube. However, this method is certainly not foolproof, and false-positive detection of  $CO_2$  with a waveform may be seen with esophageal intubation and detection of  $CO_2$  introduced into the stomach with mask ventilation; this yields low values of end-tidal  $CO_2$  which disappear within 5–6 breaths. A tube sited at or just above the larynx can detect  $CO_2$  but be at risk for dislodgment. Falsely negative  $CO_2$  detection with correct endotracheal tube placement may be seen in cardiac arrest or very low cardiac output states where pulmonary blood flow is insufficient. It may also be seen with severe bronchospasm preventing gas exchange.

**Figure 17.11** Common capnography variants. (A) Normal: note rapid upslope and flat plateau with minimal inspired CO<sub>2</sub>. (B) Large leak: causes include large endotracheal tube leak or partial disconnection of sampling line. (C) Rebreathing CO<sub>2</sub>: causes include increased anatomical dead space in patient or circuit, exhausted CO<sub>2</sub> absorber, addition of inspired CO<sub>2</sub>. (D) Large ETCO<sub>2</sub>–PaCO<sub>2</sub> gap: PaCO<sub>2</sub> was 40 mmHg in this patient with cyanotic heart disease.

A normal end-tidal CO<sub>2</sub> tracing has a rapid upslope, a long flat plateau with minimal upslope, rapid return to baseline of zero without rebreathing, and immediate transition into the next inspiration (Fig. 17.11A). Common findings include separation between end-expiratory and the next inspiration with large endotracheal tube leak (Fig. 17.11B). If the exhaled  $CO_2$  does not return to baseline of zero, rebreathing may be occurring, often caused by a faulty expiratory valve or by increased dead space in the breathing system, i.e. by a condenser humidifier too large for the patient's tidal volumes (Fig. 17.11C). A steep expiratory upslope often signifies expiratory obstruction, most often from bronchospasm. Oscillations of the ETCO<sub>2</sub> values during the plateau phase usually signify minimal ventilator volumes caused by displacement of the lungs by the cardiac stroke volume.

Besides monitoring the adequacy of ventilation, the purpose of capnography is to estimate, as accurately as possible, the patient's arterial  $CO_2$  tension to avoid hypercapnia and its undesirable effects on pulmonary artery and intracranial pressure, and hypocapnia and its undesirable effects in decreasing cerebral blood flow. The difference between end-tidal and arterial  $CO_2$  in patients with normal heart and lungs, and no increase in anatomical or physiological dead space, is less than 3-5mmHg. In pediatric anesthesia, the gap is often larger and there are several causes. Dead space in the breathing circuit (an extension of the anatomical dead space where there is flow of gas but no gas exchange, thereby diluting the exhaled CO<sub>2</sub>) is a common cause, especially for small patients. The dead space volume in endotracheal tubes, endotracheal tube connectors, condenser humidifiers, Y-pieces and elbows, and mainstream capnographs will often cause a significant underestimation of the arterial CO<sub>2</sub>. Generally, the smaller the patient, the greater the effect. Premature infants less than 1.5kg in weight are especially affected [151]. Using small-volume endotracheal tube connectors, placing condenser humidifiers proximal to the CO<sub>2</sub> sampling line, or special endotracheal tubes with a CO<sub>2</sub> sampling lumen that extends to the tip of the endotracheal tube, have all been used to increase the accuracy of capnography in small patients [152–154] (Fig. 17.12C).

Cyanotic congenital heart disease is another common cause in pediatrics. Right-to-left intracardiac shunting causes blood to bypass the lungs, reducing pulmonary blood flow and thus the volume of blood relinquishing CO<sub>2</sub> to the exhaled gas. The end-tidal to arterial CO<sub>2</sub> gap may be 15-20mmHg or greater with significant cyanosis [155] (Fig. 17.11D). The relationship varies with each patient but in general, the more cyanotic the patient (greater reduction in pulmonary blood flow), the greater the CO<sub>2</sub> gap. Improving pulmonary blood flow, such as by the placement of a systemic to pulmonary artery shunt, will decrease the end-tidal to arterial gap. Patients with significant pulmonary hypertension with or without intracardiac shunt will often have a large gap. A decreasing end-tidal to arterial CO<sub>2</sub> gap often signifies increased pulmonary blood flow, accompanied by improvement in pulmonary hypertension or cardiac output. Finally, intrapulmonary shunting, such as that caused by lobar consolidation from pneumonia or atelectasis, causes a variable increase in end-tidal to arterial CO<sub>2</sub> difference, depending on the accompanying degree of hypoxic pulmonary vasoconstriction.

Capnography is useful for monitoring of ventilation in patients without an endotracheal tube. Although the dead space is increased under a facemask, capnography is effective in monitoring the adequacy of tidal volumes with spontaneous or assisted mask ventilation. Similarly, the dead space is slightly increased with the larger bore airway of the laryngeal mask airway, but monitoring of  $CO_2$  is essential when this device is used. Finally, monitoring ventilation with a divided,  $CO_2$  sampling nasal cannula during spontaneous ventilation with a natural airway during sedation and monitored anesthesia cases is now common practice and is especially useful when there is not direct proximity to the patient, i.e. MRI scanner [156].

As with any monitor using a mechanical/electrical interface, spurious capnograms and end-tidal  $CO_2$  values can be caused by equipment malfunction or failure. A partially disconnected  $CO_2$  sampling line or cracked connector can entrain room air and artificially lower end-tidal  $CO_2$  values. A  $CO_2$  sampling line occluded by exhaled moisture or secretions will read little or no end-tidal  $CO_2$ . Automatic machine calibration at inopportune times, i.e. immediately after intubation, as well as other malfunctions make it necessary to possess adequate clinical skills of auscultation by precordial, esophageal or standard stethoscope.

### Anesthetic agent monitoring

Most modern anesthetic gas concentration monitors are sidestream units combined with capnography, and use polychromatic infrared analyzers that detect each of the halogenated agents individually, as well as CO<sub>2</sub>, N<sub>2</sub>O and O<sub>2</sub>. These units are easy to use and calibrate, economical to operate, reliable, and are reasonably accurate. Mass spectroscopy has greater accuracy and also can measure nitrogen concentration, which is important in the diagnosis of pulmonary embolus. However, these units are more expensive and have largely been superseded by the infrared monitors. And although the modern units are fairly accurate, deviations as high as 5-11% relative value are seen with infrared when compared to the gold standard gas chromatography [157]. Thus, although it is important to measure inspired and end-tidal anesthetic concentrations, assessment of the relative anesthetic depth of the individual patient is critical. As with capnography, newer microstream technology which minimizes dead space will both improve response times and allow for aspiration of smaller volumes of gas from the breathing circuit for sampling, which is important in the care of small infants [158].

### Ventilatory volumes and pressures

Modern anesthesia machines have the capability to measure airway pressures, volumes, and flows using spirometery combined with pneumotachygraph technology; however, in most cases these parameters are not measured at the patient airway but at some point proximal to all the connections of the circle breathing system. This configuration introduces the potential for significant error in measurement of pressures and tidal volumes, particularly in small patients weighing less than 5-10 kg with tidal volumes <100 cc, because of the compression volume of the circle system. In other words, the average plastic disposable circle system has a compliance volume loss of 1–3 mL per cmH<sub>2</sub>O of pressure during inspiration; as much as 60 mL tidal volume is not delivered to the patient but rather to the circle system, with peak pressures of 20 cmH<sub>2</sub>O above end-expiratory pressure (Fig. 17.12). Badgwell et al [159] determined that with a standard disposable pediatric circle system and standard adult anesthesia bellows, total compliance volume of the system is about 190 mL with a peak inspiratory pressure of 20.

It is obvious that with small infants, the anesthesia machine readout may be very inaccurate. There are two potential solutions to this problem. First, newer generation modern anesthesia machines can calculate an exact breathing circuit compression volume during a preanesthesia machine check; during volume ventilation additional volume is added to each breath equal to the

Figure 17.12 Respiratory monitoring. (A) Standard modern anesthesia machine monitoring screen with compliance-compensated tidal volume, pressures, flows, inspiratory time, anesthetic gas concentration. (B) Respiratory loops: flow–volume and pressure–volume loops. (C) Configuration to minimize dead space: pediatric circle system; small infant condenser humidifier proximal to sampling line; minimum dead space (0.5 mL) connector.

compliance compensation volume [160]. This is only accurate if the circle system configuration is not changed after the machine check, i.e. if a distensible breathing circuit is extended to its full length, the compliance volume changes. Also, some systems will limit the extent of compliance compensation allowed for small tidal volumes less than 100–200 cc as a safety measure, so that sudden large inappropriate tidal volumes are not delivered to small patients in the event of a change in compression volume. The second method of solving this issue is to use a spirometry system attached to the proximal end of the endotracheal tube so that volumes and pressures are measured at the airway; this is possible with a variety of systems whether integrated into the anesthesia delivery system or stand-alone units made for infants.

## **Temperature monitoring**

Accurate monitoring of temperature during general anesthesia is an accepted standard of care in pediatric patients, because changes in body temperature are anticipated in these patients for a variety of reasons. The physiology of maintenance of body temperature, methods of achieving this, and complications of temperature homeostasis are discussed in Chapter 40. Measurement of temperature has been simplified by easy availability of thermocouple stand-alone probes, or esophageal stethoscopes, bladder catheters, skin temperature probes, tympanic membrane probes or pulmonary artery catheters with incorporated thermistors.

Central core temperature is best measured in the esophagus, rectum or nasopharynx. These sites are generally accepted to be the most accurate, and will be equivalent if the probes are placed properly. This means in the mid-esophagus, at least 2–5 cm into the rectum, and in the case of nasopharyngeal temperature, with the probe inserted to a depth equal to the distance from the nares to the tragus of the ear, placing the tip of the probe under the cribriform plate and thus in the closest proximity to the brain. Axillary temperature is often simple and convenient, especially in short pediatric cases, but several minutes may be required for temperature equilibration, and readings will be about 1°C lower. For major intraabdominal, intrathoracic, intracranial cases or surgery in small infants, a core temperature site should be chosen. For monitored anesthesia care or sedation cases, temperature monitoring should be readily available and used if temperature change is anticipated. If the brain is particularly at risk, i.e. intracranial or cardiopulmonary bypass cases, actual brain temperature may be up to 2°C above rectal temperature [161]. Measurement of skin temperature, i.e. sole of the foot, versus core temperature may provide added information to assess the degree of heat loss or peripheral vasoconstriction during major surgery. With thermal homeostasis and adequate peripheral perfusion, skin temperature at the sole of the foot should be no more than 5° below core temperature.

## **Urinary monitoring**

Monitoring of urine output with a bladder catheter is important for major surgery, where significant blood loss, hemodynamic change or fluid shifts are anticipated. Although influenced by a multitude of factors, generally a urine output of 1 cc/kg/h or greater is assumed to indicate adequate intravascular volume status and perfusion to the kidneys. Low or absent urine output can be due to mechanical obstruction of the tubing, hypovolemia or antidiuretic hormone secretion, with hypovolemia by far the most frequent cause. Although possible, measuring urinary sodium and osmolarity is rarely performed intraoperatively. Excessive urine output can be caused by hypervolemia, hyperosmolarity of the urine as seen in hyperglycemia (renal glucose threshold approximately 180 mg/dL in infants and children, may be lower in neonates), osmotic agents such as mannitol or diuretics such as furosemide. The color of the urine may provide important information; hematuria can be seen with hemolysis from cardiopulmonary bypass or a transfusion reaction, tea-colored urine from myoglobinuria during malignant hyperthermia or significant muscle crush injury. Cloudy urine may be from calcium oxalate crystals, proteinuria with concentrated urine or from urinary tract infection.

## Blood gas and other point-of-care testing

Rapid point-of-care testing, either in the operating room or in close proximity with rapid turnaround time, has made real-time monitoring of multiple parameters possible, especially for major surgery associated with significant blood loss or unstable patients in whom frequent assessment of blood gas values, hemoglobin, and other parameters is important to guide care. There are a variety of machines available but among the most useful is the point-of-care blood gas machine that also measures electrolytes, hematocrit, glucose, ionized calcium, measured oxygen saturation, and lactate values (Fig. 17.13). Modern machines can make all of these measurements on 0.5 cc or less of heparinized whole blood, with results available in less than 2min. Temperature correction algorithms and electronic recording of values make these machines suitable for electronic medical records. In cardiac surgery, major trauma, neonatal, spine surgery, thoracic surgery,

and other major surgical cases, measuring these parameters at regular intervals may provide rapid early warning of major changes in the patient's condition, e.g. metabolic acidosis, significant anemia or worsening A-aO<sub>2</sub> gradient, that are not evident from standard monitoring, and are available significantly sooner than sending the sample out to the hospital's regular clinical laboratories.

Other rapid tests available as point-of-care tests include rapid coagulation assessment with partial thromboplastin time, thromboelastography, or rapid platelet function tests, potentially directing specific therapy to improve coagulation in the individual patient. For all new modalities, an analysis of the cost/ benefit ratio, and careful assessment of the potential to improve outcomes are important. See Chapter 11 for a further discussion of coagulation monitoring.

## Neuromuscular transmission monitoring

Accurate assessment of the status of neuromuscular blockade in children is important when non-depolarizing neuromuscular blocking agents are utilized, because simply relying on an estimate of the half-life of the drugs is notoriously inaccurate [162]. Standard nerve-stimulating devices utilize current of 30–80 mA, and the most common method is to utilize the train-of-four scheme. The most common and standard placement for leads is to use small ECG leads, placed over the ulnar nerve, so that the thumb adduction via activation of the adductor pollicis brevis nerve can be observed. Any "fade" in the amplitude of contraction, observed visually, indicates residual neuromuscular blockade. The absence of any contraction

Figure 17.14 Absorption spectrum of oxyhemoglobin, deoxyhemoglobin, water, and lipids. Reproduced by courtesy of Somanetics Corporation.

with the train of four, or contraction only after a tetanic stumulus of 50 or 100 MHz, indicates dense neuromuscular blockade, and that reversal with neostigmine or other anticholinesterase agents should not be attempted. Other sites, such as the peroneal nerve or facial nerve, may also be utilized, the latter with caution because direct muscle contraction may be observed, causing an underestimation of the degree of blockade.

## Central nervous system monitoring

## Near infrared spectroscopy

Near infrared spectroscopy (NIRS) is used to measure both cerebral and somatic oxyhemoglobin saturation. Since its now classic description in 1977 by Jobsis [163], this technology has been the subject of over 1000 publications and, because of its non-invasive, compact, portable nature and potential for measuring tissue oxygenation in the brain and other organ systems during surgery and critical illness, is gaining more widespread clinical use. This section will examine the technical aspects of NIRS, parameters measured and clinical uses in pediatric cardiac and non-cardiac surgery and critical care, evidence for effectiveness in improving clinical outcomes, and pitfalls and complications of usage.

### Technical concepts of near infrared spectroscopy

Near infrared spectroscopy (NIRS) is a non-invasive optical technique used to monitor brain tissue oxygenation. Most devices utilize 2–4 wavelengths of infrared light at 700–1000 nm, where oxygenated and deoxygenated hemoglobin have distinct absorption spectra [164–166] (Fig. 17.14). Commercially available devices measure

**Figure 17.15** (A) Bilateral NIRS probes on an infant. (B) Four-channel NIRS monitor screen. L and R designate left and right cerebral hemispheres; S3 designates renal saturation with a probe placed on the flank at the T10–11 level; S4 designates mesenteric saturation with a probe placed in the midline between the umbilicus and symphysis publis. See text for further explanation.

**Figure 17.17** Different NIRS probes for neonate cerebral 1–4 kg (*far left*), neonatal somatic 1–4 kg (*second from left*), pediatric cerebral/somatic (4–40 kg) (*second from right*), adult >40 kg (*far right*). Reproduced courtesy of Somanetics Corporation.

**Figure 17.16** NIRS method: a light or laser-emitting diode emits light, which passes through the skin, skull, and meninges and into a small portion of the frontal cerebral cortex. Some light is scattered and some is absorbed by oxy- and deoxyhemoglobin, and a portion passes through tissues and is detected by a shallow and deep detectors, 3 and 4 cm from light source. The shallow component is subtracted out, leaving mostly intracranial signal. Reproduced courtesy of Somanetics Corporation.

the concentration of oxy- and deoxyhemoglobin, using variants of the Beer–Lambert equation:

$$\log(I_{I_o}) = \varepsilon_{\lambda} LC$$

where  $I_0$  is the intensity of light before passing through the tissue, I is the intensity of light after passing through the tissue, and the ratio of  $I/I_0$  is absorption. Absorption of near infrared light depends on the optical path length (L), the concentration of the chromophore in that path (C), and the molar absorptivity of the chromophore at the specific wavelength used ( $\varepsilon_{\lambda}$ ).

Cerebral oximetry assumes that 75% of the cerebral blood volume in the light path is venous and 25% arterial. This 75/25 ratio is derived from theoretical anatomical models. Watzman et al [167] attempted to verify this index in children with congenital heart disease by measuring jugular venous bulb saturation and arterial saturation, and comparing it to cerebral saturation measured with frequency-domain NIRS. The actual ratio in patients varied widely, but averaged 85/15.

In the various models of cerebral oximeters currently on the market, the sensor electrode is placed on the forehead (Fig. 17.15A) below the hairline. A light-emitting diode or laser emits infrared light, which passes through a "banana-shaped" tissue volume in the frontal cerebral cortex, to two or three detectors placed 3-5cm from the emitter. The screen displays regional cerebral oxygen saturation (rSO<sub>2</sub>) and trend over time (Fig. 17.15B). By using different sensing optodes and multiple wavelengths, extracranial and intracranial hemoglobin absorption can be separated. Narrow arcs of light travel across skin and skull but do not penetrate the cerebral cortex. Deep arcs of light cross skin, skull, dura, and cortex (Fig. 17.16). Subtracting the two absorptions measured, shallow from deep, leaves absorption that is due to intracerebral chromophores, and this processing renders the cerebral specificity of the oximeter (Fig. 17.17). However, the accuracy of NIRS is confounded by the light scattering which alters the optical path length and the available commercial clinical devices solve this problem differently. The depth of light penetration is 2–4 cm.

Three cerebral oximeters are currently widely commercially available: the INVOS 5100, NIRO 200 and the Foresight. Of the three, the Somanetics INVOS system (Somanetics Inc., Troy, MI, USA) is in most common use and has disposable probes, including an adult probe for patients over 40 kg, as well as a pediatric probe designed

**Figure 17.18** Typical changes in regional cerebral oxygen saturation (rSO<sub>2</sub>) during cardiac surgery in a neonate with hypoplastic left heart syndrome undergoing Norwood stage I palliation, with cardiopulmonary bypass, regional cerebral low flow perfusion (RLFP), and deep hypothermic circulatory arrest (DHCA). Note precipitous decline at minute 115 with onset of DHCA for atrial septectomy, and again at minute 185 for replacement of aortic cannula.

for patients 4–40 kg which uses a different algorithm that takes into account the thinner skull and extracranial tissues compared to the adult [168]. More recently, a neonatal probe has become available which is easier to apply as it conforms well to the smaller forehead shape. It uses two wavelengths, 730 and 810nm, and has one lightemitting diode (LED) and two detectors, spaced at 3 cm and 4cm apart from the emitter, and uses spatially resolved spectroscopy (Fig. 17.18). The distinct absorption coefficients of oxy- and deoxyhemoglobin permit measurement of the relative signals from these compounds in the light path and the INVOS device reports oxyhemoglobin/total hemoglobin (oxy- + deoxyhemoglobin)  $\times$  100, as the measured regional cerebral oxygen saturation (rSO<sub>2</sub>), in percentage. The rSO<sub>2</sub> is reported as a percentage on a scale from 15% to 95%. A subtraction algorithm based on probe size removes most of the transmitted shallow (3 cm detector) signal, leaving over 85% of the remaining signal derived from brain frontal cortex. This device is United States Food and Drug Administration (FDA) approved for use in children and adults as a trendonly monitor. It is compact, non-invasive, and requires little warm-up. A signal strength indicator displays adequacy of detected signal, and the device does not depend on pulsatility like a pulse oximeter, and operates at all temperatures. Cerebral blood volume index (Crbvi) can also be calculated, representing the total hemoglobin in the light path, which may be used as an estimate of cerebral blood volume. However, this application is not approved by the FDA for clinical use but only for research purposes.

The NIRO 200 (Hamamatsu Photonics, Hamamatsu, Japan) uses three wavelengths of near infrared light (775, 810, and 850nm) emitted by a laser diode and detected by a photodiode. It uses spatially resolved spectrophotometry, and the three wavelengths allow better determination of light path length according to the Beer-Lambert Law, which allows calculation of absolute concentrations of oxygenated and total hemoglobin. The NIRO 200 reports a tissue oxygenation index (TOI), as well as hemoglobin indices, including changes in total hemoglobin and oxy- and deoxyhemoglobin. The probes are not disposable but are attached with a disposable probe holder. This device may potentially be more accurate than the INVOS system due to the increased number of wavelengths of light, but it is not FDA approved for use in the United States.

A more recent FDA-approved device is the Foresight monitor (Casmed, Branford, CT). This device uses four wavelengths of light: 690, 778, 800, and 850 nm. The purpose of the additional wavelengths is to better discriminate non-hemoglobin sources of infrared absorption, which may lead to a more accurate calculation of oxygenated and total hemoglobin concentrations [169]. The Foresight monitor reports the percentage of oxygenated hemoglobin to total hemoglobin as a cerebral tissue oxygen saturation (SCTO<sub>2</sub>), and is marketed as an absolute cerebral tissue oxygen saturation. Currently available probes are disposable, and are appropriate only for patients 2.5–8kg and >40 kg.

Comparison between these commercial devices reveals differences in measured values due to the different numbers of wavelength and subtraction algorithms, thus making direct data comparisons difficult [165]. However, regardless of the device used, it is important to remember that all devices measure combined arterial and venous blood oxygen saturation, and cannot be assumed to be identical to jugular venous bulb oxygen saturation (SjvO<sub>2</sub>). Maneuvers to increase arterial oxygen saturation, i.e. increasing FiO<sub>2</sub>, will increase cerebral oxygenation as measured by these devices, but the SjvO<sub>2</sub> may remain unchanged.

The Foresight device is still relatively new and comparison data with the INVOS are not available. However, the Foresight monitor may predict a more accurate value for the true brain saturation compared to the INVOS monitor that will make between-patient comparisons easier.

In an attempt to validate the non-invasive measurement of cerebral oxygen saturation in children with congenital heart disease,  $SjvO_2$  and  $rSO_2$  have been compared. In 40 infants and children undergoing congenital heart surgery or cardiac catheterization [170], the correlation for paired measurements was inconclusive except for infants less than 1 year of age. In 30 patients undergoing cardiac catheterization, an improved correlation (r = 0.93) was found [171], and there was a linear correlation between changes in arterial  $CO_2$  and cerebral saturation.

### Somatic near infrared oximetry

Using the same principles of unique light absorption spectra of hemoglobin species, NIRS has also been used to measure tissue oxygenation in skeletal muscle, i.e. quadriceps, forearm or thenar eminence muscle, in adults and children [172]. In addition, a probe placed over the flank at the T10–L2 level will measure tissue saturation in skeletal muscle and, in small infants, renal oxygenation due to the small light penetrance distance needed in these patients [173] (Fig. 17.19). Finally, mesenteric saturation has also been measured in infants with a probe placed in the midline between the umbilicus and the symphysis pubis [174].

## Parameters monitored with near infrared spectroscopy

To simplify terminology, the term  $rSO_2$ , for regional oxygen saturation, will be utilized for the remainder of this chapter, regardless of the device used. Cerebral  $rSO_2$ measurements are an estimate of venous-weighted oxyhemoglobin saturation in the sample volume illuminated by the light path, i.e. the frontal cerebral cortex in most situations.  $rSO_2$  can be altered by any of the factors that affect the cerebral oxygen supply/demand ratio and is especially affected by the unique features of the cerebral circulation, including cerebral autoregulation and alterations in cerebral blood flow according to PaCO<sub>2</sub>. Any factor that decreases cerebral oxygen consumption will

**Figure 17.19** Principles of somatic NIRS. In a neonate or small infant, a NIRS probe placed on the flank over the T10–12 area measures the oxyhemoglobin saturation of the tissues in the light path, particularly muscle and renal tissue beds. Reproduced courtesy of George Hoffman MD.

generally increase  $rSO_2$ , and any factor that increases oxygen delivery to the brain will also generally increase rSO2. Box 17.2 lists some of the common alterable clinical factors that can be used to change  $rSO_2$ . Since cerebral  $rSO_2$  is influenced by arterial oxygenation, improving this parameter will often increase  $rSO_2$ , even if SjvO<sub>2</sub> is little altered.

For pediatric patients undergoing congenital heart surgery, baseline  $rSO_2$  varies with cardiac lesion [166]. The baseline cerebral saturation is about 70% in acyanotic patients without large left-to-right intracardiac shunts breathing room air. On room air,  $rSO_2$  for cyanotic patients, or acyanotic patients with large left-to-right intracardiac shunts, is usually 40–60%; hypoplastic left heart syndrome (HLHS) patients receiving <21% FiO<sub>2</sub> preoperatively have lower  $rSO_2$ , averaging 53%, versus those receiving FiO<sub>2</sub> 0.21 and 3% inspired CO<sub>2</sub>, where  $rSO_2$ averages 68% [175].

Taking into account pediatric cardiac surgery outcome data (see below), some practitioners would consider a relative decline from a baseline of 20% or more (e.g. from a baseline of 60% to a nadir of 48%) cause for intervention. The software on most oximeters will continuously calculate this relative difference from baseline. Other practitioners would use an absolute value of  $rSO_2$  of 50% as cause for intervention.

Cerebral oximetry reflects a balance between oxygen delivery and oxygen consumption by the brain (CMRO<sub>2</sub>).

Box 17.2 Factors affecting cerebral oxygen consumption and delivery

#### Factors decreasing CMRO<sub>2</sub> and generally increasing rSO<sub>2</sub>

- Hypothermia
- Increasing sedation, anesthesia, analgesia with benzodiazepines, opioids, dexmedetomidine
- Treating seizures

## Factors increasing oxygen delivery to brain and generally increasing rSO<sub>2</sub>

- Increasing PaCO<sub>2</sub>
- Increasing hemoglobin
- Increasing cardiac output
- Increasing FiO<sub>2</sub> or other ventilatory maneuvers to increase SpO<sub>2</sub>
- Increasing mean arterial pressure (outside limits of autoregulation, i.e. hypotension)
- Increasing CPB flow rate
- Increasing CPP
- Minimizing cerebral venous pressure to increase CPP, i.e. obstructed venous bypass cannula

CMRO<sub>2</sub>, cerebral metabolic rate for oxygen; CPB, cardiopulmonary bypass; CPP, cerebral perfusion pressure; rSO<sub>2</sub>, regional brain oxygen saturation.

The cerebral oxygen content will therefore be affected by both the arterial saturation of hemoglobin and the hemoglobin concentration. There then must exist a cerebral saturation value, or ischemic threshold, below which brain injury is likely due to oxygen deprivation as demand outstrips supply. In a neonatal piglet study using frequency domain NIRS [176], Kurth et al showed that cerebral lactate levels rose at rSO<sub>2</sub> values of 44% or lower; major EEG changes occurred when the cerebral saturation declined to 37%, with reductions in cerebral adenosine triphosphate (ATP) levels when oximetry readings were 33% or lower. This concept was confirmed in another neonatal piglet model using hypoxic gas mixtures for 30 min at normothermia, demonstrating that rSO<sub>2</sub> >40% did not change EEG or brain pathology obtained 72h later; rSO<sub>2</sub> 30–40% produced no EEG changes but at 72 h there were ischemic neuronal changes in the hippocampus, and mitochondrial injury occurred. At rSO<sub>2</sub> <30%, there was circulatory failure, EEG amplitude decreased, and there was vacuolization of neurons and severe mitochondrial injury [177]. Finally, in a similar piglet model, the hypoxicischemic cerebral saturation time threshold for brain injury found rSO<sub>2</sub> of 35% for 2 h or more produced brain injury [178]. In general most pediatric clinical studies use either 20% below established baseline or an oximetry reading of 45-50% for the threshold for treatment based on evidence of new MRI lesions or clinical exam that brain injury is more likely to develop under these circumstances [179,180].

In the absence of absolute criteria for intervention to prevent neurological injury (see below under Outcomes), each anesthesiologist must take into account the unique pathophysiology of each patient and the monitoring system used, and decide on criteria for intervention, much like all the other physiological variables measured for surgery and critical care.

### Clinical data in pediatric cardiac surgery

Changes in cerebral oxygenation have been characterized during cardiopulmonary bypass in children with or without deep hypothermic circulatory arrest [181]. rSO<sub>2</sub> predictably decreases during deep hypothermic circulatory arrest (DHCA) to a nadir approximately 60-70% below baseline values obtained pre-bypass [181] and the nadir is reached at about 40 min, after which there is no further decrease. At this point it appears that the brain does not continue the uptake of oxygen and interestingly, this time period appears to correlate with clinical and experimental studies suggesting that 40-45 min is the limit for safe duration for circulatory arrest [182,183]. The DHCA initiation at higher temperature results in a faster fall in rSO<sub>2</sub>, reaching the nadir sooner [184]. Reperfusion immediately results in an increase in rSO<sub>2</sub> levels seen at full bypass flow before DHCA.

The question often arises whether bilateral cerebral hemisphere NIRS monitoring is necessary. In a study of 20 patients undergoing a special cardiopulmonary bypass technique, antegrade cerebral perfusion, via the right innominate artery, half of the patients had a left/right difference of >10% [185]. In 60 neonates undergoing surgery with conventional bypass, only 10% had greater than 10% difference between left and right sides at baseline, and this difference persisted in only one patient [186]. Based on these data, bilateral monitoring is probably necessary only when special cardiopulmonary bypass (CPB) techniques are used for aortic arch reconstruction or when anatomical variants, i.e. bilateral superior vena cavae or abnormalities of the brachiocephalic vessels, are present.

### Treatment of low rSO<sub>2</sub>

Whether during adult or pediatric cardiac surgery with CPB, the general approach to treating low rSO<sub>2</sub> is similar and involves increasing oxygen delivery to the brain or decreasing oxygen consumption. One approach to treatment is displayed in Box 17.3.

In critical care medicine, cerebral NIRS has been used to monitor adequacy of cerebral oxygen delivery and as a surrogate for adequacy of global oxygen delivery, in patients after cardiac surgery and those on extracorporeal membrane oxygenation (ECMO) or ventricular assist devices [169,187]. Changes in rSO<sub>2</sub> have a close correlation with changes in mixed venous saturation (SvO<sub>2</sub>) in both single- and two-ventricle patients after congenital cardiac surgery [188,189].

## Clinical uses of somatic near infrared spectroscopy in pediatric surgery and critical care

Near infrared spectroscopy can be used to measure tissue oxygenation in surgery and critical illness, and because of its non-invasive, continuous nature, has intuitive appeal in conditions where low cardiac output and other causes of shock would benefit from such continuous monitoring.

Somatic NIRS using a probe placed on the flank at T10–L2 has been studied in a series of neonates during and after single-ventricle surgical palliation by Hoffman et al [173]. In nine neonates undergoing CPB with regional cerebral perfusion (RCP), mean cerebral rSO<sub>2</sub> prebypass was 65% and somatic rSO<sub>2</sub> 59%, and during RCP cerebral rSO<sub>2</sub> was 81% versus 41% somatic rSO<sub>2</sub>, signifying relative tissue hypoxia due to lack of perfusion to subdiaphragmatic organs during this technique. After CPB, cerebral rSO<sub>2</sub> decreased to 53%, but somatic rSO<sub>2</sub> increased to 76% [173]. In 79 postoperative neonates undergoing Norwood Stage I palliation for hypoplastic left heart syndrome, a cerebral–somatic rSO<sub>2</sub> difference of <10% significantly increased the risk for biochemical shock, mortality

**Box 17.3** Treatment algorithm for low cerebral oxygen saturation (rSO<sub>2</sub>)

- Establish baseline rSO<sub>2</sub> on FiO<sub>2</sub> 0.21, PaCO<sub>2</sub> 40 mmHg, stable baseline hemodynamics, awake before induction of anesthesia, or prebypass if possible
- 2. Treat decreased  $rSO_2$  of >20% relative value below baseline, or <50% absolute value
- 3. Pre/postbypass (in order of ease/rapidity to institute):
  - (a) Increase FiO<sub>2</sub>
  - (b) Increase PaCO<sub>2</sub>
  - (c) Increase cardiac output/O<sub>2</sub> delivery with volume infusions, inotropic support, vasodilators, etc.
  - (d) Increase depth of anesthesia
  - (e) Decrease temperature
  - (f) Increase hemoglobin
- 4. During CPB:
  - (a) Increase CPB flow and/or mean arterial pressure
  - (b) Increase PaCO<sub>2</sub>
  - (c) Increase FiO<sub>2</sub>
  - (d) Decrease temperature
  - (e) Increase hemoglobin
  - (f) Check aortic and venous cannula positioning
  - (g) Check for aortic dissection

or other complications [190] (Fig. 17.20). Mean somatic  $rSO_2 <70\%$  was associated with a significantly increased risk of prolonged ICU stay, shock, and other complications.

Somatic NIRS has also been used to measure mesenteric  $rSO_2$  in neonates and infants after cardiac surgery, with a probe placed on the abdomen between the umbilicus and symphysis pubis. In a study of 20 patients, Kaufman et al [191] compared mesenteric NIRS and flank NIRS at T10–L2 to gastric pH measured by tonometry and lactate values. In 122 simultaneous measurements made in the first 48 h after surgery, mesenteric  $rSO_2$  correlated significantly with gastric pH (r = 0.79), serum lactate (r = 0.77), and  $SvO_2$  (r = 0.89). These correlations were all better than those using flank NIRS. The authors concluded that mesenteric NIRS is a sensitive monitor of splanchnic tissue oxygenation, and may have utility in managing these patients and improving outcomes.

These studies lend credence to the idea that NIRSdirected targeted interventions could be utilized to improve oxygen delivery to tissues and organs, and potentially improve outcomes from surgery, anesthesia and critical illness. To date, there is a lack of such published studies, but the non-invasive continuous nature of NIRS monitoring should make such studies more likely to be performed.

### Outcome studies of near infrared spectroscopy

There is increasing evidence from pediatric cardiac surgery studies that prolonged low NIRS values are associated

**Figure 17.20** Relationship between somatic rSO<sub>2</sub>–cerebral rSO<sub>2</sub> difference and the incidence of complications in 79 patients in the 48 h after Norwood stage I palliation for hypoplastic left heart syndrome. Reproduced from Hoffman et al [190] with permission from Lippincott Williams & Wilkins.

with adverse short-term neurological outcomes. Dent et al [179] studied 15 neonates undergoing the Norwood operation who underwent preoperative, intraoperative and postoperative rSO<sub>2</sub> monitoring. A prolonged low rSO<sub>2</sub> (>180 min with rSO<sub>2</sub>  $\leq$  45%) was associated with a higher risk of new ischemic lesions on postoperative MRI when compared to the presurgical study, with a sensitivity of 82%, specificity of 75%, positive predictive value of 90%, and negative predictive value of 60%. Therefore, both the extent of decreased cerebral saturation (ischemic threshold) and the time spent below this ischemic threshold are important in predicting the development of new postoperative brain injury by MRI.

There is additional clinical evidence suggesting that low cerebral saturations correlate with adverse neurological outcome. In a study of 26 infants and children undergoing surgery utilizing DHCA [181], three patients had acute neurological changes – seizures in one and prolonged coma in two – all of whom manifest low rSO<sub>2</sub>. In these three patients the increase in rSO<sub>2</sub> was much less after the onset of CPB and the duration of cooling before DHCA shorter. In a retrospective study of multimodality neurological monitoring in 250 infants and children undergoing cardiac surgery with bypass [180], relative cerebral oxygen desaturation of more than 20% below prebypass baseline resulted in abnormal events in 58%. If left untreated, 26% of these patients had adverse postoperative neurological events.

In a study of 16 patients undergoing neonatal cardiac surgery, with NIRS monitoring and pre- and postopera-

tive brain MRI, six of 16 patients developed a new postoperative brain injury; these patients had a lower rSO<sub>2</sub> during the aortic cross-clamp period than those without new brain injury. (48% versus 57%, p = 0.008) [192]. In a recent study of 44 neonates undergoing the Norwood operation, who were tested at age 4–5 using a visualmotor integration (VMI) test, the first 34 patients did not have NIRS monitoring and the last 10 did have NIRS monitoring with a strict treatment protocol for low rSO<sub>2</sub> values <50%. No patients with NIRS monitoring had a VMI score <85 (normal is 100), versus 6% without NIRS monitoring. Mean rSO<sub>2</sub> in the perioperative period was associated with VMI score, with no patient with mean rSO<sub>2</sub> ≥ 55 having VMI less than 96 [193].

Toet et al [194] studied 20 neonates undergoing the arterial switch operation and monitored rSO<sub>2</sub> for 4–12h preoperatively, intraoperatively, and for 36 hours postoperatively, without intervention. Seven patients had a mean preoperative rSO<sub>2</sub>  $\leq$ 35%, and two of these patients had significantly abnormal Bayley Scales of Infant Development Scores at 30–36 months, of 1–2 standard deviations below the normal population mean.

Kussman et al [195] studied 104 infants aged 9 months or less undergoing complete two-ventricle repair of transposition of the great arteries, tetralogy of Fallot or ventricular septal defect. Bilateral NIRS was monitored during the intraoperative period, and for 18h postoperatively but no intervention was made on the basis of rSO<sub>2</sub> values. The aim of the study was to evaluate changes in rSO<sub>2</sub> and to determine association between low rSO<sub>2</sub> and early postoperative outcomes, including death, stroke, seizures or choreo-athetosis. An rSO<sub>2</sub> threshhold of 45% was chosen as the cut-off for analysis. pH stat blood gas management and hematocrit of 25-35%, along with brief DHCA and some low-flow bypass, was utilized. Eightyone of 104 patients had no desaturation below 45%, 12 had brief desaturation below 45% for 1-39min, and 11 had more prolonged desaturation of 60-383 min. Because no patient in the study died or suffered any neurological complication, the relationship between low rSO<sub>2</sub> and early neurological outcome could not be determined. There was also not a relationship between low rSO<sub>2</sub> and postoperative cardiac index, lactate, severity of illness or days ventilated, in the ICU or hospital. Thirty-nine of these patients had a period of DHCA, and important data about the rate of decline of rSO<sub>2</sub> under optimal CPB conditions were reported (Fig. 17.21). The important finding is that brief periods of DHCA <30 min did not result in nadir values of rSO<sub>2</sub>, suggesting that this technique does not deplete the brain of oxygen stores and lending more credence to the idea that this practice is safe. The lack of an association between rSO<sub>2</sub> and early gross neurological outcomes is not unexpected, given that these were all two-ventricle patients, completely repaired,

**Figure 17.21** Pattern of cerebral  $rSO_2$  during deep hypothermic circulatory arrest (DHCA) in 39 infants with D-transposition of the great arteries who underwent  $\geq$ 5 min of DHCA. Data are presented as mean  $\pm$  1.96 SEM. The number of subjects (N) available for analysis at 5-min intervals of DHCA is shown. The fitted non-linear exponential decay curve (*solid line*) is based on data from 0 to 30 min with higher weight given to mean rSO<sub>2</sub> values calculated with more subjects. The fit is extrapolated beyond 30 min (*dashed line*). Reproduced from Kussman et al [195] with permission from Lippincott Williams & Wilkins.

with normal arterial oxygen saturations postoperatively. The low incidence and severity of cerebral desaturation in this population have been previously described [196] (Fig. 17.22).

Another potential benefit of routine NIRS monitoring is to avert the rare but very real and devastating potential neurological disaster from cannulation problems, where  $rSO_2$  declines dramatically from cannula malposition and cerebral arterial or venous obstruction, yet all other bypass parameters are normal [197,198]. In neonates and infants, it is clear that mixed venous saturation in the bypass circuit bears very poor association with cerebral saturation, emphazing the point that intracerebral desaturation may go unnoticed [199].

In a systematic review of 56 publications describing 1300 patients using NIRS monitoring for congenital heart disease in the operating room, intensive care unit, and cardiac catheterization laboratory, Hirsch et al [200] concluded that the technology did serve as a reliable, continuous, non-invasive monitor of cerebral oxygenation. However, to date there have not been any published prospective, randomized, controlled studies of NIRS monitoring versus no NIRS monitoring, with short- or long-term follow-up in pediatric patients. Many centers

**Figure 17.22** Frequency of rSO<sub>2</sub> values recorded at 1-min intervals in the first 48 h postoperatively in neonates undergoing repair of hypoplastic left heart syndrome (single-ventricle patients) or D-transposition of the great arteries (twoventricle patients). Reproduced from Andropoulos et al [196] with permission from Lippincott Williams & Wilkins.

where NIRS is now in routine clinical use will not have sufficient equipoise to conduct such a study.

### **Transcranial Doppler ultrasound**

Transcranial Doppler ultrasound (TCD) is a sensitive, real-time monitor of cerebral blood flow velocity and emboli during congenital heart surgery. Currently available instruments utilize pulsed-wave ultrasound at 2 Mhz frequency, which is range gated, emits a power of 100 mW, and has a sample volume length of up to 15 mm. A display of the frequency spectrum of Doppler signals is easily interpreted, and peak systolic and mean flow velocities, in cm/sec, are displayed, as well as a pulsatility index which is equal to the peak velocity minus the end-diastolic velocity, divided by the mean velocity.

The most consistent and reproducible technique for clinical use in patients of all ages is to monitor the middle cerebral artery (MCA) through the temporal window, which can usually be found just above the zygoma and just anterior to the tragus of the ear [201]. Several transducer probes are available, ranging from very small disk probes suitable for infants and children, to larger, heavier probes for adolescents and adults. The depth of the sample volume and angle of insonation are adjusted until the bifurcation of the MCA and the anterior cerebral artery (ACA) is detected. This is heralded by a maximal antegrade signal (positive deflection, toward the transducer) from the MCA, accompanied by retrograde flow (negative deflection, away from the transducer) of the same or very similar velocity and waveform, as the MCA flow. The same location should be monitored for an individual patient. Insonation at the MCA–ACA bifurcation also offers the advantage of minimizing interpatient variability. In addition, the MCA supplies the largest volume of tissue of any of the basal cerebral arteries [202]. In infants, an alternative site for monitoring is through the anterior fontanelle, using a hand-held pencil-type probe, placing the probe over the lateral edge of the fontanelle and aiming caudally, at a greater depth than for the temporal window.

Transcranial Doppler has been used extensively in pediatric cardiac surgical research to examine cerebral physiology in response to cardiopulmonary bypass, hypothermia, low-flow bypass, regional low-flow perfusion to the brain and circulatory arrest. Hillier et al [203] used TCD to study cerebrovascular hemodynamics during hypothermic bypass with DHCA in 10 infants, finding that cerebral blood flow velocity did not return to baseline levels after DHCA. Calculated cerebral vascular resistance (mean arterial pressure - central venous pressure/cerebral blood flow velocity (CBFV)) was increased immediately after DHCA, and remained so until the end of bypass. The observed decrease in CBFV during cooling was thought to be due to decreased metabolic demand by the brain and thus less blood flow, although  $\alpha$ -stat strategy was used. This could be explained

by relative cerebral vasoconstriction during cooling in smaller arterioles downstream to the MCA and ACA, since these large arteries do not change their caliber in response to changes in PaCO<sub>2</sub> [204]. TCD of the MCA through the temporal window was used to describe the cerebral pressure-flow velocity relationship during hypothermic bypass in 25 infants less than 9 months old. CBFV was examined over a wide range of cerebral perfusion pressures (varying from 6 to 90 mmHg), and at three temperatures: normothermia (36-37°C), moderate hypothermia (23–25°C), and profound hypothermia (14–20°C). Cerebral pressure flow autoregulation was preserved at normothermia, partially affected at moderate hypothermia, and totally lost at profound hypothermia, results which agree with previous research done using xenon to quantitate cerebral blood flow [205].

Transcranial Doppler has also been utilized to determine the threshold of detectable cerebral perfusion during low-flow cardiopulmonary bypass. Zimmerman et al [206] studied 28 neonates undergoing the arterial switch operation with α-stat pH management. At 14-15°C the pump flow was sequentially reduced to 0mL/kg/min. All patients had detectable cerebral blood flow down to 20 mL/kg/min, while one had no perfusion at 20 mL/ kg/min, and eight had none at 10mL/kg/min, leading the authors to conclude that 30 mL/kg/min was the minimum acceptable flow in this population. Finally, Andropoulos et al [207] used TCD of the MCA to determine the level of bypass flow necessary during regional low-flow perfusion for neonatal aortic arch reconstruction. They studied 34 neonates undergoing the Norwood operation or aortic arch advancement and established a baseline mean CBFV (22 cm/sec) under full-flow bypass (150 mL/kg/min) using pH stat management at 17–22°C. They then used TCD to determine how much bypass flow was necessary to match this value, finding that a mean of 63 mL/kg/min was necessary.

Cerebral emboli are a frequent threat during open heart surgery in children. Emboli are easily detected by TCD, although this is subject to artifacts such as electrocautery and physical contact with the ultrasound transducer [208]. The number of emboli detected in the carotid artery during pediatric congenital heart surgery did not appear to correlate with acute postoperative neurological deficits [208]. However, acute drops in cerebral blood flow detected by TCD can allow for adjustment of aortic or superior vena cava cannulas, which may avert neurological disaster [209].

## Electroencephalographic technologies

The standard electroencephalogram (EEG) employing 2–16 channels has been utilized in congenital heart surgery [180]. It is a rough guide of anesthetic depth and can document electrocerebral silence before DHCA [210].

EEG is affected by several factors including anesthetic agents, temperature, and CPB. Impracticalities of the use of an intraoperative EEG include electrical signal interference, complexity of placement and interpretation. Newer devices using processed EEG technology are more user friendly and have been extensively reviewed [211,212]. The value of perioperative EEG monitoring in congenital heart surgery is unclear. For example, hypoplastic left heart syndrome neonates frequently have a normal perioperative EEG yet frequently demonstrate abnormalities of pre- and postoperative brain MRI suggestive of ischemia [179].

The Bispectral Index (BIS) monitor (Aspect Medical Systems, Nantick, MA) is currently promoted to guide the depth of anesthesia. BIS sensor electrodes are applied to the forehead and temple, producing a frontal-temporal montage, which connects to a processing unit. The device is easy to use, electrodes are easy to place and the monitor requires no calibration or warm-up time. Via a proprietary algorithm of the Aspect Corporation, BIS uses Fourier transformation and bispectral analysis of a one-channel processed EEG pattern to compute a single number, the Bispectral BIS index [213]. This index ranges from 0 (isoelectric EEG) to 100 (awake) with mean awake values in the 90-100 range in adults, infants and children [214]. Depth of sedation is difficult to predict using BIS scores due to significant individual variability and anesthetic agent [215]. For BIS to be effective as a monitor of the depth of anesthesia, one would have to know exact BIS values for each anesthetic administered for an individual patient, thus reducing its value [216]. BIS can be used to recognize EEG burst suppression or electrical silence, which could be useful during deep hypothermic circulatory arrest. The monitor displays a real-time EEG waveform, but is subject to motion artifact, EMG activity and radiofrequency interference from electrical equipment in the operating room. Little or no data exist in children on the use of other EEG devices such as the Physiometrix<sup>®</sup>, Narcotrend® or Cerebral Function Monitor® [211].

During CPB, hemodilution and hypothermia alter pharmacokinetics and pharmacodynamics, which can lead to awareness under anesthesia. The overall incidence of awareness in adults undergoing cardiac surgery varies from 1.1% [216] to 23% which is more than in general surgical procedures [217,218]. The incidence of awareness under general anesthesia is similar in children [219]. Although there are no documented reports of awareness under anesthesia in children undergoing heart surgery, BIS monitoring may still be useful to detect a level of awareness.

In a cohort of children undergoing open heart surgery with an anesthetic tailored for "fast-tracking," BIS scores increased during rewarming, a period considered at risk for awareness under anesthesia [220]. However, in this
study, and in a similar study in infants less than 1 year of age [221], BIS did not correlate with stress hormone levels, a surrogate for light levels of anesthesia, nor with plasma fentanyl levels. At present, there is little evidence to support the use of BIS in neonates and infants undergoing anesthesia and therefore the value of BIS to assess burst suppression during DHCA is in further doubt. This is due to the different sleep arousal patterns in this subset. Because of the similarities of the full EEG in children over age 12 to the adult EEG, processed EEG monitoring in older children above the age of 12 years will produce similar patterns to those of the adult. Therefore it would appear more logical to use these devices in older patients, and especially under special anesthetic techniques, i.e. total intravenous anesthesia for spine surgery in the adolescent [222,223].

# CASE STUDY

A 3-year-old, 14.2kg, 95cm tall boy presented for major resection of stage IV Wilms tumor with IVC extension [224]. He presented 3 months before the scheduled surgery with significant right-sided abdominal distension and pain. He did not have any other medical problems, and did not exhibit the phenotype of any genetic syndrome. Initial imaging with MRI revealed unilateral large renal tumor with renal vein and IVC extension to just below the right atrium. Fine needle aspiration with computed tomography guidance revealed Wilms tumor with favorable histology. There were no intracardiac masses, but there were eight pulmonary nodules. Because of the IVC extension near the right atrium, preoperative chemotherapy with vincristine, actinomycin D, and doxorubicin was initiated. Long-term central venous access (Port-a-Cath®) was placed via the left subclavian vein 1 week after diagnosis. Echocardiography the day before surgery revealed normal cardiac anatomy and function, without intracardiac shunting, masses or valvular disease. Tumor mass could be seen in the IVC just below the right atrium. Chest radiograph was clear. Vital signs were: BP 120/85mmHg, P 125bpm, R 28/min, T 36.5°C, SpO<sub>2</sub> 98% on room air. Preoperative laboratory studies included normal electrolytes, BUN 16mg/dL, creatinine 0.6mg/dL, hemoglobin 10.5 g/dL, white blood cell count 7500/mm<sup>3</sup>, platelet count 156,000/mm<sup>3</sup>, and normal prothrombin, partial thromboplastin, international normalized ratio (INR), and liver function tests.

A combined surgical procedure with cardiac and general surgeons was planned, via a right thoracoabdominal incision with cardiopulmonary bypass standby. Four units of irradiated, CMV-safe packed red blood cells (PRBC) were cross-matched. Because of the anticipated large blood loss and plan to leave the trachea intubated postoperatively, epidural analgesia was not used. After premedication with midazolam 2mg IV, the patient was transported to the operating room where late-generation pulse oximeter, ECG, and automated oscillometric blood pressure cuff were placed. After preoxygenation, anesthesia was induced with propofol 2 mg/kg, fentanyl  $3 \mu g/kg$ , and vecuronium 0.3 mg/kg. After tracheal intubation with a 4.5 mm cuffed orotracheal tube, a 22 ga right radial arterial catheter was placed. Because of the need to cross-clamp the IVC for tumor resection, a 20 ga IV catheter was placed in the right and 18ga IV catheter in the left antecubital vein. The patient's blood volume was estimated to be 75mL/kg or 1065 mL. It was decided that transfusion would be initiated at hematocrit of 25%, so allowable blood loss was calculated as  $1065 \text{ mL} \times (32\% - 25\%)/32\% = 232 \text{ mL}$ . Because of the anticipated large blood loss and fluid shifts, and variation in cardiac output, a continuous central venous oxygen saturation (ScvO<sub>2</sub>) catheter was placed in the right internal jugular vein (IJV). Full sterile barrier precautions and ultrasound guidance were used, the IJV was entered first pass and a 4.5 Fr double-lumen ScvO<sub>2</sub> catheter was secured at 8 cm after confirmation of guidewire placement in the vein. A pediatric TEE probe was placed to monitor for intracardiac tumor emboli, and cardiac filling and function. A 10 Fr urinary catheter and rectal temperature probe were placed, a full-body forced air warming blanket placed under the patient, and he was positioned in left lateral decubitus position. Anesthesia was maintained with isoflurane, 0.5-1.5% end-tidal concentration, and intermittent boluses of fentanyl, midazolam, and vecuronium.

The surgical plan was to perform the thoracoabdominal incision, expose the right kidney and tumor with retroperitoneal dissection, and then cross-clamp the IVC to debulk the tumor and prevent emboli. If it was not possible to cross-clamp above the tumor, a short period of cardiopulmonary bypass was planned to remove the IVC and right atrial tumor. The IVC was cross-clamped successfully with retraction of the right lung, after intravascular volume loading with 15 mL/kg 5% albumin resulting in an increase of central venous pressure (CVP) from 5 to 10 mmHg. A large decrease in venous return, accompanied by decrease of CVP to 3 mmHg, decreased blood pressure to 55/35 mmHg, and increase in heart rate to 135 bpm with a decrease in ScvO<sub>2</sub> from 74% baseline (calibrated with a

measured oxygen saturation drawn from the CVP catheter) to 44%, ensued. The end-tidal CO<sub>2</sub> also decreased from 37 to 23 mmHg, reflecting decreased cardiac output and pulmonary blood flow, but TEE revealed no evidence of pulmonary embolus.

During the 30 min of IVC cross-clamp, necrotic but nonfriable tumor mass was resected from the IVC down as far as possible toward the renal veins. Blood loss was 350 mL during this phase, and was replaced with two units PRBC, with an additional six units ordered at that time. Intermittent boluses of calcium chloride (CaCl<sub>2</sub>), 10 mg/kg and a lowdose epinephrine infusion of  $0.03 \mu g/kg/min$  were used during this period to augment cardiac output and vascular tone, because of the intermittent hypotension, and decrease in  $ScvO_2$  to 40–50% range. After de-airing, and repair of the IVC incision, the cross-clamp was released and the patient suffered a period of bradycardia to a heart rate of 50 bpm, hypotension to 45/25 mmHg, arterial desaturation to 88%, and decreased ScvO<sub>2</sub> to 30%. This responded to two  $10 \mu g/$ kg boluses of epinephrine, sodium bicarbonate 2 meq/kg, intravascular volume infusion with 5% albumin 10 mL/kg, additional CaCl<sub>2</sub>, and hyperventilation. Using a point-ofcare system in the operating room, arterial blood gases after cross-clamp removal and resuscitation revealed a pH 7.25, PaCO<sub>2</sub> 34 mmHg, PaO<sub>2</sub> 250 mmHg, base deficit of -13, and lactate of 8.5 mmol/L, with hematocrit of 32%. Endtidal CO<sub>2</sub> had been as low as 18 mmHg, and returned to 32 mmHg after the period of cross-clamp. TEE revealed no tumor emboli during this period, but depressed biventricular function after removal of the cross-clamp. After additional sodium bicarbonate and increasing epinephrine to  $0.05 \mu g/kg/min$ , biventricular function normalized.

The resection of kidney and tumor, retroperitoneal lymph node dissection, and removal of tumor from renal veins and the remainder of the IVC required 6 additional hours of surgery. Hourly values of vital signs, blood gas values, hematocrit, blood loss, and ScvO<sub>2</sub> are listed in Table 17.7. Urine output became bloody 2h into the resection, and was maintained at 2mL/kg/h with intravascular volume infusions without adding diuretics. Temperature was maintained at 35.5–36.5°C throughout the case with the forced air warming blanket set at 38°C, warmed intravenous fluids, colloids, and blood, with fluid warmer set at 41°C and room temperature warmed to 25°C, as well as the use of a condenser humidifier.

A tissue factor-activated thromboelastogram (TEG) was sent 4h into the case and with turnaround time of 20 min, revealed a significant coagulopathy with prolonged r and K times, reduced  $\alpha$  angle, and reduced maximum amplitude. This occurred after a total blood loss of 1000 mL and resulted in infusion of half a pheresis unit of platelets (equivalent to three random single units), one unit of fresh frozen plasma (FFP), and two units of cryoprecipitate, to treat the thrombocytopenia, hypofibrinogenemia, and depleted coagulation factors indicated by the severely abnormal TEG. Five hours into the resection, the serum K+ level was 6.3 mmol/L, presumably secondary to transfusion of the 12 units of PRBC to that time. As serum glucose was 288 mg/dL at the time, the hyperkalemia was treated with regular insulin 3 units, 25% dextrose 0.5 mL/kg, CaCl<sub>2</sub>, and sodium bicarbonate, and by the next hour K+ was 4.4 mmol/L.

At the end of the case, total blood loss was estimated to be 3250 mL and the patient received 14 units PRBC, four units FFP, eight units cryoprecipitate, and two full pheresis units of platelets. Additional fluids were 300 mL of 5% albumin and 100 mL Plasmalyte®. Urine output total was 250 mL. Total fentanyl dose was 150 µg/kg. TEE during the case revealed no evidence of air or tumor embolus, variable biventricular function and filling, but by the end of the case hemostasis had been achieved, cardiac function was normal, and epinephrine weaned to  $0.02 \mu g/kg/min$ . The patient was transported with his trachea intubated to the pediatric intensive care unit after loading with 0.3 mg/ kg of morphine, and additional midazolam. He was extubated 48h later and made an excellent recovery without significant end-organ dysfunction, and intact neurological status.

#### Conclusions

This case illustrates the use of continuous hemodynamic monitoring, including ScvO<sub>2</sub>, to instantaneously guide treatment during a major tumor resection with wide hemodynamic swings due to massive blood loss, cross-clamping the IVC, and impendence of venous return during IVC compression. In addition, TEE was used to rule out tumor emboli, and hourly rapid point-of-care testing of arterial blood gases, electrolyes, hematocrit, glucose, lactate, and ionized calcium, as well as rapid TEG, used to direct therapy to restore intravascular volume, cardiac output and oxygen delivery, and the coagulation system. Endorgan injury was prevented by effective management guided by intensive monitoring.

# Introduction

Pediatric regional anesthesia has attained widespread use internationally because of its efficacy and safety; its use is supported by the extensive data from the international literature underlining the safety and efficacy of this technique [1-3]. Safer drugs and dedicated pediatric tools are the keys to this success. This is so despite the fact that general anesthesia is necessary in most children for the regional block to be performed easily, safely, and effectively. Indeed, the benefit/risk ratio is excellent, especially for peripheral blocks, even when beginners perform these blocks. All the regional blocks require complete knowledge of the anatomical landmarks and underlying nerve anatomy, and specialists in pediatric anesthesiology should supervise trainees closely in order to prevent repeated errors. Despite its well-known benefits, clinical failures can occur during the application of regional anesthetic technique. Neurovascular anatomy is highly variable, and currently available nerve localization techniques provide little or no information regarding the anatomical spread of local anesthesia; furthermore, traditional nerve localization techniques (nerve stimulation) rely on anatomical assumptions that may be incorrect.

Recently, ultrasound guidance has been shown to improve block characteristics, resulting in shorter block performance time, higher success rates, shorter onset, longer block duration, reduction in volume of local anesthetic agents required, and better visibility of neuraxial structures.

# Embryology and developmental physiology of the peripheral nervous system

The nervous system and the spinal cord are not fully developed at birth, and several morphological

Gregory's Pediatric Anesthesia, Fifth Edition. Edited by George A. Gregory, Dean B. Andropoulos.

<sup>© 2012</sup> Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

particularities must be considered. There are some differences in the anatomy of spinal cord meninges between a neonate and an adult. During the embryonic period, the spinal cord fills the spinal canal but from the fetal period onward, the growth of the spinal canal exceeds that of neural structures; consequently, the caudal end of the spinal cord and the dural sac occur at progressively higher levels. The tip of the spinal cord is at L3 at birth and L1-2 at 1 year. In the same way, the meninges are at S3 at birth and S4-5 at 1 year. In addition, infants and children weighing less than 15kg have a relatively high volume of cerebrospinal fluid (CSF), 4mL/kg bodyweight, compared with adult values of 2mL/kg bodyweight. The contents of the epidural space in infants differ from those of adults. Instead of having mature, densely packed fat lobules, divided by fibrous strands, they have spongy, gelatinous lobules with distinct spaces permitting the wide longitudinal spread of injected solutions.

The spine undergoes significant morphological and structural change throughout childhood and adolescence. At birth, it displays a simple regular flexure throughout, so that any epidural needle with the same orientation can be inserted in any given intervertebral space. With the development of the cervical flexure in the sitting position, i.e. head position sustained upright, and then that of the lumbar lordosis with the development of standing and walking, the orientation of the epidural needle must be modified accordingly. During infancy and early childhood, the vertebrae are cartilaginous; ossification of the vertebrae is a progressive phenomenon. The ossification nucleus can be damaged by incorrect epidural block technique. Due to the late osseous fusion of the sacrum, intervertebral epidural approaches can be performed at all sacral levels throughout childhood.

Myelination begins in cervical neuromeres during the fetal period and continues downward and upward until the 12th year of life [4]. In an infant, the fiber diameter is smaller, the myelin sheath thinner and the internodal distance smaller, so a lower concentration of local anesthetic is needed to achieve the nerve block and to avoid toxic effects. Furthermore, the relative resistance to epidural blockade of the L5–S1 nerve roots observed in adults does not occur in pediatric patients because of the smaller diameter of nerve fibers. The local distribution is excellent due also to the fact that nerve envelopes are loosely attached to underlying nerve structures, which favors the spread of local anesthetics along the nerves and the roots.

There are important differences between infants, small children and adults in the physiological effects of central blocks. It is a constant finding that the incidence of clinically significant hypotension and bradycardia following spinal or epidural anesthesia is lower than in adult patients [5]. Despite the absence of prior intravenous volume loading and the high level of sympathetic blockade, blood pressure and cardiac index are not modified by the block [6]. There is less vasodilation in infants than in older children and adults, and infants respond to high thoracic sympathetic blocade by reflex withdrawal of vagal parasympathetic tone to the heart [7].

# Local anesthetics and toxicity

Amide local anesthetics used for regional anesthesia in pediatric patients are potent sodium channel blockers and thus they block impulse conduction in axons. Local anesthetics (LAs) have other actions that may contribute to both local and systemic toxicities and to beneficial systemic actions on inflammatory responses [4] or chronic pain conditions. Amide local anesthetics are potent sodium channel blockers with marked stereospecificity, which consistently influences their action, especially their toxic action on the heart. At toxic concentrations, they induce severe arrhythmias with the potential for cardiac arrest.

The primary local anesthetic agents used in pediatric regional techniques are 2-chloroprocaine, lidocaine, bupivacaine, ropivacaine, mepivacaine, and tetracaine. The pharmacology of local anesthetics in children is similar to that in adults. In neonates and infants, however, the greater total body water volume results in a larger volume of distribution and therefore longer elimination half-life. 2-Chloroprocaine 2% or 3% has a short time to onset of action and a short duration of action. Lidocaine 0.5% to 2% has a short time to onset and medium duration of action. It can be used for peripheral blocks or epidural anesthesia. Bupivacaine 0.1% to 0.5% has a longer onset time and duration of action than lidocaine or 2-chloroprocaine but has a greater potential for severe cardiotoxicity than other agents. It can be used for peripheral blocks, spinal anesthesia, and caudal or epidural anesthesia and analgesia. Tetracaine 1% is used for spinal anesthesia. Mepivacaine is approximately equally potent to lidocaine and can safely be used for peripheral nerve blocks. It can provide a rapid onset of block, with a shorter duration of motor block that may allow for rapid recovery in the postoperative period. Ropivacaine 0.2% to 1% and levobupivacaine 0.25 to 0.5% may replace the racemic mixture of bupivacaine because of their decreased potential for central nervous system toxicity and cardiotoxicity. Ropivacaine differs from bupivacaine in various aspects: it is a pure S-enantiomer and its lipid solubility is markedly lower; these characteristics can significantly improve its safety profile. Levobupivacaine, the S-enantiomer of racemic bupivacaine, is less cardiotoxic while showing similar LA properties and the potency of racemic bupivacaine. Indeed, several cases of central nervous system

toxicity have been reported after inadvertent intravascular administration of ropivacaine or levobupivacaine in adults, but only a few cases of cardiovascular toxicity have been reported to date [8,9]. The outcome of these inadvertent intravascular administrations was favorable, even in a neonate [10].

# **Pharmacokinetic factors**

When injected into the body, the pure isomers do not undergo interconversion, meaning that they do not transform into the usual racemic compounds.

Local anesthetics bind to blood components - erythrocytes and serum proteins such as α1-acid glycoprotein (AAG) and albumin [11]. These buffer systems have different levels of importance; the AAG is by far the most important because it is specific. The red blood cells play a lesser role in sequestration of LA, with only 15-22% of bupivacaine molecules bound in erythrocytes at varying total concentrations of the LA [12]. This buffer system may become important when the LA blood concentration is very high beyond the toxic concentrations and with anemia (red blood cells bind less than 15% of molecules of LA when the hematocrit is <30%). Binding of amide LA to serum proteins is more important. Like all weak bases, amides are mainly bound to the AAG and serum albumin [11]. AAG concentration is 50-80 times lower in plasma than is albumin, particularly in infants. The determination of serum albumin LA binding is characterized by a low affinity but a high capacity, while the affinity of binding to the AAG is high but the capacity is low.

The AAG is the main serum protein involved in the binding of LA. Because AAG is a major acute-phase protein, its concentration rapidly increases when inflammatory processes develop, particularly during the first 6h of the postoperative period [13]. In addition, the affinity of LA increases with the inflammatory processes; acidosis decreases this affinity. Neonates and infants have a lower AAG concentration in serum compared to adults [14] and therefore, their free fraction of LA is increased accordingly (Fig. 18.1). This has important clinical implications since, at least in steady state, the toxic effects of LAs are directly related to the free (unbound) drug concentration. In summary, there are no differences in protein binding between R- and S-enantiomers of bupivacaine, at least when the concentrations, even toxic, are observed in clinical practice [15].

After passing through the bloodstream, the amide LAs are excreted by the liver. This phase involves cytochrome P450. The clearance of bupivacaine, like the clearance of ropivacaine and levobupivacaine, ranges from 3 to 6 mL/kg/min. The renal clearance is low so the main metabolism of these agents is hepatic.

Local anesthetics are metabolized by cytochrome P450 (CYP). The main CYP isoforms involved are CYP3A4 for

**Figure 18.1** The major proteins involved in binding and the relationship between their concentrations and age (AAG,  $\alpha$ 1-acid glycoprotein, SA, serum albumin) (*bottom*) and the relationship between free fraction of bupivacaine in serum and age (*top*). The free fraction is increased at least until 6 months of life. Reproduced from Mazoit et al [14] with permission from Lippincott Williams and Wilkins.

lidocaine and bupivacaine [16] and CYP1A2 for ropivacaine [17]. CYP3A4 is not mature at birth but is partly replaced by CYP3A7 [18]. At 1 month of age, the intrinsic clearance of bupivacaine is only one-third of that in adults, and two-thirds at 6 months. CYP1A2 is not fully mature before the age of 3 years. Indeed, the clearance of ropivacaine does not reach its maximum before the age of 8 years [19]. However, at birth this clearance is not as low as expected [20], even with levobupivacaine [21], and ropivacaine and levobupivacaine may be used even in younger patients. Finally, the S- and R-enantiomers of LA kinetics are very similar and the slight differences that have been described do not have any clinical consequences.

# Pharmacodynamic factors

The R- and S-enantiomers of a LA molecule have different pharmacodynamic effects on the myocardium and the nerve. The physiology of nerve activity is the summation of numerous complex events and interactions. A simple explanation is that in most cases, modulation of impulse frequency and not modulation of amplitude is more important in blocking function of the nerve. Upon the basic background activity is imposed an added impulse, for example a painful stimulus. The effects of LAs can be improved when the signal they are trying to block increases in frequency. Thus, in addition to the basic block (tonic block), there is added a nerve blockade (phasic block) whose intensity will increase with the frequency of nerve discharge or the heart rate, in the case of myocardial toxicity. Purkinje fibers of the myocardium are more sensitive to the blockade of sodium channels by LA than other fibers or myocytes. While heart rate is rather slow (between 40 and 200 beats/min), the frequency of nerve impulses is much faster. Therefore, the nerves, when stimulated, are immediately blocked due to this high fre-

**Figure 18.2** Rate dependence of QRS widening. QRS duration was measured at varying frequencies on isolated rabbit heart with bupivacaine, levobupivacaine and ropivacaine. The faster the heart rate, the more rapidly QRS widening occurred. Reproduced from Mazoit et al [22] with permission from Lippincott Williams and Wilkins.

quency of baseline activity, while the intensity of heart block increases with tachycardia. This is the physiological explanation for the preferential nerve block, well before any cardiac toxicity.

The S-enantiomers are unique in that they cause phasic blocks smaller than the R-enantiomers (and therefore than the racemic mixtures). In the nerve, difference is small because sodium channels involved at this level are minimally sensitive to the phasic block, because baseline frequency of nerve discharge is already rapid. In the heart, the difference is more important [22,23]. When the heart rate increases, the S-enantiomers increase the block of the sodium channels they generate much more slowly than the racemic mixtures (the difference between ropivacaine and levobupivacaine remains the same, equal to the difference in power level of the nerve) [22] (Fig. 18.2). However, though there is no intrinsic difference between newborn and adult animals, phasic block (the one that increases with frequency) plays a very important role (Fig. 18.3) [24] and we can well imagine that an infant, whose heart beats at 150 beats/min, is significantly more sensitive than an adult, whose heart beats at 75 beats/min.

The S-enantiomers levobupivacaine and ropivacaine cause moderate vasoconstriction, whatever the concentration range studied.

### **Adjuvants**

The therapeutic index of LAs in infants may be so narrow that the maximum safe infusion rates of the amides are too low to provide sole analgesia for most major surgery in the thorax and abdomen. This would indicate a need

for combining LAs with either opioids or clonidine (or S+ ketamine, not available in some countries) to provide safe synergistic analgesic effects while maintaining safe LA dosing, administering acetaminophen and non-steroidal anti-inflammatory drugs (NSAIDs) to provide an additional systemic analgesic effect, and permiting low-dose intravenous opioids as rescue analgesics.

Intrathecal and epidural opioids were first administered to human subjects in 1979 [25] and since that time they have been proven to provide effective and prolonged analgesia. The presence of high concentrations of opioid receptors in the spinal cord makes it possible to achieve analgesia with small doses of morphine administered in either the intrathecal or epidural spaces. Intrathecal and epidural morphine doses produce more profound and prolonged analgesia than comparable morphine doses administered parenterally, and are capable of relieving both visceral and somatic pain. The use of morphine by the epidural route, either caudal [26] or lumbar [27], gives prolonged analgesia (more than 12h with a single injection of morphine) following abdominal, thoracic and cardiac surgery, and allows respiratory physiotherapy without pain. In addition, intrathecal morphine injection has been used to obtain postoperative analgesia following cardiac surgery or spinal fusion. A systematic review of post-thoracotomy analgesia concluded that a thoracic epidural infusion of LA with an opioid provided the most consistently effective analgesia [27]. The usual doses of epidural morphine range from 30 to  $50 \mu g$  /kg. For single doses of epidural fentanyl, the dose range is  $1-2\mu g/kg$ , and for sufentanil  $0.5-0.75 \mu g/kg$ . The dose for intrathecal morphine is 0.01–0.02µg/kg. Continuous epidural infusion of LA can be combined with fentanyl 0.2µg/kg/h or sufentanil  $0.1 \mu g/kg/h$ .

This improvement in analgesia has to be balanced against the high incidence of undesirable side-effects which include respiratory depression (which may occur several hours after initial administration), nausea, vomiting, pruritus and urinary retention [28]. When administered for treatment of side-effects after epidural morphine, nalbuphine is better than naloxone for treating pruritus and vomiting/nausea [29]. For peripheral nerve blocks, there is little evidence for any analgesic benefit of using opioid analgesics in brachial plexus block over systemic administration.

Clonidine acts at the dorsal horn level, reducing the release of substance P. It gives an antinociceptive potentiation, prolonging the analgesic effect of bupivacaine or mepivacaine. The sedation provided by clonidine, due to an action at the locus coeruleus level, is dose dependent: sedation does not occur with a dose of  $1 \mu g / kg$  or less, it is only apparent with a dose of  $2 \mu g / kg$  or more. Usually, it is not considered a drawback for the pediatric patient (the child is both pain free and quiet) and children are

easily aroused. No side-effects have been described: no respiratory depression or hypotension (only with  $5\mu g/kg$  is there moderate hypotension). For continuous epidural infusion, clonidine doses lower than  $0.08\mu g/kg/h$  were not associated with any measurable effect, whereas doses of  $0.08\mu g/kg/h$  or greater produced both clinically and statistically significant improvements in postoperative analgesia [30]. Because a dose of  $0.12\mu g/kg/h$  was sufficient to provide excellent analgesia, higher doses may not be advisable as they produce excessive sedation with no increase in analgesia.

Ketamine is a potent anesthetic whose action is through the antagonism of N-methyl-D-aspartate receptors, present at the spinal level and involved in pain modulation. Older studies have been performed, using the preservativecontaining formula on adults and in children. Newer studies performed with preservative-free ketamine, both the racemic and the isomeric drug, show that a dose of S-ketamine ranging between 0.25 and 0.5 mg/kg is optimal for prolonging the pain relief given by local anesthetic [31].

The addition of bicarbonate reduces the pain on injection [32]. This alters the pKa of the solution, making the LA available in the active cationic form. See Chapter 33 for further discussion of pain management.

# **Systemic toxicity**

Recent reports in humans suggest that lipid emulsion (Intralipid®) is an effective therapy for cardiac toxicity from high systemic concentrations of ropivacaine and bupivacaine, even in patients for whom conventional resuscitation is ineffective [33]. The solubility of longacting local anesthetics in lipid emulsions and the high binding capacity of these emulsions most probably explain their clinical efficacy in cases of toxicity. The longchain triglyceride emulsion Intralipid® appears to be about 2.5 times more efficacious than the 50/50 mediumchain/long-chain Medialipide® emulsion [34]. No data exist in pediatrics except for a recent case in which a 20% lipid infusion was used to successfully treat a ventricular arrhythmia, after a ropivacaine and lidocaine injection in a psoas compartment block in a healthy 13-year-old child [35]. Indeed, a bolus of 1.5 mL/kg and then an infusion of 0.5-1 mL/kg/min of Intralipid® in combination with usual resucitation should be useful to treat LA cardiac toxicity in children.

Preferably, lipid rescue is administered via a central venous catheter but in its absence, peripheral veins can also be used. A 20% lipid emulsion bolus over 1 min is recommended with an initial dose of 1.5 mL/kg, immediately followed by 1 mg atropine and small boluses of  $10 \mu g/kg$  epinephrine in order to limit the increase in heart rate which is deleterious, as discussed above [22]. Chest compressions should not be interrupted. The

Intralipid bolus can be repeated with a maximum of 4 mL/kg/min. The lipid infusion is to be maintained at a rate of 0.5 mL/kg/min until hemodynamic recovery.

Lipid infusions act as an antidote to LA intoxication and should be readily available for emergencies, much in the way that type O-negative blood and dantrolene are now available universally. Intralipid® has a low cost and a shelf-life of up to 1 year. Guidelines for the management of severe LA toxicity provide essential information, which should be available in all hospitals, particularly in units where LA are administered. See Chapter 40 for further details of management of LA toxicity.

# Local tissue toxicity

Skeletal muscle toxicity is a rare and uncommon sideeffect of LAs, although experimental data show that intramuscular injections of these agents regularly result in calcified myonecrosis [36]. All LAs that have been examined are myotoxic, in which the extent of muscle damage is dose dependent and worsens with serial or continuous administration. Pathophysiologically, increased intracellular Ca<sup>2+</sup> levels appear to be the most important element in myocyte injury [37]. Lipophilicity also determines the extent of Ca<sup>2+</sup> release by local anesthetics, as the effects of racemic bupivacaine and levobupivacaine were significantly more pronounced than those of ropivacaine isomers [38]. Consequently, a rank order of myotoxic potency (ropivacaine < bupivacaine < levobupivacaine)</pre> is suggested. The clinical impact of LA-induced myotoxicity is still controversial. Only a few case reports of myotoxic complications after LA administration have been published in adults. In particular, the occurrence of clinically relevant myopathy and myonecrosis has been described after continuous peripheral blocks; some experimental data have shown more toxicity in young animals,[39] so particular care must be taken with prolonged continuous infusion in infants.

Most recently, several studies have revealed that LAs might irreversibly damage chondrocytes in articular cartilage, which may contribute to cartilage degeneration [40]. Bupivacaine especially showed profound chondrotoxic effects in experimental models and although these results cannot be directly extrapolated to the clinical setting, caution should be exercised in the intra-articular use of this agent. Ropivacaine seems to be less chondrotoxic than bupivacaine [41] whereas the chondrotoxic potency of levobupivacaine has yet to be assessed.

# **Blocks for infants and children**

# Advantages of regional anesthesia

Regional anesthesia, in combination with light general anesthesia, provides several advantages for the pediatric

patient. The most significant advantage, as demonstrated by several authors, is intra- and postoperative pain relief. Regional anesthesia is also useful when general anesthesia is technically difficult or is associated with increased morbidity and mortality, such as in the case of the expremature infant with the risk of postanesthetic apnea [42], the child with severe chronic respiratory disease [43] or the child with myopathy [44]. Regional anesthesia may offer an alternative to general anesthesia in children with a history of malignant hyperthermia.

# Disadvantages of regional anesthesia

Regional anesthesia requires extra time to perform the block and allow it to become effective. Therefore, the use of an induction room will smooth the operating room work. If general anesthesia is needed to perform the block, an assistant can be helpful in supporting the airway and monitoring the patient during performance of the block. Critics of this combined technique suggest that one may be exposing the child to the risks and complications inherent in both. This fear, however, is more a theoretical consideration than a practical one. However, pediatric anesthesiologists now view regional anesthesia as an adjunct to general anesthesia, in much the same way that a neuromuscular blocking agent or intravenous narcotic supplements general anesthesia with a volatile agent [45].

# Choice of regional anesthesia in children

Although blocks which are commonly used in adults are not always suitable for children, some regional blocks are particularly useful for children.

The recent Association of French Speaking Paediatric Anaesthetists (ADARPEF) study has clearly shown a transition in practice from predominantly central blocks to an increased number of peripheral nerve blocks, including catheter techniques (Tables 18.1, 18.2) [3]. The most common extremity blocks were axillary, both lateral and popliteal sciatic, femoral and iliofascial block. Face and trunk blocks represented the largest proportion of peripheral blocks. Trunk blocks were used significantly more often. They are characterized by the emergence of techniques that were not clearly accounted by the first ADARPEF study, i.e. (in order of decreasing frequency) ilio-inguinal, paraumbilical, pudendal, and thoracic and lumbar paravertebral blocks [1]. Facial blocks, not detailed previously, were a new and now widely used practice for facial and reconstructive surgery, particularly in cleft palate repair.

In addition, the recent ADARPEF study has recorded a significant number of catheter placements [3]. They were inserted for central as well in peripheral regional anesthe-

sia, most of them being neuraxial. Indeed, neuraxial continuous epidural analgesia is one of the preferred techniques for obtaining pain relief in children (particularly postoperative pain relief in younger children). Perineural catheters have become a common practice, primarily in hip and foot surgery. Several prospective studies demonstrated the benefits of continuous peripheral nerve blockade after orthopedic procedures in children. Placement of a brachial plexus catheter for pain control is less common in children than in adults. The emergence of peripheral nerve catheter techniques allows provision of postoperative pain relief for the majority orthopedic surgeries using regional anesthesia techniques [46,47] and to treat complex regional pain syndrome in adolescents [48]. The recent ADARPEF study confirmed this emergence of peripheral catheters, mainly axillary and sciatic popliteal, and records slightly fewer neuraxial catheters than the recently published United Kingdom audit, which reported 10,633 epidural catheters (about 2000 per year) [2]. These results confirmed a retrospective report from a single institution (10,929 regional anesthesia procedures performed during a 17-year period) revealing a dramatic decrease in central neuraxial blocks [49]; continuous postoperative analgesia via perineural catheters emerged as routine practice in children in the late 1990s following both peer recommendations and evolution of devices.

# Regional blockade with or without general anesthesia

# Without general anesthesia
