Many older patients undergoing cardiac surgical procedures have some degree of AR. In most cases, the patients are asymptomatic, and the severity of AR is graded as trace to mild. The presence of AR has implications regarding the conduct of circulatory management, administration of cardioplegia, management of hemodynamics, and possible alteration of the surgical plan. The presence of AR requires the echocardiographer to monitor for distention of the left ventricle during CPB and cardiac arrest, as well as during the administration of antegrade cardioplegia. On release of the aortic cross-clamp, the heart may not instantaneously revert to an organized rhythm, thus precluding ejection of LV blood and predisposing to ventricular distention. Ventricular distention is particularly problematic in the setting of AR. The decision whether to address the valvular dysfunction surgically should not be based on LV distention during CPB but considered in the context of the data set that includes the natural history of AR in adults, established guidelines, and published outcomes, in addition to individual patient-related variables, as previously described.

Chronic AR generally evolves in a slow and insidious manner with very low morbidity during a long asymptomatic phase. Some patients with mild AR may remain asymptomatic for decades. Others exhibit progressive worsening of the regurgitant lesion and develop LV systolic dysfunction, leading eventually to heart failure. Evaluation of LV size and function is important because of the poor correlation between symptoms and severity of cardiac disease. The nature of the transition between the compensated and uncompensated periods is poorly understood. Clinicians should be reluctant to consider valve replacement in an asymptomatic patient with preserved LV function (Fig. 16.8). Early operation exposes the patient to perioperative death and morbidity, as well as to the long-term complications of a prosthetic valve. The most recent guidelines for AV operations in patients with AR were published in 2014 by the ACC/AHA Task Force.[49] AVR is clearly indicated for symptomatic patients with chronic, severe

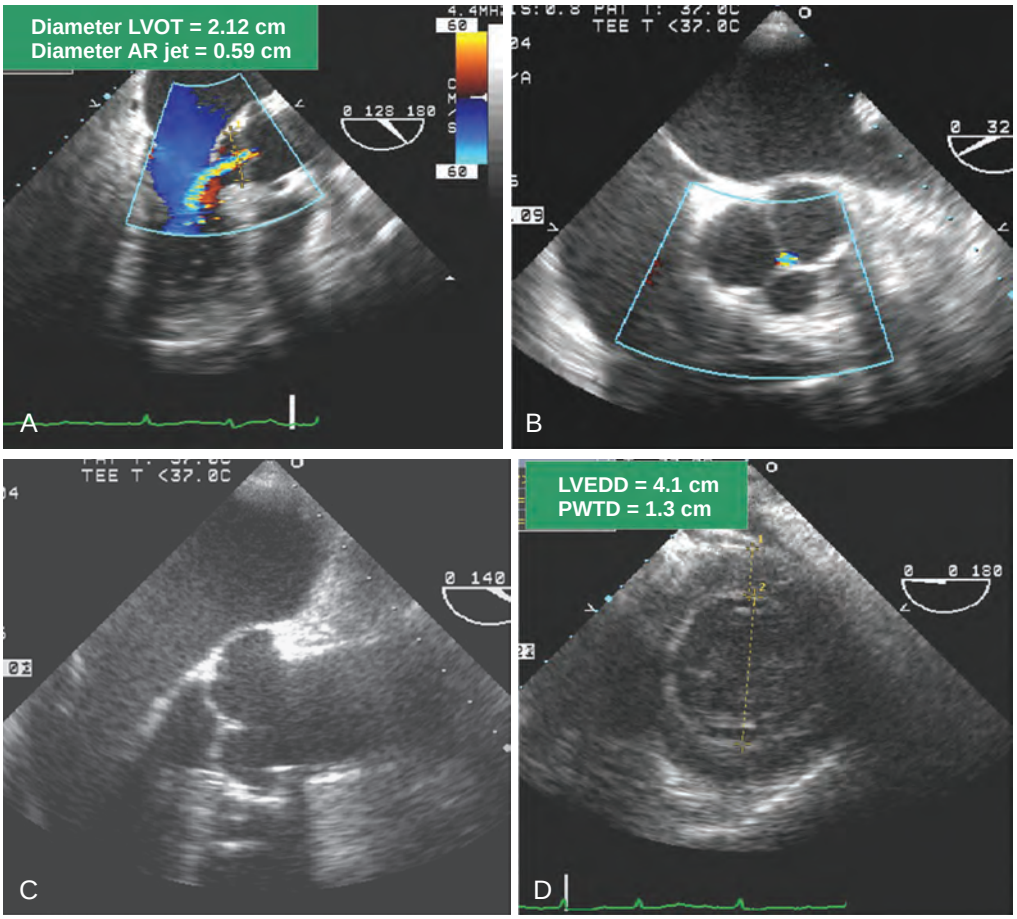

Fig. 16.8 Detection of occult aortic regurgitation *(AR)* during a nonvalvular cardiac surgical procedure. A 66-year-old woman was scheduled to undergo coronary artery bypass grafting using extracorporeal circulatory support. (A) An intraoperative transesophageal echocardiography examination detected the presence of a central AR jet that extended halfway into the left ventricle. The severity of AR, which was graded as mild, was based on assessing the retrograde flow in the left ventricular (LV) outflow tract *(LVOT)* by using color-flow Doppler imaging in midesophageal long-axis plane. The severity of AR is determined by comparing the width of the AR jet, 0.59 cm, with the diameter of the LVOT, 2.12 cm; the ratio of 0.28 is graded as mild. (B) and (C) The anatomy of the valve was that of a normal trileaflet structure with mildly thickened leaflets. No leaflet prolapse, vegetations, or annular or root dilation was present. In addition, no significant aortic stenosis was detected by Doppler examination or calcification of the leaflets. (D) LV chamber size was normal, LV end-diastolic dimension *(LVEDD)* was 4.14 cm, and the presence of LV hypertrophy was consistent with hypertension. Because the severity of AR was not clinically significant and it was not expected to increase markedly, surgical intervention in the aortic valve was deferred. However, the diagnosis of AR altered circulatory management by increasing the vigilance of the echocardiographer to monitor LV chamber size during antegrade cardioplegia and initiate supplemental retrograde cardioplegia. *PWTD,* Pulsed-wave tissue Doppler.

AR, as well as for asymptomatic patients with systolic dysfunction that has no other cause. However, the decision to perform valve replacement is less apparent for asymptomatic patients with moderate AR. The published recommendations suggest that it is reasonable (class IIa recommendation) to perform a valve replacement in asymptomatic patients with moderate AR who are undergoing a surgical procedure for another reason or in patients with an LV end-systolic dimension greater than 50 mm.

Cardiac Function and New Regional Wall Motion Abnormalities

Framing

Ventricular function is a predictor of outcome after cardiac surgical procedures and a predictor of long-term outcome in patients with cardiovascular disease. Patients with compensated congestive heart failure may have a severely decreased EF with minimal symptoms. Regional ventricular dysfunction most commonly is caused by myocardial ischemia or infarction. Hence an imperative exists to detect ventricular dysfunction and institute treatment in an attempt to prevent acute or long-term consequences.

Is ventricular function normal or abnormal? Is the abnormal function global or regional? What is the coronary artery distribution that relates to an SWMA? Is the ventricle large or small? Is the myocardium thinned or hypertrophied? Is the abnormal function new or old? Does the medical or surgical intervention improve or decrease ventricular function?

Data Collection

LV systolic function is assessed echocardiographically based on regional and global wall motion. Methods of assessment include changes in regional wall thickness, radial shortening with endocardial excursion, fractional area change, and systolic apical displacement of the mitral annulus. Quantitative assessments of EF and LV volumes can be made using software built into most modern echocardiography machines by using either 2D (Simpson's equation) or 3D data sets. The 3D techniques in particular have demonstrated accurate results in LV chamber quantification when compared with cardiac magnetic resonance imaging (MRI).[96] Speckle-tracking and measurement of LV strain have also shown promise as newer modalities to assess LV function.

Regional assessment of LV wall motion provides an index of myocardial well-being that can be linked to coronary anatomy and blood flow. Although the measurement of coronary blood flow is not achieved by TEE, the perfusion beds and corresponding myocardium for the left anterior descending, left circumflex, and right coronary arteries are relatively distinct and can be scrutinized by TEE using multiplane imaging. The transgastric short-axis and long-axis imaging views of the left ventricle are the most widely used for evaluating wall motion abnormalities. Regional myocardial ischemia produces focal changes in the corresponding ventricular walls before changes occur on the ECG.[97] Changes progress from normal wall motion to hypokinesis or akinesis. Dyskinesis, thinning, and calcification of the myocardium suggest a nonacute process, likely a previous infarction.

Assessment of RV systolic function is more problematic because it is less quantifiable. The crescent-shaped right ventricle is not amenable to quantitative measures of differences in chamber size during the cardiac cycle. Characterization of the right ventricle is accomplished by comparing the size of the RV chamber with that of the left ventricle and assessing the relative contractile function of the RV free wall and that of the interventricular septum. Early research on 3D echocardiographic techniques to assess RV function was promising,[98,99] but these findings largely relied on off-line analysis of data sets by third party or proprietary software and are thus impractical for use in real time in the operating room.

Ventricular failure can be caused by diastolic dysfunction: the compromised ability of the ventricle to accommodate diastolic filling. Diastolic dysfunction is assessed echocardiographically by examining volumetric filling of the ventricle at the mitral or tricuspid valves and annular excursion using tissue Doppler. Abnormalities of ventricular filling (eg, impaired ventricular relaxation, restriction, constriction) produce characteristic changes in the spectral recordings of Doppler inflow velocities. Abnormalities of diastolic function can lend insight into the mechanisms of circulatory instability (see Chapters 14 and 15).

Discussion

Preexisting ventricular dysfunction suggests an increased surgical risk and a poorer long-term outcome. Such ventricular dysfunction may deteriorate intraoperatively and require marked pharmacologic or mechanical support. A patient with a preoperative EF of 10% who is scheduled for CABG and MV repair is at increased risk for intraoperative ischemia, acute heart failure, and difficulty maintaining hemodynamic stability during the period immediately after bypass. Anticipating such problems, consider placement of an intraaortic balloon pump or femoral arterial catheter during the period before bypass (Fig. 16.9). The same patient is likely to benefit from the administration of inotropic agents during separation from CPB (see Chapter 36).

A marked decrement or unexpected decrease in global cardiac function after release of the aortic cross-clamp can be caused by poor myocardial preservation during cross-clamping or distention of the heart during bypass. The risk for such incidents can be reduced by monitoring of the electrical activity of the heart and pulmonary artery pressures, as well as monitoring for distention of the right and left ventricles. Effective venting of the heart is often difficult to discern by visual inspection alone, especially with the use of minimally invasive surgery through small incisions. TEE can detect ventricular distention produced by AV insufficiency.

Not all preexisting SWMAs benefit from coronary revascularization. Regions of akinesia and dyskinesia usually are the result of a myocardial infarction and may reflect nonviable myocardium, although "hibernating" myocardium is possible. Hypokinetic segments generally are viable and may represent active ischemia.[100] Preoperative positron emission tomographic scanning can detect hibernating myocardium and may be cost effective to guide CABG.[101–103] The detection of hibernating myocardium in an area of chronic ischemia and regional hypokinesis directs the surgeon to revascularize the corresponding stenosed coronary artery. In contrast, an occluded coronary artery with downstream infarction may not benefit from revascularization because contractile function may be irreversibly lost. However, in this latter situation, revascularization after infarction may provide some benefit in decreasing the risk for ventricular aneurysm formation.[104]

Diastolic dysfunction is associated with significant increases in mortality rates during long-term follow-up.[105] Characterization of abnormalities of diastolic function lends insight into the mechanisms of circulatory instability and hypotension. Severe LV hypertrophy with a noncompliant left ventricle and hyperdynamic systolic function may produce severe heart failure if adequate loading is not achieved. Hemodynamic indices obtained from a pulmonary artery catheter may be misleading. The findings of a small LV chamber size, blunted transmitral filling velocities, and an increased fractional area change demonstrate the cause of the hypotension. The decision to administer volume may be appropriate despite the increased pulmonary artery pressures.

If the intraoperative examination reveals new ventricular dysfunction, the intraoperative team must determine the cause and severity and then plan a treatment. Other causes of SWMAs such as conduction abnormalities (left bundle branch block or ventricular pacing) may be difficult to distinguish. Is the decrement in function potentially reversible with conservative therapy, or should additional intervention be considered? Treatment of myocardial ischemia may include

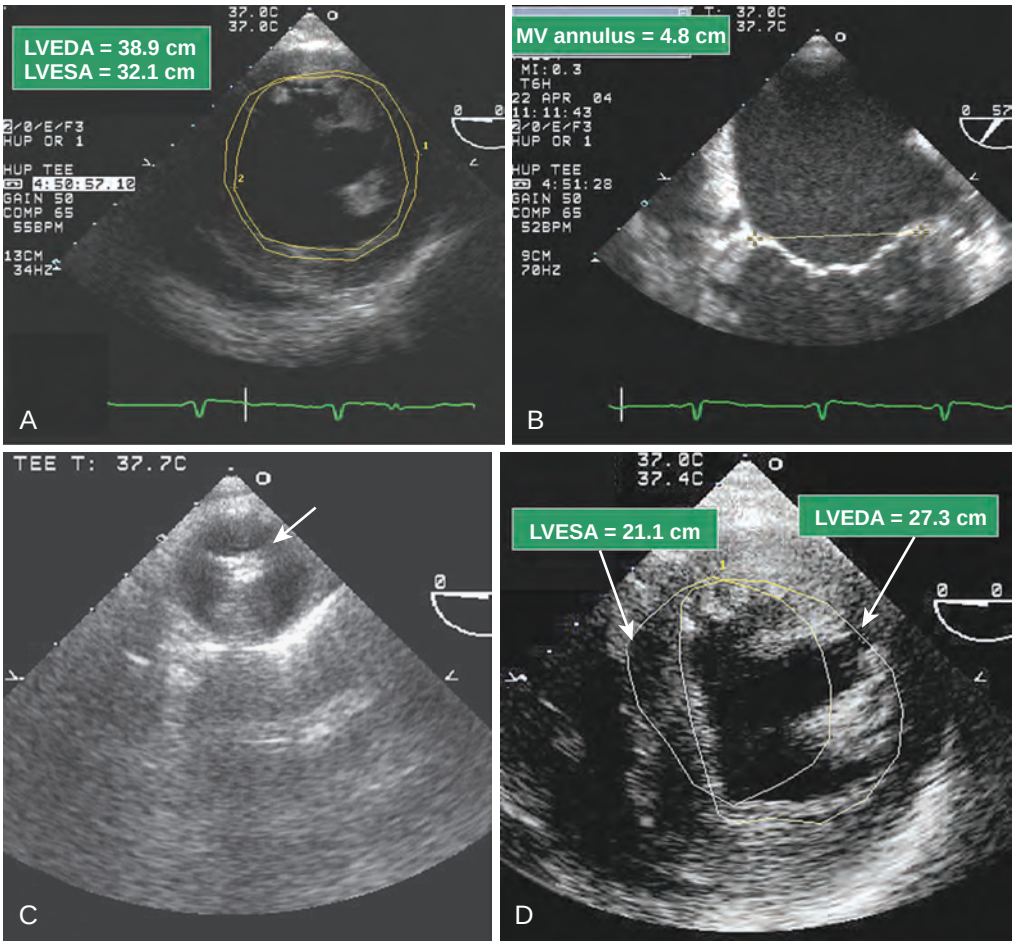

Fig. 16.9 The prebypass transesophageal echocardiography (TEE) examination may have predictive value for postbypass circulatory management. A 63-year-old woman with a medical history of hypertension, congestive heart failure, pulmonary edema, dilated cardiomyopathy, diabetes, and obesity was scheduled for coronary artery bypass grafting (CABG) and mitral valve (MV) repair. The preoperative evaluation documented moderate-to-severe mitral regurgitation (MR) with reversal of systolic pulmonary vein blood flow velocity. (A) The prebypass TEE midesophageal four-chamber view showed a markedly dilated left ventricle (LV) and mildly dilated right ventricle (RV) with mildly decreased global dysfunction. The transgastric view was characterized by severe global dysfunction and an LV end-diastolic diameter of 6.6 cm. The fractional area change (FAC) was 17% [FAC = (left ventricular end-diastolic area [LVEDA] – left ventricular end-systolic area [LVESA])/LVEDA × 100]. Revascularization alone was unlikely to significantly improve MV function. (B) The midesophageal bicommissural view of the MV demonstrated marked dilation of the MV annulus (major axis = 4.8 cm) and tethering of the leaflets below the valve plane that was caused by LV chamber dilation. A femoral arterial line was inserted for monitoring of central aortic pressure and/or possibly placing an intraaortic balloon pump. The patient underwent a CABG × 3 and MV annuloplasty for moderate MR. The separation from bypass was difficult, requiring milrinone, epinephrine, vasopressin, and placement of an intra-aortic balloon pump. (C) TEE, which was used to initially confirm the location of the femoral guidewire, was later used to position the balloon pump just downstream to the left subclavian artery. (D) Worsening of RV function that was characterized by increased central venous pressure, new-onset tricuspid regurgitation, and a hypokinetic RV can be appreciated by ventricular septal flattening and dilation of the RV. The LV ejection fraction did not decrease as might be expected; after correcting MR, the FAC improved slightly from 17% to 22% after bypass. Cardiac function continued to improve, and the counterpulsation device was removed without complication on the first day after surgery. The infusions of milrinone and epinephrine were continued for several days.

the following: optimizing hemodynamics; administering anticoagulants, nitrates, calcium channel blockers, or β-blockers; inserting an intraaortic balloon pump; or instituting CPB and coronary revascularization. The presence of new-onset SWMAs after separation from CPB is worrisome for myocardial ischemia. Even the patient without coronary artery disease remains at risk because of hypotension, a shower of air or debris into the coronary circulation, or coronary spasm. The patient with coronary artery disease who is undergoing CABG may have all the foregoing risks, technical difficulties at the anastomotic site, injury to the native coronary artery (eg, stitch caught the back wall or occlusion of the circumflex artery during MV operation), or occlusion of the coronary graft by thrombosis or aortic dissection. The coronary arteries, grafts, and anastomoses should be carefully inspected for patency and flow. Graft patency in the operating room is

difficult to determine. Techniques include manual stripping and refill, measurement of coronary flow by handheld Doppler, or administration of echocardiographic contrast agents (see Chapters 14 and 15). Hybrid operating rooms have been increasing in number with the intent of providing advanced imaging of the coronary circulation at the time of operation.[106] A new SWMA in the distribution of a new coronary graft can prompt the decision-making strategies listed in Table 16.1 (see Chapters 20, 36, and 38).

Transesophageal Echocardiography as a Rescue Device: Management of Marked Hemodynamic Instability

Framing

In many instances during the perioperative period, the patient may exhibit progressive, unremitting hemodynamic deterioration or acute cardiovascular collapse. Echocardiography offers a versatile modality to diagnose the cause of hypotension and develop management strategies quickly and accurately (see Chapters 15 and 46).

The echocardiographer may be summoned to evaluate an unstable patient in the operating room, intensive care unit, or emergency department with little or no preceding knowledge of the patient. Typically, no consent for the TEE procedure will have been obtained; occasionally, a family member may be available to provide consent on the patient's behalf. TEE may need to be postponed in the trauma patient with suspected cervical spine injury or esophageal injury. The trauma patient with an unstable cervical spine is at increased risk for spinal cord injury with passive movement of the head and neck. Until the cervical spine has been documented to be stable, TEE should be avoided, and TTE is the alternative. The risk for further esophageal injury in patients with penetrating trauma poses an additional challenge. Esophagoscopy is performed before TEE in patients with suspected esophageal injury. However, delay in diagnosis is not without cost. Time must be used efficiently because permanent vital organ injury relates to the magnitude and duration of hypotension and malperfusion. Several issues should be considered to guide the discussion and development of rational management strategies.

What is the cause of the hypotension? Does the cardiac or vascular disorder detected by TEE explain the decrease in blood pressure? Is the heart large or small? Is it full or empty? What is the global function of both ventricles? Are SWMAs present? Is fluid present in the pericardium? Is the observed decrease in cardiac function the primary cause, or is it a consequence of the decreased blood pressure? Is this event related to the patient's medical history or current operative procedure?

TABLE 16.1 Management Strategies for New-Onset Myocardial Ischemia After Bypass

Cause of Ischemia	*Diagnosis*	*Plausible Treatment*
Coronary graft occlusion	ECG changes, new wall motion abnormality, systolic dysfunction	Revise coronary graft
Coronary air emboli	ECG changes, new wall motion abnormality, systolic dysfunction, increased echogenicity of myocardium	Increase coronary perfusion pressure
Coronary calcium or atheroma emboli	ECG changes, new wall motion abnormality, systolic dysfunction	Support circulation, increase coronary perfusion pressure
Dissection of the aortic root	Dissection or hematoma in ascending aorta or aortic root	Repair dissection
Coronary spasm	ECG changes, systolic dysfunction, new wall motion abnormality	Administer coronary dilators

ECG, Electocardiography.

What specific parameters of the ventricle may help explain the current episode of hypotension? What interventions or therapy can be performed to improve hemodynamics? Once therapy is initiated, what index or parameter should be monitored to guide management?

Data Collection

Clinicians must not underestimate the importance of medical history, chief complaint, and operative course when attempting to discern the causes of hemodynamic instability in the acute setting. Important hemodynamic indices include heart rhythm, heart rate, blood pressure, concentration of exhaled carbon dioxide, and central venous or pulmonary artery pressure, if available. Echocardiography can be used to develop a rational approach based on the critical factors of cardiac performance. The determinants of cardiac performance include stroke volume and heart rate, as elucidated by the following equation: CO = Stroke volume × Heart rate. The three components of SV that can be affected are preload, afterload, and myocardial contractility. Although quantitative analysis is possible, qualitative online analysis generally yields sufficient information to form the basis of initial therapeutic intervention. Preload of the ventricle can be determined by assessing the end-diastolic area, afterload can be estimated by assessing the end-systolic area, and contractility can be estimated by the velocity of circumferential shortening, fractional area change, or EF. Mechanical causes of hypotension must be considered (eg, pericardial effusion).

Discussion

Initial inspection determines heart size and overall contractile function of both ventricles. Estimates of end-diastolic area and EF of the LV provide an index of ventricular load and global function. Attention to both RV and LV size and function helps distinguish among different inciting events.

The common causes of intraoperative or perioperative hypotension include intravascular hypovolemia, myocardial ischemia, myocardial infarction, and systemic vasodilatation, either pathologic from infection or inflammation or iatrogenic from drug administration (eg, vancomycin). Mechanical causes of hypotension typically are related to compressive forces impairing the heart's ability to fill or eject (eg, pericardial fluid, tension pneumothorax). The MV is inspected for incompetence. Acute MR is rare in the absence of myocardial ischemia or infarction. A diagnosis of dynamic LVOT obstruction, an uncommon cause during the perioperative period, is difficult to establish in the absence of more invasive monitoring such as TEE (see Fig. 16.3). Systemic hypotension with a dilated right ventricle and a small, underfilled left ventricle implies either primary RV failure (eg, myocardial ischemia or infarction in the distribution of the right coronary artery) or secondary RV failure from acute increases in pulmonary vascular resistance (eg, pulmonary embolus [Fig. 16.10], pneumothorax, or protamine reaction).

Decreased systemic vascular resistance during sepsis or a systemic inflammatory reaction is associated with decreased end-systolic area and increased ventricular contractility (increased velocity of circumferential shortening), with concomitant elevations in the EF and fractional area change. The increase in cardiac performance can be quantified by measuring the CO. In cases of hypotension associated with a markedly heightened CO, the treatment of choice would be the administration of a vasopressor, such as phenylephrine or vasopressin. If decreased systemic vascular resistance and CO are present, administration of a positive inotrope having vasopressor actions, such as epinephrine or norepinephrine, may be more appropriate.

The distribution of the right coronary arterial system of most patients (right-dominant system) includes the right ventricle and the posterior descending coronary artery, which provides blood supply to the inferior and inferoseptal walls of the left ventricle. Acute RV dysfunction is not uncommon after the release of the aortic cross-clamp. Preservation of the right ventricle is less reliable compared with the

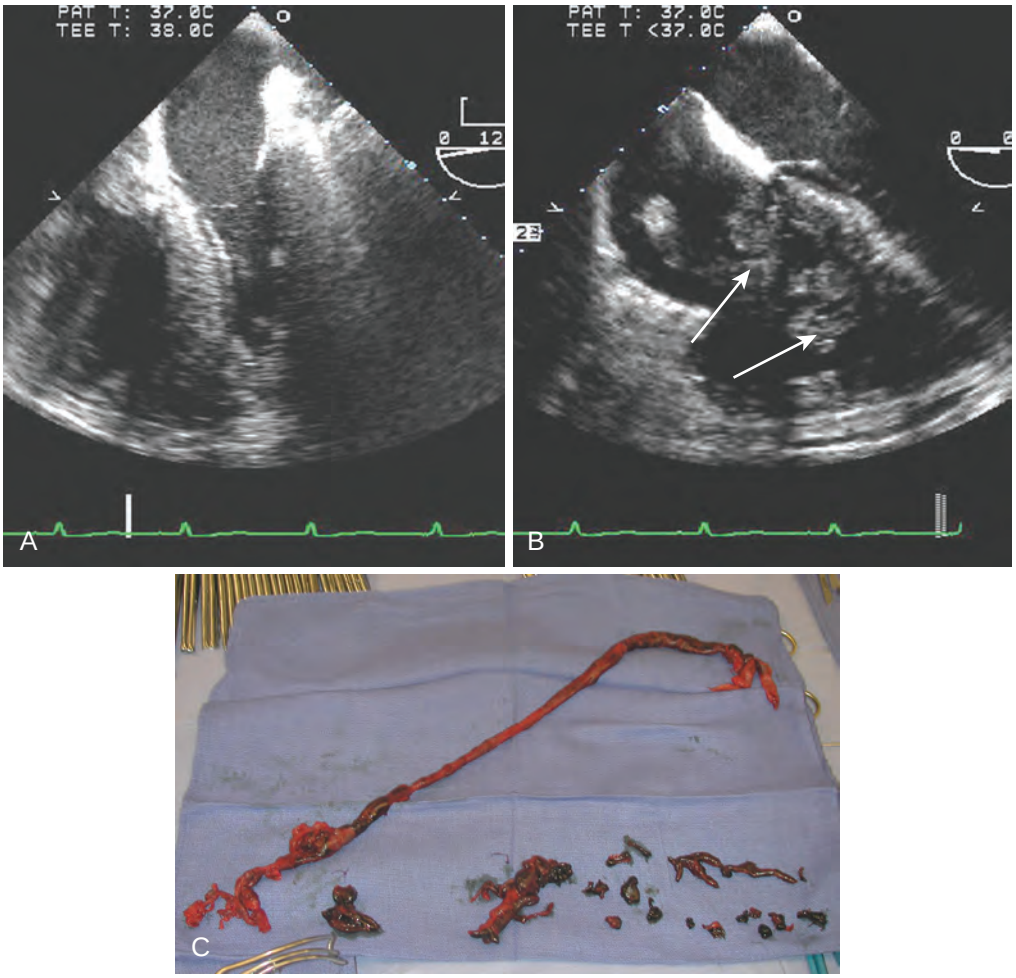

Fig. 16.10 Progressive hypoxia and hypotension after cardiac surgery. A 58-year-old morbidly obese patient with a medical history of hypertension, diabetes, and smoking had recently undergone coronary artery bypass grafting × 3. Five days after surgery, the patient experienced development of new-onset atrial fibrillation together with progressive hypoxia and hypotension requiring readmission to the intensive care unit. The patient's condition continued to deteriorate and required tracheal intubation, ventilator support, and infusions of vasoactive agents. Transesophageal echocardiography (TEE) was performed to evaluate cardiac function and rule out a pericardial effusion. (A) The midesophageal four-chamber view showed a dilated right ventricle (RV) coincident with a relatively underfilled left ventricle (LV) and abnormal positioning of the ventricular septum. The displacement of the septum into the LV was consistent with RV dysfunction and RV volume overload. (B) Inspection of the right heart revealed a dilated hypokinetic RV and a serpiginous density that extended from the right atrium into the RV. The thrombus appeared to be entangled in the chordal structure of the tricuspid valve. Although no thrombus was noted in the pulmonary arteries, the diagnosis of pulmonary embolism was made and the patient underwent an emergent embolectomy. (C) A right atriotomy was performed, and a 64-cm thrombus was extracted from the RV together with additional clots from both the right and left pulmonary arteries. The postbypass TEE documented improved right ventricular function and filling of the LV. TEE was critical in making the diagnosis and the decisions to institute and guide therapy.

left ventricle because of its exposure to ambient room temperature and variability in its coronary circulation. Open-chamber procedures increase the risk for RV dysfunction because of retained intracardiac air. In the supine patient, the right coronary ostium is located in the least-dependent portion of the aortic root, thus predisposing it to embolization of air bubbles. Air embolization to the right coronary artery produces acute ST-segment changes, marked global RV dysfunction, and SWMAs of the inferior wall of the left ventricle (Fig. 16.11). Conservative treatment includes increasing the blood pressure to promote coronary perfusion while continuing CPB.

Pericardial Effusion and Cardiac Tamponade

Framing

Small effusions are common after cardiac operations, especially after removal of chest tubes. In isolation, pericardial effusion may not require surgical intervention. Cardiac tamponade occurs when the pressure exerted by the presence of a pericardial effusion (or any structure adjacent to the heart) compresses the heart, limits diastolic filling of any of the chambers of the heart, and impairs CO. Cardiac

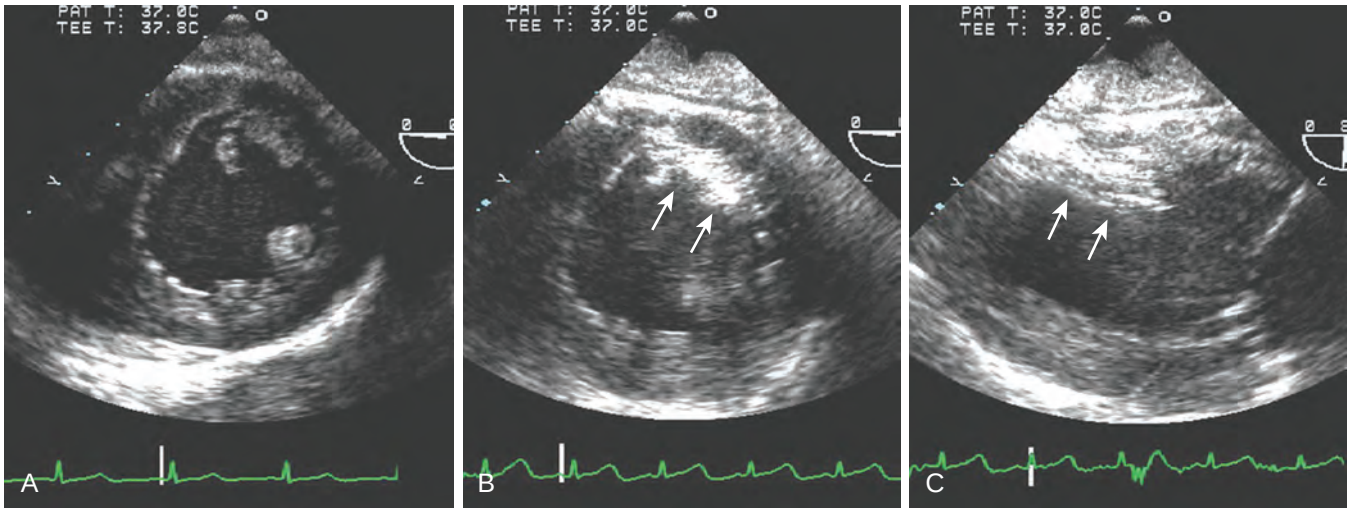

Fig. 16.11 Air embolism after open-chamber procedure. A 57-year-old patient underwent surgical intervention to treat severe mitral regurgitation (MR) and two-vessel coronary artery disease. After performing the mitral valve (MV) repair, the right superior pulmonary vein vent catheter was advanced through the mitral valve to facilitate deairing. The patient was positioned in Trendelenburg and the aortic cross-clamp removed. After ventricular ejection, the left atrium and ventricle (LV) were relatively clear of air and the left atrial vent was removed. An aortic vent that had previously served as the cardioplegia cannula was used to vent the residual air from the ascending aorta. The patient was separated from bypass in normal sinus rhythm and maintained good hemodynamics. (A) The initial postbypass transesophageal echocardiogram (TEE) showed normal ventricular function and filling. Shortly after starting administration of protamine, the blood pressure decreased and the electrocardiogram demonstrated ST-segment changes consistent with ischemia. The protamine administration was stopped, and vasopressors and inotropes were quickly administered. The TEE documented reduced cardiac function in the right ventricle and hypokinesis in the inferior and inferoseptal walls of the LV. (B and C) The transgastric short- and long-axis views of the LV showed that the myocardium in the distribution of the right coronary artery, as designated by the arrows, was characterized by increased echogenicity. Note the significantly elevated ST segments observed in B and C compared with the baseline (A). The absence of pulmonary hypertension and adequate diastolic filling of the LV supported a diagnosis other than acute anaphylactic protamine response or pulmonary embolism. The most likely culprit was air embolization causing transient myocardial ischemia. Air bubbles that migrated from the LV chamber embolized into the ostium of the right coronary artery, which lies at the most anterior aspect of the sinus of Valsalva. TEE served a crucial role in quickly evaluating and diagnosing the cause of hypotension. The hemodynamics, which were temporarily supported by boluses of vasopressors and inotropes, stabilized, and the protamine dose was completed. The patient was transferred to the intensive care unit without any further incident.

tamponade is an emergency, necessitating immediate diagnosis and intervention (see Chapters 24 and 29).

Is a pericardial effusion present? If so, does it contribute to cardiac dysfunction and the patient's present hemodynamic distress? What is the cause of the effusion (acute or chronic)? Is the pericardial effusion the sequela of another cardiovascular event or process (ie, aortic dissection or cardiac catheterization)? Are invaginations of the free walls of the right atrium, right ventricle, or left atrium present? Is the effusion free flowing or loculated? Where is it located? Is echocardiographic assessment consistent with tamponade? What is the coagulation status?

Data Collection

Echocardiography is the standard modality for diagnosis of pericardial fluid. However, the diagnosis of cardiac tamponade is a clinical diagnosis based on hemodynamics and the patient's condition. Low CO, hypotension, equalization of pressures, and high venous pressures are all signs of cardiac tamponade. Echocardiographic findings consistent with tamponade include the presence of pericardial fluid, compression of the atria, compression of the right ventricle, and loss of normal respiratory variability of ventricular inflow velocities.

The TEE examination quickly determines whether pericardial effusion is present, the location of the effusion (loculated, free-flowing), and the impact on chamber filling. Location of the effusion is paramount should pericardiocentesis be deemed necessary for acute decompression. Right atrial and RV collapse are the most sensitive signs of increased pericardial pressure. The effusion need not be a large circumferential effusion to affect cardiac function significantly. Postcardiotomy pericardial clot may be smaller and more compartmentalized than a chronic circumferential effusion, which may be free flowing. Interpreting the clinical significance of cardiac hemodynamics may be complicated by factors such as lability of hemodynamics, decreased intravascular volume, depressed cardiac function, mechanical ventilation and pulmonary dysfunction, soft tissue changes, and chest tubes that obstruct some of the echocardiographic windows. Doppler imaging is used as a complementary method of demonstrating the hemodynamic derangements of tamponade and to determine the clinical significance of an effusion. The echocardiographer should interrogate the phasic respiratory variation of blood flow through the tricuspid valve and MV. Although not specific for tamponade, the changes in respiratory variation of inflow velocity are the hallmarks of increased pericardial pressure. Significant respiratory variation of blood inflow velocities also may be seen in constrictive pericarditis or conditions associated with changes in intrathoracic pressure, such as

increased work of breathing, asthma, or positive-pressure ventilation, and it may be exacerbated in patients receiving positive end-expiratory pressure. Other important data pertaining to the cause and possible intervention include coagulation status.

Discussion

The ACC/AHA/American Society of Echocardiography (ACC/AHA/ASE) Task Force assigned a class I recommendation to the use of echocardiography in patients with suspected bleeding in the pericardial space. Echocardiography is portable, quick, and noninvasive, yet it is a sensitive and specific modality for the detection and assessment of a pericardial effusion. Pericardial effusions can be diagnosed and cardiovascular effects determined by TTE or TEE. However, during the period after cardiac operation, the presence of positive-pressure ventilation, chest tubes, and bandages may severely limit the capability of TTE to assess fluid in the pericardium.

The effusion need not be a large circumferential effusion to affect heart function significantly. Loculated effusion may impinge only on the left atrium and may not be discernible by the traditional acoustic windows used by TTE. A hemodynamically significant localized hematoma compressing only the left atrium may not produce right atrial and RV collapse or the constellation of equalization of pressures. Small effusions are common after cardiac surgical procedures, especially after removal of chest tubes, and in heart transplant recipients with a mismatch between heart size and pericardial cradle. The presence of a pericardial effusion in the patient who has not undergone cardiotomy must lead to a search for the cause of the effusion. Pericardial effusion mandates close scrutiny of the aortic root for possible aortic dissection. Pericardial effusion in a trauma patient is worrisome for cardiac rupture, ventricular contusion, or foreign body injury.

Acute cardiac tamponade in the patient who has not undergone cardiotomy can develop after introduction of as little as 60 to 100 mL of blood. Causes may include type A aortic dissection, myocardial infarction with rupture, acute pericarditis, bleeding from malignant disease, myocardial contusion, or myocardial perforation from penetrating trauma. These life-threatening conditions may manifest with hypotension, tachycardia, plethora, and jugular venous distention. Other classic findings include narrowed pulse pressure, pulsus paradoxus, widening of the mediastinum on chest radiography, and electrical alternans on the ECG. Treatment consists of immediate decrease in pericardial pressure, which can be accomplished through the removal of a relatively small volume of fluid. This temporizing measure can be lifesaving until more definitive therapy is instituted.

Not all pericardial effusions require immediate intervention. Development of cardiac tamponade is related to the rate of accumulation of pericardial fluid and the capacity for the pericardium to stretch and accommodate fluid. Chronic pericardial effusions, which occur in cases of malignant disease, uremia, connective tissue disease, Dressler syndrome, and postinfection pericarditis, uncommonly require emergency intervention. Acute pericardial effusions that occur after cardiotomy are usually more ominous and often result in hemodynamic compromise requiring treatment (see Chapters 24 and 38).

Hemodynamics may improve temporarily with the administration of volume, thus altering intrathoracic pressure (decreasing peak inflation pressure), but the patient still may require drainage of the effusion. Chronic malignant effusions improve after pericardiocentesis but often require a pericardial window for more definitive therapy. Effusions resulting from acute aortic syndromes or cardiac trauma require timely surgical intervention. Postoperative cardiac surgical patients may require urgent reexploration for evacuation of pericardial hematoma and to address the cause of continued bleeding. If hemodynamics improve after sternotomy but minimal clot is found, the physiologic tamponade may be related to generalized tissue edema and pulmonary dysfunction. In cases of poor cardiac function, the sternal incision may need to remain open and covered with a sterile dressing until edema recedes and cardiac function improves.

Occult Congenital Abnormalities: Persistent Left-Sided Superior Vena Cava

Framing

The finding of a persistent left-sided superior vena cava (SVC) is not a common incidental finding, but its diagnosis has important implications for the conduct of circulatory management during CPB.

What echocardiographic findings suggest persistent left-sided SVC? What confirmatory test can be performed? Does the finding of an anomalous left-sided SVC have implications for the conduct of CPB?

Data Collection

The echocardiographer should suspect a persistent left-sided SVC if the coronary sinus is significantly dilated or if significant difficulty was encountered while attempting to place a pulmonary artery catheter. Because the differential diagnosis of a dilated coronary sinus includes disorders associated with increased right-sided pressures, confirmation should be obtained by injecting agitated saline contrast into an intravenous catheter in the left arm. In the case of a persistent left-sided SVC, opacification of the coronary sinus occurs before that of the right atrium or right ventricle. Once the diagnosis is confirmed, the echocardiographer should look for other associated congenital anomalies, including ASDs or an unroofed coronary sinus with communication between the coronary sinus and the floor of the left atrium.

Discussion

Left-sided SVC is the consequence of arrested embryologic development that causes the left brachiocephalic vein to empty into the coronary sinus with subsequent flow into the right atrial return of blood (see Chapter 22). As a consequence, cannulation of the coronary sinus with administration of retrograde cardioplegia is ineffective for providing cardiac protection during cardiac arrest. Once the diagnosis is confirmed, the surgeon is informed to modify the conduct of cardiac protection during CPB. If TEE is unable to confirm the diagnosis (absence of venous access in the left arm to inject contrast material), the surgeon can confirm its presence by direct inspection.

Occult Congenital Abnormalities: Atrial Septal Defects and Patent Foramen Ovale

Framing

The incidental diagnosis of an ASD or a patent foramen ovale (PFO) during a TEE performed for other reasons is a common occurrence because TEE is extremely sensitive at detecting these anomalies.[107] The clinical implications of an intracardiac defect can include shunting, stroke, headaches, pulmonary hypertension, RV dysfunction, and paradoxical embolization. If transseptal flow is present across the defect, it is generally from left to right because left atrial pressure is generally greater throughout the cardiac cycle. Bidirectional flow is possible with transient increases of right atrial pressure that can be observed during normal respiratory maneuvers (ie, Valsalva, coughing, and physical straining).[108,109] Although uncommon, right-to-left shunting can produce episodes of relative hypoxia and paradoxical embolization. In most patients, an ASD or PFO is well tolerated and often remains asymptomatic into adulthood.

When a septal defect is discovered, several questions must be answered. What type of ASD is present: primum, secundum, sinus venosus, or PFO? What is the size of the defect? Does the defect produce transseptal blood flow? What is the shunt fraction: Q_s/Q_t? Does the patient have any symptoms such as congestive heart failure, increased shortness of breath, history of stroke or transient ischemic

attack, or refractory hypoxia? What are the pulmonary artery pressure and RV function? Does the patient have any associated congenital abnormalities, such as a cleft MV with a primum ASD? Does the operation as initially planned require the use of CPB? If so, was single or bicaval cannulation planned? Perhaps most importantly, does the interatrial defect need to be closed?

Data Collection

The application of 2D echocardiography, color-flow Doppler imaging, and contrast administration in the midesophageal four-chamber and midesophageal bicaval views provides for high sensitivity of detection and diagnosis of ASDs and PFOs. The clinical implication of these findings is determined by the type of disorder. The PFO may be detected in approximately 25% of adults; it occurs when the secundum septum fails to close or is stretched open because of elevated pressures in the left atrium (Fig. 16.12). Ostium secundum defects, which account for 70% of ASDs, are located in the area of the foramen ovale. The cause of this lesion is attributed to poor growth of the secundum septum or excessive absorption of the primum septum. MV prolapse is present in up to 70% of patients with this abnormality and may be related to a change in LV geometry resulting from RV volume overload. The primum ASD develops when the septum fails to fuse with the endocardial cushion at the base of the interatrial septum. A primum ASD commonly is associated with cleft anterior leaflet of the MV and MR. The tricuspid valve also may be abnormal. The final type of ASD is a sinus venosus defect, which comprises only 10% of ASDs. It commonly is associated with abnormal insertion of the pulmonary veins into the right atrium or SVC.

Discussion

In general, patients benefit from ASD closure. Although often asymptomatic, ASDs may manifest with atrial arrhythmias, heart murmur, abnormal ECG, dyspnea, cerebrovascular injury or stroke, or migraine headaches. Medical management and surgical closure of secundum ASDs were compared in randomized trials; surgical closure was associated with significantly decreased morbidity and mortality.[110] However, data concerning treatment strategies and outcomes for occult ASD or PFO detected intraoperatively are scarce. In the absence of recognized consensus guidelines, the decision to proceed with definitive closure should be based on the following factors: history of a neurologic event without a definite cause, recurrent stroke while receiving anticoagulation, significant shunting through the defect, a previous episode of hypoxia that may be related to intracardiac shunting, RV dysfunction, or a previous paradoxical embolism. Detection of a primum or sinus venosus defect requires a more involved surgical procedure, and associated anomalies must be addressed. Alternatives to operative closure are increasing as transvenous percutaneous closure devices become increasingly applicable. Transvenous catheter–based closure of an ASD by interventional cardiologists can be performed only on a secundum ASD or a PFO (Fig. 16.13). Approximately 30% of secundum ASDs are amenable to percutaneous closure.[111] The technique optimally requires a defect with limited size and a rim of tissue surrounding the defect of at least 5 mm, to prevent obstruction of the coronary sinus or impingement of the AV (see Chapters 3 and 22).

A PFO is the most common congenital finding and usually is asymptomatic. However, several studies found an increased prevalence

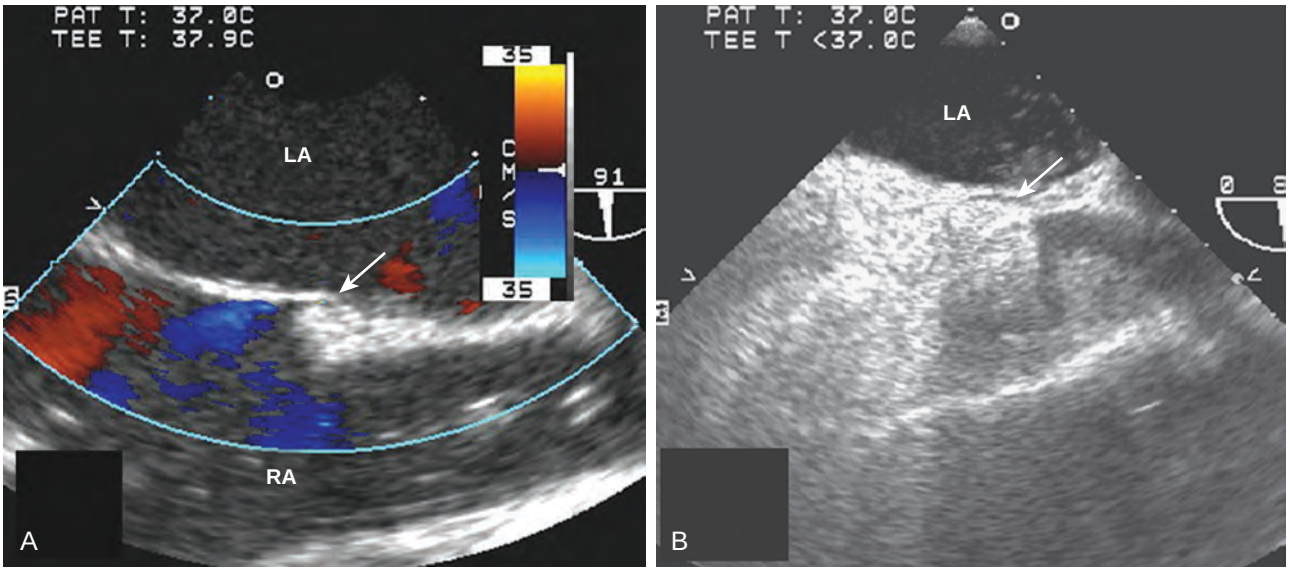

Fig. 16.12 Detection of a patent foramen ovale (PFO) in a patient undergoing cardiac surgery. A 68-year-old patient was undergoing two-vessel off-pump coronary artery bypass grafting. In addition to coronary artery disease, the patient had a medical history of hypertension, non–insulin-dependent diabetes, and a stroke of unknown cause. (A) The intraoperative transesophageal echocardiographic examination that included an inspection of the interatrial septum in the midesophageal four-chamber, and bicaval imaging planes showed a new finding of an aneurysmal interatrial septum with a PFO (*arrows*). Color-flow Doppler showed minimal shunt flow from the left atrium *(LA)* to the right atrium *(RA)*. (B) The presence of the PFO *(arrow)*, which was initially diagnosed by color-flow Doppler imaging (A), was confirmed by the transient flow of injected contrast *(arrow)* into the LA after it was injected into the venous circulation. A provocative maneuver such as Valsalva transiently increases pressure of the RA more than that of the LA, thus increasing the sensitivity of PFO detection.[47] Because of the patient's history of a cryptogenic stroke, the surgical plan and circulatory management were altered. The patient was fully heparinized and circulation was supported by an extracorporeal pump while the coronary artery bypass graft was performed and the PFO was closed.

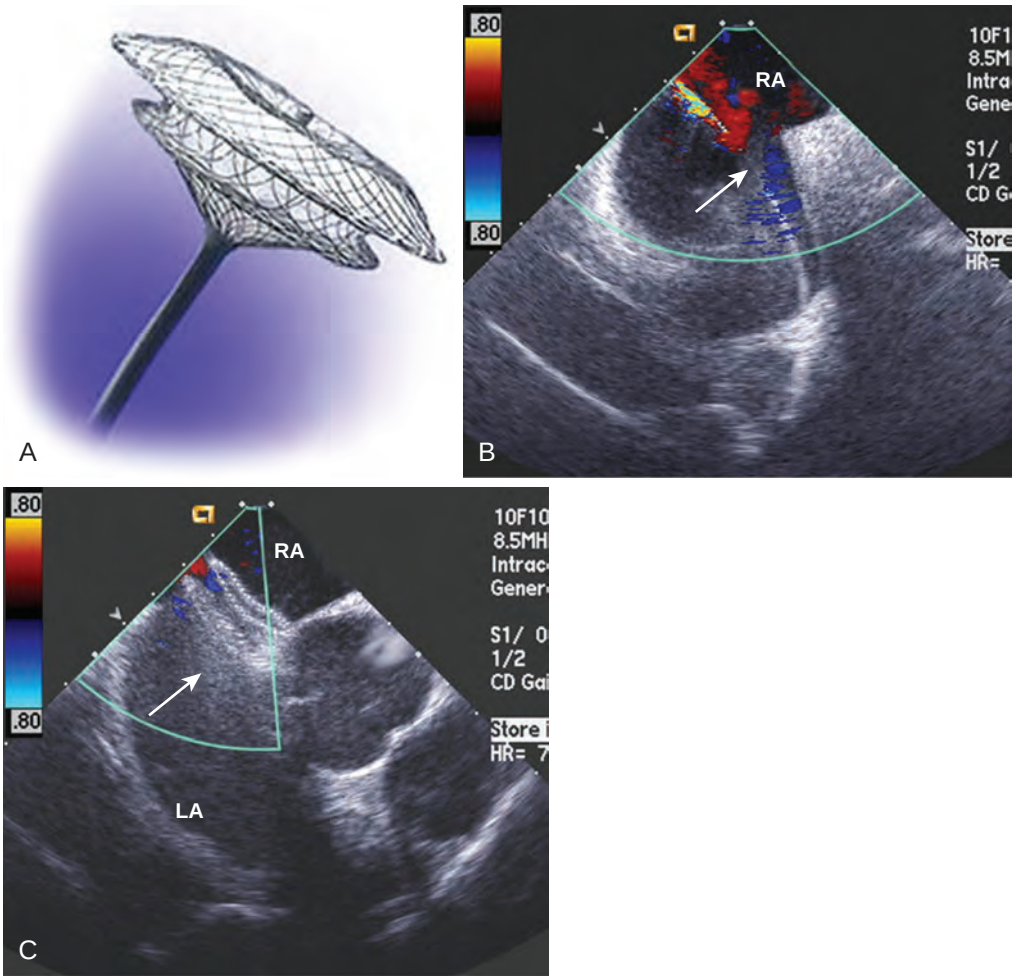

Fig. 16.13 Transvenous approach to closure of atrial septal defects (ASDs). Patent foreman ovale and secundum ASDs can be closed by deploying a transvenous closure device as an alternative to surgical intervention. (A) Self-expanding Amplatzer occlusion device (AGA Medical Corporation, Plymouth, MN) that is made of wires tightly woven into two interconnected disks. The device is deployed from the femoral vein and is positioned using transesophageal echocardiography or intravascular ultrasound. (B) Color-flow Doppler image from an intravascular ultrasound scan that shows the deployment catheter as it enters through the right atrium *(RA)* and spans the secundum ASD *(arrow)*. (C) Color-flow Doppler ultrasound image showing the Amplatzer device *(arrow)* in position across the interatrial septum, thus preventing shunt flow across the ASD. *LA,* Left atrium.

of PFO and atrial septal aneurysms in patients who had cryptogenic strokes (ie, no identified cardioembolic or large vessel source).[112–118] A metaanalysis of these case-control studies found that PFOs, atrial septal aneurysms, or both were significantly associated with ischemic stroke in patients younger than 55 years of age.[119] However, the relationship between septal disease and neurologic events in patients older than 55 years of age is less clear. Evidence also indicates that the morphology of PFOs in patient who suffer cryptogenic strokes may be different from that in patients without a history of stroke; the former tend to be larger (3.9 vs 2.9 mm) with longer tunnels and a greater incidence of atrial septal aneurysm.[120] The data on treating patients with atrial septal abnormalities for either primary or secondary prevention of stroke are limited. The Patent Foramen Ovale in Cryptogenic Stroke Study and a metaanalysis by Orgera and colleagues[121] found that warfarin treatment was superior to other antiplatelet therapy and was comparable to surgical PFO closure for the prevention of recurrent cerebral events.

A survey of cardiothoracic surgeons in the United States noted a high degree of variability in management of intraoperatively discovered PFO.[122] During planned on-pump CABG surgical procedures, 27.9% of responders stated that they always closed intraoperatively discovered PFOs, whereas 10.3% did not. Only 11% of surgeons converted a planned off-pump procedure to an on-pump procedure to close the defect, but the rate of closure increased to 96% if the patient had a history of possible paradoxical embolism. In a large, retrospective study of 13,092 cardiac surgical patients at the Cleveland Clinic in Cleveland, Ohio, 2277 (17%) were found to have a PFO during intraoperative TEE. Of these patients, 639 went on to have their PFO closed. Survival was similar between the closure and nonclosure groups, although the risk of stroke was higher in those patients who had their PFO closed (2.8% vs 1.2%).[123] Some evidence indicates that the presence of a PFO may increase the risk of postoperative atrial fibrillation after cardiac surgical procedures.[124]

The benefit of aggressive management of a PFO in the absence of other interatrial septal abnormalities is less clear than with ASD closure and is more controversial. Sometimes surgical intervention requires a significant alteration of the surgical plan that may significantly increase operative risk. If PFO detection occurs during off-pump coronary artery bypass, surgical intervention necessitates marked changes in the conduct of both the operation and circulatory management. The patient who is undergoing off-pump coronary artery bypass and who has a small PFO typically remains untreated. In the absence of recognized consensus guidelines, the decision to proceed with definitive

closure should be based on the following factors: history of a neurologic event without a definite cause, recurrent stroke while receiving anticoagulation, the morphology of the defect, significant shunting through the defect, a previous episode of hypoxia that may be related to intracardiac shunting, RV dysfunction, or a previous paradoxical embolism.

Ascending Aorta: A Source of Embolization

Framing

The most disabling complication after cardiac operations is stroke. Major focal and nonfocal neurologic deficits, cognitive decline, and coma are common postoperatively. The pathogenesis of cerebral damage is multifactorial, with embolism considered a major contributor. Other factors include hypotension, low flow, reperfusion injury, and inflammation. Embolic events are strongly associated with the severity of atherosclerotic disease, characterized by plaque thickness of greater than 4 mm, ulcerated plaques, and mobile protruding plaques in the aorta.[125,126] The severity of atherosclerosis of the descending aorta, as determined by TEE, is a significant risk factor and an independent predictor of adverse cardiac and neurologic outcomes in patients undergoing CABG.[127] Surgical manipulation of the thoracic aorta may liberate debris from diseased aortic tissue. The process of microembolization has been detected by transcranial Doppler imaging during aortic cannulation, application and removal of the aortic cross-clamp, commencement of CPB, and initiation of ventricular ejection. The clinical consequence of distal embolization depends on the number, composition (eg, air bubbles, fat particles, platelet aggregates, and calcium deposits), size, and location of the emboli (see Chapters 14, 15, 18, 20, 21, 23, 31, and 40).

Is the patient at increased risk for postoperative neurologic dysfunction? Would epiaortic ultrasound examination or TEE improve detection of significant atheromatous disease? What modifications to the conduct of the general anesthesia, monitoring, CPB, or cardiac surgical procedure could be implemented in a risk-reduction effort? Is epiaortic scanning necessary?

Data Collection

TEE imaging of the anterior wall of the ascending aorta is limited by far-field imaging resolution and its juxtaposition to air in the open chest. Imaging of the middle and distal ascending aorta by TEE is limited by the interposition of the airway with the esophagus and aorta. Epiaortic ultrasound examination can provide high-definition imaging of these otherwise hidden portions of the aorta. Epiaortic scanning offers higher sensitivity for detection of atheroma of the ascending aorta, as compared with TEE, especially in the middle and distal segments.[3,128] The descending aorta is immediately adjacent to the esophagus and is easily imaged using conventional TEE. A common practice is the interrogation of the descending thoracic aorta for high-grade atheroma. In the absence of atheromatous disease in the descending aorta, the ascending aorta and locus of aortic cannulation are significantly less likely to have high-grade disease. If the descending aorta contains high-grade or mobile atheroma, it may be prudent to examine the ascending aorta with epiaortic scanning for potential sites for aortic cannulation and clamping (Fig. 16.14).

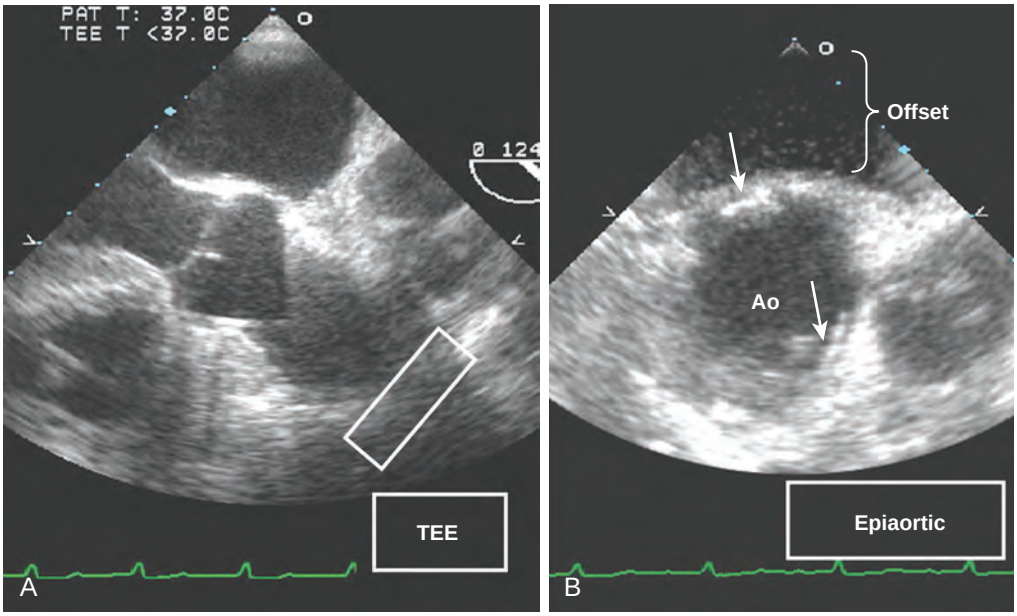

Fig. 16.14 Detection of atheromatous plaque by epiaortic ultrasound. A 67-year-old patient was scheduled to undergo triple coronary artery bypass grafting. Transesophageal echocardiographic *(TEE)* examination was performed to evaluate the mitral valve for mitral regurgitation that could necessitate surgical intervention. Routine examination of the descending thoracic aorta detected severe atherosclerotic disease characterized by several ulcerated areas and plaques with a thickness of 4 mm. Because the severity of atherosclerotic disease in the descending aorta predicts significant disease in the ascending aorta,[127] examination of the ascending aorta was attempted. (A) TEE examination of the ascending aorta at the site of aortic cross-clamp and cannulation *(white rectangle)* was limited by poor resolution in the far field and interposition of the trachea. (B) A handheld probe that was placed in a sterile sleeve was used to examine the aorta. The bottom of the sleeve was filled with saline solution as an offset to image the anterior surface of the aorta *(Ao)* more clearly. Several calcified plaques *(arrows)* were detected. Based on findings of the epiaortic scanning, the surgeon modified the site of cannulation and used a single cross-clamp technique to avoid a second clamping of the aorta during the proximal anastomosis.

Discussion

Historically, surgeons palpate the ascending aorta to determine the extent of intraluminal atherosclerotic disease in an effort to choose an appropriate location for cannulation, cross-clamping, and proximal graft anastomosis. However, palpation is a notoriously poor predictor of atheromatous disease.[129–131] The occurrence of atheroma in the ascending aorta of cardiac surgical patients may be as high as 60% to 90%.[130,132] Advanced age, hypertension, and diabetes are risk factors for atheromatous disease of the aorta and stroke after cardiac operations.[133] The information provided by ultrasound imaging of the aorta defines the location and severity of atheromatous disease and can guide the surgeon to choose the cannulation, cross-clamp, and anastomotic sites more strategically.

Possible modifications to the conduct of cardiac surgery and CPB include the following:

1. Altering the site of cannulation
2. Aborting CPB altogether and performing the CABG operation as an off-bypass procedure
3. Performing the operation on a fibrillating heart without aortic cross-clamping
4. Performing aortic atherectomy or replacement of the ascending aorta
5. Attempting a "no-touch" technique using deep hypothermic circulatory arrest.

Epiaortic scanning combined with a modification of surgical techniques in patients undergoing CABG decreased the number of emboli as detected by transcranial Doppler imaging and significantly reduced neurologic behavioral changes at 1 week and 1 month postoperatively.[134] Modifications in the methods used in CABG revascularization, including the avoidance of proximal aortic graft anastomoses after detection of atheroma by echocardiography, resulted in a lower incidence of late neurologic complications.[2]

The application of epiaortic scanning for all patients undergoing cardiac surgical procedures is controversial. Epiaortic scanning takes time and expertise in its interpretation and poses the potential risk for wound contamination. Data are insufficient to support its use in all cardiac patients, although high-risk patients (advanced age, diabetes, hypertension) are the most likely to benefit.[135,136] As the population of patients undergoing cardiac operations ages, these patients will have a greater incidence of atherosclerosis of the aorta and the presence of concomitant risk factors for postoperative complications. Echocardiographers working in the operating room need the skill set to interrogate the aorta by handheld ultrasound scanning and the ability to guide the surgeon in performing the examination. Such scanning could be potentially lifesaving in high-risk patients. A diagnostic scan of the ascending aorta and arch to evaluate the location of possible cannulation and clamp sites can be performed in several minutes. Standardized approaches to a comprehensive organized intraoperative epiaortic and epicardial examination are useful guides.[137]

Case Study 2: Putting It All Together: A Case Study in Acute Aortic Syndromes

It is midnight on a gloomy, rainy night. The hospital helicopter calls in "… young woman, unrestrained driver, deceleration injury, steering wheel impact, chest contusion, unconscious, hypotensive. She is intubated with bilateral breath sounds. Her blood pressure is 70/40 mm Hg with a heart rate of 125 beats/minute and sinus tachycardia. She is being fluid resuscitated and being transported directly to the cardiac operating room." The patient is too unstable for MRI or computed tomography (CT) scanning. The patient arrives in the operating room with a portable chest radiograph obtained as she was whisked through the emergency department; the radiograph shows a widened mediastinum. The vital signs have not changed except that she is receiving dopamine at 10 μg/kg per minute. Pulses are palpable in the groin and the neck. The patient is transferred to the operating room table, and everyone turns to the anesthesiologist-echocardiographer for guidance. The attending surgeon asks, "I need to know is this an anterior injury with heart contusion, injury to the ascending aorta, tamponade with blood in the pericardium, or a transected aorta at the isthmus or arch, or is this a nonoperable injury?" An injury to the ascending aorta will require a sternotomy, while a transection of the descending aorta or isthmus will require a left thoracotomy. "If we make the incorrect decision, the patient will surely die." The patient is stabilized in the operating room, and the TEE probe is inserted. TEE reveals no blood in the pericardium, an intact aortic root with no evidence of type A dissection, a step-up in the intima at the site of the left subclavian artery, and a small left pleural effusion. The patient is positioned in the left lateral decubitus position, and the operation proceeds to save a young life.

Framing

The unstable patient with suspected acute aortic disease or injury is often the most challenging of TEE cases. Few more crucially important decisions are posed to the intraoperative echocardiographer than to diagnose the nature and extent of acute aortic injury quickly and accurately. Hypotension and respiratory distress may prevent a complete and comprehensive evaluation preoperatively (Fig. 16.15). The patient's history often is unobtainable. The echocardiographer becomes a detective. Clues are quickly gathered from the available clinical presentation, history, and associated physical findings. TEE is often the only modality used to establish the diagnosis and define the surgical plan.

The sensitivity and specificity of TEE to detect and diagnose injury or disease of the thoracic aorta are significantly better than the sensitivity and specificity of TTE and are comparable to CT scan and MRI.[138,139] TEE provides information on cardiac performance and the presence of other critically important sequelae that may be important in determining the approach and timing for surgical intervention. Hence TEE is indicated even if MRI or CT scanning has confirmed the diagnosis.

Can consent be obtained from the patient or family members? In these emergency circumstances, it may be more prudent to proceed with the TEE examination rather than delaying diagnosis and treatment in an attempt to find family members. What is the differential diagnosis of a widened mediastinum? How does TEE discriminate among the different causes of a widened mediastinum? Is TEE performed in the awake distressed patient, or is the examination done under more controlled conditions of an anesthetized, intubated patient? Does a risk exist for cervical spine injury? Does a risk exist for esophageal injury? Can insertion of the TEE probe further compromise the patency of mediastinal structures? Is fluid present in the pericardium? What is the biventricular function? Is myocardial rupture present? Is aortic rupture present? Is the thoracic aorta intact? Are an intimal flap and a dissection present? Is a transection present? Is a pleural or periaortic effusion or hematoma present? Is an intramural hematoma (IMH) present? What factors determine the urgency of intervention and strategies for management?

Data Collection

Because the diagnosis and cause of instability are not established, the entire mediastinum, including the left pleural space, is interrogated before definitive therapy is initiated. Rarely does the echocardiographer have enough time to do a complete TEE examination. The operative team can often proceed with confidence in the management of these critically ill patients with only TEE to guide the treatment. The primary events in aortic dissection are a tear and separation of the aortic intima. It is uncertain whether the inciting event is a primary rupture of the intima with secondary dissection of the media or hemorrhage within the media and subsequent rupture of the overlying intima. Systolic ejection forces blood into the aortic media through a tear that leads to

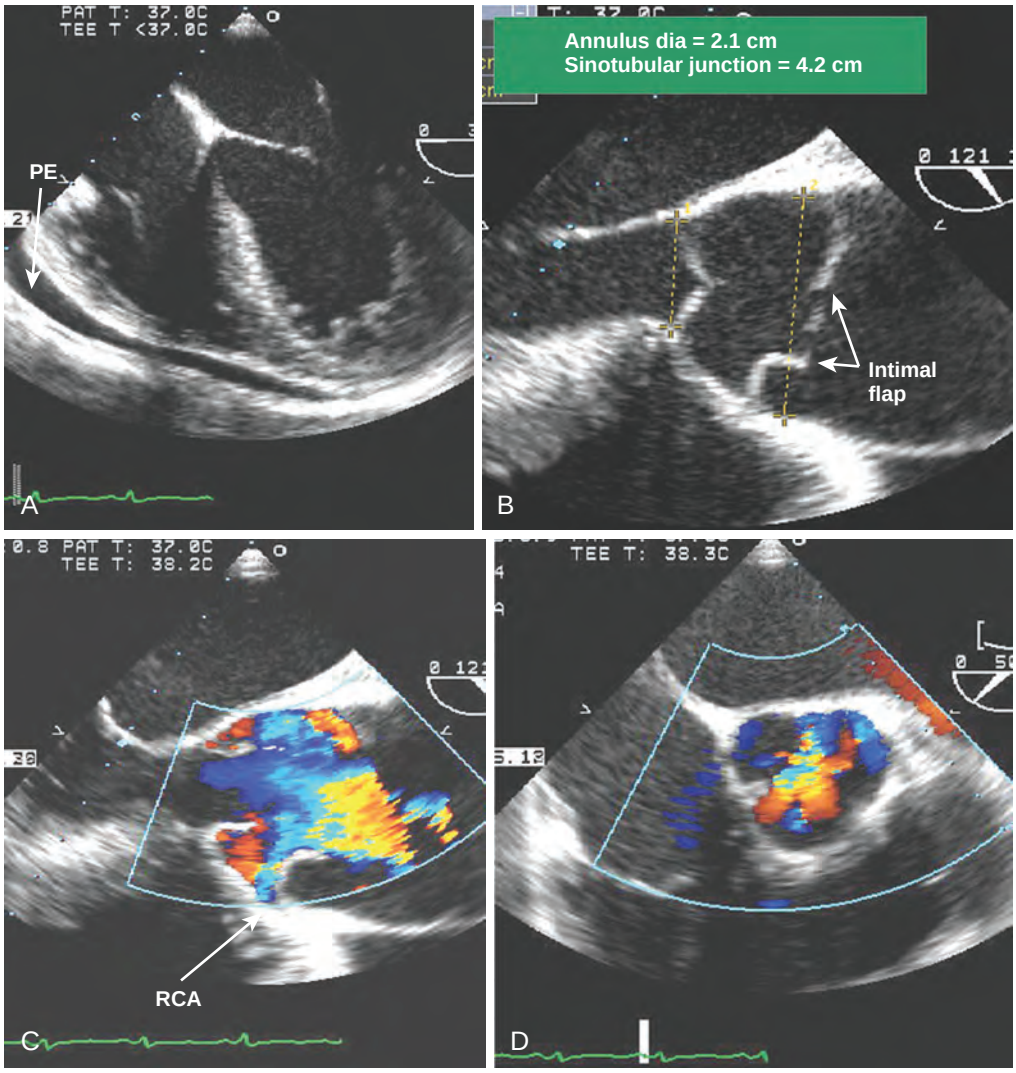

Fig. 16.15 Acute aortic syndrome as the cause of hemodynamic compromise. A 62-year-old previously healthy, unrestrained driver had a motor vehicle accident. On arrival to the emergency department, the patient was hypotensive (blood pressure = 90/45 mm Hg) and tachycardic (heart rate = 120 beats/minute). He described an episode of loss of consciousness that was associated with severe chest pain but could not recall whether the syncopal episode preceded the accident. The chest radiograph was significant for several fractured ribs, a widened mediastinum, and a pleural effusion. The patient became progressively more unstable and was transferred to the operating room to perform diagnostic transesophageal echocardiography and a definitive surgical procedure if necessary. The echocardiographer performed a quick transthoracic echocardiographic examination that confirmed the presence of pericardial effusion with findings that were consistent for tamponade. After fluid resuscitation and induction of anesthesia, a transesophageal echocardiographic examination was performed. (A) The midesophageal four-chamber view showed the presence of a pericardial effusion *(PE)* that compromised right atrial filling. (B) The midesophageal long-axis view of the aortic valve showed a type A dissection that was characterized by intimal flaps within the aortic root and that extended distally into the descending thoracic aorta. The annulus of the aortic valve was of normal size, but the sinus and root were markedly enlarged (diameter *[dia]* of sinotubular junction = 4.22 cm). (C) The dissection extended into the noncoronary and right coronary sinus segments, narrowing blood flow at the right coronary ostia *(arrow)*. Although the electrocardiogram did not show acute ischemia, the right ventricular function and inferior wall of the left ventricle were mildly hypokinetic. (D) Although an effaced aortic root, ascending aortic aneurysm, and acute dissection in this age group are suggestive of a congenital bicuspid aortic valve, the short-axis view of the aortic valve showed a trileaflet valve with a coaptation defect with aortic insufficiency at the noncoronary cusp. The surgeon resuspended the aortic valve and replaced the ascending aorta and hemiarch with a tube graft. The valve repair was successful with only +1 aortic insufficiency and cardiac return to normal postoperatively. *RCA*, Right coronary artery.

the separation of the intima from the surrounding media, thus creating a false lumen. Blood flow may exist in both the false and true lumina through communicating fenestrations. Elucidating which lumen is the true lumen and which is the false lumen is of utmost importance in an aortic dissection and has important implications for arterial cannulation for CPB. Traditionally, the true lumen expands during systole, has earlier and more robust blood flow in systole, and is smaller than the false lumen, but each of these characteristics may be misleading in individual cases. When possible, it may be most accurate to find the separation point of the intima from the aortic wall and follow it circumferentially, thereby identifying which lumen is bordered on all sides by intima (true lumen). Aortic dissections are classified by one of two anatomic schemes (the DeBakey and Stanford classifications). Transection is diagnosed through the detection of paraaortic hematoma near the isthmus and a "step-up" in the internal media wall (see Chapter 23).

Discussion

Acute dissections (Stanford type A or DeBakey type I or type II) involving the ascending aorta or arch are considered acute surgical emergencies because of the high risk for a life-threatening complication such as AR, cardiac tamponade, myocardial infarction, rupture, and stroke. The mortality rate is as high as 1% to 2% per hour early after symptom onset.[140] Neither acute myocardial ischemia nor cerebral infarction should contraindicate urgent intervention. Although patients with stroke in progress may be at increased risk for hemorrhagic cerebral infarction because of intraoperative anticoagulation, leading to hemorrhagic stroke, we have seen several patients who experienced dramatic neurologic recovery. Operative mortality for ascending aortic dissections at experienced centers varies from 7% to 36%, much lower than the greater than 50% mortality rate with medical therapy.[141–147]

In contrast, dissections confined to the descending aorta (distal to the left subclavian artery; Stanford type B or DeBakey type III) are treated medically unless the patient demonstrates proximal extension, hemorrhage, or malperfusion. From the International Registry of Acute Aortic Dissection, 73% of the 384 patients with type B dissections were managed medically with an in-hospital mortality rate of 10% (compared with 32% for those patients managed surgically).[148] The long-term survival rate after applying medical therapy was approximately 60% to 80% at 4 to 5 years and 40% to 45% at 10 years.[148–152] In those patients who present with an acute complicated type B dissection (characterized by aneurysmal enlargement, rupture, or malperfusion), thoracic endovascular aortic repair (TEVAR) with a stent graft has become the standard of care, with relatively low rates of both mortality (5–6%) and spinal cord ischemia (2–3%).[152] TEVAR is also starting to gain traction as a therapy for uncomplicated type B dissections because one study showed reduced 5-year mortality and progression of disease rates compared with medical therapy alone[153] (see Chapter 48).

Aortic IMH is often considered a variant of aortic dissection.[154] Although many patients present with chest or back pain, many of the associated sequelae, such as pericardial or pleural effusions, stroke, and myocardial infarction, are absent.[155,156] Aortic IMH is characterized by the absence of a detectable intimal tear. The hematoma is likely produced by a hemorrhage of the vasa vasorum into the aortic wall. In a metaanalysis, acute aortic IMH was most often associated with long-standing hypertension; trauma was a significant factor in 6% of cases.[157] In a metaanalysis of 143 cases, 81% were diagnosed by CT, and in the remaining patients aortic IMH was diagnosed by MRI, TEE, or both; the sensitivity and specificity of TEE to detect IMH were reported to be 100% and 91%, respectively.[155,157] The diagnosis is characterized by the absence of a dissecting flap or intimal disruption with specific regional thickening of the aortic wall of greater than 7 mm in a crescent or circular shape. When seen in the ascending aorta (involved in 33–57% of cases), IMH appeared to represent the early stage of a classic dissection,[156–160] whereas traumatic IMHs typically involved the descending thoracic aorta.[159] Acute management is similar to that of classic aortic dissection.

Traumatic aortic rupture is a life-threatening vascular injury that often results in lethal hemorrhage. In a multicenter trial of 274 patients, the overall mortality rate reached 31%, with 63% of deaths attributable to aortic rupture.[161] Aortic transection and rupture usually occurred at the aortic isthmus (between the left subclavian and the first intercostal arteries) and resulted from shear forces generated by unrestrained frontal collisions.[162] Although aortography had been considered the gold standard for the diagnosis of transection, TEE and contrast-enhanced spiral CT and MRI are currently favored, especially for patients with renal insufficiency.[163–166] Intravascular ultrasonography has been proposed as a potential diagnostic tool for the identification of limited aortic injuries.[167] Traumatic aortic rupture must be distinguished from aortic dissection. Imaging of a dissected aorta typically reveals true and false lumina at multiple levels. The focal aortic injury of aortic transection is localized and may be overlooked during a cursory examination. A second potential diagnostic problem is that protuberant atherosclerotic changes of the aorta may be difficult to differentiate from partial aortic tears. The thick and irregular intraluminal flap, which corresponds to disruption of both intimal and medial aortic layers, can be imaged in both the short-axis and long-axis planes in the vicinity of the isthmus. In the longitudinal view, the medial flap is nearly perpendicular to the aortic wall because traumatic lesions are usually confined within a few centimeters distal to the left subclavian. The formation of a localized contained rupture of the false aneurysm is common.[164,168] Color-flow Doppler imaging and spectral Doppler imaging can be used to detect turbulence associated with nonlaminar flow at the aortic defect and the presence of a pressure gradient. Traditional treatment includes immediate surgical invention using a right lateral decubitus approach and resection of the aorta with insertion of a tube graft, but TEVAR is increasingly becoming the treatment of choice because it avoids the need for a major open surgical procedure, one-lung ventilation, and high-dose anticoagulation in patients who often have significant coexisting injuries.[152]

In conclusion, the intraoperative echocardiographer is confronted with a broad array of diseases that require on-site decision making in the perioperative setting. The key ingredients to sound decision making are a broad fund of knowledge (database), a systematic approach with attention to all vantage points and frames, and the identification, addressing, and prioritization of the pertinent questions.

Education and Simulation in Echocardiography

KHURRAM OWAIS, MD | FEROZE MAHMOOD, MD, FASE

KEY POINTS

1. Transesophageal echocardiography is invasive, yet it requires repetition and practice for gaining proficiency, thus making it an ideal target for simulation training.
2. Current echocardiography simulators evolved in a stepwise development process over a span of 2 decades with incremental improvements in quality of simulation and features.
3. Substantial evidence supports the utility of echocardiography simulation in its current form; however, new features and their applications will continue to require ongoing research to refine best practices.
4. An understanding of key definitions, terms, and features across different simulation platforms is important for both education and research in this area.
5. In the future, echocardiography simulation is likely to be formally incorporated into training curricula, assessment protocols, and accreditation processes.

Patients are necessary for medical trainees to hone their skills just as airplanes are for pilots to fly. However, the need to ensure safety in both these situations conflicts with the need for new operators to practice new skills. Simulation plays a key role in uncoupling these two goals. Although the aviation industry has systematically and thoroughly embraced the learning opportunity presented by modern simulation, medical training has been relatively slow to adapt. For a long time, clinical educators were content with employing low-tech simulators such as mannequin models and role-playing actors.[1] However, technologic advances in clinical procedures have elicited the development of simulation systems to keep pace with the needs of health care providers.[2]

The introduction of minimally invasive surgery in the 1990s heralded the development of simulators to "rehearse" procedures. The rationale was based on the understanding that repetitive exposure of novices to the task at hand could significantly decrease the initial learning curve.[3] Early simulators in this category consisted of anatomic models on which to practice laparoscopic surgical skills. These simulators were quickly incorporated into training programs for purposes of both "task training" and "warming up." UltraSim (MedSim, Fort Lauderdale, FL), for example, was the first ultrasound-based teaching simulator, and it consisted of data sets of normal and pathologic anatomy from actual patients[4] (Fig. 17.1).

Traditionally, echocardiography education has been imparted incidental to patient care. This model presents several challenges to ideal training. First, the principle of "do no harm" asserts that patients take precedence over trainees in any given situation. With the hospitals' and physicians' primary responsibility being to their patients, medical training is a desirable byproduct of the patient-physician interaction. Second, a patient can undergo a procedure only so many times, thus limiting the number of examinations available for trainees to conduct. This is especially problematic for tasks requiring repetition to achieve manual dexterity. Moreover, in clinical settings, the complexity of disease cannot be purposefully graduated from basic to advanced levels to suit the trainees' learning requirements at particular points in time. In fact, the clinical experience can vary significantly from day to day and among different settings. In addition, expert echocardiographers often conduct examinations incorporating significant mental reconstruction and imagination based on their experience, gliding seamlessly and quickly through different views, and making it difficult for the operator to explain and the observer to follow.[5,6]

In the Halstedian model of medical education, these roadblocks were addressed by the assumption that a sufficiently long period of time enables all trainees to attain a minimum level of proficiency required for independent practice. However, more recent developments in medical education advocate moving from a duration-based *assumption* to a competency-based *proof* of proficiency.[7] With the incorporation of work-hour regulations in training programs, residents and fellows today are expected to learn more in less time and demonstrate acquisition of competency and proficiency. These challenges have led to the development of rigorous simulation training programs to shorten the learning curves associated with routinely performed tasks in the course of patient care. Fundamentals of endoscopic surgery, laparoscopic surgery, and anesthesia crisis resource management are examples of simulation programs that have been incorporated into training curricula with demonstrable benefit.[8]

The expanding role of echocardiography within and outside the operating room has also necessitated the development of efficient training tools for echocardiographers.[9] Unlike other imaging modalities, echocardiography requires that its operators be adept at both obtaining and interpreting images. The complex geometry of the heart and the nonintuitive orientation of images make echocardiography a difficult task to master cognitively. For example, images on both transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) are flipped from left to right on the screen. Anterior structures figure at the apex of the sector on TTE, whereas the reverse is true for TEE. Furthermore, mastery of probe handling and manipulation adds a significant manual dexterity component that must be developed alongside abilities of three-dimensional (3D) mental reconstruction.

At present, an accredited cardiac anesthesia fellowship is the only route to obtaining advanced certification in perioperative TEE.[5] The educational opportunities offered by national organizations (American Society of Anesthesiologists, Society of Critical Care Medicine) mainly consist of didactic courses without hands-on training. The introduction of the Basic TEE Certification by the National Board of Echocardiography for noncardiac anesthesiologists has further underscored the paucity of clinical training resources in this area.[5] The availability of high-fidelity echocardiography simulators has the potential

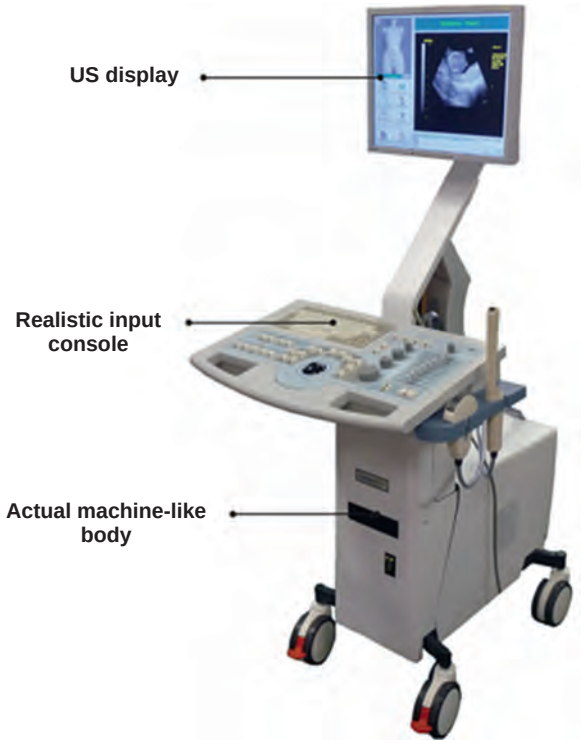

Fig. 17.1 The latest version of UltraSim, the first ultrasound simulator to hit the market. Note that with continued development, the simulator hardware and software interfaces have fully embraced the look and feel of an actual ultrasound machine. *(Courtesy MedSim, Fort Lauderdale, FL.)*

to train not only anesthesiologists, but also other health care providers who frequently use this imaging modality, including cardiologists, intensivists, emergency physicians, and nurses who practice in similar settings. This chapter reviews the history of simulators for echocardiography training, tracks the progression of technology, assesses the current state of simulation in echocardiography, and examines its future direction.

Early Development

For an echocardiography simulator to be effective the images displayed by the simulator must mimic those a trainee can expect in a real patient. Before the advent of the digital graphics revolution, achieving realistic depictions of medical images constituted a major hurdle to developing reliable simulators. One solution to this problem was to use real data and display images from actual patients on the screen in response to the trainees' actions. An arrangement that allows the operator to access and manipulate real-world data as part of a broader device is ordinarily referred to as *augmented reality*. In contrast, *virtual reality* refers to a completely computer-generated environment that mimics the real world and allows the user to perform tasks virtually as they would in reality. A simulator that allows augmented or virtual realities to be manipulated by physical, or *haptic*, controls is referred to as a *mixed* simulator. A simulation cockpit that allows a pilot to fly through a virtual city by using a physical control stick is an example of a mixed simulator.

Using the same concepts, the first TTE simulator developed and reported by Weidenbach and colleagues[10] in 2000 was based on a 3D virtual model of the heart (virtual reality), computationally registered to real, two-dimensional (2D) echocardiographic images (augmented reality). This virtual heart model could be sliced using a virtual scan plane to yield the corresponding 2D image on the screen.[10] The virtual scan plane, in turn, was coregistered to an actual, physical probe equipped with tracking sensors to detect its motion (Fig. 17.2). Although much progress has since been made, the basic idea behind echocardiography simulators has remarkably remained the same ever since: a virtual heart model, sliced by a virtual scan plane coupled to a tracked, physical probe.

In subsequent developments, Weidenbach's group equipped the physical probe and a dummy torso with a 3D electromagnetic tracking system. This allowed for the echocardiographic data set from the computer to be projected and registered to a reference area within the torso. Users of this system were able to move the probe on a plastic torso and see echocardiographic representations of their imaging planes on the screen in real time. This system allowed the operator to develop an understanding of the anatomy as seen in the scan plane and on the torso, as well as hand-eye coordination for probe movements.[11]

Although the invention of a TTE simulator was a sentinel step in echocardiography education, a similar tool for TEE held greater promise on account of the semiinvasive nature of TEE. The EchoComTEE simulator first appeared in 2007 and drew on the same technology as the TTE simulator reported earlier.[12] This simulator allowed the operator to practice conducting a TEE examination without the time-limiting pressures of a cardiac operating room or the inability to perform examinations repeatedly. The virtual heart model used in the EchoComTEE simulator was the same model as the one stitched together using real TTE data sets. Because only apical views were used to construct that model, it did not include upper esophageal views or the great vessels. Including those views would require either a model based on TEE images or a different approach altogether (ie, a completely virtual system based on computer-generated representations of real and echocardiographic anatomy).

Commercialization

Soon after the successful development of EchoComTTE and EchoComTEE simulators for research purposes, commercial vendors entered the fray to address the need for simulation in echocardiography. Today, several different vendors, including Inventive Medical, CAE Healthcare, Simbionix, and Blue Phantom, offer mannequin-based devices for TTE and TEE training. Scan planes through beating, virtual heart models are processed into 2D echocardiographic images, displayed simultaneously on the screen. These "echocardiographic images" are in fact graphic renderings of what an ultrasound image would look like on a real heart. Hence the key difference in the software interface of the new simulators and that of the earlier EchoComTEE and EchoComTTE devices is the complete replacement of augmented reality by virtual reality. As the trainee moves from one position to the other within the virtual heart, the corresponding changes in virtual echocardiographic imagery can be followed on the screen.

All simulators afford multiple display options to the operator, who can choose to view the virtual model alone, the ultrasound image alone, or both side by side. Newer versions of these simulators also incorporate quantitative echocardiography modules and physical foot switches to enable image capture and other controls by the operator while the same operator performs a bimanual examination such as TEE. Excluding the "body-simulator" by Blue Phantom, currently available TEE and TTE trainers are more alike than they are different. However, each one incorporates certain salient features, as described here.

HeartWorks

Manufactured by Inventive Medical (London, United Kingdom), the HeartWorks TEE simulator was the first commercially available echocardiography simulator to hit the market, in 2008[13] (Fig. 17.3). The cardinal feature of this system is a realistic model of the heart and great vessels that facilitates an easy suspension of disbelief. This high-fidelity model was constructed using state-of-the-art animation technology, and its use was made possible by advances in graphics processing units for personal computers. Since the initial TEE-only module, the

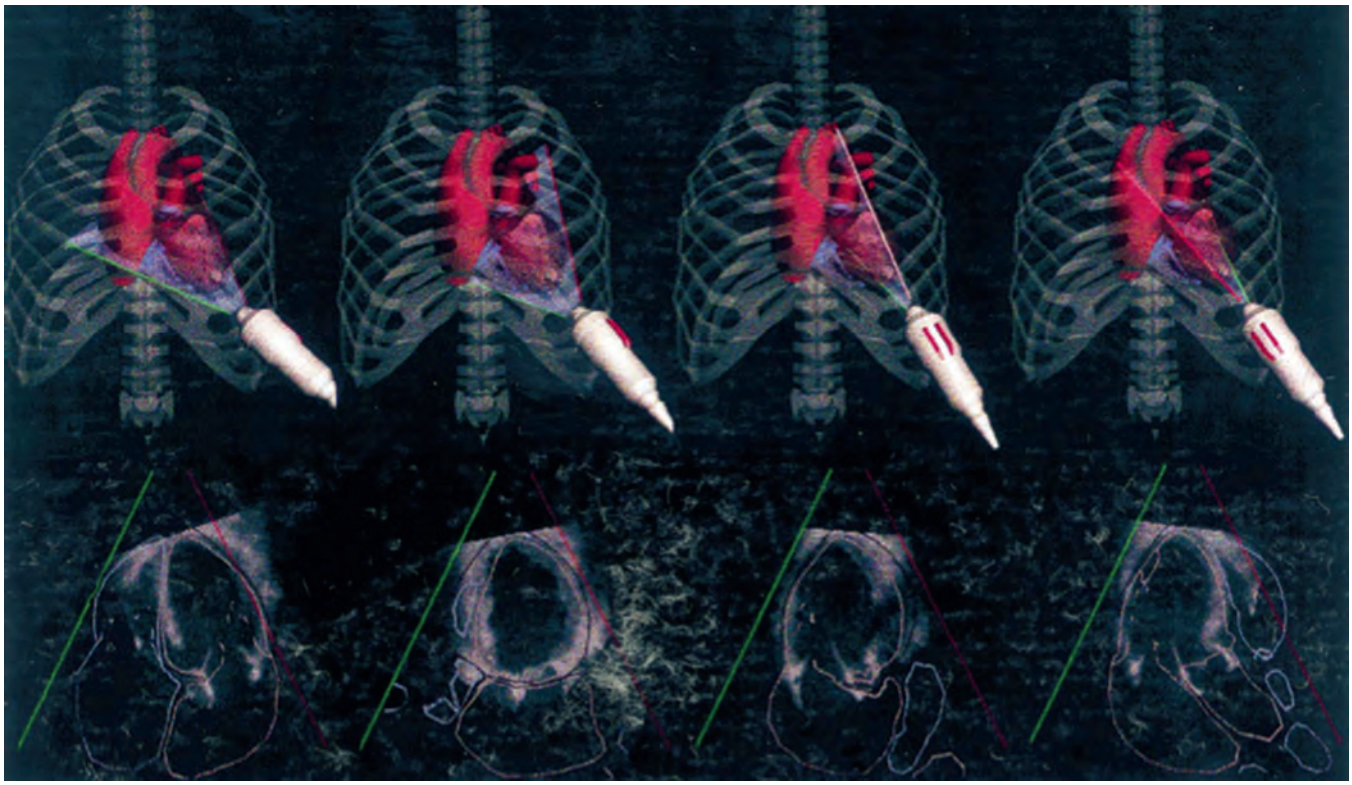

Fig. 17.2 Images obtained from different probe positions within the first EchoComTTE echocardiography simulator. The *top section* displays the virtual heart model and a virtual probe and scan plane (virtual reality). The *bottom section* shows actual echocardiographic images that are expected at the corresponding probe position. These images are also labeled with outlines and colored scan plane boundaries to facilitate comprehension of image orientation and underlying and overlying anatomy (augmented reality).

Fig. 17.3 The HeartWorks echocardiographic simulation system by Inventive Medical *(Courtesy Inventive Medical, London, United Kingdom. © Inventive Medical Ltd.)*

simulator has been marketed in different forms including a combined TTE-TEE simulator, individual TEE and TTE simulators coupled to mannequins, and a laptop-only station for demonstration purposes. The mannequin-based package includes a rubber-torso mannequin with TTE or TEE probes, or both. All packages are shipped loaded with the simulation software.

Imaging on the station can be controlled by keyboard and mouse or by mannequin-based probe motions. Although rarely used, a comprehensive descriptive text is available for quick reference for independent learners. The ability to add labels and individually highlight as well as visualize as many as 160 cardiac structures in isolation from the rest of the heart significantly increases the simulator's educational value (Fig. 17.4). More recent updates to the system have incorporated the ability to simulate color-flow Doppler, continuous-wave Doppler, and pulse-wave Doppler imaging. Although the manufacturer has provided regular upgrades since the first release, the process of upgrading requires uninstalling and reinstalling the software using DVD drives, thus making the upgrade process time consuming and cumbersome.

CAE Vimedix

Vimedix was initially created as a stand-alone company, but the Vimedix simulation system was later acquired and is currently sold by CAE Healthcare (Montreal, Canada; Fig. 17.5). Like HeartWorks, the simulator is based on a digital heart model. In addition, it includes virtual intrathoracic and intraabdominal structures that allow the operator greater orientation to surrounding anatomy such as ribs, lung, liver, stomach, and as far down as the urinary bladder. In fact, Vimedix is not only capable of simulating cardiac ultrasound imaging (TTE and TEE), but it also doubles up for intraabdominal ultrasound.[14] For that purpose, the simulator can be bundled with a curvilinear probe to simulate abdominal imaging if required. This makes the device especially suitable for training emergency room health care providers.

The current version allows users to perform the following functions: run M-mode and Doppler examinations; disable lung and rib artifacts if required; vary the level of noise on ultrasound images through gain and depth settings; enable the display of ideal probe positions to obtain an echocardiographic window; and, finally, generate echocardiography reports as done on actual machines. Although the update process on the Vimedix system is cloud based, automatic, and seamless, the quality of the virtual heart model and the corresponding gray-scale echocardiographic renderings need further improvement to mimic real anatomy and images more closely.

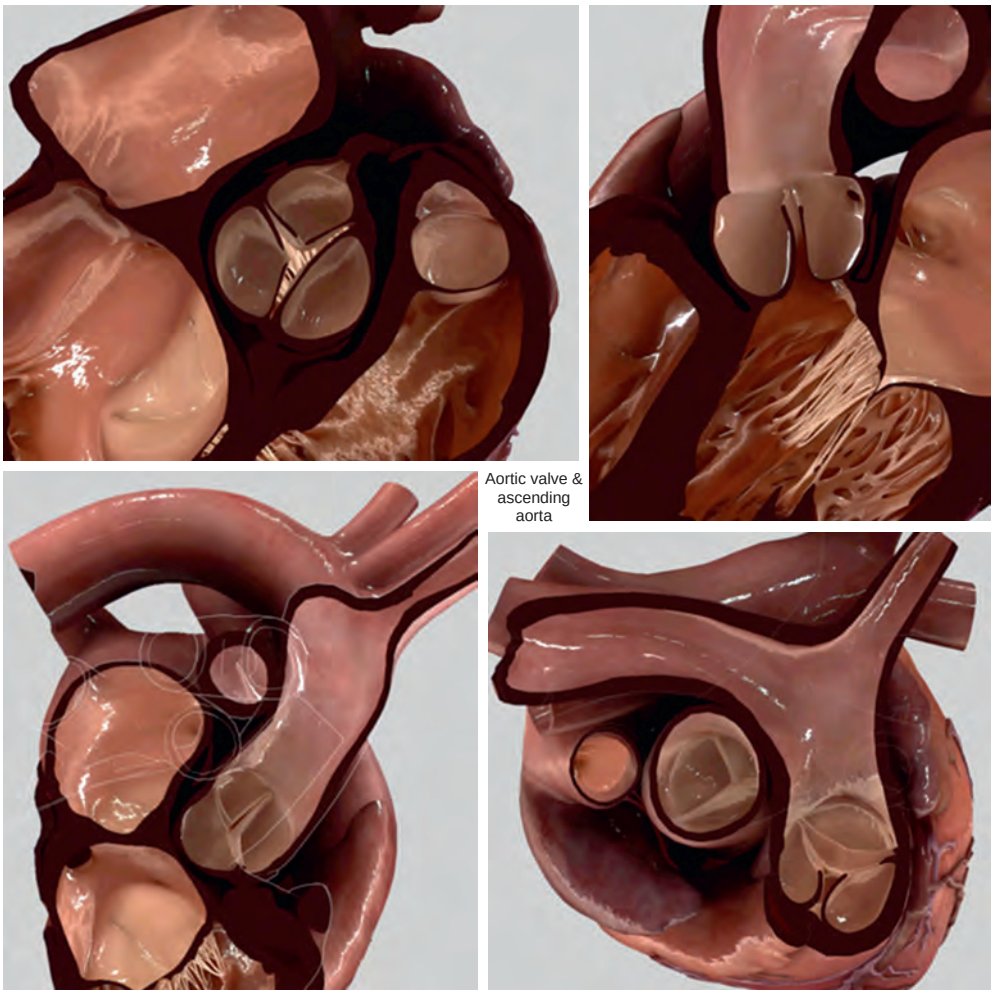

Fig. 17.4 Sections through the virtual heart model built into the HeartWorks echocardiography simulation center. The *top two panels* demonstrate the aortic valve short-axis *(left)* and long-axis *(right)* views. The *bottom panels* showcase the ascending aorta short-axis *(left)* and long-axis *(right)* views. The virtual heart model built into this simulator is surrounded by models of adjacent structures, including ribs, stomach, lung, spine, and others. The simulator also includes a curvilinear probe and virtual abdominal anatomy for abdominal ultrasonography simulation. *TEE*, Transesophageal echocardiography; *TTE*, transthoracic echocardiography. *(Courtesy CAE Healthcare, Montreal, Canada. © CAE Healthcare, Inc.)*

Simbionix

The Simbionix simulator sold by 3D Systems (Cleveland, OH) is the most recent entry into the echocardiography simulation market (Fig. 17.6). This system offers some new features that differentiate it from other devices, and it delivers most of the functionalities already mentioned and in a fashion similar to that described earlier. Some distinct features include the following: preset step-by-step instructions for a complete examination; recording and browsing capability, including freeze and cine-loop; and pressure-sensitive mannequin-probe interaction. This simulator also includes modules for both echocardiography and abdominal ultrasound imaging, thereby enabling its use for a wider set of health care providers in a given educational setting. Specific to echocardiography, the modules are divided into bedside echocardiography, advanced TTE, and TEE. In general, the Simbionix system offers more options for independent learning, compared with its older cousins.

Blue Phantom Training Model

Also sold by CAE Healthcare, the Blue Phantom training model consists of a life-sized mannequin with an oral cavity and esophageal conduit built in tissue-like consistency, an anatomically correct nonbeating model of the heart made of a composite material suspended in the thoracic cavity, and accurate surface anatomy on the outside

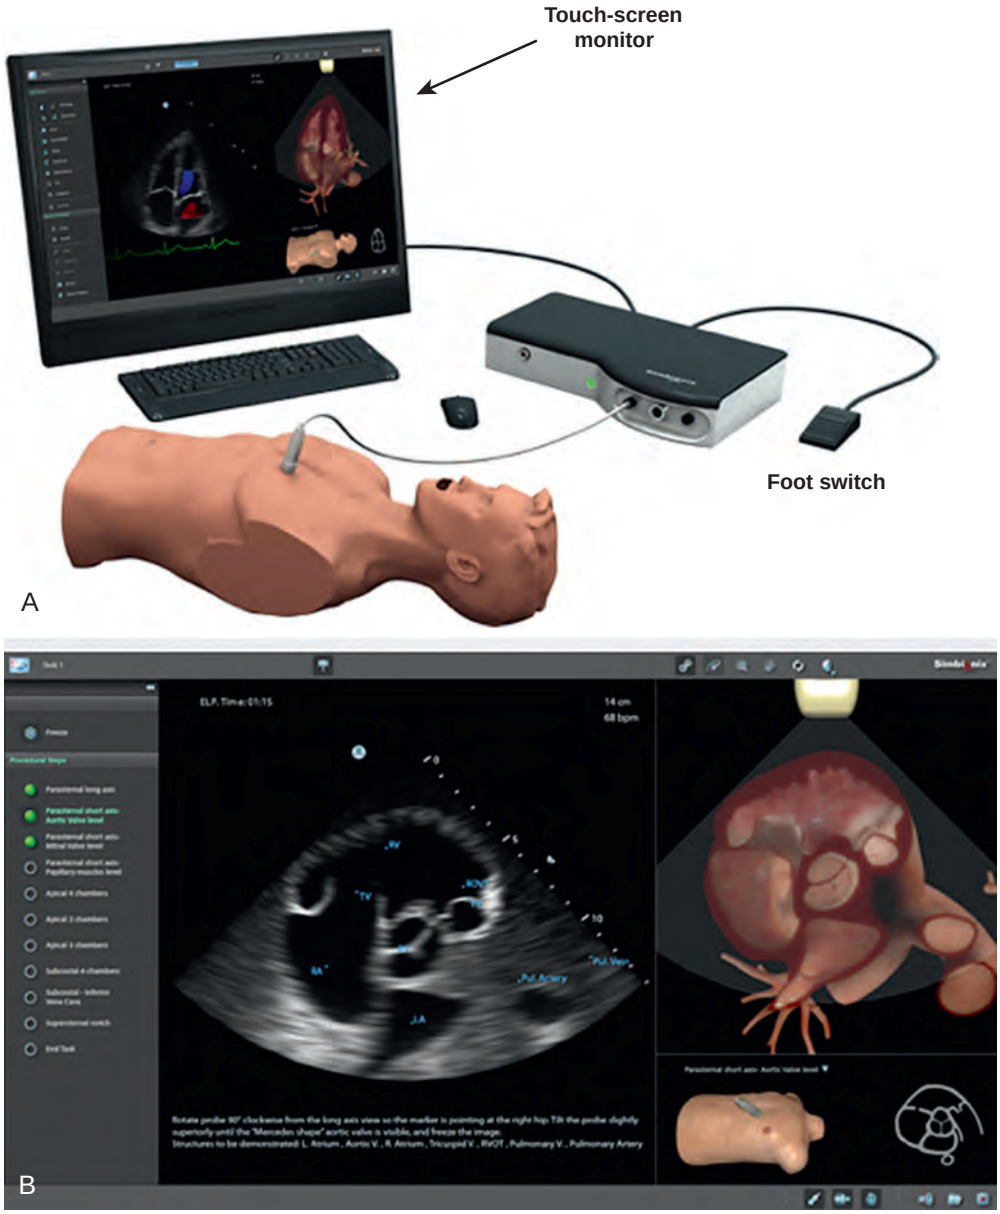

Fig. 17.6 The Simbionix echocardiography simulator by 3D Systems. (A) The simulator hardware includes an all-touch monitor and a foot switch to allow image capture functionality during bimanual transesophageal echocardiography examination. (B) Features include the ability to turn on labels for cardiac structures on the gray-scale–rendered images and a step-by-step, self-administrable examination that requires the examinee to acquire different views in succession, thereby capturing their windows through the footswitch. The list of views can be seen on the *left,* with the *green dots* representing accurate acquisitions. *(Courtesy 3D Systems, Cleveland, Ohio. © 3D Systems, Inc.)*

(Fig. 17.7). The main advantage of this simulator is the ability of trainees to use actual ultrasound systems and TEE probes for an echocardiographic examination.[5] Additionally, trainees can practice and learn image optimization and manipulation techniques on the actual ultrasound system that they would be using intraoperatively, thus facilitating clinical transferability. The ability to inject fluid into the pericardial space to practice image-guided pericardiocentesis is an additional feature that can be very useful for intensivists and cardiology fellows.

These properties make the Blue Phantom training model especially suitable for training in the latest developments in echocardiography (eg, 3D imaging, to learn and master workflow of the examination). The current echocardiography simulators lack the technologic interface to simulate 3D echocardiographic imaging, and the Blue Phantom simulator provides a relatively low-cost, but effective training tool for teaching 3D imaging. Similarly, the exigencies of the cardiac operating room environment preclude the training of a large number of physicians in 3D echocardiography during the course of patient care.

Although the images obtained are not completely representative of actual echocardiographic pictures, they enable the user to practice operating the machine. This model delivers on realistically mimicking some key aspects of echocardiography that are missed by other simulators (eg, probe insertion, image optimization on real machines, and knobology).

Online Learning

The period of early development of echocardiography simulators was also a time of rapid growth in information technology. Being an

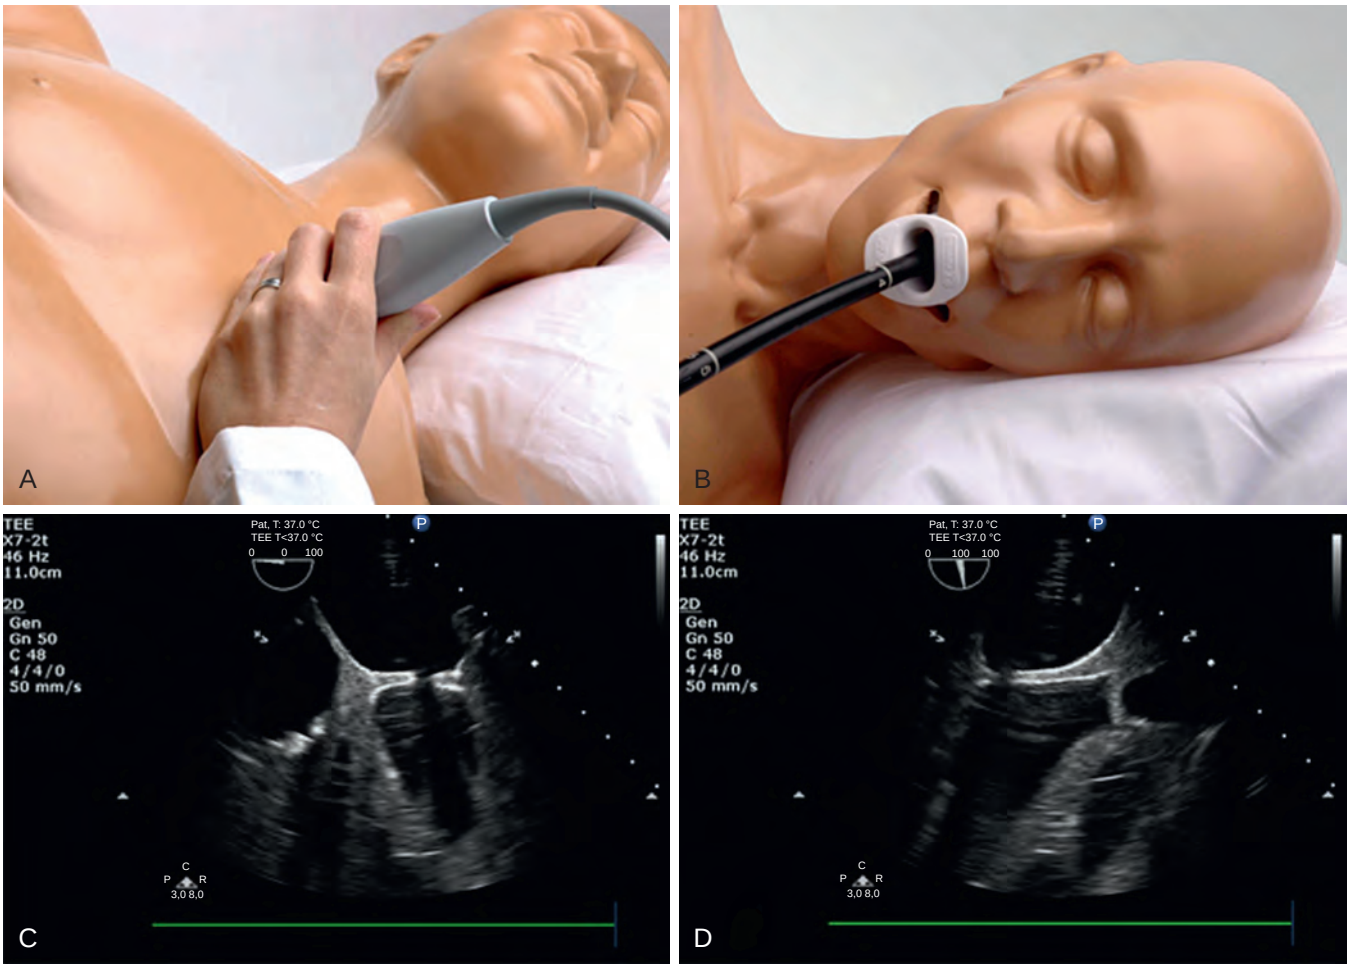

Fig. 17.7 The Blue Phantom model by CAE Healthcare. The model includes a plastic heart. (A) and (B) The ability to use both transthoracic echocardiography and transesophageal echocardiography probes to practice image acquisition and optimization skills on a real machine. (C) and (D) Image quality obtained on transesophageal echocardiography midesophageal four-chamber and aortic valve long-axis views. *(Courtesy CAE Healthcare, Montreal, Canada.)*

operator-dependent imaging modality, echocardiography lends itself to superior comprehension through vivid, interactive imagery as opposed to textual discourse. Realizing this potential, the Internet was identified early on as a useful medium of interactive instruction for purposes of echocardiography education. One of the first such efforts was the development of a computer application consisting of a static heart model, a virtual TEE probe, and representative knobs on the computer screen that could be controlled using a computer mouse (Fig. 17.8). Developed by Hartman and associates,[15] the interface permitted full manipulation of the probe relative to the heart (depth of insertion, retroflexion or anteflexion, rotation, left or right deflection, transducer angle advancement). The user could also control the viewing vantage point, by choosing either a cephalad-posterior view (top of the table; standard for most anesthesiologists) or an anterior-posterior approach (facing the patient; standard for most cardiologists).[15] Although ahead of the curve at the time, the project failed to come to fruition because the application never came online.

A similar echocardiography learning tool under the name of CT2TEE came online in 2009 as a noncommercial research project.[16] Built by Aleksander Kempny and Adam Piórkowski, the program is freely available online (http://www.ct2tee.agh.edu.pl; flash version is also available for download). This simulator is different in that it draws on computed tomography (CT) data to showcase the anatomy as seen on a particular echocardiographic scan plane (Fig. 17.9A). Because the CT data set is a complete 3D model of internal anatomy, the user can

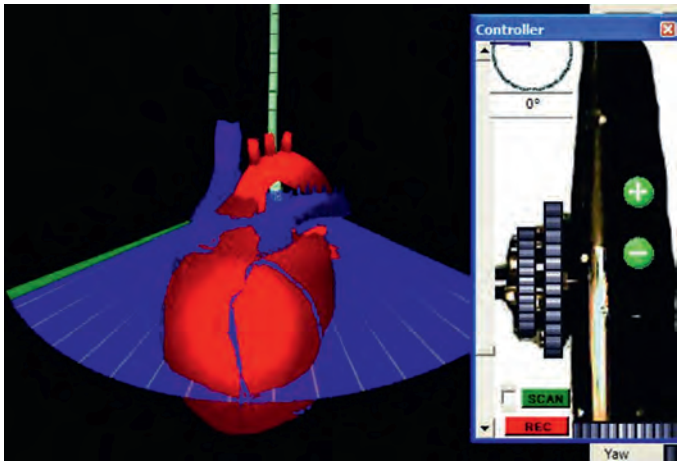

Fig. 17.8 Early virtual transesophageal echocardiography simulator developed by Hartman and colleagues. *(From Hartman GS, Christopher W, Mullin M. A virtual reality transesophageal echocardiography (TEE) simulator to facilitate understanding of TEE scan planes. Anesthesiology. 2001;95:A545.)*

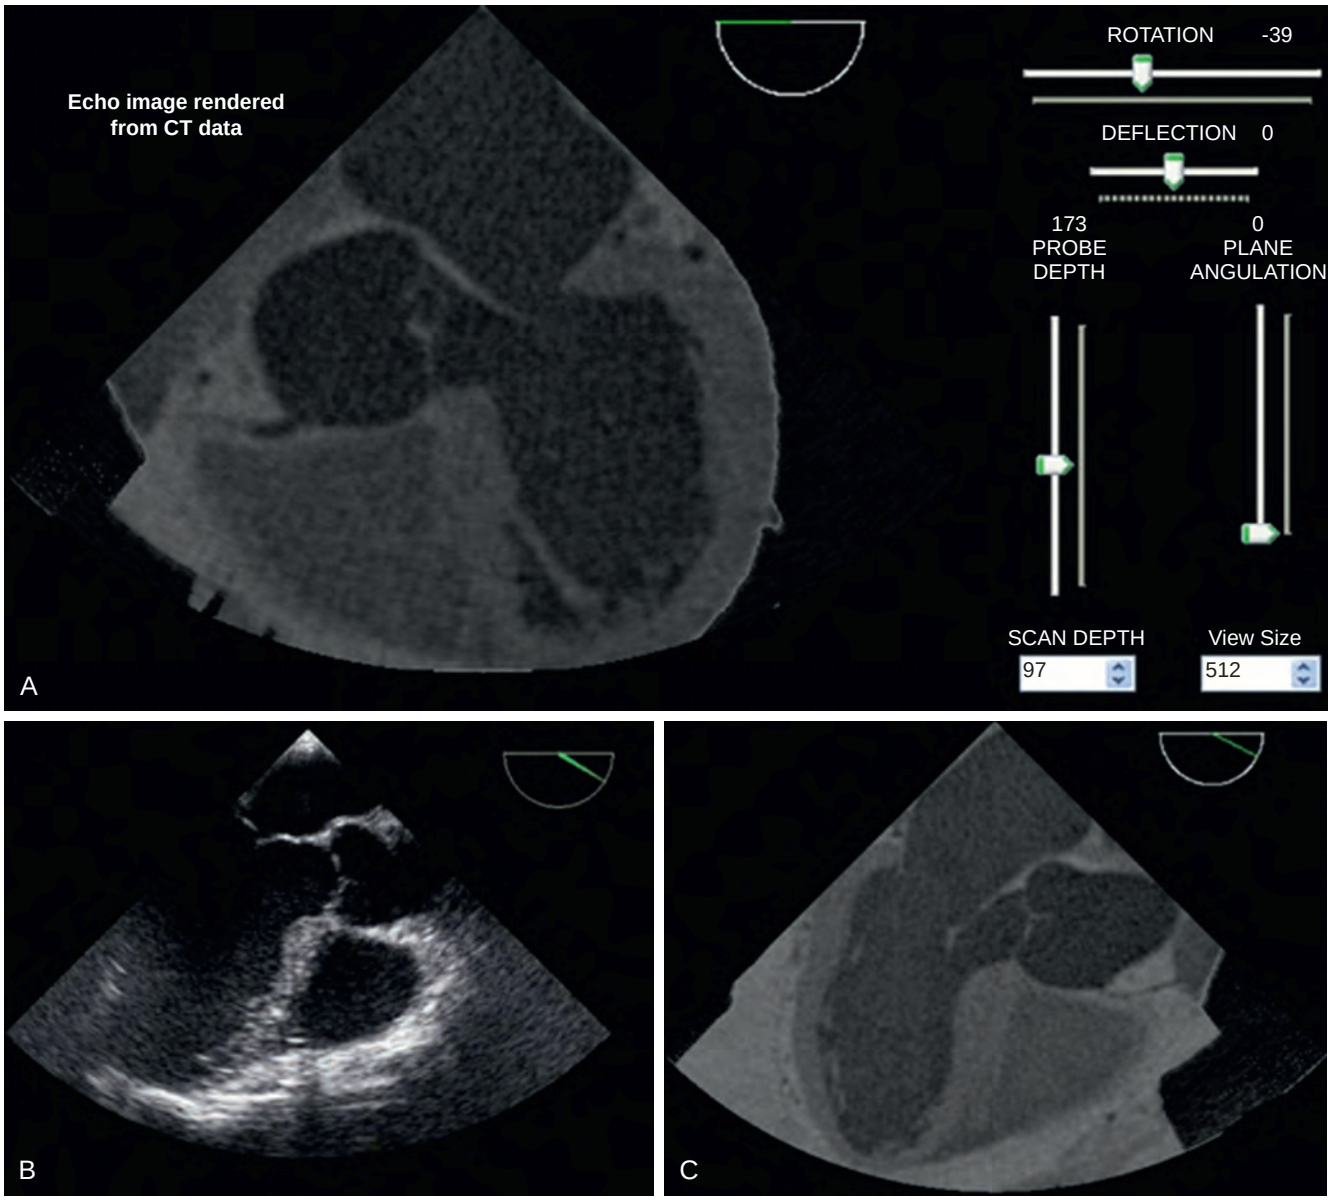

Fig. 17.9 CT2TEE virtual simulator. (A) Note that by manipulating the controls such as probe depth, plane angulations and rotation, the corresponding echocardiographic *(Echo)* window is rendered using computed tomography *(CT)* data. (B) and (C) Comparison of the same view obtained using actual transesophageal echocardiography and the CT2TEE simulator, respectively.

virtually "move" and "rotate" the probe in any direction to view the anatomic features expected on the corresponding echocardiographic window. The slider buttons within the simulator interface can be controlled by keyboard and mouse, thus enabling the user to "glide" the probe into the esophagus and angulate it into a scan plane position. The application then generates a corresponding 2D image from the corresponding CT data sets. Although CT and echocardiograms yield significantly different pixel gray values for the same tissue, the simulator does a good job of orienting the user to the anatomic features, and the images generated are comparable to TEE images (Fig. 17.9B–C).

Perhaps the most comprehensive, freely available online resource for echocardiography education is the TEE simulator developed by Michael Corrin at the University of Toronto (http://pie.med.utoronto.ca/TEE/). This interface includes a static heart model, a virtual TEE probe, and a scan plane. The scan plane can be rotated and the TEE probe manipulated using keyboard and mouse controls. Users can also select specific training modules or switch to 3D TEE views. The Standard Views module includes the 20 standard TEE views illustrated with the scan plane through the heart model along with the corresponding echocardiographic images (Fig. 17.10). It is possible to rotate the heart model and remove portions of the anatomy to visualize the structures that fall within a given TEE view.

The Alternative Views module includes the 19 nonstandard TEE views, whereas the TEE simulation module allows a virtual TEE examination, starting from probe insertion to positioning and maneuvering in reference to the virtual heart model. Standard assessment of the heart structures with spectral and color Doppler imaging is covered in the Spectral and Color Doppler modules. A descriptive text and an interactive quiz also help the user learn about disorders detectable on TEE. The Standard, Alternative, and Color Doppler TEE modules are also available on an iPad application. Overall, the virtual TEE trainer is a robust learning tool that can be accessed by novices on the go as they orient themselves to echocardiographic anatomy, even before they have access to a simulator.[17–19]

Commercial Online Courses

Both Inventive Medical and CAE Healthcare, the makers of HeartWorks and Vimedix simulators, respectively, currently offer e-learning courses for echocardiography (accessible online at http://www.inventivemedical.com/elearn-a-complete-introduction-to-tee/ and http://www.caeiccu.com/lms). Although the HeartWorks course includes only TEE, the CAE HealthCare course offers both TTE and TEE modules, which must be purchased separately. The courses include audiovisual resources, animations, vivid illustrations, tutorials, and quizzes on topics in basic TTE and TEE. Being major participants in the echocardiography simulation market, these companies offer professionally designed, robust tools for remote learning for individual trainees and institutions that may not have access to their mannequin-based simulators. In this regard, they may be cost-effective alternative actual simulators for individual trainees or centers with a small number of trainees. Importantly, these courses are accredited by the American Society of Echocardiography, and candidates can redeem continuing medical education credits for successful completion of these courses.

Simulating Pathologic Conditions

The ability to simulate abnormal and pathologic variants of anatomy is a critical piece in making simulation-based medical education realistic. After orienting the trainees to normal anatomy, a simulation program must also introduce them to abnormal structure and function. This is vital for the newly acquired skills to be applicable to the clinical realm. Simulation of pathologic conditions can be instrumental in training the uninitiated eye to register an abnormality and pursue a suitable course of action accordingly.

Since the introduction of echocardiography simulators, incorporating pathologic features within various modules and programs has been a work in progress. The early EchoComTEE simulator included pathologic states (eg, pericardial effusion, mitral valve prolapse, left ventricular thrombus, and thrombus in the left atrial appendage).[12] The TTE version of the same simulator also incorporated congenital heart defects, including transposition of the great arteries, tetralogy of Fallot, ventricular septal defect, and atrial septal defect.[20] Currently, all three mannequin-based simulators available on the market include packages that simulate various adult and congenital disorders (Fig. 17.11). The Vimedix system, for example, can simulate up to 50 disease states that can be loaded on the system for a trainee to diagnose by either TTE or TEE. However, the base module includes only a few: dilated cardiomyopathy, hyperdynamic left ventricle, and recent myocardial infarction. Modules containing further pathologic conditions must be purchased separately in packages of 10. Similarly, the HeartWorks device can be loaded with several disease modules, one each for ventricular, valvular, vascular, and structural dysfunctions.

The Simbionix system also offers the ability to simulate pathologic conditions, notably allowing for variation in the severity. From a clinical standpoint, this is an important distinction and one that ideally needs to be further developed toward dynamic pathologic variation. In real patients, a disease spectrum often changes over the course of a surgical case. However, abnormal findings in current simulators do not dynamically vary (ie, tamponade does not worsen, wall motion does not change).[21] In the future, simulators that showcase worsening or improving disorders in response to trainees' actions (eg, crisis management simulations) may prove to be important tools in preparing clinicians for the stresses of a challenging clinical environment.

Evidence for Simulation

To date, numerous studies have been undertaken to investigate the utility and efficacy of echocardiography simulation as an educational tool. Some investigators have assessed the use of simulators as adjuncts to traditional didactic learning.[19,22–29] Yet others have explored the noninferiority of simulators to both live instructors as well as live volunteer models.[26,30] A comprehensive description of studies on the subject is included in Table 17.1.

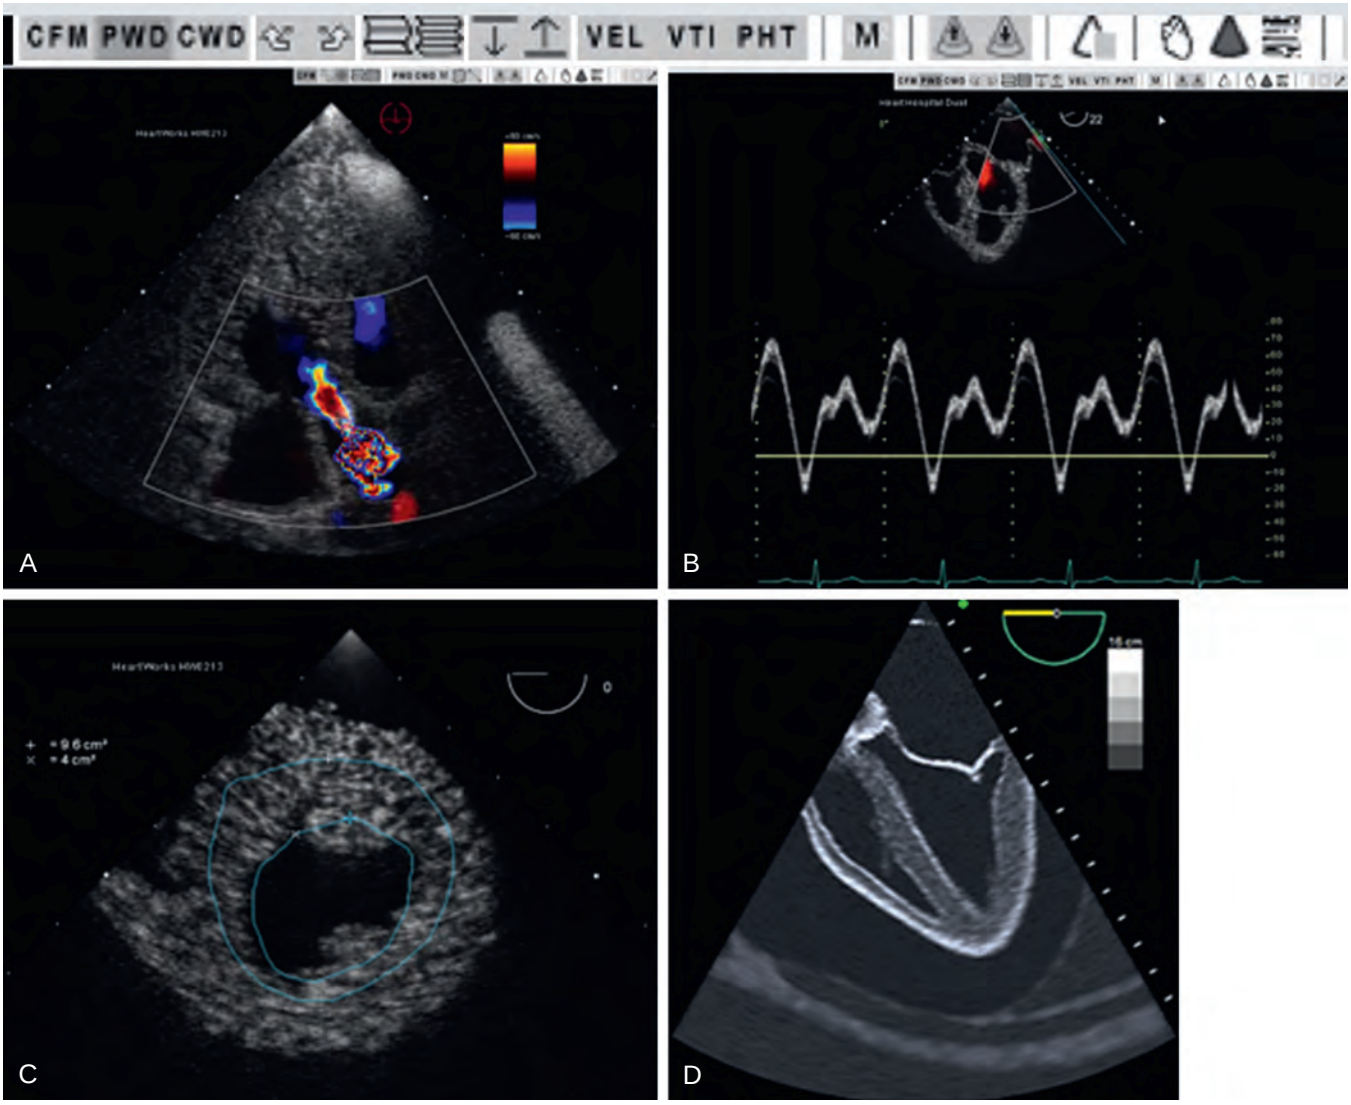

Fig. 17.11 Disorders as seen on different simulators. Current simulators offer ample opportunity to practice Doppler and M-mode *(M)*, as well as quantitative echocardiography skills such as computation of velocity time integral *(VTI)* and pressure half-time *(PHT)*. The *top strip* shows the control bar in the Doppler module of a HeartWorks simulator. (A) Aortic stenosis with color-flow Doppler imaging (HeartWorks). (B). Global left-ventricular dysfunction (HeartWorks). (C) Planimetry of left ventricle in the midpapillary view at systole and diastole showing areas of 4 and 9.6 cm^2, respectively, with significant anterior wall dysfunction (HeartWorks). A major limiting factor of most studies is the low number of participants because of constraints of program sizes, as well as the precedence taken by clinical work, especially for trainees who serve as subjects for these studies. However, a high degree of correlation is seen in the results, which are in line with the generally accepted notion that simulator training improves task performance. Most participants in these studies also report satisfaction with the quality of simulators and welcome the idea of simulation itself as part of their training.

A key element identified is that simulation delivers the greatest benefit for trainees at the beginning of their careers.[29] In other words, simulation is especially instrumental in helping echocardiography-naive residents and fellows through the initial learning curve as they first become oriented to echocardiographic anatomy. For more experienced echocardiographers, the law of diminishing returns sets in, and the benefits offered by simulators dwindle.

Assessment

The utility of simulators as task training and educational tools in echocardiography has been sufficiently established, especially for the new learner. Going forward, the use of simulation use in performance assessment would constitute a quantum jump in its role as a holistic educational and credentialing tool in echocardiography.[31] Fundamentals of laparoscopic surgery comprise one example in which successful completion of a simulation course as part of the broader curriculum fulfills an accreditation requirement. For a similar course in echocardiography, a need exists for assessment metrics that can be used to verify proficiency and be objectively applied across the board for all trainees. So far, written pretests and posttests have been the mainstays of assessing trainee performance in response to simulation. Although such tests provide some insight into the theoretic know-how

TABLE 17.1 Studies Carried Out to Date That Investigate the Realism, Feasibility, and Efficacy of Simulation-Based Echocardiography Training

Author (year)	*N*	*Study Type*	*Simulator Studied*	*Results and Conclusions*
Weidenbach et al[12] (2007)	56	Questionnaire-based survey of opinions after using the simulator (25 experts and 31 novices)	EchoComTEE[a]	The simulator was graded as "realistic" by experts; novices felt an improvement in spatial orientation, which may be especially important when starting out
Weidenbach et al[20] (2008)	43	Prospective observational (12 experts, 16 intermediates, 15 beginners); validity assessed by accuracy of diagnosis of congenital defects	EchoComTEE[a]	Construct validities were significantly different among the three groups; experts diagnosed almost all data sets correctly
Bose et al[22] (2011)	14	First-year anesthesia residents prospectively randomized into two groups and assessed using pretests and posttests	HeartWorks TEE[b]	A statistically significant difference between two groups was noted, with the simulation group scoring higher on the posttest; simulation is superior in teaching anatomic correlation, structure identification, and image acquisition
Jerath et al[17] (2011)	10	Prospective observational; benefit assessed using pretests and posttests after an average of 130-min access over 3-day period.	UofT virtual TEE; standard module	Significant improvement in knowledge of cardiac anatomy on TEE occurred after review of an online application; significant increases in posttest scores compared with pretest were seen after a short training period
Platts et al[23] (2012)	82	40 trainee sonographers; 42 TEE workshop attendees; prospective observational survey assessing usability and realism	Vimedix TTE and TEE[c]	Simulation provides a realistic method of training in image acquisition and improves spatial orientation
Neelankavil et al[24] (2012)	61	Anesthesia residents prospectively randomized; assessed using pretests and posttests and TTE examination on volunteers	HeartWorks TTE[b]	Simulation group scored higher on all criteria: written posttest, subject image quality, anatomy identification, and percentage of correct views; simulation is superior to lecture-based methods of TTE instruction
Vegas et al[18] (2013)	10	Prospective observational among novice echocardiographers; benefit assessed using pretests and posttests after 1 h of simulation	UofT virtual TEE; standard module	A 1-h exposure to the virtual TEE simulation produced a significant improvement in the posttest score; use of online simulation improves knowledge of navigating the 20 standard TEE views
Damp et al[25] (2013)	27	Prospective randomized; assessed by checklist for 37 different views and self-assessment questionnaire	HeartWorks TEE[b]	TEE simulator training improves proficiency and helps speed learning and comfort with TEE among cardiology fellows
Sohmer et al[26] (2013)	30	Prospective randomized; TEE novices underwent simulation and a human instructor or simulation and a slide presentation	Vimedix TEE[c]	Regardless of the method of instruction, scores on simulator based image-acquisition posttest improved significantly and similarly in both groups; a simulation-based curriculum may obviate the need for faculty
Sharma et al[45] (2013)	28	Prospective randomized; benefit assessed by pretests and posttests following Internet-based and simulation-based training	UofT virtual TEE; HeartWorks TEE[b]	Internet- and simulation-based teaching significantly improves TEE knowledge when compared with traditional methods among echocardiography-naive anesthesia residents
Jelacic et al[27] (2013)	30	Prospective observational; senior anesthesiology residents assessed by MCQs before and after simulator instruction	HeartWorks TEE[b] (normal version; no disorders)	Echocardiography-naive residents showed significant improvement in echocardiographic anatomy score on posttest, but not in patient safety, clinical application, probe manipulation, or pathology
Wagner et al[28] (2013)	10	Prospective observational among pediatric residents; benefit assessed using MCQs and performance-based pretests and posttests	EchoComTEE[a] (pediatric mannequin)	Scores showed significant improvement in both MCQs and performance tests assessing image orientation and ability to identify and diagnose congenital heart defects
Ferrero et al[29] (2014)	42	Prospective randomized between didactic and simulator training; assessed by examination on anesthetized patient	HeartWorks TEE[b]	Simulator-trained anesthesia residents demonstrated superior image acquisition skills; mean difference in image quality scores was greatest for junior and echocardiography-naive residents
Edrich et al[30] (2014)	46	Prospective randomized between simulator and live volunteer training; written pretest followed by written and practical posttests	Vimedix TTE[c]	Practical image acquisition and written test scores improved similarly and significantly after both simulator- and volunteer-based instructions; simulators are noninferior to live models for echocardiography education
Matyal et al[37] (2014)	18	Prospective observational; trainee performance tracked using kinematic analysis during the simulation course	Vimedix TEE[c]	Novices demonstrated reduction in the time taken to acquire images and greater economy of motion over the course; benefits of simulation can be quantified for assessment purposes; clinical transferability was demonstrated

a trainee has achieved, they offer little information on the image acquisition and interpretation skills or on manual dexterity components of echocardiographic ability. Other indicators of proficiency reported in earlier studies have largely drawn on binary measures of ability, or lack thereof, to achieve a certain view or subjective assessments of image quality.[25]

Some of the currently available simulators have also sought to integrate subjective assessments of image acquisition and quality within their software platforms. In the HeartWorks' START (Student Assessment and Reporting Tool), for example, a tutor can set up student profiles and assign different tests such as basic TTE, TEE, or mitral valve examination to individual students depending on their level of proficiency. Students, in turn, access their respective user accounts (on the same simulator) and record what they believe is an accurate representation of each of the views within that examination. The tutor logs back into the students' accounts (in their own time), reviews the images as obtained and uploaded by each student, and grades them on a scale of 0 to 2. Although this arrangement eliminates the need for a tutor and a pupil to stand side by side simultaneously to enable trainee evaluation, it does not fundamentally alter the subjectivity in assessing proficiency in proper probe positioning, economy of motion, or the time taken to achieve the results. A video recording feature is planned for the future, but it may offer only yet another subjective measure of how comfortable a trainee appears visually.

The Simbionix system takes a step further and offers the ability to "automatically adjudicate" whether a trainee has acquired a correct image in response to a task assignment. For example, in test mode, the software can ask a trainee to acquire images, one by one, for the standard TEE views on the mannequin (see Fig. 17.6B). The trainee then acquires each image as directed, by using a foot switch to signal

final acquisition for that particular view. Based on the preset image for that view stored within the application, the software determines whether the trainee-acquired image is good enough to progress or not. Although the system allows for setting "difficulty" (or tolerance) levels of easy, medium, and hard, it can be difficult to achieve the exact image as stored within the application. This difficulty makes the particular assessment tool unrealistic, despite the advantage of allowing self-directed assessment by the trainee alone. Moreover, the extent of assessment is once again limited to the quality of image obtained and ignores other yardsticks of echocardiographic ability.

For simulation-based assessment to be broadly valid and applicable, a paradigm shift from subjective assessment of image quality is required. Quantification of measures of echocardiographic proficiency can help remediate this situation. Objective measurement of skills can also help overcome challenges posed by nonuniform clinical experiences by enabling verification of echocardiographic competency among trainees. In general, it is reasonable to define *echocardiographic competency* as the ability to perform a complete echocardiographic examination, including all standard views, in a time-limited and safe fashion. Achievement of such competency is meant to "prime" echocardiography-naive trainees for clinical exposure before their first, actual echocardiographic examination, as opposed to replacing clinical experience in any form.[6] More recent years have seen significant development in the arena of objective performance measurement, with the greatest progress stemming from the introduction of kinematic analysis in echocardiography simulation.[32,33]

Automated Kinematics

Kinematics refers to the study of motion and moving objects. In the context of echocardiography, it can be defined as the study of probe motion as an operator attempts to acquire a certain image. In purely physical terms, motion can be described by parameters such as acceleration and velocity. Recall that both these measures take certain other parameters into account: time, direction (or angle), and distance. It follows that probe motion can be broken down into several different parts, hence giving rise to the term *kinematic analysis.* Previously, such analysis of motion was used to evaluate training for endoscopic procedures and identify trainees requiring further instruction.[34,35] Setting benchmarks and hard targets in the context of simulation is associated with improved resident motivation to participate in a curriculum by *gamification* of their learning experience.[36]

For an echocardiography simulator to achieve kinematic capability, it would need to document the starting point precisely and track the change in position in the x, y, and z positions of the probe during its motion. The angular rotation of the scan plane as well as the roll, pitch, and yaw of the TEE probe would also need to be recorded over time. The z-axis refers to the distance of the probe from the chest wall; the x-axis and y-axis refer to the horizontal and vertical (cephalad-to caudad) motion of the probe in the chest. Roll, pitch, and yaw refer to angular motion of the probe along the x-axis, y-axis, and z-axis, respectively[37] (Fig. 17.12).

The electromagnetic technology that detects and records probe motion in a given field has existed since the very first simulators. Indeed, were it not for this technology, probe-responsive echocardiography simulation would not have existed. However, the idea to use this technology as a means of recording, measuring, and tracking trainee performance is a relatively late development. The starting point for this arrangement to work is the creation of a "target." In case of echocardiography, this would imply a "target image" or a *target cut plane* (TCP) that the trainee must acquire. Ordinarily, the TCP is an expert-acquired "ideal" 2D echocardiographic image, which can be stored on the system for use if and when required. Once a particular TCP is loaded, the "motion recording" option can be activated. "Motion recording" begins documenting the trainees' probe movements as they start, stop, turn, rotate, stop again, start again, accelerate, and finally refine their acquisition into a final image corresponding to the originally loaded TCP. Once the image acquisition is complete, the recording is stopped, and a report is generated with all the measurements obtained during the exercise.[33]

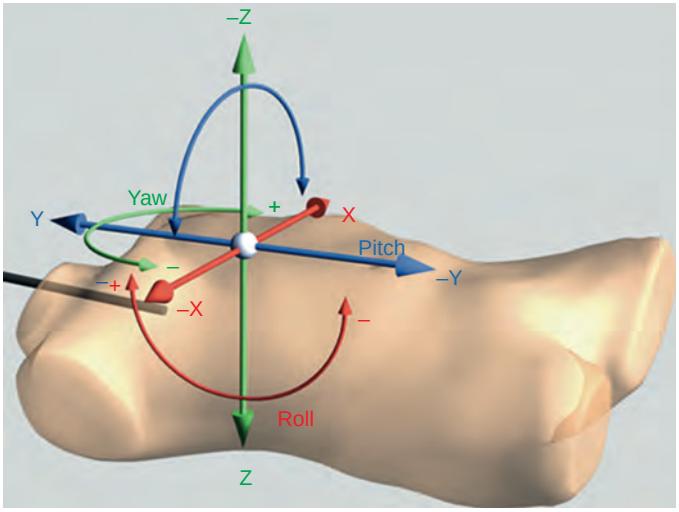

Fig. 17.12 The geometric dimensions measured by the CAE Vimedix system during motion tracking. *(Courtesy CAE Healthcare, Montreal, Canada. © CAE Healthcare, Inc.)*

At present, this feature is offered by the Vimedix system alone. On this simulator, the motion metrics interface has four different windows (Fig. 17.13):

1. The virtual reality 3D heart model with two superimposed scan planes: the red, static plane representing TCP; and the blue, dynamic scan plane that moves in response to trainee probe movements
2. The 2D computer-rendered target echocardiographic image, as defined by the TCP
3. The computer-rendered 2D ultrasound image corresponding to the trainee's scan plane, which changes with the trainee's probe manipulations
4. The target plane in relation to the body's surface anatomy

The system allows motion metrics to be used for both training and evaluation. In the training mode, the trainees are able to visualize the TCP on the screen, along with the ideal probe position in relation to the body to help guide them as they move and rotate the probe. In the evaluation mode, the trainees can be asked to acquire the desired image by using only their own memory, cognition, and manual dexterity to guide the probe to the correct position without the visual cue from an onscreen target image. Once a desired echocardiographic image has been acquired, the 3D tracking of the probe manipulation can be terminated. At the end of the tracking, the simulator automatically displays a detailed report with measurements for each of the recorded parameters (Fig. 17.14). This report can also be exported by a universal serial bus drive.

In their article on kinematic analysis, Matyal and colleagues[37] described the utility of motion metrics in measuring and tracking trainee performance. These investigators identified and reported parameters that show improvement in response to a simulation-based curriculum. These parameters include the following:

- The total time required to acquire the image measured in seconds from the time of activation of tracking until such time as the learner feels confident of the acquisition (and verified by an instructor)
- The sum of all linear and angular movements of the probe measured as centimeters of total distance moved
- The time before initiation of the first motion of the TEE probe after being instructed to acquire a specific image
- The number of times the subject performed accelerations as evidenced by sudden changes in speed or direction of the TEE probe
- Area under the curve of total distance plotted against total time for the acquisition (ie, economy of both time and motion)

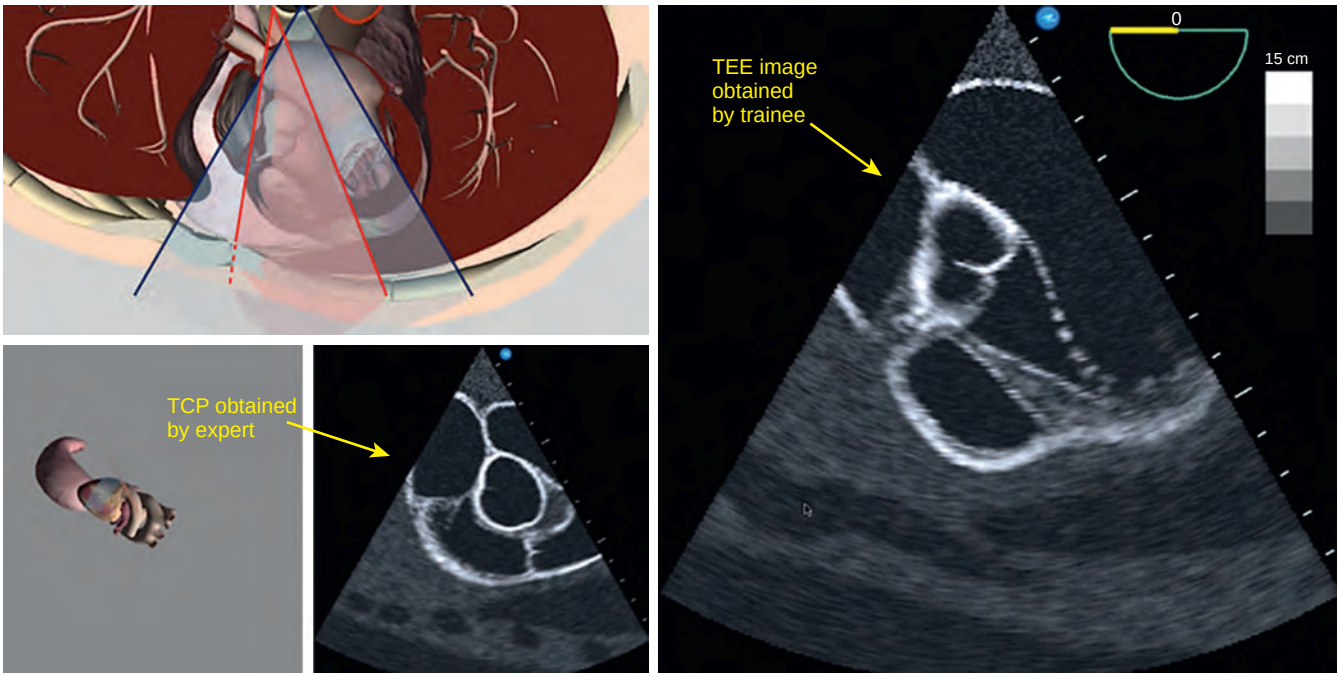

Fig. 17.13 A screenshot showing the different windows visible during a motion tracking acquisition. *TCP,* Target cut plane; *TEE,* transesophageal echocardiography.

Comparison of Captured vs. Target Cut Plane	
Total position difference (cm)	16.8535
Total angle difference (cm)	165.3490
Time (sec)	20.4999
Time until initial movement (sec)	5.1580
Total distance travelled (cm)	11.6659
Total angular movement (degree)	183.6045
Number of acceleration from Rest	19
Lateral(x) Position difference (cm)	-10.4056
Longitudinal(y) position difference (cm)	8.5449
Anteroposterior(z) postion difference (cm)	10.1366
Roll difference (degree)	-82.2843
Pitch difference (degree)	-8.5513
Yaw difference (degree)	-126.8527
Beam depth of field difference (cm)	-1.0000
Beam angle difference(degree)	0.0000

Fig. 17.14 Data generated by CAE Vimedix motion tracking algorithm at the end of a metrics acquisition for a single view.

The total distance traveled (path length) and the number of accelerations (Fig. 17.15) also helped differentiate between novices and experts, thus underscoring the importance of these parameters as potential metrics to establish competency for accreditation purposes. Importantly, progress on these parameters was shown to indicate readiness for clinical echocardiography, as evidenced by the ability to perform a complete, standard TEE examination on a real patient in the operating room. Meanwhile, another important concept that could be useful in context of echocardiography is that of *automaticity*, or the ability to engage in a process without devoting significant attention.[38] Surgical residents who demonstrate automaticity in tasks during simulation training have been reported to demonstrate a more complete transfer of skills to the clinical setting compared with surgical residents who do not.[39] A similar association for echocardiography education and practice is worth exploring in the future.

Future of Echocardiography Education

In recent years, the field of ultrasonography in general has witnessed a steep increase in the use of ultrasound as a diagnostic, guidance, and monitoring tool. Echocardiography has also had tremendous growth as an integral tool for perioperative physicians. Given this increase in number of users, the need for effective education in echocardiography has never been greater.[40] More importantly, given the current and evolving role of echocardiography in acute diagnosis and clinical decision making, adequate education in echocardiographic technique and operation carries direct implications for patient safety and potentially improved outcomes.[41,42] Given these requirements, the appearance of simulation in echocardiography education has been a timely and welcome development. To address the growing requirements of effective and large-scale echocardiography education, current simulators must keep improving and evolving in their roles as adjuncts to clinical experience, particularly in reducing the initial learning curve, as well as validating logbook scorings through objective assessment for basic and advanced certifications.

Despite technologic progress, the role of simulation in formal echocardiography education is yet to be defined. Moving forward, a curriculum-based approach including a combination of didactic lectures, online instruction, and hands-on simulation training holds significant promise.[43] Simultaneous use of multiple modalities can help provide a uniform, graduated, and coordinated learning experience to large numbers of trainees at the same time. For example, trainees can learn the basics of hemodynamics by didactic or online lectures and then practice quantitative echocardiography and its use in valve area calculations. The same coordinated learning strategy can be applied across all areas of initial echocardiography learning including wall motion assessment and aortic valve, mitral valve, and tricuspid valve evaluations.[44] At present, echocardiography education relies on a "top-down" approach with set milestones for achievement of final certifications. Adoption of simulation technology in training curricula can

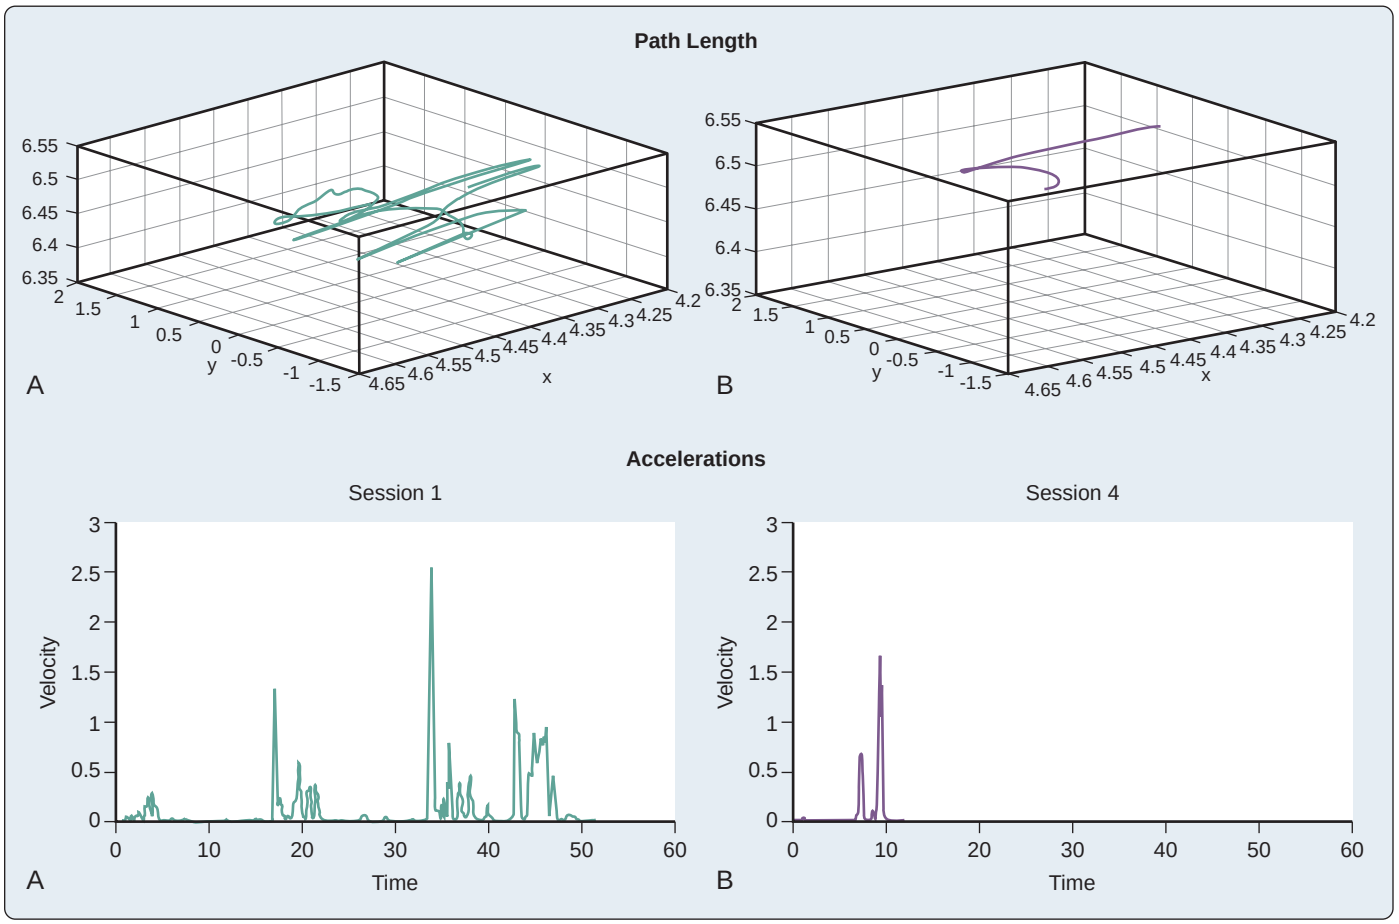

Fig. 17.15 The progress noted among simulation training sessions during a curriculum-based simulation course. *(Top)* The reduction in total distance moved by the probe by a particular trainee in an attempt to acquire a midesophageal four-chamber view. *(Bottom)* The number of accelerations, as evidenced by changes in velocity (speed or direction of the probe) over the course of an acquisition. The final session shows a decrease in both the number of accelerations and the time taken to acquire the image.

enable a "bottom-up" approach, with prerequisites specified for initiation of clinical echocardiography training.[6] Having attained comfort in areas such as basic ultrasound principles, echocardiographic anatomic orientation, and machine knobology in the simulation center, the trainees can acquire more meaningful and wholesome learning experiences right from their very first exposure.

One important caveat for echocardiography simulation going forward is its cost. Currently available simulators typically cost upward of $55,000 in the United States, with additional costs for annual software and hardware upgrades and service contracts. Moreover, storage costs, time devoted to teaching, and trainee time are also substantial. Streamlining simulation within the broader training program can help mitigate some of the personnel cost and clinical time lost in the simulation center.[21] Evidence suggests that echocardiography simulation may be at the cusp of widespread adoption as part of broader ultrasound curricula. However, the onus to achieve economy of scale remains on device vendors, who can pave the way for widespread adoption by price control. In case of failure to do so, virtual simulation could be a viable, cost-effective alternative to explore. Several studies have evaluated and demonstrated the effectiveness of virtual tools in reducing the learning curve for student echocardiographers.[17,18,45] Although such tools lack a manual dexterity component, they do address gaps in theoretic and cognitive knowledge in the absence of physical mannequin-based simulators.

Finally, although current simulators have come a long way since their earlier cousins, numerous areas of potential improvements remain. Building machine-like simulation consoles with knobs and buttons (eg, the current version of UltraSim; see Fig. 17.1), integrating data obtained from other monitors, deploying dynamic pathophysiologic changes, and eliciting diagnosis for evolving conditions are all features that future simulators could include to evaluate technical, cognitive, and behavioral responses to acutely unstable patients, as in a real environment. Further development of quantitative echocardiography tools and their role in diagnosis and decision making could also be helpful in filling gaps in clinical experience as well as accreditation-related assessment. Such high-fidelity simulation would serve to train not merely good "image acquirers," but rather *perioperative echocardiologists.*[46]

18 Central Nervous System Monitoring

HARVEY L. EDMONDS, Jr, PhD | EMILY K. GORDON, MD | WARREN J. LEVY, MD

KEY POINTS

1. Cardiac surgery–associated brain injury is common, multifactorial, and often preventable.
2. Electroencephalography can detect both cerebral ischemia or hypoxia and seizures and can measure hypnotic effect.
3. Middle-latency auditory-evoked potentials objectively document inadequate hypnosis.
4. Brainstem auditory-evoked potentials measure the effects of cooling and rewarming on deep brain structures.
5. Somatosensory-evoked potentials may detect developing injury in cortical and subcortical brain structures and peripheral nerves.
6. Transcranial electric motor-evoked potentials monitor function of the descending motor pathways.
7. Transcranial Doppler ultrasound examination assesses the direction and character of blood flow through large intracranial arteries and identifies microemboli.
8. Cerebral oximetry, using spatially resolved transcranial near-infrared spectroscopy, provides a continuous measure of change in the balance of cerebral oxygen supply and demand.
9. Used in concert, these technologies can reduce the incidence of brain injury and ensure the adequacy of hypnosis.

Yearly, nearly one-half of the 1 million patients undergoing cardiac surgical procedures worldwide will likely experience transient neurologic, cognitive, or neuropsychological dysfunction; in one-quarter of these patients, the changes will be persistent.[1] The direct annual cost to US insurers for brain injury from just one type of cardiac operation, myocardial revascularization, is estimated at $2 billion.[2] Furthermore, the same processes that injure the central nervous system (CNS) also appear to influence dysfunction of other vital organs. Thus, enormous clinical and economic incentives exist to improve CNS protection during cardiac surgical procedures.

Historically, neurophysiologic monitoring during cardiac surgical procedures has elicited little enthusiasm because of the presumed key role of macroembolization. It is widely assumed that most brain injuries during cardiac operations in adults result from cerebral embolization of atheromatous or calcified material dislodged from sclerotic blood vessels during the manipulation of these vessels. Until the introduction of myocardial revascularization without cardiopulmonary bypass (CPB) or aortic clamp application, these injuries often were viewed as unavoidable and untreatable.

Technical developments are altering this perception. First, CNS injuries still occur despite reductions in aortic manipulation with the newer approaches to coronary artery bypass grafting (CABG) and aortic surgical procedures.[3] Second, neurophysiologic studies have implicated hypoperfusion and dysoxygenation as major causative factors in CNS injury[4,5] (Box 18.1). Because these functional disturbances are often detectable and correctable, the impetus is to examine the role of neurophysiologic monitoring in organ protection (see Chapter 40).

The familiarity of cardiac anesthesiologists with neuromonitoring is becoming increasingly important. The information from compact and simplified monitors of brain electrical activity, blood flow velocity, and oxygenation can now be integrated into a unified display to facilitate cardiac anesthetic management. The goal of this chapter is to highlight the practical issues involved with each of these neuromonitoring technologies. This emphasis on practicality limits discussion to devices cleared for use by the US Food and Drug Administration (FDA). Because many of the practical issues in the application of these technologies are similar, the technical and physiologic underpinnings are presented first, with the later portion of the chapter devoted to clinical applications.

Electroencephalography

Electroencephalographic (EEG) monitoring for ischemia detection has been performed since the first CPB procedures.[6] However, in contrast to its widespread use during carotid endarterectomy (CEA), EEG monitoring of cardiac operations has been performed primarily in academic centers or those specializing in pediatric surgery. This limited use appears to have several causes.

First, small, practical, and affordable EEG monitors have only recently become available. For example, using a book-sized box of electronics and a notebook computer, it is now possible concurrently to display multichannel conventional and processed EEG findings, as well as bilateral transcranial Doppler (TCD) ultrasonic spectra and cerebral oxygen saturation. All the resulting data can be easily transmitted over high-speed data lines for Internet-based consultation or archival or post hoc analysis.

Second, the traditional diagnostic approach to EEG analysis depended on complex pattern recognition of 21-channel analog waveforms to identify focal ischemic changes.[7] This analytic format necessitated extensive training and constant vigilance. As a result, the direct monitoring of EEG findings during cardiac operations by anesthesia providers was viewed as impractical. However, reduced electrode array perioperative EEG recordings that include bilateral activity appear to be effective in identifying cortical ischemia and seizure activity in the perioperative and critical care settings.[8] Anesthesia-oriented training materials now permit providers to learn the basics of EEG artifact recognition[9] and waveform interpretation[10–12] quickly. In addition, computerized processing of EEG signals provides simplified trend displays that have helped to overcome many of the earlier interpretational complexities.[13]

Third, EEG analysis during cardiac surgical procedures was often confounded by anesthetic agents, hypothermia, and roller pump artifacts.[14] Fortunately, these technical problems have now been overcome by (1) elimination or replacement of the troublesome roller pumps with centrifugal pumps, (2) routine use of mild hypothermic or normothermic bypass, and (3) adoption of fast-track anesthesia protocols that avoid marked EEG suppression.

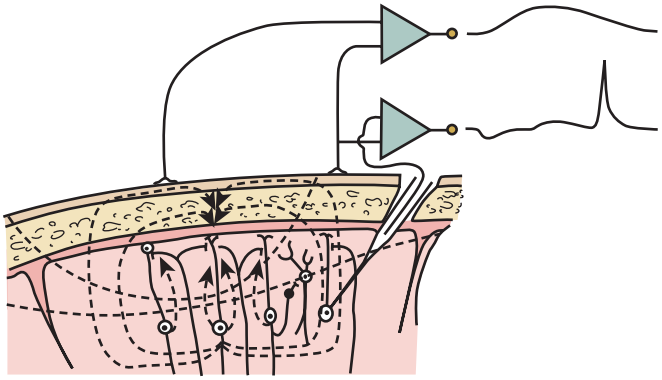

Fig. 18.1 Production of electroencephalographic (EEG) waves. Scalp electrodes record potential differences that are caused by postsynaptic potentials in the cell membrane of cortical neurons. The *closed loop dashed lines* represent the summation of extracellular currents produced by the postsynaptic potentials. *Open segment dashed lines* connect all points having the same voltage level. The two scalp electrodes record changes in the voltage difference over time *(top trace at upper right).* The *lower trace* from a microelectrode inserted in a single cortical neuron has little direct relationship with the summated EEG wave. *(Modified from Fisch BJ.* EEG Primer. *3rd ed. New York: Elsevier, 1999:6.)*

Physiologic Basis of Electroencephalography

Electroencephalographically directed interventions designed to correct cerebral hypoperfusion during cardiac surgical procedures require an appreciation of the underlying neurophysiologic substrate. Scalp-recorded EEG signals reflect the temporal and spatial summation of long-lasting (10–100 milliseconds) postsynaptic potentials that arise from columnar cortical pyramidal neurons (Fig. 18.1). These potentials are produced by dipoles distributed over soma-dendritic surfaces. Pyramidal neurons have a long, vertically oriented apical dendrite and shorter basal dendrites radiating from the soma base. Near-synchronous excitation (or inhibition) of neighboring dendritic membranes produces large-amplitude spatially summating vertical dipoles, whereas radial current layers are generated in the somatic region. Simultaneous current generation in the two regions may appear to be self-canceling at distant surface electrodes. In addition, traditional EEG tracings depict only voltage change, not absolute voltage. Thus, sustained high-frequency neuronal activity may result in a large but nonvarying surface voltage deviation that would be invisible on the conventional EEG tracing. These important EEG characteristics should be appreciated when interpreting low-amplitude signals; they do not necessarily indicate synaptic quiescence.

EEG rhythms represent regularly recurring waveforms of similar shape and duration. These signal oscillations depend on the synchronous excitation of a neuronal population. The descriptive nature of conventional EEG findings characterizes the oscillations (measured in cycles per second [cps] or Hertz [Hz]) as sinusoids that were classified according to their amplitude and frequency. The terminology used to describe the frequency bands of the most common oscillatory patterns is illustrated in Fig. 18.2. In addition, a high-frequency (25–55 Hz) gamma band is recognized (Table 18.1).

TABLE 18.1 Electroencephalographic Frequency Bands

Delta (δ)	0.1–4 Hz
Theta (θ)	4–8 Hz
Alpha (α)	8–14 Hz
Beta (β)	14–25 Hz
Gamma (γ)	25–55 Hz

EEG oscillatory patterns are functional manifestations of specific intraneuronal networks. The extent of cortical processing among neighboring neuronal columns influences the extent of scalp-recorded EEG waveform synchronization and does not necessarily depend on the subcortically mediated arousal level. At a high level of cortical processing, each neuronal palisade may function in relative independence. The resultant EEG signal will be of low amplitude, representing the distance-weighted average of many desynchronized micropotentials. The large number of small potentials is reflected in an EEG pattern characterized by a high dominant frequency (14- to 25-Hz beta waves). Such a pattern may be seen during very different vigilance states, such

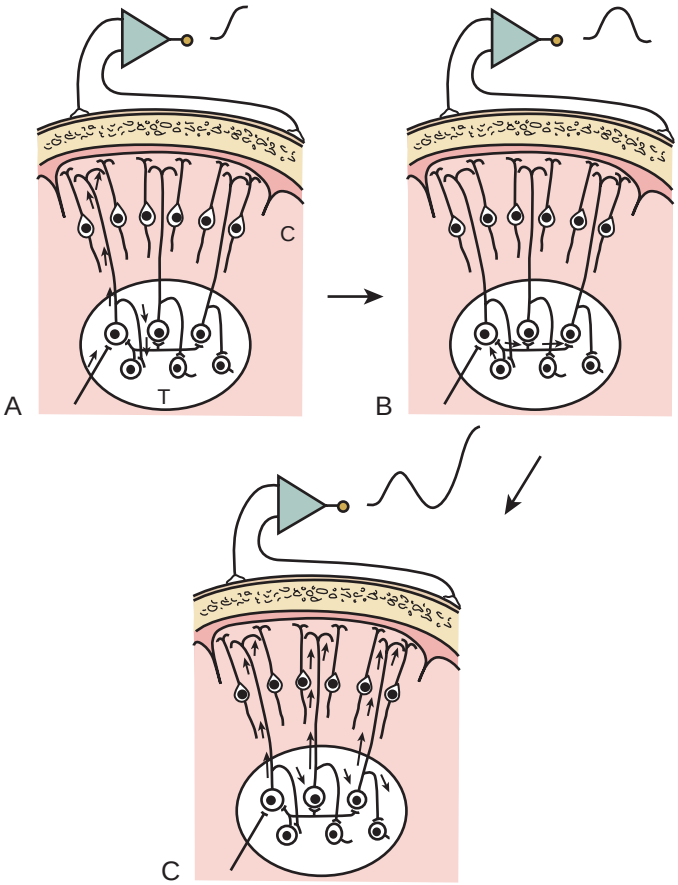

Fig. 18.3 Steps involved in the production of rhythmic electroencephalographic (EEG) activity. (A) Initiation of an EEG wave results from afferent excitation of a thalamocortical relay neuron (TCR) in the thalamus *(T)* and subsequent simultaneous transmission to a cortical and inhibitory thalamic interneuron. (B) Output from the thalamic inhibitory interneuron suppresses neighboring TCR neurons, thus leading to the termination of the first EEG wave. (C) Following the inhibitory phase, additional TCR depolarization produces another EEG wave. *(Modified from Fisch BJ.* EEG Primer. *3rd ed. New York: Elsevier, 1999:10.)*

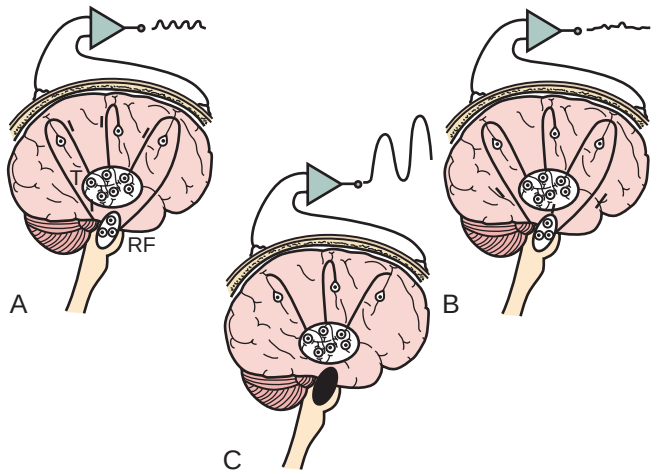

Fig. 18.4 Role of the mesencephalic reticular formation *(RF)* in the generation of rhythmic electroencephalographic (EEG) activity. (A) In the absence of strong RF input, the thalamic pacemaker cells produce rhythmic EEG activity. (B) RF activation sends inhibitory signals to the thalamus, thereby suppressing rhythmic EEG and leading to a desynchronized pattern. (C) In contrast, anesthetic or hypnotic RF suppression augments cortical EEG rhythms. *(Modified from Fisch BJ.* EEG Primer. *3rd ed. New York: Elsevier, 1999:12.)*

as awake and mentally alert status (see Fig. 18.2, top trace) versus rapid-eye-movement (ie, dream) sleep (see Fig. 18.2, bottom trace). Partial cortical columnar synchronization develops with a reduction in information processing, thus resulting in higher-amplitude and lower-frequency EEG oscillations associated with a relaxed, drowsy state (see Fig. 18.2; 8- to 14-Hz alpha rhythm). Progressive suppression is associated with lower-frequency 4- to 8-Hz theta waves. Minimal processing leads to the very high-amplitude, low-frequency hypersynchronous 0.1- to 4-Hz delta waves seen during the low-vigilance states of deep coma, deepest sleep, hypoxia, ischemia, and some forms of surgical anesthesia.

Synchronization of cortical columns is influenced by subcortical structures, including the thalamus (Fig. 18.3) and reticular activating system (Fig. 18.4). Reticular inhibition can block the passage of sensory information to the cortex that is routed through thalamic relays. This state of functional deafferentation results in unconsciousness, an essential component of both natural sleep and surgical anesthesia.[15] However, the individual components of a modern balanced anesthetic technique may differentially affect the separate control mechanisms for sensory processing and vigilance. Thus an EEG pattern suggestive of a low-vigilance state (ie, surgical hypnosis) does not necessarily guarantee the absence of subcortical (ie, unconscious) sensory perception (ie, reflexive response to painful stimuli).[16] Furthermore, because the neuronal basis for the electroencephalogram is primarily of cortical origin, it is not surprising that many univariate (ie, single variable) EEG amplitude or frequency descriptors are only weakly correlated with clinical measures of anesthetic effect or developing disease involving primarily or exclusively subcortical structures.

Practical Considerations of Electroencephalographic Recording and Signal Processing

The process of converting these tiny potentials into interpretable EEG displays begins with choice of scalp electrodes (subdermal needle, metallic disk, or silver-silver chloride gel self-adhesive patch) and their location. All three electrode types provide high-quality signals. Single-use sterile needle electrodes are easy to apply but are invasive, relatively expensive, and not well tolerated by conscious patients. They also predispose to hematoma formation or bleeding in heparinized patients. Reusable disk electrodes, held in place with conductive gel, gel-free self-abrading plastic retainers or built into a nylon mesh cap, may be used on conscious patients and are the least costly option. Adhesive patch electrodes are generally used only on glabrous skin and have a cost midway between the other options.

Standardized electrode placement is based on the International 10–20 System (Fig. 18.5). It permits uniform spacing of electrodes, independent of head circumference, in scalp regions known to correlate with specific areas of cerebral cortex. Four anatomic landmarks are used—the nasion, inion, and preauricular points. Electrodes are located at 10% or 20% segments of the distance between two of these landmarks. The alphanumeric label for each site uses an initial upper case letter to signify the skull region (ie, frontal, central, temporal, parietal, occipital, auricular, and mastoid). Second and sometimes third letters, in lowercase, further delineate position (eg, "p" represents frontal pole, whereas "z" indicates zero or midline). Subscripted numbers represent left (odd) or right (even) and specific hemispheric location, with the lowest numbers closest to the midline. The prime notation (′) is used to signify specialized locations designed for certain evoked potential applications (eg, C_3' and C_4' represent 2 cm posterior to C_3 and C_4, directly over the upper limb sensory cortex).

The differential amplifiers used in EEG recording measure the voltage difference between two inputs. By convention, a negative voltage at input 1 relative to input 2 results in an upward deflection of the tracing. With a referential arrangement (montage) of recording channel selections (Fig. 18.6, left), the input 2 connections from a

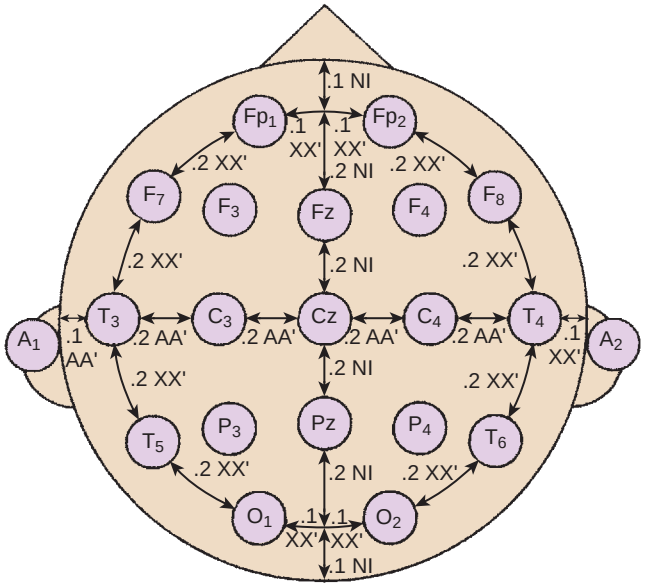

Fig. 18.5 Electroencephalographic electrode positions in the International 10–20 system. The sagittal hemicircumference (labeled *AA′*) is measured from the root of one zygoma (just anterior to the ear) to the other, across the vertex. The third measurement is the ipsilateral hemicircumference *(XX′)* measured from a point 10% of the coronal hemicircumference above the zygoma. Through these intersecting lines all the scalp electrodes may be located, except the frontal *(F_3, F_4)* and parietal (P_3, P_4). The frontal and parietal electrodes are placed along the frontal or parietal coronal line midway between the middle electrode and the electrode marked in the circumferential ring.

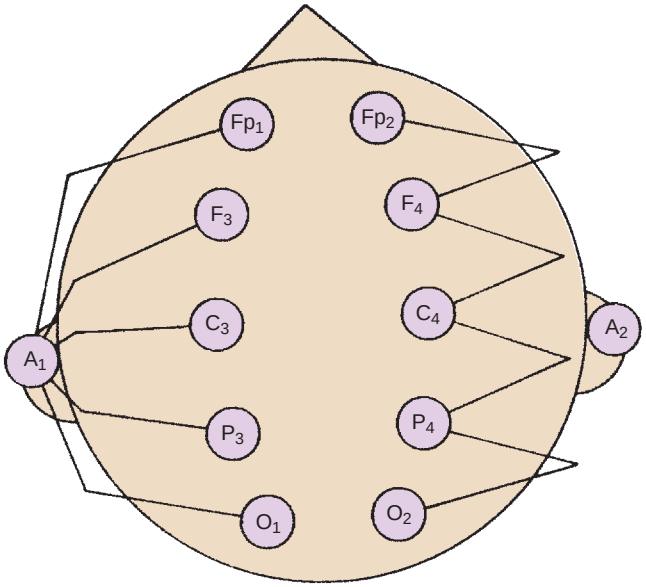

Fig. 18.6 Bipolar and common reference electroencephalographic (EEG) montages. The left parasagittal electrodes are connected in a common reference montage using the left earlobe *(A_1)* as the common reference electrode. Five channels are recorded, each of them between the parasagittal electrode and the ear electrode. Differences among these channels represent differences in cerebral activity among the various parasagittal electrodes because each channel is recorded as the difference between the activity at the parasagittal electrode and the activity at the ear electrode. For comparison, the right parasagittal electrodes are connected in a bipolar chain. In this configuration, only four channels of EEG data are recorded. Each channel of data represents the electrical difference between the two electrodes.

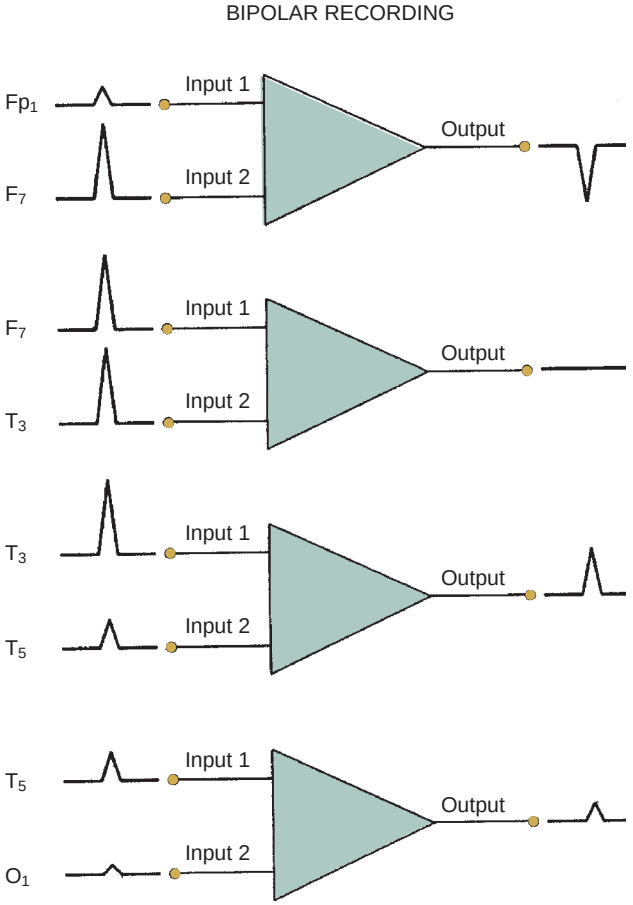

Fig. 18.7 Detection of focal electroencephalographic (EEG) abnormalities. Their accurate characterization requires that one of the amplifier's inputs be outside the field distribution of the transient EEG abnormality. If both inputs lie within the transient field, the signal may become invisible because of in-phase cancellation. (*Modified from Goldensohn ES, Legatt AD, Koszer S, et al, eds.* Goldensohn's EEG Interpretation. *2nd ed. Armonk, NY: Futura; 1999:16 with permission of the publisher.)*

series of channels are connected to a single electrode, whereas input 1 electrode connections all differ. (This approach is occasionally and erroneously referenced as "unipolar.") Alternatively, in bipolar recordings, a common reference is not used (see Fig. 18.6, right).

Although an array of scalp electrodes theoretically permits many possible montages to be used, the capability to change montage quickly varies greatly among different EEG monitors. This ability to change recording montage quickly may be important in the detection and characterization of both focal and diffuse abnormalities. With bipolar montages (Fig. 18.7), the transient will be distorted if both amplifier inputs lie within the transient electric field.

Montage choice also influences susceptibility to artifact. For example, millivolt ECG potentials may contaminate the thousand-fold smaller EEG signal, and cardiac pacing is often readily identifiable even in high-quality recordings. Contamination is often problematic with an ear or mastoid reference montage, but it may be invisible with an anterior-to-posterior bipolar montage. The extreme lateral placement of ear or mastoid references maximizes contamination by the perpendicularly oriented high-voltage dipole generated by the heart.

The frequency range involved in production of the EEG waveform is termed its *bandwidth*. The upper and lower bandwidth boundaries are controlled by filters that reject frequencies above and below the EEG bandwidth. Both the appearance of the unprocessed EEG waveform and the value of univariate numeric EEG descriptors such as the mean dominant frequency (MDF) may be heavily influenced by signal bandwidth that is often user controlled by high- and low-frequency

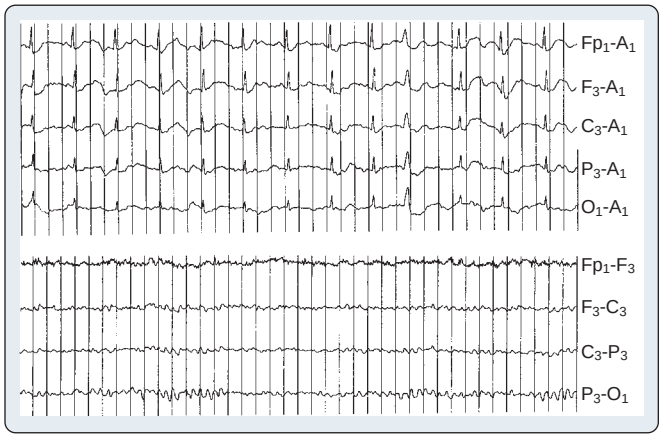

Fig. 18.8 Electroencephalographic (EEG) waveform notable features and the bispectral index (BIS). (A) Two EEG traces and corresponding BIS values are shown. These traces reflect a hypothetic situation in which bilateral frontal EEG recordings are taken. The right channel shows an underlying slow delta wave pattern with higher-frequency waves (eg, faster delta, theta, and alpha waves) also apparent. The left channel shows a burst suppression pattern. Such asymmetry could occur with unilateral *(left)* frontal hypoperfusion. (B) The EEG traces are obtained from a BIS monitor. Cardiopulmonary bypass had been initiated, and the patient's electroencephalogram was persistently suppressed. Marked electrocardiographic (ECG) artifact is evident in the persistently suppressed EEG trace. Automated analysis may not recognize the ECG signal as readily as a trained anesthesia provider. (C) The results of EEG filtering are depicted. The first trace shows a typical EEG epoch during general anesthesia, with an underlying slow delta pattern. Also apparent are higher-frequency waves (eg, faster delta, theta, and alpha waves). In the second trace, the higher-frequency waves are still apparent, but the underlying slow delta pattern has been attenuated by a user-selectable low-frequency filter. The default BIS setting automatically outputs a filtered EEG trace; these filters may obscure useful information. In this case, large delta waves consistent with deep anesthesia were filtered out, thus potentially preventing the anesthesia provider from appreciating the true anesthetic depth. EEG tracings were obtained using a BIS Quatro Sensor (version XP; Covidien, Boulder, Colo.). (*From Kertai MD, Whitlock EL, Avidan MS. Brain monitoring with electroencephalography and the electroencephalogram-derived bispectral index during cardiac surgery.* Anesth Analg. *2012;114:533, with permission of the publisher, Lippincott Williams & Wilkins, Baltimore.)*

filter settings (Fig. 18.8). Similarly, the same cerebral biopotential recorded by different EEG devices may result in dissimilar waveforms and numeric values.

Modern EEG monitors use digital microprocessors to analyze the amplified analog biopotentials. Yet analog-to-digital conversion imposes limitations on signal processing. Digitization converts a continuously varying biopotential into a series (ie, sample) of discrete quantal values. To minimize conversion inaccuracies, at least two samples per period are required. Sampling (Nyquist) frequency must be greater than twice the highest frequency of interest. For example, with an EEG bandwidth of 50 Hz, the minimum acceptable sampling frequency is 100 Hz (eg, 10-millisecond sampling interval). Aliasing, the counting of high-frequency signals as low-frequency input, may occur if the complex biopotential contains frequencies above the Nyquist frequency. Therefore most EEG monitors contain antialiasing filters that sharply attenuate waveform components above the Nyquist frequency. The details of filtering further add to the manufacturer-specific characteristics of processed electroencephalograms.

The continuous analog signal is also simplified into a (usually) discontinuous set of segments of a fixed duration (ie, epoch). Window functions can minimize, but not totally eliminate, digital distortion produced by the abrupt truncation of a continuously varying waveform. These window functions are numeric series containing the same number of elements as the epoch. Their purpose is to reduce the value

BOX 18.2 LAW OF THE ELECTROENCEPHALOGRAM

- In the absence of disease, electroencephalographic amplitude and frequency are inversely related.
- Simultaneous decrease may indicate ischemia, anoxia, or excessive hypnosis.
- Simultaneous increase may indicate seizure or artifact.

of epoch terminal elements. In addition to windowing, commercial EEG analyzers often use another form of signal conditioning called *whitening*. The energy content of the electroencephalogram is not uniform at all frequencies but instead is heavily skewed to the lower range. Whitening mathematically alters the momentary frequency-amplitude relationships to achieve nearly equal energy per octave and may improve pattern recognition in processed waveforms. Antialiasing, windowing, and whitening may vary not only among different devices but also among software versions used with a single device. The user should be aware that a standard unprocessed analog EEG signal may generate digitally processed displays and numeric descriptors that are unique for each monitor design and software version.

Display of Electroencephalographic Information

Time-Domain Analysis

Traditional display of the electroencephalogram is a graph of biopotential voltage (y-axis) as a function of time and consequently is described as a time-domain process. The objective of a diagnostic electroencephalogram is to identify the most likely cause of a detected abnormality at one moment in time. Typically, a diagnostic electroencephalogram is obtained under controlled conditions, using precisely defined protocols. Recorded EEG appearance is visually compared with reference patterns. Interpretation is based on recognition of unique waveform patterns that are pathognomonic for specific clinical conditions. In contrast, the goal of EEG monitoring is to identify clinically important change from an individualized baseline. Unlike diagnostic EEG interpretation, monitoring requires immediate assessment of continuously fluctuating signals in an electronically hostile, complex, and poorly controlled recording environment. Therefore, of necessity, interpretation relies less on pattern recognition and more on statistical characterization of change. Numeric descriptors thus may appropriately form an integral part of EEG monitoring.

Both EEG diagnostic and monitoring interpretations are based in part on the "law of the electroencephalogram" (Box 18.2). It states that amplitude and dominant frequency are inversely related. As described earlier, synchronously generated postsynaptic potentials may produce large-amplitude biopotentials. However, long membrane time constants limit the number of changes that may occur per second (eg, high amplitude, low frequency). Conversely, summation of spatially distributed asynchronous potentials results in EEG signals of low amplitude but relatively high frequency. Thus the inverse relationship between amplitude and frequency generally is maintained during unchanging cerebral metabolic states. Parallel increases in both may occur in some hypermetabolic states such as seizure activity, whereas decreases may be seen in hypometabolic states such as hypothermia. In the absence of these influences, simultaneous decreases in both amplitude and frequency may indicate ischemia or anoxia (Fig. 18.9); a parallel increase may represent artifact (Fig. 18.10).

Time-domain analysis of traditional electroencephalography uses linear signal amplitude (ie, voltage) and time scales. The amplitude range of EEG signals is quite large (several hundred microvolts), and univariate statistical measures of its central tendency and dispersion may contain clinically useful information.[17] Furthermore, amplitude variation may show clinically significant changes in reactivity that can be obscured by frequency-domain analysis. Advances in the technology

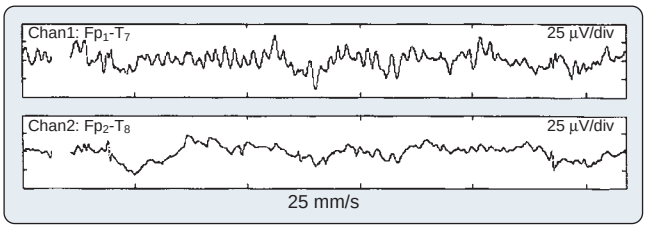

Fig. 18.9 The importance of electroencephalographic (EEG) baseline recording. This two-channel EEG recording was made immediately after induction of anesthesia, before head repositioning for insertion of a central venous catheter. Anesthetic induction apparently uncovered a preexisting asymmetry that was not evident in the waking electroencephalogram. Although the patient had a history of an earlier mild cerebrovascular accident and transient ischemic attacks, he appeared neurologically normal at preoperative assessment. *(Modified from Yli-Hankala A, ed.* Handbook of Four-Channel EEG in Anesthesia and Critical Care. *Helsinki, Finland: GE Medical Datex-Ohmeda Division; 2004:31, with permission of the publisher.)*

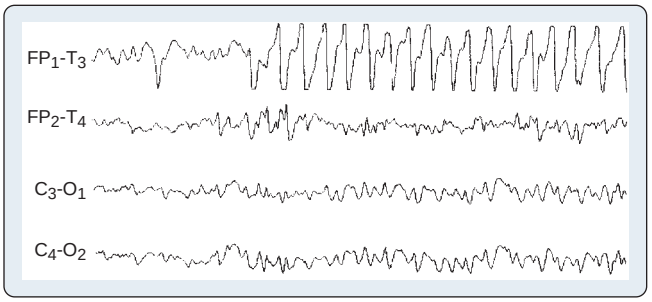

Fig. 18.10 Electroencephalographic (EEG) contamination by electrical artifact. The large-amplitude 2-Hz triangular waves in the left frontotemporal derivation *(top trace)* are the result of temporalis muscle activation with a nerve stimulator. Current spread from the stimulating to the EEG recording electrodes may be minimized with use of the appropriate facial nerve stimulation site at the jaw angle. *(Modified from Yli-Hankala A, ed.* Handbook of Four-Channel EEG in Anesthesia and Critical Care. *Helsinki, Finland: GE Medical Datex-Ohmeda Division; 2004:18, with permission of the publisher.)*

of EEG amplitude integration have prompted a resurgent interest in this attractively simple approach, particularly in pediatrics.[18]

Frequency-Domain Analysis

An alternative method, frequency-domain analysis, is exemplified by the prismatic decomposition of white light into its component frequencies (ie, color spectrum). As the basis of spectral analysis, the Fourier theorem states that a periodic function can be represented in part by a sinusoid at the fundamental frequency and an infinite series of integer multiples (ie, harmonics). The Fourier function at a specific frequency equals the amplitude and phase angle of the associated sinusoid. Graphs of amplitude and phase angle as functions of frequency are called Fourier spectra (ie, spectral analysis). The EEG amplitude spectral scale (Fig. 18.11) squares voltage values to eliminate troublesome negative values. Squaring changes the unit of amplitude measure from microvolts to either picowatts (pW) or nanowatts (nW). However, a power amplitude scale tends to overemphasize large-amplitude changes. Clinically important changes in low-amplitude components that are readily discernible in the linearly scaled unprocessed EEG waveform may become invisible in power spectral displays.

Simplification of the large amount of spectral information generally has been achieved through the use of univariate numeric descriptors. Most commonly, the power contained in a specified traditional EEG frequency band (delta, theta, alpha, or beta) is calculated in absolute, relative, or normalized terms. Relative amplitude represents the fraction of total power (TP; 0.1–55 Hz) contained in a specified frequency band (relative delta power = [delta power / TP] × 100). Normalization equalizes the TP of successive epochs to that of some arbitrary reference before the calculation of relative power (the delta power is described as z-score change from a previous individualized baseline). The latter two derived measures are particularly useful in minimizing misinterpretation of spectral changes. For example, during the production of hypothermia, absolute delta power declines in parallel with cerebral metabolism, although the fraction of the TP in the delta band remains unchanged. In this circumstance, exclusive focus on absolute delta power may lead to the erroneous conclusion that the hypnotic state is decreasing.

The most widely used univariate frequency descriptors (Box 18.3) are as follows:

1. TP
2. Peak power frequency (PPF), the single frequency of the spectrum that contains the highest amplitude
3. MDF, the sum of power contained at each frequency of the spectrum times its frequency divided by the TP
4. Spectral edge frequency (SEF), the frequency below which a predetermined fraction, usually 90% or 95%, of the spectral power occurs
5. Suppression ratio (SR), the percentage of flat-line electroencephalogram contained within sampled epochs

Trended changes in three of the foregoing descriptors (PPF, MDF, and SEF) occurring during total CPB are shown in Fig. 18.12.

Pronk[19] evaluated computer-processed univariate descriptors of EEG changes occurring before, during, and after CPB. MDF alone was sufficient to describe all EEG changes adequately except those changes occurring at very low amplitudes. Addition of a single-amplitude factor improved agreement with visual interpretation to 90%. Further factor addition did not improve agreement.

Multivariate (ie, composed of several variables) descriptors have been developed to improve simple numeric characterization of clinically important EEG changes. With this approach, algorithms are used to generate a single number that represents the pattern of amplitude-frequency-phase relationships occurring in a single epoch. Several commercially available monitors provide unitless numbers that have been transformed to arbitrary (ie, 0–100) scales. Each monitor provides a different probability estimate of a patient's response to verbal instruction. Current monitors designed for use by anesthesia providers are listed in Table 18.2. BIS (bispectral index, Covidien, Boulder, Colo), NT (NarcoTrend, Monitor Technik, Bad Bramstedt, Germany), PSI (Sedline, Masimo, Irvine, Calif), and SNAP II (Stryker Instruments, Kalamazoo, Mich) are rule-based proprietary indices empirically derived from patients' data. In contrast, CSI (Danmeter A/S, Odense, Denmark) uses a fuzzy logic-based algorithm, whereas SE applies standard entropy equations to EEG analysis. Each product is designed to require the use of proprietary self-adhesive forehead sensors. Collectively, these products are now in widespread use as objective measures of hypnotic effect.

Scalp-recorded cerebral biopotentials are complex physiologic signals. They represent the algebraic summation of voltage changes produced from cortical synaptic activity (ie, electroencephalogram), upper facial muscle activity (ie, facial electromyogram [fEMG]), and eye movement (ie, electro-oculogram [EOG]). During consciousness and light sedation, high-frequency gamma power (ie, 25–55 Hz) is a mixture of electroencephalography and subcortically influenced facial electromyography. Muscle activity makes a larger contribution because of the closer proximity of signal generators to the recording electrodes. Hypnotic and analgesic agents typically suppress both cerebral and muscle activities, with resulting reduced gamma power. Because the upper facial muscles are relatively insensitive to moderate neuromuscular blockade, they may remain reactive to noxious stimuli.[20] Nociception results in sudden gamma power increase, independent of activity in the lower-frequency classic EEG bands.

The EEG analyzers just described either provide separate quantitative estimates of the high-frequency information or incorporate this information into the hypnotic index. For example, the Datex-Ohmeda Entropy Module (GE Healthcare/Datex-Ohmeda, Helsinki,

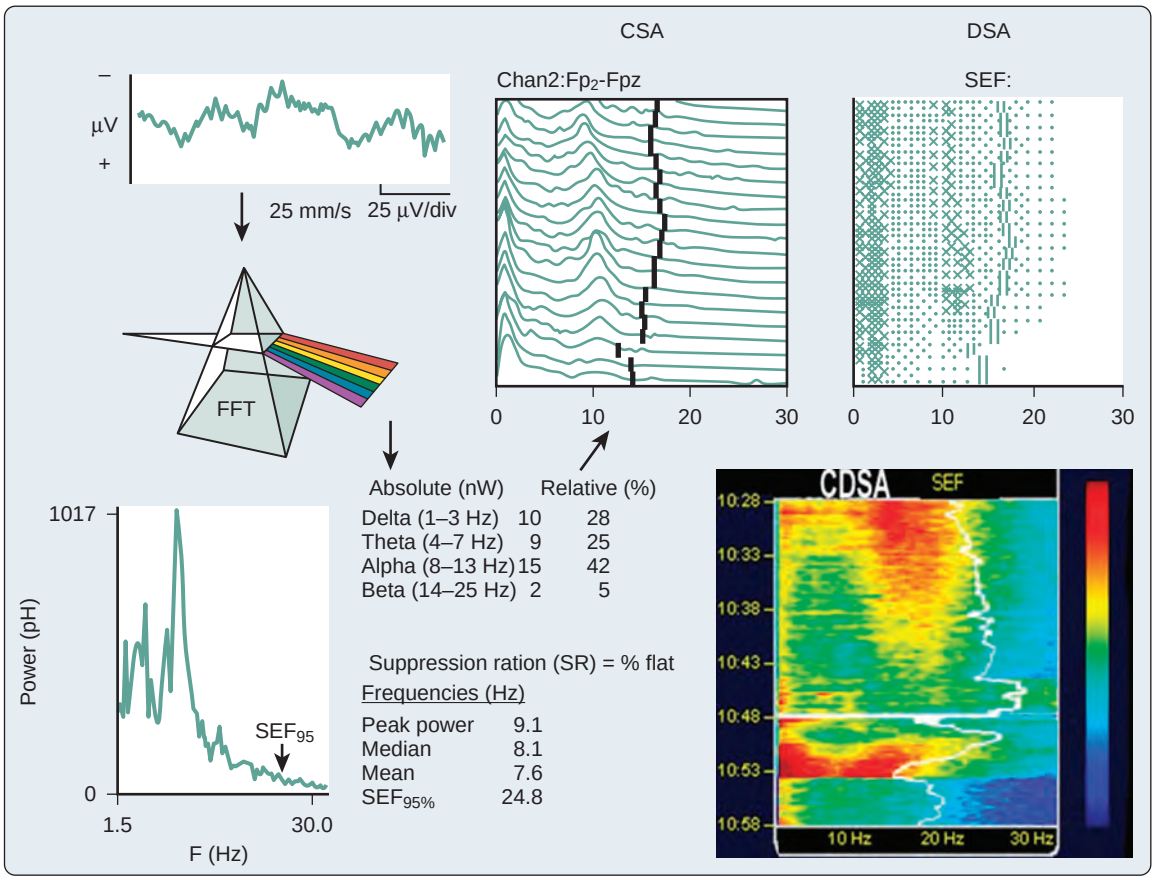

Fig. 18.11 Comparison of time- and frequency-domain electroencephalographic (EEG) displays. The traditional analog EEG signal shown in the *upper left* is a time-domain graph of scalp-recorded amplitude *(μV)* as a function of time. Digitized EEG segments (epochs) are computer processed using the fast Fourier transform *(FFT),* which, like a prism, decomposes a complex electromagnetic signal into a series of sinusoids, each with a discrete frequency. The instantaneous relationship is then graphically depicted by the power spectrum *(lower left),* a frequency-domain plot of power (μV^2 or *pW*) as a function of frequency. The spectral edge frequency *(SEF)* defines the signal amplitude upper boundary. The three-dimensional compressed spectral array *(CSA)* plots successive power spectra with time on the z-axis *(upper middle).* The density-modulated spectral array *(DSA; upper right*) improves data compression by using dot density to represent signal amplitude (ie, power). Amplitude resolution is improved through color coding in the color density spectral array *(CDSA)* shown at the *lower right.* The SEF is shown as the *white vertical line.* Note the EEG suppression at the bottom of each spectral trend.

Finland) separately analyzes the 32- to 47-Hz band and terms the signal Response Entropy (RE). Addition of RE to the lower-frequency state entropy (SE) is claimed by the manufacturer to facilitate distinction between changes in hypnosis and analgesia, although supporting evidence for this proposition awaits carefully designed and adequately powered randomized, prospective studies. EEG suppression decreases both entropy indices because noise-free flat-line EEG segments are generally thought to have near-zero entropy. However, during cardiac surgical procedures, EEG signals that appear to be totally suppressed may be associated with paradoxically very high entropy values. To minimize this problem, SE uses a special algorithm that assigns zero entropy to totally suppressed EEG epochs.

In addition to the quantitative EEG numeric indices, many monitors also display pseudo-three-dimensional plots of successive power spectra as a function of time. This frequency-domain approach was

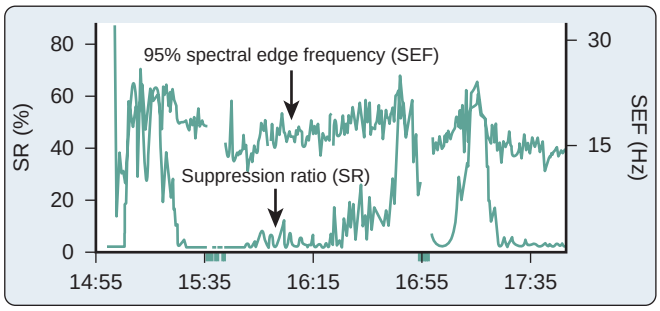

Fig. 18.12 Certain univariate electroencephalographic descriptors are particularly susceptible to the confounding influence of electronic interference. Note the peak in the suppression ratio *(SR)* trend at 17:00, correctly identifying marked EEG suppression. In contrast, the spectral edge frequency remains unchanged because of the presence of low-intensity electronic noise.

originated by Joy[21] and was popularized by Bickford, who coined the term "compressed spectral array" (CSA).[22] Its popularity stems in part from enormous data compression. For example, the essential information contained in a 4-hour traditional EEG recording consuming more than 1000 pages of unprocessed waveforms can be displayed in CSA format on a single page.

With CSA (see Figs. 18.11 and 18.12), successive power spectra of brief (2- to 60-second) EEG epochs are displayed as smoothed histograms of amplitude as a function of frequency. Spectral compression is achieved by partially overlaying successive spectra, with time represented on the z-axis. Hidden-line suppression improves clarity by avoiding overlap of successive traces. Although the display is esthetically attractive, it has limitations. The extent of data loss resulting from spectral overlapping depends on the nonstandard axial rotation that varies among EEG monitors. More important, epoch duration and the frequency with which each is measured (ie, update rate) may critically affect the presentation of clinically important change. For example, three distinctly different burst-suppression CSA patterns are recognized: high-amplitude bursts, flat line, or a combination of the two.[23]

Fleming and Smith[24] designed an alternative to the CSA display to reduce data loss. Density-modulated spectral array (DSA) uses a two-dimensional monochrome dot matrix plot of time as a function of frequency (see Fig. 18.11). The density of dots indicates the amplitude at a particular time-frequency intersection (eg, an intense large spot indicates high amplitude). Clinically significant shifts in frequency may be detected earlier and more easily than with CSA. However, the resolution of amplitude changes is reduced. Therefore color DSA (CDSA) was developed to enhance amplitude resolution (see Fig. 18.11). The CSA, DSA, and CDSA displays are not well suited for the detection of nonstationary or transient phenomena such as burst suppression or epileptiform activity.

In summary, a quick assessment of EEG change in either the time or frequency domain focuses on (1) maximal peak-to-peak amplitude, (2) relation of maximal amplitude to dominant frequency, (3) amplitude and frequency variability, and (4) new or growing asymmetry between homotopic (ie, same position on each cerebral hemisphere) EEG derivations. These objectives are generally best achieved through the viewing of both unprocessed and processed displays with a clear understanding of the characteristics and limitations of each (Box 18.4).

Auditory-Evoked Potentials

Auditory-evoked potentials (AEPs) assess specific areas of the brainstem, midbrain, and auditory cortices. Because of their simplicity and reproducibility, AEPs are suitable for monitoring patients during cardiovascular surgical procedures. Specific applications of AEP monitoring in this environment are the assessment of temperature effects

BOX 18.4 MEASURES THAT DEFINE ELECTROENCEPHALOGRAPHIC CHANGES

- Amplitude and frequency variability
- Right-to-left symmetry

on brainstem function and the evaluation of hypnotic effect. Direct involvement of cardiac anesthesia providers with AEP monitoring is likely to increase following the introduction of EEG/AEP modules designed for use with available operating room physiologic monitors.

Acoustic stimuli trigger a neural response integrated by a synchronized neuronal depolarization that travels from the auditory nerve to the cerebral cortex. Scalp-recorded signals, obtained from electrodes located at the vertex and ear lobe, contain both the AEPs and other unrelated EEG and electromyographic activity. Extraction of the relatively low-amplitude AEP from the larger-amplitude background activity requires signal-averaging techniques.[25] Because the AEP character remains constant for each stimulus repetition, averaging of many repetitions increases the signal amplitude linearly, whereas the inconstant background voltages are increased by the square root of the number of signals averaged. Thus increases in the signal-to-noise ratio of 10-fold to 30-fold are commonly achieved. For the AEP sensory stimulus, acoustic clicks are the most commonly used. These broadband signals are generated by unidirectional rectangular short pulses (40–500 microseconds) with frequency spectra lower than 10 KHz.

The AEPs comprise a series of biopotentials generated at all levels of the auditory system in response to an acoustic stimulus (Fig. 18.13). Using scalp electrodes, a dozen peaks have been identified within the first 100 milliseconds after stimulus onset. Each peak is described by its poststimulus latency and peak-to-peak amplitude. AEPs are commonly classified as early or middle-latency potentials. Fig. 18.14 is a schematic representation of the AEPs most commonly used for surgical monitoring. Early AEPs are generated from the auditory nerve and the brainstem and include a series of wavelets recorded within the first 10 milliseconds after stimulus. These evoked responses have been designated brainstem AEPs (BAEPs). Seven waves (I–VII) characterize the adult BAEPs. Peaks I and II are generally thought to originate from the distal and proximal parts of the eighth nerve, and peak III arises from the cochlear nucleus. Peak IV sources include the superior olivary complex, cochlear nucleus, and nucleus of the lateral lemniscus. Peak V contributors seem to include both the lateral lemniscus and the inferior colliculus. Peak VI and VII origins are not well defined, but these peaks may arise from the medial geniculate body and the acoustic radiations. BAEPs are useful in assessing brainstem and subcortical function during surgical procedures, in part because of their relative resistance to the suppressant effects of most anesthetic agents.[26]

The middle-latency AEPs (MLAEPs), with poststimulus latencies between 10 and 100 milliseconds, are generated in the midbrain and primary auditory cortex. In an awake adult subject, the MLAEPs usually consist of three main peaks: Na, Pa, and Nb, with respective latencies near 15, 28, and 40 milliseconds (see Fig. 18.14). Children under general anesthesia commonly display the trimodal configuration of the adult MLAEP waveform (Na, Pa, Nb waves), although neonates may exhibit only a small Pa wave.[27] Many agents with hypnotic effects prolong the latency and suppress the amplitude of Pa and Nb in a concentration-dependent manner.[26] It appears that the latency and amplitude changes allow reliable detection of consciousness and nociception during cardiac surgical procedures.[28] In addition, parallel monitoring of MLAEP and quantitative EEG descriptors (ie, BIS) may permit distinction between the hypnotic and antinociceptive anesthetic components.[28] This approach has also been used successfully

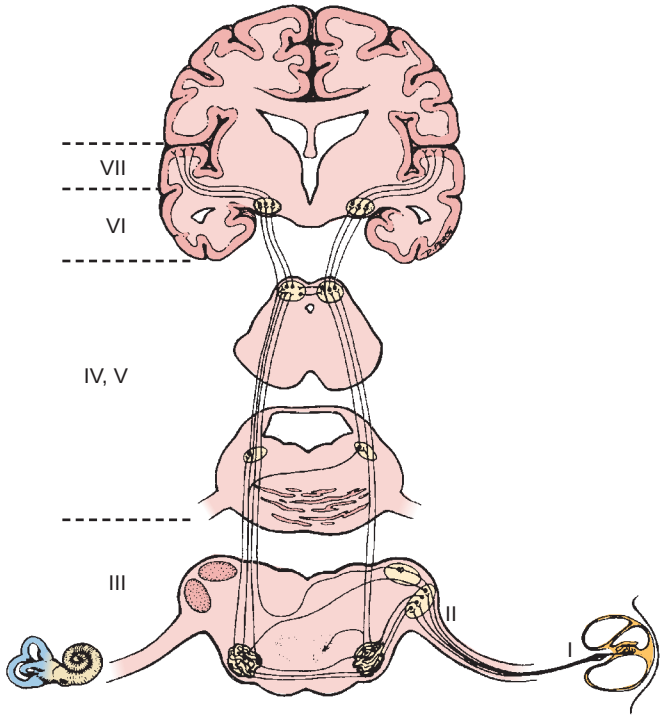

Fig. 18.13 Putative sites at which the brainstem auditory-evoked potential is generated include the cochlear nerve, cochlear nucleus, trapezoid complex, lateral lemniscus, inferior colliculus, medial geniculate nucleus, and auditory radiations. Wave I is generated in the distal cochlear nerve near the spiral ganglion, and wave II is generated in the proximal cochlear nerve near the brainstem. All other waveforms are generated in multiple brainstem sites and do not bear a one-to-one relation to any particular structures, although the later waveforms do tend to be generated in more rostral sites. *(Modified from Friedman WA, et al:* Advances in anesthesia. *Chicago: Yearbook Medical Publishers, 1989, p 244.)*

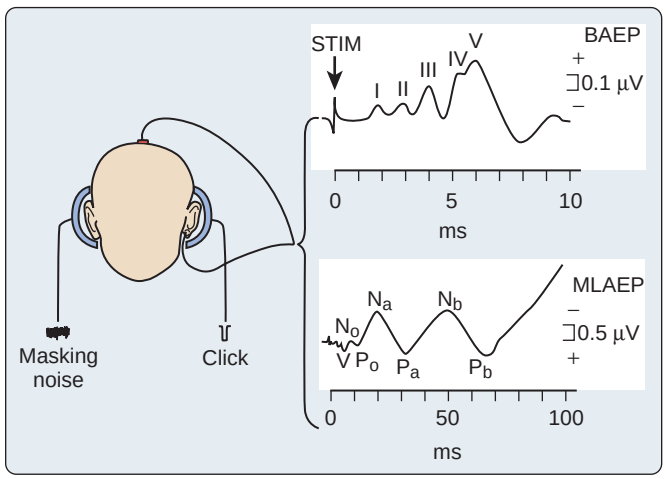

Fig. 18.14 Brainstem auditory-evoked potential *(BAEP)* and middle-latency auditory-evoked potential (MLAEP) waveforms. Stimulation *(STIM)* of one ear and recording between the ipsilateral earlobe and vertex produce sequences of peaks that can be displayed at two different recording speeds and gain settings. Recording with a short 10-millisecond time base at a high gain reveals the first five peaks that comprise the BAEP. With a longer 100-millisecond time base and lower gain, the MLAEP peaks become evident. By a rather confusing convention, BAEP peaks represent positive deflections, whereas MLAEP peaks indicate negative deflections. *(Modified from Spehlmann R.* Evoked Potential Primer. *Boston: Butterworth; 1985:196, with permission of the publisher.)*

in pediatric cardiac surgical patients to assess postoperative sedation objectively.[29]

To facilitate continuous perioperative monitoring, amplitude and latency from each of the primary MLAEP components have been integrated into a proprietary autoregressive linear function (A-Line Danmeter A/S, Odense, Denmark).[30] Subsequently, this metric was expanded to the A-Line Autoregressive Index, AAI, which included the quantitative EEG descriptors: (1) percentage of burst suppression and (2) beta ratio (ie, percentage of total EEG power contained in the high-frequency beta-frequency band).[31]

Somatosensory-Evoked Potentials

In many ways, the somatosensory-evoked potential (SSEP) is similar to the AEP. An electrical stimulus is applied peripherally to the arms or legs, or both, and the progression of the neuronal transmission through the spinal cord and subcortical structures is tracked, with various neurogenerators producing specific positive or negative deflection of the recorded signal at various times. In this way, SSEPs provide an objective measure of ascending sensory pathway function. Like AEPs, they are recorded by signal averaging over a large number of stimuli, with the duration of recording after each stimulus being somewhat longer and thus the frequency of stimulation somewhat lower. SSEPs are moderately sensitive to depression from inhaled anesthetic agents, but they do not generally preclude the use of potent agents in a balanced technique or as supplement to a high-dose narcotic approach. Fig. 18.15A illustrates the key neural structures involved in a prominent upper limb sensory pathway suitable for cardiac surgical neuromonitoring.

Motor-Evoked Potentials

By relying on the delivery of a rapid stimulus pulse train, it is now possible to monitor the integrity of descending motor pathways continuously by using transcranial electric motor-evoked potentials (MEPs).[32] The most frequent application of this emerging monitoring modality for cardiothoracic surgical procedures currently is during open surgical or endovascular repair of the descending aorta.[33] The need for improved spinal cord protection remains critical because, even with modern spinal cord preservation techniques, the infarction rate during type I and II aneurysm repairs in patients remains disturbingly high.[33]

The neurophysiologic basis for the MEP is illustrated in Fig. 18.16. Individual high-intensity transcranial stimuli depolarize cortical motor neurons directly in the axon hillock region or indirectly by activation of interneurons. Synaptic transmission of individual impulses to segmental α-motor neurons lowers the postsynaptic membrane potential, but it is often insufficient to initiate cell firing. Instead, this goal is achieved through use of a pulse train that triggers lower motor neuron discharge by temporal summation of individual subthreshold responses.

Precise placement of subdermal stimulating electrodes (Fig. 18.17A) is important because of the influence on motor pathway activation. The transcranial electric current generated from closely spaced electrodes depolarizes a discrete cortical region that may control only a restricted muscle group. In contrast, current produced using wide electrode separation bypasses the anesthetic-susceptible cortical neurons. This results in direct depolarization of descending motor tracts that affects both upper and lower limb muscles (Fig. 18.17B). Even though lower limb MEPs are necessary to document the functional integrity of motor pathways in the thoracolumbar spinal cord, upper limb recording is also important. The upper limb responses identify generalized MEP suppression. Its causes include anesthetic-induced synaptic inhibition, hypocapnia, and hypothermia, as well as position-related ischemia involving cerebral or upper limb motor pathways, or both (Fig. 18.18). The effects of anesthetic agents on evoked potentials are summarized in Table 18.3. In addition to these generalized effects, volatile anesthetic agents suppress both cortical and spinal cord motor

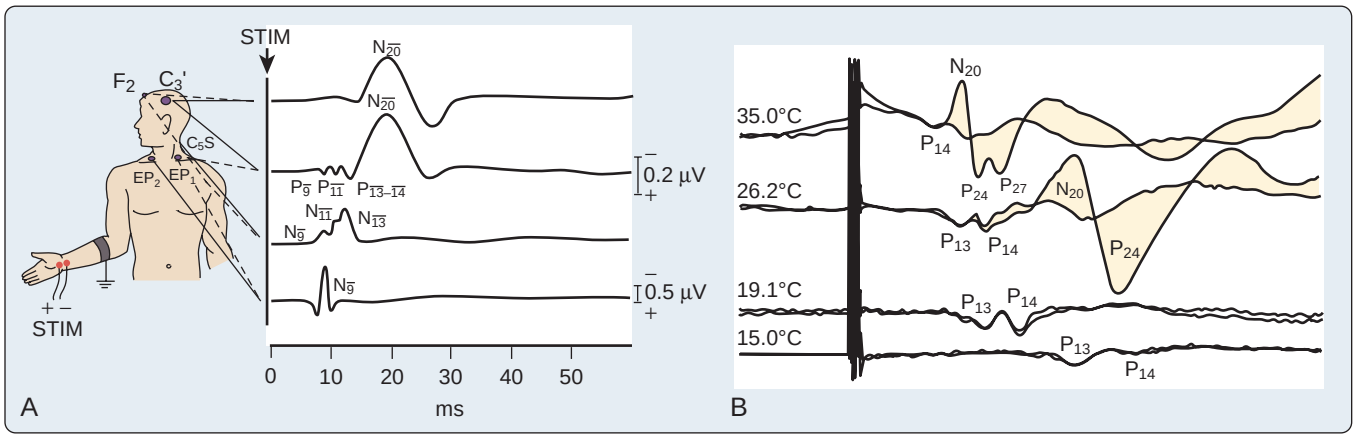

Fig. 18.15 Upper limb somatosensory-evoked potential (SSEP) waveforms. (A) The waveforms show ascending responses to median nerve electrical stimulation. With the aid of noncephalic reference electrodes, the N_9 clavicular (Erb point) potential reflects signal passage through the brachial plexus, whereas the N_{13} potential represents activation of the cervical and brainstem lemniscal structures. Signals passing through the cortical radiations and sensory cortex result in the N_{20} potential when recorded between a scalp active electrode and cephalic reference. (B) Each pair of upper limb SSEP waveforms is created by the superimposition of parietal recordings ipsilateral and contralateral to single limb median nerve stimulation. The *shaded area* represents signal generated within the cortical mantle. Cooling to 26.2°C increases the latency of both subcortical and cortical waveform components and results in the emergence of a second (ie, P_{13}) brainstem potential. Although that deep hypothermia at 19.1°C suppressed cortical activity, brainstem P_{13} and P_{14} responsiveness persists. *(A, From Misulis KE, Fakhoury T. Spehlmann's Evoked Potential Primer. 3rd ed. Boston: Butterworth-Heinemann; 2001:98, with permission of the publisher. B, Modified from Guérit JM. Intraoperative monitoring during cardiac surgery. In: Nuwer MR, ed.* Handbook of Clinical Neurophysiology. *Vol. 8.* Intraoperative Monitoring of Neural Function. *New York: Elsevier; 2008:834.)*

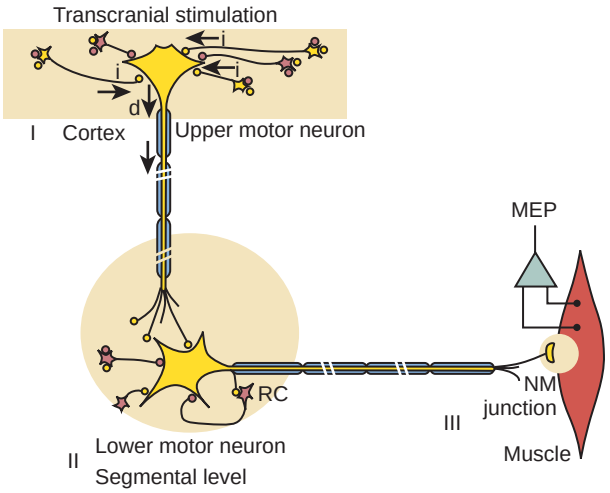

Fig. 18.16 Neural generators of transcranial motor-evoked potentials *(MEP)*. High-intensity transcranial electric or magnetic stimulation results in direct *(d)* activation of upper motor neurons. In addition, indirect motor neuron activation *(i)* results from transcranial activation of horizontally oriented excitatory (light) and inhibitory (dark) neuronal axons. Descending motor potentials are conducted unidirectionally through the corticospinal, rubrospinal, tectospinal, vestibulospinal, and cerebellospinal tracts to lower (alpha) motor neurons in the lateral and anterior spinal cord. In the absence of complete pharmacologic neuromuscular *(NM)* blockade, alpha motor neuron action potentials then produce muscle fiber contraction that is recorded by electromyography. *(Modified from Journee JL. Motor EP physiology, risks and specific anesthetic effects. In: Nuwer MR, ed.* Handbook of Clinical Neurophysiology. *Vol. 8.* Intraoperative Monitoring of Neural Function. *New York: Elsevier; 2008:219.)*

neurons. Thus the use of these drugs should be avoided or minimized during attempted MEP monitoring.[34]

In contrast to AEPs and SSEPs, the large amplitude of MEP electromyographic responses obviates the need for signal averaging. However, the inherent variability of these individual responses (see Fig. 18.18) means that precise measurement of peak amplitude and latency is more difficult to achieve than with the more stable averaged sensory-evoked potentials. Nevertheless, Kawanishi and colleagues[35] found 100% sensitivity and 98% specificity for MEP detection of motor pathway dysfunction. Their criterion for noteworthy change was a persistent 25% peak-to-peak amplitude decline. Correct interpretation of MEP amplitude change requires precise monitoring and control of neuromuscular blockade.[36] Information on the extent of neuromuscular blockade obtained from evoked electromyographic train-of-four responses in both upper and lower limb muscles bilaterally helps guide relaxant administration and detects limb ischemia.

Transcranial Doppler Ultrasound

Ultrasound Technology

Ultrasonic probes of a clinical TCD sonograph contain an electrically activated piezoelectric crystal that transmits low-power 1- to 2-MHz acoustic vibrations (ie, insonation) through the thinnest portion of temporal bone (ie, acoustic window) into brain tissue. Consequently, variations in cranial anatomy influenced by age, sex, and race may preclude TCD monitoring in a substantial fraction of certain demographic groups (eg, older African American women).[37] Overall, bilateral functional cranial windows may be anticipated in approximately three-quarters of older patients.[37] Blood constituents (predominantly erythrocytes) contained in large arteries and veins reflect these ultrasonic waves back to the probe, which also serves as a receiver. Because of laminar blood flow, erythrocytes traveling in the central region of a large blood vessel move with higher velocity than those near the vessel wall (Fig. 18.19). Thus, within each vascular segment (ie,

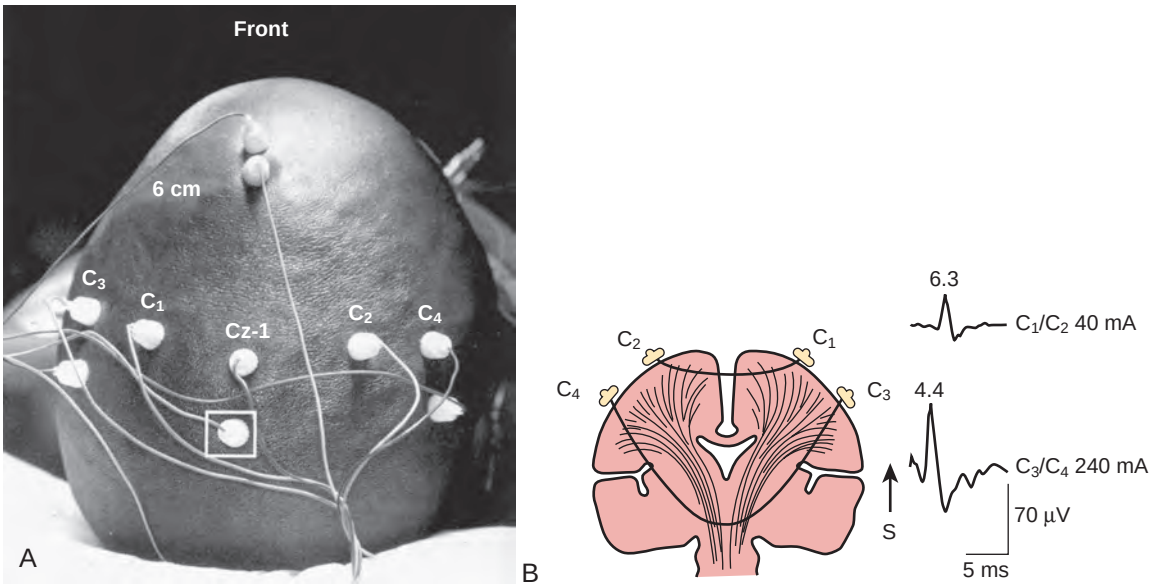

Fig. 18.17 Motor-evoked potential (MEP) transcranial stimulation. (A) Placement of transdermal electrodes for generation of MEP by transcranial electrical stimulation. (B) Transcranial electric current paths following cortical (C_1/C_2) and subcortical (C_3/C_4) stimulation. The direct MEP responses were obtained from an electrode placed adjacent to exposed upper thoracic spinal cord. Note the large 240-mA current required for subcortical stimulation and the shorter latency between the stimulus *(S)* and C_3/C_4 response because of the reduced distance between stimulating and recording electrodes. *(A and B, Modified from Deletis V, Sala F. Corticospinal tract monitoring with D- and I-waves from the spinal cord and muscle MEPs from limb muscles. sample volume), a series of echoes associated with varying velocities is created. The frequency differences between the insonation signal and each echo in the series are proportional to the associated velocity, and this velocity is determined from the Doppler equation (see Fig. 18.19). Although several large intracranial arteries may be insonated through the temporal window, the middle cerebral artery is generally monitored during cardiac operations because it carries approximately 40% of the hemispheric blood flow.

Pulsed-Wave Spectral Display

Pulsed-wave Doppler examination samples the ultrasonic echoes at a user-selected distance (ie, single gate) below the scalp. The frequency composition of these Doppler-shifted echoes is analyzed by Fourier analysis, the same technique used to quantify EEG frequency patterns (see Fig. 18.19). The analysis produces a momentary amplitude spectrum displayed as a function of blood flow velocity (eg, Doppler-shift frequency). This relationship is mapped as one vertical strip in the

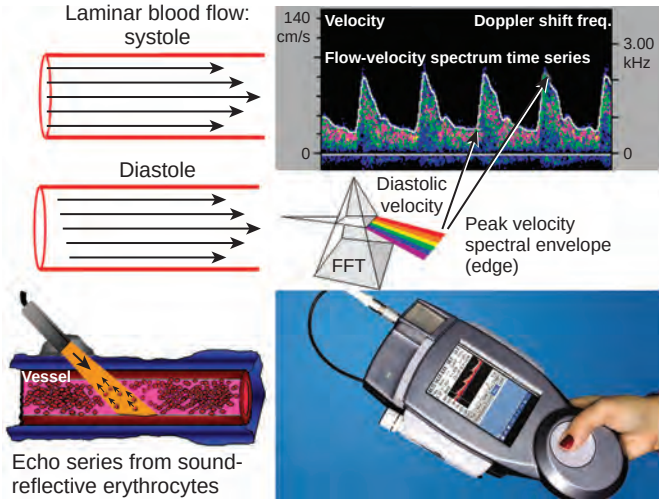

Fig. 18.19 Physiologic basis of the transcranial Doppler (TCD) ultrasound display. Large-vessel laminar flow results in a cross-sectional series of erythrocyte velocities, with the lowest values nearest the vessel wall. Ultrasonic vessel insonation produces a series of erythrocyte echoes. The frequency differences (ie, Doppler-shift frequencies) between the insonating signal and its echoes are proportional to erythrocyte velocity and flow direction. Fast Fourier transform *(FFT)* analysis of this complex echo produces an instantaneous power spectrum analogous to that used in electroencephalographic analysis. The time-series of successive Doppler-shift spectra (*upper right)* resembles an arterial pressure waveform but represents fluctuating erythrocyte velocities during each cardiac cycle. Some modern TCD sonographs are small enough to be handheld or incorporated into multimodal neurophysiologic signal analyzers. *(Image of the 500P Pocket Transcranial Doppler courtesy Multigon Industries, Inc, Yonkers, NY.)*

spectrogram display (see Fig. 18.19, upper right). Amplitude at each frequency is expressed as log change (ie, dB) from the background composed of random echoes. The momentary analysis is repeated 100 times per second to produce a scrolling spectrogram of time-related changes in flow velocity.

Signal amplitude at each frequency shift–time intersection is indicated by monochromatic dot density or color coding. The maximum velocity, the upper edge (envelope) of the velocity spectrum (analogous to the EEG SEF), represents the maximum Doppler shift (erythrocyte velocity) in the vessel center. Peak-systolic and end-diastolic velocities are derived from this spectral edge. Intensity-weighted mean velocity is calculated by weighted averaging of the intensity of all Doppler spectral signals in a vessel cross-section. Sampling echoes at multiple loci (multigating) produces spectrograms for each of the different probe-to-sample site distances (Fig. 18.20).

Power M-Mode Doppler Display

An alternative method for processing pulsed-wave Doppler echoes is nonspectral power M-mode Doppler (PMD) (Fig. 18.21). Unlike the series of spectra generated with multigating, PMD creates one image with each depth represented by a plot of signal amplitude (ie, power) and depth as functions of time. A color scale signifies flow direction (red is flow directed toward the probe; blue is flow away from the probe), whereas color intensity is directly related to signal power.

Embolus Detection

Erythrocytes (approximately 5 million/mL) are the most acoustically reflective nonpathologic blood elements (ie, have the greatest acoustic impedance). However, gaseous and particulate emboli are better reflectors of sound than are erythrocytes. The presence of high-intensity transient signals (HITS) within either the PMD or spectral TCD display may signify the presence of an embolus.[38] Because a gaseous or particulate embolus cannot simultaneously appear at all distances from the probe, either PMD or a multigated spectral display may be used to distinguish them from acoustic artifact (tapping on the ultrasonic probe produces a high-intensity transient acoustic artifact at all distances).

Fig. 18.22 illustrates the appearance of HITS in the two TCD display formats. The bottom spectral displays are generated from a small vascular segment at a distance of 50 ± 3 mm (6-mm sample volume) from the probe surface. The midpoint of the spectral sample is indicated on the top PMD displays as a light horizontal line at a 50-mm depth. An embolic track labeled "*a*" is a single embolus that is shown in the top PMD display moving toward the probe (ie, decreasing distance from the probe face over time). Embolic tracks "*b*" and "*d*" display the characteristic "lambda" acoustic signature in the spectral display. The PMD shows that this pattern reflects embolus direction reversal within the spectral sample volume. The true behavior of the spectrally paradoxical track "*c*" (start and end points of the single acoustic signature are not connected) becomes clear in the PMD view. Track "*c*" direction reversal is invisible on the spectral display because it occurs outside the sampling region. Currently available spectral or PMD TCD monitors can determine neither the size nor the composition of embolic form material responsible for HITS. TCD devices designed for surgical monitoring typically provide a semiquantitative estimate of aggregate HITS, irrespective of their origin (Box 18.5). Nevertheless, the HITS aggregate has been shown to be predictive of neurodeficit following aortic surgical procedures.[39]

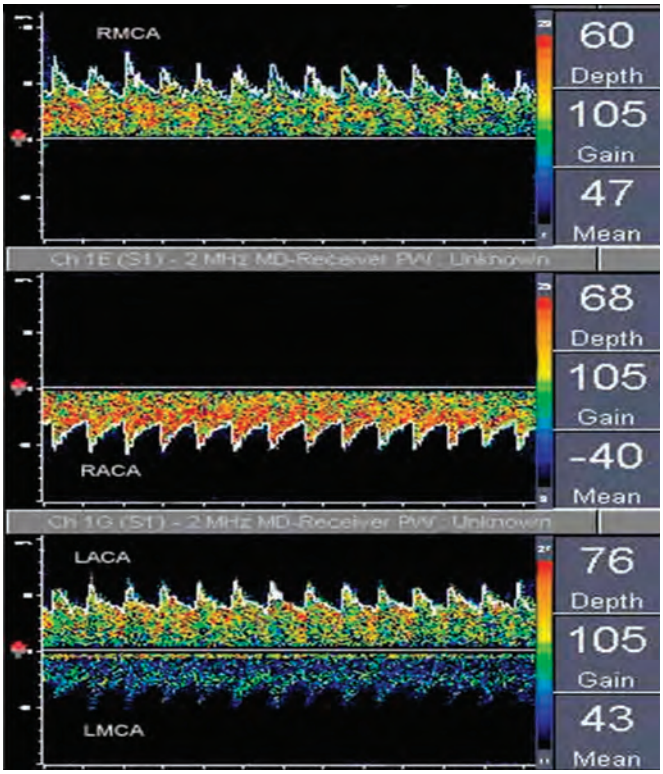

Fig. 18.20 Multigated transcranial Doppler ultrasound display. Multigating of pulsed-wave Doppler signals permits simultaneous display of echo spectra generated at several different intracranial loci. *LACA,* Left anterior cerebral artery; *LMCA,* left middle cerebral artery; *RACA,* right anterior cerebral artery; *RMCA,* right middle cerebral artery.

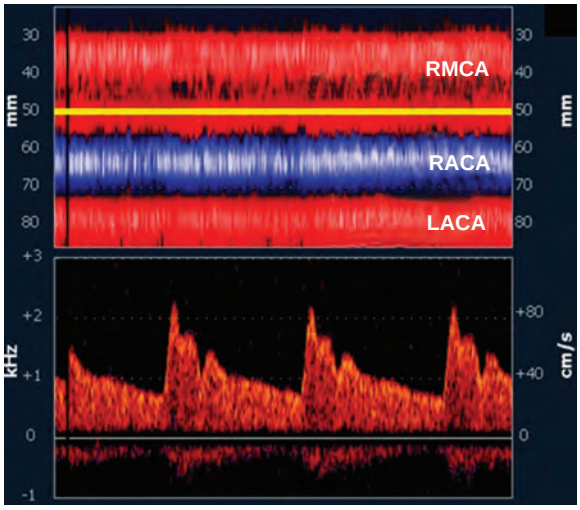
Intervention Threshold

Because erythrocyte velocity and flow may be differentially influenced by vessel diameter,[40] blood viscosity,[41] and pH,[41] as well as temperature,[41] TCD does not provide a reliable measure of cerebral blood flow. However, in the absence of hemodilution, *change* in TCD velocity does correlate closely with *change* in blood flow.[41] Sudden large changes in velocity or direction are readily detected by continuous TCD monitoring. The clinical significance of velocity changes has been assessed in conscious patients during implantable cardioverter-defibrillator and tilt-table testing.[42] In both circumstances, clinical evidence of cerebral hypoperfusion was accompanied by a mean velocity decline of greater than 60% and absent diastolic velocity. During vascular operations, the ischemia threshold appears to be an 80% decrease below the preincision baseline.[43]

In general, reduction of flow velocity indicating severe ischemia is associated with profound depression of EEG activity.[42] However, with adequate leptomeningeal collateral flow, cerebral function may remain unchanged in the presence of a severely decreased or absent middle cerebral artery flow velocity.[43] Together, these findings form the rationale for a TCD-based intervention threshold. During cardiac surgical procedures, mean velocity reductions of greater than 80% or velocity losses during diastole suggest clinically significant cerebral hypoperfusion.

BOX 18.5 TRANSCRANIAL DOPPLER ULTRASONOGRAPHY

- Detects change in intracranial blood flow
- Detects particulate or gaseous emboli



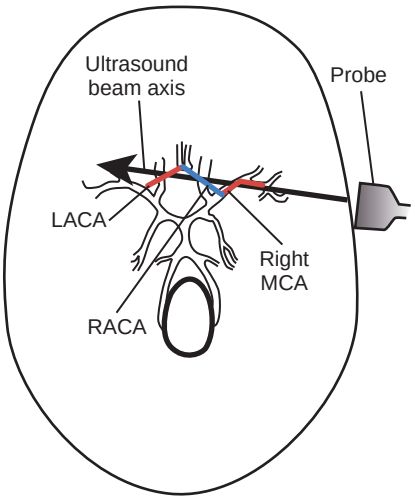


Fig. 18.21 Comparison of the transcranial Doppler (TCD) M-mode and spectral displays. The TCD continuous wave M-mode *(upper left)* and pulsed-wave spectral *(lower left)* displays are compared. The horizontal bands of the M-mode display represent a series of Doppler-shift echoes. Signals in the 30- to 50-mm depth range *(upper red band)* represent flow in the right middle cerebral artery *(right MCA)* ipsilateral to the ultrasonic probe. The *red color* signifies flow directed toward the probe *(right diagram).* Echoes arising between 55 and 70 mm from the probe emanate from the ipsilateral (right) anterior cerebral artery (RACA) are shown in the *middle blue band* of the M-mode display. Signals in the 72- to 85-mm range arise from the contralateral (left) ACA (LACA) with flow directed toward the probe *(lower red band).* The M-mode *yellow line* at a depth of 50 mm indicates the measurement site for the TCD frequency spectral display shown at the *lower left. (Courtesy Dr. Mark Moehring, Spencer Technologies, Seattle, Wash.)*

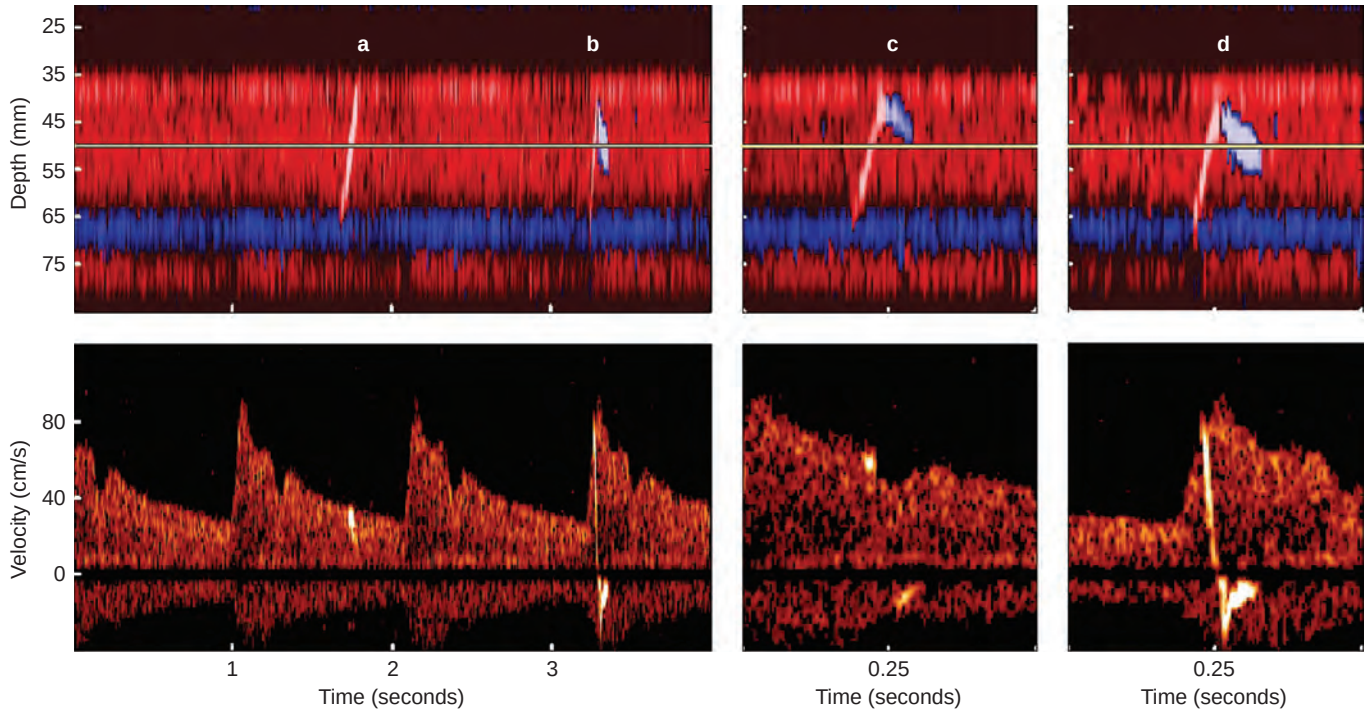

Fig. 18.22 Embolic signals detected by the transcranial Doppler M-mode and spectral displays. The appearance of emboliform high-intensity transient signals (HITS) is compared using the M-mode and frequency spectral displays. The *white horizontal line* at a depth of 50 mm depicts the site of the spectral measurement along the axis of the vessel. HITS *(white transient)* represents linear migration of an embolus in the M2 segment of the ipsilateral middle cerebral artery. HITS *(white dot)* is noted on the spectral display as the embolus passes through the 50-mm measurement site. In contrast, emboli in the remaining panels suddenly change direction as they pass into a smaller branch vessel. HITS *b* and HITS *d* direction changes are noted on the spectral displays as the characteristic "lambda" sign. However, the HITS *c* behavior is misidentified as two emboli because the direction change occurs outside the spectral sample volume. *(Courtesy Dr. Mark Moehring, Spencer Technologies, Seattle, Wash.)*

Jugular Bulb Oximetry

Oximeter catheters transmitting three wavelengths of light may be inserted into the cerebral venous circulation to measure cerebral (jugular) venous oxygen saturation ($SjvO_2$) directly and continuously. Commercially available devices are modifications of the catheter oximeter originally developed for the pulmonary circulation. External pre-insertion calibration of the catheter and documentation of catheter position in the jugular bulb are required for accurate measurements. In vivo calibrations against co-oximeter samples can also be performed. Reflected light signals are averaged, filtered, and displayed. Conditions affecting the accuracy of these measurements include catheter kinking, blood flow around the catheter, changes in hematocrit, fibrin deposition on the catheter, and changes in temperature. The normal $SjvO_2$ range is widely assumed to be between 55% and 70%.[44] However, a study using radiographically confirmed catheter placement observed a much wider 45% to 70% range in healthy subjects.[45]

This technology has two major limitations. First, $SjvO_2$ represents a global measure of venous drainage from unspecified cranial compartments. Because cerebral and extracranial venous anatomy is notoriously varied, clinical interpretation of measured change is a major challenge. The difficulty is exemplified by the study of Guo and Wong.[46] These investigators used a new magnetic resonance imaging technique called velocity-selective excitation and arterial nulling to image cerebral venous oxygen saturation quantitatively. The average saturation value obtained from the large veins (ie, $SjvO_2$) differed substantially from the checkerboard pattern of regional hemoglobin oxygen saturation (rSO_2) values representing the microcirculation. Second, accurate measurement using jugular oximetry requires continuous adequate flow past the catheter. Low-flow or no-flow states such as profound hypoperfusion or complete ischemia render $SjvO_2$ unreliable.[47] Despite these limitations, the global measure of brain oxygen balance has been used successfully (1) as a transfusion trigger,[48] (2) to document the deleterious effect of even modest cerebral hyperthermia,[49] and (3) to compare the frequency of cerebral oxygen desaturation during myocardial revascularization with and without CPB.[50]

Cerebral Oximetry

Near-Infrared Technology

Because the human skull is translucent to infrared light, intracranial intravascular rSO_2 may be measured noninvasively with transcranial near-infrared spectroscopy (NIRS) (Fig. 18.23). An infrared light source contained in a self-adhesive patch affixed to glabrous skin of the scalp transmits photons through underlying tissues to the outer layers of the cerebral cortex. Adjacent sensors separate photons reflected from the skin, muscle, skull, and dura from those of the brain tissue (Fig. 18.24). NIRS measures all hemoglobin, pulsatile and nonpulsatile, in a mixed microvascular bed composed of gas-exchanging vessels with a diameter of less than 1 mm.[51] The measurement is thought to reflect approximately 70% venous blood.[51] Cerebral oximetry appears both to quantify change reliably from an individualized baseline and to offer an objective measure of regional hypoperfusion.[52] Unlike pulse and jugular bulb oximetry, cerebral oximetry may be used during nonpulsatile CPB and circulatory arrest.

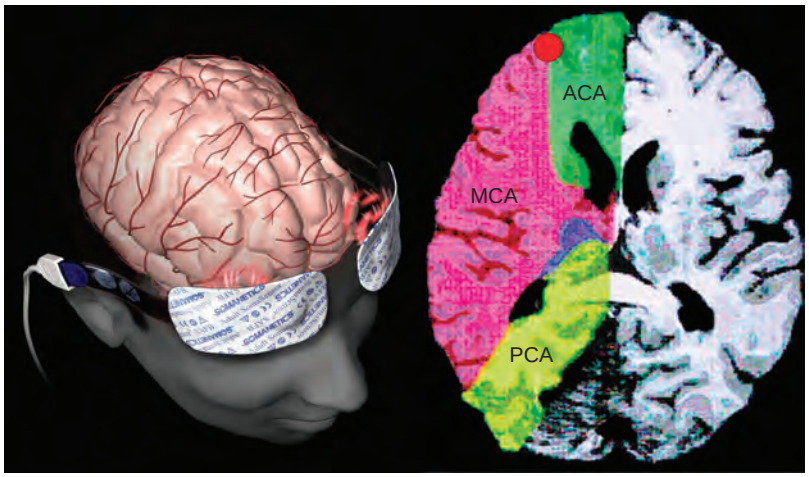

Fig. 18.23 Cerebral oximetry monitors the anterior arterial watershed region. The frontal cortex anterior cerebral artery (ACA) and middle cerebral artery (MCA) watershed region may be sampled bilaterally by cerebral oximeter sensors located on the forehead above each eye. The diagram at the *right* illustrates the anterior *(green)* and middle cerebral artery *(pink)* flow-distributions and the approximate size and location of the oximetric sampling region *(red dot). PCA,* Posterior cerebral artery. *(Courtesy Covidien, Boulder, Colo.)*

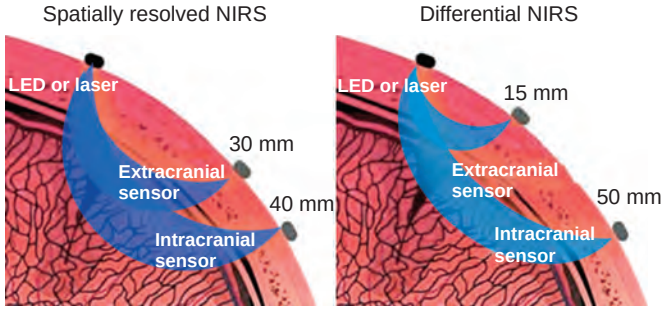

Fig. 18.24 Comparison of transcranial spatially resolved near-infrared spectroscopy *(spatially resolved NIRS)* and differential NIRS. Unabsorbed photons travel a parabolic (ie, banana-shaped) path through the adult cranium from scalp-mounted infrared sources to nearby sensors. The average penetration depth of these reflected photons is given by the square root of the source-detector separation. Spatially resolved NIRS uses a pair of sensors located at sufficient distances from the light source to ensure that both signals detect photons reflected from extracranial and intracranial tissue (*left panel*). Two-point extracranial and intracranial measurement permits partial suppression of both the extracranial signal and the interpatient variance in intracranial photon scatter. The resultant cerebral oxygen saturation measurement appears to be approximately 65% intracranial.[50a] In contrast, differential NIRS uses a sensor placed very near the light source to record exclusively extracranial signal and another more distant sensor for extracranial and intracranial measurement *(right panel)*. Single-point subtraction suppresses much of the extracranial signal, but not the intersubject variation in intracranial photon scatter. Mitigation of this confounding influence is attempted through the use of additional infrared wavelengths.[77] The proportion of the differential regional hemoglobin oxygen saturation signal that represents intracranial tissue has not been established. *LED,* Light-emitting diode. *(Spatially resolved NIRS diagram courtesy Covidien, Boulder, Colo.)*

Similar to TCD monitoring, cerebral oximetry is primarily used to quantify change because the substantial NIRS intersubject baseline variability makes it difficult to establish a reliable threshold value signifying tissue injury.[53] An adverse shift in oxygen supply-demand balance is indicated by a decreasing oxyhemoglobin fraction. The clinical significance of the decline has been demonstrated in conscious subjects and patients during G-force studies with high-speed centrifugation,[54] implantable cardioverter-defibrillator testing,[42] tilt-table testing,[42] carotid artery occlusion,[55] and intracranial artery balloon occlusion.[56] In each setting, a decline of greater than 20% was associated with syncope or signs of focal cerebral ischemia. During adult[52,57] and pediatric[58,59] cardiac surgical procedures, the magnitude and duration of cerebral dysoxygenation are associated with hospital cost-driver increase as well as the incidence and severity of adverse clinical outcomes.

The first commercial device to receive FDA clearance for measurement of rSO_2 was the single-channel INVOS 3100 cerebral oximeter (Somanetics Corporation, Troy, Mich). The latest model, 5100C (Covidien, Boulder, Colo), is a four-channel device that is approved for monitoring of cerebral and somatic tissue oxygenation in patients larger than 2.5 kg. Measurement is achieved with self-adhesive patches (ie, optodes), each of which contains a light-emitting diode (LED) infrared light source and two infrared sensors. Because unabsorbed photons are known to traverse a parabolic course through chromophore-containing media, light source-sensor separations of 30 mm or more ensure that both signals represent extracranial and intracranial tissue.[51] Two wavelengths of infrared light are sufficient to determine oxygen saturation, the oxyhemoglobin fraction of total hemoglobin.[51] The process of spatial resolution uses the sensor signal ratio to suppress influences of extracranial hemoglobin absorption and intersubject variation in intracranial photon scatter.[51] The resultant rSO_2 metric is approximately 65% intracranial[60] (see Fig. 18.24, left panel).

Three other cerebral oximeters also have received FDA clearance. Like INVOS, the CAS Medical (Branford, Conn) Fore-Sight also uses an optode containing an LED light source and two infrared sensors.[61] A small, 15-mm light source-proximal sensor separation is used to detect extracranial photon migration exclusively, whereas a larger, 50-mm distal separation measures photons arising from both extracranial and intracranial tissues (see Fig. 18.24, right panel). Cerebral saturation is determined from the proximal-distal differential signal. Although this approach appears to suppress extracranial contamination, the single-point intracranial measurement may be influenced by individual variations in intracranial photon scatter. Additional wavelengths of infrared light are used in an attempt to mitigate the influence of photon scatter variations on the rSO_2 measurement.[62]

Nonin (Minneapolis, Minn) manufacturers the EquanOX 7600 cerebral oximeter. This device relies on dual LED light sources and four wavelengths of infrared light.[63] The rSO_2 value appears to represent the average of two neighboring extracranial versus intracranial differential measurements.[64] Reports are now available that describe its performance in a variety of clinical applications including cardiac operations.[65]

The Ornim Medical (Foxborough, Mass) CerOx measures microcirculatory rSO_2 and blood flow in brain or peripheral tissue by using a combination of multiple-wavelength near-infrared light and pulsed ultrasound.[66] The technology has unique theoretic advantages in that the ultrasound produces vibration of the red cells, and this vibration is transmitted to the optical signal when the light interacts with the erythrocytes (opticoacoustic coupling). Gating the optical signal to only the portion recovered after a specific time delay following an ultrasound pulse allows for determination of the tissue depth at which the optical signal originated. Relative blood flow can also be determined by this device. Device performance in monitoring patients with traumatic brain injury has been described,[67] but the technology is too new to be adequately evaluated in the cardiac surgical population.

The clinical performance of cerebral oximetry systems appears to be device specific.[53] Supporting evidence for one device does not necessarily apply to competing products. Objective comparison of these devices remains difficult because of the lack of a universally accepted direct reference standard measure of regional brain microcirculatory oxygen saturation.[51]

Technologic Limitations

The technical limitations of cerebral oximetry primarily involve factors influencing photon migration. Cranial and perispinal sensor placement is currently limited to glabrous skin because hair may compromise the measurement as a result of environmental light piping. Convenient forehead placement prevents monitoring the critical posterior watershed at the juncture of the anterior, middle, and posterior cerebral arteries (see Fig. 18.23). Mutoh and colleagues[68] overcame this limitation with a parietotemporal optode placement in head-shaved neurosurgical patients to monitor vasospasm treatment successfully. Weak signals may also result from hematoma or sensor placement over a venous sinus.[69] In either case, the large hemoglobin volume acts as a photon sink. Conversely, recording failures may arise from excessively large signals, such as those produced by a skull defect.[70] Issues can also occur when the optode is placed over a sinus because transmission through (or around) an air-filled sinus is quite different from transmission through aqueous or bony tissue.

Very significant differences exist between pediatric and adult cranial anatomy, and they dramatically favor the transmission of optical signal in the pediatric population. As a result, extrapolation of conclusions from studies in the pediatric population to adults should be undertaken with great care.

Validation

The rSO_2 value has been validated from arterial and jugular bulb oxygen saturation measurements in adults and children.[71,72] Hypoxemia involving cerebral tissue proximate to the cranial optodes was consistently detected. Except during ischemia and CPB, $SjvO_2$ and rSO_2 generally correlate in the midrange saturation, although discrepancies may appear at the extremes.[73] The validity of rSO_2 also has been assessed by comparison with direct microprobe measurement of brain tissue oxygen partial pressure. The two measures appear to be directly and significantly related; however, the invasive monitoring of tissue oxygenation would be appropriate in few cardiac surgical situations.[74]

Normative Values

Kishi and associates[75] examined surgical patients' demographic influences on rSO_2. The measure appeared to be independent of weight, height, head size, or sex, although it was negatively correlated with age and positively correlated with hemoglobin concentration. Values were also affected as the sensor was moved laterally from the recommended position above the eye. The normative INVOS rSO_2 value of 71 ± 6% reported for healthy adults[71] is significantly higher than that obtained from cardiac surgical patients.[76] An even larger difference is observed between healthy infants[77] and infants with congenital heart disease.[59] Because of the previously discussed technical differences among competing oximeters, clinicians should appreciate that *rSO_2 normative values are device dependent and not interchangeable.*[78]

Multimodality Neuromonitoring

Because each monitoring modality may evaluate only a portion of the CNS, multimodal monitoring would appear to be desirable to monitor neurologic wellness more completely (Table 18.4). The variety of techniques for neuromonitoring and the plethora of display formats provide visually confusing information for the anesthesiologist trying to understand the data in the context of the anesthetic regimen and the surgical procedure. The anesthesia record is fundamentally a time-based record (time on the y-axis), having a display rate of several hours per page. Cerebral oximetry and BIS are (potentially) displayed similarly, whereas a raw electroencephalogram has a horizontal time base but a display rate of only seconds per page. Processed electroencephalograms, TCD ultrasound findings, and evoked potentials are commonly displayed with time on the y-axis, but to emphasize symmetry (or asymmetry), processed electroencephalogram and TCD ultrasound findings are commonly displayed with the frequency axes in opposite directions for data from left and right hemispheres. Considerable improvement is needed in ergonomics or the development of alternative display technologies for effective and facile intraoperative use by the cardiac anesthesiologist.

General Procedural Considerations

The list of possible neurologic injuries during cardiac operations is long, and many injuries can be detected by more than one monitoring modality. Because the actual incidence of these injuries is generally low, it is common for studies of surrogate events to provide efficacy data in support of the use of commercial monitoring equipment. For example, changes in regional oxygen saturation are commonly used as a surrogate for cerebral ischemia in assessing the functionality of NIRS systems. Unfortunately, the use of such surrogates overestimates the potential value of these devices, especially when they lack tight physiologic thresholds.

Surgery on the Aorta

Repair or replacement of the ascending and transverse aorta to treat aneurysms and dissections has become more common in recent years.

TABLE 18.4 Multimodality Neuromonitoring for Cardiac Surgical Procedures

Modality	*Function*
Electroencephalography	Cortical synaptic activity
Brainstem auditory-evoked potentials	Cochlear, auditory nerve, and brainstem auditory pathway function
Middle latency auditory-evoked potentials	Subcortical-cortical afferent auditory pathway function
Somatosensory-evoked potentials	Peripheral nerve, spinal cord, and brain somatosensory afferent pathway function
Transcranial motor-evoked potentials	Cortical, subcortical, spinal cord, and peripheral nerve efferent motor pathway function
Transcranial Doppler ultrasonography	Cerebral blood flow change and emboli detection
Tissue oximetry	Regional tissue oxygen balance

Because the operation invariably involves modification of the normal cerebral perfusion up to and including circulatory arrest, the use of various modalities to monitor the CNS is common. The particular modality may vary depending on surgical approach and clinical preference (see Chapter 23).

Circulatory Arrest

When the planned technique includes circulatory arrest, with or without retrograde cerebral perfusion, the first imperative is to ensure that the brain is adequately cooled to withstand the necessary period of cerebral ischemia. Optimal protection of cerebral cortical tissue by cooling occurs when electrical silence has occurred on the electroencephalogram because more than 60% of the brain's metabolic effort is expended in the generation of electrical signals. Cooling slows the electroencephalogram in a dose-dependent fashion (Fig. 18.25),[79] with recovery following a similar pattern but not necessarily following the same curve or returning completely to baseline. The actual temperature at which electrical silence occurs can vary from 11 to 18°C,[80] and therefore reliance on temperature alone may prolong cooling (and therefore rewarming and bypass) unnecessarily.

The BIS monitor is not a particularly useful tool in establishing electrical silence. This discordance occurs because the intrinsic algorithm considers EEG activity to be suppressed when the amplitude is less than 5 μV,[81] whereas voltages lower than 2 μV are generally considered isoelectric.[80]

Cooling prolongs SSEP peak and interpeak latencies and suppresses amplitude of the cortical response predominantly (see Fig. 18.15B). Consequently, SSEP responses can also be used to assess cooling.[82] However, because subcortical SSEP responses involve far fewer synapses than the electroencephalogram, these responses often persist when cortical neuronal activity is totally cold suppressed. Thus detection of cerebral ischemia by SSEPs can be achieved during EEG quiescence (Fig. 18.26). Because clinical results with EEG guidance of cooling are quite good,[80] it is not clear that SSEP monitoring offers any advantage.

A subset of patients undergoing circulatory arrest has aortic dissections, and in this population, evidence indicates that TCD monitoring may be beneficial. One prospective investigation demonstrated that TCD monitoring during acute aortic dissection repair reduced the incidence of transient neurologic deficit from 52% to 15%, although no significant change was observed in the incidence of stroke or in-hospital or 30-day mortality rates. This reduction was achieved in part through TCD-directed changes in perfusion cannula placement and adjustments in the management of retrograde cerebral perfusion,[83] and it may be related to specifics of surgical techniques used in this particular observational single-institution study.

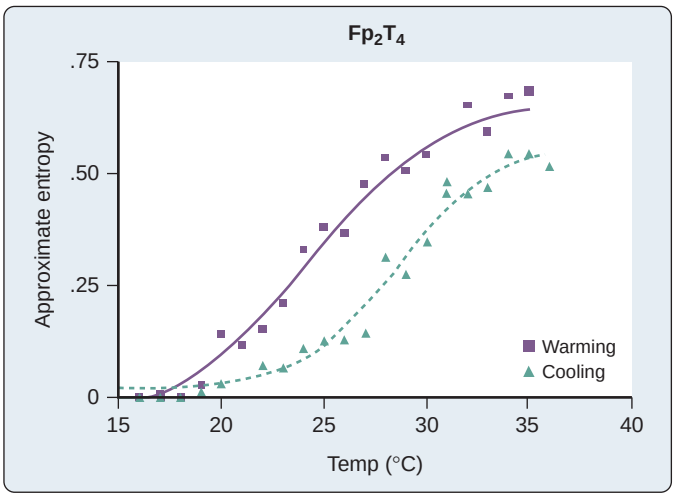

Fig. 18.25 Cooling and rewarming in circulatory arrest. The approximate entropy was calculated from a single channel of the electroencephalogram during cooling to 18°C for circulatory arrest and subsequent rewarming. The delay in the resumption of electroencephalographic activity as a function of nasal temperature is clearly evident. *(From Levy WJ, Pantin E, Mehta S, et al. Hypothermia and the approximate entropy of the electroencephalogram.* Anesthesiology. *2003;98:53–57, with permission of the publisher.)*

Antegrade Cerebral Perfusion

Management of aortic surgical procedures using antegrade cerebral perfusion through the right subclavian artery typically involves only moderate hypothermia. However, the potential for cerebral ischemia secondary to an incomplete circle of Willis emphasizes the need for the early detection of ischemia with some form of neuromonitoring. The circle of Willis is completely normal in only a small fraction (25%) of patients, although many of the anomalies consist of hypoplasia (not absence) of a single segment and may not predispose patients to ischemia. Papantchev and colleagues[84] examined circle of Willis variations in cadavers and found that 42.4% of specimens exhibited variations that could lead to hemodynamically significant alteration in flow during unilateral selective cerebral perfusion. Theoretic arguments favor a multichannel EEG montage because the region of malperfusion cannot be predicted with certainty. In practice, TCD, NIRS, and BIS all appear capable of demonstrating asymmetry in the presence of such malperfusion should it occur in the region monitored. The acute occurrence of asymmetry in any monitored modality coincident with initiation of perfusion through the right subclavian artery would suggest a need to change surgical technique. Clearly, NIRS and BIS have benefits in ease of use compared with both multichannel EEG and TCD techniques. Numerous case reports and case series have identified such rSO_2 assymetry.[85–89] Comparative studies to demonstrate a practical value of the more complex monitoring techniques remain to be done and may be impossible because of the need for a large sample size.

The use of only moderate hypothermia with antegrade cerebral perfusion potentially predisposes patients to another neurologic complication: spinal cord ischemia. Because the brain is perfused but the body is not, a theoretic concern exists about the integrity of the spinal neurons that could justify SSEP monitoring. Clinical reports of spinal cord complications following aortic repair using antegrade cerebral perfusion are infrequent, a finding suggesting that this complication is more theoretic than real. Minatoya and associates[90] compared three groups of patients (N = 229) who underwent aortic arch operations using bilateral selective cerebral perfusion and circulatory arrest temperatures of 20°, 25°, and 28°C, respectively. Stroke and TND rates were not significantly different in the three groups, and no postoperative paraplegia occurred in any group.

Descending Aorta Surgery

Surgical procedures on the descending thoracic aorta may involve partial (left atrial-to-left femoral) bypass, complete circulatory arrest, or entirely endovascular techniques. If circulatory arrest is used because proximal cross-clamping is not possible, the issues already discussed regarding circulatory arrest remain considerations. In addition, and regardless of the management of bypass, operations on the descending aorta imposes significant risk of spinal cord ischemia and warrant consideration of neurologic monitoring for early diagnosis and treatment. Three modalities have the potential to provide this information—SSEPs, MEPs, and tissue oxygenation, although the last is currently viewed as highly experimental. As described earlier, SSEP monitoring documents sensory function through the peripheral nerves and posterior columns of the spinal cord, whereas MEP monitoring documents motor function through the structures of the anterior spinal cord. Anatomic considerations of the vascular supply to the spinal cord suggest that the anterior structures, perfused by radicular arteries from the aorta, are at greater risk than are the posterior columns, whose perfusion is derived as an extension of the vertebral artery. These considerations would suggest that MEP monitoring would be the preferred technology. However, in the period when the

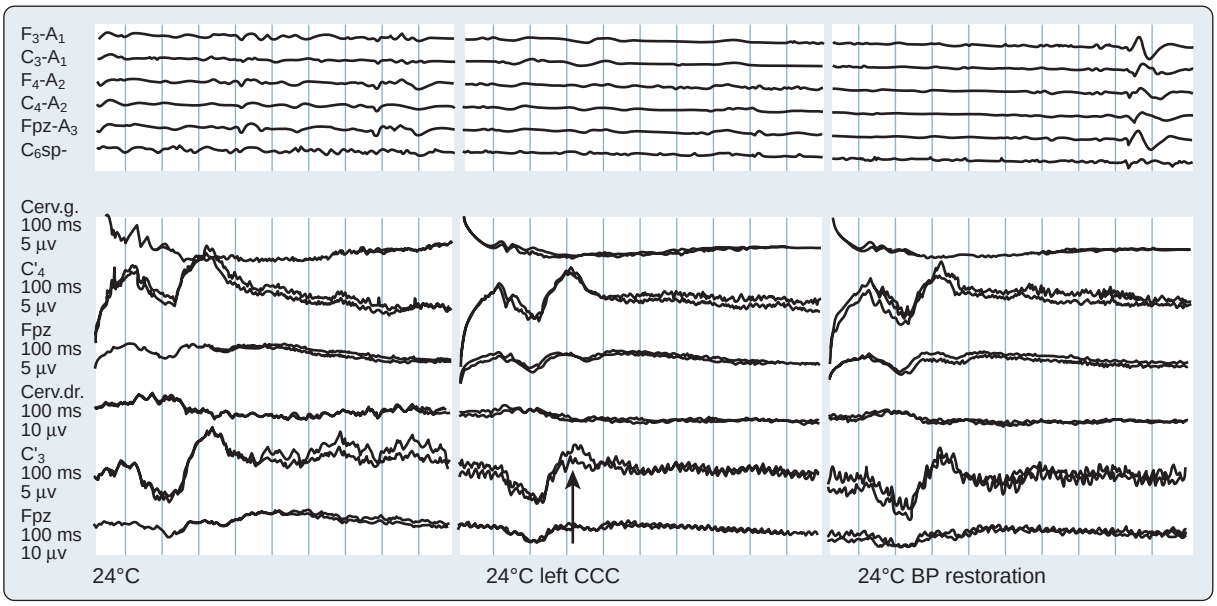

Fig. 18.26 Comparison of electroencephalographic (EEG) and somatosensory-evoked potential (SSEP) changes to regional cerebral hypoperfusion. The upper traces represent bihemispheric cold-suppressed EEG activity derived from scalp (Fpz, F_3, F_4, C_3, and C_4), cervical spine (C_6sp), and earlobe (A_1, A_2, and linked A_3) recorded at 24°C. The lower traces represent contemporaneous bihemispheric upper limb SSEP responses. The *arrow* points to left hemispheric N_{20} suppression accompanying left common carotid artery clamping *(CCC)*. Blood pressure *(BP)* increase restored the N_{20} amplitude. This regional cerebral hypoperfusion was not apparent in the hypothermia-suppressed EEG recording. *Cerv.dr.,* Cervical droite (right median nerve stimulation); *Cerv.g.,* cervical gauche (left median nerve stimulation). *(Modified from Guérit JM. Intraoperative monitoring during cardiac surgery. In: Nuwer MR, ed.* Handbook of Clinical Neurophysiology. *Vol. 8.* Intraoperative Monitoring of Neural Function. *New York: Elsevier; 2008:835.)*

technology to monitor MEPs did not exist, SSEP monitoring was used to identify spinal cord ischemia and guide therapy. Studies using this approach have shown significant association between permanent loss of SSEPs and poor outcome.[91] Comparative studies of MEP and SSEP monitoring have shown very high predictive values for ischemia if the changes are permanent. If the change is transient, SSEPs have a lower incidence of false-positive predictions of neurologic injury than MEPs, thus further suggesting that SSEPs are as useful as MEPs. Other studies support the use of MEPs preferentially to guide sacrifice or reimplantation of intercostal arteries.[92] An added advantage of SSEP monitoring is its relative resistance to potent agents and muscle relaxants, thereby allowing intraoperative use. By comparison, exclusion of these common techniques greatly complicates the anesthetic management of patients when MEP monitoring is planned.

A custom-built NIRS optode and an indocyanine green tracer technique were used to validate translaminar perispinal oxygen saturation (SsO_2). The neuromonitoring technique demonstrated both local blood flow autoregulation and carbon dioxide reactivity.[93] SsO_2 monitoring has been achieved by placing optodes designed for adult transcranial tissue oximetry over the lower thoracic and upper lumbar spine. Case reports and series involving both open and endovascular techniques have suggested possible roles for optical technologies.[94–97] Conversely, these approaches have no possibility of distinguishing anterior from posterior spinal cord ischemia, and the experience with them is too limited to define thresholds for therapeutic intervention or to recommend such an "off-label" application.

Routine Coronary Artery Bypass Graft and Valve Procedures

For purposes of discussing the application of neuromonitoring in routine CPB procedures, a distinction must be made between techniques that can be managed by the anesthesiologist without technical assistance and those that require the presence and assistance of at least a neuromonitoring technician, if not a neurologist or neurophysiologist, skilled in the interpretation of intraoperative changes. Processed electroencephalography and NIRS fall into the former group, whereas multichannel electroencephalograms, evoked potentials, and TCD ultrasound would generally fall into the latter category. These latter choices, because of their increased cost and complexity, must demonstrate clear superiority in patient-related outcomes; in general, such data are lacking. For NIRS and processed electroencephalography, however, technical issues pose no significant constraint, and the costs are modest, potentially leading to a more favorable balance.

NIRS monitoring has been the most thoroughly studied of the neuromonitoring techniques in recent years. The profusion of interest comes both from the (apparent) simplicity of the device and the stimulus of commercial enterprises to justify their use. As mentioned earlier, different devices use different proprietary techniques to extract the signal, and they may result in different values of rSO_2 under identical clinical conditions. This renders the determination of the threshold for treatment somewhat arbitrary and results in the assessment of value on the basis of improvement in surrogate measures (eg, improvement in rSO_2) and not on the prevention of complications. A detailed cardiac surgical intervention algorithm based on this criterion was proposed by Deschamps and colleagues.[98] The value of such an approach remains to be demonstrated by prospective randomized studies.

Carotid Endarterectomy in Combination With Coronary Artery Bypass Graft and Valve Procedures

Patients undergoing combined CEA and CABG or valve operations comprise another group warranting discussion (see Chapter 24). Unfortunately, data regarding monitoring in this specific population

is not extensive. The largest review of the published literature of combined CEA and CABG did not even consider the use or type of neurophysiologic monitoring in its comparison of combined surgical approaches.[99] Even in the literature describing cases of CEA only, robust data are in short supply. A Cochrane review found only 6 randomized or quasirandomized trials including only 1270 patients comparing routine with selective shunting, and the decision to shunt was determined using a variety of neuromonitoring modalities.[100] No outcome preference was demonstrated, and no particular form of neuromonitoring could be recommended. A similar result was found in a retrospective analysis using data from the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database.[101]

If robust data supporting selective shunting are not available, it is hardly surprising that such data in support of a particular form of neurologic monitoring are even more limited. Comparisons have been published for the following: cerebral oximetry and BIS[102]; SSEPs, MEPs, and electroencephalography[103]; cerebral oximetry and 16-channel electroencephalography[104]; and cerebral oximetry and TCD ultrasound.[105] An extensive review of the literature for comparisons of cerebral oximetry and other modalities (TCD, electroencephalography, stump pressure, and SSEPs) suggested value for cerebral oximetry but could not even define what the thresholds for intervention should be.[106] Studies evaluating BIS in patients undergoing awake CEA also support[107,108] and refute[109] the usefulness of BIS monitoring during CEA. Despite the general acceptance of multichannel electroencephalography as the gold standard of monitoring for CEA, the body of evidence would suggest that any neuromonitoring technique, properly applied, can be justified.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is becoming more common for the support of patients with failing cardiac or pulmonary function (see Chapter 33). The magnitude of the support can encompass complete bypass of the native cardiopulmonary function; however, some cardiac ejection commonly occurs even though ECMO flows are providing essentially all systemic needs. This small cardiac output consists of blood that has gone through the lungs and may be inadequately oxygenated if the patient has respiratory failure. This blood preferentially perfuses the innominate artery, and thus the right side of the brain may be receiving hypoxic blood even though arterial blood gas measurements (obtained from an indwelling catheter in the groin or left radial artery) appear normal. Although application of pulse oximeters to fingers of both hands may detect such right-sided desaturation, the pulse waveform during ECMO is often inadequate for detection of the saturation by pulse oximetry. Cerebral oximetry is well suited for assessing the development of unilateral desaturation in these patients who may need to be monitored continuously for days or weeks.

Depth of Anesthesia

For assessment of anesthetic depth, BIS or other processed EEG methods are the most commonly used technologies. These hypnotic indices appear to provide clinically useful information. However, their *fundamental differences may result in monitor-specific performance, so agreement among these measures during surgical procedures should not be expected.* Consequently, it may be inappropriate to apply clinical outcome evidence obtained with one proprietary index to competing indices.[110–115] Reported rates of intraoperative awareness during cardiac operations range from 0.2% to 2%, a 10-fold increase in risk compared with the general surgical population.[116–119] Three randomized clinical trials of the impact of BIS monitoring on awareness included a relatively large number of patients undergoing cardiac surgical procedures (27%, 49%, and 36%) or lung transplantation, or both.[116,118,119] Based on data, the American Society of Anesthesiologists Practice Advisory on Awareness and Brain Monitoring made the recommendation that the decision to use a brain monitor, including a BIS monitor, should be made on case-by-case basis and should not be considered standard of care.[120]

Summary

Cardiac surgical procedures vary significantly in their associated risk of neurologic injury, the portion of the nervous system at risk, and the options for treatment if injury is identified. Aggressive treatment of clinically insignificant or ambiguous changes may carry unrecognized risks that effectively counter the expected benefit of treatment. An understanding of the methodologies, the underlying physiology, and the therapeutic options is necessary for appropriate application of these technologies during cardiac surgical procedures.

Disclosure and Acknowledgment

Dr. Edmonds is a member of the speakers' bureau for Covidien. Drs. Gordon and Levy have no disclosures to report. Dr. Edmonds is grateful for the editorial assistance of his wife, Jeanne.

Coagulation Monitoring

LINDA SHORE-LESSERSON, MD | LIZA J. ENRIQUEZ, MD | NATHAEN WEITZEL, MD

KEY POINTS

1. Monitoring the effect of heparin is done using the activated coagulation time (ACT), a functional test of heparin anticoagulation. The ACT is susceptible to prolongation because of hypothermia and hemodilution and to reduction because of platelet activation or thrombocytopathy.
2. Heparin resistance can be congenital or acquired. Pretreatment heparin exposure predisposes a patient to altered heparin responsiveness because of antithrombin III depletion, platelet activation, or activation of extrinsic coagulation.
3. Heparin-induced thrombocytopenia is a prothrombotic disorder caused by an abnormal immunologic response to the heparin–platelet factor 4 complex and is sometimes associated with overt thrombosis.
4. Protamine neutralization of heparin can be associated with "protamine reactions," which include vasodilatory hypotension, anaphylactoid reactions, and pulmonary hypertensive crises (types 1, 2, and 3, respectively).
5. Before considering a transfusion of plasma, it is important to document that the effect of heparin has been neutralized. This can be done using a heparinase-neutralized test or a protamine-neutralized test.
6. Point-of-care tests are available for use in transfusion algorithms that can measure coagulation factor activity (normalized ratio, activated partial thromboplastin time) and platelet function.
7. Fibrinolysis is common after cardiopulmonary bypass when antifibrinolytic therapy is not used.
8. Newer thrombin inhibitor drugs are available for anticoagulation in patients who cannot receive heparin. These can be monitored using the ecarin clotting time or a modified ACT. Bivalirudin and hirudin are the two direct thrombin inhibitors that have been used most often in cardiac surgical procedures.
9. Platelet dysfunction is the most common reason for bleeding after cardiopulmonary bypass. Point-of-care tests can be used to measure specific aspects of platelet function.
10. The degree of platelet inhibition as measured by standard or point-of-care instruments has been shown to correlate with decreased ischemic outcomes after coronary intervention. However, cardiac surgical patients who are receiving antiplatelet medication are at increased risk for postoperative bleeding.

Cardiac surgery is an area in which coagulation monitoring has vital applications. Cardiopulmonary bypass (CPB) procedures could not be performed without an effective method of preventing blood from clotting in the extracorporeal circuit. In the early part of the 20th century, heparin was discovered to have anticoagulant properties; it remains the anticoagulant most commonly used during CPB. Reversal of heparin effect is most frequently performed using protamine, although several different pharmacologic agents and reversal techniques can be used.

CPB itself induces a "whole-body inflammatory response" because of contact of blood and cellular elements with the extracorporeal circuit. The resultant alterations include leukocyte activation, release of inflammatory mediators, free radical formation, complement activation, kallikrein release, platelet activation, and stimulation of the coagulation and fibrinolytic cascades. This complex interplay of systems induces coagulopathy characterized by microvascular coagulation, platelet dysfunction, and enhanced fibrinolysis.[1,2] The hemostatic perturbations incurred during CPB are major causes of the postbypass coagulopathy that is seen even after the effects of heparin are reversed with protamine.

The need to monitor anticoagulation during and after surgical procedures is the reason that the cardiac surgical setting has evolved into a major area for the evaluation and use of hemostasis monitors. The rapid and accurate identification of abnormal hemostasis has been the major impetus toward the development of point-of-care (POC) tests that can be performed at the bedside or in the operating room. The detection and treatment of specific coagulation disorders in a timely and cost-efficient manner are major goals in hemostasis monitoring for the cardiac surgical patient. This chapter discusses the mechanisms of normal coagulation and how they are affected by CPB. It then discusses the laboratory and POC tests available for monitoring the coagulation system. A comprehensive overview of hemostasis, transfusion medicine, and the management of coagulopathy and bleeding disorders after CPB is provided in Chapters 34 and 35.

Hemostasis

Hemostasis is the body's normal response to vascular injury, and it involves a complex interplay of systems within the body that helps to

seal the endovascular defect and prevent exsanguination. The three major components of hemostasis are as follows: (1) the vascular endothelium; (2) the platelets, which constitute primary hemostasis; and (3) the coagulation cascade glycoproteins, which constitute secondary hemostasis. Fibrinolysis, the normal physiologic response to clot formation, ensures that coagulation remains localized to the area of vascular injury (see Chapter 35).

Anticoagulation for Cardiopulmonary Bypass

CPB could not be accomplished safely without anticoagulation of blood in preparation for its contact with the extracorporeal circuit. An ideal anticoagulant agent should be easy to administer, rapid in onset, titratable, predictable, measurable in a timely fashion, and reversible. Heparin use during CPB has continued until the present time, most likely because of the drug's rapid onset, ease of measurement, and ease of reversibility.

Heparin acts as an antithrombin III (AT III) agonist and accelerates AT III binding to thrombin.[3–5] In the absence of AT III, heparin is clinically ineffective as an anticoagulant agent; adequate AT III activity is necessary in patients about to undergo heparinization for cardiac surgical procedures.[6–9]

Monitoring Heparin Effect

Cardiac surgical procedures had been performed for decades with empiric heparin dosing in the form of a bolus and subsequent interval dosing. Empiric dosing continued because of the lack of an easily applicable bedside test to monitor the anticoagulant effects of heparin. However, many assays are currently available to measure the response to the heparin dose given to institute extracorporeal circulation. These assays are functional tests of anticoagulation or quantitative measures of the level of circulating heparin.

The first clotting time used to measure heparin effect was the whole-blood clotting time (WBCT) or the Lee-White WBCT.[10] This test simply requires whole blood to be placed in a glass tube, maintained at 37°C, and manually tilted until blood fluidity is no longer detected. This test fell out of favor for monitoring cardiac surgical patients because it was so labor intensive and required the undivided attention of the person performing the test for up to 30 minutes. Although the glass surface of the test tube acts as an activator of factor XII, the heparin doses used for cardiac surgical procedures prolong the WBCT to such a profound degree that the test is impractical as a monitor of the effect of heparin during cardiac operations.[11] To speed the clotting time so that the test was appropriate for clinical use, activators were added to the test tubes, and the activated coagulation time (ACT) was introduced into practice.[12]

Activated Coagulation Time

The ACT was first introduced by Hattersley in 1966 and is still the most widely used monitor of heparin effect during cardiac surgical procedures.[13] Whole blood is added to a test tube containing an activator, either diatomaceous earth (celite) or kaolin. The presence of activator augments the contact activation phase of coagulation, which stimulates the intrinsic coagulation pathway. The ACT can be performed manually, whereby the operator measures the time interval from when blood is injected into the test tube to when clot is seen along the sides of the tube. More commonly, the ACT is automated, as it is in the Hemochron (International Technidyne Corp., Edison, NJ) and ACT Plus (Medtronic Perfusion Services, Minneapolis, MN) systems. In the automated systems, the test tube is placed in a device that warms the sample to 37°C. The Hemochron device rotates the test tube, which contains celite activator and a small iron cylinder, to which 2 mL of whole blood is added. Before clot forms, the cylinder rolls along the bottom of the rotating test tube. When clot forms, the cylinder is pulled away from a magnetic detector, interrupts a magnetic field, and signals the end of the clotting time. Normal ACT values range from 80 to 120 seconds. The Hemochron ACT also can be performed using kaolin as the activator in a similar manner (Fig. 19.1).

Fig. 19.1 The Hemochron Response (Accriva Diagnostics/International Technidyne Corp., Edison, NJ) is a dual-chamber point-of-care coagulation monitor that can measure clotting times that are compatible with Hemochron technology. This system has software capability for calculation, data management, and storage of results. *(Courtesy International Technidyne, Edison, NJ.)*

The ACT Plus (formerly Hemotec ACT) device is a cartridge with two chambers that contain kaolin activator and is housed in a heat block. Blood (0.4 mL) is placed into each chamber, and a daisy-shaped plunger is raised and passively falls into the chamber. The formation of clot slows the rate of descent of the plunger. This decrease in velocity of the plunger is detected by a photo-optical system that signals the end of the ACT test. The Hemochron and Hemotec ACT tests have been compared in several investigations and have been found to differ significantly at low heparin concentrations.[14] However, differences in heparin concentration, activator concentration, and the measurement technique make comparison of these tests difficult and have led to the realization that the results of the Hemochron and Hemotec ACT tests are not interchangeable. In adult patients given 300 IU/kg of heparin for CPB, the Hemochron and Hemotec (Hepcon) ACTs were both therapeutic at all time points, although the Hemochron ACT was statistically longer at two time points[15] (Fig. 19.2).

This difference was even more pronounced in pediatric patients, who have greater heparin consumption rates (Fig. 19.3). The apparent "overestimation" of ACT by the Hemochron device during hypothermic CPB may result from the different volumes of blood that each assay warms to 37°C.[15]

In another study of heparin monitoring and ACT threshold values, investigators noted that the two most commonly used ACT devices correlated with each other, yet one of the instruments had significant bias.[16] Another observational study showed that many ACT tests correlated poorly with heparin level as assessed by anti–factor Xa plasma activity.[17] Patteril and colleagues[18] demonstrated that after switching their cohort population to a newer ACT device, the new instrument yielded a lower mean ACT value compared with temporal controls (557 vs 618 seconds) despite a higher dose of heparin needed to achieve a minimum ACT of 480 seconds.

The ACT test can be modified by the addition of heparinase. With this modification, the coagulation status of the patient can be monitored during CPB while the anticoagulant effects of heparin are eliminated. Because this test is a side-by-side comparison of the untreated ACT with the heparinase ACT, it also has the advantage of being a rapid test for assessment of a circulating heparin-like substance or for residual heparinization after CPB.[19]

With the introduction of ACT monitoring into cardiac surgical practice, clinicians have been able to titrate heparin and protamine

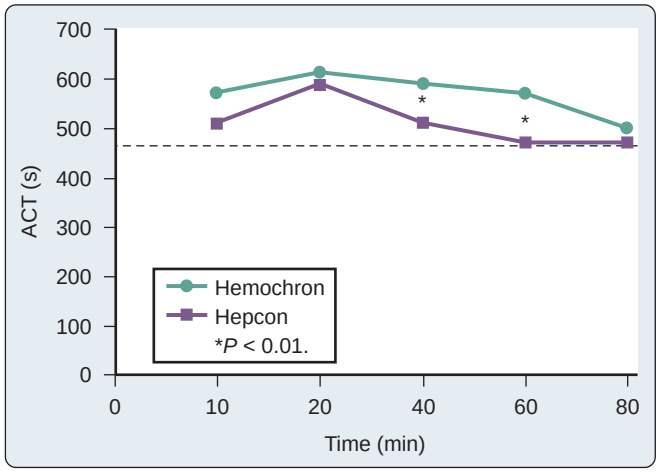

Fig. 19.2 The Hemochron (International Technidyne Corp., Edison, NJ; *circles*) and Hemotec (Hepcon, Medtronic Perfusion Services, Minneapolis, MN; *squares*) activated coagulation time *(ACT)* values in 20 adults at 5 time points during cardiopulmonary bypass (CPB). At 40 and 80 minutes on CPB, the Hemochron ACT was significantly greater. *(From Horkay F, Martin P, Rajah SM, Walker DR. Response to heparinization in adults and children undergoing cardiac operations.* Ann Thorac Surg. *1992;53:822–826, by permission of The Society of Thoracic Surgeons.)*

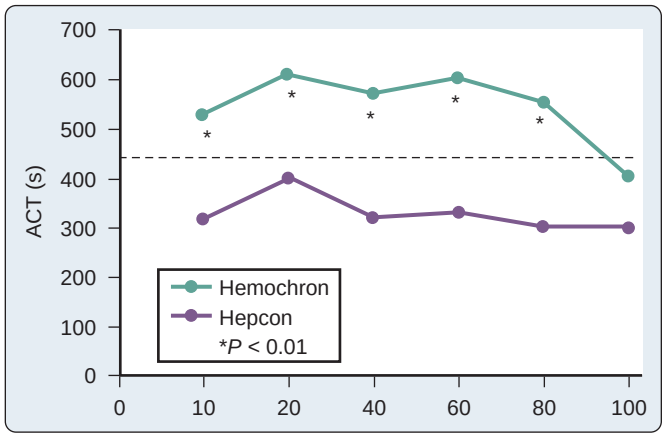

Fig. 19.3 The Hemochron (International Technidyne Corp., Edison, NJ; *green circles)* and Hemotec (Hepcon, Medtronic Perfusion Services, Minneapolis, MN; *purple circles*) activated coagulation time *(ACT)* values in 22 pediatric patients at six time points during cardiopulmonary bypass. Hemochron ACT was significantly greater than Hemotec ACT at five time points. *(From Horkay F, Martin P, Rajah SM, Walker DR. Response to heparinization in adults and children undergoing cardiac operations.* Ann Thorac Surg. *1992;53:822–826, by permission of The Society of Thoracic Surgeons.)*

dosages more accurately.[12,20] As a result, many investigators report reductions in blood loss and transfusion requirements, although many of these studies used retrospective analyses.[21] The improvements in postoperative hemostasis documented with ACT monitoring are potentially attributable to better intraoperative suppression of microvascular coagulation and improved monitoring of heparin reversal with protamine.[22]

ACT monitoring of heparinization is not without pitfalls, and its use has been criticized because of the extreme variability of the ACT and the absence of a correlation with plasma heparin levels (Fig. 19.4). Many factors have been suggested to alter the ACT, and these factors are prevalent during cardiac surgical procedures. When the extracorporeal circuit prime is added to the patient's blood volume, hemodilution occurs and may theoretically increase the ACT. Evidence suggests

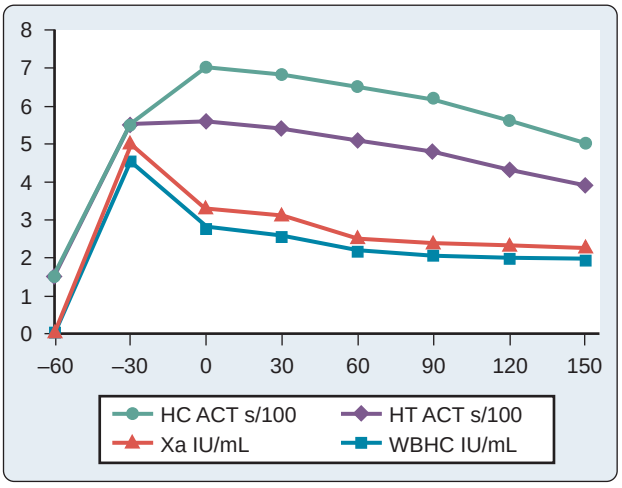

Fig. 19.4 Anticoagulation measured at baseline (–60 minutes), at heparinization (–30 minutes), and six time points after institution of cardiopulmonary bypass. Note the close correlation between the anti–factor Xa *(Xa; triangles)* activity and whole-blood heparin concentration *(WBHC; squares),* which does not parallel the change in Hemochron (International Technidyne Corp., Edison, NJ) activated coagulation time (ACT) *(HC ACT; circles)* or Hemotec (Medtronic Perfusion Services, Minneapolis, MN) ACT *(HT ACT; diamonds). (Modified from Despotis GJ, Summerfield AL, Joist JH. Comparison of activated coagulation time and whole blood heparin measurements with laboratory plasma anti-Xa heparin concentration in patients having cardiac operations.* J Thorac Cardiovasc Surg. *1994;108:1076–1082.)*

that this degree of hemodilution alone is not enough to alter the ACT. Hypothermia increases the ACT in a "dose-related" fashion. Culliford and associates[23] showed that, although hemodilution and hypothermia significantly increase the ACT of a heparinized blood sample, similar increases do not occur in the absence of added heparin. The effects of platelet alterations are more problematic. At mild-to-moderate degrees of thrombocytopenia, the baseline and heparinized ACTs are not affected. It is not until platelet counts are reduced to less than 30,000 to 50,000/μL that the ACT may be prolonged.[24] Patients treated with platelet inhibitors such as prostacyclin, aspirin, or platelet membrane receptor antagonists have a prolonged heparinized ACT compared with patients not treated with platelet inhibitors.[25] This ACT prolongation is not related exclusively to decreased levels of platelet factor 4 (PF4) (PF4 is a heparin-neutralizing substance) because it also occurs when blood is anticoagulated with substances that are not neutralized by PF4. Platelet lysis, however, significantly shortens the ACT because of the release of PF4 and other platelet membrane components, which may have heparin-neutralizing activities.[26] Gravlee and colleagues[27] showed that anesthesia and operation decrease the ACT and create a hypercoagulable state, possibly by creating a thromboplastic response or through activation of platelets.

During CPB, heparin decay varies substantially, and its measurement is problematic because hemodilution and hypothermia alter the metabolism of heparin. In a CPB study, Mabry and associates[28] found that the consumption of heparin varied from 0.01 to 3.86 IU/kg/min, and no correlation was noted between the initial sensitivity to heparin and the rate of heparin decay.[28] In the pediatric population, the consumption of heparin is increased to more than that of adult levels. The heparin administration protocol for pediatric patients undergoing CPB should account for a large volume of distribution, increased consumption, and a shorter elimination half-life. In monitoring the effects of heparin in pediatric patients, the minimum acceptable ACT value should be increased or an additional monitor should be used. The discrepancy between the Hemochron ACT and the Hemotec ACT that is demonstrated in Fig. 19.2 is even more pronounced in pediatric patients (see Fig. 19.3). Some investigators recommend maintaining heparin concentrations in addition to the ACT during operations for

pediatric congenital heart conditions to ensure that optimal anticoagulation is being achieved.[29,30]

Cascade Point-of-Care System

A completely different technology for measuring the effect of heparin is used by the Cascade POC analyzer (Helena, Beaumont, Tex; formerly Rapid Point Coagulation Analyzer Bayer Diagnostics, Tarrytown, NY). This test system contains disposable cards with celite activator for the measurement of heparin activity. This variation of the ACT is called the heparin management test (HMT). The card contains paramagnetic iron oxide particles that move in response to an oscillating magnetic field within the device. When clot formation occurs, movement of the iron oxide particles is decreased, and the end of the test is signaled. This system is capable of measuring prothrombin time (PT) and activated partial thromboplastin time (aPTT), discussed later. The suitability of this platform for ACT monitoring during cardiac surgical procedures has been demonstrated in clinical studies.[31,32] Suitability for monitoring heparinization in the interventional cardiology laboratory also has been reported. The HMT correlates well with anti–factor Xa heparin activity in patients undergoing CPB and is less variable than standard ACT measures. In a comparison with ACT, the coefficients of variation were similar between the tests at baseline, but these values were three times greater for the ACT during heparinization. This degree of agreement with plasma anti–factor Xa measurements has not been demonstrated universally when studying blood from patients undergoing CPB.[33]

Heparin Resistance

Heparin resistance is documented by an inability to increase the ACT of blood to expected levels despite an adequate dose and plasma concentration of heparin. In many clinical situations, especially when heparin desensitization or a heparin inhibitor is suspected, heparin resistance can be treated by administering increased doses of heparin in a competitive fashion. If an adequately prolonged clotting time is ultimately achieved using greater than expected doses of heparin, a better term than heparin resistance would be heparin tachyphylaxis or "altered heparin responsiveness." During cardiac surgical procedures, the belief that a safe minimum ACT value of 300 to 400 seconds is required for CPB is based on a few clinical studies and a relative paucity of scientific data. However, an inability to attain this degree of anticoagulation in the heparin-resistant patient engenders the fear among cardiac surgical providers that the patient will experience microvascular consumptive coagulopathy or that clots will form in the extracorporeal circuit. This potential for fibrin formation in the extracorporeal circuit was reported by Young and associates,[34] who found increased production of fibrin monomer and consumption of fibrinogen and platelets in six of nine rhesus monkeys when the ACT declined to less than 400 seconds. However, Metz and Keats[35] reported no adverse effects of thrombosis or excessive bleeding in 51 patients undergoing CPB whose ACT was less than 400 seconds. In a porcine model, the group whose ACT was maintained between 250 and 300 seconds did not have excessive consumption of coagulation factors, increases in fibrin monomer formation, or changes in oxygenator performance compared with the group whose ACT was maintained at greater than 450 seconds.[36]

Many clinical conditions are associated with heparin resistance.[37] Sepsis, liver disease, and pharmacologic agents represent just a few[38,39] (Table 19.1). Many investigators have documented decreased levels of AT III secondary to heparin pretreatment,[40] whereas others have not found decreased AT III levels.[41] Esposito and colleagues[42] measured coagulation factor levels in patients receiving preoperative heparin infusions and found that a lower baseline ACT was the only risk factor for predicting heparin resistance compared with patients not receiving preoperative heparin.

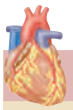
Patients receiving preoperative heparin therapy traditionally require larger heparin doses to achieve a given level of anticoagulation when that anticoagulation is measured by the ACT. Presumably, this "heparin resistance" is the result of deficiencies in the level or activity of AT III.[39,42–45] Other possible causes include enhanced factor VIII activity and platelet dysfunction leading to a decrease in ACT response to heparin. Levy and associates[45] showed that the in vitro addition of AT III enhances the ACT response to heparin. Lemmer and Despotis[44] demonstrated that this heparin resistance, as measured by the ACT, does not correlate with preoperative AT III levels. It is unclear that these patients have increased heparin requirements during CPB because the ideal ACT and monitoring techniques have yet to be elucidated. Nicholson and colleagues[46] demonstrated that the temporal courses of ACT and AT III concentration do not parallel each other, thus further suggesting that AT III depletion is not the sole cause of heparin resistance during CPB. Lower ACTs (<480 seconds) were tolerated in this study with no adverse outcome.

AT III concentrate is available as a heat-treated human product or in recombinant form, and its use is a reasonable method of treating patients with documented AT III deficiency (Box 19.1). Heparin responsiveness in the form of increased ACT levels is documented both in vitro and in vivo when heparin-resistant patients are treated with AT III. In a multicenter, randomized, placebo-controlled trial using 75 IU/kg of recombinant AT III, patients treated with AT III received less fresh frozen plasma to augment ACT levels and also had evidence of less hemostatic activation while undergoing CPB.[47] The trend was toward increased blood loss in the AT III group, which is potentially a dose effect that requires further investigation.[48,49]

TABLE 19.1 Disease States Associated With Heparin Resistance

Disease State or Condition	*Comment*
Newborn status	Decreased AT III levels until 6 months of age
Venous thromboembolism	May have increased factor VIII level Accelerated clearance of heparin
Pulmonary embolism	Accelerated clearance of heparin
Congenital AT III deficiency	40–60% of normal AT III concentration
Type I	Reduced synthesis of normal/abnormal AT III
Type II	Molecular defect within the AT III molecule
Acquired AT III deficiency	<25% of normal AT III concentration
Preeclampsia	Levels unchanged in normal pregnancy
Cirrhosis	Decreased protein synthesis
Nephrotic syndrome	Increased urinary excretion of AT III
DIC	Increased consumption of AT III
Heparin pretreatment	85% of normal AT III concentration because of accelerated clearance
Estrogen therapy	Decreased postheparin triglyceride hydrolase activity
Cytotoxic drug therapy (L-Asparaginase)	Decreased protein synthesis

AT III, Antithrombin III; *DIC,* disseminated intravascular coagulation.



BOX 19.1 HEPARIN RESISTANCE

- It is primarily caused by antithrombin III deficiency in pediatric patients.
- It is multifactorial in adult cardiac surgical patients.
- The critical activated coagulation time value necessary in patients who demonstrate acquired heparin resistance is not yet determined.
- Heparin resistance also can be a sign of heparin-induced thrombocytopenia.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a potentially life-threatening disorder that occurs in patients receiving unfractionated heparin (UFH) and, less commonly, low-molecular-weight heparin (LMWH). The incidence is between 0.2% and 5% in patients exposed

TABLE 19.2 Pretest Scoring System for Heparin-Induced Thrombocytopenia: the 4 Ts

4 Ts	*2 Points*	*1 Point*	*0 Points*
Thrombocytopenia	Platelet count fall >50% and platelet nadir ≥20%[a]	Platelet count fall 30–50% or platelet nadir 10–19%	Platelet count fall <30% and platelet nadir <10%
Timing of platelet count fall	Clear onset between days 5–10 or platelet fall ≤1 day (previous heparin exposure within 30 days)[b]	Consistent with days 5–10 fall, but not clear (eg, missing platelet counts); onset after day 10[c]; or fall ≤1 day (previous heparin exposure 30–100 days ago)	Platelet count fall <4 days without recent exposure
Thrombosis or other sequelae	New thrombosis (confirmed); skin necrosis[d]; acute systemic reaction postintravenous unfractionated heparin bolus	Progressive or recurrent thrombosis[e]; non-necrotizing erythematous) skin lesions[d]; suspected thrombosis (not proven)[f]	None
Thrombocytopenia of other causes	None apparent	Possible[c]	Definite[c]

[a]Greifswald, Germany (GW): platelet count fall >50% or nadir 20–100%; Hamilton, Canada (but not GW): platelet count fall >50% directly resulting from surgical procedure counts as 1 point, rather than 2 points.
[b]GW: onset from days 5–14 (rather than days 5–10); platelet fall within 1 day (heparin exposure within 100 days).
[c]GW: onset after day 14.
[d]Skin lesions at heparin injection sites.
[e]Progression refers to objectively documented increase in thrombus size (usually, extension of deep vein thrombosis by ultrasonography); recurrence refers to newly formed thromboembolus in previously affected region (usually, new perfusion defects in a patient with previous pulmonary embolism).
[f]In GW, suspected thrombosis (not proven) was not included as a criterion. Determination of whether the presence of another apparent cause of thrombocytopenia was possible or definite was at the discretion of the investigator.

to heparin, with reports of incidence as high as 15% to 20% in patients undergoing cardiac surgical procedures. HIT most often occurs 5 to 14 days after heparin administration and is mediated by antibodies binding to the complex formed between heparin and PF4. This complex binds to platelets, thereby causing platelet activation and subsequently thrombocytopenia. Associated immune-mediated endothelial injury and complement activation cause platelets to adhere, aggregate, and form platelet clots, or "white clots." Among patients in whom HIT develops, the incidence of thrombotic complications approximates 20%. These complications, in turn, may carry a mortality rate as high as 40%.

Diagnosis of HIT requires both clinical evidence (thrombocytopenia and thrombosis) and laboratory findings. Laboratory tests include a functional assay or antibody-based assay. Examples of functional assays are the serotonin release assay (SRA) and the heparin-induced platelet activation (HIPA) assay. These tests detect heparin-dependent antibodies by using platelets from normal donors incubating with the patient's sera. The main advantage of the SRA is its high sensitivity and specificity; however, it is technically demanding and not widely available. The HIPA assay is highly specific but not as sensitive. The most commonly used antibody-based assay is the enzyme-linked immunosorbent assay, which measures immunoglobulin G (IgG), IgM, or IgA antibodies that bind to the heparin-PF4 complex. This test is readily available, although it is less specific than the SRA. Hybrid assays are being developed that can overcome some of the limitations of these tests. Aiding in the diagnosis of HIT is a scoring system called the "4 Ts" as described by Warkentin and Heddle.[50] This systematic method estimates the probability of HIT based on clinical presentation and has the following criteria: thrombocytopenia, timing of platelet count decline, thrombosis, and possible other causes of thrombocytopenia. When combined with a laboratory test, this scoring system provides the highest predictivity for HIT[50,51](Table 19.2).

The risks and appropriate courses of action in patients with HIT are unclear because the antibodies associated with HIT often become undetectable several weeks after discontinuing heparin. Moreover, the clinical syndrome does not always recur on repeat exposure to heparin and sometimes resolves despite continued drug therapy. Many patients never have thrombosis and disseminated intravascular coagulation despite positive laboratory testing. HIT possibly should be considered in the differential diagnosis of intraoperative heparin resistance in patients receiving preoperative heparin therapy.

The options for treating these patients are few. If the clinician has the luxury of being able to discontinue heparin for a few weeks, often the antibody disappears and allows a brief period of heparinization for CPB without complication.[52–55] Changing the tissue source of heparin was an option when bovine heparin was predominantly in use. Some types of LMWH have been administered to patients with HIT, but reactivity of the particular LMWH with the patient's platelets should be confirmed in vitro. Supplementing heparin administration with pharmacologic platelet inhibition using prostacyclin, iloprost, aspirin, or aspirin and dipyridamole have been reported, all with favorable outcomes. Tirofiban with UFH has been used in this clinical circumstance. Plasmapheresis may be used to reduce antibody levels. The use of heparin could be avoided altogether through anticoagulation with direct thrombin inhibitors such as argatroban or bivalirudin. These thrombin inhibitors have become the standard of care in the management of the patient with HIT (Box 19.2). Bivalirudin has been studied in multicenter trials in patients with HIT who must undergo CPB.[56] The use of this drug in patients with acute or subacute HIT requiring urgent cardiac operation has been supported in evidence-based guidelines published by the American College of Chest Physicians.[55] Monitoring the direct thrombin inhibitors during CPB is discussed later in this chapter.

BOX 19.2 HEPARIN-INDUCED THROMBOCYTOPENIA

- The immunologic form is mediated by an antibody to the heparin–platelet factor 4 complex.
- This disease has variable penetrance even in the same patient.
- It has an associated 30% risk for thrombosis.
- Thrombosis carries a 50% mortality rate.

Measurement of Heparin Sensitivity

Even in the absence of heparin resistance, patients' responses to an intravenous bolus of heparin are extremely variable.[57] The variability stems from different concentrations of various endogenous heparin-binding proteins such as vitronectin and PF4. This variability exists whether measuring heparin concentration or the ACT; however, variability seems to be greater when measuring the ACT. Because of the large interpatient variation in heparin responsiveness and the potential for heparin resistance, it is critical that a functional monitor of heparin anticoagulation (with or without a measure of heparin concentration) be used in the cardiac surgical patient. Bull and associates[58] documented a threefold range of ACT response to a 200 IU/kg heparin dose and similar discrepancy in heparin decay rates and thus recommended the use of individual patient dose-response curves to determine the optimal heparin dose. This is the concept on which POC individual heparin dose-response (HDR) tests are based.

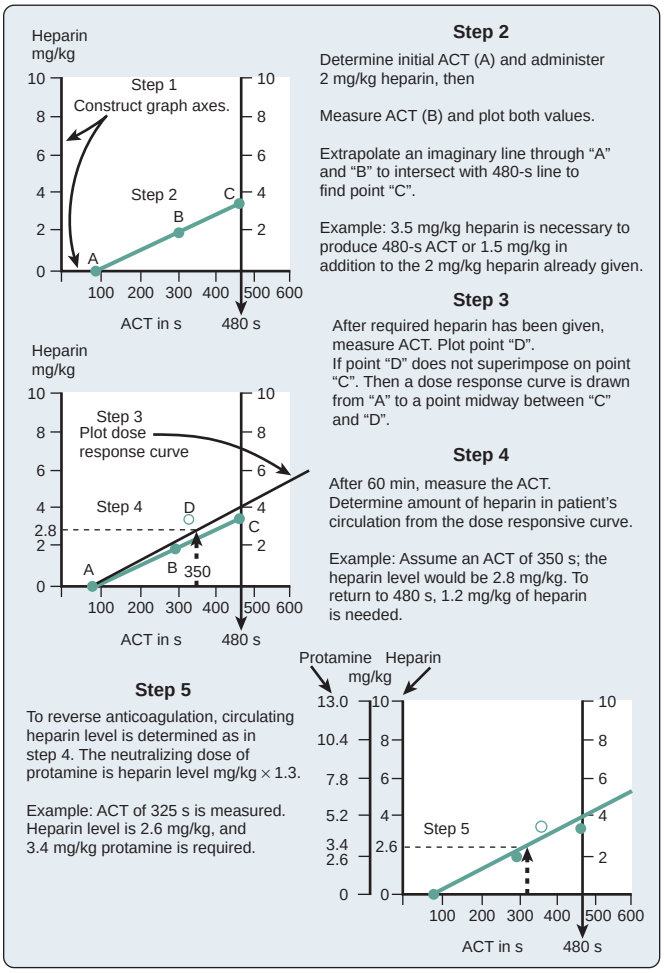


Fig. 19.5 Construction of a dose-response curve for heparin. *ACT,* Activated coagulation time. *(From Bull BS, Huse WM, Brauer FS, et al. Heparin therapy during extracorporeal circulation. II. The use of a dose-response curve to individualize heparin and protamine dosage.* J Thorac Cardiovasc Surg. *1975;69:685–689.)*

An HDR curve can be generated manually by using the baseline ACT and the ACT response to an in vivo or in vitro dose of heparin. Extrapolation to the desired ACT provides the additional heparin dose required for that ACT. Once the actual ACT response to the heparin dose is plotted, further dose-response calculations are made based on the average of the target ACT and the actual ACT (Fig. 19.5). This method was first described by Bull and associates[58] and forms the scientific basis for the automated dose-response systems in the proprietary Hemochron and Hemotec devices. The Hemochron RxDx (International Technidyne Corp., Edison, NJ) system uses the heparin-response test, which is an ACT with a known quantity of in vitro heparin (3 IU/mL). A dose-response curve is generated that enables calculation of the heparin dose required to attain the target ACT by using an algorithm that incorporates the patient's baseline ACT, estimated blood volume, and heparin-response test. The patient's heparin sensitivity can be calculated in seconds per international units per milliliter (s/IU/mL) by dividing the heparin-response test by 3 IU/mL.

The Hemochron RxDx system also provides an individualized protamine dose based on the protamine-response test (PRT). This is an ACT with one of two specific quantities of protamine, depending on the amount of circulating heparin suspected (2 or 3 IU/mL). The protamine dose needed to return the ACT to baseline can be calculated on the basis of a protamine-response curve using the patient's heparinized ACT, the PRT, and an estimate of the patient's blood volume. Jobes and colleagues[59] reported that the heparin dose directed by the

Fig. 19.6 The HMS heparin management system (Medtronic Perfusion Services, Minneapolis, MN) has an automated dispenser that places the appropriate volume of whole blood into each chamber of the test cartridge. A variety of assays can be performed in this instrument, depending on the cartridge used. *(Courtesy Medtronic Perfusion Services, Minneapolis, MN.)*

Hemochron RxDx system resulted in ACT values far greater than the target ACT. In their patients, in vivo heparin sensitivity was higher than in vitro sensitivity. Hemochron RxDx also resulted in lower protamine doses, lower postoperative mediastinal tube losses, and reduced transfusion requirements compared with a ratio-based system of heparin and protamine administration. In a larger study that standardized the treatment of heparin rebound, the reduced protamine dose was confirmed; however, the reductions in bleeding were not substantiated.[60] The use of a protamine dose-response curve has successfully reduced the protamine dose in vascular surgical procedures compared with standard weight-based protamine dosing.[61]

The Hepcon HMS (Medtronic Perfusion Services, Minneapolis, MN) system uses the HDR cartridge in the Hepcon instrument (Fig. 19.6). Each cartridge houses six chambers. Chambers 1 and 2 contain heparin at a concentration of 2.5 IU/mL, chambers 3 and 4 contain heparin at a concentration of 1.5 IU/mL, and chambers 5 and 6 do not contain heparin. Once information regarding a patient's weight, height, and CPB prime volume is entered, the information that can be obtained from this test includes the baseline ACT (chambers 5 and 6) and an HDR slope. The dose-response slope, which is the increase in ACT from 1.5 to 2.5 IU/mL heparin, is extrapolated to the desired target ACT or target heparin concentration, and the heparin dose is calculated.[37,62]

Heparin Concentration

Proponents of ACT measurement to guide anticoagulation for CPB argue that a functional assessment of the anticoagulant effect of heparin is mandatory and that the variability in ACT represents a true variability in the coagulation status of the patient. Opponents argue that during CPB, the sensitivity of the ACT to heparin is altered, and ACT does not correlate with heparin concentration or with anti–factor Xa activity measurement. Heparin concentration can be measured using the Hepcon HMS system, which uses an automated protamine titration technique. With a cartridge with four or six chambers containing tissue thromboplastin and a series of known protamine concentrations, 0.2 mL of whole blood is automatically dispensed into the chambers. The first channel to clot is the channel in which the protamine concentration most accurately neutralizes the heparin without a heparin or a protamine excess. Because protamine neutralizes heparin in the

ratio of 1 mg protamine per 100 IU heparin, the concentration of heparin in the blood sample can be calculated. A cartridge that monitors heparin concentration over a wide range can be used first, followed by another cartridge that can measure heparin concentrations within a more narrow range. The maintenance of a stable heparin concentration rather than a specific ACT level usually results in administration of larger doses of heparin because the hemodilution and hypothermia during CPB increase the sensitivity of the ACT to heparin. The measure of heparin concentration has been shown to correlate more closely with anti–factor Xa activity measurements than the ACT during CPB[63] (Fig. 19.7), although the precision and bias of the test may not prove to be acceptable for exclusive use clinically (Fig. 19.8).

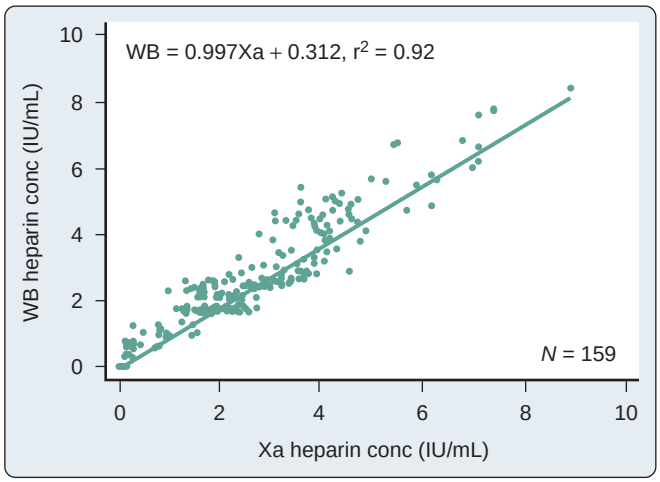

Fig. 19.7 A strong linear relationship exists between whole-blood heparin *([Hep])* concentration *(WB heparin conc)* and the anti–factor Xa plasma heparin concentration *(Xa heparin conc)*. WB heparin conc was measured using the Hepcon (Medtronic Perfusion Services, Minneapolis, MN) protamine titration assay and was corrected for hematocrit value. The Xa heparin conc was measured in plasma by using a substrate assay. *(From Despotis GJ, Summerfield AL, Joist JH. Comparison of activated coagulation time and whole blood heparin measurements with laboratory plasma anti-Xa heparin concentration in patients having cardiac operations.* J Thorac Cardiovasc Surg. *1994;108:1076–1082.)*

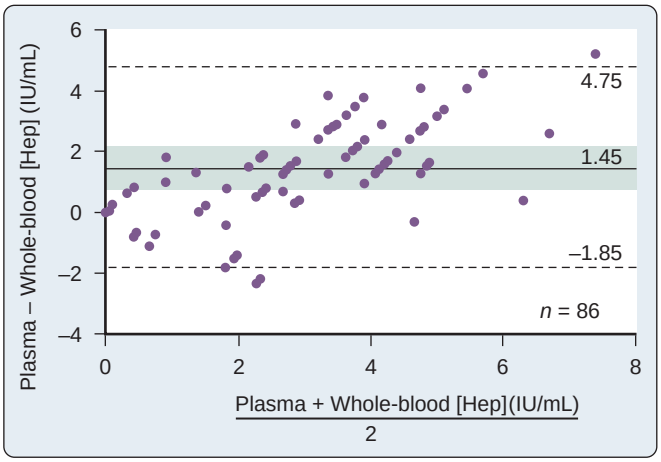

Fig. 19.8 A Bland-Altman plot analyzing the limits of agreement between the whole-blood heparin concentration and the plasma anti–factor Xa heparin concentration. The bias (1.45) and two standard deviations are determined to be the limits of agreement. The limits of agreement do not lie within the predetermined acceptable difference between the tests. *(From Hardy JF, Belisle S, Robitaille D, et al. Measurement of heparin concentration in whole blood with the Hepcon/HMS device does not agree with laboratory determination of plasma heparin concentration using a chromogenic substrate for activated factor X.* J Thorac Cardiovasc Surg. *1996;112:154–161.)*

In a small, prospective, randomized study comparing ACT and heparin concentration monitoring, Gravlee and associates[64] demonstrated increased mediastinal tube drainage postoperatively in the heparin concentration group, a finding that was initially attributed to greater total heparin doses. However, heparin rebound was not systematically assessed. In a follow-up study, these investigators found a greater incidence of heparin rebound in the heparin concentration group that, after treatment, resulted in no difference in bleeding between the ACT and heparin concentration groups.[65] In a prospective, randomized trial, Despotis and colleagues[66] demonstrated that by using a transfusion algorithm in association with Hepcon-based heparin management, chest tube drainage was minimally reduced and transfusion of non–red blood cell products could be significantly reduced relative to a group of patients who had ACT-based heparin management. These investigators attributed their results to better preservation of the coagulation system by high heparin doses because the doses of heparin administered in the Hepcon group were nearly twice the doses used in the ACT management group. However, Gravlee and associates[64] were unable to confirm suppression of ongoing coagulation using Hepcon CPB management. With the exception of during cold CPB, fibrinopeptide A levels in patients who had heparin concentration monitoring were virtually indistinguishable from those in patients who had ACT monitoring (Fig. 19.9). Hepcon, however, remains one of the more sensitive tests for detecting residual heparinization after protamine reversal because the heparin concentration can be measured by protamine titration to levels as low as 0.4 IU/mL (see later).

Other tests that have been used to measure the heparin concentration include polybrene titration (functions similarly to protamine titration) and factor Xa inhibition. The factor Xa inhibition test requires plasma separation and is not practical for intraoperative monitoring. A modification of the thrombin time (TT) can be useful in monitoring heparin levels. One application would be an assay in which a known quantity of thrombin is added to a patient's blood or plasma. When mixed with a fibrin product, cleavage of the fibrin product can be measured fluorometrically. Only thrombin not bound by the heparin–AT III complex is available to cleave fibrin, thus yielding an indirect measure of heparin concentration.

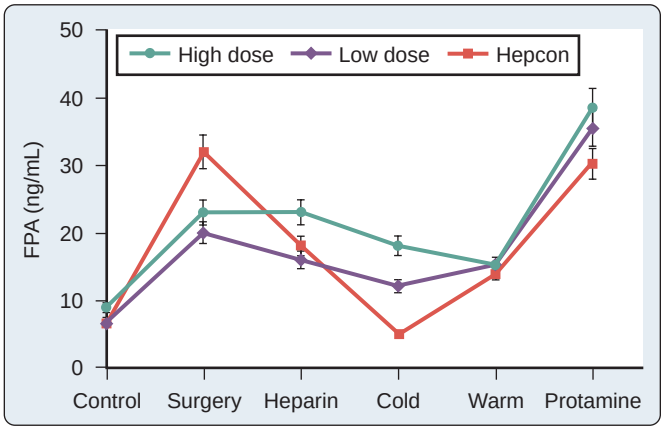

Fig. 19.9 Fibrinopeptide A *(FPA)* levels during cardiopulmonary bypass (CPB) were measured in three groups of patients before anesthetic induction *(Control)*, after heparin administration *(Heparin)*, at lowest temperature on CPB *(Cold)*, at esophageal temperature higher than 36°C *(Warm)*, and 5 minutes after completion of the protamine dose *(Protamine)*. Group 1, patients receiving heparin 300 IU/kg with activated coagulation time (ACT) heparin management; group 2, patients receiving heparin 250 IU/kg with ACT management; group 3, patients receiving 350 to 400 IU/kg with Hepcon (Medtronic Perfusion Services, Minneapolis, MN) heparin management. No differences were noted in FPA levels among groups except during cold CPB group 3 versus group 1; $P < 0.05$. *(From Gravlee GP, Haddon WS, Rothberger HK, et al. Heparin dosing and monitoring for cardiopulmonary bypass: a comparison of techniques with measurement of subclinical plasma coagulation.* J Thorac Cardiovasc Surg. *1990;99:518–527.)*

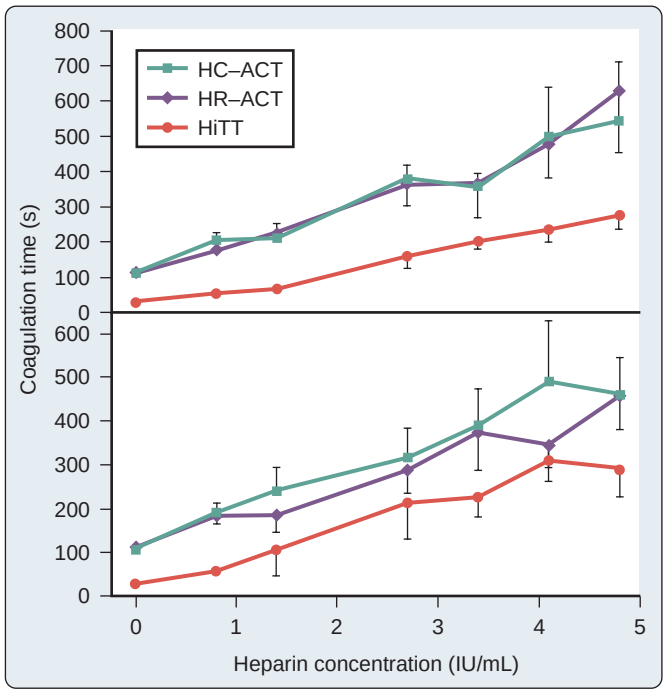

Fig. 19.10 Hemochron (International Technidyne Corp., Edison, NJ) activated coagulation time (ACT) *(HC-ACT; squares),* Hepcon (Medtronic Perfusion Services, Minneapolis, MN) *ACT (HR-ACT; diamonds),* and high-dose thrombin time *(HiTT; circles)* at different in vitro heparin concentrations. The relationship is linear in each group. *(From Wang JS, Lin CY, Karp RB. Comparison of high-dose thrombin time with activated clotting time for monitoring of anticoagulant effects of heparin in cardiac surgical patients.* Anesth Analg. *1994;79: 9–13.)*

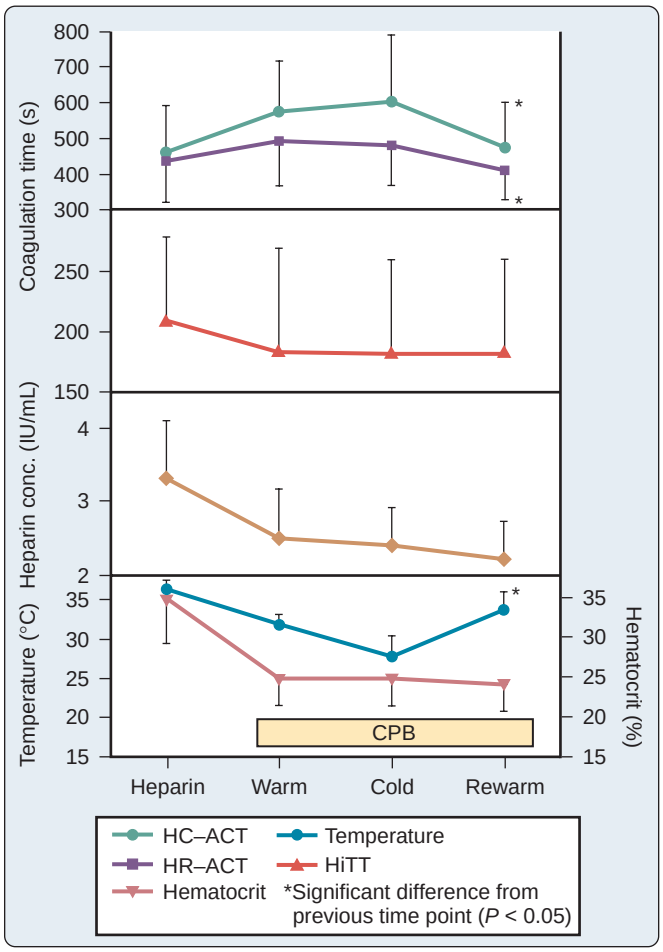

Fig. 19.11 Changes over time in the Hemochron (International Technidyne Corp., Edison, NJ) activated coagulation time (ACT) *(HC-ACT; green circles),* Hepcon (Medtronic Perfusion Services, Minneapolis, MN) ACT *(HR-ACT; squares),* and high-dose thrombin time *(HiTT; upward triangles)* in cardiac surgical patients. HiTT is unaffected by the changes in temperature *(blue circles)* and hematocrit *(downward triangles)* during cardiopulmonary bypass *(CPB).* The HC-ACT and HR-ACT increase with the initiation of CPB, and the heparin concentration *(Heparin conc.)* and HiTT decrease. *(From Wang JS, Lin CY, Karp RB. Comparison of high-dose thrombin time with activated clotting time for monitoring of anticoagulant effects of heparin in cardiac surgical patients.* Anesth Analg. *1994;79: 9–13.)*

High-Dose Thrombin Time

A functional test of heparin-induced anticoagulation that correlates well with heparin levels is the high-dose thrombin time (HiTT; International Technidyne Corp., Edison, NJ). The TT is a clotting time that measures the conversion of fibrinogen to fibrin by thrombin. The TT is prolonged by the presence of heparin and by hypofibrinogenemias or dysfibrinogenemias. Because the TT is sensitive to very low levels of heparin, a high dose of thrombin is necessary in the TT to assay the high doses of heparin used for CPB accurately. The HiTT is performed by adding whole blood to a prewarmed, prehydrated test tube that contains a lyophilized thrombin preparation. After the addition of 1.5 mL of blood, the tube is inserted into a Hemochron well, and the time to clot formation is measured. In vitro assays indicate that the HiTT is equivalent to the ACT in evaluation of the anticoagulant effects of heparin at heparin concentrations in the range of 0 to 4.8 IU/mL (Fig. 19.10). Unlike the ACT, the HiTT is not altered by hemodilution and hypothermia and has been shown to correlate better with heparin concentration than the ACT during CPB.[67] During CPB, heparin concentration and the HiTT decrease, whereas the Hemochron and the Hepcon ACTs increase (Fig. 19.11).

Another potential advantage of HiTT monitoring is for patients receiving aprotinin therapy. In the presence of heparin, aprotinin augments the celite ACT,[68] possibly because its kallikrein-inhibiting capacity prolongs activation of the intrinsic coagulation pathway by factor XIIa. This finding should not be interpreted to represent enhanced anticoagulation. The kaolin ACT is less affected by aprotinin therapy than the celite ACT, perhaps because kaolin, unlike celite, activates the intrinsic pathway by stimulation of factor XI directly.[69] Other investigators have suggested that kaolin binds to aprotinin and reduces the anticoagulant effect of aprotinin in vitro. However, the heparinized kaolin ACT is still somewhat prolonged in the presence of aprotinin. The HiTT is not affected by aprotinin therapy and can be used as a measure of heparinization for patients receiving aprotinin therapy during CPB.[68] The high-dose thromboplastin time is another measure of anticoagulation that is not affected by aprotinin therapy.[70] The high-dose thromboplastin time is a WBCT in which celite is replaced by 0.3 mL of rabbit brain thromboplastin to which 1.2 mL of blood is added. This test measures the time to coagulation by activation of the extrinsic pathway. This pathway of coagulation is also stimulated during pericardiotomy because of the rich thromboplastin environment of the pericardial cavity.

Heparin Neutralization

Protamine Effects on Coagulation Monitoring

Reversal of heparin-induced anticoagulation is most frequently performed with protamine. Biologically, protamine binds to positively charged groups such as phosphate groups and may have important properties in angiogenesis and immune function. Different successful dosing plans have been proposed.[71,72] The recommended dose of

protamine for heparin reversal is 1 to 1.3 mg protamine per 100 IU heparin; however, this dose often results in a protamine excess.

Protamine injection causes adverse hemodynamic effects.[73] Protamine reactions have been classified into three types.[74] The most common is the type I reaction, characterized by hypotension. Type II (immunologic) reactions are categorized as IIA (anaphylaxis), IIB (anaphylactoid), and IIC (noncardiogenic pulmonary edema). Type III reactions are heralded by hypotension and catastrophic pulmonary hypertension leading to right-sided heart failure.[38,61,75]

In addition to hemodynamic sequelae, protamine has adverse effects on coagulation.[76] Large doses prolong the WBCT and the ACT, possibly by thrombin inhibition.[77] In animals and in humans, protamine has been associated with thrombocytopenia, likely because of activation of the complement cascade.[73] The anticoagulant effect of protamine also may be caused by inhibition of platelet aggregation, alteration in the platelet surface membrane, or depression of the platelet response to various agonists.[77–79] These alterations in platelet function result from the presence of the heparin-protamine complex, not protamine alone. Protamine-heparin complexes activate AT III in vitro and result in complement activation. The anticoagulant effects of free protamine occur when protamine is given in doses in excess of those used clinically; however, the risk that free protamine causes a hemostatic defect is small, given the rapid clearance of protamine relative to heparin.

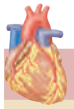
Monitoring for Heparin Rebound

The phenomenon referred to as heparin rebound describes the re-establishment of a heparinized state after heparin has been neutralized with protamine. Various explanations for heparin rebound have been proposed.[9,65,80,81] The most commonly postulated explanation is that rapid distribution and clearance of protamine occur shortly after protamine administration, thus leaving unbound heparin remaining after protamine clearance. Furthermore, endogenous heparin antagonists have an even shorter life span than protamine and are eliminated rapidly, resulting in free heparin concentrations. Also possible is the release of heparin from tissues considered heparin storage sites (endothelium, connective tissues). Endothelial cells bind and depolymerize heparin through PF4. Uptake into the cells of the reticuloendothelial system, vascular smooth muscle, and extracellular fluid may account for the storage of heparin that contributes to the reactivation of heparin anticoagulation referred to as heparin rebound.[9]

Residual low levels of heparin can be detected by sensitive heparin concentration monitoring in the first hour after protamine reversal and can be present for up to 6 hours postoperatively. The study by Gravlee and colleagues[65] suggested that without careful monitoring for heparin rebound in the postoperative period, increased bleeding as a result of heparin rebound may occur, specifically when larger doses of heparin have been administered. Monitoring for heparin rebound can be accomplished using tests that are sensitive to low levels of circulating heparin.[61,66,82,83] These tests are also useful monitors for confirmation of heparin neutralization at the conclusion of CPB (see later).

Heparin Neutralization Monitors

To administer the appropriate dose of protamine at the conclusion of CPB, it would be ideal to measure the concentration of heparin present and give the dose of protamine necessary to neutralize only the circulating heparin. As a result of heparin metabolism and elimination, which vary considerably among individual patients, the dose of protamine required to reverse a given dose of heparin decreases over time. Furthermore, protamine antagonizes the anti–factor IIa effects of heparin more effectively than the anti–factor Xa effects and thus varies in its potency depending on the source of heparin and its anti–factor IIa properties. Administration of a large fixed dose of protamine or a dose based on the total heparin dose given is no longer the standard of care and may result in an increased incidence of protamine-related adverse effects. An optimal dose of protamine is desired because unneutralized heparin results in clinical bleeding, and an excess of protamine may produce undesired coagulopathy. The use of individualized protamine dose-response curves uniformly results in a reduced protamine dose and has been shown to reduce postoperative bleeding.[58,82] One such dose-response test, the Hemochron PRT test, is an ACT performed on a heparinized blood sample that contains a known quantity of protamine. With knowledge of the ACT, PRT, and the estimated blood volume of the patient, the protamine dose needed to neutralize the existing heparin level can be extrapolated. The Hepcon instrument also has a PRT, which is the protamine titration assay. The chamber that clots first contains the dose of protamine that most closely approximates the circulating dose of heparin. The protamine dose required for heparin neutralization is calculated on the basis of a specified heparin/protamine dose ratio by measuring the circulating heparin level.



BOX 19.3 HEPARIN NEUTRALIZATION

- The most benign form of bleeding after cardiac surgical procedures results from residual heparinization.
- Treatment is with either protamine or another heparin-neutralizing product.
- Transfusion of allogeneic blood products is rarely indicated.
- Residual heparin can be measured by using the following:
  - A protamine titration assay
  - A heparin neutralized thrombin time assay
  - A heparinase activated coagulation time (ACT) compared with ACT
  - Any other heparinase test that compares itself with the test without heparinase added

At the levels of heparinization needed for cardiac surgical procedures, tests that are sensitive to heparin become unclottable. The ACT is relatively insensitive to heparin and is ideal for monitoring anticoagulation at high heparin levels, but it is too insensitive to detect incomplete heparin neutralization accurately. Reiner and associates[84] showed that the ACT had a high predictive value for adequate anticoagulation (confirmed by laboratory aPTT) when the ACT was longer than 225 seconds but was poorly predictive for inadequate anticoagulation when the ACT was shorter than 225 seconds. The low levels of heparin present when heparin is incompletely neutralized are best measured by other, more sensitive tests of heparin-induced anticoagulation, such as heparin concentration, aPTT, and TT. Thus, after CPB, confirmation of return to the unanticoagulated state should be performed with a sensitive test for heparin anticoagulation[85–88] (Box 19.3).

Thrombin Time

The TT is the time it takes for the conversion of fibrinogen to fibrin clot when blood or plasma is exposed to thrombin. Fibrin strands form in seconds. Detection of fibrin formation with standard laboratory equipment involves incubation of the blood or plasma sample within the chamber in which an optical or electrical probe sits. A detector senses either movement of the probe or the creation of an electrical field (electrical detection) because of fibrin formation and hence signals the end of the test. International Technidyne manufactures a Hemochron POC TT test that uses a lyophilized preparation of thrombin in a Hemochron test tube to which 1 mL of blood is added. Identification of fibrin formation in a Hemochron machine uses the standard Hemochron technology described previously with the ACT. The manufacturer suggests that the normal TT is 39 to 53 seconds for whole blood and 43 to 68 seconds for citrated blood. Because the TT specifically measures the activity of thrombin, it is very sensitive to heparin-induced enhancement of AT III activity. It is a useful test in the post-CPB period for differentiating the cause of bleeding when both the PT and the aPTT are prolonged because it excludes the intrinsic and extrinsic coagulation pathway limbs and evaluates the conversion of factor I to factor Ia. The TT is increased in the presence of heparin,

hypofibrinogenemia, dysfibrinogenemia, amyloidosis, or antibodies to thrombin.[89] The TT is also increased in the presence of fibrin degradation products if the systemic fibrinogen concentration is low.

The TT is an appropriate laboratory test for monitoring the degree of fibrinolytic activity in patients receiving thrombolytic therapy. Measurements of the quantity of fibrinogen, plasminogen, or plasma proteins generated during fibrinolysis are difficult to interpret and yield no prognostic information for dose adjustments. Thrombolytic agents activate the fibrinolytic system to generate plasmin, which then causes clot dissolution and decreases the quantities of fibrinogen and fibrin. This effect can be monitored using the TT. The TT should be measured at baseline (before institution of fibrinolytic therapy) and 3 to 4 hours after therapy is initiated. If the TT is prolonged by 1.5 to 5 times the baseline value, therapy should be considered effective. If the TT is prolonged by greater than seven times the baseline value, an increased risk for bleeding is incurred; if the TT is not prolonged at all, therapy has failed to activate fibrinolysis.

Bedside Tests of Heparin Neutralization

The HMS Plus Hemostasis Management System (Medtronic Perfusion Services, Minneapolis, MN) measures heparin concentration by a protamine titration assay. Cartridges with varying ranges of protamine concentration are available for use. The cartridge with the lower concentration of protamine in the titration is useful for the detection of residual circulating heparin and is sensitive to levels of heparin as low as 0.2 IU/mL. Whole-blood PT and aPTT assays are sensitive to deficiencies in coagulation factors and overly sensitive to low levels of heparin (aPTT); they lack specificity in assessing residual heparinization. The heparin-neutralized thrombin time (HNTT) is a TT assay with a small dose of protamine sufficient to neutralize 1.5 IU/mL of heparin. Because the TT is increased in the presence of heparin, hypofibrinogenemia, or dysfibrinogenemia, HNTT and TT should be performed together to discriminate among these three causes. A normal HNTT in the presence of an increased TT virtually confirms residual heparin effect and indicates the need for protamine administration. If the HNTT is prolonged as well as the TT, the cause of bleeding may be attributed either to a fibrinogen problem or to a concentration of heparin greater than that which could be neutralized by the HNTT. In a study comparing bedside monitors of anticoagulation, the TT-HNTT difference bore a significant correlation with the aPTT increase. Using the line of best fit, an aPTT elevation of 1.5 times the control corresponded to a 31-second difference in the TT and HNTT, thus indicating a convenient threshold value of TT-HNTT for the administration of protamine.[89]

Platelet Factor 4

A component of the α granule of platelets, PF4 binds to and inactivates heparin. The physiologic role of PF4 is that at the site of vascular injury, PF4 is released from platelets, binds heparin (or heparin-like compounds), and promotes thrombin and clot formation. PF4 adequately neutralizes heparin inhibition of factors Xa and IIa and may be superior to protamine in neutralizing anti–factor Xa effects. Animal data suggest that PF4 is devoid of the adverse hemodynamic effects seen with protamine and that it may be able to be infused more rapidly.[90,91] Heparin reversal has been documented by WBCT, ACT, and heparin concentration at a PF4 concentration of 40 IU/mL, approximately twice the reversal dose of protamine.[83] Levy and colleagues[92] subsequently found the reversal dose of PF4 to be approximately 60 IU/mL and documented similar ACT and viscoelastic measurements of clot formation compared with protamine.

Heparinase

Heparinase (Neutralase I) is an enzyme that specifically degrades heparin by catalyzing cleavage of the saccharide bonds found in the heparin molecule. As demonstrated by the ACT, heparinase in a dose of 5 mg/kg has been shown to neutralize heparin effects successfully in healthy volunteers and in patients who have undergone CPB. A dose of 7 mg/kg has been demonstrated to be even more efficacious in returning ACT to baseline values. Doses sufficient to neutralize a dose of 300 IU/kg of heparin had no significant hemodynamic effects in a canine model.[93] Investigators have not found any platelet-depressive effects of heparinase, in contrast to the well-documented platelet dysfunction associated with protamine therapy.[78] Return to the unanticoagulated state after the use of heparinase has been confirmed using ACT monitoring or heparin concentration monitoring.

Tests of Coagulation

Standard tests of coagulation, the PT and the aPTT, are performed on plasma to which the anticoagulant citrate has been added. Because these tests are performed on plasma, they require centrifugation of blood and generally are not feasible for use at the bedside. The aPTT tests the integrity of the intrinsic and the final coagulation pathways and is more sensitive to low levels of heparin than the ACT. Factors IX and X are most sensitive to heparin effects, and thus the aPTT is prolonged even at very low heparin levels. The test uses a phospholipid substance to simulate the interaction of the platelet membrane in activating factor XII. (Thromboplastin is a tissue extract containing tissue factor and phospholipid. The term *partial thromboplastin* refers to the use of the phospholipid portion only.) The aPTT is prolonged in the presence of the following deficiencies: factors XII, XI, IX, and VIII; HMWK (high-molecular-weight kininogen); and kallikrein. The aPTT reaction is considerably slower than the PT, and an activator such as celite or kaolin is added to the assay to speed activation of factor XII. After incubation of citrated plasma with phospholipid and activator, calcium is added, and the time to clot formation is measured. Normal aPTT is 28 to 32 seconds, which often is expressed as a ratio with a control plasma sample from the same laboratory. This is important because partial thromboplastin reagents have different sensitivities to heparin, and many have nonlinear responses to heparin in various concentration ranges.

The PT measures the integrity of the extrinsic and common coagulation pathways. The PT is prolonged in the presence of factor VII deficiency, warfarin sodium (Coumadin) therapy, or vitamin K deficiency. Large doses of heparin also prolong the PT because of factor II inactivation. The addition of thromboplastin to citrated plasma results in activation of extrinsic coagulation. After a 3-minute incubation and recalcification, the time to clot formation is measured and is recorded as the PT. Normal PT is 12 to 14 seconds; however, because of differences in the quality and lot of the thromboplastin used, absolute PT values are not standardized and are difficult to compare across different testing centers. The international normalized ratio (INR) has been adopted as the standard for coagulation monitoring. The INR is an internationally standardized laboratory value that is the ratio of the patient's PT to the result that would have been obtained if the International Reference Preparation had been used instead of the laboratory reagents. Each laboratory uses reagents with a specific sensitivity (International Sensitivity Index [ISI]) relative to the International Reference Preparation. The ISI of a particular set of reagents is provided by each manufacturer so that the INR can be reported.

Bedside Tests of Coagulation

The PT and aPTT tests performed on whole blood are available for use in the operating room or at the bedside. The Hemochron PT test tube contains acetone-dried rabbit brain thromboplastin to which 2 mL of whole blood is added, and the tube is inserted into a standard Hemochron machine. Normal values range from 50 to 72 seconds and are automatically converted by a computer to the plasma-equivalent PT and INR. The Hemochron aPTT contains kaolin activator and a platelet factor substitute and is performed similarly to the PT. The aPTT is sensitive to heparin concentrations as low as 0.2 IU/mL and displays a linear relationship with heparin concentration up to 1.5 IU/mL.

The former Thrombolytic Assessment System (TAS; Pharmanetics, Raleigh, NC), now the Cascade POC (Helena, Beaumont, TX), previously discussed for its ability to measure heparin by the HMT, also measures the PT and aPTT. The sample is added to a cartridge containing paramagnetic iron oxide particles, which oscillate in a magnetic field. Specific activating reagents are used for each test. The analytes used include rabbit brain thromboplastin for the PT, aluminum magnesium silicate for the aPTT, and celite for the HMT. The blood moves by capillary action and mixes with paramagnetic iron oxide particles and reagent within the testing chamber. The decreased movement of the particles is detected optically as the sample clots, and the resultant time is displayed in seconds and as INRs for the PT.

The CoaguChekProDM (Roche Diagnostics, Mannheim, Germany; former CoaguChek-plus, and formerly Ciba Corning Biotrack 512) coagulation monitor for evaluating the bedside PT and aPTT, uses 0.1 mL of whole blood placed into a disposable plastic cartridge for either the PT or aPTT. The sample is drawn by capillary action into a heated chamber where exposure to reagents occurs. The PT uses rabbit brain thromboplastin. The aPTT uses soybean phosphatide as the platelet substitute and bovine brain sulfatide as the activator. From the reaction chamber, blood traverses a reaction path where clot formation is detected by a laser optical system. The resulting time to clot formation is converted to a ratio of the control value by a microprocessor that has control values encoded.

Many investigators studied the former Ciba Corning Biotrack system for monitoring anticoagulation in different clinical situations. For patients receiving oral anticoagulant therapy, the Biotrack 512 monitor was found to be suitable for monitoring the PT and INR. Reiner and associates[84] compared the bedside Biotrack aPTT with the laboratory aPTT and heparin level in patients receiving therapeutic heparinization after interventional cardiac catheterization. These investigators found a strong correlation ($r = 0.89$) between the Biotrack aPTT and the aPTT from the hospital laboratory. The correlation between Biotrack aPTT and heparin level was not strong, probably because of the many other factors such as heparin neutralization and clearance that affect the heparin concentration in vivo.[94] Another study in patients receiving heparin compared the Ciba Corning Biotrack aPTT assay with the standard laboratory aPTT and documented that Biotrack was less sensitive to heparin than the laboratory aPTT; however, the correlation coefficient of these two tests was $r = 0.82$.[95] In patients receiving warfarin therapy, the Biotrack aPTT was more sensitive than the laboratory aPTT and yielded consistently greater results for aPTT value. In another study in patients undergoing anticoagulation for nonsurgical applications, the bedside aPTT was similar to the standard aPTT in its prediction of treatment in simple therapeutic algorithms. However, in more complex clinical situations, less agreement was noted between the bedside aPTT and the laboratory aPTT.[96]

In a comparison of bedside coagulation monitors after cardiac surgical procedures, Reich and associates[89] documented acceptable accuracy and precision levels for the Hemochron and Ciba Corning Biotrack PTs in comparison with the standard laboratory plasma PT, thus making them potentially valuable for use in the perioperative period. Neither the Hemochron aPTT nor the Ciba Corning aPTT reached this level of clinical competence compared with standard laboratory tests. Other investigators documented that this monitor seems to be more precise for the PT than for the aPTT.[97] Because of rapid turnaround times, these POC coagulation monitors may be useful in predicting which patients will bleed after cardiac surgical procedures,[98] and they have also been used successfully in transfusion algorithms to decrease the number of allogeneic blood products given to cardiac surgical patients.[99,100]

Measures of Fibrin Formation

The "Tenase complex" is the group of factors and cofactors that includes factor Xa, platelet-bound factor Va, platelet factor 3, and calcium. All adhere on the platelet surface and catalyze the cleavage of prothrombin (factor II) to thrombin (factor IIa). Thrombin then catalyzes the cleavage of fibrinogen to form fibrin monomer and fibrinopeptide A and fibrinopeptide B. These end products of fibrinogen cleavage are commonly measured serum markers that help quantify the degree of coagulation that occurs in certain experimental or clinical situations.

One such experimental situation is the use of heparin-bonded extracorporeal circuits during CPB with the expectation that thrombin activation and fibrin formation will be minimized. Coating of the extracorporeal circuit with the heparin ligand makes the circuit more biocompatible such that the inflammatory response elicited is diminished or nonexistent. Heparin-bonded circuits have been extensively studied and considered advantageous because of their ability to reduce the inflammatory response to CPB. Human studies reveal decreases in enzymes that mark leukocyte activation, thus showing a reduction in the whole-body inflammatory response similar to that seen with leukocyte-depletion techniques (see Chapters 31–33).[101–103]

Further enhancements in biocompatibility include less leukocyte activation and preserved platelet function. Reductions in thrombin generation have been difficult to document.[104] The increases in the fibrinogen fragment F1.2 and in D-dimer levels when heparin-coated circuits are used are similar to those seen when uncoated circuits are used.[105,106] Human studies have documented less bleeding and reduced transfusion requirements with the use of a heparin-coated extracorporeal circulation when these circuits are used in conjunction with a reduced systemic heparin dose.[107,108] In this circumstance, markers of thrombin generation are increased even greater than those in patients treated with full-dose heparin and uncoated circuits. In fact, increases are seen in fibrinopeptide A, prothrombin fragment F1.2, thrombin–AT III complexes, D-dimers, and plasminogen activators during CPB and after protamine administration regardless of whether heparin-coated circuits are used and regardless of heparin dose.[109] Despite this finding, the use of reduced heparin doses and coated circuitry has resulted in diminished transfusion requirements and reduced chest tube drainage volumes without evidence of complications.[106,110] Because microvascular coagulation is not fully inhibited, the use of a reduced dose of heparin cannot be systematically advocated and should be implemented with caution.

Fibrinogen Level

Fibrinogen concentration is traditionally measured using clottable protein methods, end-point detection techniques, or immunochemical tests. Of the clottable protein methods, the most commonly used fibrinogen assay relies on the method of Clauss. This method involves a 10-fold dilution of plasma, which ensures that fibrinogen is the rate-limiting step in clot formation. Subsequently, an excess of thrombin is added to the sample, and the time to clot formation is measured. The clotting time is inversely related to the fibrinogen concentration. Because this assay relies on detection of actual clot, it can be affected by fibrin degradation products, polymerization inhibitors, or other inhibitors of fibrin formation. Given the thrombin excess, small clinical concentrations of heparin do not affect fibrinogen determination according to the Clauss technique.

A whole-blood POC fibrinogen assay is available using the Hemochron system. The specific test tube contains a lyophilized preparation of human thrombin, snake venom extract, protamine, buffers, and calcium stabilizers. The test tube is incubated with 1.5 mL of distilled water and is heated in the Hemochron instrument for 3 minutes. Whole blood is placed into a diluent vial, where it is 50% diluted, and from this vial, 0.5 mL of diluted whole blood is placed into the specific fibrinogen test tube. The clotting time is measured using standard Hemochron technology, as described previously. The fibrinogen concentration is determined by comparison with a standard curve for this test. Normal fibrinogen concentration of 180 to 220 mg/dL correlates with a clotting time of 54 ± 2.5 seconds. Fibrinogen deficiency of 50 to 75 mg/dL correlates with a clotting time of 150 ± 9.0 seconds.

Unlike the method of Clauss, the end-point detection assays rely on the detection of changes in turbidity of plasma when clot is formed.

This technique does not require the maintenance of a stable cross-linked fibrin product (is not functional) and therefore does not report underestimated fibrinogen measurements in the presence of inhibitors. Immunochemical measures of fibrinogen concentration comprise a direct and accurate measurement technique; however, they are expensive and time consuming and require specialized laboratory facilities. Coagulation assays and fibrinogen assays can also be performed using viscoelastic testing, as discussed later.

Monitoring Fibrinolysis

Fibrinolysis, the dissolution of fibrin, is the normal modifier of hemostasis that ensures that coagulation does not proceed unchecked. It occurs in the vicinity of a clot and dissolves clot when local endothelial healing occurs. Fibrinolysis is mediated by the serine protease plasmin, which is the product of the cleavage of plasminogen by tissue plasminogen activator (tPA). Fibrinolysis is a normal phenomenon in response to clot formation; when it occurs systemically, it represents a pathologic condition.

Fibrinolysis can be primary or secondary. Primary fibrinolysis occurs when fibrinolytic activators are released or produced in excess and does not represent a response to the coagulation process. Examples of primary fibrinolysis include the release of plasminogen activators during liver transplantation operations and the exogenous administration of fibrinolytic agents such as streptokinase. During primary fibrinolysis, plasmin cleaves fibrinogen, to yield fibrinogen degradation products. These end products can be measured using immunologic techniques.

When fibrinolysis is a result of enhanced activation of the coagulation system, secondary fibrinolysis ensues. A well-known extreme form of secondary fibrinolysis is seen during disseminated intravascular coagulation, in which both systemic coagulation and fibrinolysis occur in excess. During CPB, fibrinolysis is most likely secondary to the microvascular coagulation that is occurring despite attempts at suppression using high doses of heparin.[111,112]

Fibrinolysis can be identified through either direct measurement of the clot lysis time (manual or viscoelastic tests) or measurement of the end products of fibrin degradation. The manual clot lysis time simply involves the placement of whole blood into a test tube. This blood clots in a matter of minutes. Visual inspection determines the end point for observation of clot lysis, and this time period is the clot lysis time. This technique is time consuming and requires constant observation by the person performing the test.

Viscoelastic Tests

Viscoelastic tests measure the unique properties of the clot as it is forming, organizing, strengthening, and lysing. As a result, fibrinolysis determination by this method requires that time elapse during which clot formation is occurring. Clot lysis parameters can be measured subsequent to clot formation and platelet-fibrin linkages. For this reason, viscoelastic tests often require longer than 1 hour to detect the initiation of fibrinolysis; however, if fibrinolysis is enhanced, results often can be obtained in 30 minutes.

End Products of Fibrin Degradation

Other methods for quantifying fibrinolysis include measurement of the end products of fibrin degradation. Fibrin degradation products are the result of the cleavage of fibrin monomers and polymers and can be measured using a latex agglutination assay. When plasmin cleaves cross-linked fibrin, dimeric units are formed that comprise one D-domain from each of two adjacent fibrin units. These "D-dimers" are frequently measured by researchers in clinical and laboratory investigations. They are measured by either enzyme-linked immunosorbent assays or latex agglutination techniques and thus are not available for on-site use. Controversy still exists regarding whether D-dimer levels or fibrin degradation products are the most sensitive test for detecting fibrinolysis, but most investigators agree that the presence of D-dimers is the most specific test for cross-linked fibrin degradation.[113]

Monitoring the Thrombin Inhibitors

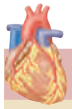
A newer class of drugs, the selective thrombin inhibitors, provides a viable alternative to heparin anticoagulation for CPB. These agents include hirudin, argatroban, bivalirudin, and experimental agents. A major advantage of these agents over heparin is that they can effectively inhibit clot-bound thrombin in an AT III–independent fashion.[114] The platelet thrombin receptor is believed to be the focus of thrombin's procoagulant effects in states of thrombosis such as after coronary artery angioplasty. Because surface-bound thrombin is more effectively suppressed, thrombin generation can be reduced at lower levels of systemic anticoagulation than are achieved during anticoagulation by the heparin–AT III complex. This translates into less bleeding despite the lack of a clinically useful antidote for the thrombin antagonists.[115,116] Thrombin antagonists are also not susceptible to neutralization by PF4 and thus are not neutralized at endothelial sites where activated platelets reside. They are also useful in patients with HIT, in whom the administration of heparin and subsequent antibody-induced platelet aggregation would be dangerous.[117] The lack of a potent antidote (eg, protamine) and a prolonged duration of action are the major reasons that hirudin and other thrombin inhibitors have not found widespread clinical acceptance for use in CPB procedures (see Chapter 35).

Hirudin

Hirudin, a coagulation inhibitor isolated from the salivary glands of the medicinal leech *(Hirudo medicinalis)*, is a potent inhibitor of thrombin that, unlike heparin, acts independently of AT III and inhibits clot-bound thrombin, as well as fluid-phase thrombin. Hirudin does not require a cofactor and is not susceptible to neutralization by PF4. This would seem to be beneficial in patients in whom platelet activation and thrombosis are potential problems. Recombinant hirudin was administered as a 0.25 mg/kg bolus and an infusion to maintain the hirudin concentration at 2.5 μg/mL, as determined by the ecarin clotting time in studies by Koster and colleagues.[118–126] The ecarin clotting time, modified for use in the Cascade POC analyzer, has been used in large series of patients with HIT.[118–123] Compared with standard treatment with heparin or LMWHs, recombinant hirudin–treated patients maintained platelet counts and hemoglobin levels, and had few bleeding complications, when renal function was normal.[124,125] Hirudin is a small molecule (molecular weight, 7 kDa) that is eliminated by the kidneys and is easily hemofiltered at the end of CPB.[126] In patients with abnormal renal function, bivalirudin is preferable to hirudin. An alternative treatment in this setting would be administration of UFH with a platelet antagonist, such as tirofiban, to prevent the hyperaggregability of platelets that occurs in patients with HIT.[125]

Bivalirudin

Bivalirudin is a small, 20–amino acid molecule with a plasma half-life of 24 minutes. It is a synthetic derivative of hirudin and thus acts as a direct thrombin inhibitor. Bivalirudin binds to both the catalytic binding site and the anion-binding exosite on fluid-phase and clot-bound thrombin. The part of the molecule that binds to thrombin is actually cleaved by thrombin itself, so the elimination of bivalirudin activity is independent of specific organ metabolism. Bivalirudin has been used successfully as an anticoagulant agent in interventional cardiology procedures as a replacement for heparin therapy. In fact, in interventional cardiology, bivalirudin has been associated with less bleeding and equivalent ischemic outcomes compared with heparin in combination with a platelet inhibitor.[127] The reason for these effects may be that bivalirudin is both an antithrombin anticoagulant and an antithrombin at the level of the platelet. Merry and associates[128] showed equivalence with regard to bleeding outcomes and an improvement in graft flow after off-pump coronary artery bypass operations



BOX 19.4 THROMBIN INHIBITORS

- These anticoagulant drugs are superior to heparin.
- They inhibit both clot-bound and soluble thrombin.
- They do not require a cofactor, activate platelets, or cause immunogenicity.
- These drugs include hirudin, argatroban, and bivalirudin.
- Heparin remains an attractive drug because of its long history of safe use and the presence of a specific drug antidote, protamine.

when bivalirudin was used (0.75 mg/kg bolus, 1.75 mg/kg/h infusion). Case reports confirm the safety of bivalirudin use during CPB.[129–131]

Multicenter clinical trials comparing bivalirudin with heparin anticoagulation in off-pump coronary artery bypass operations[132] and in CPB[133] demonstrated "noninferiority" of bivalirudin. Efficacy of anticoagulation and markers of blood loss were similar in the two groups, a finding suggesting that bivalirudin can be a safe and effective anticoagulant agent in CPB. These multicenter trials used the ACT as the monitor of anticoagulant activity intraoperatively, but ideal monitoring is performed using the ecarin clotting time, as seen with hirudin.[134] The ecarin clotting time has a closer correlation with anti–factor IIa activity and plasma drug levels than does the ACT. For this reason, standard ACT monitoring during antithrombin therapy is not preferred if ecarin clotting time can be measured. A plasma-modified ACT can be used to assay the anticoagulant effects of the thrombin inhibitor drugs more accurately than ACT. This test requires the addition of exogenous plasma and thus is not readily available as a POC assay.[135]

The anticoagulant effects of the thrombin antagonists can be monitored using the ACT, aPTT, or TT. The bleeding time (BT) also may be prolonged. In a canine CPB model, dogs receiving a synthetic thrombin inhibitor had less postoperative blood loss and greater platelet counts than those receiving heparin; however, those who received a large dose of the thrombin inhibitor still had ACT increases at 2 hours after CPB.[136] No differences in hemodynamics were noted in the groups.

Bivalirudin has been compared favorably with heparin in patients undergoing coronary angioplasty for unstable angina.[137] The half-life of aPTT prolongation is approximately 40 minutes, and reductions in formation of fibrinopeptide A are evidence of thrombin inhibition and fibrinogen preservation. Careful monitoring should be used because of a possible rebound prothrombotic state after cessation of therapy that could lead to recurrence of anginal symptoms (Box 19.4).

Evaluation of Prolonged Activated Partial Thromboplastin Time

The first step in evaluation of a prolonged aPTT is the elimination of heparin contamination as a cause of the elevation. Other potential causes of an elevated aPTT are the presence of factor deficiencies or inhibitors of coagulation. Factor deficiencies can be ruled out by mixing studies in which patient plasma is mixed with an equal volume of plasma derived from healthy volunteers. The test results should return to normal if a deficiency is present because mixing with normal plasma yields greater than the required concentrations of coagulation proteins for adequate clotting. If an inhibitor is present, mixing studies will not return the aPTT to normal values.

Inhibitors of factors VIII and IX and the "lupus anticoagulants" are the most common inhibitors encountered. The lupus anticoagulants are antiphospholipid antibodies that react with the phospholipid surfaces required for coagulation, hence the prolongation of the clotting time. In patients who do not have systemic lupus erythematosus, this syndrome is referred to as primary antiphospholipid syndrome. Testing for this inhibitor has been performed using the aPTT or a dilute viper venom time. The dilute viper venom time consists of activation of factor X by venom and measurement of the clotting time, which will be prolonged if an inhibitor is present. Immunologic assays for anticardiolipin antibodies also are available. Patient serum is incubated with solid-phase cardiolipin, and bound immunoglobulin is measured.

Monitoring Platelet Function

Circulating platelets adhere to the endothelium by platelet surface receptors that bind exposed collagen and become activated. This process initiates platelet activation because collagen is a potent platelet activator. The unstimulated platelet, which is discoid, undergoes a conformational change when activated. The activated platelet is spheric, extrudes pseudopodia, and expresses an increased number of activated surface receptors that can be measured to quantify the degree of platelet reactivity. The intensity of this platelet activation occurs in proportion to the quantity and nature of the platelet stimulus and increases in a graded fashion with increasing concentrations of agonists. The glycoprotein IIb/IIIa (GpIIb/IIIa) receptor is the primary receptor responsible for fibrinogen binding and the formation of the platelet plug.

Platelet Count

Numerous events during cardiac surgical procedures predispose patients to platelet-related hemostasis defects. The two major categories are thrombocytopenia and qualitative platelet defects. Thrombocytopenia commonly occurs during cardiac surgical procedures as a result of hemodilution, sequestration, and destruction by nonendothelial surfaces. Platelet counts commonly decline to 100,000/μL or less; however, the final platelet count greatly depends on the starting value and the duration of platelet-destructive interventions (ie, CPB).[138] Between 10,000 and 100,000/μL, the BT decreases directly; however, at platelet counts greater than 50,000/μL, neither the BT nor the platelet count has any correlation with postoperative bleeding in cardiac surgical patients. In contrast, platelet size or mean platelet volume does have some correlation with hemostatic function. Larger, younger platelets are more hemostatically active than smaller ones.[139] Mean platelet volume multiplied by the platelet count gives an estimation of overall platelet mass and is referred to as the "plateletcrit." It is important to appreciate the inverse relationship between platelet volume and platelet count when using a measure such as the plateletcrit to assess the viability of the existing platelet population. Because the mean platelet volume depends on the method of specimen collection, the anticoagulant used, and temperature of the storage conditions, its reproducibility depends on standardized laboratory procedures.

Qualitative platelet defects occur more commonly than thrombocytopenia during CPB. The range of possible causes of platelet dysfunction includes traumatic extracorporeal techniques, pharmacologic therapy, hypothermia, and fibrinolysis; the hemostatic insult increases with the duration of CPB.[140] The use of bubble oxygenators (although infrequent), noncoated extracorporeal circulation, and cardiotomy suctioning causes various degrees of platelet activation, initiates the release reaction, and partly depletes platelets of the contents of their α granules. Many of these changes are only transiently associated with CPB. Khuri and colleagues[141] characterized the hematologic changes associated with CPB in a group of 85 patients. Whereas the platelet count declined and reached a plateau at 2 hours after CPB, mean platelet volume reached its nadir at 2 hours after CPB and then began to increase during the ensuing 72 hours[141] (Figs. 19.12 and 19.13). The relative thrombocytopenia seen up to 72 hours after cardiac surgical procedures is not consistently associated with a bleeding diathesis. Similarly, the clotting proteins fibrinogen, factor VIII–von Willebrand factor, and factor VIII-C also increase to levels greater than baseline in the 2 to 72 hours after CPB (Fig. 19.14).

Large doses of heparin have been shown to reduce the ability of the platelets to aggregate and to reduce clot strength.[77] This effect is not reversed when protamine is administered; however, it may be

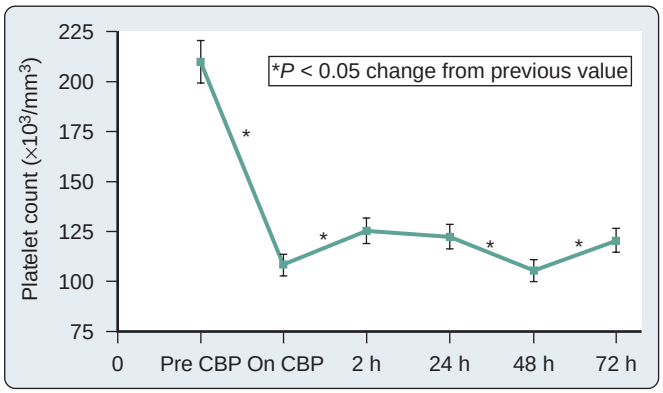


Fig. 19.12 Platelet count changes in patients undergoing cardiopulmonary bypass *(CPB)*. Significant decrease in platelet count occurs on initiation of CPB and remains until at least 72 hours postoperatively. *(From Khuri SF, Wolfe JA, Josa M, et al. Hematologic changes during and after cardiopulmonary bypass and their relationship to the bleeding time and nonsurgical blood loss.* J Thorac Cardiovasc Surg. *1992;104:94–107.)*

BOX 19.5 PLATELET FUNCTION

- The platelet count does not correlate with bleeding after cardiac surgical procedures.
- Patients frequently have extreme degrees of thrombocytopenia but do not bleed because they have adequate platelet function.
- The measure of platelet function correlates temporally with the bleeding course seen after cardiac surgical procedures.
- The thromboelastogram maximal amplitude, mean platelet volume, and other functional platelet tests are useful in transfusion algorithms.

mitigated by the prophylactic administration of aprotinin or other platelet-protective drugs.[142] The adverse effects of heparin on platelet function may result from the ability of heparin to inhibit the formation of thrombin, the most potent in vivo platelet activator.[143] However, heparin also activates the fibrinolytic system, a system that, through plasmin and other activators, can depress platelet function through other mechanisms. In an extracorporeal baboon model, intravenous heparin administration resulted in increases in plasmin activity, in the quantity of immunoreactive plasmin light chain, and in immunoreactive fibrinogen fragment E.[144] In addition, various degrees of fibrinolysis occur after CPB. Circulating plasmin causes dissolution of the GpIb platelet receptor and decreases the adhesiveness of platelets. Because fibrinolysis is partly responsible for the platelet dysfunction seen after heparin administration and CPB, the efficacy of antifibrinolytic agents as hemostatic drugs can be better appreciated. In addition to reducing platelet adhesiveness to von Willebrand factor, the fibrin degradation products formed depress platelet responsiveness to agonists.[145,146]

Protamine-heparin complexes and protamine alone also contribute to platelet depression after CPB. Mild-to-moderate degrees of hypothermia are associated with reversible degrees of platelet activation and platelet dysfunction.[147] Overall, the potential coagulation benefits of normothermic CPB compared with hypothermic CPB require further study in well-conducted randomized trials (Box 19.5).

Bleeding Time

The BT test is performed by creating a skin incision and measuring the time to clot formation by the platelet plug. The Ivy BT is performed on the volar surface of the forearm, above which a cuff is inflated to 40 mm Hg (above venous pressure). Two parallel incisions are made using a template, and the incisions are blotted with filter paper every 30 seconds until no further bleeding occurs. The time from incision to cessation of blood seepage is the template BT. The Duke BT is performed on the earlobe and has advantages for cardiac surgical procedures because the earlobe is more accessible and less likely to be subjected to the peripheral vasoconstriction seen after hypothermia. However, because neither the width or depth of the incision nor the venous pressure can be controlled in the Duke BT, the Ivy BT is considered the superior test. Normal BT is 4 to 10 minutes.

Numerous prospective blinded investigations confirmed that the BT has little or no value in predicting excessive hemorrhage after cardiac surgical procedures.[148] Even in patients receiving therapeutic doses of aspirin, an increase in the BT does not necessarily translate to an increase in mediastinal tube drainage or transfusions if reinfusion and blood conservation techniques are used aggressively. Substantial evidence indicates that platelet-directed therapy in the form of platelet transfusions or desmopressin acetate shortens a prolonged BT in

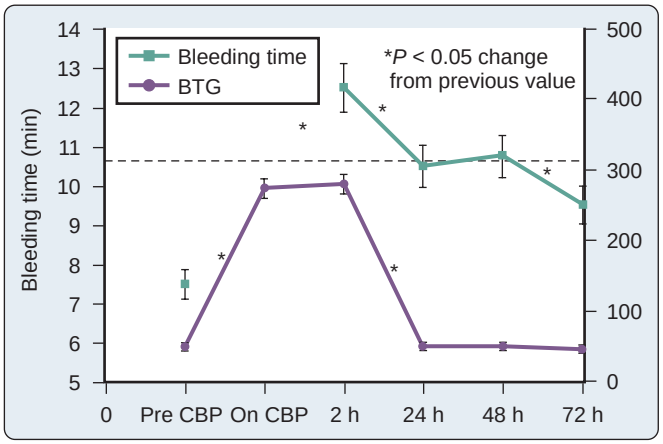

Fig. 19.15 Bleeding time *(squares)* increases on cardiopulmonary bypass *(CPB)* and remains increased until at least 72 hours postoperatively. However, platelet activation is maximal during CPB. The increase in β-thromboglobulin *(BTG; circles)*, indicating platelet activation, occurs on initiation of CPB and returns to baseline by 24 hours afterward. *(From Khuri SF, Wolfe JA, Josa M, et al. Hematologic changes during and after cardiopulmonary bypass and their relationship to the bleeding time and nonsurgical blood loss.* J Thorac Cardiovasc Surg. *1992;104:94–107.)*

patients with clinical hemorrhage.[149] In a study of 85 patients undergoing CPB, Khuri and associates[141] demonstrated that the BT becomes abnormal during CPB and does not return to baseline even by 72 hours postoperatively, whereas markers of platelet activation return to baseline by 24 hours postoperatively (Fig. 19.15). Although this type of data on the BT exists, the BT is considered by most investigators to be an antiquated test and is rarely used clinically.

Aggregometry

Activated platelets undergo aggregation, which is initially a reversible process. Activation also induces the release of substances from α and dense platelet granules and platelet lysosomes. Because platelet granules contain many platelet agonists, the release of granular contents further stimulates platelet activation and is responsible for the secondary phase of platelet aggregation. This secondary phase of platelet aggregation depends on the release of thromboxane and other substances from the platelet granules, is an energy-consuming process, and is irreversible.

Aggregometry is a useful research tool for measuring platelet responsiveness to a variety of different agonists. The end result, platelet aggregation, is an objective measure of platelet activation. Platelet aggregometry uses a photo-optical instrument to measure light transmittance through a sample during whole-blood or platelet-rich plasma. Platelet-rich plasma undergoes a decrease in light transmittance on the early phase of platelet activation because of the change in platelet shape from discoid to spheric. When exposed to a platelet agonist such as thrombin, adenosine diphosphate (ADP), epinephrine, collagen, or ristocetin, the initial reversible aggregation phase results in increased light transmittance because of the platelet aggregates that decrease the turbidity of the sample. Known major platelet activators are listed in Table 19.3. The larger the platelet aggregates, the greater is the transmittance of light. In the absence of further activation, disaggregation occurs, and the plasma sample becomes turbid. However, when the platelet release reaction occurs, thromboxane and other activators are released from the platelet α granules and the phase of secondary, or irreversible, aggregation occurs. This results in a further increase in light transmittance.

Defects in platelet aggregation can be seen in patients with storage pool deficiency, Bernard-Soulier syndrome, or Glanzmann thrombasthenia, as well as in patients taking salicylates. Impaired platelet aggregation has been demonstrated to occur after CPB, but investigators

TABLE 19.3 Major Platelet Activators Involved in Clot Formation

Reagents	*Receptors and Key Actions*
Collagen	GpVI and the integrin $\alpha_2\beta_1$ Critical for stable platelet adhesion to site of injury
vWF	GpIb Initial adhesion to collagen and slowing down rolling of platelets
Thrombin	GpIb, PAR 1, and PAR 4 Platelet activation for aggregation and clot formation
AA	Thromboxane A_2 receptor Activation and aggregation of platelets Aspirin inhibits COX 1 enzyme of thromboxane A_2 synthesis
ADP	GPCR receptors ($P2Y_1/P2Y_{12}$) Activation and aggregation of platelets Clopidigrel binds and irreversibly inhibits $P2Y_{12}$ receptor
Epinephrine	Epinephrine receptor on platelet membrane Weak activation and aggregation signaling
Fibrinogen	GpIIb/IIIa receptors Bridging between platelets during aggregation Abciximab or eptifibatide blocks the receptor and platelet aggregation

have had difficulty showing a correlation between impaired aggregation and clinical bleeding.[150,151] One ex vivo study demonstrated a significant correlation between platelet aggregation and 3-hour postoperative bleeding; however, correlations were greatest when preoperative aggregometry was performed using whole-blood samples and when postoperative measurements were performed using platelet-rich plasma.[151] The assessment of the platelet defect induced by aspirin consumption is more sensitive when whole-blood aggregometry is performed. The extreme sensitivity of this assay to minor defects in platelet function has resulted in a high negative predictive value, but a low positive predictive value, for bleeding. The inability of this test to be performed easily in the clinical setting has restricted platelet aggregometry to use as a research tool with occasional clinical applications.

Platelet-Mediated Force Transduction

An instrument that measures the force developed by platelets during clot retraction has been shown to be directly related to platelet concentration and function.[152,153] This instrument is called the Hemostasis Analysis System (Hemodyne Inc., Bethesda, MD). The apparatus consists of a cup and a parallel upper plate. The cup is filled with blood or the platelet-containing solution, and the upper plate is lowered onto the clotting solution. Clot forms and adheres to the outer edges of the cup and to the plate above it. A thin layer of oil is deposited onto the surfaces that are exposed to air. The upper plate is coupled to a displacement transducer that translates displacement caused by platelet retraction into a force. Normal values for platelet force development have been suggested by the investigators.[152] The antiplatelet effects of heparin have been evaluated using this force retractometer. Using this instrument, investigators have shown that high heparin concentrations completely abolish platelet force generation.[77] Furthermore, the concentration of protamine required to reverse the anticoagulant effects of heparin is not sufficient to reverse these antiplatelet effects. The antiplatelet effects of protamine alone also have been evaluated using this monitor.

Fluorescence Flow Cytometry

The introduction of fluorescence flow cytometry into the clinical laboratory provided a sensitive and specific means for assessing causes of

TABLE 19.4 Platelet Adhesion and Aggregation

Ligand	*Receptor*	*Properties*
Collagen	GpIa/IIa, GpIIb/IIIa, GpIV	Adhesion, aggregation, secretion
Thrombospondin	GpIV, $\alpha_v\beta_3$	Adhesion, antiadhesion
vWF	GpIb/IX, GpIIb/IIIa	Adhesion

platelet dysfunction. The disadvantages of the in vitro assays, such as shear-induced stress and clot retraction measurements, are that they represent nonspecific markers of platelet defects. The measure of specific serum markers of platelet activation, such as β-thromboglobulin and PF4, can be performed; however, plasma collection techniques for these tests are cumbersome, and the assays are often affected by other metabolic functions. Aggregometry is only a semiquantitative process and requires a high concentration of platelets for its optimal performance.

Flow cytometry is ideal for the detection of low concentrations of specific proteins within a large population of cells. These proteins either may be static portions of the platelet surface or dynamic products of platelet activation. The platelet release reaction enables specific integrin proteins, which are a part of the platelet α-granule membrane, to incorporate themselves into the platelet surface membrane through a mechanism analogous to exocytosis. A portion of the GpIIb/IIIa receptor is also a protein of the α-granule membrane that becomes exposed on the surface membrane of the platelet in response to platelet activation. Flow cytometry allows for the detection and quantification of many of these surface membrane constituents as a result of immunofluorescent innovations.

Flow cytometry techniques were enhanced by the development of specific monoclonal antibodies, which recognize antigens on the platelet (or white blood cell) surface. The ligands present on the surface of platelets are responsible for initiating and propagating the activities of adhesion and aggregation when they are bound by the appropriate agonist (Table 19.4). Antibodies developed are so specific that different ligand binding sites can be measured on the same GpIIb/IIIa molecule that characterizes different phases of receptor activation. Some of the epitopes for which monoclonal antibodies have been developed include the following: platelet activation–dependent granule–external membrane (PADGEM) and platelet α-granule membrane protein-140 (GMP-140), markers of platelet activation; the activated GpIIb/IIIa complex; and the GpIb receptor.[154–156] Many monoclonal antibodies are available for identification of specific platelet ligand-binding sites (Table 19.5). Antibodies that bind specifically to activated platelets but minimally to unstimulated platelets are referred to as "activation dependent." In using activation-dependent monoclonal antibodies, flow cytometry measures the platelet reactivity or response to the addition of platelet agonists. The technique of flow cytometry can be performed using whole blood or platelet-rich plasma. The fluorescent-labeled monoclonal antibody directed against a specific platelet membrane protein is quantified by the flow cytometer, which is an instrument equipped with a laser or a light source of a specific excitation wavelength. Light scatter data are collected that help to differentiate platelets from other cellular particles. Fluorescent antibody detection is expressed as percentage of the total number of particles or as fluorescence intensity.

The ability to identify platelet defects specifically by fluorescence flow cytometry has greatly aided in the characterization of hematologic disease states such as the Bernard-Soulier syndrome and Glanzmann thrombasthenia.[157,158] In the cardiac surgical setting, flow cytometry has aided in diagnosis of platelet function disorders induced by CPB and protamine administration.[159,160] Kestin and colleagues[143] used

TABLE 19.5 Monoclonal Antibodies to Platelet Antigens

Antibody Binding Site (Other Name)	*Antibodies Available*	*Requirement for Binding/ Functional Activity*
GpIb (CD42b)	AP-1; 6D1	von Willebrand receptor; platelet adhesion
GpIX	FMC25	Platelet adhesion to endothelium
GpIIb/IIIa complex ($\alpha IIB\beta_3$, CD41)	7E3; 10E5; 4F10; A2A9	Fibrinogen receptor; platelet aggregation
GpIIb/IIIa ($\alpha IIB\beta_3$, CD41a)	PAC1	Active conformation of GpIIb/IIIa only
Fibrinogen	2G5; 9F9	Receptor-induced changes because of bound fibrinogen
GpIIb heavy chain of GpIIb/IIIa	P2; PMI-1	Ligand-induced changes in GpIIb
IIIa portion of GpIIb/IIIa (CD61)	AP6; Ab15; Y2/51	Receptor bound by fibrinogen
GMP140 (CD62P, P-selectin)	S12; KC4; VH10	αGranule membrane protein, mediator of platelet–leukocyte interactions
LAMP-1 (CD63)	CLB-gran/12; H5G11	Lysosome membrane protein, expressed after platelet secretion
40-kDa protein	D495	Dense granule membrane protein
Thrombospondin	P8	Bound thrombospondin
Factor VIIIa light chain	1B3	Present on a procoagulant surface
Factor Va light chain	V237	Present on a procoagulant surface

flow cytometry techniques to study the effects of CPB on the in vivo time-dependent up-regulation of P-selectin in blood emerging from a bleeding wound. These investigators showed that P-selectin expression was depressed after heparinization and during CPB and recovered at approximately 2 hours after the conclusion of CPB. In contrast, in vitro activation of CPB blood with the platelet agonist phorbol myristate acetate did not reveal this depression of P-selectin expression at any time point. Using another platelet activator (thrombin-receptor agonist peptide) and flow cytometry, other investigators did not demonstrate depression of P-selectin expression early in CPB, but they did so after 90 minutes of CPB and after protamine administration.[161]

Uncertainty still exists regarding GpIb receptor modulation in response to CPB. Using flow cytometry, George and associates[162] found a modest reduction in platelet surface GpIb during CPB. However, a subsequent study by van Oeveren and colleagues,[163] confirming a reduction in GpIb, subjected the platelets to centrifugation and processing techniques that may have induced in vitro artifactual platelet activation. Kestin and associates[143] used monoclonal antibodies to many epitopes expressed on GpIb and concluded that expression of this receptor is not reduced during CPB.

As a result of the many monoclonal antibodies directed at specific epitopes on the GpIIb/IIIa receptor, investigations into the dynamics of this receptor during CPB have yielded variable results. Some studies confirmed modest reductions in the expression of GpIIb/IIIa, although not all used whole-blood techniques. Rinder and associates,[159] used a whole-blood technique and demonstrated a small decrease in GpIIb/IIIa expression. Monoclonal antibodies are available that bind to the GpIIb/IIIa fibrinogen binding site, and others recognize receptor-bound fibrinogen. Flow cytometry techniques also have helped to characterize the mechanisms of action of several pharmacologic agents that have shown hemostatic potential in the perioperative period.

Bedside Coagulation and Platelet Function Testing

Viscoelastic Tests: Thromboelastography, Thromboelastometry, and Sonoclot

In the late 19th century, investigators first began to explore the possibility that viscoelastic tests of blood could yield information on

TABLE 19.6 Mechanisms of Point-of-Care Platelet Function Monitors

Instrument	*Mechanism*	*Platelet Agonist*	*Clinical Utility*
Thrombelastograph (Haemonetics, Braintree, MA)[168]	Viscoelastic	Thrombin (native), ADP, arachidonic acid	Post CPB, liver transplant, pediatrics, obstetrics, drug efficacy
Sonoclot (Sienco, Arvada, CO)[287]	Viscoelastic	Thrombin (native)	Post CPB, liver transplant
ROTEM (TEM Systems, Durham, NC)[169]	Viscoelastic	Thrombin (native)	Post CPB, transfusion algorithm
HemoSTATUS (Medtronic Perfusion Services, Minneapolis, MN)[149]	ACT reduction	PAF	Post CPB, DDAVP, transfusion algorithm
Plateletworks (Helena Laboratories, Beaumont, TX)[269]	Platelet count ratio	ADP, collagen	Post CPB, drug therapy
PFA-100 (Siemens Medical Solutions USA, Malvern, PA)[288]	In vitro bleeding time	ADP, epinephrine	vWD, congenital disorder, aspirin therapy, post CPB
VerifyNow (Accriva Diagnostics, Accumetrics, San Diego, CA)[289]	Agglutination	TRAP, ADP	GpIIb/IIIa receptor blockade therapy, drug therapy, post-CPB
Clot Signature Analyzer (Xylum, Scarsdale, NY)[290]	Shear-induced in vitro bleeding time	Collagen (one channel only)	Post CPB, drug effects
Whole-blood aggregometry[151]	Electrical impedance	Multiple	Post CPB
Impact Cone and Plate(let) Analyzer (Matis Medical, Beersel, Belgium)[291]	Shear-induced platelet function	None	Post CPB, congenital disorder, drug effects
Multiplate Analyzer (Roche Diagnostics, Indianapolis, IN)[292]	Electrical impedance	ADP, arachidonic acid, collagen, ristocetin, TRAP-6	Drug therapy, congenital disorder, post CPB

coagulation status. The changes that occur in the viscosity of blood as it clots could be studied and measured, and this information would reflect certain aspects of coagulation function. During the early part of the 20th century, many primitive viscometers were developed that used the basic mechanisms and principles on which modern viscoelastic tests are based. Bedside coagulation tests based on these principles demonstrate utility in real-time diagnostic decision making (ie, treating coagulopathy following CPB), and they also show promise in risk stratification and bleeding risk prediction. Viscoelastic testing has been increasingly studied, yet the technique is plagued by questions of reliability and reproducibility. In 2011, the TEG-ROTEM International Working Group published results of an effort to standardize and compare reproducibility in the two devices using platelet rich plasma and factor VIII–deficient plasma from nine different laboratories.[164] Overall coefficient of variance exceeded 10% for both devices in all parameters, with some values as high as 40%. This difference in values from location to location is a major obstacle in the acceptance and reliability of these types of devices.

Thromboelastography

The coaguloviscometers developed in the 1920s formed the basis of viscoelastic coagulation testing that is now known as thromboelastography. Thromboelastography in its current form was developed by Hartert[165] in 1948 and has been used in many different clinical situations to diagnose coagulation abnormalities. Although not truly portable, the Thrombelastograph (TEG, Haemonetics, Braintree, MA) can be used on site either in the operating room or in a laboratory and provides rapid whole-blood analysis that yields information about clot formation and clot dissolution (Table 19.6 and Fig. 19.16). Within minutes, information on the integrity of the coagulation cascade, platelet function, platelet-fibrin interactions, and fibrinolysis is obtained. The principle is as follows: whole blood (0.36 mL) is placed into a plastic cuvette into which a plastic pin is suspended; this plastic pin is attached to a torsion wire that is coupled to an amplifier and recorded; the cuvette then oscillates through an arc of 4 degrees, 45 minutes at 37°C. When the blood is liquid, movement of the cuvette does not affect the pin. However, as clot begins to form, the pin becomes coupled to the motion of the cuvette, and the torsion wire generates a signal that is recorded. The recorded tracing can be stored by computer, and the parameters of interest are calculated using a simple software package. Alternatively, the tracing can be generated online with a recording speed of 2 mm/min. The tracing generated has a characteristic conformation that is the signature of the TEG (Fig. 19.17). The most current commercially available Thrombelastograph incorporates this viscoelastic measurement into a cartridge-based

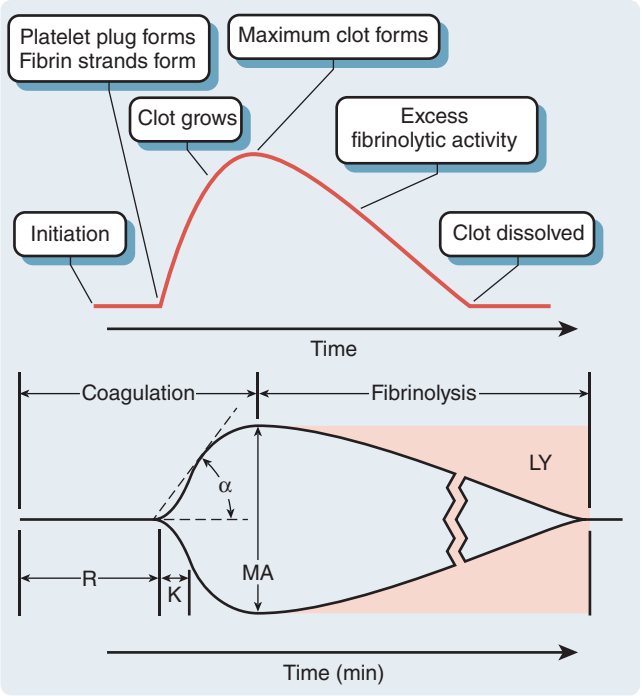

Fig. 19.16 Normal Thrombelastograph (TEG, Haemonetics, Braintree, MA) tracing with standard parameters. *R* is the reaction time or the latency time from placing blood in the cup until the clot begins to form and the tracing opens to 2 mm (typically relates to function or amount of coagulation factors). *K* is a parameter arbitrarily assigned as the time between the TEG trace reaching 2 mm and going up to 20 mm (thought to reflect fibrinogen levels). α is the angle between the line in the middle of the TEG tracing and the line tangential to the developing TEG tracing (predictive of maximal amplitude). *MA* is maximal amplitude (largest measured width on the TEG tracing) is considered to represent maximal thrombin-induced platelet activity and clot formation (total clot strength representing platelet function and clot interactions); LY is lysis index, which is the percent of lysis, typically measured as LY30 or 30 minutes after achieving MA.

hemostasis test, thus eliminating the need for blood pipetting and reducing the instrument sensitivity to motion.

The specific parameters measured by TEG include the reaction time (R value), coagulation time (K value), "α" angle, maximal amplitude (MA), amplitude 60 minutes after the maximal amplitude (A60), and clot lysis indices at 30 and 60 minutes after MA (LY30 and LY60,

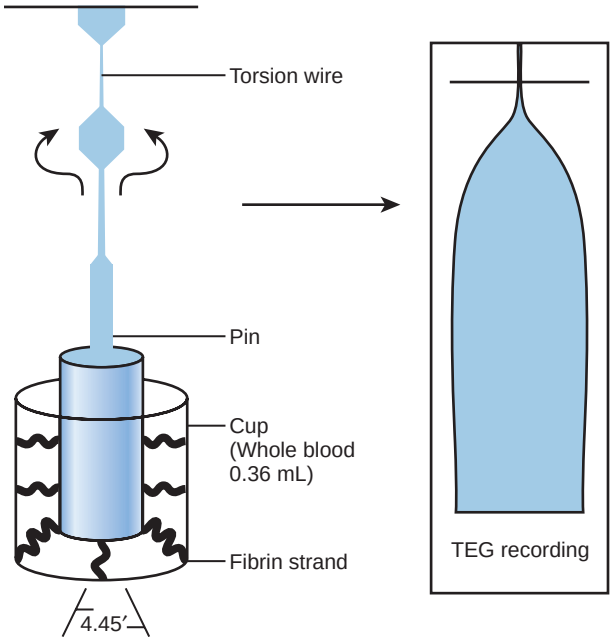

Fig. 19.17 Schematic diagram of Thrombelastograph (*TEG;* Haemonetics, Braintree, MA) instrumentation *(left)* and a sample tracing *(right).* A whole-blood sample is placed into the cup into which a plastic pin is suspended. respectively) (Fig. 19.18). The R value represents the time for initial fibrin formation and measures the intrinsic coagulation pathway, the extrinsic coagulation pathway, and the final common pathway. R is measured from the start of the bioassay until fibrin begins to form, and the amplitude of the tracing is 2 mm. Normal values vary by activator, but they range from 7 to 14 minutes using celite activator, or in the rapid TEG from 1 to 3 minutes using tissue factor activator. The K value is a measure of the speed of clot formation and is measured from the end of the R time to the time the amplitude reaches 20 mm. Normal values (3–6 minutes) also vary with the type of activators used. The α angle, another index of speed of clot formation, is the angle formed between the horizontal axis of the tracing and the tangent to the tracing at 20-mm amplitude. The α values normally range from 45 to 55 degrees. Because both the K value and the α angle are measures of the speed of clot strengthening, each is improved by high levels of functional fibrinogen. MA (normal is 50–60 mm) is an index of clot strength as determined by platelet function, the cross-linkage of fibrin, and the interactions of platelets with polymerizing fibrin. The peak strength of the clot, or the shear elastic modulus "G," has a curvilinear relation with MA and is defined as follows: G = (5000 MA) / (96 – MA). The percentage reduction in MA after 30 minutes reflects the fibrinolytic activity present and normally is not more than 7.5%.

Characteristic TEG tracings can be recognized to indicate particular coagulation defects. A prolonged R value indicates a deficiency in coagulation factor activity or level and is seen typically in patients with liver disease and in patients receiving anticoagulant agents such as warfarin (Coumadin) or heparin. MA and the α angle are reduced in states associated with platelet dysfunction or thrombocytopenia and are reduced even further in the presence of a fibrinogen defect. LY30, or the lysis index at 30 minutes after MA, is increased in conjunction with fibrinolysis. These particular signature tracings are depicted in Fig. 19.19.

TEG is a useful tool for diagnosing and treating perioperative coagulopathy in patients undergoing cardiac surgical procedures because of a variety of potential coagulation defects that may exist.[166,167] Within 15 to 30 minutes, on-site information is available regarding the integrity of the coagulation system, the platelet function, fibrinogen function, and fibrinolysis.[168,169] With the addition of heparinase, TEG can be performed during CPB and can provide valuable and timely information regarding coagulation status.[170] Because TEG is a viscoelastic test and evaluates whole-blood hemostasis interactions, proponents suggest that TEG is a more accurate predictor of postoperative hemorrhage than are routine coagulation tests.[168,170,171] Detractors of POC testing point to variance in the results with the earlier instruments and to some evidence that standard parameters have better correlation with bleeding.[163,172] Central laboratory testing certainly has its drawbacks in the surgical setting. In a prospective study of 16-hour postoperative blood loss, Gravlee and associates[173] reported on 897 cardiac surgical patients in whom routine coagulation tests were measured immediately on heparin reversal in the operating room. The weak correlations and poor predictive values of these tests confirmed that these tests perform poorly as predictors of bleeding. TEG was not studied in this trial. Currently the greatest area of benefit with viscoelastic coagulation testing is its use in goal-directed transfusion therapy.

Thromboelastography Modifications

Thromboelastography was originally performed using recalcified citrated whole blood or celite activator. More recent modifications of the original TEG reaction include the Rapid TEG, Functional Fibrinogen, and PlateletMapping (Haemonetics, Braintree, MA). Rapid TEG uses recombinant human tissue factor as an activator to accelerate the rate of thrombin formation and thus the formation of fibrin and stable clot.[174] Rapid TEG has been used to a great degree in trauma settings because the added tissue factor activator shortens the R time to less than 1 minute, and the time to obtain the MA is usually 20 minutes. Disadvantages include loss of some sensitivity to the coagulation factor component of the standard R time. Studies in trauma indicate the utility of TEG in diagnosing trauma-induced coagulopathy, as well as accelerated fibrinolysis, which has been used in a risk prediction model with correlations with mortality rates in trauma.[174–178]

A new application of thromboelastography in the clinical setting is its use in monitoring platelet receptor blockade in patients treated with specific antiplatelet agents.[179,180] In a platelet-rich plasma research model, TEG with tissue factor acceleration and the addition of large concentrations of GpIIb/IIIa-receptor blockers yields an MA value that is reduced from baseline by a degree relative to the platelet inhibition.[179] These TEG MA values correlate strongly with thrombin receptor agonist peptide (TRAP)–activated aggregation studies.

Because the MA is a function of the platelet-fibrinogen interaction, a reduction in the MA can be accomplished by the addition of potent GpIIb/IIIa-receptor blockade to the assay. The resultant MA reflects the fibrinogen concentration and the strength of fibrin alone. This value correlates with plasma fibrinogen concentration and is marketed as the functional fibrinogen test. Functional fibrinogen testing has been validated for use in the TEG system and allows for rapid evaluation of functional levels of fibrinogen.[181] Publications on this test have been limited, and some more recent studies have questioned the correlation of functional fibrinogen levels in clinical applications such as cardiac surgical procedures or in general surgical patients.[182,183]

The thienopyridine ADP receptor blockers clopidogrel, prasugrel, and ticagrelor are widely used in cardiovascular medicine (see Chapter 35).[184] The ability to measure the platelet defect induced by these drugs is difficult unless sophisticated laboratory techniques such as ADP aggregometry are used. Routine TEG analysis does not measure the thienopyridine-induced platelet defect because the formation of thrombin in the assay has an overwhelming effect on the development of the MA. PlateletMapping is a modification of TEG that assesses platelet function by comparing the MA tracing induced by activation with arachidonic acid (AA) or ADP receptors (MA_{pi}) to the MA achieved with no platelet activity (MA_{f}), and with maximal platelet activation (MA_{kh}). For PlateletMapping, the reaction is carried out in the setting of heparinized blood, thus inhibiting thrombin platelet activation. The MA produced in this setting, when reptilase and

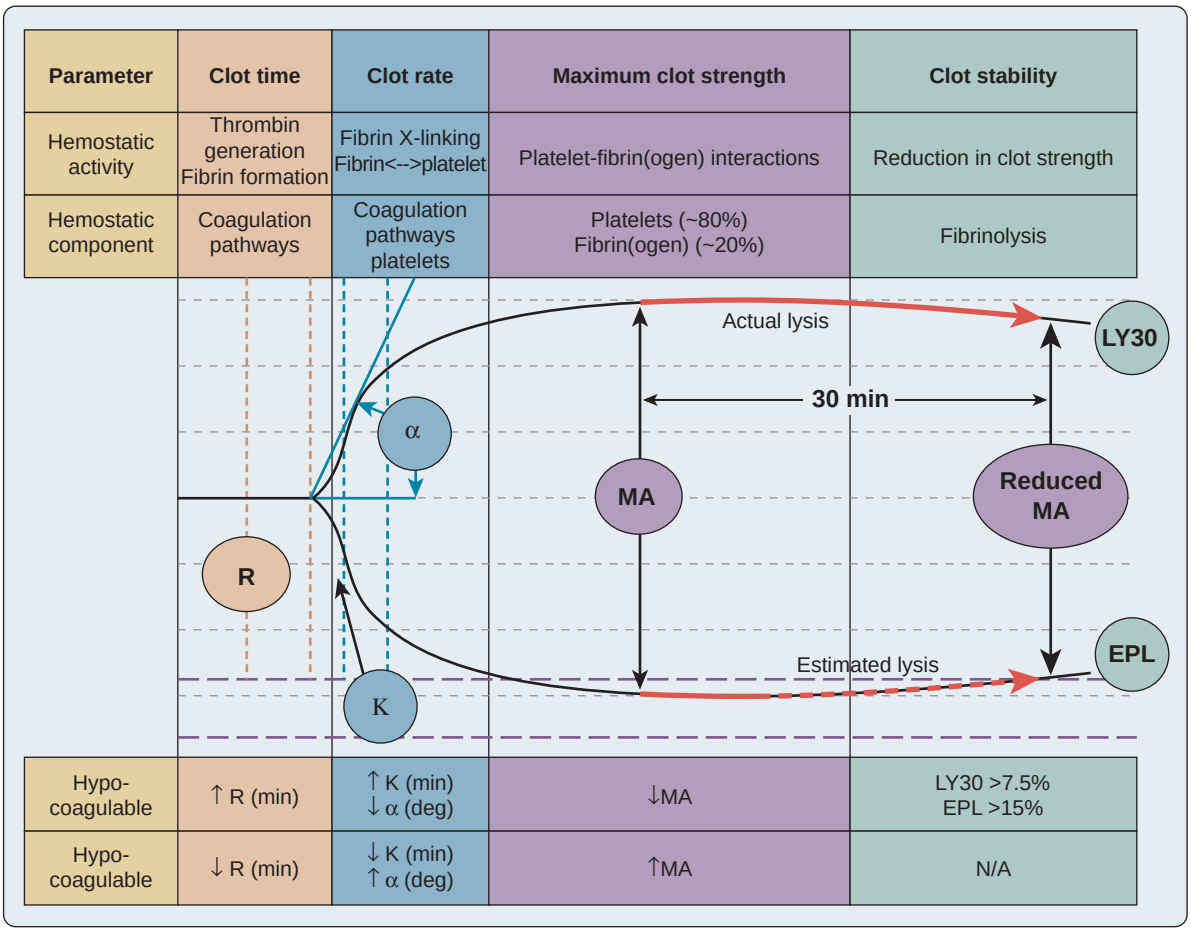

Fig. 19.18 Normal Thrombelastograph (TEG, Haemonetics, Braintree, Mass) tracing with standard parameters. α, An angle between the line in the middle of the TEG tracing and the line tangential to the developing TEG tracing (predictive of maximal amplitude); *K*,A parameter arbitrarily assigned as the time between the TEG trace reaching 2 mm and going up to 20 mm (may represent fibrinogen levels); *LY*, lysis index; *MA*, maximal amplitude, considered to represent maximal thrombin-induced platelet activity and clot formation (total clot strength representing platelet function and clot interactions); *R*, reaction time or the latency time from placing blood in the cup until the clot begins to form, reaching a TEG tracing amplitude of 2 mm (typically relates to function or amount of coagulation factors).

factor XIII are used to form the clot, is the MA with "no platelet activity," or MA_f (fibrin). The MA_{pi} is the maximal activation of platelets and fibrin and is the largest-amplitude that can be achieved with the specific platelet activators (ADP or AA). MA_{pi} (platelet inhibitor) tracings are compared with the MA_f. In addition, a standard kaolin-heparinase–activated TEG tracing is created to demonstrate maximal platelet activation that occurs when thrombin is present (MA_{kh}) (Fig. 19.20). The following formula calculates the percentage reduction in platelet activity using this assay:

$$\%\,\text{inhibition} = 100 - [(MA_{pi} - MA_f)/(MAkh - MA_f) \times 100]$$

PlateletMapping has demonstrated consistent correlation with optical platelet aggregation assays.[185–187]

PlateletMapping has implications in clinical models, and numerous publications now exist. Studies demonstrate sensitivity in detecting aspirin resistance,[188] as well as updated timeframes on when platelet function returns following cessation of clopidogrel therapy.[189] The Timing Based on Platelet Function Strategy to Reduce Clopidogrel-Associated Bleeding Related to CABG (TARGET-CABG) study published by Mahla and colleagues[190] in 2012 investigated the utility of PlateletMapping in stratifying the waiting period for patients needing coronary artery bypass grafting (CABG) who were taking clopidogrel. Results indicated not only that PlateletMapping could be used to individualize this waiting period based on platelet activity, but also that a 50% reduction in these wait times occurred without any increased bleeding complications.[190] PlateletMapping has been shown to be useful in prediction of post-CPB bleeding in multiple small-scale studies, mostly in patients receiving antiplatelet medications.[191–193] The percentage of inhibition, as well as the MA_{ADP} was shown to predict postoperative chest tube output, which was the strategy used in the TARGET-CABG trial.[190,191,193] Finally, TEG reports on the overall clot strength (G), which has been shown to be related to mortality rates in trauma,[194] and a specific ADP-activated platelet clot strength model was proposed that was associated with poststenting ischemic events.

Sonoclot

Another test of viscoelastic properties of blood is the Sonoclot. In 1975, von Kaulla introduced the Sonoclot Analyzer (Sienco, Arvada, CO), which is a coagulation analyzer that measures the changing impedance on an ultrasonic probe immersed in a coagulating blood sample.[195] A tubular probe oscillates up and down at an amplitude of 1 μm and a frequency of 200-Hz within the disposable cuvette containing the blood sample. As fibrin formation occurs, the sample exerts viscous drag, or resistance, on the probe that does not allow the probe to vibrate freely. This resistance is electronically converted into an

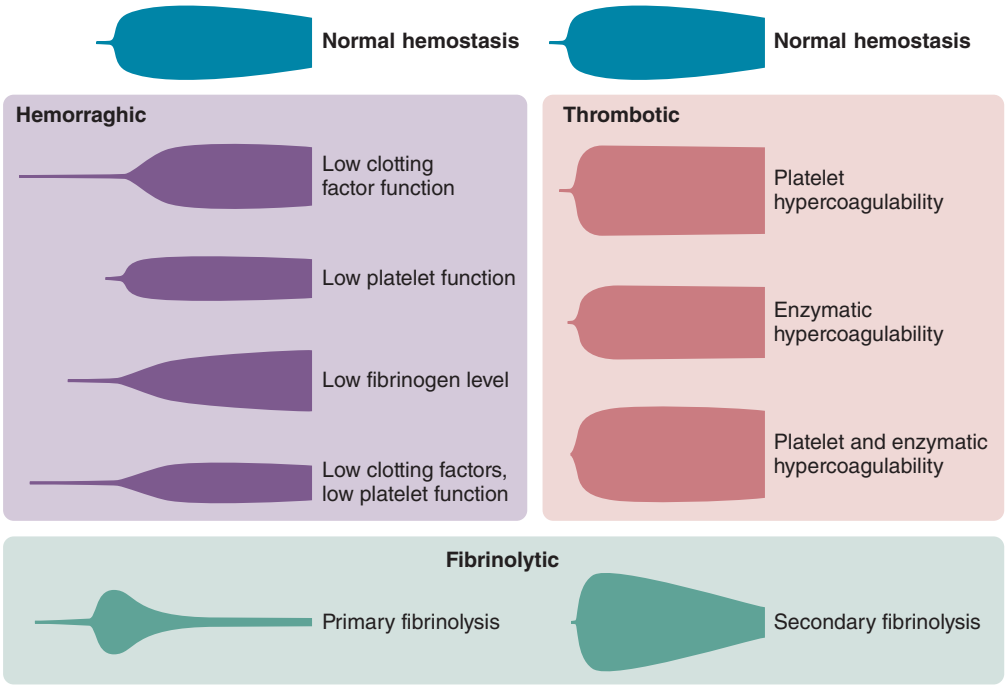

Fig. 19.19 Thrombelastograph (TEG, Haemonetics, Braintree, MA) tracings in various coagulation states.

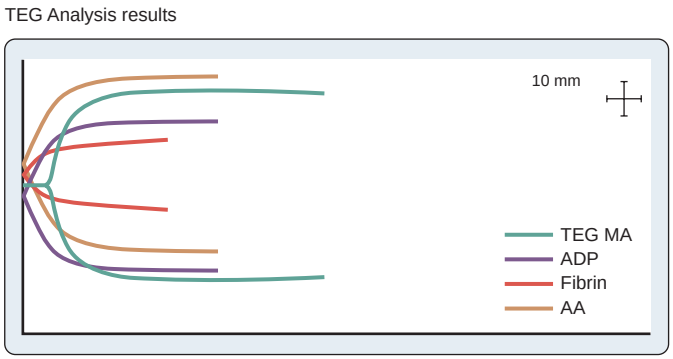

Fig. 19.20 Multitracing displaying standard four reactions involved in the PlateletMapping modification of the Thrombelastograph (TEG, Haemonetics, Braintree, MA). The percentage of inhibition (% inhibition) of platelets is calculated according to the following equation: % inhibition = 100 – [(MApi – MAf) / (TEG MA – MAf) × 100] where MAf is maximum amplitude of fibrin-activated curve, MApi is maximum amplitude by specific platelet activators (either adenosine diphosphate *[ADP]* or arachidonic acid *[AA]*, and *TEG MA* is maximum amplitude of kaolin-activated TEG.

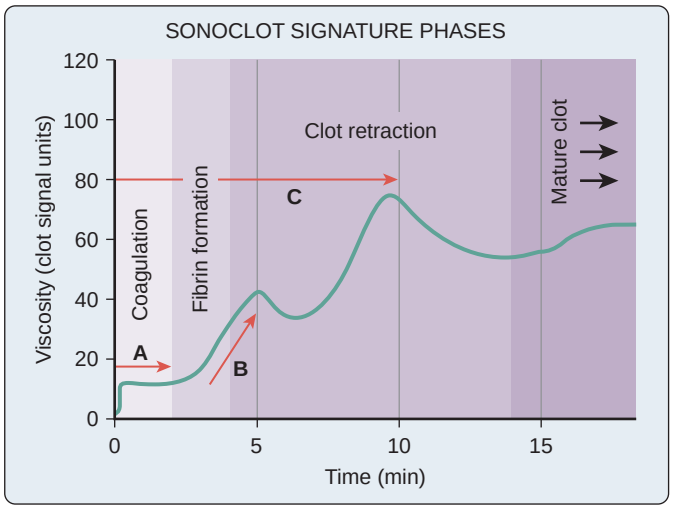

Fig. 19.21 Sonoclot (Sienco, Arvada, CO) Signature phases. *A*, Onset time or activated clotting time; *B*, clot rate; and *C*, time to peak, also known as platelet function time.

output signal, called the Sonoclot Signature (Fig. 19.21). The Sonoclot Signature reflects coagulation in real time, from the start of fibrin formation, to fibrin cross-linkage, platelet-mediated clot strengthening, and, eventually, to clot retraction and fibrinolysis.

The Sonoclot Signature is defined by three distinct parameters: the Onset or ACT, the Clot Rate (CR), and the Time to Peak (TP), which is also referred to as Platelet Function. The ACT is the time for initial fibrin formation and is defined as the time taken to reach an amplitude of 1 mm represented by point A in Fig. 19.21. This is measured in seconds, corresponds to the Hemocron method for ACT, and is typically shorter than the R time in the TEG because the TEG R time reflects a more developed stage of fibrin clot development.[187] The CR phase encompasses two peaks on the Signature trace, and the CR represents the maximal slope based on the rate of fibrin formation. The rate of rise of the first peak represented by point B is expressed as the percentage of the peak amplitude per unit time (normal values, 18–45%). Typically, a shoulder or a dip occurs before the second rise in amplitude and subsequent peak that results from the action of platelets and fibrin in producing clot retraction. As the clot retracts from the walls of the cuvette, the impedance to vibration briefly decreases. As fibrinogen converts to fibrin and fibrin polymerizes, the speed of clot formation and the platelet-fibrin interactions are represented by the TP, which is represented by point C. In the presence of greater concentrations of fibrinogen, a larger clot mass is represented by a greater amplitude of the second peak because of a greater impedance to vibration. The amplitude of this peak is therefore related to the concentration of normal functional fibrinogen. The subsequent downward slope that occurs results from platelet-mediated clot retraction that causes plasma expulsion and clot size diminution and thus reduced impedance. The magnitude of the clot retraction reflects platelet number and

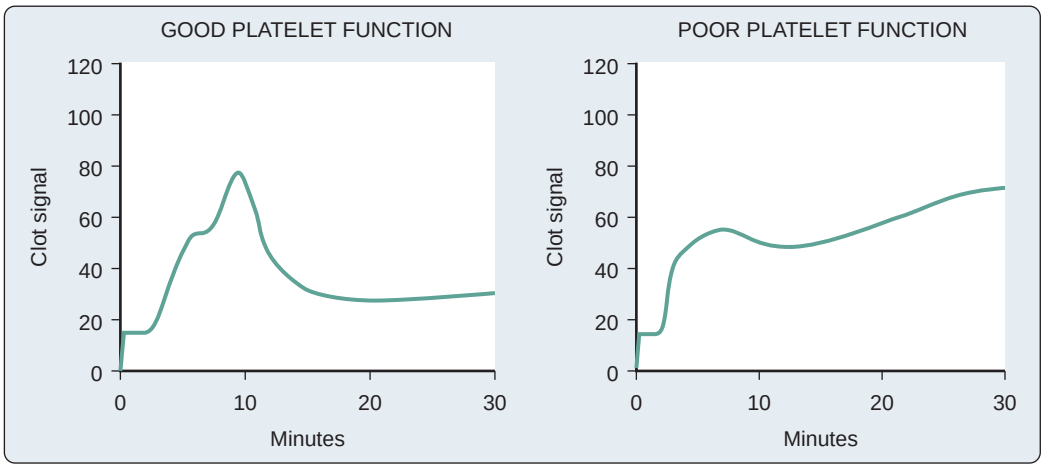

Fig. 19.22 Comparison of a normal Sonoclot (Sienco, Arvada, CO) tracing with a tracing in the setting of poor platelet function. Notice the lack of clot retraction and the slow uptrending curve on the right tracing.

function. Fig. 19.22 demonstrates a tracing with normal and abnormal platelet function.

Sonoclot has been studied and used in both the clinical setting and the research laboratory. As with other POC devices, frequent applications are in the perioperative setting, the catheterization laboratory, intensive care unit, and specialty clinics.[196–199] Early studies along with TEG demonstrated an accuracy of 74% using Sonoclot and an accuracy of 88% using TEG to predict bleeding after cardiac surgical procedures.[170] The reason that viscoelastic tests have been able to predict bleeding so successfully probably relates to their ability to measure platelet function, a major determinant of postoperative hemostasis.[200] Significant correlations have been documented between specific Sonoclot parameters and platelet count and coagulation factor assays. This reproducibility has allowed the use of Sonoclot also to predict and successfully treat coagulation abnormalities in patients undergoing liver transplantation.[201] Published studies indicate Sonoclot's utility in the setting of coagulopathy from CPB,[199] monitoring the use of recombinant factor VIIa,[202] and coagulation changes associated with the use of colloid starches.[197] A novel application is to evaluate hypercoagulabilty associated with oral contraceptive use in women.[196] In addition, Sonoclot was used in combination with HIT to study the clotting reaction to heparin, and it may result in an improved screening tool for HIT.[203]

ROTEM (Rotational Thrombelastometry)

Rotational Thrombelastometry (ROTEM, TEM Systems, Durham, NC) gives a viscoelastic measurement of clot strength in whole blood. A small amount of blood and coagulation activators is added to a disposable cuvette that is then placed in a heated cuvette holder. A disposable pin (sensor) that is fixed on the tip of a rotating shaft is lowered into the whole-blood sample. The loss of elasticity on clotting of the sample leads to changes in the rotation of the shaft that is detected by the reflection of light on a small mirror attached to the shaft. A detector records the axis rotation over time, and this rotation is translated into a graph or thromboelastogram. ROTEM functions to measure changes in viscoelastic properties of clot formation in a fashion similar to that of TEG, but with some key differences.

The main descriptive parameters associated with the standard ROTEM tracing (Fig. 19.23) are the following:

- CT (clotting time): corresponding to the time in seconds from the beginning of the reaction to an increase in amplitude of the tracing of 2 mm. It represents the initiation of clotting, thrombin formation, and start of clot polymerization.
- CFT (clotting formation time): the time in seconds of an increase in amplitude from 2 to 20 mm. This identifies the fibrin polymerization and stabilization of the clot with platelets and factor XIII.
- Alpha (α) angle: the tangent to the clotting curve through the 2-mm point. It reflects the kinetics of clotting. Therefore, a larger α angle reflects the rapid clot formation mediated by thrombin-activated platelets, fibrin, and activated factor XIIIfactor XIIIa); CFT becomes shorter as the alpha angle becomes larger, and the two parameters are closely linked.
- A10 (amplitude obtained at 10 minutes): this directly relates to maximum clot firmness and can be used to predict MCF and platelet function.
- MCF (maximum clot firmness): the maximum amplitude in millimeters reached in the tracing that correlates with platelet count, platelet function, and with the concentration of fibrinogen
- LI30 (lysis index % at 30 minutes): a parameter representing fibrinolysis at a determined time point (typically 30 minutes). It correlates to the MCF (clot % remaining).
- ML (maximum lysis): this is the ratio of the lowest amplitude after reaching the maximum clot firmness to the maximum clot firmness. Like the LI30, this parameter can evaluate for hyperfibrinolysis.

ROTEM has been used extensively in Europe and increasingly in the United States after receiving approval from the US Food and Drug Administration (FDA) in 2011. ROTEM tests coagulation by using various reagents (Table 19.7), and the most common tests include INTEM (intrinsic system), EXTEM (extrinsic system), HEPTEM (intrinsic system in presence of heparin), FIBTEM (measures fibrinogen activity), and APTEM (tissue factor activation + tranexamic acid or aprotinin). Standard ROTEM reactions are conducted on the ROTEM Delta platform (Fig. 19.24). Fig. 19.25 provides an example of a series of ROTEM reactions for a hematologically normal patient, compared with a patient with platelet dysfunction.

In 2015, ROTEM released a module (see Fig. 19.24) that attaches to the standard Delta platform that adds the capability to monitor platelet aggregation function in response to three platelet agonists (ADP, AA, and TRAP) called the ADPTEM, ARATEM, and TRAPTEM, respectively. This system functions using the same concept as standard whole-blood aggregometry and is similar to the Multiplate aggregometer (described in detail later). Differences between ROTEM and TEG include the method for detection of viscoelastic changes and the sensitivity to movement. Investigators have suggested that the variance for ROTEM may be lower than for TEG.[204] Significant numbers of published studies of adult and pediatric patients support the use of ROTEM to evaluate various aspects of coagulation abnormalities.[169,205–219]

TABLE 19.7 Standard Rotational Thrombelastometry Reagents and Assessment Pattern

EXTEM	Tissue factor activation; factors VII, X, V, II, I, platelets, and fibrinolysis
INTEM	Contact phase activation; factors XII, XI, IX, VIII, II, I, platelets, and fibrinolysis
FIBTEM	EXTEM + cytochalasin D (platelet blocking); assessment of fibrinogen
APTEM	EXTEM plus aprotinin; useful to rule out fibrinolysis when compared to EXTEM
HEPTEM	INTEM plus heparinase; useful to detect residual heparin

APTEM, Tissue factor activation + tranexamic acid/aprotinin; *EXTEM,* extrinsic system; *FIBTEM,* measure of fibrinogen activity; *HEPTEM,* intrinsic system in presence of heparin; *INTEM,* intrinsic system.

Transfusion Algorithms, Bleeding Prediction, and Comparisons of Viscoelastic Testing

Espinosa and associates[218] reported a comparison of TEG, ROTEM, and Sonoclot in 35 patients undergoing elective CABG with sample collection for all three tests before bypass, 1 hour postoperatively, and at 24 hours. All the TEG parameters measured, the ROTEM parameters (CT/CFM), and the ACT value for Sonoclot showed differences after bypass and could be used to track changes in hemostasis during surgical procedures. Plasma fibrinogen level correlated well with TEG, ROTEM, and Sonoclot assays at all time points. Correlations with standard laboratory tests were difficult to interpret and underscore the difference in using POC whole-blood testing versus plasma-based tests. INR did not correlate with TEG R time, ROTEM CT, or Sonoclot ACT.

The largest impact of POC testing, however, has been in the development of goal-directed transfusion algorithms based on POC results. Initial research in the 1990s, including a retrospective evaluation in more than 1000 patients by Spiess and colleagues,[219] found that the institution of a transfusion algorithm using TEG resulted in a significant reduction in the incidence of mediastinal exploration and in the rate of transfusion of allogeneic blood products. This study was followed by a prospective trial by Shore-Lesserson and associates[220] in 105 patients assigned to algorithm-based transfusion decisions versus clinical judgment. Results demonstrated reductions in transfused

products in the POC testing group and set the stage for future studies looking into algorithm-based approaches to transfusion.[220] Numerous studies now support this concept using TEG, ROTEM, and platelet function testing such as Multiplate Aggregometry (MEA) (see later).

A review by Gorlinger and colleagues[221] in 2013 quantified 16 studies including both retrospective and prospective trials totaling 8507 patients. The authors reported benefits including consistent reductions in transfusion products using POC-guided algorithms, with the greatest effect in patients with more complex coagulopathy, reduced re-exploration for bleeding, reduced massive transfusion, and overall hospital costs.[169,217,219,220,222–234] Four of these studies demonstrated improvements in patient-related outcomes including reductions in intensive care unit stay, thrombotic events, pulmonary dysfunction, ventilator time, and 6-month mortality rates.[217,224,225,234] A Cochrane review in 2011 that did not include many of these studies indicated fewer transfusions and fewer bleeding complications.[235] More recently, Mishra and associates[236] published a small observational trial in patients undergoing CABG and receiving antiplatelet medications and tested standard TEG along with MEA. These investigators reported that increased bleeding complications in patients receiving antiplatelet agents were best predicted by abnormal test results with MEA. This finding was not surprising because standard TEG does not specifically test platelet function in a comparable manner.[236] Karkouti and colleagues[237] published a retrospective comparison study after institution of a new algorithm using both ROTEM and platelet function testing with Plateletworks in 1170 patients, compared with 1311 cases "pre-algorithm." Results were in line with those of previous studies, indicating reduced transfusion requirements for all products (packed red blood cells, fresh frozen plasma, and platelets).

An interesting innovation with the concept of transfusion algorithms was published by Welsh and associates in 2014.[238] This clinical pathology group established a central laboratory–based rapid testing algorithm for high-risk bleeding cases such as cardiac surgical procedures to guide transfusions. These investigators were able to achieve rapid turnaround of standard clinical laboratory tests such as fibrinogen, PT/PTT/INR, and TEG and VerifyNow results. Initial results suggested their ability to return these test results in as little as 15 to 30 minutes, and preliminary outcomes indicated reductions in blood product transfusions.[238] The utility of POC-guided transfusion algorithms is not isolated to cardiac surgical procedures because these algorithms have also shown promise in trauma settings.[239] Tapia and colleagues[239] reported that a TEG-based transfusion algorithm may improve trauma mortality rates compared with the 1:1:1 massive transfusion protocol, and in some situations higher ratios of plasma or platelets may be advantageous. In conclusion, POC is likely to have the greatest clinical impact in patients with complex coagulopathy and in guiding transfusion practices. Important considerations beyond the use of algorithms include the content of the algorithm itself. In addition to allogeneic blood products, various pharmacologic hemostatic agents and recombinant agents, such as fibrinogen concentrate, prothrombin complex concentrate, and factor VIIa, are being introduced into algorithms guided by POC testing (Fig. 19.26).

Point-of-Care Tests of Platelet Response to Agonists

In contrast to viscoelastic testing, various platforms are now available as POC devices that allow for platelet function testing in response to agonists. Each system uses unique concepts, although most have been well validated with laboratory-based light transmission aggregometry (LTA), and some have been validated with the previously described viscoelastic tests. Some methods described here are included for historical purposes only, given that they are not readily available, whereas others are in use clinically.

HemoSTATUS

HemoSTATUS (Medtronic Perfusion Systems, Minneapolis, MN) was a POC platelet function assay that used the Hepcon HMS monitoring system to measure platelet reactivity. A six-channel cartridge measured the heparinized kaolin–activated ACT without platelet activator (channels 1 and 2) and with incrementally increasing doses of platelet-activating factor (PAF; channels 3 to 6). The respective doses of PAF in channels 3 through 6 were 1.25, 6.25, 12.5, and 150 nmol/L. For each channel 3 through 6, the degree of shortening of the ACT as a ratio to the ACT without PAF was the "clot ratio" and was calculated as $1 - (ACT_{activated} / ACT_{control})$. A comparison of the patient's clot ratio with the maximal clot ratio (derived from normal volunteers) yielded a comparative measure of platelet function, termed the "percentage of maximal platelet function." Several studies looked into this test in the late 1990s, but this POC platelet function assay is no longer available.[161,240–243]

VerifyNow

VerifyNow (Accumetrics, San Diego, CA) is a POC monitor (previously called Ultegra) initially designed to measure the platelet response to a TRAP and is approved by the FDA for use as a platelet function assay. In whole blood, it measures TRAP activation–induced platelet agglutination of fibrinogen-coated beads by using an optical detection system. After anticoagulated whole blood is added to the mixing chamber, the platelets become activated if they are responsive to the agonist. The activated GpIIb/IIIa receptors on the platelets bind to adjacent platelets through the fibrinogen on the beads and cause agglutination of the blood and the beads. Light transmittance through the chamber is measured and increases as agglutination increases, much as in standard aggregometry. Antithrombotic drug effects cause diminished agglutination (measured by light transmittance); the degree of platelet inhibition can thus be quantified. VerifyNow has agonists to examine the antiplatelet activity of GpIIb/IIIa inhibitors, aspirin, and clopidogrel and can report and quantify the degree of platelet inhibition with good correlation with LTA.[244–246] However, the system may be less sensitive than PlateletMapping for assessment of aspirin resistance.[188] VerifyNow has been used as part of a novel pathology-based transfusion algorithm service with this algorithm as a preoperative platelet function assessment tool.[238] The platelet function testing ability of VerifyNow has been used extensively to study the response to antiplatelet medications. Ample evidence suggests increased major cardiac adverse events in nonresponders to antiplatelet therapy both in the setting of cardiac surgical procedures and in coronary stenting.[247–250]

Clot Signature Analyzer

The Clot Signature Analyzer (CSA; Xylum, Scarsdale, NY) is a global hemostasis screen that assesses both platelet function and fibrin clot formation.[251] The test has three components: platelet hemostasis time (PHT), clot time (CT), and collagen-induced thrombus formation (CITF). Whole blood is placed under a constant driving pressure of 60 mm Hg as it is forced out into a synthetic vessel. The pressure distally in the vessel is monitored. The tubing of this synthetic vessel is perforated, and the distal pressure decline is measured. The time to restoration of this distal pressure is a function of the development of a platelet plug (PHT). Thus the PHT is a measure of platelet function. A subsequent time is measured, and that is the time to complete pressure loss caused by complete vessel occlusion (CT). This clot is the result of coagulation and clot formation, and the time to the second pressure decline reflects coagulation function. Another chamber of this device contains a collagen-coated fibril on which platelets adhere and form a plug. A similar pressure measurement technique indicates the formation of a platelet thrombus and yields the CITF. In cardiac surgical patients, preoperative platelet reactivity did not have predictive accuracy for bleeding.[252] Data evaluating the CSA in the postoperative period to predict bleeding are lacking.

Platelet Function Analyzer

The Platelet Function Analyzer (PFA-100; Siemens Medical Solutions USA, Malvern, PA) is a monitor of platelet adhesive capacity that is currently approved by the FDA and is valuable in its diagnostic abilities to identify drug-induced platelet abnormalities, platelet dysfunction of von Willebrand disease, and other acquired and congenital platelet defects.[253,254] The test is conducted as a modified in vitro BT. Whole blood is drawn through a chamber by vacuum and is perfused across an aperture in a collagen membrane coated with an agonist (epinephrine or ADP). Platelet adhesion and formation of aggregates seal the aperture, thus indicating the "closure time" measured by the PFA-100.[253,255] In cardiac surgical patients, the preoperative PFA-100 closure time significantly correlated with postoperative blood loss ($r = 0.41$; $P = 0.022$).[256] However, a follow-up study was unable to demonstrate the ability of PFA-100 to differentiate low-bleeding from high-bleeding patients.[257] PFA-100 has demonstrated shear stress–induced platelet dysfunction in patients undergoing heart valve operations,[258,259] and it was used to guide therapy with desmopressin in one study.[260] PFA-100 may be used as a screening test for type II von Willebrand disease, although it does not reliably detect type I von Willebrand disease.[261,262] The PFA-100, like other platelet function tests, seems to have the greatest impact for measuring aspirin resistance in patients with coronary artery disease and coronary stents and after cardiac surgical procedures.[263–265] PFA was demonstrated to have antiplatelet sensitivity similar to that of the Multiplate analyzer, but lower sensitivity than VerifyNow.[246] Test results are more susceptible to inaccuracies as a result of collection, transfer, and transport.[266–268]

Plateletworks

Plateletworks (Helena Laboratories, Beaumont, TX) is a test that uses the principle of the platelet count ratio to assess platelet reactivity. The instrument is a Coulter counter that measures the platelet count in a standard tube containing ethylenediaminetetraacetic acid and compares this with the response to the available agonists: collagen, ADP, and AA. Addition of blood to these agonist tubes causes platelets to activate, adhere to the tube, and effectively be eliminated from the platelet count. The ratio of the activated platelet count to the nonactivated platelet count is a function of the reactivity of the platelets. Results are obtainable in less than 5 minutes. Early investigation in cardiac surgical patients indicated that this assay was useful in providing a platelet count and that it could measure platelet dysfunction that accompanies CPB[269] (Box 19.6).

Plateletworks correlates well with LTA, although results are less sensitive than with PlateletMapping for detection of the effects of aspirin and nonsteroidal antiinflammatory drugs.[186,270] Plateletworks showed utility for preoperative testing and for predicting post-CPB chest tube output, and it correlated with post-CABG transfusion requirements.[271,272] Plateletworks has also been used to monitor response to desmopressin (DDAVP) therapy for platelet dysfunction.[273] The Do Platelet Function Assays Predict Clinical Outcomes in Clopidogrel-Pretreated Patients Undergoing Elective Percutaneous Coronary Intervention (POPULAR) study published results of different POC platelet function tests in detecting resistance to clopidogrel in patients with coronary stent and found that all the assays tested differentiated responders from nonresponders. LTA, VerifyNow, Plateletworks, and PFA-100 were also associated with the composite end points of all-cause death, nonfatal acute myocardial infarction, stent thrombosis, and ischemic stroke.[274,275] In 2014, Orlov and associates[276] reported on

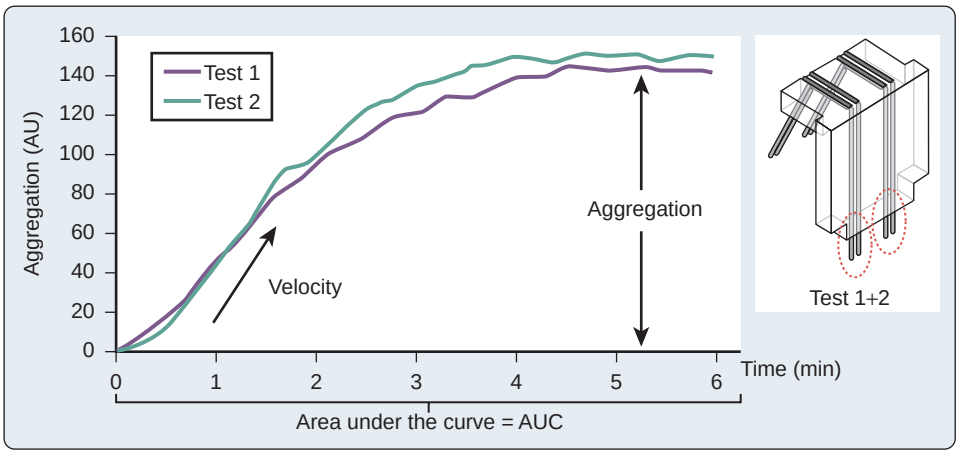

Fig. 19.27 Multiplate Analyzer (Helena Laboratories, Beaumont, TX) tracing. The attachment of platelets onto the Multiplate sensors generates an increase in impedance that is transformed into arbitrary aggregation units *(AU)* and plotted against time. During a measurement period of 6 minutes, the parameters calculated by the software are the mean values of the two curves. *(From* http://www.multiplate.net.*)*

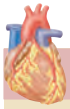

BOX 19.6 PLATELET FUNCTION TESTS

- The appropriate test to measure platelet function depends on the suspected platelet defect.
- The Thrombelastograph (TEG, Haemonetics, Braintree, MA), Rotational Thromboelastometry (ROTEM TEM Systems, Durham, NC), and thromboelastometry, and possibly other viscoelastic tests, are useful to measure platelet defects after cardiopulmonary bypass. VerifyNow (Accumetrics, San Diego, CA) and Multiplate (Helena Laboratories, Beaumont, TX) are useful to measure the effects of glycoprotein IIb/IIIa and adenosine diphosphate receptor-blocker therapy and aspirin therapy.
- The PFA-100 test (Siemens Medical Solutions USA, Malvern, PA) is useful to measure the effects of aspirin on platelet adhesion.
- It is important to understand the platelet defect being sought to use the proper test accurately.

outcomes from a prospective trial in 100 patients undergoing CPB and found that low collagen reactivity during rewarming and after protamine was predictive of excessive bleeding. This observation was in line with findings using collagen agonists in the PlateletMapping assay, in which low collagen activation was found to be predictive of bleeding.[192]

Impact Cone and Plate(let) Analyzer

In the Impact Cone and Plate(let) Analyzer (Matis Medical, Beersel, Belgium), whole blood is exposed to uniform shear by the spinning of a cone in a standardized cup. This allows for platelet function testing under conditions that mimic physiologic blood flow, thus achieving the most accurate pattern of platelet function. After automated staining, platelet adhesion to the cup is evaluated by image analysis software. The test yields two parameters: average size and surface coverage, which determine platelet function in terms of adhesion and aggregation. These values constitute a general platelet function parameter. This device identifies both congenital and acquired platelet defects, as well as the effects of antiplatelet drugs including GpIIb/IIIa antagonists, aspirin, and clopidogrel.[277] Studies suggest that the Impact Cone and Plate(let) Analyzer appears to be a useful tool for testing perioperative platelet function and may help in predicting postoperative blood loss.[278] Experience and clinical publications remain limited with this device, but a few reports focus on detection of responders and nonresponders to antiplatelet medications.[279]

Multiplate Analyzer

The Multiplate Analyzer (Roche Diagnostics, Indianapolis, IN) is a test of platelet function in whole blood that uses impedance aggregometry.[280,281] First introduced in 2005, it is one of the most widely applied platelet aggregometers in Europe today. The analysis is performed in a single-use test cell, which incorporates a magnetic stirrer, as well as two independent impedance sensors. Activated platelets adhere and aggregate on the electrodes and thus enhance the electrical resistance between them. Sample wells are available in "standard" (600 µL) test cells or "mini" test cells (360 µL). Either cell provides reliable results, but results among cell sizes are not intercomparable.[282] The resistance change is transformed to arbitrary aggregation units (AUs) and is plotted against time. The area under the aggregation curve is used to quantify the aggregation response and is expressed in units (1 unit corresponds to 10 AU/min). The mean values of the two independent determinations are expressed as the area under the curve of the aggregation tracing (Fig. 19.27). Multiple channels (or tests) can run simultaneously to evaluate pathways of platelet inhibition. Several specific test reagents are available to detect changes induced by drugs, as well as by acquired or hereditary platelet disorders. These include TRAPtest (thrombin), ASPItest (aspirin), COL test (collagen), ADPtest (clopidogrel), and RISTOtest (ristocetin factor). These reagents allow testing for platelet dysfunction associated with many of the most commonly used platelet antagonist drugs.[187]

The system has a high sensitivity for antiplatelet drugs (aspirin, clopidogrel, prasugrel, GpIIb/IIIa antagonists),[266] and it can predict thromboembolism in stent recipients who are nonresponsive to platelet inhibitors.[283] Many studies now show that Multiplate predicts transfusion requirements in cardiac surgical procedures.[236,280,281,284–286] MEA is available and used widely in Europe, but it is used only for research purposes in the United States and Canada at this time.

Summary

It is essential to understand the complex array of hemostatic insults that result from extracorporeal circulation before selecting an appropriate coagulation or hemostasis monitor during cardiac surgical procedures. Preoperative, intraoperative, and postoperative testing may be mandated for patients in whom a coagulation defect may predispose to serious degrees of postoperative coagulopathy. Even in hemostatically normal patients, CPB induces a heparin effect, platelet dysfunction,

fibrinolysis, and coagulation factor defects for which many clinical laboratory tests are available for accurate diagnoses. With the increase in prescriptions for antithrombotic platelet inhibitors, the hemostatic defect after CPB is even more pronounced. This chapter has introduced the basic principles of hemostasis and the utility of many commonly used monitors for detecting disorders of the coagulation cascade, platelet function, and fibrinolysis. In addition, an increased emphasis on health care economics has created a milieu in which patients have a rapid transit time through the cardiac operating room with minimal exposure to allogeneic blood products. Prophylactic measures such as heparin-bonded circuitry and antifibrinolytic agents have reduced the actual incidence of microvascular bleeding in this population. However, when microvascular bleeding does occur, rapid diagnosis and therapeutic intervention are made possible by POC hemostasis testing, which can take place directly in the operating room. If on-site testing is not available or does not provide sufficient timely information regarding the patient's coagulation defect, transfusion therapy for cardiac surgical patients will remain indiscriminate and empiric at best.

Anesthesia for Myocardial Revascularization

ALEXANDER J.C. MITTNACHT, MD | MARTIN J. LONDON, MD | JOHN D. PUSKAS, MD | JOEL A. KAPLAN, MD, CPE, FACC

KEY POINTS

1. Guideline updates emphasize the efficacy of surgical approaches to myocardial revascularization in patients with multivessel coronary artery disease.
2. Perioperative risk reduction includes careful consideration of all of the patient's relevant antihypertensive, antiplatelet, and antianginal medications.
3. Significant valvular abnormalities in patients scheduled for coronary revascularization should be evaluated and considered in surgical planning.
4. Off-pump coronary artery bypass surgery is an established alternative to on-pump myocardial revascularization (ie, coronary artery bypass grafting [CABG]). The choice and outcomes of either approach are highly surgeon dependent. Despite apparent advantages of avoiding cardiopulmonary bypass (CPB), evidence from large prospective trials enrolling mostly low-risk patients has not shown clear reductions in mortality with an off-pump approach.
5. Mitral valve repair for ischemic mitral regurgitation (MR) at the time of coronary revascularization is still controversial; however, it should probably be considered in patients who have a dilated annulus and at least moderate ischemic MR.
6. Possible indications for pulmonary artery catheter use in CABG surgery include patients with pulmonary hypertension, right-sided heart failure, or severely impaired ventricular function, particularly those who require postoperative cardiac output monitoring.
7. Fast-tracking, including early extubation and mobilization, has been almost universally adopted for patients undergoing myocardial revascularization.
8. Anesthetic drugs, especially inhaled anesthetic agents, may help to ameliorate myocardial injury associated with CPB and aortic cross-clamping by their preconditioning and postconditioning effects. However, the magnitude of these effects on outcome remains controversial.

The role of the cardiac anesthesiologist in the perioperative care of patients undergoing myocardial revascularization continues to evolve. Achievements of the past 2 decades include providing safe anesthesia that allows rapid recovery and optimizing monitoring that includes the establishment of transesophageal echocardiography (TEE) as a standard of care in the cardiac operating room. More recent developments in patient care include the introduction of a perioperative surgical home, which affects the management of patients undergoing myocardial revascularization.

The anesthesiologist is vitally important in the multidisciplinary approach to patient care. Optimal perioperative care requires close collaboration and coordination between the various specialties involved on the heart team.[1,2] The process begins with the decision to proceed to surgery and continues with preoperative optimization, state-of-the art perioperative and postoperative care, and rehabilitation after hospital discharge.[3–5]

Epidemiology

According to the American Heart Association Heart Disease and Stroke Statistics, most recently updated in 2014,[6] epidemiologic data relevant to cardiovascular disease can be summarized as follows. Overall rates of death attributable to cardiovascular disease have declined 31%; for CAD, including a 39.2% decrease from 2000 to 2010. This was partially attributed to improvements in acute treatment of patients with acute coronary syndromes (ACSs), secondary preventive therapies after myocardial infarction (MI), treatment of acute heart failure (HF), revascularization of chronic CAD, and other preventive therapies. However, the prevalence remains high, with cardiovascular disease accounting for 31.9% of all deaths in the United States. Based on current estimates, by 2030, 43.9% of the US population will have some form of cardiovascular disease. Similarly, 15.4 million individuals had CAD in 2010; and ischemic heart disease causes approximately 1 of every 6 deaths in the United States. In 2010, 379,559 Americans died of CAD, and statistically, every 34 seconds one person in the United States has a coronary event.

Between 2000 and 2010, the total number of inpatient cardiovascular procedures in the United States increased by 28%, with a total of 7,588,000 cardiovascular procedures performed in 2010. In 2010, an estimated 219,000 patients underwent 397,000 CABG procedures (Fig. 20.1). The in-hospital mortality rate for CABG declined by 50% despite an increase in the comorbidity index. CAD alone resulted in more than $44 billion in expenses, making it the most expensive condition treated. The total direct and indirect cost of cardiovascular disease and stroke was estimated to be $315.4 billion in 2010, more than for any other diagnostic group.

Pathophysiology of Coronary Artery Disease

Anatomy

The anesthesiologist should be familiar with coronary anatomy if only to interpret the significance of angiographic findings. An extensive review of cardiac anatomy can be found in cardiology or cardiac

surgery texts or journals.[7,8] The following is an abbreviated description of the epicardial coronary anatomy. The coronary circulation and common sites for placement of distal anastomoses during CABG are shown in Figs. 20.2 through 20.4.

The right coronary artery (RCA) arises from the right sinus of Valsalva and is best seen in the left anterior oblique view on coronary cine angiography (see Fig. 20.2). It passes anteriorly for the first few millimeters and then follows the right atrioventricular (AV) groove and curves posteriorly within the groove to reach the crux of the heart, the area where the interventricular septum (IVS) meets the AV groove. In 84% of cases, it terminates as the posterior descending artery (PDA), which is its most important branch because it is the sole supply to the posterosuperior IVS. Other important branches are those to the sinus node in 60% of patients and the AV node in approximately 85% of patients. Anatomists consider the RCA to be dominant when it crosses the crux of the heart and continues in the AV groove regardless of the origin of the PDA. Angiographers, however, ascribe dominance to the artery—right coronary or left coronary (ie, circumflex)—that gives rise to the PDA.

The vertical and superior orientation of the RCA ostium allows easy passage of air bubbles during aortic cannulation, cardiopulmonary bypass (CPB), or open valve surgery. In sufficient volume, myocardial

Fig. 20.5 The vertical and superior orientation of the right coronary artery *(RCA)* arising from the aortic root is identified by transesophageal echocardiography (TEE). The TEE transducer in the esophagus is at the top of the screen, and the patient's chest wall is at the bottom. Retained air preferentially enters the RCA, which may cause inferior ischemia, depending on the amount of air and the coronary perfusion pressure. Elevation of perfusion pressure using phenylephrine is often used to treat coronary air embolus. The left main coronary artery (not visible) arises at approximately 3 o'clock on this image. *(Courtesy Martin J. London, MD, University of California, San Francisco, CA [www.ucsf.edu/teeecho].)*

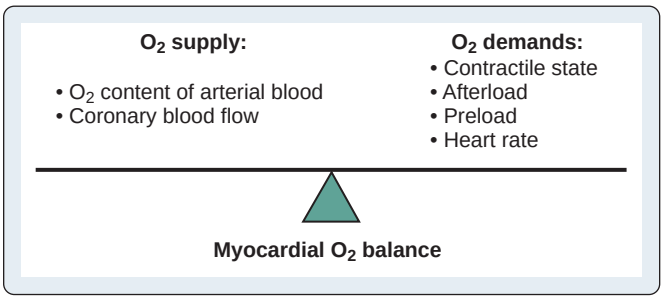

Fig. 20.6 Factors determining myocardial oxygen supply and demand.

ischemia involving the inferior left ventricular (LV) wall segments and the right ventricle may occur (Fig. 20.5). In contrast, the near-perpendicular orientation of the left main coronary ostium makes air embolization much less common.

The left coronary artery arises from the left sinus of Valsalva as the left main coronary artery. It is best seen in a shallow right anterior oblique projection (see Fig. 20.3). The left main coronary artery courses anteriorly and to the left, where it divides in a space between the aorta and pulmonary artery. Its branches are the left anterior descending (LAD) artery and circumflex artery. The LAD passes along the anterior interventricular groove. It may reach only two-thirds of the distance to the apex or extend around the apex to the diaphragmatic portion of the left ventricle. Major branches of the LAD are the diagonal branches, which supply the free wall of the left ventricle; and septal branches, which course posteriorly to supply the major portion of the IVS. Although there may be many diagonal and septal branches, the first diagonal and first septal branches serve as important landmarks in the descriptions of lesions of the LAD (see Fig. 20.4).

The circumflex artery arises at a sharp angle from the left main coronary artery and courses toward the crux of the heart in the AV groove. When the circumflex artery gives rise to the PDA, the circulation is left dominant, and the left coronary circulation supplies the entire IVS and the AV node. In approximately 40% of patients, the circumflex artery supplies the branch to the sinoatrial node. Up to four obtuse marginal (OM) arteries arise from the circumflex artery and supply the lateral wall of the left ventricle (see Fig. 20.4).

All of the previously described epicardial branches give rise to small vessels that supply the outer third of the myocardium and penetrating vessels that anastomose with the subendocardial plexus. The capillary plexus is unique in that it functions as an end-arterial system. Each epicardial arteriole supplies a capillary plexus that forms an end loop rather than anastomosing with an adjacent capillary from another epicardial artery.[9] Significant collateral circulation does not exist at the microcirculatory level.

The capillary anatomy explains the distinct areas of myocardial ischemia or infarction that can be related to disease in a discrete epicardial artery. CAD most commonly affects the epicardial muscular arteries with rare intramyocardial lesions (with the exception of the transplanted heart). However, severe disorders of the microcirculation and primary impairment of coronary vascular reserve in normal coronary arteries have been described, especially in diabetics, females, and those with variant angina.[10–12] Atherosclerosis in all organs is most common at the outer edges of vessel bifurcations because blood flow in these regions is slower and changes direction during the cardiac cycle, resulting in less net shear stress (ie, frictional force per unit area) than in other regions with more steady blood flow and higher shear stress.[13] Low shear stress stimulates the atherogenic phenotype in the endothelium.

Epicardial lesions can be single but are more often multiple. A combined lesion of the RCA and both branches of the left coronary artery is referred to as *triple-vessel disease*.

Venous drainage of the myocardium primarily occurs through the coronary sinus, which enters the right atrium between the inferior vena cava and the tricuspid valve. A small fraction enters the cardiac chambers directly through the Thebesian veins.[14]

Myocardial Ischemia and Infarction

In patients with CAD, myocardial ischemia usually results from increases in myocardial oxygen demand exceeding the capacity of the stenosed coronary arteries to increase oxygen supply (Fig. 20.6). The mechanisms of coronary blood flow (CBF) in health and coronary disease are reviewed in Chapter 7.

In atherosclerotic heart disease, the fundamental lesion is an intimal lipid plaque in the epicardial portion of a coronary artery that causes chronic stenosis and episodic thrombosis and sudden plaque rupture that results in almost complete occlusion (Figs. 20.7 and 20.8). Characteristics of the vulnerable plaque include a high lipid content, a thin fibrous cap, a reduced number of smooth muscle cells, and increased macrophage activity.[15] Chronic inflammation and acute processes such as a plaque rupture result in the release of vasoactive substances from platelets and leukocytes producing endothelial dysfunction and vasoconstriction and further reducing CBF.[15,16] A larger plaque disruption and prolonged thrombosis produce a Q-wave infarction with transmural myocardial necrosis.

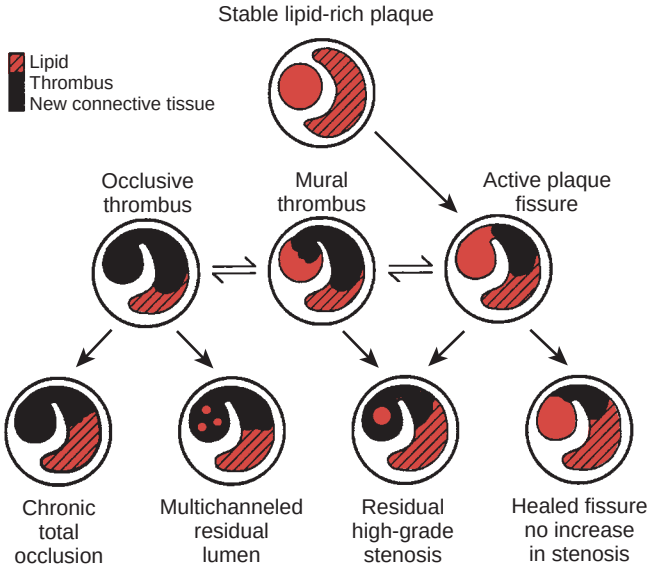

Fig. 20.8 Possible outcomes of intimal plaque rupture. *(From Davies MJ. A macro and micro view of coronary vascular insult in ischemic heart disease. Circulation 82[3 suppl]:II38, 1990.)*

Several studies have found that the coronary artery responsible for an acute infarction is only moderately obstructed chronically.[17,18] The extent of plaque rupture and thrombosis determines the size and extent of an infarction rather than the degree of stenosis. Patients with severely obstructed coronary arteries often have extensive collateral circulations that protect them from infarction. Similar findings have been reported for patients developing postoperative MI after noncardiac surgery.[19–21]

An atherosclerotic lesion produces a pressure gradient and decreases distal coronary perfusion pressure (CPP) that depends on the severity and length of the coronary lesion. Perfusion distal to the lesion depends on the distensibility of the affected coronary artery[22] and flow across the lesion. An increase in blood flow velocity across a stenotic lesion results in a decrease in pressure; whereas a decrease in velocity increases the pressure (see Chapter 21). An increase in flow velocity caused by an atherosclerotic plaque increases the pressure drop and further decreases distal perfusion.[23] Compensatory mechanisms with intact autoregulation include distal vasodilation; however, in the setting of a high-grade stenosis, the microvasculature distal to it may already be maximally dilated, even at rest, further increasing the risk for ischemia.

Collateral vessels exist in normal hearts, but in the setting of CAD, they are increased in size and number.[24] Collaterals may develop between the ischemic zone and an adjacent nonischemic area supplied by a different vessel. Although beneficial at rest, during exercise or periods of increased oxygen demand, CBF may be shunted away from the ischemic myocardium to areas with intact autoregulation able to vasodilate; this is referred to as a *coronary steal*.[25] In experimental models, a partial lesion of the epicardial artery supplying the collateral vessel is required to produce a coronary steal.[26] This anatomic configuration, called *steal-prone anatomy*, occurred in 23% of patients with symptomatic CAD in one large registry of coronary angiograms.[27]

Risk Assessment in Patients Scheduled for Coronary Artery Bypass Grafting

Preoperative risk assessment for patients undergoing CABG has evolved dramatically over the past 3 decades. The institution of federally mandated accounting of surgical outcomes for cardiac surgery in the Department of Veterans Affairs in the 1970s led to the establishment of what is considered the first large-scale, multicenter surgical outcomes database, which applies rigorous statistical methodology for comparing outcomes between centers.[28,29] The applied methodology allows adjustment for different severities of illness between patients (ie, risk adjustment) by using multiple preoperative and perioperative variables thought to be of intrinsic value (usually by expert consensus) that easily can be captured and have high consistency of definition. Statistical models are then used to calculate an expected outcome (eg, mortality). By simple comparison of the observed (O) to expected (E) outcome of a certain procedure such as CABG, hospitals in a particular system can be ranked from best (ie, low O/E ratio) to worst (ie, high O/E ratio).[30]

Although statistical models can be used to compare outcomes and drive performance improvement measures (eg, surgical site infection prevention), experts have cautioned that gaming of the system by exploiting variables with imprecise definitions is an inherent problem.[31] Nonetheless, this methodology and its variants have been adopted widely by many organizations as a measure of quality of care.[29,32] For example The Society of Thoracic Surgeons (STS) instituted a voluntary clinical database system with this approach in the early 1990s, which has continued to grow rapidly as cardiac surgical groups have become increasingly interested in benchmarking their practices against others.[33–36] The STS National Cardiac Database includes more than 98% of all cases performed annually in the United States. New York and many other states maintain risk-adjusted mandatory reporting systems for hospital and individual surgeon performance.[37–39]

Perioperative outcomes can be assessed by a multitude of clinical and nonclinical parameters. The most important outcome measure for surgical risk assessment is operative mortality, defined in the STS database as all deaths, regardless of cause, that occur during hospitalization for the operation or within 30 days after surgery if hospital discharge has already occurred.[40] Mortality rates vary widely with patient risk, acuity, additional procedures (eg, CABG, valve replacement), and previous cardiac surgery. The 1990s saw a notable decline in mortality rates despite increases in patient risk (Fig. 20.9).[41] Risk-adjusted mortality rates for isolated CABG have been consistently between 1.5% and 2% for patients included in the STS database in the past few years.[42] The short-term mortality rate has become a relatively insensitive marker of further improvements[43] and long-term mortality rates,[44] and other outcome measures such as hospital readmission are increasingly investigated.[45,46]

Perioperative or long-term mortality rates seem to be of limited use for the cardiac anesthesiologist. Predicting patients who are difficult to wean from CPB or who develop acute HF requiring pharmacologic or mechanical circulatory support, rhythm abnormalities, or prolonged mechanical ventilation are often considered of greater interest to the anesthesiologist. An analysis of 1009 patients undergoing CABG at Duke University, all of whom were monitored with TEE, found six independent predictors of inotrope support, which was required for 39% of the cohort during weaning from CPB (Fig. 20.10; Table 20.1).[47] However, because many of the factors associated with acute complications frequently encountered in the operating room or intensive care unit (ICU) are also found in the risk assessment scores that predict CABG mortality, the scores are of value and relevant to cardiac anesthesiologists even in the immediate perioperative care setting[48,49] (Box 20.1).

The two risk score models most commonly used to predict outcomes for CABG are the STS score mostly used in North America and the European System for Cardiac Operative Risk Evaluation (EuroSCORE) in Europe. Both assessments are available free of charge online, and a risk score can be automatically calculated.[50,51] Many studies have compared the STS and EuroSCORE regarding their ability to accurately predict perioperative mortality for CABG patients.[52–54] Both models reliably predict mortality associated with cardiac surgery. However, the matter is complicated by a growing variety of surgical procedures used for myocardial revascularization. In addition to on-pump CABG, off-pump coronary artery bypass (OPCAB) surgery, minimally invasive

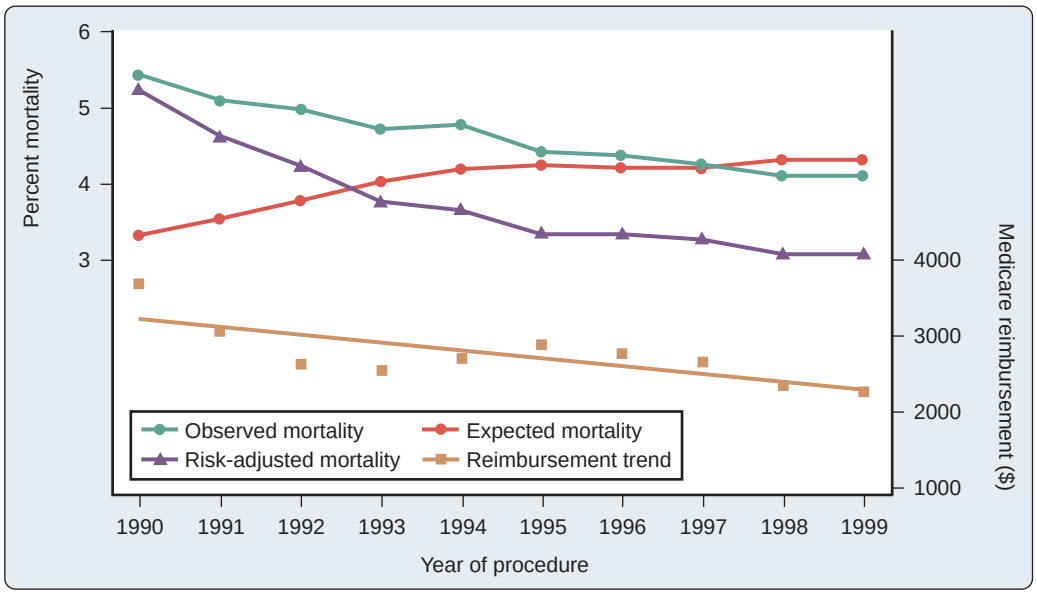

Fig. 20.9 Composite figure demonstrates an increase in the risk profile with declining mortality rates and part B Medicare reimbursement for patients undergoing coronary artery bypass grafting between 1990 and 1999. *(From Ferguson TB Jr, Hammill BG, Peterson ED, et al. procedures, and hybrid revascularization strategies are increasingly used, which complicate the use and comparability of available outcome models.[55,56]

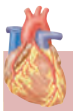
Morbidity and mortality also are influenced by events in the operating room, including time on CPB and aortic cross-clamping, adequacy of revascularization, and complications such as cardiovascular decompensation or bleeding. Several investigators have attempted to delineate the association of perioperative events and hemodynamic data with outcomes for larger cohorts of patients. For example, Reich and coworkers[57] merged computerized anesthesia record data from 2149 CABG patients (with CPB) at two New York Hospitals from 1993 to 1995 with outcome data from the state's mandatory reporting database. Four independent predictors of mortality were identified: high



BOX 20.1 PREOPERATIVE HIGH-RISK CARDIAC CHARACTERISTICS

1. Acute unstable angina, acute myocardial infarction, uncompensated congestive heart failure, cardiogenic shock
2. Left main lesion, proximal left anterior descending artery lesions
3. Ejection fraction <30% (normal >55%)
4. Concurrent significant valvular disease
5. Advanced age (>70 years)
6. Electrocardiographic signs of acute or ongoing ischemia
7. Aortic calcification (ie, inability to cross-clamp aorta)
8. High-grade occlusive carotid artery disease
9. Preexisting neurologic deficits

mean pulmonary arterial pressure (PAP) before CPB (>30 mm Hg; odds ratio [OR] = 2.1), low mean arterial pressure (MAP) during CPB (40 to 49 mm Hg; OR = 1.3), tachycardia (HR >120 beats/min; OR = 3.1), and high diastolic pulmonary arterial pressure (>20 mm Hg; OR = 1.2) after CPB.

Newer monitoring technologies such as cerebral oximetry have been used to predict outcomes in cardiac surgery. de Tournay-Jetté and colleagues, for example, showed that intraoperative cerebral desaturation is associated with cognitive dysfunction after CABG.[58]

Many of the immediate complications related to CABG manifest after CPB and in the cardiac ICU. Specific scores have been developed for predicting the risk of death of critically ill patients, and some scores have been assessed in the cardiac surgery setting.[59–63] However, the performance of general critical care scoring systems is often inadequate and of limited value for cardiac surgery patients. For example, Doerr and associates[64] compared the performance of four intensive care outcome prediction scoring systems (ie, Acute Physiology and Chronic Health Evaluation II [APACHE II], Simplified Acute Physiology Score II [SAPS II], Sequential Organ Failure Assessment [SOFA], and Cardiac Surgery Score [CASUS]) for patients after cardiac surgery. Two of the critical care scores (ie, APACHE II and SAPS) failed to reliably stratify risks for cardiac surgery patients.

Effective resource management is becoming increasingly important, and predicting ICU length of stay (LOS) is critical for this purpose. Existing predictive models have been tested and new ones developed to predict resource use and particularly LOS. For example, the Surgical Procedure Assessment (SPA) score was compared with four other critical care scores in predicting ICU LOS for cardiac surgical patients.[65] The preoperative assessment using the SPA score is mostly based on procedure complexity, and it reliably predicted ICU LOS and was better than other scores tested. In another study, the Parsonnet Score reliably predicted ICU LOS and postoperative complications for cardiac surgery patients.[66]

Because of the increasing popularity and almost universal use of the STS and EuroSCORE, many of the other critical care risk scores have almost been abandoned in the cardiac surgery ICU setting. Several studies have shown that the EuroSCORE and STS score are suitable for capturing the risk associated with cardiac surgery. A comparison of six commonly used risk scores found the EuroSCORE to yield the highest predictive value for 30-day mortality for cardiac surgery patients (STS score was not included).[67] In another study, the EuroSCORE was compared with the Cardiac Anesthesia Risk Evaluation (CARE) score, which was developed in the mid-1990s.[68] Both scoring systems performed well in predicting cardiac surgical mortality. Ettema and coworkers[69] tested 20 risk score models for their ability to predict ICU LOS for more than 11,000 cardiac surgery patients. The Parsonnet score and the EuroSCORE were superior in identifying patients with longer ICU stays. However, the commonly used risk calculators do not consider some important physical comorbidities (eg, hepatic dysfunction) and psychosocial factors (eg, mental strength, attitude, family support system) that powerfully impact patient outcomes and LOS.

Percutaneous coronary interventions (PCI) and modern coronary stent technology continue to advance. The past few decades have seen shifts in treatment paradigms, and guidelines for surgical versus percutaneous intervention in patients with CAD are updated on a regular basis, reflecting data from the most recent clinical trials.[70]

The SYNergy between percutaneous coronary intervention with TAXus drug-eluting stent and cardiac surgery (SYNTAX) trial, a prospective, randomized, multicenter trial, originally was designed to evaluate current practice patterns and optimal revascularization strategies in patients with three-vessel disease and left main CAD in Europe and the United States.[71] For the purpose of risk stratification in this trial, the SYNTAX score was developed, characterizing the complexity of coronary pathology. The SYNTAX score is based on existing classifications and takes the number, location, complexity, and functional impact of the coronary lesions into consideration.[72] Patients with more complex disease and potentially worse prognosis have higher SYNTAX scores. The initial analysis showed that there was no difference in outcomes (ie, major adverse cardiovascular and cerebrovascular events [MACCEs]) among patients randomized to surgery between those who had low, intermediate, or high scores (MACCE of 14.4%, 11.7%, 10.7%, respectively).[73]

In patients randomized to PCI, however, the SYNTAX score was able to predict adverse outcomes for the described risk groups at 12 months (13.5%, 16.6%, 23.3%, respectively). Comparing outcomes between patients randomized to surgery versus PCI, those with low SYNTAX scores (<22) had similar outcomes irrespective of treatment assignment. Those with more complex CAD (intermediate SYNTAX score of 23 to 32 or high SYNTAX score >32) had better survival and MACCE-free survival with surgery. Longer-term follow-up of the SYNTAX trial through 5 postoperative years confirms the survival advantage of surgery over PCI for patients with CAD of intermediate or high complexity, and this survival advantage increases with increasing duration of follow-up.

Anesthesia for Coronary Artery Bypass Grafting

The practitioner providing anesthesia care for patients undergoing coronary revascularization has to implement an anesthetic plan that takes patient- and surgery-specific factors into consideration, but it should also include the most recent recommendations and guidelines regarding the perioperative care of patients with CAD.

In the earlier days of cardiac surgery, the focus on anesthesia management for patients undergoing CABG was mainly on maintaining hemodynamic stability and preventing ischemia. This reflected the lack of anesthetic agents with minimal hemodynamic effects. Later reports supported a lack of effect of the technique, suggesting that hemodynamic control was more important (ie, it is not what you use, but how you use it).[74,75]

With the introduction of modern anesthetic agents, the focus shifted to investigating how the various regimens and techniques could help to improve outcomes of patients undergoing myocardial revascularization. For example, considerable data demonstrate the beneficial effects of using potent inhalation agents[76,77] or sympathetic blockade[78] on markers of myocardial ischemia and postoperative MI, such as improved recovery and shorter LOS. However, many data are derived from in vitro studies. In vivo investigations mostly suffer from inadequate statistical power and reporting single-center experiences, and they have problems with standardization of definitions and reporting of surrogate outcomes. Clinically recognizable advantages appear to be modest and demonstration of overt reductions in serious morbidity or mortality rates in large-scale, multicenter cohorts have not been reported.[79,80]

Premedication

The concept of premedication has been evolving beyond the traditional ordering of sedative-hypnotics or related agents to reduce patient anxiety and promote amnesia. The cardiac anesthesiologist must be familiar with the potential benefits of administering or hazards of not administering a variety of medications, including antianginal, β-blocker, and antiplatelet drugs.

Anxiolysis, Amnesia, and Analgesia

The purposes of premedication are to pharmacologically reduce apprehension and fear, to provide analgesia for potentially painful events before induction (eg, vascular cannulation), and to produce some degree of amnesia. In patients with CAD, premedication may help prevent preoperative anginal episodes that are relatively commonly observed and may be elicited by tachycardia due to anxiety or painful stimuli. Short-acting benzodiazepines are the mainstay of drugs administered for this purpose. When given intravenously in the preoperative holding area to patients with CAD, supplemental oxygen should be administered and the patients monitored by pulse

oximetry, an electrocardiogram (ECG), and noninvasive blood pressure methods.

The sedative and anesthetic-sparing actions of α_2-adrenergic agonists (eg, clonidine, dexmedetomidine) were evaluated for their efficacy in several older studies of CABG patients alone or in combination with a benzodiazepine.[81–85] However, some of the side effects, such as decreased HR, MAP, cardiac output (CO), and contractility and transiently increased systemic vascular resistance [SVR]), warrant caution for patients with CAD who are prone to myocardial ischemia. Currently, α_2-adrenergic agonists play only a minor role in premedication for patients undergoing myocardial revascularization.

Management of Preoperative Medications

Patients undergoing myocardial revascularization routinely take medications aiming to prevent acute coronary events, worsening of ischemia, or HF symptoms. Many of these drugs have implications for anesthesia management, and the anesthesiologist should be familiar with the current guidelines and recommendations outlining their use in the perioperative setting (Box 20.2) (see Chapters 1 and 11).

β-Blocking Agents

β-Blocking agents are routinely administered to many patients with CAD. As early as the mid-1970s, Kaplan suggested that it was safe to continue β-blockade in patients with ischemic heart disease undergoing cardiac or noncardiac surgery, even those with poor ventricular function.[86,87] This was confirmed in many prospective, randomized trials that established the safety of continuing β-blockade in the perioperative period. Slogoff and colleagues,[88] for example, performed a randomized trial evaluating the safety of propranolol administration within 12 hours of surgery. Based on a significantly greater increase in the incidence of pre-CPB ischemia in patients withdrawn from propranolol, they recommended continuation of therapy until the time of surgery. Further work in the 1980s documented the efficacy of β-blocker continuation through CABG surgery for reducing pre-CPB ischemia and the superior efficacy over the then increasingly popular calcium channel blockers.[89–93]

Although early work established safety of use and harm of discontinuing β-blockers in the perioperative setting, the past 2 decades have seen a few landmark prospective, randomized, controlled trials demonstrating the benefits of β-blockade for patients at risk for adverse cardiac events. For example, Mangano and associates[94] compared the use of atenolol with placebo in high-risk patients undergoing noncardiac surgery. Atenolol reduced mortality rates and the incidence of cardiovascular complications. Several observational studies documented associations of β-blocker therapy with reduction in perioperative mortality rates for CABG patients.[95,96] Ferguson and coworkers[97] considered 629,877 patients in the STS database (1996–1999) for whom a modest but statistically significant reduction in the 30-day risk-adjusted mortality rate was reported. This treatment effect was observed in many high-risk subgroups, although a trend toward increased mortality rates was seen for patients with an ejection fraction (EF) of less than 30%.

In a metaanalysis, Wiesbauer and associates[98] found that perioperative β-blockers reduced perioperative arrhythmias after cardiac surgery, but they were unable to show an effect on MI or mortality. Based on the existing evidence from a few randomized, controlled trials, retrospective studies, and metaanalyses, β-blocker use was recommended by many specialty societies for patients undergoing CABG or those at risk for adverse cardiac events who were undergoing noncardiac surgery. Considerable efforts were being expended by major organizations such as the STS and American College of Cardiology (ACC) in increasing compliance with these guidelines and recommending the use of β-blockers at the time of hospital discharge, along with the use of aspirin, statins, and angiotensin-converting enzyme (ACE) inhibitors.[99–101]

The role of β-blockers gained renewed interest with the disclosure of flawed research data that contributed significantly to the recommendations regarding β-blocker use in the perioperative setting.[102] Conclusions drawn from the POISE trial[103] raised questions about the suggested benefits of high-dose β-blockade in patients undergoing surgical procedures and suggested potential harm of this practice.

Due to the adoption of preoperative β-blocker therapy as a national quality standard, most patients who undergo CABG are prescribed β-blockers before surgery. There is no doubt that the acute discontinuation of β-blockers is associated with rebound tachycardia, arterial hypertension, and worsening of HF, which are particularly unwarranted in patients at risk for myocardial ischemia. However, the routine use of β-blockers even in low-risk CABG patients has been questioned. Brinkman and associates[104] retrospectively analyzed 505,110 adult patients listed in the STS database who underwent elective CABG between 2008 and 2012. After risk adjustment, there was no significant difference in major outcomes, including operative mortality, stroke, prolonged mechanical ventilation, renal failure, sternal wound

BOX 20.2 PREOPERATIVE MEDICATION MANAGEMENT

1. β-Adrenergic blockers
   - Should be administered for at least 24 hours before coronary artery bypass grafting (CABG) to all patients without contraindications (eg, hypotension, third-degree heart block, bronchospasm).
   - After CABG surgery, should be reinstituted as soon as possible in all patients without contraindications.
2. Statins: All patients undergoing CABG should receive them unless contraindications apply.
3. Calcium channel blockers: Patients already on calcium channel blockers should continue them perioperatively.
4. Angiotensin-converting enzyme inhibitor:
   - Preoperative discontinuation is controversial (ie, increased risk of hypotension and vasoplegic syndrome).
   - Postoperatively, should be initiated and continued indefinitely in CABG patients who are stable unless contraindications apply.
5. Diuretics: No firm recommendations, but ensure adequate serum potassium levels.
6. Aspirin: Should be administered preoperatively. The decision about whether and when to discontinue aspirin before surgery depends on patient-specific factors such as individual risk for bleeding and presence of an acute coronary syndrome. Postoperatively, aspirin should be started as early as possible (ie, within 6 to 24 hours after surgery).
7. Antiplatelet agents such as oral inhibitors of purinergic receptor P2Y12: Because they are associated with an increased risk of bleeding, recommendations call for withholding for a few days before surgery. However, in high-risk patients and/or after placement of drug-eluting stents, recommendations may change, and intravenous glycoprotein IIb/IIIa inhibitors or cangralor may be continued perioperatively despite increased risk of bleeding.
8. Heparin: Regimen often depends on the surgeon. Usually discontinued 4 hours preoperatively for stable patients, continued up to and through pre–cardiopulmonary bypass period for critical left main disease or acutely unstable angina patients.
9. Oral hypoglycemic agents: No firm recommendations; consider withholding administration. However, glucose control must be ensured.
10. Antibiotic prophylaxis: Optimal timing and weight adjustment (especially important with antibiotics that have slow tissue penetration such as vancomycin). Typically, a second-generation cephalosporin such as cephazolin (2 g IV) or cefuroxime (1.5 g IV) administered 20 to 60 minutes before incision; vancomycin (15 mg/kg) administered as a slow infusion to avoid hypotension and flushing (due to slow tissue penetration, infusion should be completed 20 to 30 minutes before skin incision).

infection, and reoperation, between patients who received β-blockers and those who did not. Patients who received β-blockers within 24 hours of surgery had a higher incidence of new-onset atrial fibrillation (AF).

LaPar and colleagues[105] looked at 43,747 patients listed in the STS database who had isolated CABG between 2001 and 2011. Most (80%) patients used β-blockers preoperatively. Even though the β-blocker group had a lower predicted mortality score compared with the non–β-blocker group, there was no observed benefit in mortality, morbidity, LOS, or hospital readmission associated with its use. The investigators concluded that based on their findings, the routine use of β-blockers for CABG should not be used as a quality outcome measure.

The 2011 American College of Cardiology Foundation and American Heart Association (ACCF/AHA) guideline for CABG surgery[106] recommended that β-blockers should be administered for at least 24 hours before CABG to all patients without contraindications to reduce the incidence or clinical sequelae of postoperative AF. The guidelines state that β-blockers in CABG patients with an EF greater than 30% can be effective in reducing the risk of in-hospital mortality and the incidence of perioperative myocardial ischemia. In patients with severely depressed LV function (EF <30%), the effectiveness of preoperative β-blockers in reducing the in-hospital mortality rate is uncertain. After CABG, β-blockers should be reinstituted as soon as possible for all patients without contraindications.

In 2015, the AHA published a scientific statement complementing the existing guidelines that focused on secondary prevention measures after CABG.[107] The expert statement supports the recommendation to give β-blockers starting before surgery, including administering them to patients with prior MI unless contraindicated (eg, bradycardia, severe reactive airway disease). In patients with previous MI, β-blockers are specifically recommended for patients with HF symptoms and an EF below 40%.

There remains little doubt that β-blockers are beneficial for many patients undergoing surgery who are at risk for myocardial ischemia and adverse cardiac events. However, defining and refining indications, exact end points (ie, HR), exclusion criteria, and specific drug formulas requires further investigations.[108]

Antiplatelet Drugs

In accordance with current guidelines, most patients undergoing CABG are treated with platelet inhibitors. Aspirin is a well-recognized component of primary and secondary prevention strategies for all patients with ischemic heart disease.[109,110] Clopidogrel administration is established practice after coronary artery stent placement, and it is recommended in combination with aspirin for patients with ACS.[111–113] Studies in the 1980s showed benefits of antiplatelet therapy, including prevention of early graft thrombosis in patients after CABG.[114] Additional benefits of antiplatelet therapy also were recognized. For example, in a large observational analysis, Mangano and coworkers[115] reported a substantial reduction in the overall mortality rate (1.3% vs 4.0%) and ischemic complications of the heart, brain, kidneys, and gastrointestinal tract in 5065 patients at 70 hospitals when aspirin was administered within 48 hours after surgery.

The combination of aspirin and potent inhibitors of platelet function such as clopidogrel are even more effective than single agents in treating patients with ACS and preventing early graft thrombosis after CABG.[116] However, controversy exists regarding timing and specifically when to discontinue preoperative antiplatelet therapy.

The risk of hemorrhagic complications should be weighed against the potential benefits of antiplatelet therapy. Several metaanalyses have documented risks of potent antiplatelet agents in patients undergoing CABG. Sun and colleagues found that patients receiving aspirin immediately before surgery had more mediastinal bleeding and received more blood products.[117] In another metaanalysis, late discontinuation of adenosine diphosphate (ADP) receptor antagonists (2–7 days preceding CABG) was associated with an increased risk of death and reoperation for bleeding.[118] Another metaanalysis acknowledged the role of antiplatelet agents in patients with ACS but also recommended discontinuing clopidogrel at least 5 days before CABG to account for an adequate washout period.[119] Biancari and associates found that recent exposure to clopidogrel before CABG was associated with an increased risk of postoperative death, reoperation for bleeding, blood loss, and the need for blood transfusions.[120] Several retrospective and observational studies have reported that CABG in patients receiving clopidogrel is associated with increased bleeding and transfusion requirements.[121,122] Filsoufi and coworkers reported longer ICU and hospital LOS and increased all-cause morbidity and mortality rates for patients who were administered clopidogrel preoperatively.[123] In a multicenter retrospective study, Berger and associates[124] reported that clopidogrel-treated patients were at increased risk for reoperation, major bleeding, and increased LOS.

Guidelines summarizing the current evidence regarding antiplatelet drugs in patients undergoing surgery have been published by various specialty societies and are updated regularly. The most recent update of the STS guidelines on the use of antiplatelet drugs in patients undergoing CABG was published in 2012.[125] The highest level of evidence (class I recommendation, level A evidence) was found for aspirin administration within 6 to 24 hours after surgery in nonbleeding patients to optimize vein graft patency and for dual antiplatelet therapy for patients undergoing CABG after ACS as soon as the bleeding risk is diminished to decrease adverse cardiovascular outcomes. The class I recommendation with level B evidence advised discontinuing inhibitors of the purinergic receptor P2Y12 (ie, chemoreceptor for ADP) for a few days before surgery to reduce the risk of bleeding and need for blood transfusion.

In 2012, the task force acknowledged that there was insufficient data to make definitive statements regarding the exact interval required between drug discontinuation and surgery and that it should be adjusted depending on many factors, including individual drug responsiveness and thrombotic risk. There is a class IIa recommendation with level B evidence that aspirin can be safely discontinued a few days before surgery in patients at high risk for bleeding and patients without ACS. For patients on dual antiplatelet therapy, surgery should be delayed for a day or two if possible to decrease the risk of bleeding.

The 2011 ACCF/AHA guideline for CABG surgery[106] recommended that aspirin should be administered to CABG patients preoperatively. For elective CABG, clopidogrel and ticagrelor should be discontinued for at least 5 days before surgery and prasugrel for at least 7 days to limit the need for blood transfusions. For urgent surgery, clopidogrel and ticagrelor should be discontinued for at least 24 hours to reduce major bleeding complications. Postoperatively, aspirin should be started within 6 hours after surgery. For those allergic to aspirin, clopidogrel should be used instead. Low-dose aspirin should be continued indefinitely. The 2015 AHA scientific statement on secondary prevention measures after CABG confirmed these recommendations and recommended dual antiplatelet therapy with aspirin and clopidogrel for 1 year.[107]

HMG CoA Reductase Inhibitors

Potent antiinflammatory and antithrombotic effects and beneficial effects on endothelial function and angiogenesis have been reported for 3-hydroxy-3-methyl-glutaryl–coenzyme A (HMG CoA) reductase inhibitors (ie, statins).[126–129] Administered acutely during PCI,[130–132] statins have direct effects on platelet aggregation and plasminogen activator inhibitors (eg, tPA).[133,134] Improved outcomes also have been described for patients undergoing CABG.[135–138] This includes attenuation of myocardial reperfusion injury after CPB,[139] reducing short- and long-term mortality rates, and decreasing early graft occlusion in CABG patients.[140–145]

From a large metaanalysis evaluating the impact of preoperative statin use on adverse clinical outcomes after cardiac surgery, Liakopoulos and colleagues[146] reported that preoperative statin use significantly reduced all-cause mortality rates. Retrospective analysis of 14, 834 patients undergoing myocardial revascularization (ie, PCI or CABG) showed that statin therapy was associated with a significant risk reduction for major adverse cardiovascular events in the

follow-up period.[147] Statins also decrease the need for postoperative renal replacement therapy, although results regarding a reduction in acute renal dysfunction were conflicting.[142,148] Statins have decreased the incidence of AF after cardiac surgery.[149] Postoperative withdrawal of statin treatment is independently associated with increased hospital mortality rates after CABG.[143]

Based on the accumulating evidence for the beneficial effects of statin therapy in patients undergoing myocardial revascularization, guidelines have been adjusted. The 2011 ACCF/AHA guideline for CABG surgery[106] recommended that unless contraindications apply, all patients undergoing CABG should receive statin therapy with the goal of lowering low-density lipoprotein (LDL) cholesterol by at least 30% or to less than 100 mg/dL. Even lower targets may be advisable (<70 mg/dL) for very-high-risk patients. The most recent AHA scientific statement on secondary prevention measures after CABG confirmed these recommendations, and recommended statin therapy starting preoperatively and continued after surgery,[107,150]

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are widely considered to be vasculoprotective, particularly with regard to ventricular remodeling after acute MI, and they appear to reduce damage after ischemic reperfusion.[151] The role of ACE inhibitors in improving major outcomes for patients with ischemic heart disease and those undergoing myocardial revascularization has been investigated.[151,152] The QUinapril on Vascular Ace and Determinants of Ischemia (QUO VADIS) study[153] showed a significant reduction in ischemic events in patients on ACE inhibitors before CABG.

Although patients with ischemic heart disease and HF may benefit from ACE inhibitor therapy, the effect on many other CABG-relevant outcome parameters is less clear. Although, some studies found an association with ACE inhibitor therapy before CABG and a reduced risk of acute kidney injury[154] and prevention of new-onset AF,[155] preoperative ACE inhibitor therapy is also associated with hypotension during induction or even profound degrees of vasodilation (ie, vasoplegic syndrome) during CPB and weaning due to their vasodilatory effects.[156–163] Hypotension and vasoplegia may counteract some of the potential beneficial properties and increase the risk of adverse events. For example in a large, retrospective, observational study of more than 10,000 patients undergoing CABG, preoperative ACE inhibitor therapy was associated with an increased incidence of perioperative hypotension, and ACE inhibitor therapy was found to be an independent predictor of mortality, need for inotropic support, postoperative renal dysfunction, and new-onset postoperative AF.[164]

In a later retrospective analysis, Shi and coworkers compared 1239 patients who received renin-angiotensin system inhibitors with a control group.[165] The patients in the study group had a significantly lower risk of acute kidney injury, operative mortality, and sepsis. A metaanalysis (ie, 13 studies including a total of 31,390 patients) found preoperative ACE inhibitor administration to be associated with hypotension, postoperative MI, and renal dysfunction; no effect on mortality rates was found.[166]

Miceli and colleagues found that preoperative ACE inhibitor use doubled the risk of death and was independently associated with the use of inotropic drugs.[164] Bandeali and associates[167] retrospectively analyzed 8889 patients undergoing CABG; 3983 used ACE inhibitors preoperatively. Patients who received ACE inhibitors had a higher risk of major adverse events; most significantly renal dysfunction and AF. Drenger and coworkers also investigated ACE inhibitor use in 4224 patients undergoing CABG.[168] ACE inhibitors administered preoperatively and continued after surgery and ACE inhibitors started after surgery were associated with improved in-hospital outcomes. Discontinuation of ACE inhibitors was associated with nonfatal in-hospital ischemic events, but no difference in mortality was found.

The 2011 ACCF/AHA guideline for CABG surgery[106] recommended that preoperative use of ACE inhibitors and angiotension II receptor blockers (ARBs) should prompt reinstitution postoperatively after the patient is stable unless contraindicated. Independent of preoperative use, ACE inhibitors and ARBs should be initiated postoperatively and continued indefinitely in CABG patients who are stable unless contraindications apply. The task force also acknowledges that the safety of the preoperative ACE inhibitors or ARBs in patients on chronic therapy is uncertain. The most recent AHA scientific statement on secondary prevention measures after CABG confirmed these recommendations and recommended administering ACE inhibitors or ARB therapy after CABG to all patients with LV dysfunction.[107,150]

Calcium Channel Antagonists

Early observational studies suggested that calcium channel antagonists were ineffective in the treatment and prevention of myocardial ischemia, particularly when compared with β-blockers.[89,90] There was even less enthusiasm for their use because of concerns in the mid-1990s about excess mortality with shorter-acting preparations, particularly nifedipine, which was thought to cause reflex adrenergic activation due to abrupt vasodilation with each dose.[169]

The two metaanalyses published in 2003 evaluating their efficacy in noncardiac surgery produced conflicting information.[170,171] However, one metaanalysis and a large observational cohort study with propensity-matching adjustment suggested there might be a role for calcium antagonists in reducing mortality rates for CABG patients.[172,173] For patients chronically taking calcium channel antagonists, they should probably be continued perioperatively. However, drug interactions must be considered. Data suggest that calcium channel blockers decrease clopidogrel-mediated platelet inhibition, which plays a crucial role in the management of CAD.[174]

Monitoring

Electrocardiogram

On arrival in the operating room, the patient undergoing CABG should have routine monitors placed, including pulse oximetry, noninvasive BP, and the ECG. A five-lead system is standard for patients undergoing cardiac surgery. Monitoring leads V_5 and II allows detection of 90% of ischemic episodes and assessment of the rhythm to diagnose various atrial and ventricular arrhythmias. Electrocardiographic detection of myocardial ischemia is reviewed in Chapter 12 (Box 20.3).

Arterial Pressure Monitoring

The radial artery usually is cannulated for BP monitoring during CABG. Choosing the best site for radial artery cannulation depends on surgery-specific considerations and institutional and practitioner preferences. Procedures such as previous transradial artery catheterization (TRAC), radial artery harvesting, or axillary CPB cannulation may influence the site chosen for invasive arterial pressure monitoring. The newer TRAC sheaths can be problematic for monitoring during emergency CABG, and they have been associated with many complications.[175] The radial artery on the side of a previous TRAC procedure probably should not be used for monitoring purposes.

With modern sternal retractors, blunting of the arterial pressure tracing on the ipsilateral site of internal mammary artery (IMA) dissection is not typically seen. Some practitioners use bilateral arterial cannulation or choose a more central artery, such as the axillary or femoral artery, to ensure accurate pressure readings after CPB. Radial arterial pressures have proved to be inaccurate immediately after hypothermic CPB. Substantial reductions in radial arterial pressure compared with aortic pressure have been reported in several clinical investigations and often require 20 to 60 minutes after CPB to resolve.[176–180] Decreased forearm vascular resistance is thought to be responsible for this common phenomenon. This problem can be overcome by temporarily transducing the arterial pressure directly from the aorta by a needle or a cardioplegia cannula.

Central Venous Cannulation

Placement of a central venous pressure (CVP) catheter routinely is performed in cardiac anesthesia for right atrial pressure measurement and for infusing vasoactive drugs. Some centers routinely place two

BOX 20.3 INTRAOPERATIVE MONITORING FOR MYOCARDIAL REVASCULARIZATION

1. ECG: V_5 most sensitive for myocardial ischemia; inferior lead II for rhythm monitoring and inferior wall ischemia.
2. Arterial blood pressure: Continuous invasive arterial blood pressure monitoring and blood gas sampling by indwelling arterial catheter. (Consider site of radial artery harvesting, reoperation, bilateral radial artery monitoring for axillary CPB cannulation, femoral artery cannulation for emergency IABP insertion, and more central arterial cannulation (eg, axillary, femoral) for more accurate readings after discontinuation of CPB).
3. PAC: No evidence of improved outcome with PAC use. However, commonly used for treatment guidance in conjunction with TEE monitoring and for postoperative care in the ICU, particularly in patients with severely reduced ventricular function and those with pulmonary hypertension.
4. TEE: Recommended for all cardiac operations. TEE can assist in pre-CPB evaluation of cardiac function, associated valvular lesions (including functional mitral regurgitation), evaluation of atheromatous plaques in the aorta (ie, site of cannulation and aortic cross-clamping, possible no-touch technique), detection of patent foramen ovale, or persistent left superior vena cava (ie, retrograde cardioplegia problem), CPB cannulation (including retrograde cardioplegia cannula positioning, aortic cannula positioning and associated complications such as iatrogenic aortic dissection and venous cannula positioning), volume status, ventricular function and response to inotropic agents, de-airing after release of aortic cross-clamp and during weaning off CPB.
5. Neurophysiologic monitoring: Increasing reports that cerebral oximetry aids in detecting catastrophic events; pending data from large prospective studies regarding outcome.
6. Temperature monitoring: Bladder or esophageal (ie, core temperature) and nasopharyngeal or tympanic (ie, brain temperature) are recommended for all CPB cases to minimize temperature gradients and cerebral hyperthermia during rewarming. For OPCABs, bladder temperature only is sufficient.
7. Foley placement for all patients.

CPB, Cardiopulmonary bypass; *ECG*, electrocardiogram; *IABP*, intraaortic balloon pump; *ICU*, intensive care unit; *OPCAB*, off-pump coronary artery bypass; *PAC*, pulmonary artery catheter; *TEE*, transesophageal echocardiography.

catheters (ie, large introducer and smaller CVP catheter) in the central circulation to facilitate volume infusion and vasoactive or inotropic drug administration. Central venous catheter placement and monitoring is extensively covered in Chapter 13.

Pulmonary Artery Catheterization

The use of a pulmonary artery catheter (PAC) in medical and surgical settings has declined steadily, mostly due to the increasing amount of data from large, randomized studies showing that major clinical outcomes (particularly death) are not changed by PAC use and that the adverse effects of PAC monitoring should be considered. During surgery for myocardial revascularization and in the ICU setting, patient outcomes are independent of PAC use despite the substantial amount of physiologic information obtained.

In a prospective observational study, Tuman and associates,[181] examined the effect of PAC use on the outcomes of 1094 patients undergoing CABG surgery. Although no direct data on LV function were provided, there was no difference in the incidence of LV dysfunction between the group treated with a CVP catheter and the group treated with a PAC. In this study, the investigators could not demonstrate that a PAC had any effect on outcome; however, 7% of the patients initially assigned to CVP monitoring subsequently required a PAC for management.

Several other reports have focused exclusively on PAC use in CABG surgery. Stewart and colleagues[182] reported a retrospective analysis of 312 patients undergoing CABG in 1996 who were thought to be low risk and suitable for CVP monitoring alone. Of these, 32% had a PAC placed and received greater volumes of fluid, gained more weight, and had longer times to extubation. Ramsey and coworkers[183] retrospectively analyzed a commercial health care outcomes-benchmarking database with 13,907 patients who underwent nonemergent CABG in 56 hospitals (Fig. 20.11). Patients (58%) who had a PAC placed for perioperative monitoring had a higher risk of death after risk adjustment (relative risk = 2.1), longer LOS, and higher total costs, particularly in the hospitals with low rates of PAC use.

Schwann and colleagues[184] retrospectively analyzed 2685 consecutive CABG patients at a single private center (1994–1998) in which PAC use was highly selective (ie, used in only 9% based on consideration of multiple cardiac risk factors). Of these instances of PAC use, 6.6% were planned, with the remainder placed postoperatively in response to adverse intraoperative events. Multivariate analysis revealed EF, STS risk score, use of intraaortic balloon pump (IABP), HF, reoperation, and New York Heart Association (NYHA) class IV to be independent predictors of PAC use.

In another multicenter, prospective, observational study, 5065 patients undergoing CABG between 1996 and 2000 were enrolled.[185] Propensity score matching was applied to adjust for differences in patient characteristics that might have led to PAC insertion. In this patient cohort, PAC during CABG was associated with an increased mortality rate (3.5% vs 1.7%) and higher risk of severe end-organ complications.

London and associates[186] documented a high rate of PAC use based on analysis of 3256 CABG patients included in a large, multicenter, observational study of patients undergoing cardiac surgery in the Department of Veterans Affairs (1994–1996). More than 95% of cases were monitored with a PAC, and 49% of these cases used the more expensive mixed venous oxygen saturation catheter. Use of the catheter was center specific, and with the exception of a small reduction in number of postoperative arterial blood gas and thermodilution cardiac output measurements, it was not associated with improvement in outcome over the routine PAC. In a retrospective study, Resano and coworkers[187] did not find significant differences in mortality, conversion to on-pump procedures, or inotropic drug use between the group treated with a CVP catheter and the group treated with a PAC.

Judge and colleagues[188] surveyed the members of the Society of Cardiovascular Anesthesiologists to assess current PAC use. The use of a PAC for myocardial revascularization was practice dependent, with anesthesiologists in private practices using PACs for hemodynamic monitoring the most, followed by those in academic and government practice settings. OPCAB and minimally invasive CABG procedures were more likely to be monitored with a PAC.

Based on the existing literature, it is not possible to give precise criteria for PAC use during CABG. PAC use during CABG depends on institutional and practitioner preference, and most patients undergoing myocardial revascularization can be safely managed without a PAC. Patient risk factors that may warrant PAC placement include significant impairment of ventricular function, known pulmonary hypertension, and right-sided HF. Some physicians have advocated a wait-and-see approach. In a prospective, observational study, Djaiani and associates[189] showed the safety and usefulness of delaying the insertion of a PAC until the clinical need arises in the operating room or in the ICU after CABG.

The 2011 ACCF/ACC guideline for CABG surgery[106] suggested that PAC placement can be useful in patients in cardiogenic shock or hemodynamically unstable patients. PAC use is reviewed in Chapter 13.

Transesophageal Echocardiography

The earliest signs of myocardial ischemia include diastolic dysfunction followed by systolic regional wall motion abnormalities (RWMAs),

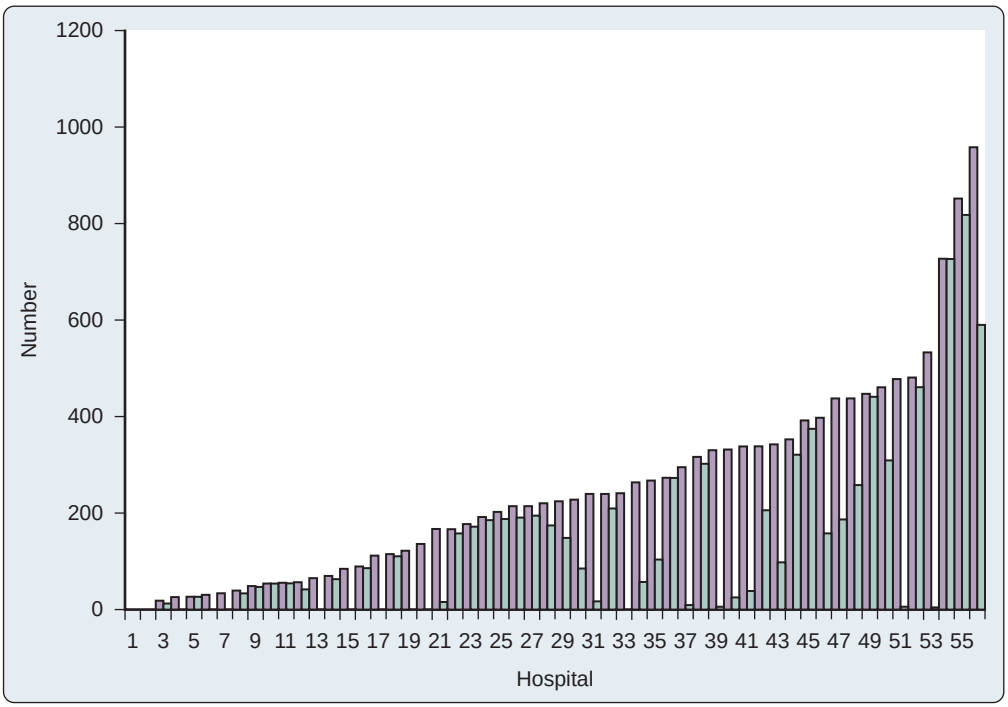


Fig. 20.11 Variation in the use of pulmonary artery catheterization (PAC) for elective coronary artery bypass grafting (CABG) in 13,907 patients at 56 community-based hospitals in 26 states in 1997, with data obtained from an administrative health outcomes benchmarking database. PAC was used in 58% and was associated with greater risk of in-hospital mortality, particularly in hospitals with the lowest use of PAC, hospital length of stay, and costs. *Purple bars* indicate the total number of CABG cases; *green bars* indicate the number of patients with PAC. *(From Ramsay SD, Saint S, Sullivan SD, et al. Clinical and economic effects of pulmonary artery catheterization in nonemergent coronary artery bypass graft surgery.* J Cardiothorac Vasc Anesth. *2000;14:113.)*

which occur within seconds of acute coronary occlusion. Worsening of RWMAs after CABG is associated with an increased risk of long-term adverse cardiac morbidity and has been suggested as a prognostic indicator of adverse cardiovascular outcome.[190] New RWMAs detected in the intraoperative period frequently may result from nonischemic or ischemic causes such as changes in loading conditions, alteration in electrical conduction in the heart, post-CPB pacing, myocardial stunning due to ischemia before or during weaning from CPB, or poor myocardial preservation. TEE is highly sensitive but lacks specificity for myocardial ischemia monitoring.[191,192] Additional limitations apply because not all wall segments can be monitored continuously in real time and compared with preoperative findings.

Despite these limitations, TEE use in patients undergoing CABG can provide invaluable information beyond ischemia detection. TEE can assist in the pre-CPB evaluation of cardiac function, assessment and quantification of associated valvular lesions that may impact the surgical plan (eg, concomitant functional mitral regurgitation [MR], aortic stenosis), or CPB management (eg, aortic regurgitation).

In the setting of valvular heart disease at the time of CABG, the 2011 ACCF/AHA guideline for CABG surgery[106] recommended adding the following surgical procedures. A class I recommendation with level of evidence (LOE) B applies to aortic valve replacement for moderate aortic stenosis, and mitral valve repair or replacement should be undertaken for severe MR. A class IIa recommendation and LOE B applies to mitral valve repair or replacement for moderate MR. However, the value or risk of adding mitral valve repair that requires open heart surgery at the time of CABG remains controversial, and a prospective, randomized trial did not find improved 1-year outcomes.[193] Recommendations will likely be adjusted as more long-term evidence emerges.

The aorta can be assessed for the presence and severity of atheromatous plaques, and TEE can help to locate appropriate cannulation and cross-clamp sites or avoid the manipulation of the aorta altogether (ie, no-touch techniques). Cannulation techniques, including retrograde cardioplegia cannula positioning, a persistent left superior vena cava cannula (ie, retrograde cardioplegia problem), venous cannula positioning allowing unobstructed venous drainage, and an aortic cannula position in the aortic arch, can be assisted by TEE guidance. TEE can detect complications such as iatrogenic aortic dissection and can evaluate de-airing after release of the aortic cross-clamp. TEE monitoring can guide hemodynamic management after CPB, including the assessment of ventricular function, volume status, and the choice of and response to inotropic support.

The American Society of Anesthesiologists (ASA) and the Society of Cardiovascular Anesthesiologists (SCA) developed practice guidelines in 1996 for the perioperative use of TEE.[194] The guidelines were updated in 2010,[195] and the routine use of TEE was recommended for all cardiac or thoracic aortic surgery, including all CABG or OPCAB procedures. The ASA Task Force thereby acknowledged that TEE information could impact perioperative anesthesia, surgical management, and patient outcomes. A comprehensive TEE examination is recommended by the ASE/SCA Task Force before and after CPB or after completion of revascularization in OPCAB surgery.[196,197]

Despite existing guidelines recommending TEE for all patients undergoing cardiac surgery, many centers still do not use TEE for elective CABG. Morewood and coworkers[198] obtained more than 1800 survey responses from members of the SCA in 2000. Of approximately 1500 clinicians involved in CABG, 11% reported never using TEE, and more than 30% used it frequently or always. The number using TEE is probably much higher today because of its widespread availability and ongoing popularity of the technology. Proper education and certification are critical, and guidelines on training requirements and certification have been published[199,200] (see Chapter 17). Adequate training is essential to minimize the rare but potentially serious complications of

this minimally invasive technique.[201–206] Perioperative TEE is reviewed in Chapters 14 though 17.

Neuromonitoring

Stroke and neurocognitive dysfunction are feared complications associated with CABG, whether or not CPB is used, and they occur at a high enough rate that further improvements are needed.[207–209] Intraoperative awareness is frequently reported by cardiac surgery patients. Cerebral oximetry and processed electroencephalography are monitoring modalities that have become more widespread. They play an important role in patient management and detecting adverse events.

Although monitoring alone cannot change outcomes, early recognition of potentially harmful events and interventions with an associated outcome benefit may be useful. There is no consensus about which neuromonitoring modality should be selected. However, specialty societies have increasingly recommended neuromonitoring in an effort to decrease the incidence of poor neurologic outcomes associated with cardiac surgery, including CABG and OPCAB. The 2011 ACCF/AHA guideline for CABG surgery,[106] recommended central nervous system monitoring for patients undergoing myocardial revascularization (class IIb recommendation). However, they also recognized that more evidence demonstrating clear benefits was needed and that the effectiveness of detecting cerebral hypoperfusion based on the available data is uncertain. The 2013 American Society of Extracorporeal Technology (AmSECT) standards and guidelines for perfusion practice also recommend the use of neuromonitoring.[210]

Cerebral Oximetry

The technologic background of near-infrared spectroscopy–based cerebral oximetry monitoring is reviewed in Chapter 18.[211–213] The use of cerebral oximetry has been suggested for cardiac surgical patients for several reasons. It is unique in its ability to continuously monitor regional tissue oxygenation, even during periods of low-CO nonpulsatile flow during CPB and with nonpulsatile ventricular assist devices. Many case reports have demonstrated that cerebral oximetry can provide early warning signs for detecting catastrophic events not detected by other monitoring devices such as pulse oximetry.[214–216] The cerebral cortex can be seen as an index organ. Although autoregulatory mechanisms have to be considered, cerebral tissue oxygenation correlates with measures of systemic oxygen delivery and consumption.[217]

Data from large, randomized, controlled studies with clearly defined treatment protocols and outcome measures are needed to demonstrate that interventions based on cerebral oximetry can improve neurologic outcomes for CABG patients. Two prospective trials of CABG patients have been published. Slater and colleagues[218] randomized 265 CABG patients to a blinded control group or an unblinded intervention group. There were no statistically significant differences in cognitive decline and major postoperative complications (eg, cerebrovascular accident, MI, renal insufficiency, reoperation for bleeding) between the two study groups, a result the investigators attributed to poor compliance with the treatment protocol. In the multivariate analysis, prolonged regional cerebral oxygen desaturation was an independent risk factor for postoperative cognitive decline regardless of the assigned study group.

In a similar study, Murkin and associates[219] demonstrated that treatment of cerebral oxygen desaturation improved outcomes of patients undergoing CABG. They randomized 200 patients undergoing CABG to an intervention group, in which cerebral tissue desaturation was linked to a treatment intervention protocol attempting to return the readings to baseline values, or to a control group, in which cerebral oximetry readings were blinded to the practitioner. The hypothesis was that most of the interventions to optimize cerebral oxygen saturation would also influence systemic perfusion. There was no difference in the overall incidence of adverse complications, but significantly more patients in the control group had major organ morbidity or outcomes such as death, ventilation for more than 48 hours, stroke, MI, and reoperation for exploration.

Further studies are needed to determine whether postoperative cognitive dysfunction can be reduced by treatment of intraoperative cerebral oxygen desaturation. A clear threshold below which the risk of postoperative cognitive dysfunction is increased needs to be defined.

Processed Electroencephalography Monitoring

Processed electroencephalography monitoring is based on fast Fourier transformation analysis and bispectral analysis of one-channel electroencephalographic (EEG) data obtained from electrodes on the patient's forehead (see Chapter 18). Several devices have been approved by the US Food and Drug Administration (FDA).[220–223] Processed EEG monitoring is frequently associated with anesthesia depth monitoring in an attempt to decrease intraoperative awareness. *Recall* is defined as postoperative memory for intraoperative events, an infrequent but well-recognized phenomenon during general anesthesia.[224,225] *Awareness*, a conscious subjective experience (ie, implicit memory), may be much more common than conscious recall (ie, explicit memory) of intraoperative events.[226–228]

Patients undergoing cardiac surgery always have been considered to be at increased risk of intraoperative awareness, with older reports of an incidence up to 23%.[229] This situation resulted from anesthetic regimens intentionally devoid of high doses of inhalation anesthetics (ie, era of high-dose, opioid-based anesthetics), frequent periods of light anesthesia in the setting of hemodynamic instability caused by surgical manipulation of the heart and great vessels, depressed contractility after CPB, or bleeding. However, the frequent use of inhalation agents and short-acting benzodiazepines in modern anesthetic regimens has reduced the risk of intraoperative awareness for this type of surgery.[230] Ranta and coworkers[231] found definite intraoperative awareness with recall in 0.5% of patients undergoing cardiac surgery, and Dowd and colleagues[232] reported a low incidence (0.3%) of intraoperative awareness, attributing it to the continuous administration of volatile anesthetics or propofol.

The role of processed EEG monitoring (eg, bispectral index [BIS]) in preventing intraoperative awareness by patients undergoing cardiac surgery is not clear. Myles and associates[233] studied 2463 patients considered to be at high risk for awareness in a prospective, randomized, double-blinded, multicenter trial with 45% of patients undergoing high-risk cardiac surgery or OPCAB. Among those surgical patients, three possible awareness events occurred. Possible awareness events occurred irrespective of the use of BIS monitoring. Similarly, Barr and coworkers[234] found no correlation between bispectral EEG analysis of anesthesia depth and conscious recall in a small series of patients undergoing cardiac surgery.

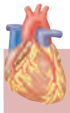
Besides monitoring anesthetic depth, there may be a role for processed EEG monitoring in titration of intravenous anesthetic agents to their effective dose, and this may be associated with improved satisfaction of patients undergoing CABG.[235,236] The raw EEG data also can help to ensure adequacy of burst suppression for hypothermic circulatory arrest.

Induction and Maintenance of General Anesthesia

The main considerations in choosing an induction technique for patients undergoing CABG are LV function and coronary pathology. No single approach to anesthesia for CABG is suitable for all patients. Most hypnotics, opioids, and volatile agents have been used in different combinations for the induction and maintenance of anesthesia, with good results in the hands of experienced clinicians. Limiting the amount of opioids or use of short-acting drugs is encouraged for patients eligible for fast-tracking and early extubation. With modern cardioplegia techniques and assuming an uneventful intraoperative course, cardiac function typically is well preserved, and the goal should be to extubate the patient within 6 hours postoperatively (Box 20.4).

Anesthetic Agents

The cardiac effects of commonly used induction agents have been investigated over many years, sometimes with conflicting results (see



BOX 20.4 CONSIDERATIONS FOR ANESTHESIA INDUCTION AND MAINTENANCE DURING MYOCARDIAL REVASCULARIZATION

1. Anesthetic induction with tight control of hemodynamic parameters (ie, avoid tachycardia, hypotension), particularly in patients with left main or proximal LAD disease.
2. Fast-track anesthetic protocols aiming for early extubation are favored for most patients.
3. Given the increasing evidence for preconditioning effects, a potent volatile agent should be part of the anesthetic regimen. Avoid nitrous oxide because of the possibility of expanding gaseous emboli.
4. Maintain CPP without increasing myocardial oxygen demand (eg, phenylephrine, nitroglycerin, avoid tachycardia).
5. Antifibrinolytic therapy (ie, ε-aminocaproic acid or tranexamic acid) except in OPCAB patients. Aprotinin is no longer available in the United States.
6. Consider low tidal volume mechanical ventilation and no PEEP during LIMA dissection.
7. Heparin usually is administered before clamping the LIMA pedicle to avoid thrombosis. Papaverine, if injected retrograde into the LIMA by the surgeon, is frequently associated with hypotension.
8. Heparin administration (300–400 IU/kg) or as calculated by heparin titration (Hepcon) in CABG patients with CPB. ACT >480 seconds and/or heparin level >2.5 U/mL is required for institution of CPB.

ACT, Activated coagulation time; *CABG*, coronary artery bypass grafting; *CPP*, coronary perfusion pressure; *LAD*, left anterior descending coronary artery; *LIMA*, left internal mammary artery; *OPCAB*, off-pump coronary artery bypass; *PEEP*, positive end-expiratory pressure.

Chapter 10). Unraveling the direct or indirect effects of a particular drug on the heart and circulation is complex because overall effects are based on contractility, vascular tone, and response of the autonomic nervous system and baroreceptors. Additional concerns are the details of the animal preparation (eg, species, acute vs chronic preparation, open vs closed chest) or clinical setting (eg, type and speed of induction). One drug is usually not used exclusively (ie, balanced anesthesia), and all drugs must be titrated to effect with the overall goal of avoiding hypotension, excessive hypertension, tachycardia, and myocardial depression.

Thiopental had been used for decades for induction in patients undergoing CABG. It is rarely used today, and in the United States, thiopental is no longer available. Its predominant hemodynamic effects include reductions in MAP and CO accompanied by a modest increase in HR. These effects are thought to result from a combination of direct myocardial depression, venodilation, and a decrease in central sympathetic outflow. Thiopental is reported to have greater negative inotropic effects than propofol.[237–240] However, opposite findings also have been reported[241] and may be related to the greater degree of vasodilation seen with propofol, which maintains overall cardiac output.[242,243] Adverse effects on airway resistance, a greater propensity to elicit bronchospasm, and a greater association with postoperative nausea and vomiting are other factors accounting for its decreased use.

Etomidate is often the preferred induction agent in patients with depressed cardiac function because it has minimal or no direct negative inotropic or sympathomimetic effects.[237,240] In an isolated rabbit heart preparation, Komai and colleagues[244] demonstrated that etomidate at very high concentrations inhibited the influx of extracellular calcium but had no effect on availability of intracellular calcium required for excitation-contraction coupling. Despite the observed hemodynamic stability, unwanted side effects are common. Significant pain during injection, particularly in a small superficial vein, is unpleasant for the patient and causes tachycardia and hypertension, both of which increase myocardial oxygen demand. Unless combined with adequate amount of opioids, blunting of the adrenergic response to intubation is poor and may result in hypertension and tachycardia. Even a single dose of etomidate can inhibit adrenal mitochondrial hydroxylase activity, resulting in reduced steroidogenesis[245,246]; however, outcome differences in cardiac surgery patients have not been documented consistently.[247,248] Myoclonic jerking can be observed in the absence of muscle relaxation, and a greater association with postoperative nausea and vomiting are adverse effects seen with etomidate administration.

Propofol is commonly used as an induction agent in patients undergoing CABG, for anesthesia maintenance, and for sedation postoperatively in the ICU.[249–251] Its isolated effects on contractility are controversial, with conflicting findings depending on the research model used. A sophisticated analysis of its effects in CABG patients using TEE assessment of preload-adjusted maximal power, a load-independent measure of contractility, at four different plasma concentrations (0.6–2.6 mg/mL) found no direct effect on contractility, although it lowered preload and afterload.[252] It previously was evaluated in numerous clinical studies for induction and maintenance with an opioid, and it was compared with a volatile-opioid combination for CABG in patients with normal or depressed EF. These studies reported minimal differences in hemodynamics or the incidence of myocardial ischemia.[253–258] However, more sophisticated and larger contemporary studies closely evaluating ventricular function on weaning from CPB and perioperative release of biomarkers of ischemia consistently reported better myocardial protective properties with the use of volatile agents over a total intravenous anesthesia (TIVA) technique with propofol. This effect is thought to be related to the anesthetic preconditioning and postconditioning effects of volatile agents (see Chapter 10).

Although there seem to be well-documented advantages for using inhalation anesthetics in patients at risk for myocardial injury, benefits of propofol also have been reported. Propofol has strong free radical–scavenging properties that in one CABG study appeared to attenuate myocardial lipid peroxidation in atrial tissue biopsies.[259] In a multicenter, prospective study comparing an inhalation-based anesthetic with TIVA in patients undergoing combined valvular and CABG surgery, no observed beneficial effect of sevoflurane on the composite end point of mortality, prolonged ICU stay, and troponin levels was found.[260] A large metaanalysis that included 133 studies and 14,516 cardiac and noncardiac surgery patients found no difference in mortality when propofol was used.[261] In a prospective, randomized controlled trial, patients were assigned to an inhalation or propofol-based anesthetic.[262] Patients in the inhalation group had a shorter time to extubation and a higher prevalence of hypotension requiring vasoconstrictive support; mortality rates, ICU LOS, and hospital LOS did not differ. Dexmedetomidine is an alternative drug available for sedation in the ICU, and both drugs have been compared in clinical trials with mixed findings.[263,264]

Ketamine is rarely used in CABG patients. In patients with severely decreased LV function, etomidate is usually the preferred drug. Administration of ketamine is associated with increases in HR and MAP through indirect central and peripheral sympathetic stimulation (eg, inhibition of neuronal reuptake of catecholamines). In states associated with depletion of catecholamines and in isolated preparations, ketamine has direct negative inotropic and vasodilating effects,[265] and it may have a negative lusitropic effect, decreasing diastolic compliance.[266] In a double-blind, randomized, controlled trial, Zilberstein and associates[267] documented a potent antiinflammatory effect (ie, suppression of increases in superoxide anion production after CPB) with a very small dose of ketamine (0.25 mg/kg) that persisted for several days postoperatively.

Benzodiazepines are commonly used in CABG patients for preoperative sedation and in combination with a narcotic to induce anesthesia. Historically, diazepam was added to high-dose morphine or fentanyl as the main anesthetic for patients undergoing CABG.[268–270] With the introduction of short-acting benzodiazepines, particularly midazolam, diazepam has almost become obsolete for induction and maintenance in cardiac surgery.[271–282]

Midazolam is very well tolerated, with minimal hemodynamic effects even in patients with severe cardiac dysfunction. There has been relatively little research on midazolam's direct cardiac effects, which are difficult to evaluate in the clinical setting because it is typically administered with other drugs. For example, Messina and coworkers[283] reported a clinical study of 40 CABG patients in whom 0.1 mg/kg of midazolam was administered after induction and intubation with thiopental, fentanyl, and pancuronium. Contractility was mildly depressed, although afterload was reduced simultaneously, resulting in no net change in the cardiac index.

High-dose opioid anesthesia was introduced into cardiac surgery by Lowenstein and coworkers[284] in 1969, in an attempt to provide safe anesthesia without myocardial depression in patients with severe valvular heart disease and compromised cardiac function. Although this revolutionized anesthesia for patients with cardiac dysfunction, it was apparent that morphine had several disadvantages: vasodilation from histamine release, increased requirements for fluids and vasoconstrictors, and prolonged respiratory depression. Even when morphine was given to patients with normal LV function, dramatic hemodynamic responses occurred with surgical stress, amnesia could not be guaranteed, and the anesthesia often was inadequate. In modern practice, a high-dose morphine anesthetic has become obsolete.

In the late 1970s, Stanley and collaborators first reported the use of high doses of fentanyl for CABG, with and without supplemental benzodiazepines.[269,270,285] Clinicians worldwide perceived the lack of histamine release to be a very favorable property and rapidly adopted fentanyl into their clinical practice.[286–292] However, it was recognized early on that recall still could be a problem.[293] Reports on the use of the more potent sufentanil appeared at the same time as fentanyl, although most studies were not reported until the late 1980s.[272,279,280,294–300] It was also widely adopted, although there was concern about its very potent bradycardic effects at high doses, particularly when administered with nonvagolytic muscle relaxants.[301,302] Sufentanil's substantially higher costs compared with fentanyl also have limited its use. Most evidence suggests that despite documented associations of sufentanil use with shorter times to extubation, overall costs and hospital LOS have been unaffected relative to fentanyl.[79,303,304]

In the mid-1990s, remifentanil was introduced, and fueled by intense interest in fast-tracking (promoted in the same time frame), it was intensively investigated.[305–314] Careful planning with regard to when it is terminated and adequate continuation of pain control is required. Combination with neuraxial anesthetics also has been advocated.[315]

The previously described opioids are pure opioid agonists, and none provides complete anesthesia as defined by predictable dose-response relationships for suppression of the stress response and release of endogenous catecholamines (particularly norepinephrine), even with high serum concentrations.[316–318] Hypertension and tachycardia commonly have been reported in response to induction or intubation and surgical stimuli (particularly with sternotomy) in older studies of high-dose opioid anesthesia with fentanyl or sufentanil.[292,319] Figs. 20.12 and 20.13 demonstrate this lack of association of serum levels with hemodynamic responses.

Philbin and colleagues[320] investigated the relationship between opioid dose and hemodynamic effect with fentanyl or sufentanil in a randomized study of CABG patients. Forty patients were allocated to receive fentanyl or sufentanil boluses, and an additional 40 patients were randomized to sufentanil bolus dosing followed by continuous infusion. Plasma opioid and catecholamine concentrations were obtained after intubation and after sternotomy. A hemodynamic response was defined as a 15% or greater increase in systolic blood pressure (HRs were not reported), and a hormonal response was a 50% or greater increase from control. In the bolus-only group, the frequency of hemodynamic responders was unrelated to drug and dose administration. Similarly, in the sufentanil-infusion group, the frequency of response was unrelated to plasma sufentanil levels. Although the study had design flaws (eg, small sample sizes, lack of reporting of hemodynamics), it provided some evidence that even high-dose opioids alone could provide incomplete anesthesia.

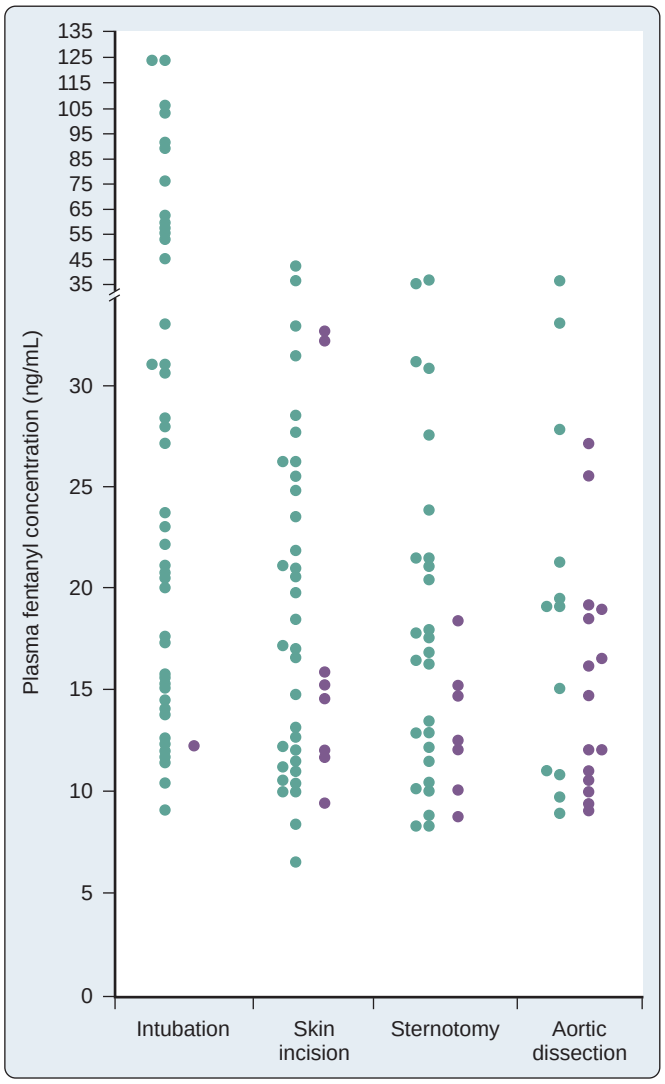


Fig. 20.12 The plasma fentanyl concentration and number of patients with a hypertensive response at each event studied. *Purple circles* indicate hypertensive status; *green circles* indicate normotensive status. *(From Wynands JE, Townsend GE, Wong P, et al. Blood pressure response and plasma fentanyl concentrations during high and very high-dose fentanyl anesthesia for coronary artery surgery.* Anesth Analg. *1983;62:661.)*

In current practice, anesthesia using only a high-dose opioid is rarely practiced. To provide complete anesthesia, the usual practice is to supplement opioids with inhaled or other intravenous agents. This permits a reduction in the total dose of opioid and, particularly with volatile agents, more rapid return of respiratory drive, facilitating early extubation. Thomson and associates[321] incorporated this approach and extended the concepts investigated by Philbin and coworkers[322] in a small but sophisticated study of CABG patients. Specific effect-related concentrations of fentanyl or sufentanil were targeted by using a computer-assisted infusion pump. Three targeted concentrations for each opioid were evaluated (sufentanil at 0.4, 0.8, and 1.2 ng/mL; fentanyl at 5, 10, and 15 ng/mL), and the end-tidal concentration of isoflurane required to control MAP and HR in the pre-CPB period by predetermined criteria was monitored. The sufentanil subgroups required 1.9, 3.1, and 4.9 μg/kg, and fentanyl subgroups received 18.8, 33.9, and 50.4 μg/kg in this period. The average end-tidal concentration of isoflurane was significantly greater between the low- and medium- or high-concentration groups, with no difference found

between the medium- and high-concentration groups. Most of the responses were increases in MAP.

Regression analysis of the study results revealed significant correlations between serum opioid concentrations and isoflurane concentrations at most of the time points sampled in the pre-CPB period. By inspecting plots of the data pairs, the investigators were able to ascertain the inflection point at which the isoflurane concentration began to rise rapidly, indicating poor control of hemodynamics by the respective opioid. For sufentanil, this was 0.71 ± 0.13 ng/mL, and for fentanyl, it was 7.3 ± 1.1 ng/mL. Given the use for fast-tracking of approximate levels of 20 µg/kg for fentanyl and 3 µg/kg for sufentanil for the entire procedure, it is unlikely these concentrations can be obtained. However, the perioperative use of β-blockers, α_2-agonists, and other drugs such as benzodiazepines provide additional hemodynamic control.

Neuromuscular blocking agents have been used to produce adequate intubating conditions and muscle relaxation during CABG (Table 20.2). Traditionally, pancuronium was advocated for use with high-dose narcotic techniques because it offset opioid-induced bradycardia. Despite the availability of newer short-acting neuromuscular blocking agents (NMBAs), pancuronium remained popular among practicing cardiac anesthesiologists for patients undergoing on-pump and off-pump cardiac surgical procedures 10 to 15 years ago.[323] However, it has long been recognized that clinically significant tachycardia resulting in myocardial ischemia could occur during induction of anesthesia with high-dose fentanyl and pancuronium.[324]

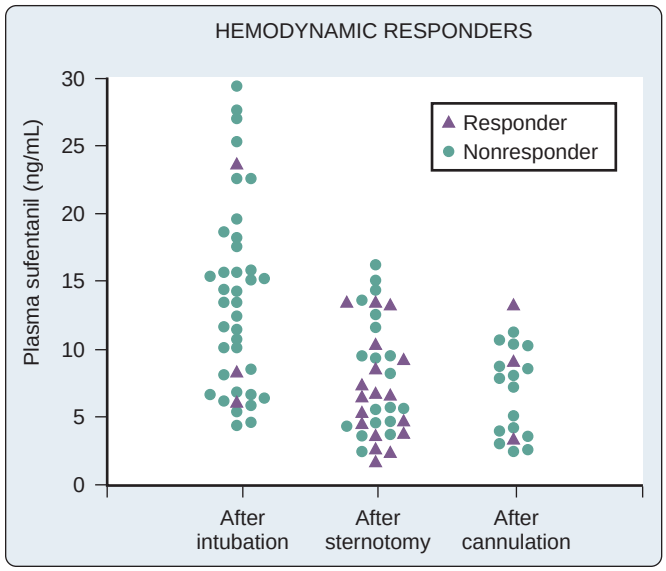

Fig. 20.13 The graph plots patients with a hemodynamic response and the plasma sufentanil concentration at that time, as well as the sufentanil concentrations for the nonresponders. Therapy was initiated at the time of the initial response, and no further data points were included for those patients. *(From Philbin DM, Rosow CE, Schneider RC, et al. Fentanyl and sufentanil anesthesia revisited: how much is enough?* Anesthesiology. *73:5, 1990.)*

Several studies have compared the durations of action of pancuronium with modern, shorter-acting NMBAs such as rocuronium.[325–327] Whether used as a single intubating dose or a continuous infusion, pancuronium use resulted in significantly longer neuromuscular blockade and delayed time to extubation.[328–330] Especially in fast-track cardiac surgery, shorter-acting NMBAs have completely replaced pancuronium, allowing earlier extubation and ICU discharge.[331]

Additional considerations are warranted for patients with underlying comorbidities such as chronic renal failure, which may alter pharmacokinetics. When magnesium is administered to cardiac surgical patients for prophylaxis of perioperative arrhythmias, blockade from nondepolarizing NMBAs may be significantly prolonged.[332] The question remains about whether continuous neuromuscular blockade for cardiac surgery is necessary at all. Gueret and colleagues[333] showed that a single intubating dose of atracurium or cisatracurium provided adequate paralysis and surgical conditions, leading to quicker neuromuscular blockade recovery for cardiac surgical patients. Advocates of this technique also point to potential advantages with regard to prevention of recall (as indicated by patient movement). However, potential disadvantages include the possibility of greater oxygen demand and consumption and movement during surgery.

α2-Agonists can help to prevent hypertension and tachycardia during intubation, surgical stimulation, and emergence from anesthesia and can decrease plasma catecholamine levels.[334–338] Zhang and associates summarized the role of dexmedetomidine in patients undergoing cardiac surgery.[334] Currently, α_2-agonists are rarely administered preoperatively, but they play a larger role in sedation and transitioning to the postoperative ICU.

Jalonen and coworkers, in a randomized, double-blind study, administered dexmedetomidine or placebo to CABG patients starting 30 minutes before induction and continued until the end of surgery.[83] Patients receiving dexmedetomidine had significantly lower plasma norepinephrine levels and more stable hemodynamics (ie, less increase in MAP and HR during induction, less intraoperative variability of systolic arterial pressure). Dexmedetomidine administration was associated with decreased incidences of intraoperative and postoperative tachycardia (5% vs 32% and 4% vs 40%, respectively) compared with placebo. Patients who received dexmedetomidine also were less likely to receive β-blocker therapy for tachycardia. However, a higher incidence of hypotension (MAP <30 mm Hg) was seen during CPB (22% vs 0% of patients for dexmedetomidine vs placebo). These data demonstrate that dexmedetomidine can be effective in attenuating sympathetic stress responses, although the same effect may predispose patients to hypotension.

Inhalation Anesthetics and Myocardial Protection

Inhalation anesthetics are routinely used in patients undergoing CABG due to the shift from using a high-opioid anesthetic to fast-tracking and because of mounting evidence that potent inhalation anesthetics protect the myocardium against ischemia by eliciting protective cellular responses similar to those seen with ischemic preconditioning.[76,77,339–348]

Murry and colleagues[349] first showed that brief periods of ischemia before a prolonged period of coronary artery occlusion significantly reduced infarction size after myocardial reperfusion. This concept is referred to as *ischemic preconditioning*. Brief periods of ischemia initiate signaling pathways that render the myocardium resistant to

TABLE 20.2 Nondepolarizing Neuromuscular Blocking Agents Used in Cardiac Anesthesia

Relaxant	*Intubating Dose (mg/kg)*	*Maintenance Dose*	*Clinical Duration (min)*	*Hemodynamic Effects*	*Special Considerations*
Pancuronium	0.08–0.12	0.01 mg/kg q20–60min	60–120	Strong vagolytic effects at clinical doses, releases norepinephrine	Reduce dose or avoid in renal insufficiency
Vecuronium	0.08–0.2	0.8–2 µg/kg/h	45–90	Insignificant	Accumulation of active metabolite with long-term use
Cisatracurium	0.15–0.2	1–2 µg/kg/min	40–75	Insignificant	Hoffman elimination
Rocuronium	0.4–1.0	0.01 mg/kg/min	35–75	Mildly vagolytic (high dosage)	No active metabolites

subsequent prolonged periods of ischemia (ie, memory effect).[350] There is a clear evolutionary advantage to self-defense by adjusting to repeated stressors. After a short ischemic period (ie, preconditioning signal), the myocardium is rendered more resistant to prolonged ischemia when the subsequent ischemic event occurs within a certain time window. Research has identified two distinct phases, also referred to as *early preconditioning* (about 2 hours) and *delayed or late preconditioning* (24 to 72 hours).

Although multiple approaches are used to protect the heart during CPB (eg, blood cardioplegia, topical hypothermia, pharmacologic additives), aortic cross-clamping defines a period of myocardial ischemia that often results in transient or prolonged dysfunction after reperfusion.[351,352] Clinical research of patients undergoing CABG appears to support the concept of ischemic preconditioning. Brief periods of aortic cross-clamping with consequent reperfusion intervals before a period of ventricular fibrillation have been shown to preserve ATP content, decrease markers of ischemia such as troponin I, and improve cardiac function in patients undergoing CABG.[353–356] However, ischemic preconditioning is not practical in clinical practice because controlled periods of myocardial ischemia are difficult to achieve, cumbersome, and potentially dangerous.[357] Repeatedly cross-clamping an atherosclerotic aorta may result in embolism formation and endothelial damage, increasing mortality.[358] Some degree of myocardial protection may be conferred when brief periods of ischemia are applied to organs or tissues remote from the heart, also referred to as *remote preconditioning*, improving the applicability of ischemic preconditioning.[359–363]

There is evidence that pharmacologic agents such as potent inhalation anesthetics and opioids mimic the effects seen with ischemic preconditioning, a concept called *pharmacologic or anesthetic preconditioning*.[364,365] Not all anesthetic drugs have preconditioning effects. For example, the commonly used induction agents etomidate and ketamine do not have cardioprotective properties.[366,367]

The pathways associated with myocardial preconditioning involve a variety of triggering stimuli, mediators, receptors, and effectors.[368] It is thought that activation of sarcolemmal and mitochondrial ATP-sensitive K^+ (K^+_{ATP}) channels play a pivotal role in the preconditioning process.[369] Channel opening protects the myocardium by preventing cytosolic and mitochondrial Ca^{2+} overload. The exact mechanisms of preconditioning are much more complex and continue to be investigated.

After the administration of a preconditioning signal such as ischemia or certain pharmacologic agents, membrane-bound receptors (eg, A_1 adenosine, adrenergic, bradykinin, muscarinic, δ_1-opioid) coupled to inhibitory G-proteins are activated.[370–375] Consequently, products of intracellular transduction pathways (eg, protein kinase C [PKC], tyrosine kinases, MAP kinases) mediate the opening and stabilization of mitochondrial K^+_{ATP} channels, the effectors thought to be mainly responsible for the preconditioning phenomenon.[376,377] Increased formation of nitric oxide (NO),[378–380] free oxygen radicals,[368] and enzymes such as cyclooxygenase 2[381] are also involved in the preconditioning process.

The delayed phase of myocardial protection, which may last well beyond the documented 24 to 72 hours, probably is based on transcriptional changes of protective proteins,[382,383] which may explain the time gap between early and late preconditioning.[384] Inhalation anesthetics also preserve cardiac function after reperfusion and decrease ischemia-induced intracoronary adhesion of polymorphonuclear neutrophils and platelets.[385–389]

Whether early results from in vitro studies and PCIs could be generalized to cardiac surgery has been investigated in multiple clinical studies. For example, Belhomme and associates[344] exposed patients to 5 minutes of preconditioning with a 2.5 minimum alveolar concentration (MAC) of isoflurane after the onset of CPB but before aortic cross-clamping. Troponin I and creatinine kinase MB subtype (CK-MB) levels were not significantly different from those of the control group. Nevertheless, patients who were exposed to isoflurane had increased activity of 5-nucleotidase, a marker for PKC activation, which is early evidence of preconditioning pathway activation similar to the in vitro findings.

Julier and coworkers,[342] in a double-blind, placebo-controlled, multicenter study, reported the effect of sevoflurane preconditioning on biochemical markers for myocardial and renal dysfunction in patients undergoing CABG. Patients who had sevoflurane preconditioning during the first 10 minutes of CPB had lower levels of biochemical markers of myocardial and renal impairment. Brain natriuretic peptide level as an indicator of myocardial dysfunction was significantly decreased in the sevoflurane group.

Conzen and colleagues[341] studied randomized patients undergoing OPCAB surgery with a propofol infusion or a continuous inhalation-based anesthetic technique with sevoflurane. Patients in the sevoflurane group had significantly lower troponin I levels and better LV function. Nader and associates[346] added vaporized sevoflurane (2%) versus oxygen alone to a cold blood cardioplegia solution in a small, randomized trial of patients undergoing CABG. Markers of the inflammatory response (ie, neutrophil β-integrins, tumor necrosis factor-α, and interleukin-6) were lower, and cardiac function (ie, stroke work index and wall motion analysis) was better preserved in the sevoflurane group (Fig. 20.14).

Whether the biochemical markers of improved cardiac outcome translate into reduced mortality rates or improved long-term outcomes is unclear. Garcia and coworkers[343] reported the results of a prospective, randomized study of the effect of sevoflurane preconditioning (10 minutes before aortic cross-clamping) on late cardiac events. Coronary artery reocclusion, HF, and cardiac death were assessed at 6 and 12 months postoperatively, and preconditioning with sevoflurane appeared to significantly reduce the incidence of late cardiac events. In a prospective, randomized, nonblinded study, De Hert and colleagues[77] compared the inhalation anesthetics desflurane and sevoflurane with intravenous anesthesia using a continuous propofol infusion in high-risk patients undergoing CABG. In the volatile anesthetic group, myocardial function was better preserved, troponin I levels were lower, and ICU and hospital LOS was shorter compared with propofol or

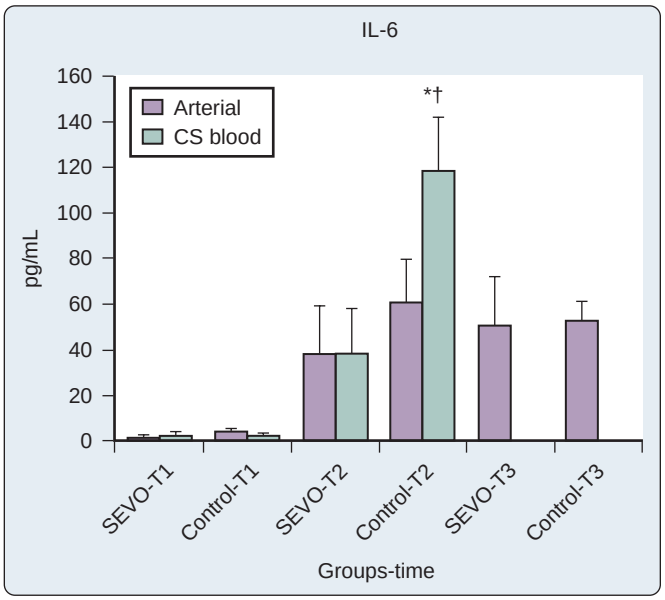

Fig. 20.14 Blunting of elevation of interleukin-6 (IL-6) levels in response to cardiopulmonary bypass (CPB) in patients receiving 2% sevoflurane *(SEVO)* added to the cardioplegia solution (1.4 ± 1.2 to 38.2 ± 21.6 pg/mL vs 4.1 ± 1.4 to 118.2 ± 23.5 pg/mL, $P < .05$). Levels were similar by 6 hours after CPB. *CS,* Coronary sinus; *T1,* baseline; *T2,* after separation from CPB; *T3,* 6 hours after separation from CPB. *(From Nader ND, Li CM, Khadra WZ, et al. Anesthetic myocardial protection with sevoflurane.* J Cardiothorac Vasc Anesth. *2004;18:269.)*

midazolam-based anesthesia regimens in this setting.[76] Guarrancino and associates[390] showed that desflurane-based anesthesia resulted in reduced troponin I release, inotropic drug use, and number of patients requiring prolonged hospitalization compared with a propofol-based technique in OPCAB procedures.

Several metaanalyses looked at preconditioning and mortality rates or long-term outcomes for patients undergoing cardiac surgery. In a metaanalysis that included only studies with sevoflurane and desflurane, Landoni and coworkers showed a reduction in mortality rates and the incidence of MI after cardiac surgery.[391] In two other meta-analyses that also included isoflurane, no such benefit was seen.[392,393]

Landoni and colleagues later published another metaanalysis applying Bayesian methodology, allowing them to investigate the various inhalation anesthetics compared with each other and ranking them in order of efficacy. Standard metaanalysis confirmed that the use of volatile anesthetics was associated with a reduction in mortality rates compared with TIVA, and the Bayesian analysis showed that sevoflurane and desflurane conferred the greatest benefits among the inhalation agents.[394]

Data from a Danish database used in a retrospective, multicenter analysis that included 10,535 patients did not show a difference in overall postoperative mortality or MI rates between propofol- and sevoflurane-based anesthesia.[395] To further investigate these controversial findings, Bignami and associates[396] conducted a longitudinal survey of 64 Italian cardiac surgical centers to study the correlation between the use of volatile anesthetics and 30-day mortality rates for CABG. The results showed that risk-adjusted 30-day mortality rate was significantly reduced when volatile agents were used during cardiac surgery, especially when there was prolonged use of these agents. The most consistent results were found when isoflurane was used. In a multicenter trial comparing desflurane or sevoflurane with propofol-based anesthesia, De Hert and coworkers[397] were unable to find a difference in troponin release, but they did show that the use of inhalation anesthetics reduced hospital LOS and that patients in the inhalation anesthetic group had a lower 1-year mortality rate.

The optimal timing and duration of inhalation anesthetic administration are uncertain.[398–401] Whereas some of the studies use brief periods of anesthetic preconditioning before aortic cross-clamping, others have reported the use of volatile anesthetics throughout the operative period. The older studies using brief periods of preconditioning showed improved cardiac function, although levels of markers of myocardial injury such as CK-MB or troponin I often were not significantly different from those of the control group. De Hert and colleagues[340] showed that the best results for myocardial protection were achieved when sevoflurane was administered throughout the intraoperative period rather than immediately before the planned myocardial ischemic event.

Most similarly designed studies have confirmed De Hert's findings. However, Bein and associates[401] found that levels of myocardial cell damage and dysfunction were lower in patients who received sevoflurane in an interrupted manner. Frassdorf and coworkers[400] also demonstrated that preconditioning-related myocardial protection was superior with multiple periods of sevoflurane administration applied rather than one short period. When sevoflurane was added to the anesthesia regimen after the coronary anastomoses were completed (ie, postconditioning), myocardial recovery was faster compared with propofol-based anesthesia. Nevertheless, patients who received sevoflurane during the entire procedure had the lowest troponin I levels, and the stroke volume changed the least compared with baseline levels. Most available data suggest not limiting the use of inhalation anesthetics to brief periods but rather using prolonged administration.

Research on pharmacologic preconditioning is not restricted to inhalation anesthetics only. There is increasing evidence that a variety of drugs that are commonly administered perioperatively have cardioprotective properties involving preconditioning pathways. Besides inhalation anesthetics, opioids (ie, δ-opioid receptor), adenosine (ie, adenosine A_1 receptor), and bradykinin have been investigated for their preconditioning effects, with various results.[364,365,402,403]

During cardiac surgery, several of the known preconditioning triggering agents may be used and appear to have additive or synergistic effects. Toller and colleagues[404] reported that the administration of sevoflurane and mechanical ischemic preconditioning reduced infarction size significantly compared with either stimulus alone. Ludwig and associates[364] demonstrated the additive effect of isoflurane and morphine on the reduction of infarction size.

There are insufficient data on how the potential beneficial effects of potent inhalation anesthetics differ between OPCAB and on-pump CABG patients. Some data show that OPCAB patients may benefit more.[405]

Several clinical factors appear to impair the protective effects of preconditioning. Diabetics and female patients appear to have attenuated responses to mechanical preconditioning signals during PCI.[406] Intraoperative hyperglycemia blocks the preconditioning effect, although this effect may be reversed by *N*-acetylcysteine, an oxygen radical scavenger.[366,407–410]

The role of postconditioning has also been investigated.[411,412] Short periods of flow followed by ischemia at the onset of myocardial reperfusion, referred to as *postconditioning*, elicit cellular mechanisms that help reduce MI size. Mitochondrial K^+_{ATP} channels, NO, and PKC also are thought to play important roles in postconditioning.[384,413–415] The beneficial effects of ischemic postconditioning have been shown in humans during coronary angioplasty for acute MI.[416,417] As in preconditioning, postconditioning has been found to work when applied remotely.[418] Postconditioning has improved contractile function[419] and attenuated postischemic arrhythmias.[420] However, similar to preconditioning, it is unlikely that repeated cross-clamping of the aorta during reperfusion would be achievable in clinical practice without risking major embolic strokes.

Inhalation anesthetics mimic some of the postconditioning effects and can blunt the deleterious effects of postischemic reperfusion injury and the inflammatory response syndrome after cardiac surgery.[421,422] The data suggest that the protective properties of potent inhalation anesthetics may not be restricted to the myocardium but also extend to other organ systems.[423–426]

The 2011 ACCF/AHA guideline for CABG surgery[106] provided level A evidence for using volatile-based anesthesia for patients undergoing myocardial revascularization to reduce the risk of perioperative myocardial ischemia and infarction. In the 2014 ACC/AHA guidelines on the management of patients undergoing noncardiac surgery, there was no preference given to a volatile or intravenous anesthetic (class of recommendation IIa, LOE A).[427] This is consistent with the lack of data demonstrating the protective effects during noncardiac surgery.

In summary, there is increasing evidence suggesting that potent inhalation anesthetics should be part of the anesthetic regimen for patients undergoing cardiac surgery, particularly patients undergoing CABG or OPCAB procedures.[428]

Role of Central Neuraxial Blockade

A balanced general anesthetic is still the most commonly used technique for patients undergoing CABG. However, there are many publications on the use of neuraxial techniques, particularly from Europe and Asia, for patients undergoing cardiac surgery.[429–431] It has been long appreciated that thoracic sympathectomy has favorable effects on the heart and coronary circulation.[432] The coronary vasodilating effects from thoracic epidural anesthesia (TEA) have been well documented, and the use of chronically implanted patient-controlled catheters has been reported.[433–438]

In the United States, medicolegal concerns about the rare but real danger of a devastating neurologic injury, the substantial logistic issues regarding placement of the catheter the night before surgery (most patients undergoing nonemergent CABG in the United States are admitted on the morning of surgery), and the potential for cancellation of a procedure in the event of a bloody tap during epidural catheter placement. The ubiquitous use of potent antiplatelet drugs in patients with CAD and the insufficient data regarding when to safely

discontinue those drugs before TEA and before catheter removal postoperatively are major concerns. The advent of fast-tracking may be a driving force (ie, ability to extubate faster and have a more comfortable patient with TEA), although most evidence suggests that a wide variety of techniques can be used effectively to facilitate early extubation. The cardioprotective effects of volatile agents may be as effective as the beneficial effects of thoracic sympathectomy.

High TEA for conscious OPCAB surgery has been reported mostly from centers outside the United States.[439–446] Karagoz and coworkers[447] described 137 patients, of whom 97% were successfully managed under awake TEA. In the reported series, most grafts were single-vessel left internal mammary artery (LIMA)–to–LAD grafts, although two-vessel and a small number of three-vessel procedures were performed successfully. In most series, 2% to 3% of catheters were unable to be placed in potential candidates, and 2% to 3% of procedures had to be converted to general anesthesia. Patients were fast-tracked, an ICU stay was not used, and some were discharged from the hospital the day of surgery. The rate of patient acceptance appeared to be quite high. In these small series, no TEA-related complications were observed. This is an area of growing interest and one that has potential advantages, particularly for countries with different health care systems, resource constraints, and cultural variations.

Although feasibility of using TEA has been demonstrated, outcome benefits associated with neuraxial blockade in patients undergoing OPCAB surgery need to be measured. Study designs are inherently flawed because it is impossible to perform a double-blind study, and operator bias and practitioner preference influence reported findings. In most studies, no significant difference in major outcome parameters, such as perioperative mortality and major morbidity rates, were found when neuraxial techniques were compared with general anesthesia alone or as a combined technique.[74,75,448,449] However, differences in minor outcome findings, such as quality of analgesia and time to extubation, are frequently reported.[450,451] Priestley and colleagues[452] conducted a prospective randomized study and did not find improved pulmonary or cardiac function with TEA or decreased LOS, despite improved analgesia and earlier extubation.

In 2006, Hansdottir and associates[453] randomized patients who had general anesthesia for cardiac surgery to TEA (given before surgery) or intravenous morphine for postoperative analgesia. Although time to extubation was shorter in the TEA group, none of the other examined outcome parameters was significantly different between the two groups. The investigators concluded that TEA combined with general anesthesia offered no major advantage compared with general anesthesia alone.

Bracco and coworkers[454] found fewer postoperative complications such as delirium, pneumonia, acute renal failure, and myocardial dysfunction in patients undergoing cardiac surgery who had TEA in addition to general anesthesia compared with general anesthesia alone. Based on shorter ICU LOS and mechanical ventilator times for patients with TEA, they calculated $8800 cost savings per person if TEA was used. Another trial enrolling obese patients (BMI >30 kg/m^2) undergoing OPCAB surgery showed better analgesia, improved lung function tests, and shorter time to extubation and ICU LOS for patients who had TEA in addition to general anesthesia.[455]

Liu and colleagues[456] reported a metaanalysis of 15 randomized trials of TEA with 1178 cardiac patients. In contrast to an earlier mixed metaanalysis (ie, cardiac and noncardiac surgery, observational and randomized),[457] there were no effects on postoperative MI or mortality rates. However, significant favorable effects were observed for arrhythmias, pulmonary complications, time to extubation, and reduction in visual analog pain scales. In a later study, Stenger and colleagues matched patients undergoing elective cardiac surgery to TEA or control groups (508 patients in each group) using EuroSCORE criteria.[458] Patients in the epidural group had a lower 6-month mortality rate and a lower incidence of MI, and TEA was associated with a reduced risk of postoperative dialysis (OR = 0.22 [0.06–0.74]).

The potential advantages of TEA on cardiac function were investigated in several studies. Berendes and coworkers[78] reported improved regional LV function by wall motion score index and lower troponin I and atrial and brain natriuretic peptide levels. However, the control for this study was a TIVA technique, and it is unclear whether a volatile anesthetic would have similar effects.

In a prospective, controlled study, Barrington and colleagues[459] randomized 120 patients to general anesthesia with or without high TEA. Although postoperative analgesia was improved in the TEA group and led to earlier extubation, there were no significant differences found in troponin levels in the two groups. Crescenzi and associates[460] evaluated the effect of TEA on N-terminal pro–brain natriuretic peptide (NT-proBNP) levels in elderly patients undergoing CABG. TEA in addition to general anesthesia significantly attenuated NT-proBNP release.

Lee and coworkers[461] addressed a slightly different question using total spinal sympathectomy (37.5 mg of bupivacaine) before induction of general anesthesia. Patients randomized to bupivacaine had less β-receptor dysfunction in response to CPB of more than 1 hour, lower catecholamine levels, a higher cardiac index, and lower pulmonary vascular resistance index in the post-CPB period. In another study, Bektas and colleagues[462] randomized 34 patients to intravenous morphine patient-controlled analgesia and high TEA with continuous levobupivacaine infusion after anesthesia induction. General anesthesia was maintained in both groups with a TIVA technique. TEA was associated with lower troponin I and CK-MB levels and a higher cardiac index after CABG.

Safety concerns are a major consideration in the use of neuraxial techniques in patients undergoing cardiac surgery because of chronic use of antiplatelet agents, systemic anticoagulation during surgery, and potential coagulopathy induced by CPB. The true incidence of serious complications (particularly epidural hematoma) is unknown.[463,464] A widely quoted estimation of the risk of epidural hematoma with TEA for patients undergoing cardiac surgery is 1 in 12,000 with a 95% confidence interval (CI) of 1 in 2100 to 1 in:68,000 and 1 in 1000 with 99% confidence.[465] A later risk assessment of neuraxial anesthesia in cardiac surgery estimates the risk of a catheter-related epidural hematoma in patients undergoing cardiac surgery to be 1 in 5493 with a 95% CI of 1 in 970 to 1 in 31,114.

Large, retrospective studies attempting to explore safety concerns with neuraxial manipulation in patients undergoing cardiac surgery have been published. Chakravarthy and associates[466] presented an audit of 2113 cardiac operations using TEA over a 13-year period with no permanent neurologic deficits, a 0.9% dural puncture rate, and 0.2% rate of transient neurologic deficits. Jack and coworkers published their experience of thoracic epidural catheter placement in 2837 patients undergoing cardiac surgery.[467] No epidural hematoma was seen in this series. Similar results were reported by Royse and colleagues,[468] who reviewed 874 cardiac surgery cases involving epidural anesthesia over a 7-year period with no complications attributable to epidural catheter use. Pastor and associates[469] reported 714 uneventful cases over a 7-year period, emphasizing their use of safety guidelines mandating discontinuing antiplatelet drugs 7 days before surgery, and routine coagulation tests and neurologic examinations were performed postoperatively. Even with these studies, the major concerns about adding a neuraxial technique are the subsequent heparin administration and the not infrequent coagulopathy associated with cardiac surgery. There are isolated reports of spontaneous spinal hematomas after cardiac surgery without neuraxial manipulation, which further complicates this issue.[470,471]

Planning a neuraxial technique for cardiac surgery patients requires careful attention to the most recent guidelines on neuraxial anesthesia in the setting of evolving anticoagulant and antiplatelet agents. The American Society of Regional Anesthesia and Pain Medicine published the Consensus Statements on Neuraxial Anesthesia and Anticoagulation.[472] They include recommendations for appropriate withdrawal of anticoagulant and antiplatelet therapy before neuraxial anesthesia and can be found at https://www.asra.com.

In summary, although neuraxial techniques can be performed for patients undergoing myocardial revascularization, outcome parameters

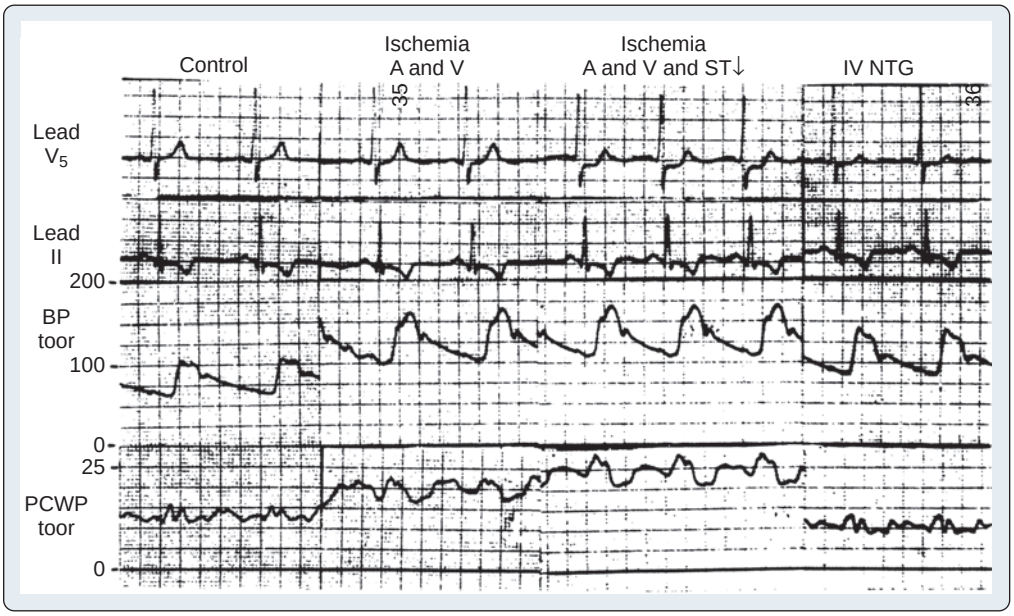

Fig. 20.15 Nitroglycerin *(NTG)* relieved postintubation intraoperative myocardial ischemia, as evidenced by large V waves in the pulmonary capillary wedge pressure *(PCWP)* tracing and then by ST-segment depression. *BP,* Blood pressure. *(From Kaplan JA, Wells PH: Early diagnosis of myocardial ischemia using the pulmonary arterial catheter.* Anesth Analg. *1981;60:789.)*

such as major morbidity and mortality rates are minimally affected by the anesthetic technique and probably depend more on patient-related factors and the quality of surgical intervention. This makes the risk-benefit ratio for TEA very questionable.

Myocardial Ischemia in Patients Undergoing Revascularization Surgery

In addition to providing anesthesia, a major concern of the anesthesiologist is the prevention and treatment of myocardial ischemia. The 2011 ACCF/AHA guideline for CABG surgery[106] recommended that determinants in coronary perfusion (ie, HR, diastolic pressure or MAP, and right ventricular [RV] or LV end-diastolic pressure [LVEDP]) should be monitored to reduce the risk of perioperative ischemia. Monitoring relevant hemodynamic parameters, detecting myocardial ischemia, and prompt treatment are of paramount importance for patients undergoing myocardial revascularization.

Diastolic dysfunction detected with TEE or a PAC is one of the earliest changes associated with myocardial ischemia, and it may precede the development of abnormal systolic function. RWMAs also have been described as early signs of ischemia. They occur within seconds of inadequate blood flow or oxygen supply. RWMAs detected by TEE provide a more sensitive indicator of myocardial ischemia compared with ST-segment changes.[191] However, a major limitation is that multiple TEE views monitored simultaneously are required to detect subtle changes in RWMAs. Fig. 20.15 demonstrates how hypertension (ie, increase in wall stress), even in the absence of tachycardia, as a response to surgical stress (eg, skin incision) can be associated with pulmonary hypertension, elevated pulmonary capillary wedge pressure (PCWP), and prominent A and V waves on the PCWP waveform. Signs of myocardial ischemia (ie, ischemic MR) often resolve with administration of a nitroglycerin (NTG) infusion (see Chapters 11 through 16).[473]

Intraoperative Treatment of Myocardial Ischemia

The main hemodynamic goals are to ensure an adequate CPP (ie, diastolic blood pressure minus LVEDP) and HR control; HR is the single most important treatable determinant of myocardial oxygen consumption. Table 20.3 summarizes the treatment of acute perioperative myocardial ischemia. Some of the routinely used pharmacologic interventions for intraoperative myocardial ischemia are discussed in the following section (see Chapter 11).

Intravenous Nitroglycerin

Since the introduction in 1976 by Kaplan and coworkers of the V_5 lead to diagnose myocardial ischemia[474] and intravenous NTG to treat it,[475] the drug has been one of the mainstays for treating perioperative myocardial ischemia. Intravenous NTG acts immediately to reduce LV preload and wall tension, primarily by decreasing venous tone at lower doses, and at larger doses, it decreases arterial and epicardial coronary arterial resistance.[476–478] It is most effective in treating acute myocardial ischemia with ventricular dysfunction accompanied by sudden elevations in left ventricular end-diastolic volume, LVEDP, and PAP. The elevations in LV preload and wall tension further exacerbate perfusion deficits in the ischemic subendocardium and usually respond immediately to NTG (Fig. 20.16).

Preoperatively, NTG often is used to treat patients with unstable angina or ischemic MR.[479,480] In the pre-CPB period and during OPCAB, NTG is used to treat signs of ischemia such as ST-segment depression, hypertension uncontrolled by the anesthetic technique, ventricular dysfunction, and coronary artery spasm (Box 20.5). During CPB, NTG can be used to control the MAP,[481] but only about 60% of patients are responders because of alterations of the pharmacokinetics and pharmacodynamics of the drug with CPB. Factors contributing to the reduction of its effectiveness include adsorption to the plastic in the CPB system, alterations in regional blood flow, hemodilution, and hypothermia. Booth and colleagues[482] showed that different oxygenators and filters sequester up to 90% of circulating NTG during CPB. After revascularization, NTG is used to treat residual ischemia or coronary artery spasm, reduce preload and afterload, and it may be combined with vasopressors (eg, phenylephrine) to increase the CPP when treating coronary air embolism (Box 20.6).

Studies of the prophylactic role of NTG in preventing perioperative myocardial ischemia have had mixed results, with most studies showing no effects of NTG infusions on the incidence of perioperative myocardial ischemic events.[483–485] In a prospective, double-blind, placebo-controlled study, Zvara and associates[486] randomized patients undergoing CABG using a fast-track anesthesia technique to 2 μg/kg per minute of NTG or placebo starting before induction

TABLE 20.3 Acute Treatments for Suspected Intraoperative Myocardial Ischemia[a]

Associated Hemodynamic Finding	*Therapy*	*Dosage*
Hypertension, tachycardia[b]	Deepen anesthesia	
	Intravenous (IV) β-blockade	Esmolol, 20–100 mg ±50–200 μg/kg/min prn Metoprolol, 0.5–2.5 mg Labetalol, 2.5–10 mg
	IV nitroglycerin	Nitroglycerin, 10–500 μg/min[c]
Normotension, tachycardia[b]	Ensure adequate anesthesia, change anesthetic regimen	
	IV β-blockade	β-Blockade, as above
Hypertension, normal heart rate	Deepen anesthesia	
	IV nitroglycerin or nicardipine	Nicardipine, 1–5 mg ±1–10 μg/kg/min Nitroglycerin, 10–500 μg/min[c]
Hypotension, tachycardia[b]	IV α-agonist	Phenylephrine, 25–100 μg Norepinephrine, 2–4 μg
	Alter anesthetic regimen (eg, lighten)	
	IV nitroglycerin when normotensive	Nitroglycerin, 10–500 μg/min[c]
Hypotension, bradycardia	Lighten anesthesia	
	IV ephedrine	Ephedrine, 5–10 mg
	IV epinephrine	Epinephrine, 4–8 μg
	IV atropine	Atropine, 0.3–0.6 mg
	IV nitroglycerin when normotensive	Nitroglycerin, 10–500 μg/min[c]
Hypotension, normal heart rate	IV α-agonist/ephedrine	α-Agonist, as above
	IV epinephrine	Epinephrine, 4–8 μg
	Alter anesthesia (eg, lighten)	
	IV nitroglycerin when normotensive	Nitroglycerin, 10–500 μg/min[c]
No abnormality	IV nitroglycerin IV nicardipine	Nitroglycerin, 10–500 μg/min[c] Nicardipine, 1–5 mg ±1–10 μg/kg/min

[a]Ensure adequacy of oxygenation, ventilation, and intravascular volume status and consider surgical factors, such as manipulation of heart of coronary grafts.
[b]Tachyarrhythmias (eg, paroxysmal atrial tachycardia, atrial fibrillation) should be treated directly with synchronized cardioversion or specific pharmacologic agents.
[c]Bolus doses (25–50 μg) and a high infusion rate may be required initially.

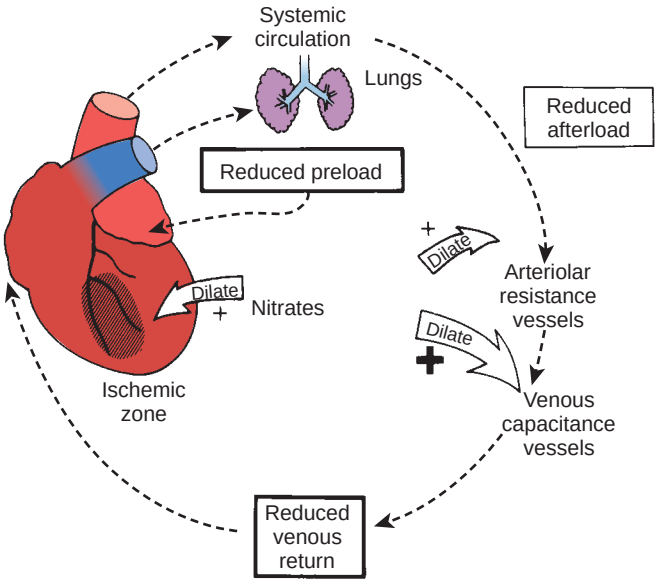

Fig. 20.16 The effects of nitrates on the circulation include prominent venodilation and reduction of preload. Afterload is decreased because of mild arteriolar dilatation. Coronary dilation also occurs and benefits the ischemic myocardium. *(From Opie LH: Drugs and the heart: II. Nitrates.* Lancet. *1980;1:750.)*

BOX 20.6 USES OF INTRAVENOUS NITROGLYCERIN ON TERMINATION OF CARDIOPULMONARY BYPASS

- Myocardial ischemia or stunning
- Diastolic dysfunction
- Elevated pulmonary artery pressure, pulmonary capillary wedge pressure, central venous pressure, pulmonary vascular resistance, systemic vascular resistance
- Increase coronary perfusion pressure along with a vasopressor
- Prevention of arterial graft spasm (ie, radial artery graft)
- Coronary artery spasm
- Reinfusion of oxygenator volume

BOX 20.5 INTRAOPERATIVE USE OF INTRAVENOUS NITROGLYCERIN

Hypertension
Elevated pulmonary artery pressure
New-onset AC and V waves (ischemic mitral regurgitation)
Acute ischemia (ST changes >1 mm)
New regional wall motion abnormalities on transesophageal echocardiography
Diastolic dysfunction
Systolic dysfunction (with adequate coronary perfusion pressure)
Coronary artery spasm

and continuing until 6 hours after extubation in the ICU. They found a similar incidence, severity, and duration of myocardial ischemia whether the patients received NTG or placebo (37% vs 35%, respectively). Although there were more patients in the placebo group with positive enzyme and electrocardiographic signs of MI, the findings were not statistically significant. Similarly, in a prospective, randomized, controlled study, 0.5 to 1 μg/kg per minute of NTG administered after aortic cross-clamp release in patients undergoing CABG did not decrease the incidence of postoperative myocardial ischemia.[487]

Intravenous NTG has been compared with other vasodilators such as nitroprusside and calcium channel blockers. Kaplan and Jones[476] first demonstrated that NTG was preferable to nitroprusside during CABG. Both drugs controlled intraoperative hypertension and decreased myocardial oxygen consumption, but NTG improved ischemic changes on the ECG, whereas nitroprusside did not. Nitroprusside decreased CPP or produced an intracoronary steal in about one third of patients with myocardial ischemia.

Calcium Channel Antagonists

The calcium antagonists are a structurally diverse group of drugs that inhibit the passage of calcium through the slow channels of the cell membrane. These agents collectively relax arterial smooth muscle, with little effect on most venous beds. Despite areas of commonality, the calcium antagonists have different actions and hemodynamic effects. For example, nifedipine acts primarily on vascular smooth muscle and has little effect on the AV node. In contrast, verapamil acts mainly on

the cardiac conduction system and has less effect on vascular smooth muscle. Diltiazem and verapamil do not significantly increase CBF or consistently decrease coronary vascular resistance. Both drugs produce significant hemodynamic changes with myocardial depression and conduction disturbances during anesthesia.[488,489] This limits their use in the treatment of perioperative myocardial ischemia.

Nicardipine is a short-acting dihydropyridine calcium antagonist similar to nifedipine, but it possesses a tertiary amine structure in the ester side chain. Nicardipine is stable as a parenteral solution and therefore can be administered intravenously.[490] It has highly specific modes of action, which include coronary antispasmodic and vasodilatory effects and systemic vasodilation. Among the calcium antagonists, nicardipine is unique in its consistent augmentation of CBF and its ability to induce potent vasodilator responses in the coronary bed. Nicardipine produces minimal myocardial depression and significantly improves diastolic function in patients with ischemic heart disease.[491,492] Despite these beneficial properties, nicardipine is typically not the primary choice in treating myocardial ischemia during CABG. However, its relatively rapid onset and cessation of action make it an attractive drug for the perioperative management of hypertension.[493–498]

Van Wezel and coworkers[499] used a 3 to 12 μg/kg per minute infusion of nicardipine and compared it with a 1 to 3 μg/kg/min infusion of nitroprusside. Both drugs were equally effective in controlling BP, but there was a 24% incidence of ST-segment depression in the nitroprusside group versus 9% in the nicardipine group. Van Wezel and colleagues[500] also compared intravenous NTG with intravenous administration of verapamil or nifedipine in patients undergoing CABG. Nitroglycerin was found to be the drug of choice because it controlled BP while not producing as much tachycardia (as nifedipine) or myocardial depression and conduction blockade (seen with verapamil).

Apostolidou and associates[487] randomized patients undergoing CABG with CPB to nicardipine (0.7 to 1.4 μg/kg per minute), NTG (0.5 to 1 μg/kg per minute), or placebo. Immediately after coronary revascularization (after aortic cross-clamp release until end of surgery), there were significantly fewer episodes of myocardial ischemia in the nicardipine group (0% vs 10% vs 24%, respectively). During the postoperative period, there was no difference in myocardial ischemia among the drug groups.

Clevidipine was introduced for the treatment of perioperative hypertension.[501] Clevidipine is an ultrashort-acting, intravenously administered, dihydropyridine calcium channel blocker that acts as an arterial-selective vasodilator, and its action is rapidly terminated by blood and tissue esterases. In a randomized, double-blind, placebo-controlled, multicenter trial of the drug in patients undergoing cardiac surgery, clevidipine effectively reduced arterial blood pressure.[502] The Evaluation of Clevidipine In the Perioperative Treatment of Hypertension (ECLIPSE) trial compared clevidipine with NTG, sodium nitroprusside, and nicardipine for acute hypertension treatment in cardiac surgery patients.[503] Clevidipine effectively maintained the arterial blood pressure within a prespecified range. Compared with nitroprusside, clevidipine-treated patients had a significantly reduced mortality rate ($P = .04$).

β-Blockers

Hypertension, tachycardia, arrhythmias, and myocardial ischemia from sympathetic stimulation are common occurrences in the perioperative period. Despite the benefits of early use of β-blockers in the treatment of myocardial ischemia, the relatively long half-life and prolonged duration of action of previously available β-blockers had significantly limited their use during surgery and the immediate postoperative period.[504] However, with the introduction of esmolol in the late 1980s, an ultrashort-acting cardioselective β_1-blocker with a half-life of 9 minutes became available. Esmolol was soon adopted by many clinicians for the prevention and treatment of myocardial ischemia. A mean esmolol dose of 17 ± 16 mg/min, with a range of 8 to 24 mg/min, was found to be effective in alleviating chest pain while increasing CO in patients with unstable angina.[505]

Kirshenbaum and coworkers[506] showed that esmolol was effective in treating acute myocardial ischemia, even in patients with poor LV function (ie, increased PCWP of 15–25 mm Hg). Esmolol was infused in these patients in doses up to 300 μg/kg per minute and produced decreases in HR, BP, and cardiac index. However, the PCWP was not significantly altered by the drug infusion. The results suggested that even in the setting of moderate LV dysfunction, esmolol could safely reduce BP and HR in patients with acute myocardial ischemia.

Because of the favorable pharmacologic properties and encouraging clinical findings, esmolol was soon used frequently during CABG to treat hypertension and tachycardia and to prevent myocardial ischemia.[507–509] Before the introduction of newer mechanical stabilizing devices, it had also been used to slow the HR to facilitate OPCAB procedures.

Weaning Patients From Cardiopulmonary Bypass After Coronary Revascularization

Chapter 36 discusses the predictors and techniques of weaning a patient successfully from CPB. Some factors and concerns are specific to patients undergoing myocardial revascularization. Good surgical technique that provides high-quality anastomoses and preserves the heart during aortic cross-clamping is key to cardiac function immediately after separation from CPB. Because administration of cardioplegia can be problematic in patients with CAD, various techniques are used, including a combination of hypothermia and antegrade and retrograde cardioplegia, by some surgeons.

In patients with normal preoperative function, minimal or no inotropic support is usually required. In patients with impaired ventricular function, TEE evaluation immediately before weaning off CPB can provide invaluable information for choosing an inotrope, vasodilator, or vasoconstrictor. In patients who arrive in the operating room with an IABP inserted, support typically is continued into the postoperative period. In patients with very poor ventricular function, the insertion of an IABP to support ventricular function during weaning from CPB can be helpful.[510,511] In a metaanalysis, preoperative IABP insertion in patients undergoing CABG was associated with a significant reduction in 30-day mortality rates (3.5% vs 11%).[512]

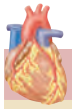
The Immediate Postoperative Period

Sedation

Patients usually are sedated to facilitate transport to the ICU and during the immediate postoperative period until extubation criteria are fulfilled (see Chapter 37). Dexmedetomidine, propofol, and midazolam are intravenously administered agents with favorable properties in this setting.

α_2-Adrenergic receptor agonists have unique properties (Box 20.7) that explain their increasing use in some cardiac surgery centers. Although the FDA approved clonidine in 1974, it was available only as an oral formulation in the United States, limiting its widespread use. In 1999, the FDA approved dexmedetomidine for continuous (up to 24 hours) intravenous sedation in the ICU. It is a more selective α_2-adrenoceptor agonist than clonidine, and exhibits central sympatholytic and peripheral vasoconstrictive effects. Intravenous bolus administration causes a transient increase in MAP and SVR due to stimulation of peripheral α- and β_2-adrenergic receptors in vascular smooth muscle. A continuous infusion (0.2–0.8 μg/kg per hour) has dose-dependent hemodynamic effects; most consistently decreases in HR, plasma catecholamine levels, and MAP.[513,514] Higher doses of dexmedetomidine result in more profound sedation with some analgesia sparing effects, and large doses may be associated with increases in MAP, SVR, and PAP.[515]

There are limited data from animal studies demonstrating potential coronary vasoconstrictive and cardiodepressant effects for dexmedetomidine.[83,516–518] Coronary vasoconstriction was seen mainly with bolus doses of 10 μg/kg and higher. At the recommended loading (0.5–2 μg/kg) and maintenance (0.2–0.7 μg/kg per hour) doses,



BOX 20.7 α_2-AGONIST PROPERTIES

- Sedation
- Anxiolysis
- Analgesia
- Hemodynamic stability
- Central sympatholytic effect
- Decreased blood pressure and heart rate
- Decreased perioperative oxygen consumption
- Decreased plasma catecholamine levels
- Decreased incidence of tachyarrhythmias
- Prevention of histamine-induced bronchoconstriction
- Treatment and prevention of postoperative shivering
- Sedation in patients with postoperative delirium
- Blunting of withdrawal symptoms in drug and alcohol addicts
- Possible inhibition of inflammatory response

dexmedetomidine most likely has a favorable effect on myocardial perfusion.[519] Roekaerts and colleagues[520,521] showed an increase in the endocardial-to-epicardial blood flow ratio in the postischemic myocardium, with an overall reduction of myocardial oxygen demand after experimentally induced myocardial ischemia in dogs. The greatest reduction in oxygen demand was seen when baseline HR and arterial BP were increased.

Dexmedetomidine may be a useful agent in the early postoperative period because its sedative properties are associated with minimal respiratory depression and appear to mimic natural sleep patterns.[522] When administered continuously in postoperative patients, it caused no changes in respiratory rate, oxygen saturation, arterial pH, and arterial carbon dioxide (CO_2) tension compared with placebo.[523] These patients usually were effectively sedated but still arousable and cooperative in response to verbal stimulation.[524] Due to its analgesic properties, it significantly reduced additional opioid analgesia requirements in mechanically ventilated patients in the ICU.[525–527]

The α_2-agonists have been used successfully in patients with postoperative delirium,[528] administered for withdrawal symptoms in alcohol or drug addicts, and are associated with a low rate of shivering.[529,530] A study of 724 patients undergoing CABG showed a lower risk of delirium and higher 30-day and 1-year survival rates when dexmedetomidine was administered after CPB and continued in the ICU.[531] Increasing data show that dexmedetomidine administration is associated with a decreased risk of tachyarrhythmias after cardiac surgery,[264,532] but the incidence of bradycardia is increased.

Propofol has been used extensively intraoperatively and for sedation in the ICU. Several studies compared propofol and dexmedetomidine in the postoperative period after surgery.[533,534] Venn and associates[524] randomized a small number of patients to propofol or dexmedetomidine sedation in the immediate postoperative period. Dexmedetomidine reduced the requirement for opioid analgesia, but for patients after myocardial revascularization, it reduced HR more than propofol, whereas the arterial blood pressure did not differ between the two groups.

In a multicenter, randomized study, Herr and coworkers[263] compared a dexmedetomidine-based sedation regimen with propofol sedation after CABG in the ICU. Although there were no differences in time to extubation, the investigators found a significantly reduced need for additional analgesics (ie, propofol-sedated patients required four times the mean dose of morphine), antiemetics, and diuretics and they had fewer episodes of tachyarrhythmias requiring β-blockade (ie, ventricular tachycardia in 5% of the propofol-sedated group vs none in the dexmedetomidine group). However, hypotension was more common in the dexmedetomidine group compared with the propofol-sedated patients (24% vs 16%) (Fig. 20.17). Approximately 25% of the dexmedetomidine-associated hypotension occurred in the first hour of the study, particularly during or within 10 minutes after the loading infusion of 1 μg/kg. To avoid hypotension seen with a large loading dose of dexmedetomidine, loading doses are infrequently administered in clinical practice, but a continuous maintenance dose is started earlier to achieve appropriate plasma levels at the time of patient transfer from the operating room.

With regard to patient satisfaction, there are insufficient data to clearly favor one of the agents. Corbett and colleagues[535] randomized 89 adult patients after CABG to dexmedetomidine or propofol. Patients were interviewed regarding awareness, recall, generalized comfort, level of pain, ability to interact with health care providers and family, feelings of agitation and anxiety, ability to sleep and rest, and overall satisfaction with their ICU stay. The level of awareness and additional morphine and midazolam requirements did not differ between the groups. Patients favored propofol for sleep and rest, there was more patient discomfort and pain in the dexmedetomidine group, and the investigators concluded that dexmedetomidine did not offer any advantages over propofol for short-term sedation after CABG. The increased incidence of pain in the dexmedetomidine group was surprising because most studies have shown reduced opioid requirements with α_2-adrenoceptor agonists.

Barletta and associates[536] compared propofol and dexmedetomidine after CABG or valve surgery, or both, in a fast-track recovery room setting. Patients ($N = 100$) were matched according to surgery type and LV function. Dexmedetomidine resulted in lower opioid requirements, but this did not result in shorter duration of mechanical ventilation, improved quality of sedation, or rate of adverse events.

In summary, although there are theoretic advantages to using dexmedetomidine for sedation after CABG, no clear benefits have been documented for either drug. Sedation-related costs are higher with dexmedetomidine administration.

Coronary Artery and Arterial Conduit Spasm

Since 1981, when Buxton and coworkers[537] first reported coronary artery spasm immediately after CABG, there have been numerous descriptions of this complication. Spasm usually has been associated with profound ST-segment elevation on the ECG, hypotension, severe dysfunction of the ventricles, and myocardial irritability. Many hypotheses have been put forward to explain the origin of coronary artery spasm (Fig. 20.18).[538] The underlying mechanism may be similar to the coronary spasm seen with Prinzmetal variant angina.

Therapy is usually effective with a wide range of vasodilators such as NTG, calcium channel blockers, milrinone, or combinations of NTG and calcium channel blockers in both situations. Arterial grafts with a vessel such as the LIMA and particularly radial artery grafts are prone to spasm after revascularization, and prevention and recognition are crucial to prevent serious complications.[539]

He and colleagues[540] tested the reactivity of ring segments of human IMAs in organ baths to various constrictor and dilator agents. Thromboxane was the most potent IMA constrictor, followed by norepinephrine, serotonin, phenylephrine, and potassium chloride. NTG, nitric oxide, papaverine, milrinone, and the calcium channel blockers nifedipine, verapamil, and diltiazem produced relaxation. In a similar study, Mussa and associates[541] observed the vasodilating properties of topically applied phenoxybenzamine. It prevented vasoconstriction with a long-lasting effect (>5 hours) in response to various vasoconstrictors, followed by verapamil/NTG (5 hours), and papaverine (1 hour). In vivo, for prophylaxis of IMA spasm, the calcium antagonists, especially diltiazem, were thought to be as useful as NTG.[542–544]

Prevention and treatment of arterial conduit spasm with diltiazem may cause serious side effects such as low CO or conduction abnormalities. Diltiazem is also a more expensive drug compared with NTG. Shapira and coworkers[545] showed in vitro (ie, radial artery, IMA, and saphenous vein) and in vivo (ie, radial artery) that NTG was a superior vasodilator compared with diltiazem. The same investigators monitored patients undergoing CABG using radial artery grafts who were randomized to receive NTG or diltiazem intravenously after induction of anesthesia followed by a NTG patch or oral diltiazem postoperatively for 6 months. There was no significant difference in outcome (ie, morbidity, MI, and CK-MB) between the two groups. The

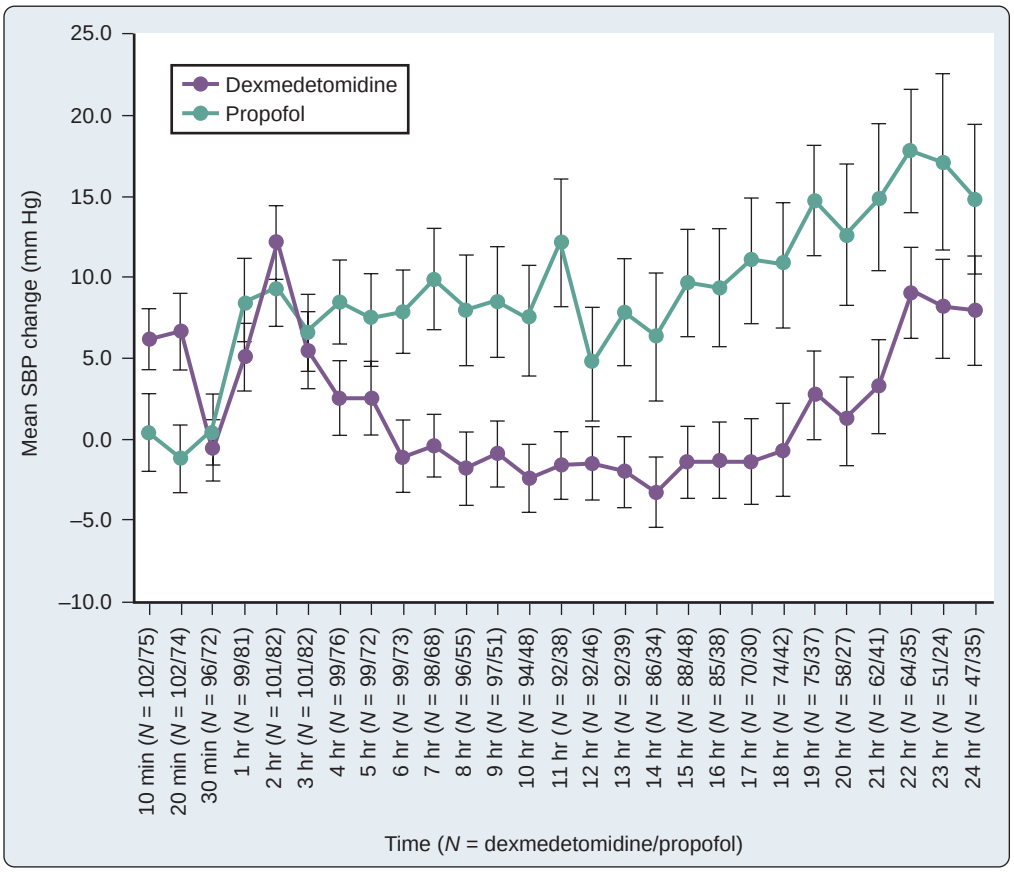


Fig. 20.17 Changes from baseline in systolic blood pressure *(SPB)* between coronary artery bypass grafting patients sedated with dexmedetomidine or propofol. The baseline is the mean SPB for each treatment group just before sternal closure. Numbers of patients receiving each drug (x-axis) declines progressively as they are extubated postoperatively. *(From Herr DL, Sum-Ping ST, England M: ICU sedation after coronary artery bypass graft surgery: dexmedetomidine-based versus propofol-based sedation regimens.* J Cardiothorac Vasc Anesth. *2003;17:576.)*

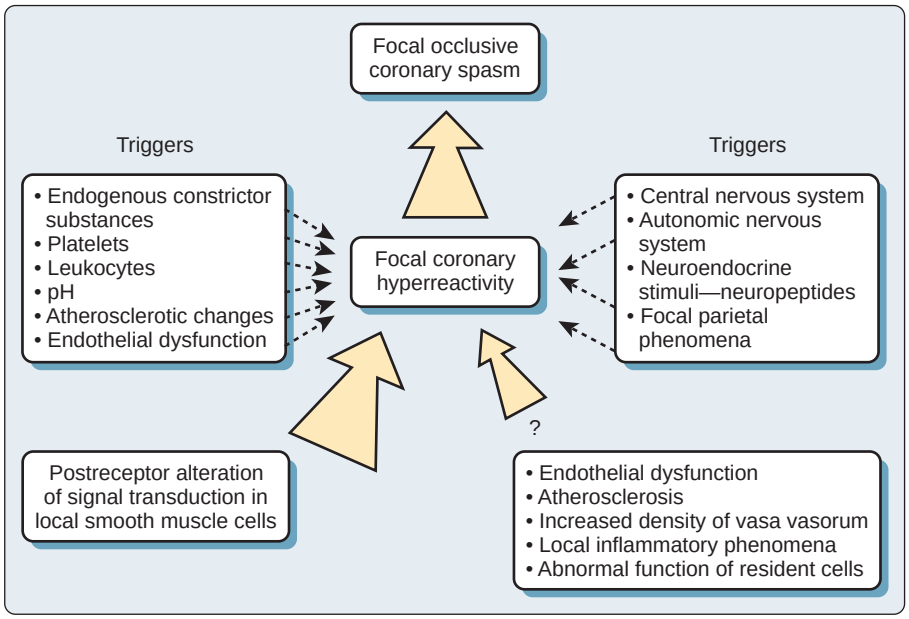

Fig. 20.18 Schematic representation of the pathogenesis of coronary artery spasm.

6-month diltiazem treatment was associated with 16-fold higher costs and significantly more patients requiring cardiac pacing compared with NTG (28% vs 13%, respectively).[546]

In a double-blind, randomized study, Mollhoff and colleagues[547] compared milrinone (0.375 μg/kg per minute) to nifedipine (0.2 μg/kg per minute) in patients with impaired LV function undergoing CABG. ST changes after revascularization (including use of the IMA graft) indicative of myocardial ischemia occurred in 33.3% of the milrinone group compared with 86.6% of the nifedipine group. Levels of biochemical markers of myocardial damage (ie, CK-MB and troponin I) after 24 hours were significantly higher in the nifedipine group.

Fast-Track Management for Coronary Artery Bypass Grafting

Fast-tracking was introduced into patient management when costs started to play a more significant role in patient care in the late 1970s and early 1980s. Diagnosis-related groups (DRGs) had been introduced about the same time in an effort to reduce Medicare reimbursements to hospitals. With this reimbursement model, less resource use, mostly driven by shorter ICU and hospital LOSs, became linked to financial benefits for the hospitals.

In 1990, Krohn and associates[548] reported a study of 240 patients undergoing CABG at a private southern California hospital between 1984 and 1986. They described a clinical pathway emphasizing early extubation, rapid mobilization, intraoperative fluid restriction, and steroid administration. This management strategy was associated with a median postoperative LOS of 4 days and in-hospital mortality rate of only 2%. The strategy was forged from intense economic competition with the first major incursion of managed care into this area's competitive market.

In 1994, the term *fast-track* in cardiac anesthesia was introduced by Engelman and colleagues in their article "Fast-Track Recovery of the Coronary Bypass Patient." It included a complete care plan, which was associated with a reduced hospital LOS.[549] In a similar time frame, reports appeared from the financially constrained UK health care system, in which formal ICU care was bypassed based primarily on rapid early extubation (with apparent success).[550,551]

The publicity associated with these reports contributed to Medicare's interest in cost reduction, leading to the Medicare Participating Heart Bypass Center Demonstration conducted between 1991 and 1996 in which seven participating hospitals agreed to a single, sharply discounted rate for CABG in return for preferential market share.[552] Over the 5-year period, it was estimated that $50.3 million dollars were saved. In their summary report, reduction of cost and LOS by retooling processes of care was emphasized, and reducing time to extubation was considered a key factor. In the participating centers, LOS and mortality rates declined annually despite increased severity of the case mix.

Although the fast-track clinical pathway encompasses a variety of perioperative and after-discharge management strategies, early extubation is the one that has received the greatest attention (Box 20.8).[553,554] Early extubation is acknowledged as a key component of the fast-track clinical pathway and one that was considered the most radical change in practice during the peak of scrutiny of the fast-track pathway in the middle to late 1990s (Box 20.9).

Reports of prolonged ventilatory management after cardiac surgery first appeared in the late 1950s (for valve surgery because CABG was not yet performed), and those from the 1960s (including the first reports of CABG patients) strongly advocated its routine use.[555] This was further emphasized with the adoption of high-dose morphine and with fentanyl and sufentanil at the end of that decade.[269,284]

As early as 1974, the first reports advocating early extubation, primarily by greater reliance on volatile anesthesia, appeared.[556] In 1980, Quasha and coworkers[557] reported the first small, randomized, controlled trial enrolling CABG patients ($N = 38$), in which 89% were extubated in less than 8 hours. Ramsay and colleagues[558] reported a small, randomized, controlled trial ($N = 20$) in which opioid reversal with nalbuphine was used. However, this resulted in an unacceptable increase in postoperative pain. The larger and more rigorous, randomized, controlled trial reported by Cheng and associates[559] in 1996 ($N = 100$), in which mean time to extubation was 4.1 hours, is recognized as the most influential of the contemporary studies of early extubation. Reports of successful use of fast-tracking in a variety of patient populations have been reported since, including academic,[79,560] private,[309,561–564] elderly,[565–567] rural settings, and Veterans Affairs patients[80,568] from the United States and many other countries. It is used as a quality improvement marker in many health care systems.[79,560,569] In some of these systems, alterations of the traditional models of ICU care have been adopted,[570] although many use routine ICU models with shorter stays (see Chapter 37).

The first metaanalyses of early extubation reported were based on accumulated data from randomized, controlled trials. Myles and coworkers[553] reviewed studies in which fast-tracking was defined as use of reduced opioid dosing (ie, fentanyl ≤20 μg/kg) with stated intention to attempt extubation in less than 10 hours postoperatively. They identified 10 trials ($N = 1800$) with most involving CABG patients from 1989 to 2002. The fast-track groups had shorter times to extubation (by 8.1 hours), with no significant differences in major morbidity or mortality rates and only one instance of reintubation. ICU LOS was reduced by 5.4 hours, although hospital LOS was not shortened.

Hawkes and colleagues[571] reported a metaanalysis from the UK-based Cochrane Collaboration. The investigators considered only randomized, controlled trials that defined time to extubation as within 8 hours and that specifically evaluated mortality rates (ie, in ICU, at 30 days, and up to 1 year), incidence of postoperative myocardial ischemia (eg, biomarkers, ECG), and pulmonary outcomes (eg, reintubation, respiratory dysfunction). Secondary outcomes of ICU and hospital LOS were analyzed. Given their more stringent requirements and

BOX 20.8 PERIOPERATIVE GOALS OF FAST-TRACK MANAGEMENT

- Preoperative education
- Same-day admission whenever possible
- Anesthetic technique tailored to early extubation
- Effective postoperative analgesia
- Flexibility in the use of recovery areas (eg, postanesthesia care unit instead of intensive care unit)
- Protocol-driven care
- Early mobilization
- Early intensive care unit and hospital discharge
- Follow-up (eg, telephone, office visits) after hospital discharge
- Interdisciplinary continuous quality improvement strategies

BOX 20.9 SUGGESTED CRITERIA FOR EARLY EXTUBATION

- Body temperature >35°C
- Normal acid-base status
- Stable hemodynamics on minimal inotropic support
- Adequate hemostasis with decreasing or stable mediastinal drainage
- Stable cardiac rhythm
- Spontaneous respiratory rate and adequate tidal volumes and inspiratory force
- Chest radiograph without major abnormalities (eg, minimal atelectasis)
- Adequate urine output
- Adequate reversal of neuromuscular blockade
- Awake, alert, cooperative, and moving all extremities

predetermined hypotheses for testing, they found only six studies ($N = 871$) meeting the criteria, and almost one-half of the patients were from a single study (Reyes and associates).[557,559,572–575]

The study by Reyes and coworkers[574] is unusual because both treatment groups received high-dose fentanyl, in contrast to all other studies of fast-tracking in which opioid doses were deliberately lower. However, exclusion of this study did not alter the findings. Overall, there was no difference in ICU and 30-day mortality rates; the 1-year mortality rate was assessed in only one study, which showed difference between groups. All other outcome parameters, including postoperative myocardial ischemia, incidence of early reintubation within 24 hours (1.6%), late reintubation (>24 hours), and atelectasis, did not vary significantly between groups. The ICU LOS was significantly reduced by 7 hours, and hospital LOS was reduced by 1.1 days.

Some centers have adopted an even more aggressive form of fast-tracking. Walji and colleagues[564] coined the term *ultrafast-tracking* to describe their practice and reported a 56% hospital discharge rate by postoperative day 4 and 23% discharge rate by postoperative day 2, although the readmission rate was 3.9%, but there was no early mortality. Ovrum and associates[576] from Norway reported a cohort of 5658 CABG patients, 99% of whom were extubated by 5 hours (median, 1.5 hours), with a 1.1% reintubation rate. More than 99% of patients were transferred to the ward the next morning.

Although postoperative pain management is detailed in Chapter 42, it should be mentioned that nonopioid analgesics are frequently administered to patients who are fast-tracked. The use of nonsteroidal antiinflammatory drugs (NSAIDs) after CABG is controversial; particularly after the FDA issued a black box warning in 2005 recommending against their use after cardiac surgery. However, recent data seem to support the safety of NSAIDs in the cardiac surgery setting.[577–579] More data are required to make conclusive recommendations.

Coronary Artery Bypass Grafting Without Cardiopulmonary Bypass

Introduction and Surgical Considerations

Although OPCAB gained increasing popularity in the late 1990s, surgery on the beating heart had already been performed in the 1950s and early 1960s, preceding the widespread use of on-pump CABG. Limitations included a lack of adequate equipment and CPB techniques in the early days of cardiac surgery. After CPB could be safely accomplished, many surgeons lost interest in OPCAB surgery, preferring a nonbeating heart for coronary anastomoses. However, the inherent risks of CPB and aortic cross-clamping continued to be a major factor in CABG morbidity and mortality. Avoiding CPB altogether seemed to offer a solution, but technical limitations with the then available surgical equipment were significant. It was not until the middle to late 1990s, when surgical researchers developed efficient mechanical stabilizer devices that minimized motion around the anastomotic site, that OPCAB surgery regained more widespread interest.

The pace and tempo of OPCAB surgery differs substantially from that of conventional CABG.[580] Surgical manipulations involve a variety of geometric distortions of the cardiac anatomy, with resulting hemodynamic effects. Communication between all members of the surgical team and anticipation of these changes are vitally important to minimize resulting adverse hemodynamic effects on the heart and other organs. Significant hemodynamic changes that cannot be reversed may necessitate emergent conversion to CPB at any time during OPCAB surgery.

Cardiovascular Effects of Off-Pump Coronary Artery Bypass Grafting

Hemodynamic changes encountered during OPCAB involve the two independent variables of distortion of the right or left atria and ventricles by stabilizer and suspension devices and the effects of myocardial ischemia during anastomosis. The ability to expose the posterior surface of the heart to access the posterior descending and the circumflex vessels using suction devices placed on the apex or anterolateral wall of the heart, pericardial retraction sutures, slings, or other techniques without producing major hemodynamic compromise is critical for multivessel application of OPCAB surgery. Lifting of the heart to work on the posterior vessels commonly is referred to as *verticalization*, in contrast to *displacement* for the LAD and diagonal anastomoses (Figs. 20.19 through 20.21).

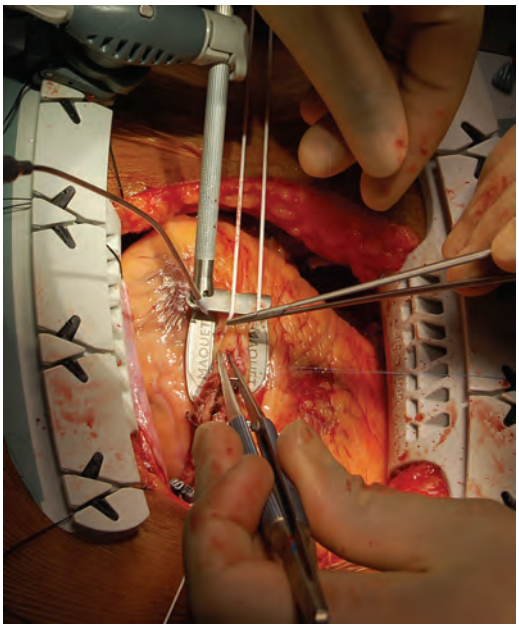

Fig. 20.19 Image depicting left anterior descending (LAD) artery anastomosis during off-pump coronary artery bypass grafting using a left internal mammary artery (LIMA) graft. The view is from the head of the patient. The Maquet mechanical stabilizer (Maquet, Wayne, NJ) is in place along with vascular snare sutures used to transiently occlude the artery. The LIMA is being anastomosed to the LAD, assisted by use of pressurized and heavily humidified carbon dioxide ("mister blower" metal cannula) to facilitate visualization of the vessel lumen. *(Courtesy Alexander Mittnacht, MD, Mount Sinai School of Medicine, New York, NY.)*

The effects of positional maneuvers, including verticalization of the heart, have been investigated in humans and animal models. Grundeman and coworkers[581] have investigated hemodynamics, CBF, and echocardiographic changes with the use of the suction cup Octopus stabilizer systems (Medtronic, Minneapolis, MN) during verticalization to 90 degrees and anterior displacement of the posterior wall (as used to access circumflex vessels during OPCAB) in an anesthetized and β-blocked pig model. With the stabilizer alone, they found significant reductions in SV (44% reduction), CO (32%), MAP (26%), and HR (26%) that were corrected with a 20% head-down tilt.

They also evaluated CBF in the three major coronary distributions using flow probes.[582] With a 42% decrease in CO, coronary flow was reduced in all three distributions, with the greatest decline in the circumflex distribution (50%). However, with the Trendelenburg position, the changes largely were ameliorated. Placement of a TEE probe demonstrated substantial compression of the right ventricle, with a decrease in diastolic cross-sectional area of 62%, but the LV area declined only by 20% (Fig. 20.22). No valvular incompetence was observed, and institution of right-heart CPB restored all hemodynamic parameters; LV bypass had only marginal effects. This work documents the importance of compression of the thin-walled, low-pressure right ventricle in hemodynamic compromise during OPCAB.

The investigators also reported the use of a different stabilizer system, the Starfish apical suction device (Medtronic, Minneapolis, MN) using the pig model.[581,583] They observed substantially fewer hemodynamic changes, with only a 6% reduction in SV and 5%

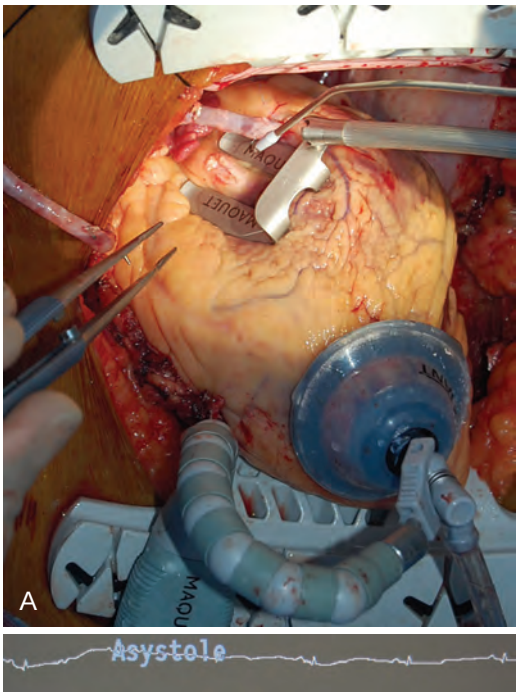

Fig. 20.20 (A) Posterior descending artery (PDA) anastomosis during off-pump coronary artery bypass grafting (CABG) uses a saphenous vein graft. The view is from the head of the patient. The Maquet access device (Maquet, Wayne, NJ) uses suction to position the heart (ie, verticalization) for easy access to the inferior surface of the left ventricle. The stabilizer is in place, and the anastomosis to the PDA is being performed. (B) Characteristic electrocardiographic (ECG) tracing during verticalization of the heart facilitates exposure of the PDA for anastomosis during off-pump CABG. Heart manipulations modify the positional relationship between the heart and surface electrodes. The shape of the tracing is altered, and the amplitude is reduced. The low-voltage electrocardiogram is interpreted by the device as asystole, an audible alarm sounds, and the practitioner is alerted with *Asystole* next to the ECG tracing. *(Courtesy Alexander Mittnacht, MD, Mount Sinai School of Medicine, New York, NY.)*

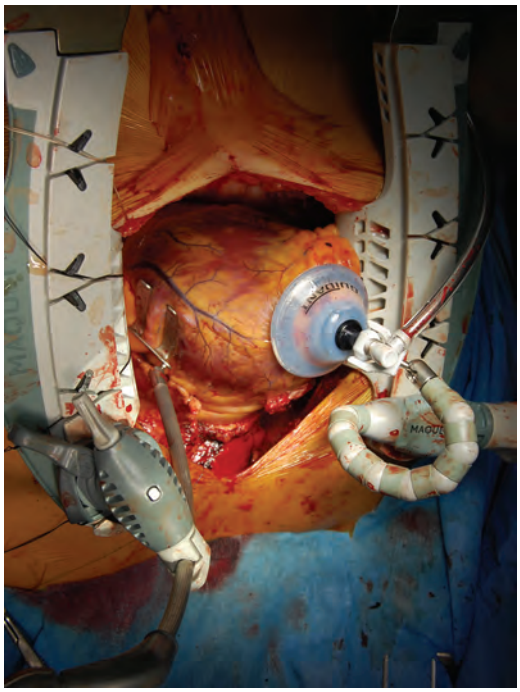

Fig. 20.21 First obtuse marginal anastomosis during off-pump coronary artery bypass grafting using a saphenous vein graft. The view is from the head of the patient. The previously completed left internal mammary artery to left anterior descending anastomosis is seen. The Maquet access device (Maquet, Wayne, NJ) uses suction to position the heart (ie, verticalization) for easy access to the circumflex coronary artery system. *(Courtesy Alexander Mittnacht, MD, Mount Sinai School of Medicine, New York, NY.)*

reduction in MAP, no reduction in coronary flows, and approximately 30% increases in RV end-diastolic pressure (RVEDP) and LVEDP. With institution of a Trendelenburg position, mild overshoot occurred in SV and MAP, with greater increases in RVEDP and LVEDP, suggesting that the maneuver is not required.

Using a sheep model, Porat and colleagues[584] demonstrated significant hemodynamic benefits using a right-heart internal cannula system that expels blood from the right atrium into the pulmonary artery, bypassing the compressed right ventricle and increasing CO and MAP, with a reduction in CVP of 49%.

Hemodynamic effects have also been reported from human clinical series.[585,586] Most data have been obtained from patients with normal or only mildly depressed ventricular function without significant valvular disease. Mathison and associates[587] evaluated the effects of displacement with the Octopus stabilizer in the Trendelenburg position. RVEDP increased in each position, with the greatest increase occurring with exposure of the circumflex vessels (Fig. 20.23). This position was associated with the greatest deterioration of SV (approximately 29% vs 22% for PDA and vs 18% for LAD). When comparing patients with EFs of more than or less than 40%, there were nonsignificant trends toward greater reductions in MAP and CO with lower EF. TEE, used in 31 patients, revealed moderate or severe biventricular compression with circumflex artery and PDA positioning.

Nierich and coworkers[588] reported use of the Octopus stabilizer in 150 patients, including 54 patients with anterolateral thoracotomy exposure undergoing LAD or diagonal anastomosis only. Stroke volume decreased 6% with LAD, 14% with RCA, and 21% with OM anastomoses. The Trendelenburg position was required in only 50% of LAD anastomoses, increasing to 100% with OM anastomosis. Dopamine was used in only 5% of LAD anastomoses, increasing to 30% with OM anastomoses (Fig. 20.24).

Mishra and colleagues[589] have reported large-scale, prospective observational data on patients undergoing OPCAB surgery. TEE and PAC were used in all patients, and approximately 40% were considered high risk. Verticalization for exposure of the posterior wall was associated with a reduction in MAP of 18%, an increase in CVP of 66%, and a reduction in SV of 36% and cardiac index of 45%. New RWMAs were common (60%), and global function decreased in a similar proportion. Their practice involved the use of inotropes during this period (79% vs 22% for the anterior wall). However, only 11% required IABP, and 0.7% required CPB. On multivariate analysis, an EF less than 25%, MI within the prior month, HF, and preoperative hemodynamic instability (which was only marginally significant) were identified as independent predictors of conversion to CPB.

Specific Anesthetic Considerations in Patients Undergoing Off-Pump Coronary Artery Bypass Grafting

The anesthesia technique used for patients undergoing OPCAB surgery does not differ much from on-pump CABG (Box 20.10). The anesthesia technique should be tailored to the individual patient, and among other factors, it depends on the indication for OPCAB surgery. Fast-tracking, including early ICU and hospital discharge, is frequently a goal associated with OPCAB surgery,[590,591] particularly for patients with adequate LV function.

Patients with advanced age, significant ascending aortic disease, poor LV function, and multiple comorbidities may be scheduled for OPCAB surgery to avoid aortic cross-clamping, and a single

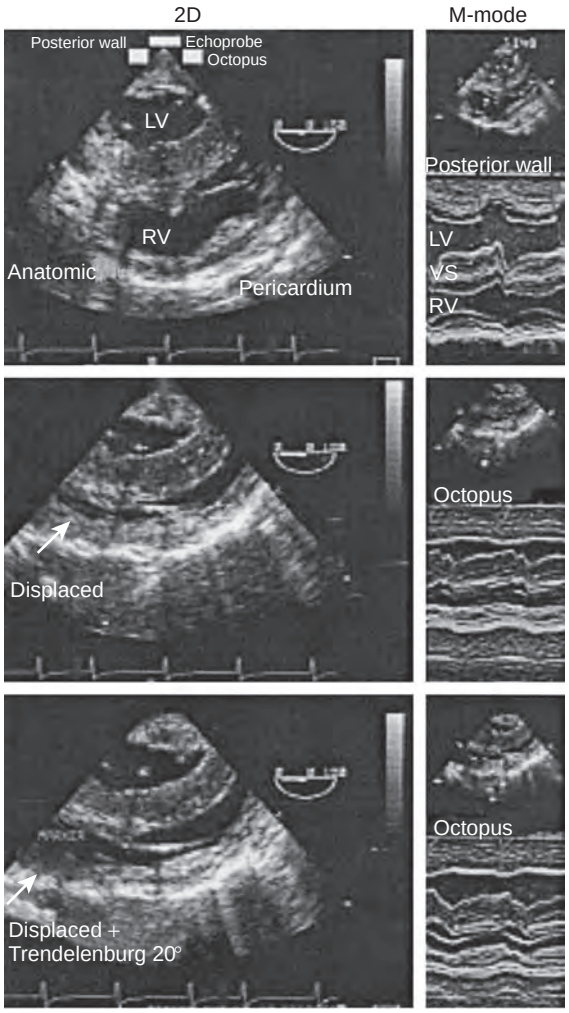

Fig. 20.22 Alteration in right ventricular and left ventricular chamber sizes with verticalization of the heart and subsequent Trendelenburg positioning in a porcine open chest model obtained from a transesophageal echocardiographic probe placed between the two arms of a stabilizer device on the posterior wall. Two-dimensional *(left)* and M-mode images *(right)* are displayed. *LV,* Left ventricle; *RV,* right ventricle; *VS,* ventricular septum. *(From Grunderman PF, Borst C, Verlaan CW, et al. Exposure of circumflex branches in the tilted, beating porcine heart: echocardiographic evidence of right ventricular deformation and the effect of right or left heart bypass.* J Thorac Cardiovasc Surg. *1999;118:316.)*

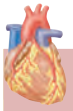
LIMA-to-LAD anastomosis is sometimes performed. These patients may not be ideal for ultrafast-track anesthesia. A neuraxial technique may be considered for postoperative analgesia or as the primary anesthesia technique. However, significant limitations (eg, preoperative antiplatelet agents) and concerns regarding the safety of neuraxial manipulation with subsequent heparinization remain.

A challenge during OPCAB surgery can be the hemodynamic changes encountered during positioning of the heart. PAP, PCWP, and CVP typically are increased during this phase; the occurrence of large v waves should alert the practitioner to acute ischemia or MR. Wall motion abnormalities and acute, significant MR frequently are seen on TEE. Exacerbation or new onset of MR may be related to structural changes from positioning the heart (eg, annular distortion), stabilizer application, or ischemia.[592,593]

Hemodynamic compromise during OPCAB surgery can be managed with Trendelenburg positioning, volume administration, and temporary vasoconstrictor administration to maintain CPP during distal anastomosis. Opening of the right pleural space may accommodate



BOX 20.10 ANESTHETIC CONSIDERATIONS FOR OFF-PUMP CORONARY ARTERY BYPASS SURGERY

1. Use standard monitoring, including invasive arterial blood pressure monitoring and central venous access.
2. A PAC should be considered in patients with poor LV function or significant mitral regurgitation.
3. TEE is recommended for all patients undergoing OPCAB surgery, unless contraindicated.
4. Use warming devices to maintain normothermia.
5. Dose of heparin according to institutional or surgeon's preference.
6. Fast-tracking, including early extubation, is often a goal in OPCAB surgery.
7. A neuraxial anesthesia technique may be used for postoperative analgesia or as the primary anesthetic technique. The patient must be carefully evaluated for absolute contraindications (eg, potent antiplatelet regimens).
8. Hemodynamic compromise may occur with positioning of the heart or stabilizer application. Positional maneuvers, volume administration, and vasoactive medications are used to maintain hemodynamic stability. CPB always should be immediately available.

CPB, Cardiopulmonary bypass; *LV*, left ventricular; *OPCAB*, off-pump coronary artery bypass grafting; *PAC*, pulmonary artery catheter; *TEE*, transesophageal echocardiography.

the right ventricle, relieving the compression and improving hemodynamics. The right limb of the sternal retractor should be routinely elevated on a rolled towel to create space and avoid compressing of the right atrium or right ventricle against the right sternal border. Similarly, the right-sided pericardial traction sutures must be loosened when the heart is rotated to the right to avoid compression of the hemodynamically vulnerable right atrium and right ventricle against the right pericardial edge. Maintaining the CPP is critical during distal coronary anastomosis, and MAP is typically kept above 80 mm Hg during this phase.

Depending on the severity of the lesion and the degree of collateralization, ischemia and RWMAs can be seen. In poorly collateralized vessels, severe hemodynamic compromise may result from clamping the target vessel. It is important for the surgeon to graft and reperfuse collateralized vessels early in the operative sequence and to graft collateralizing vessels only after the vessels to which they provide collateral flow have been bypassed. This avoids the dangerous scenario in which the myocardium subtended by the collateralizing and the collateralized vessels is rendered ischemic during temporary occlusion of the collateralizing vessel to construct its distal graft anastomosis.

Vasoconstrictor and volume therapy are preferred with inotrope use only in cases of severe hemodynamic compromise. In the setting of ongoing ischemia, the greater increase in oxygen demand with inotropes may place the patient at substantial risk for myocardial injury. In the setting of significant MR not responsive to antiischemic treatment, further increasing the afterload may worsen the clinical picture. Positive inotropic medications are then temporarily indicated if the surgeon cannot correct the position of the heart during critical phases of surgical anastomosis. The surgeon may or may not place temporary intracoronary shunts to allow distal coronary perfusion. There are controversial data and opinions about whether shunts have a clinical benefit in providing myocardial protection or instead cause endothelial damage.[594–596]

CPB should always be immediately available during OPCAB surgery in case the hemodynamic situation cannot be managed pharmacologically. A lower arterial blood pressure typically is preferred during the proximal (aortic) anastomosis to avoid complications seen with partial aortic clamping (ie, aortic side-clamp). Automated suture devices and techniques that eliminate aortic cross-clamping are being

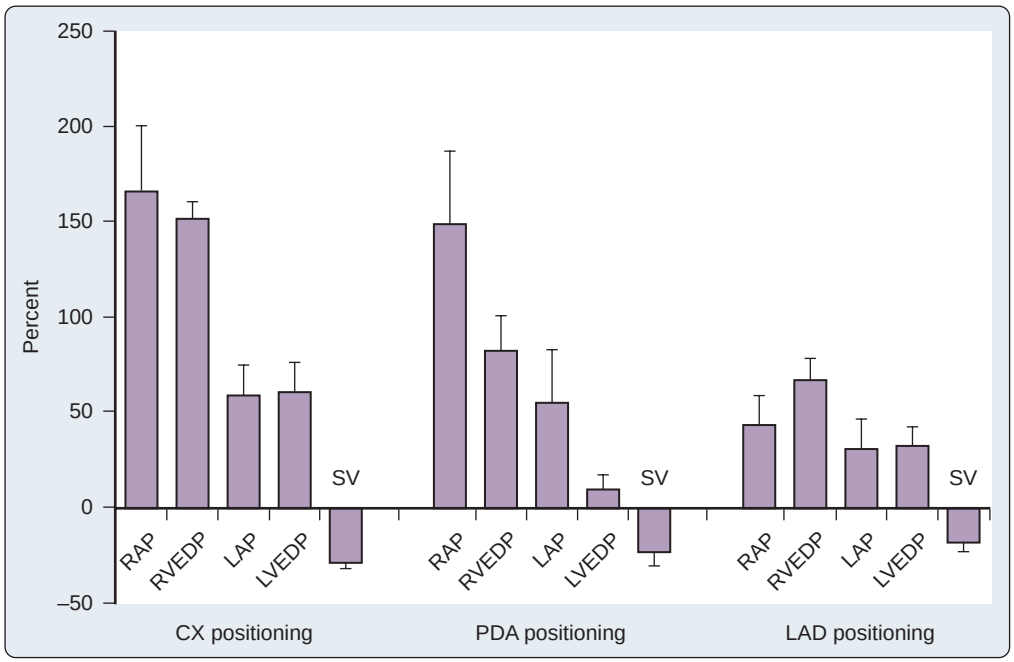


Fig. 20.23 Hemodynamic changes (mean ± standard error) with off-pump coronary artery bypass (OPCAB) grafting cardiac positioning with application of the stabilizer in 44 patients. *CX*, Circumflex artery; *LAD*, left anterior descending artery; *LAP*, left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PDA*, posterior descending artery; *RAP*, right atrial pressure; *RVEDP*, right ventricular end-diastolic pressure; *SV*, stroke volume. *(From Mathison M, Edgerton JR, Horswell JL, et al. Analysis of hemodynamic changes during beating heart surgical procedures.* Ann Thorac Surg. *2000;70:1355.)*

used.[597–599] Avoidance of aortic partial clamping has been associated with a striking reduction in cerebral emboli and neurologic events during OPCAB. Regardless of the specific technique or device used, the MAP should be kept around 60 mm Hg during manipulation of the aorta and proximal anastomosis. Vasodilators such as NTG are frequently administered and titrated to achieve this goal.

Because CPB with a heat exchanger is not available for maintaining a target temperature, patients are at increased risk for hypothermia during OPCAB surgery. This is particularly problematic if fast-tracking with early extubation is the goal. The room temperature should be adjusted accordingly, and patient-warming devices should be applied.

Anticoagulation in patients undergoing OPCAB surgery is an area of controversy, and the topic always should be discussed with the surgeon before anesthesia induction. Some surgeons prefer low-dose heparinization (eg, 100–200 U/kg of heparin) with a target activated coagulation time (ACT) of 250 to 300 seconds, whereas others may choose full heparinization (eg, 300 U/kg) during the procedure. The ACT is measured every 30 minutes, and heparin is administered accordingly to maintain the target ACT.

Patients who are immobilized, undergoing major surgery, and hypercoagulable are at increased risk for thrombotic events. A potential concern in OPCAB surgery is early graft occlusion with potentially catastrophic consequences, including sudden cardiac death after revascularization. Some surgeons continue antiplatelet medications until the day of surgery, and potent antiplatelet drugs such as clopidogrel may be reinstituted immediately after the procedure. When planning the anesthesia, it is important to follow current recommendations for neuraxial catheter placement in patients on anticoagulant medications. A neuraxial technique may not be feasible or may be contraindicated.

Outcomes for Off-Pump Coronary Artery Bypass Grafting

Although the literature base is increasing, the final word about differences in outcomes and which patients may benefit from OPCAB has not been written.[600–602] This is not surprising given the technical challenges of OPCAB surgery and highly operator-dependent outcomes, which are difficult to account for even in large, prospective, randomized trials.[602,603]

Raja and Dreyfus reviewed observational and randomized trials and scored the efficacy of OPCAB by levels of literature evidence for outcomes related to various organ systems and processes of care.[601] Although the grading must be considered informal because of a lack of a formal consensus panel of experts, it mirrors results obtained from a metaanalysis of randomized trials by Cheng and associates.[600] These investigators analyzed 37 randomized trials of 3369 patients with comparable treatment groups, with the exception of a marginal difference in the average number of grafts performed (2.6 OPCAB vs 2.8 CABG). All but one of the studies specifically excluded high-risk patients. Although various definitions were used, most excluded patients with low EF, repeat procedures, and renal failure, and several studies excluded patients with diseased circumflex vessels. The investigators found no significant differences in 30-day or 1- to 2-year mortality rates, MI, stroke (at 30 days and 1 to 2 years), renal dysfunction, need for IABP, wound infection, or reoperation for bleeding or reintervention (for ischemia).

OPCAB was associated with significant reductions in AF (OR = 0.58), numbers of patients transfused (OR = 0.43), respiratory infections (OR = 0.41), need for inotropes (OR = 0.48), duration of ventilation (weighted mean difference [WMD] of 3.4 hours), ICU LOS (WMD of 0.3 day), and hospital LOS (WMD of 1.0 days). Changes in neurocognitive dysfunction were not different in the immediate postoperative period; they were significantly improved at 2 to 6 months (OR = 0.57), but there were no differences seen at 12 months.

The critical issue of graft patency was addressed in only four studies, which varied substantially with regard to when assessment occurred (ie, 3 months in two and 12 months in two studies). Only one study reported a difference (ie, reduction in circumflex patency with OPCAB). Because of the small numbers of patients, the overall data for this category were considered inadequate for metaanalysis.

Four randomized, controlled trials have analyzed quality of life. Various methods precluded inclusion in the metaanalysis, but it

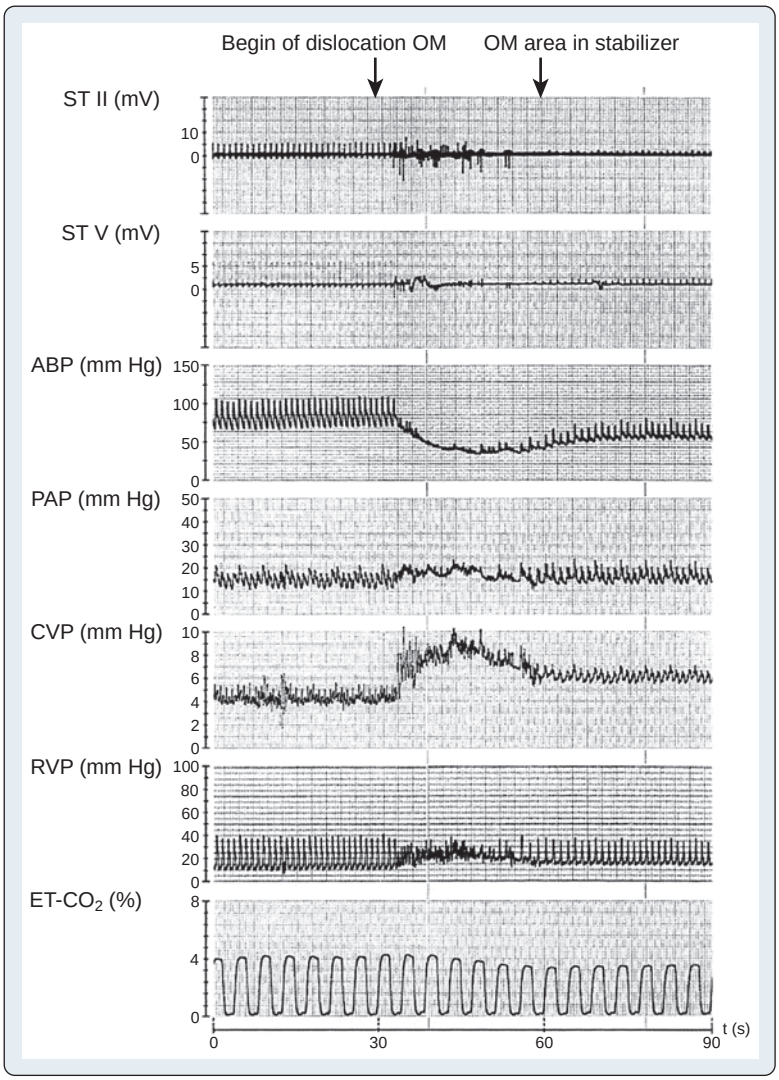

Fig. 20.24 Acute hemodynamic alterations during verticalization and placement of a stabilizer in a patient, demonstrating reduction in electrocardiographic voltage *(mV)*, wedging of the pulmonary artery catheter, decrease of end-tidal carbon dioxide *(ET-CO_2)*, and increase in central venous pressure *(CVP)*. Changes partially resolve after stabilizer placement. *ABP*, Arterial blood pressure; *OM*, obtuse marginal arteries; *RVP*, right ventricular pressure. *(From Nierich AP, Diephuis J, Jansen EW, et al. Heart displacement during off-pump CABG: how well is it tolerated?* Ann Thorac Surg. *2000;70:466.)*

appears there is little difference between operations. Of the 20 trials reporting conversion rates, 8% of OPCAB patients required conversion to on-pump CABG. The conversion rate for OPCAB in these low- to medium-risk patients is substantial and is expected to be even higher in higher-risk patients with greater disease burdens, more complex lesions, or impaired ventricular function, in whom tolerance of stabilization and verticalization may be less. The comprehensive analysis suggested that for every 1000 patients undergoing OPCAB, 91 fewer patients would develop AF, 143 fewer would require transfusion, 83 fewer would require inotropes, 53 fewer would develop respiratory infections, 100 fewer would have cognitive dysfunction at 2 to 6 months postoperatively, and there would be 300 fewer ICU days and 1000 fewer hospital days. The neutral findings regarding stroke, renal failure, MI, and mortality are surprising, but they may be found to be different for higher-risk patients after additional trial data are analyzed.

A working group of the AHA Council on Cardiovascular Surgery and Anesthesia analyzed the then current literature and several small metaanalyses, although not the same ones as Cheng and coworkers (discussed earlier). In an informal manner, they concluded that OPCAB probably was associated with less bleeding, less renal dysfunction, less short-term neurocognitive dysfunction (especially in patients with calcified aortas), and shorter hospital LOS. However, they also observed that it is more technically demanding, has a greater learning curve, and may be associated with lower rates of long-term graft patency.[602] Perhaps related to the greater technical demands, surgeons appear to place fewer grafts compared with on-pump CABG, and incomplete revascularization may influence long-term outcomes. The investigators emphasized the ongoing need for large-scale, randomized study data.

The fact that OPCAB surgery is technically more demanding and requires a significant learning curve was highlighted by Shroyer and colleagues,[605] who published the results of their prospective, randomized study of on-pump versus off-pump CABG. The investigators reported worse composite outcomes and poorer graft patency in the off-pump group. The study was criticized, however, for inadequate surgeon experience with the off-pump technique (a minimum of 20 cases' experience was required for study participation), a conversion rate to on-pump of 12.4% (<1% with experienced surgeons[606])

with associated higher mortality rates,[607] and a higher rate of incomplete revascularization in the OPCAB group. The 2203 patients were almost exclusively male (female patients are higher-risk patients who can benefit from OPCAB[608]). When patients who were converted to on-pump CABG were excluded from the analysis, there was no significant difference in the 1-year primary end point.

Puskas and colleagues[609] reviewed 12,812 CABG patients (1997–2006) and compared in-hospital major adverse events and long-term survival after OPCAB versus on-pump CABG. Long-term (10-year follow-up) outcomes did not differ significantly between on-pump and off-pump patients. OPCAB was associated with significant reductions in short-term outcomes such as operative mortality, stroke, and major adverse cardiac events. Further data analysis showed that short-term outcome (ie, operative mortality rate) did not differ between the two groups for patients at low risk (ie, STS predicted risk of death), whereas lower mortality rates were found for OPCAB surgery in high-risk patients.[610] Female gender was associated with higher rates of death, stroke, MI, and other major adverse cardiac events. Women undergoing OPCAB surgery had a lower mortality rates compared with those for on-pump CABG.

Bakaeen and coworkers conducted a large, multicenter, observational study comparing OPCAB to on-pump CABG surgical outcomes for 65,097 patients undergoing myocardial revascularization at VA hospitals between 1997 and 2011.[611] In the propensity score–matched patients, 30-day or in-hospital mortality rates were not significantly different between OPCAB and on-pump CABG. In a previous analysis from the same group and same patient population looking at long-term outcomes, adjusted mortality rates after 5 years and 10 years were higher for the OPCAB group.[612]

OPCAB presents the possibility of minimizing or avoiding aortic manipulation (ie, anaortic OPCAB). With the knowledge that aortic atheroembolism is an important source of adverse neurologic events during cardiac surgery performed on CPB, an off-pump approach that avoids aortic partial clamping should be associated with a reduced risk of perioperative stroke, transient ischemic attack, and neurocognitive dysfunction. Daniel and colleagues[613] reported that the odds ratio for stroke after CABG among 10,054 consecutive patients was 2.6 for on-pump double-clamp (ie, cross-clamp plus partial-clamp) versus a single-clamp technique. Similarly, patients who had OPCAB with a partial clamp had an odds ratio of 1.46 for stroke compared with OPCAB patients whose proximal anastomoses were performed with a clampless facilitating device.

Edelman and associates[614] performed a metaanalysis of stroke after anaortic OPCAB versus partial-clamped OPCAB and anaortic OPCAB versus conventional CABG on CPB. They reported that in each comparison, the risk of perioperative stroke was significantly reduced when aortic manipulation was reduced or avoided altogether. Emmert and coworkers[615] compared the incidence of stroke or MACCE after OPCAB performed with a partial clamp versus a Heartstring clampless facilitating device. They reported a striking reduction in adverse neurologic events in the clampless group.

In summary, increasing data show that OPCAB surgery can be performed safely and may benefit certain patient populations. Remaining concerns are incomplete revascularization, especially in patients with poor targets, and the significant learning curve and surgeon experience required. Patient selection is critical in obtaining good results. With ongoing technologic advances, it is likely that the number of patients who are candidates and the surgical complexity of procedures will continue to expand.

Minimally Invasive Coronary Artery Surgery

First reported in 1967, minimally invasive direct coronary artery bypass (MIDCAB) was performed with a limited left thoracotomy and LIMA-to-LAD graft on a beating heart.[616] In the subsequent 5 decades, coronary artery surgery through a midline sternotomy has become the most commonly used approach. In the earlier years of cardiac surgery, this involved a large midline incision with associated complications such as wound infection and brachial plexus injury. Less invasive techniques were sought and developed with the goals of avoiding these complications, faster patient recovery, earlier hospital discharge, and improved patient satisfaction (eg, cosmetically more appealing incision). The following terminology is a sample of what is being used to describe the various surgical approaches.

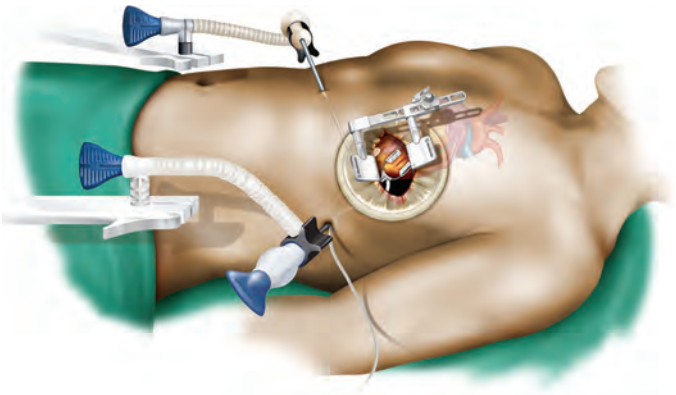

Fig. 20.25 Stabilization of the left anterior descending artery with a commercialized retractor during multivessel small thoracotomy revascularization using nonsternotomy surgical solutions such as the Octopus NS Tissue Stabilizer and Starfish NS Heart Positioner (Medtronic, Minneapolis, MN.)

The original term *MIDCAB* refers to LIMA takedown and anastomosis to the LAD through a small anterior thoracotomy (Fig. 20.25).[617–619] It can be performed off-pump or on-pump with femoral cannulation. Thoracoscopic and robotic techniques have been developed to avoid chest wall retraction and associated complications.[620–622] Experience with robotically assisted CABG is limited, and clear outcome benefits have not been reported.[623] Because of limited access to the coronary artery system using this approach, the procedure is often combined with percutaneous revascularization using coronary stents (ie, hybrid coronary revascularization [HCR]).[624] The hybrid approach is gaining popularity for selected patients with complex proximal-ostial LAD stenosis and typically one other lesion in a non-LAD vessel that can be easily stented.

Totally endoscopic coronary revascularization (TECAB) describes complete surgical revascularization through small chest wall incisions using thoracoscopic instruments and a robot to access coronary lesions that are not close to the chest wall incision (Fig. 20.26).[625] The procedure can be performed with or without CPB; the latter is called *beating-heart TECAB*.[626] Endoscopically assisted CABG (EndoACAB) was developed to avoid the high costs associated with robotic use.[627] In place of expensive robotic equipment, EndoACAB uses thoracoscopic and nondisposable instruments to harvest the LIMA. The coronary anastomosis is performed on a beating heart.

The advantages and problems encountered with the minimally invasive techniques goes beyond the scope of this text and have been published extensively elsewhere. Proper patient selection and experience of the surgeon are crucial in obtaining good results.[628] The following paragraphs describe specific anesthesia considerations for patients undergoing minimally invasive coronary artery surgery.

Most minimally invasive coronary artery surgical techniques are technically demanding and require close cooperation by the multidisciplinary surgical team to plan the exact approach, including the type and location of surgical incision; on-pump versus off-pump, patient access during surgery (especially in robotic surgery); and goals of fast-tracking, including early extubation and adequate pain relief. Although a fast-track anesthesia technique often is preferred, anesthesia induction and maintenance do not differ from the approach used in a midline sternotomy (Box 20.11).

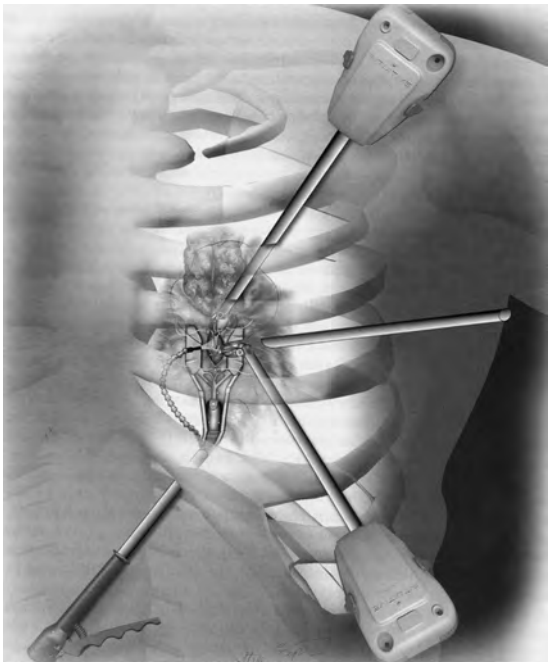

Fig. 20.26 Totally endoscopic coronary artery revascularization on the beating heart: The stabilizer is inserted through a subxiphoid incision.

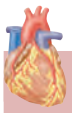

BOX 20.11 ANESTHETIC CONSIDERATIONS FOR MINIMALLY INVASIVE CORONARY ARTERY SURGERY

1. Apply fast-track anesthesia techniques, including adequate postoperative pain management.
2. Intraoperative monitoring should include central venous access, invasive arterial pressure monitoring, and transesophageal echocardiography. In complex multivessel coronary artery revascularization, the benefits of pulmonary artery catheter monitoring may outweigh the risks.
3. Defibrillator pads are mandatory and need to be placed with regard to the exact location of surgical incisions.
4. Lung separation may be required for off-pump procedures.
5. Intrathoracic carbon dioxide insufflation can cause hemodynamic changes.
6. In prolonged procedures, measurements of adequate body perfusion and oxygen balance should be performed frequently.
7. Emergency conversion to an on-pump procedure and/or emergency sternotomy may be required.

An important difference is the requirement for lung deflation on the side of the surgical incision during a beating-heart minimal thoracotomy or thoracoscopy approach. Lung separation techniques, including a double-lumen tube and bronchial blockers with a standard endotracheal tube, have been described.[629–631] Alternatively, jet ventilation has been reported to facilitate surgical access.[632] Additional challenges compared with thoracic surgery with one-lung ventilation are thoracic insufflation of CO_2, which is required for intrathoracic surgical instrument manipulation and access to surgical anastomosis on the heart, and its hemodynamic consequences. Insufflation pressures are typically kept below 10 to 15 mm Hg; nevertheless, significant increases in CVP and PAP typically occur.[633–635]

RWMAs have been described with thoracic insufflation,[636] as has decreased CO at higher insufflation pressures.[637] Fluid administration and vasoconstrictor or inotropic support are frequently used to maintain hemodynamic stability. Urine output, plasma lactate, and SvO_2 should be monitored frequently, especially during long procedures.

If hemodynamic stability cannot be maintained or is acutely compromised (including uncontrolled surgical bleeding), the use of femoral-femoral cannulation and prompt initiation of CPB can be lifesaving. Any otherwise unexplained rise in end-tidal CO_2 should alert the practitioner to increased CO_2 absorption from the positive-pressure thoracic insufflation. Sudden decreases in end-tidal CO_2 have been described with positive-pressure CO_2 insufflation in different settings, and if encountered, they should alert the practitioner to possible massive CO_2 embolization.[638,639]

Due to the hemodynamic changes associated with thoracic inflation and prolonged one-lung ventilation in long surgical cases, adequate monitoring of hemodynamic and oxygenation parameters is considered prudent.[640] TEE is recommended, and although outcome data are lacking, a PAC catheter is frequently inserted, especially if more than a single- vessel LIMA anastomosis is planned.

Access to the heart is limited, and defibrillator pads have to be placed before the patient is positioned and draped. This is further complicated by interference with surgical instruments and left chest wall incisions, and the defibrillator pad position may have to be modified accordingly. Because of the frequently cited advantages of early patient mobilization and hospital discharge, fast-track anesthesia is often part of the perioperative management strategy. A midline sternotomy is less painful for most patients compared with a small thoracoscopic incision with chest wall retraction. Adequate pain management is therefore mandatory in achieving fast-tracking goals for these patients. Long-acting intercostal nerve or other types of nerve blocks, administered before skin incision and redosed at the end of the surgical procedure, can facilitate overall anesthesia and pain management.[641]

Conclusions

Anesthesia for myocardial revascularization continues to evolve, with advances in surgical approach and technique, anesthetic pharmacology, monitoring technologies, and basic science, clinical, and epidemiologic research. As part of a multidisciplinary team, anesthesiologists are increasingly involved in the management of these patients.

Considerable health care resources are consumed by revascularization procedures, and there is an urgent need to better control costs. Adjusting anesthesia techniques to better meet the needs of the current health care environment, such as facilitating fast-tracking and reducing LOS, is important in this process. Ensuring that quality of care measures are met allows anesthesiologists to take more responsibility in the care of CAD patients.

Valvular Heart Disease: Replacement and Repair

HARISH RAMAKRISHNA, MD, FASE, FACC | RYAN C. CRANER, MD | PATRICK A. DEVALERIA, MD | DAVID J. COOK, MD | PHILIPPE R. HOUSMANS, MD, PhD | KENT H. REHFELDT, MD, FASE

KEY POINTS

1. Although various valvular lesions generate different physiologic changes, all valvular heart disease is characterized by abnormalities of ventricular loading.
2. The left ventricle normally compensates for increases in afterload by increases in preload. This increase in end-diastolic fiber stretch or radius further increases wall tension in accordance with Laplace's law, resulting in a reciprocal decline in myocardial fiber shortening. The stroke volume is maintained because the contractile force is augmented at the higher preload level.
3. Factors that influence heart function include afterload stress, preload reserve, ventricular compliance, contractility, and the existence of pathology such as valve lesions and hypertrophy.
4. Treatment modalities for hypertrophic obstructive cardiomyopathy, a relatively common genetic malformation of the heart, include β-adrenoceptor antagonists, calcium channel blockers, and myectomy of the septum. Newer approaches include dual-chamber pacing and septal reduction (ie, ablation) therapy with ethanol.
5. The severity and duration of symptoms of aortic regurgitation may correlate poorly with the degree of hemodynamic and contractile impairment, delaying surgical treatment while patients are undergoing progressive deterioration.
6. Mitral regurgitation causes left ventricular volume overload. Treatment depends on the underlying mechanism and includes early reperfusion therapy, angiotensin-converting enzyme inhibitors, and surgical repair or replacement of the mitral valve.
7. Rheumatic disease and congenital abnormalities of the mitral valve are the main causes of mitral stenosis, a slowly progressive disease. Surgical treatment options include closed and open commissurotomy and percutaneous mitral commissurotomy.
8. Most tricuspid surgery occurs in the context of significant aortic or mitral disease, and anesthesia management primarily is determined by the left-sided valve lesion.
9. Innovations in surgical valve repair include aortic valve repair and closed- and open-chamber procedures for mitral regurgitation.

In many ways, surgery for coronary artery disease (CAD) has matured, and although there continue to be incremental advances such as off-pump surgery, anastomotic connectors, and endoscopic vein harvest, coronary artery surgery may have seen its best days, in no small part because of advances in interventional cardiology. The same has not been true of valve surgery. At institutions where valve surgery is well represented, surgical volumes remain stable. This reflects the aging of the population and the lesser impact of cardiac interventions on the valvular heart disease (VHD) process.

From the standpoint of anesthesia care, valve surgery is usually very different from coronary artery bypass grafting (CABG). Over the natural history of VHD, the physiology changes markedly. In the operating room, physiologic conditions and hemodynamics are quite dynamic and are readily influenced by anesthesia. For some types of valve lesions, it can be relatively difficult to predict before surgery how the heart will respond to the altered loading conditions associated with valve repair or replacement.

It is essential to understand the natural history of adult acquired valve defects and how the pathophysiology evolves. Clinicians must also understand surgical decision making for valve repair or replacement. A valve operated on at the appropriate stage of its natural history has a good and more predictable outcome compared with a heart operated on at a later stage, for which the perioperative result can be poor. The dynamic physiology and natural history of each valve defect govern the anesthesia plan, which must include the requirements for preload, pacing rate, and rhythm; use of inotropes or negative inotropes; and use of vasodilators or vasoconstrictors to alter loading conditions.

Although valvular lesions impose different physiologic changes, a unifying concept is that all VHD is characterized by abnormalities of ventricular loading. The status of the ventricle changes over time because ventricular function and the valvular defect itself are influenced by the progression of volume or pressure overload. The clinical status of patients with VHD can be complex and dynamic. It is possible to have clinical decompensation in the context of normal ventricular contractility or have ventricular decompensation and performance with normal ejection indices. The altered loading conditions characteristic of VHD may result in a divergence between the function of the heart as a systolic pump and the intrinsic inotropic state of the myocardium. The divergence between cardiac performance and inotropy results from compensatory physiologic mechanisms that are specific to each of the ventricular loading abnormalities.

In analyzing the physiologic response of the left ventricle (LV) to a variety of abnormal loading conditions, it is useful to consider the concepts of *afterload mismatch* and *preload reserve*.[1] They frame discussions about the pathophysiology of individual valvular lesions. Other concepts essential to understanding VHD and its evolution are *pressure-volume loops* and the linear *end-systolic pressure-volume*

relationships (ESPVRs). The former provides a graphic analysis of ventricular pressure-volume relationships in a single beat, and the latter is a method for quantifying the intrinsic contractility of the myocardium over multiple contractions and is relatively independent of changes in loading conditions (see Chapters 6 and 13 through 16).

Pathophysiology

Pressure-Volume Loops

The pressure and volume changes that occur during a normal cardiac cycle are depicted in Fig. 21.1. A pressure-volume loop is generated when ventricular volumes are plotted against simultaneously occurring ventricular pressures for a single contraction (Fig. 21.2).

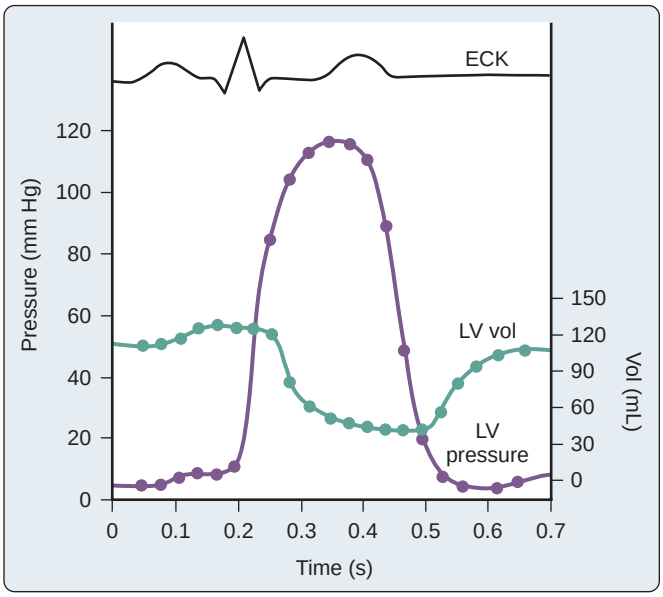

Fig. 21.1 Simultaneous left ventricular *(LV)* volume and pressure during one cardiac cycle. *ECG*, Electrocardiogram. *(From Barash PG, Kopriva DJ. Cardiac pump function and how to monitor it. In: Thomas SJ, ed.* Manual of Cardiac Anesthesia. *New York: Churchill Livingstone; 1984:1.)*

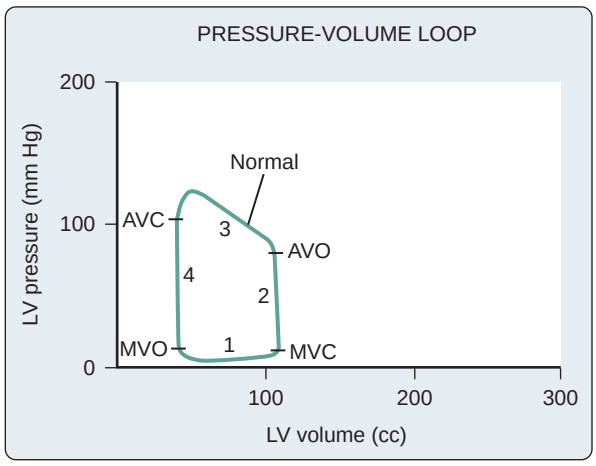

Fig. 21.2 An idealized pressure-volume loop for a single cardiac cycle. *AVC*, Aortic valve closure; *AVO*, aortic valve opening; *LV*, left ventricular; *MVC*, mitral valve closure; *MVO*, mitral valve opening; *1–4*, phases of the cardiac cycle. *(From Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease.* Semin Anesth. *1982;1:239.)*

Familiarity with this graphic analysis of cardiac function, the normal pressure-volume loop of the LV, provides a basis for appreciating a load-insensitive index of contractility, the ESPVR.

Phase 1 in Fig. 21.2 shows ventricular filling and represents loading of the heart before contraction (ie, preload). During early and middle diastole, filling of the ventricle is rapid, depending on the pressure gradient between the left atrium and the LV. In late diastole, the left atrium contracts (ie, *a* wave), which results in the final left ventricular end-diastolic volume (LVEDV) and pressure (LVEDP). Atrial contraction in the normal heart accounts for 15% to 20% of ventricular filling. The normal ventricle accommodates large changes in ventricular volume with only a small change in ventricular diastolic pressure.

Ventricular systole occurs in the isovolumic and ejection phases. During isovolumic (isometric) systole (ie, phase 2 of the cardiac cycle), intraventricular pressure increases dramatically. However, there is little or no concurrent decrease in ventricular volume because the aortic valve is still closed. Phase 3 is the systolic ejection period. When intraventricular pressure exceeds aortic pressure, the aortic valve opens, and ejection begins. At the end of phase 3, the aortic valve closes. This point is the end-systolic pressure-volume coordinate, which may uniquely reflect the cardiac inotropic state.

Afterload Stress and Preload Reserve

Fig. 21.3 shows the response of the LV to changes in afterload (with preload held constant) in the context of the pressure-volume loops from single contractions. These curves are constructed experimentally by infusing a pure α-adrenergic agonist while simultaneously measuring the corresponding end-systolic volumes (ESVs). The resultant curves describe the diastolic pressure-volume relationship (ie,

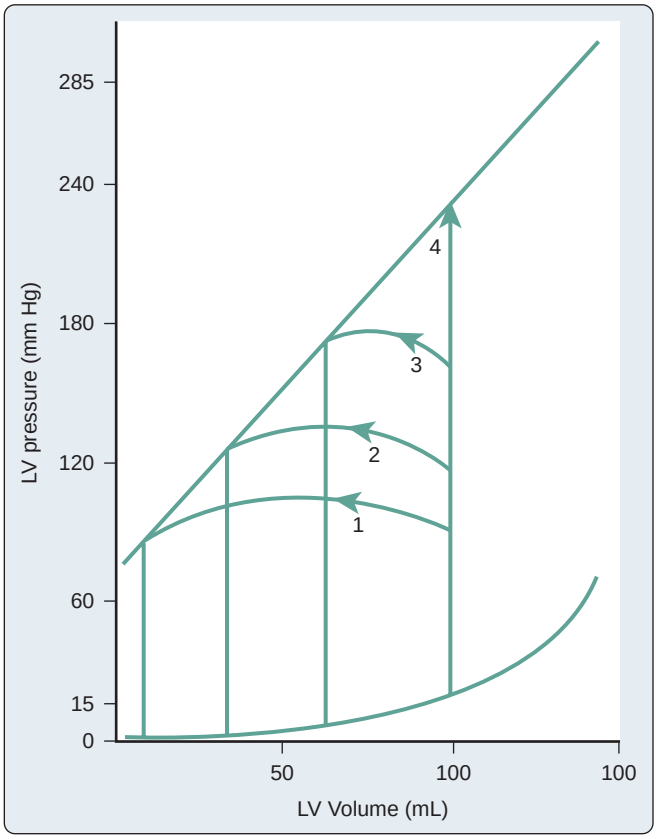

Fig. 21.3 Pressure-volume loops show the left ventricular *(LV)* response to progressive increases in afterload *(1–4)* when the preload is artificially held constant. *(From Ross J Jr. Afterload mismatch in aortic and mitral valve disease: implications for surgical therapy.* J Am Coll Cardiol. *1985;5:811.)*

ventricular compliance) and the linear ESPVR at a given level of myocardial contractility.

Each counterclockwise loop represents a cardiac cycle. The stroke volume (SV) progressively decreases as the impedance to ejection increases from beats 1 to 3. This pattern continues until beat 4, when the peak ventricular systolic pressure fails to open the aortic valve and only isovolumic contraction ensues.[1] This inverse relationship between afterload and SV (ie, inverse force-velocity relation) also was documented experimentally in a canine preparation in which the LVEDV was held constant (Fig. 21.4).[2]

In the intact heart, afterload is a function of ventricular size and arterial pressure.[3] Its pivotal role in cardiovascular regulation is summarized in Fig. 21.5. *Afterload* is as the tension, or force per unit of cross-sectional area, in the ventricular wall during ejection.[4] Laplace's law provides a mathematical expression for the wall tension[5] (in which P is the intraventricular pressure) developed in a spherical chamber of radius, R, and wall thickness, h:

$$\text{Wall tension} = P \times R/2h$$

This means that ventricular afterload, a function of the constantly changing intraventricular pressure and radius, varies continuously during systole. It is difficult to precisely quantify afterload in the clinical setting, and commonly used approximations such as blood pressure or systemic vascular resistance (SVR) are inherently misleading because they fail to reflect instantaneous pressure-volume variations.

Left ventricular size or preload is a determinant of the SV and afterload.[6] Normally, the LV compensates for increases in afterload by increases in preload. The increase in end-diastolic fiber stretch or radius further increases wall tension in accordance with Laplace's law, resulting in a reciprocal decline in myocardial fiber shortening (ie, inverse force-velocity relationship). Despite the relative decline in fiber shortening, the SV is maintained because contractile force is augmented at the higher preload (ie, Starling or length-active tension effect). The increased contractility at higher LVEDVs may be mediated by an increased sensitivity to the inotropic effects of extracellular calcium at longer muscle lengths.[7–9]

Use of this preload reserve allows the LV to maintain its SV in the face of an afterload stress,[1] as shown in Fig. 21.6.[1] The increase in afterload (ie, beat 2) elicits a compensatory increase in end-diastolic volume (EDV) (ie, beat 3), preserving SV at the higher afterload. However, when the ventricle reaches the limit of its preload reserve, it overdistends, and preload behaves as if it were fixed. SV then decreases with further increases in the systolic pressure (ie, afterload mismatch; beat 4), a clinical corollary of the inverse force-velocity relation.

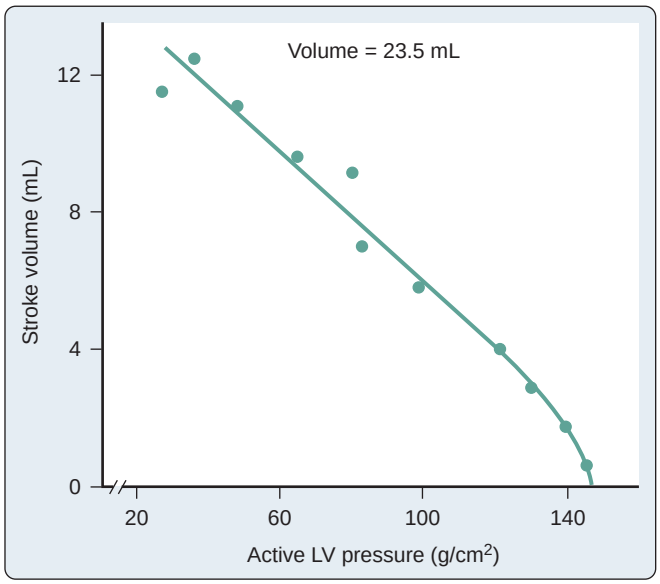

Fig. 21.4 Plot of left ventricular *(LV)* stroke volume versus LV systolic pressure when the ventricle's end-diastolic volume is held constant (ie, inverse force-velocity relationship). *(From Burns JW, Covell JW, Ross J Jr. Mechanics of isotonic left ventricular contractions.* Am J Physiol. *1973;224:725.)*

Ventricular Compliance

Translating the physiologic analysis to the clinical setting is complicated by several practical constraints. One of the most important is the inconstant relationship between LVEDV and LVEDP. The diastolic pressure-volume relationship for the normal mammalian LV is a curvilinear function (Fig. 21.7).[3,10] The slope of this curve (ie, ratio of change in volume to change in pressure during diastole) is the *ventricular compliance* (dV/dP). Although the normal ventricle is extremely compliant in the physiologic range, the instantaneous compliance decreases with increments in diastolic filling. This progressively increasing slope of the pressure-volume curve becomes evident at the extremes of ventricular volume, in which succeeding increments in volume result in exponentially greater increases in end-diastolic pressure (EDP). Patients with acute aortic regurgitation (AR) experience the hemodynamic consequences of this phenomenon. The catastrophic increases in ventricular filling pressure reflect the absolute magnitude of the volume overload and are a corollary of a precipitously declining compliance relationship.

The hemodynamic manifestations of acute shifts up and down a single compliance curve must be distinguished from chronic, pathologic alterations in ventricular compliance, which produce shifts of the entire curve relating diastolic pressure and volume. For example, in animal models of chronic volume overload, the entire pressure-volume curve is shifted to the right, and substantial increases in ventricular volume are tolerated with relatively little change in EDP (Fig. 21.8).[11] The slope of the new pressure-volume curve (ie, compliance) is decreased. Similarly, time-dependent, rightward shifts of the entire pressure-volume relationship occur in patients with severe ventricular volume overload resulting from chronic AR.[12] In these examples, the

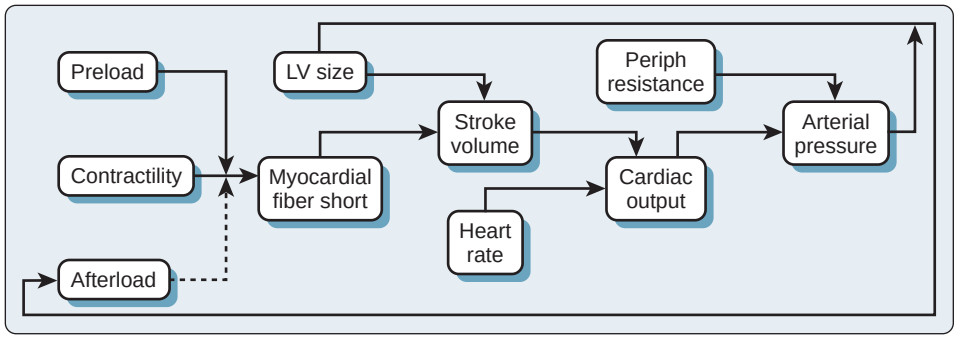

Fig. 21.5 Role of afterload in cardiac regulation. *LV*, Left ventricular; *Periph*, peripheral. *(From Braunwald E. Regulation of the circulation.* N Engl J Med. *1974;290:1124.)*

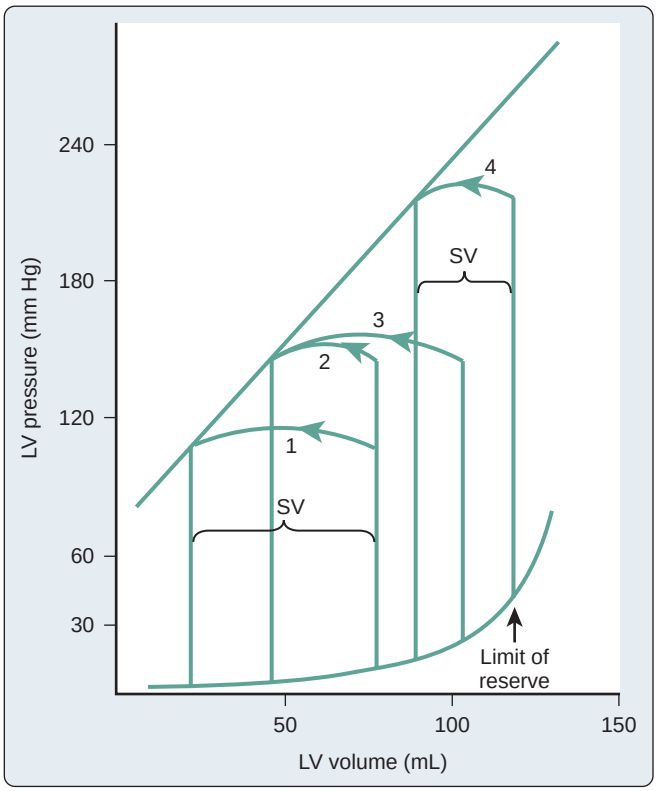

Fig. 21.6 Pressure-volume loops illustrating the concept of preload reserve. Increases in afterload (1–4) elicit compensatory increases in left ventricular *(LV)* end-diastolic volume such that stroke volume *(SV)* is maintained at the higher afterload. *(From Ross J Jr. Afterload mismatch in aortic and mitral valve disease: implications for surgical therapy.* J Am Coll Cardiol. *1985;5:811.)*

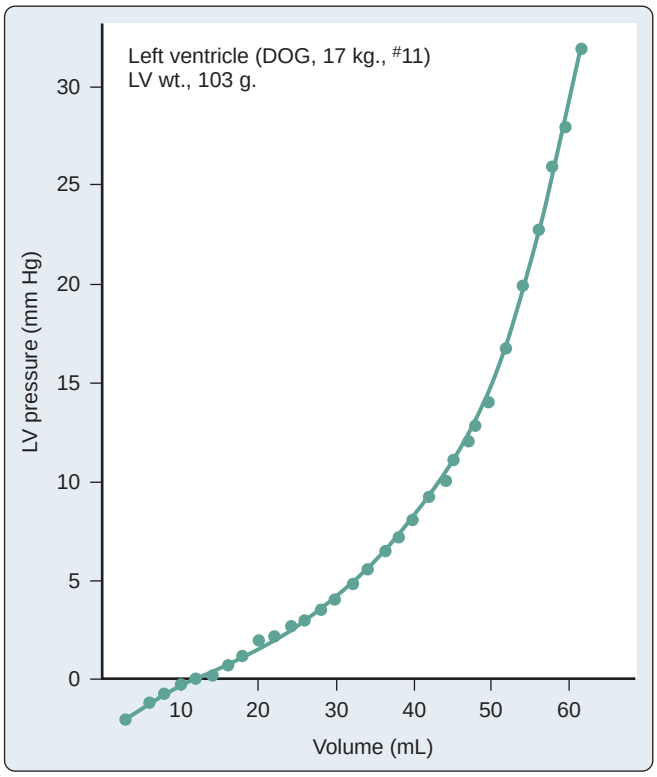

Fig. 21.7 The normal diastolic pressure-volume relationship. *LV,* Left ventricular. *(From Spotnitz HM, Sonnenblick EH, Spiro D. Relation of ultrastructure to function in the intact heart: sarcomere structure relative to pressure-volume curves of the intact left ventricles of dog and cat.* Circ Res. *1966;18:49.)*

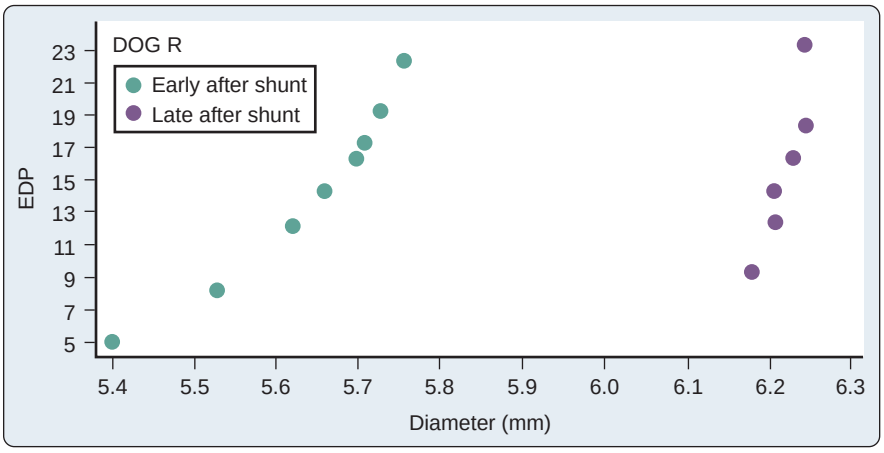

Fig. 21.8 Relationships between left ventricular *(LV)* end-diastolic pressure *(EDP)* and volume *(diameter)* in an animal studied early *(green circles)* and late *(purple circles)* after the production of chronic volume overloading (ie, arteriovenous fistula). *(From McCullagh WH, Covell JW, Ross J Jr. Left ventricular dilation and diastolic compliance changes during chronic volume overloading.* Circulation. *1972;45:943.)*

development of a new relationship between pressure and volume may reflect the physiologic process of *creep*, the time-dependent change in the size or dimension of tissue maintained at a constant level of stress.[4]

Myocardial wall thickness is an important determinant of diastolic compliance. In clinical settings of chronic pressure overload (eg, aortic stenosis [AS], chronic hypertension), diastolic compliance and ventricular wall thickness are linearly and inversely related (Fig. 21.9).[13] This may explain why the normal, thinner-walled right ventricle (RV) is more compliant than the normal LV, although the ventricles share similar qualities of intrinsic myocardial stiffness.[3,14] The association between pathologic hypertrophy of the ventricle and deterioration in its diastolic compliance is a well-documented but poorly understood phenomenon.

It has become customary to characterize diastolic function in certain disease states as normal or abnormal (eg, diastolic dysfunction, diastolic failure).[15,16] Diastolic failure is a distinct pathophysiologic entity that results from increased resistance to ventricular filling and leads to an inappropriate upward shift of the diastolic pressure-volume

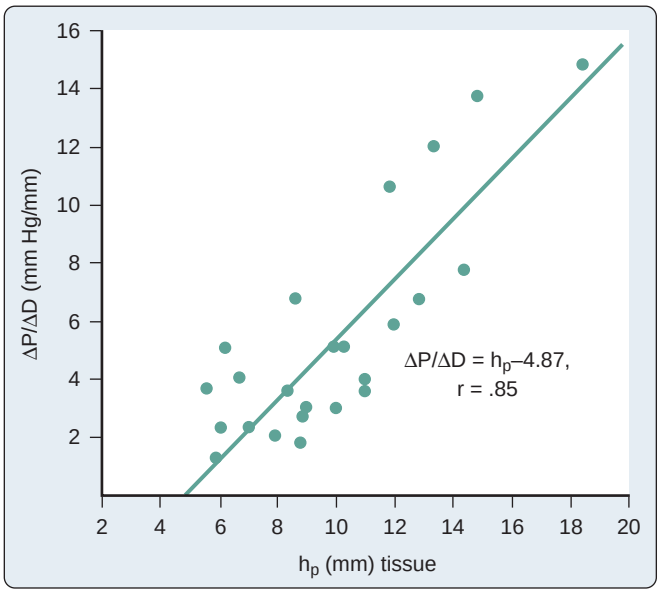

Fig. 21.9 Relationship between chamber stiffness (*ΔP/ΔD*), which is the inverse of compliance) and ventricular wall thickness (h_p). *(From Grossman W, McLaurin P, Moos SP, et al. Wall thickness and diastolic properties of the left ventricle.* Circulation. *1974;49:129.)*

relationship.[17] For example, diastolic dysfunction is seen in ischemic cardiomyopathy, particularly when combined with pressure-overload hypertrophy.[18]

In certain diseases, primary derangements of diastolic function may predominate over abnormalities of diastolic function associated with ventricular hypertrophy. For example, in hypertrophic cardiomyopathy (HCM), the impaired ventricular relaxation inherent in the myopathic process appears to play the greater role in the observed abnormalities of diastolic filling because the diastolic dysfunction is often disproportionate to the degree of ventricular hypertrophy.[19,20] The effects of pathologic hypertrophy on diastolic compliance and ventricular relaxation are complex and are considered in more detail later in the "Aortic Stenosis" and "Hypertrophic Cardiomyopathy" sections.

Filling of one ventricle or changes in its configuration or compliance properties can significantly alter the diastolic pressure-volume characteristics of the other ventricle.[21,22] Progressive increases in right ventricular filling shift the left ventricular compliance curve up and to the left. This effect is greatest at high right ventricular filling pressures and is accentuated by the pericardium.[23] With severe right ventricular distention, the interventricular septum encroaches on the LV, which reduces the size of the LV and alters its geometric configuration such that its compliance declines.[21] As a result, left ventricular filling pressures may fail to reflect directional changes in left ventricular size.[24]

Contractility

Myocardial contractility is the ability of the heart to generate force at a given preload.[25] Although most clinicians and researchers seem to be comfortable with their intuitive notions of the cardiac inotropic state, a consensus on a quantitative yardstick of ventricular inotropy has proved to be elusive. Its accurate and reproducible measurement is of more than theoretic interest because the contractile function of the heart is a key determinant of prognosis for most cardiac diseases, and it is especially important in critical decisions regarding the timing of surgical correction in patients with VHD.

Historically, methods of assessing myocardial contractility have been divided into two groups based on analysis of the isovolumetric or the ejection phase of cardiac contraction.[4] Details of their clinical determination and relative reproducibility are beyond the scope of this discussion, but more information can be found in several excellent reviews[4,26,27] and in Chapters 6 and 13. Isovolumetric indices include measurements such as maximal velocity of myocardial fiber shortening (V_{max}), peak pressure development (dP/dt), and peak dP/dt measured at an instantaneous pressure (dP/dt/P). Although relatively insensitive to loading conditions, these tests poorly reflect basal levels of contractility and are unreliable for comparing contractility among patients or assessing directional changes in contractility in an individual patient over time.[26]

Ejection phase indices, such as the ejection fraction (EF), are determined in part by the intrinsic inotropic state and can be used to define basal levels of contractility.[26] The measurements are extremely useful for evaluating ventricular function in patients with CAD or other conditions that do not significantly alter ventricular loading conditions.[28] Ejection phase indices are understandably popular because they are readily available, and they are the most widely used clinical measures of left ventricular function. However, these indices are directly proportional to preload, vary inversely with ventricular afterload, and are unreliable for assessing contractile performance in patients with most forms of VHD.

The use of the pressure-volume diagram and analysis of the ESPVR allow a more precise appreciation of left ventricular contractility, which is independent of preload.[29] The extent of myocardial shortening and therefore of end-systolic fiber length is a direct function of afterload (ie, inverse force-velocity relationship), and myocardial contractility can be evaluated by making use of this fundamental property. In most instances, end-systolic pressure (ESP) can be substituted for afterload. Only with pathologic degrees of ventricular hypertrophy is there a major divergence between ESP and afterload. This means that for any level of contractility, the ESV to which a ventricle contracts is a linearly increasing function of ESP. A stronger ventricle contracts to a smaller ESV (ie, empties more completely) at any given level of ventricular afterload.

Changes in the inotropic state also can be viewed in the context of the idealized pressure-volume loop. Positive inotropic interventions shift the curve up and to the left, increasing the work that can be performed at any given EDV (ie, preload). Conversely, negative inotropic interventions shift the curve down and to the right[30] (Fig. 21.10; see Chapters 6 and 13). Load-independent indices of contractility are largely research tools, but in the future, it may be possible to construct pressure-volume loops and quantify ESPVRs in real time with echocardiographic equipment featuring automated border detection[31] (see Chapters 14 and 15).

Clinical studies of patients with relatively normal loading conditions have shown that variations in the ESV reliably correlate with changes in ejection phase indices (Fig. 21.11).[32] The ESPVR represents an index of contractility that depends on systolic ventricular pressure (ie, afterload) but is independent of end-diastolic length (ie, preload).[28,33,34] Pressure-volume loops also provide a framework for considering the interactions between systolic (ie, inotropic) and diastolic (ie, lusitropic) function. Although the preload (ie, EDV) is an independent determinant of SV, because of the circular nature of blood flow, the SV ultimately determines venous return and the resultant preload for the next cardiac cycle.[30]

The inotropically determined ESV is the other element besides the venous return that contributes to the EDV. Just as the ESPVR uniquely describes systolic function, the end-diastolic pressure-volume relationship is a manifestation of the intrinsic relaxation (ie, lusitropic) properties of the ventricle. Positive lusitropic interventions facilitate ventricular filling and shift the end-diastolic pressure-volume relationship down and to the right, and a negative lusitropic intervention shifts it up and to the left (Fig. 21.12).

Aortic Stenosis

Clinical Features and Natural History

Aortic stenosis (AS) is the most common cardiac valve lesion in the United States. Approximately 1% to 2% of people are born with a

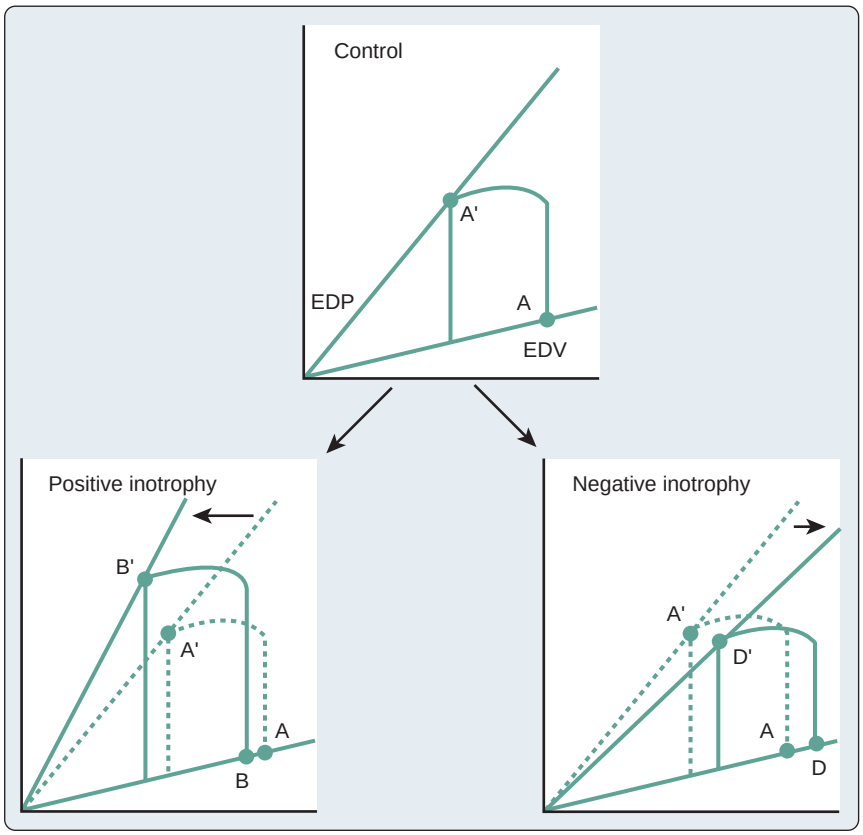

Fig. 21.10 A positive inotropic intervention increases the heart's ability to do work at a given end-diastolic volume *(EDV)* and end-diastolic pressure *(EDP)*. As illustrated, increased inotropy need not imply an increased stroke volume *(SV)*; however, SV is maintained despite a greater peak systolic pressure, producing the upward and leftward shift of the end-systolic pressure-volume point. Negative inotropy shifts the end-systolic pressure-volume point down and to the right. The SV is unchanged, but the EDV and end-systolic volume are increased, and the peak systolic pressure achieved is reduced. *(From Katz AM. Influence of altered inotropy and lusitropy on ventricular pressure-volume loops.* J Am Coll Cardiol. *1988;11:438.)*

bicuspid aortic valve, which is prone to stenosis with aging, and the population is aging. Clinically significant aortic valve stenosis occurs in 2% of unselected individuals older than 65 years and in 5.5% of those older than 85 years.[35] Incipient aortic valve stenosis with calcification and stiffening is observed in 50% of people between the ages of 75 and 80 years and in up to 75% in those older than 85 years.

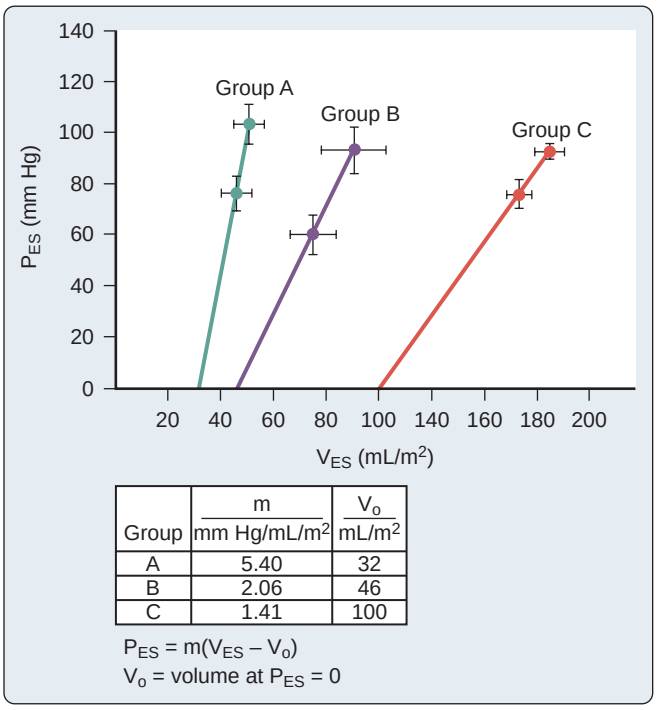
Bicuspid aortic valve is a common congenital cardiac abnormality, occurring in approximately 1% of the population.[36] The heritability coefficient is estimated at 89%, suggesting that the bicuspid aortic valve is almost entirely genetic in nature.[37] It is a risk factor for premature AS and ascending aortic aneurysms. The ascending aorta in bicuspid valvular disease has the same histopathologic features as Marfan syndrome, such as medial degeneration, decreased fibrillin 1 levels, and enhanced matrix metalloproteinase activity in the aortic wall.

Data from the International Registry of Acute Aortic Dissection show that patients with bicuspid aortic valve have a 6.14% lifetime risk of aortic dissection (ie, nine times that of the general population), compared with 40% for patients with Marfan syndrome. Bicuspid aortic valvular disease is a hundred times more common than Marfan syndrome and is therefore responsible for a larger number of aortic dissections.[36]

Calcific AS has several features in common with CAD. Both conditions are more common in men, older people, and patients with hypercholesterolemia, and both result in part from an active inflammatory process. Clinical evidence indicates an atherosclerotic process is the cellular mechanism of aortic valve stenosis. There is a clear association between clinical risk factors for atherosclerosis and the development of AS: increased lipoprotein levels, increased low-density lipoprotein (LDL) cholesterol, cigarette smoking, hypertension, diabetes mellitus, increased serum calcium and creatinine levels, and male sex.[38] Homozygous familial hypercholesterolemia produces a severe form of AS in children.[39] The early lesion of aortic valve sclerosis may be associated with CAD and vascular atherosclerosis. The extent of aortic valve calcification is an important predictor of poor outcomes for patients with AS.[40] Studies suggest that aortic valve calcification is an inflammatory process promoted by atherosclerotic risk factors.

The early lesion of AS resembles that of the initial plaque of CAD, and there is a close correlation between calcification found in coronary arteries and the amount of calcification found in the aortic valve. Pathologic studies of aortic valves revealed the presence of LDL, suggesting a common cellular mechanism for the genesis of valvular and vascular atherosclerotic disease.[38] Degenerative lesions on aortic valves contain an inflammatory infiltrate of nonfoam cells and foam cell macrophages, T lymphocytes, and other inflammatory cells. Lipid is accumulated in the fibrosa immediately below the endothelium layer on the aortic side of the valve. LDL- and apolipoprotein E–containing lipoproteins also exist.

Little is known about the synthesis of bone matrix proteins in calcific aortic valve stenosis. The calcifications are composed of hydroxyapatite on a matrix of collagen, osteopontin, and other bone matrix proteins. A potential mechanism for cellular inflammation involves the combination of macrophages, LDL, and secretion by macrophages of transforming growth factor-β and platelet-derived growth factor



Group	m mm Hg/mL/m²	V_o mL/m²

Fig. 21.11 Average values of end-systolic pressure (P_{ES}) versus end-systolic volume (V_{ES}) at two levels of afterload plotted for groups *A, B,* and *C* with different contractile performance as evaluated by ejection fraction (A >0.6; B = 0.41–0.59; C <0.4). The V_{ES} point correlates inversely with contractility. *(From Grossman W, Braunwald E, Mann T, et al. Contractile state of the left ventricle in man as evaluated from end-systolic pressure-volume relations.* Circulation. *1977;56:845.)*

to stimulate the conversion of valvular fibroblast cells into osteoblasts that produce bone proteins.[38]

The 3-hydroxy-3-methyl-glutaryl–coenzyme A reductase inhibitors (ie, statins) can retard progression of CAD and AS.[41,42] The odds ratio of AS progression was 0.46 for 38 treated patients compared with 118 untreated patients.[43] Other studies have shown similar results, and it is possible that therapy with statins or other drugs may be used to block or slow the progression of valve lesions in the future.[38,44]

In addition to recruitment of inflammatory cells and lipid accumulation into valves, calcification is a prominent feature that contributes to leaflet thickness and rigidity. Early development of aortic valve calcification may be related to vitamin D–receptor genotypes or mutations in the *NOTCH* gene.[35] Calcification is an active process that includes osteopontin, osteonectin, osteocalcin, and other bone morphogenic proteins that regulate calcification and ossification. Active osteoblastic bone formation and osteoclastic bone resorption occur in stenotic valves. Increased fibroblasts produce collagen, leading to fibrosis. Concomitant elastin degradation also contributes to valve stiffening. Whereas normal valves are avascular, microvessels form in thickened stenotic valves, ensuring the continued supply of inflammatory cells and lipids.

Advances in genetic epidemiology have demonstrated the strong heritability of a bicuspid aortic valve. The three loci on chromosomes 18q, 5q, and 13q likely contain genes responsible for a bicuspid aortic valve.[37] The mode of inheritance of other valvular diseases is unclear. No heritability or inheritance studies have been reported for calcific aortic valve disease. In smaller genetic studies, a few candidate genes such as *VDR, APOE, APOB, IL10,* and *ESR1* have been identified as possibly playing a role in aortic valve disease.

A breakthrough in the genetics of aortic valve disease was identification of the *NOTCH1* signaling pathway. It is involved in embryonic patterning and is highly expressed within the developing embryonic aortic valve. The NOTCH1 protein is a repressor of the transcription factor RUNX2, which regulates osteoblast development. This finding supports the concept that a developmental program may be reactivated in disease processes.[37]

The average rate of progression is a decrease in aortic valve area (AVA) of 0.1 cm^2/year, and the peak instantaneous gradient increases by 10 mm Hg/year.[45] The rate of progression of AS in men older than 60 is faster than in women, and it is faster in women older than 75 than in women 60 to 74 years old.[46] Treatment with hemodialysis, the use of calcium supplements, and increased serum creatinine levels correlated with rapid progression of AS.[47] Plasma brain natriuretic peptide, produced to a large extent by the ventricles, and the N-terminal–brain natriuretic peptide (NT-proBNP) may serve as early markers of left ventricular hypertrophy (LVH), whereas atrial natriuretic peptide and NT-proBNP reflect an atrial pressure increase.[48] Repeated measurements of this marker may provide information on the stage of AS and its hemodynamic impact.[49]

Angina, syncope, and congestive heart failure (CHF) are the classic symptoms of the disease, and their appearance is of serious prognostic significance because postmortem studies indicate that symptomatic AS is associated with a life expectancy of only 2 to 5 years.[50–52] The early natural history studies were completed before the availability of cardiac catheterization studies, and some patients, although symptomatic, might have had objectively less severe degrees of stenosis. The "hemodynamically insignificant murmur of AS" seen often in cardiologic consultations does not portend such dire consequences, although it is sometimes difficult to correlate AS severity with clinical symptoms. There is evidence that patients with moderate AS (ie, valve areas of 0.7 to 1.2 cm^2) are also at increased risk for the complications, with the appearance of symptoms further increasing their risk.[53]

According to the American College of Cardiology (ACC) and American Heart Association (AHA) guidelines, a peak velocity greater than 4 m/s, a mean gradient greater than 40 mm Hg, and a valve area less than 1.0 cm^2 constitute hemodynamically severe AS.[54] Aortic valve surgery should be performed promptly for symptomatic patients. In asymptomatic patients, a high aortic valve calcium content and a positive exercise test result are features that suggest a benefit from early aortic valve replacement (AVR).

The question of whether the natural history of AS has changed significantly over time is prompted by two trends.[55] In North America, the first is related to the steadily diminishing number of patients with rheumatic disease. Today, AS is essentially the bicuspid, calcific, or senile variety. The second trend is that people are living longer, particularly those with heart disease. The typical patient with AS is older and much more likely to have other significant medical problems, including major coexisting cardiac disease, most often CAD.

Angina is a frequent and classic symptom of the disease, occurring in approximately two-thirds of patients with critical AS and about one-half of symptomatic patients have anatomically significant CAD.[56–58] However, controversy persists about the incidence of CAD among patients with AS who do not have angina, and the controversy probably reflects the underlying sense of change in the natural history of the disease. Some studies report that the absence of angina virtually excludes the possibility of atherosclerotic heart disease.[59,60] In contrast, a 25% incidence rate of angiographically significant (>70% obstruction) coronary occlusions was described for angina-free patients, most of whom had single-vessel disease.[61] However, a much larger study found that 14% of patients with triple-vessel or left main CAD and AS had no angina.[62] Underscoring the continued lack of a consensus on this topic is the finding of a review that the reported incidence rates of significant CAD for asymptomatic patients range from 0% to 33%.[63]

Identification of asymptomatic patients is important because although coexistent, untreated (ie, unbypassed) CAD has a detrimental effect on early and late survival rates after AVR; concomitant CABG with AVR does not increase perioperative mortality rates.[64–67] It appears that a substantial number of patients with coexisting CAD may have symptoms other than chest pain.[68] However, there do not appear to be other significant differences in the clinical or hemodynamic

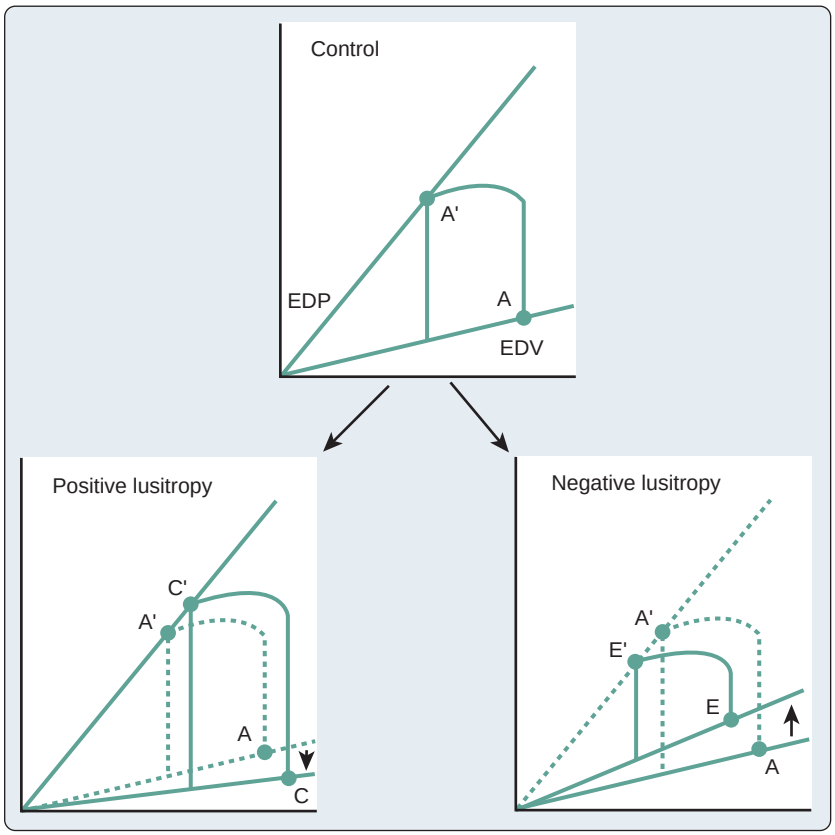

Fig. 21.12 Positive lusitropic interventions enhance diastolic filling, shifting the end-diastolic pressure-volume point down and to the right. findings between patients with normal coronary arteries and those with coexistent coronary stenoses.

If the traditional natural history of AS is perhaps more ominous in the elderly patient with likely coexistent CAD, is there any rationale for prophylactic AVR? With steady improvement in surgical results, this question has been raised, although rigorous studies still suggest that asymptomatic patients with hemodynamically significant disease face a very low risk of sudden death before the onset of symptoms.[69–71] In an attempt to settle this question, an editorial by Braunwald[72] stated that there was no role for prophylactic AVR and that "operative treatment is the most common cause of sudden death in asymptomatic patients with AS." These patients warrant careful follow-up, and the case against prophylactic surgical intervention is further supported by studies showing that ventricular function is preserved and myocardial hypertrophy regresses after successful valve replacement.[73–75]

It is probably never too late to operate on patients with symptomatic AS.[76,77] Unlike AR patients, most symptomatic patients undergo valve replacement when left ventricular function is still normal. Even when impaired left ventricular function develops in AS, the relief of pressure overload almost always restores normal function or produces considerable improvement. Morbidity rates, mortality rates, and clinical results are favorable even for the oldest surgical candidates.[78,79] Advances in operative techniques and perioperative management have contributed to excellent results after AVR in patients 80 years of age or older, with minimal incremental postoperative morbidity.[80] The principal postoperative complication is respiratory failure.

Preoperative assessment of AS with Doppler echocardiography includes measurement of the AVA and the transvalvular pressure gradient.[81,82] The latter is calculated from the Doppler-quantified transvalvular velocity of blood flow, which is increased in the setting of AS. The maximal velocity (v) is then inserted into the modified Bernoulli equation to determine the pressure gradient (PG) between the LV and the aorta (see Fig. 21.2):

$$PG = P(\text{left ventricle}) - P(\text{aorta}) = 4(v^2)$$

The *pressure gradient* is the maximal difference between the LV and aortic pressures that occurs during ventricular systole.[83,84] The maximal instantaneous gradient is not the same as the peak-to-peak gradient determined by cardiac catheterization. The peak-to-peak gradient is determined by separate measurements of events that are not synchronous in real time. Of more practical interest is the fact that the best estimate of obstruction severity, as determined from pressure data alone, is the mean systolic gradient, which is calculated online by Doppler equipment[85] (see Chapters 3, 6, and 13 through 15).

The Doppler-calculated gradient is subject to the same flow limitation as invasively calculated gradients. Best understood by considering the extreme, this means that a patient with true end-stage AS would exhibit a relatively low calculated gradient because of minimal flow across a critically narrowed valve. In part because of this flow dependency, pressure gradients determined invasively or by Doppler echocardiography correctly classify AS severity in less than 50% of cases compared with estimates of AVA.[86] However, the latter also can be determined by Doppler echocardiographic techniques. The preferred method requires only two Doppler-generated velocities: those proximal or distal to the stenotic valve. These values are inserted into the continuity equation, which relates the respective velocities and cross-sectional areas proximal and distal to a stenotic area (see Fig. 21.3):

$$V_{max} \times AVA = \text{area(LVOT)} \times V(\text{LVOT})$$

In the equation, AVA is the aortic valve area, V is the volume, and LVOT is the left ventricular outflow tract. Several studies have demonstrated the reliability of these Doppler-determined valve areas.[83–86]

Although advances in Doppler technology allow completely noninvasive evaluation of a large number of patients, coronary angiography is probably indicated for all patients older than 50 years who have significant AS. Angiography and, if indicated, CABG may improve the long-term outlook for patients with CAD who undergo AVR.[62] Angiography also can identify a smaller number of patients whose CAD alone warrants CABG.

Pathophysiology

The normal AVA is 2.6 to 3.5 cm^2, with hemodynamically significant obstruction usually occurring at cross-sectional valve areas of 1 cm^2 or less. Accepted criteria for critical outflow obstruction include a systolic pressure gradient greater than 50 mm Hg, with a normal cardiac output, and an AVA of less than 0.4 cm^2. In view of the ominous natural history of severe AS (AVA <0.7 cm^2),[55,87] symptomatic patients with this degree of AS are usually referred for immediate AVR.[88] The Hakki equation is a simplification of the Gorlin equation to calculate the AVA based on the cardiac output (CO) and the peak pressure gradient (PG) across the valve.

$$\text{AVA} = \text{CO}/\sqrt{(\text{PG})}$$

A corollary of the previously described relationship is that minimal pressure gradients may reflect critical degrees of outflow obstruction when the CO is significantly reduced (ie, generation of a pressure gradient requires some finite amount of flow). Clinicians have long recognized this phenomenon as a paradoxical decline in the intensity of the murmur (ie, minimal transvalvular flow) as the AS worsens.

Stenosis at the level of the aortic valve results in a pressure gradient from the LV to the aorta. The intracavitary systolic pressure generated to overcome this stenosis directly increases myocardial wall tension in accordance with Laplace's law:

$$\text{Wall tension} = \text{P} \times \text{R}/2\text{h}$$

In the equation, P is the intraventricular pressure, R is the inner radius, and h is the wall thickness.

The increase of wall tension is thought to be the direct stimulus for the further parallel replication of sarcomeres, which produces the concentrically hypertrophied ventricle characteristic of chronic pressure overload.[89,90] The consequences of LVH include alterations in diastolic compliance, potential imbalances in the myocardial oxygen supply and demand relationship, and possible deterioration of the intrinsic contractile performance of the myocardium.

Fig. 21.13 shows a typical pressure-volume loop for a patient with AS. Two differences from the normal curve are immediately apparent.

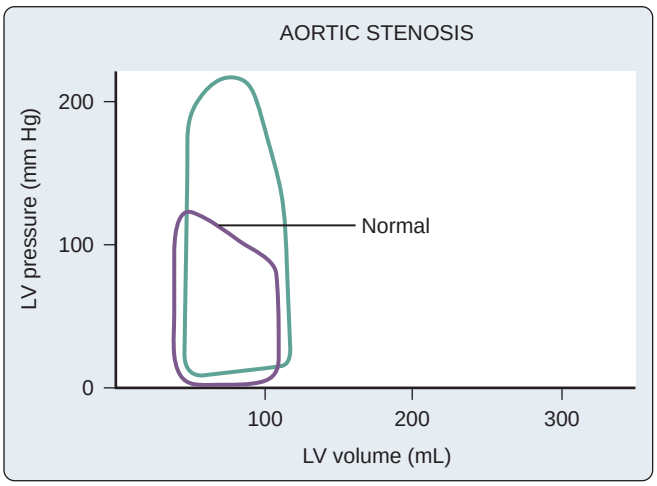

Fig. 21.13 Pressure-volume loop *(green)* in a patient with aortic stenosis and a normal patient *(purple)*. *LV*, Left ventricular. *(From Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease.* Semin Anesth. *1982;1:239.)*

First, the peak pressure generated during systole is much greater because of the high transvalvular pressure gradient. Second, the slope of the diastolic limb is steeper, reflecting the reduced left ventricular diastolic compliance that is associated with the increase in chamber thickness.[13] Clinically, small changes in diastolic volume produce relatively large increases in ventricular filling pressure.

Increased chamber stiffness places a premium on the contribution of atrial systole to ventricular filling, which in patients with AS may account for up to 40% of the LVEDV rather than the 15% to 20% characteristic of the normal LV. Echocardiographic and radionuclide studies have documented that diastolic filling and ventricular relaxation are abnormal in patients with hypertrophy from a variety of causes, and significant prolongation of the isovolumic relaxation period is the most characteristic finding.[91–94] This necessarily compromises the duration and amount of filling achieved during the early rapid diastolic filling phase and increases the relative contribution of atrial contraction to overall diastolic filling (Fig. 21.14). A much greater mean left atrial (LA) pressure is necessary to distend the LV in the absence of the sinus mechanism. One treatment of junctional rhythm is volume infusion.

The systolic limb of the pressure-volume loop shows preservation of pump function, as evidenced by maintenance of the SV and EF (see Fig. 21.13). Use of preload reserve and adequate LVH are likely the principal compensatory mechanisms that maintain forward flow. Clinical studies have confirmed that ejection performance is preserved at the expense of myocardial hypertrophy, and the adequacy of the hypertrophic response has been related to the degree to which it achieves normalization of wall stress, in accordance with the Laplace relation.[95–97] LVH can be viewed as a compensatory physiologic response that completes a negative feedback loop (Fig. 21.15). It is possible, however, that severe afterload stress and proportionately massive LVH could decrease subendocardial perfusion and superimpose a component of ischemic contractile dysfunction.

In patients with AS, LVH results from the increase in pressure load. The development of LVH and its regression after therapeutic interventions are accompanied by changes in the cardiac extracellular matrix guided by an increase in *ECM1* gene expression during LVH and complete regression after complete correction.[98]

Systemic hypertension and AS represent an increase in afterload to the LV, and each contributes to left ventricular remodeling and LVH. In a large series of 193 patients with AS, 62 of whom were hypertensive, symptoms manifested with larger AVAs and lower stroke work loss.[99] Patterns of left ventricular remodeling (ie, concentric vs eccentric remodeling and hypertrophy) were not different for hypertensive and normotensive patients. Left ventricular mass decreased by 23% 1 year after AVR, returning to the normal range, in patients with normal preoperative ventricular function; diastolic function improved concomitantly. Improvements in myocardial blood flow and coronary vasodilator reserve after AVRs result from reduced extravascular compression and increased diastolic perfusion time.[100–102]

Ejection phase indices of contractile function are abnormal in many patients with AS.[103,104] However, indices of contractile function, which are exquisitely sensitive to afterload, are inherently unreliable for quantitating the inotropic state in a disease such as AS, in which the essence of the hemodynamic insult is the severely increased ventricular afterload. This in no way excludes the possibility that a subset of patients also may experience some intrinsic depression of myocardial contractility. For example, patients with AS may be particularly at risk for superimposed ischemic ventricular dysfunction, but this possibility can be assessed only by the application of load-insensitive measurements of contractile function.

In most patients, load-insensitive indices of contractility (ie, end-systolic stress-diameter determinations) are virtually identical before and after the development of hypertrophy, suggesting that the increase in chamber thickness compensates for the afterload stress and that myocardial contractility is therefore normal, albeit appropriate for the higher afterload. Fig. 21.16 illustrates the adaptation of the LV to chronic pressure overload. Fig. 21.16A shows the pressure-volume

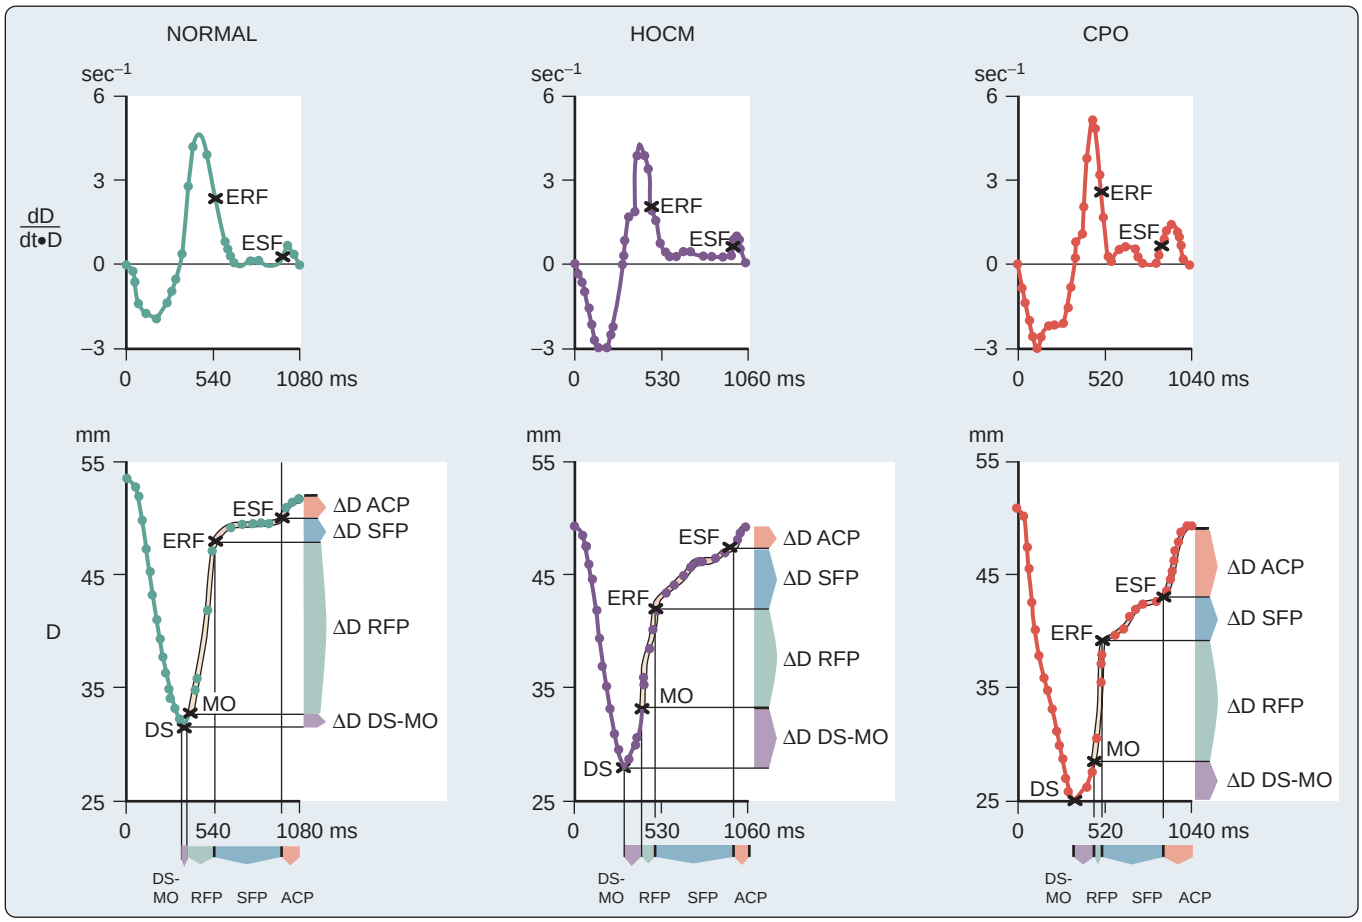

Fig. 21.14 Computer-generated echograms of left ventricular *(LV)* cavity size in healthy subjects and patients with ventricular hypertrophy (ie, hypertrophic obstructive cardiomyopathy *[HOCM]* or chronic pressure overload *[CPO]*). *Top panels* show the rate of ventricular dimensional change. In the *bottom panels*, for patients with both forms of hypertrophy, the mitral valve opening *(MO)* with regard to the end-systolic LV dimension *(DS)* is delayed, and the dimensional change during this interval *(ΔD DS-MO)* is abnormally large. The duration of the rapid-filling phase *(RFP)* and the volume change during this interval *(ΔD RFP)* are correspondingly reduced. This is followed by a large dimensional increase during the atrial contraction phase *(ΔD ACP)* in the patient with chronic pressure overload; *ERF*, End point of rapid filling phase; *ESF*, end point of slow filling phase; *SFP*, slow filling phase. *(From Hanrath P, Mathey DG, Siegert R, et al. Left ventricular relaxation and filling pattern in different forms of left ventricular hypertrophy: an echocardiographic study.* Am J Cardiol. *1980;45:15.)*

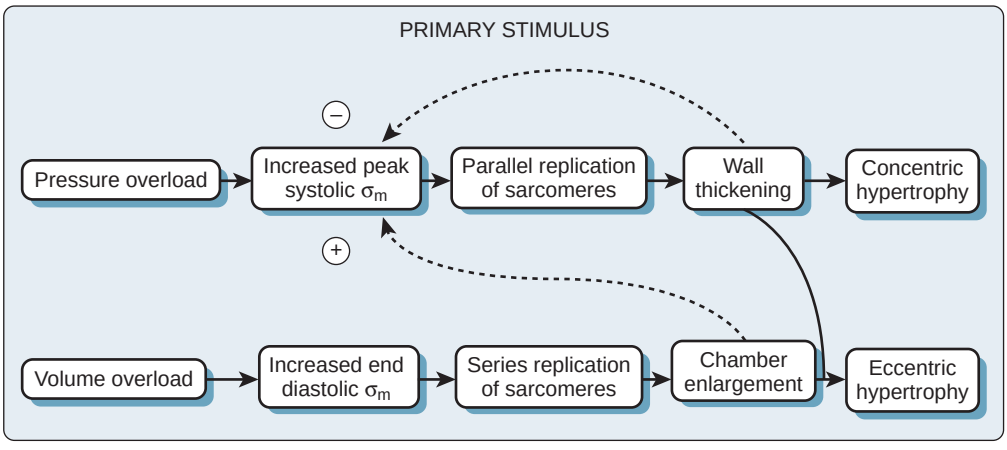

Fig. 21.15 The increased peak systolic wall stress (σ_m) resulting from chronic pressure overload directly stimulates concentric ventricular hypertrophy, which tends to counteract or normalize the increased ventricular wall stress. *(From Grossman W, Jones D, McLaurin LP. Wall stress and patterns of hypertrophy in the human left ventricle.* J Clin Invest. *1975;56:56.)*

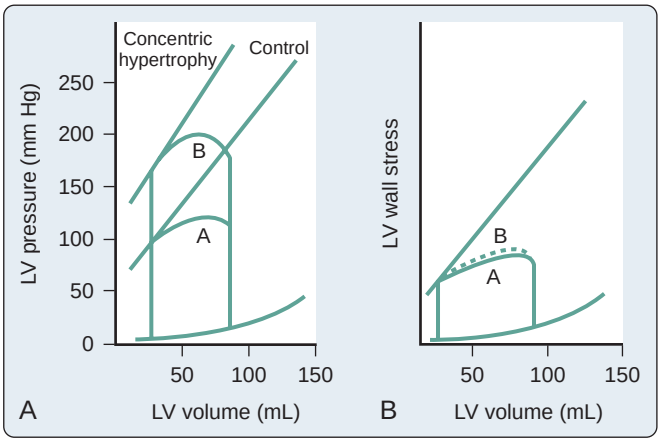

Fig. 21.16 Adaptation to pressure overload. (A) Pressure-volume curves and the linear end-systolic pressure-volume relationship before *(A)* and after *(B)* the development of concentric hypertrophy. After hypertrophy development, the end-systolic pressure-volume relationship is shifted upward and to the left (ie, apparent supranormal contractility). (B) The same relationships are plotted with stress-volume loops. The loops before *(A)* and after *(B)* concentric hypertrophy are essentially the same, reaching the identical end-systolic wall stress–volume point (ie, contractility unchanged). *LV*, Left ventricular. *(From Ross J Jr. Afterload mismatch in aortic and mitral valve disease: implications for surgical therapy.* J Am Coll Cardiol. *1985;5:811.)*

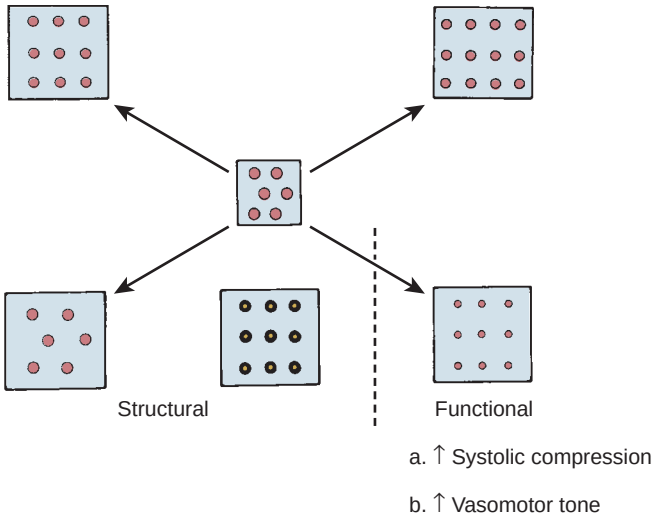

Fig. 21.17 Possible coronary circulatory changes accompanying ventricular hypertrophy. The *box size* indicates myocardial mass, and the *circle area* indicates the cross-sectional area of coronary vasculature. The relationship may be normal, as illustrated by the *top left box*, when growth of the coronary bed has kept pace with ventricular hypertrophy. Experimental data support two possible anatomic derangements: inadequate growth of structurally normal vessels *(bottom left)* or appropriate growth of abnormally thickened resistance vessels whose luminal area is accordingly compromised *(bottom center)*. The *bottom right box* illustrates compression of coronary vascular channels by extra-vascular forces *(a)* and vascular tone *(b)*. *(From Marcus ML. Effects of cardiac hypertrophy on the coronary circulation. In: Marcus ML, ed.* The coronary circulation in health and disease. *New York: McGraw-Hill, 1983.)*

relationship before (ie, loop A) and after (ie, loop B) development of concentric hypertrophy. The linear ESPVR is shifted up and to the left after concentric hypertrophy occur. However, the ESPVR may not be as accurate or load insensitive in assessing contractility at the extremes of afterload. Fig. 21.16B shows normalization of the apparently supranormal contractility, when wall stress (rather than pressure) is used as a more exact measure of ventricular afterload. Concentric hypertrophy normalizes wall stress, and contractility remains unchanged.

A decline in any index of myocardial contractility in patients with AS may represent relatively inadequate hypertrophy for the degree of wall stress, some intrinsic depression of contractility, or a combination of these two factors.[56,105,106] The fact that most patients have normal contractility is the reason for the usually favorable response to AVR.

In AS, signs and symptoms of CHF usually develop when preload reserve is exhausted, not because contractility is intrinsically or permanently impaired. This contrasts with mitral regurgitation (MR) and AR, in which irreversible myocardial dysfunction may develop before the onset of significant symptoms. An important exception is the patient with AS whose symptoms of CHF occur in the setting of associated MR. The latter may accompany hypertrophy-induced left ventricular chamber or mitral annular enlargement. MR in patients with AS is often referred to as *functional* rather than anatomic mitral insufficiency. The implication is that with relief of the high intracavitary systolic pressure, the MR can largely resolve if the mitral valve is anatomically normal. Grade 2 or 3 MR often is significantly reduced after AVR.

Intrinsic contractility is commonly preserved, and the major threat to the hypertrophied ventricle is its exquisite sensitivity to ischemia. Ventricular hypertrophy directly increases basal myocardial oxygen demand ($M\dot{V}O_2$). The other major determinants of overall $M\dot{V}O_2$ are heart rate, contractility, and most important, wall tension. Increases in wall tension occur as a direct consequence of Laplace's law in patients with relatively inadequate hypertrophy. The possibility of ischemic contractile dysfunction in the inadequately hypertrophied ventricle arises from increases in wall tension, which directly parallels the imbalance between the increased peak systolic pressure and the degree of mural hypertrophy. Although there is considerable evidence for supply-side abnormalities in the myocardial supply and demand relationship in patients with AS, clinical data also support increased $M\dot{V}O_2$ as important in the genesis of myocardial ischemia.

On the supply side, the greater LVEDP of the poorly compliant ventricle inevitably narrows the diastolic coronary perfusion pressure (CPP) gradient. With severe outflow obstruction, decreases in SV and resultant systemic hypotension may critically compromise coronary perfusion. A vicious cycle may develop because ischemia-induced abnormalities of diastolic relaxation can aggravate the compliance problem and further narrow the CPP gradient.[107] This sets the stage for ischemic contractile dysfunction, additional decreases in SV, and worsening hypotension.

Cardiac hypertrophy is associated with structural abnormalities of the coronary circulation (Fig. 21.17).[108,109] Animal models have documented that epicardial coronary vessels do not enlarge proportionately when the LV is subjected to a chronic pressure load.[110,111] LVH accompanying chronic hypertension is associated with an increased wall lumen ratio of the coronary arterioles, a change that limits vessel dilation and augments active constriction.[112,113] Animal models of pressure-induced myocardial hypertrophy also have shown a decrease in the capillary density of about 20% to 30%.[108,110,112–116] In LVH caused by pressure overload, a reduction in the coronary vascular reserve may underlie episodes of myocardial ischemia[117,118] (see Chapters 6 and 7).

Echocardiographic and hemodynamic assessments of the myocardial oxygen supply and demand ratio are not significantly different in the presence or absence of angina in patients with AS.[119] However, considerable data indicate that dynamic factors relative to oxygen supply may be crucial to the pathogenesis of angina in these patients.[120] Several clinical studies have documented a decrease in coronary vascular reserve in adult and pediatric patients with significant LVH or right ventricular hypertrophy (RVH).[121–123] It is further postulated that repeated episodes of subendocardial ischemia may contribute to the development of subendocardial fibrosis, a component of ischemic contractile dysfunction.[108]

Myocardial ischemia may underlie the impaired ventricular relaxation that has been documented in patients with myocardial hypertrophy due to a variety of causes.[91,93,94] Prolongation of ventricular relaxation and resultant diastolic dysfunction (ie, poor compliance) are probably universal features of myocardial ischemia in a variety of

TABLE 21.1 Pressure-Overload Hypertrophy

Beneficial Aspects	*Detrimental Aspects*
Increases ventricular work	Decreases ventricular diastolic distensibility
Normalizes wall stress	Impairs ventricular relaxation
Normalizes systolic shortening	Impairs coronary vasodilator reserve, leading to subendocardial ischemia

From Lorell BH, Grossman W. Cardiac hypertrophy: the consequences for diastole. *J Am Coll Cardiol.* 1987;9:1189.

clinical settings.[124–128] Experimental data suggest that ischemia-induced impairment of calcium sequestration by the sarcoplasmic reticulum may underlie the increased diastolic chamber stiffness.[129] Prevention of ischemia-induced myoplasmic calcium overload may be the mechanism by which the calcium channel blockers are able to improve diastolic dysfunction in patients with CAD.[130] These drugs also ameliorate ventricular relaxation and diastolic filling in patients with HCM, although the mechanism of action is controversial.[91,131–133] The absence of diastolic filling abnormalities in patients with physiologic rather than pathologic hypertrophy also may reflect the relative likelihood of ischemia in the two conditions.[134–136]

In summary, the pathophysiologic response to chronic pressure overload is a complex one characterized by interactions among the divergent effects of hypertrophy on systolic and diastolic function. Mural thickening enhances systolic performance, maximizing the mechanical work performed while minimizing its metabolic cost. The price of systolic efficiency is relatively inadequate growth of the coronary microcirculation, which contributes to relaxation abnormalities, diastolic dysfunction, and the potential for superimposition of ischemia-induced abnormalities of systolic dysfunction (Table 21.1).[137] The potentially deleterious effects of LVH cannot be overemphasized. Even in the absence of AS, in which LVH can be viewed as a compensatory and potentially beneficial pathophysiologic response, LVH has been found to have an independent adverse effect on survival.[138,139]

Difficulty of Low-Gradient, Low-Output Aortic Stenosis

A subset of patients with severe AS, left ventricular dysfunction, and low transvalvular gradient suffers a high operative mortality rate and poor prognosis.[140] It is difficult to assess accurately the AVA in low-flow, low-gradient AS because the calculated valve area is proportional to forward SV and because the Gorlin constant varies in low-flow states. Some patients with low-flow, low-gradient AS have a decreased AVA as a result of inadequate forward SV rather than anatomic stenosis. Surgical therapy is unlikely to benefit these patients because the underlying pathology is a weakly contractile myocardium. However, patients with severe anatomic AS may benefit from valve replacement despite the increased operative risk associated with the low-flow, low-gradient hemodynamic state.[140] ACC/AHA guidelines call for a dobutamine echocardiography evaluation to differentiate patients with fixed anatomic AS from those with flow-dependent AS with left ventricular dysfunction.[141] Low-flow, low-gradient AS is defined as a mean gradient of less than 30 mm Hg and a calculated AVA less than 1.0 cm^2.

Dobutamine echocardiography revealed three basic response patterns—fixed AS, relative AS, and absence of contractile reserve—in an initial study by deFilippi and colleagues.[142] In a series of 45 patients with low-flow, low-gradient AS, the 30-day operative mortality rate was 8% for patients with contractile reserve and 50% for those without contractile reserve.[143]

Dobutamine challenges during cardiac catheterization provided unique insights into low-flow, low-gradient AS, and the details are summarized in Fig. 21.18.[144] In Fig. 21.18A, the transvalvular gradient and cardiac output increased, and the valve area did not change. Patients represented in Fig. 21.18B increased their CO with little or no change in gradient, and the calculated valve area increased slightly. This group still benefited from surgery. The third group of patients had no contractile reserve because CO did not increase with dobutamine, and the transvalvular gradient decreased (see Fig. 21.18C). Dobutamine infusion in the cardiac catheterization laboratory appears to be helpful in identifying patients with low-flow, low-gradient AS who have a truly fixed anatomic stenosis that may benefit from valve replacement.

The findings of these studies also emphasize that contractile reserve is an important prognostic indicator for these patients and that dobutamine challenge may help select patients for valve replacement. Those with contractile reserve and fixed AS have a relatively good prognosis with valve replacement. Left ventricular contractile reserve appears to be a critical variable for prognosis. Studies have focused on AS with low transvalvular gradients and normal ventricular EF. The pathophysiology of the low transvalvular gradient has been explained by decreased EDV caused by excessive ventricular hypertrophy accompanied by increased SVR. In a series of patients with severe AS (AVA <0.8 cm^2) with ventricular dysfunction (EF <35%) with or without a low transvalvular gradient (<30 mm Hg), mortality predictors were advanced age, low EF, renal insufficiency, and lack of AR. Regardless of ventricular function, patients who underwent AVR had a significantly better survival rates.[36]

Developments in the Hemodynamic Management of Critical Aortic Stenosis Patients

The use of vasodilators is traditionally contraindicated for patients with severe AS because cardiac output is relatively fixed across a narrowed orifice. Vasodilation reduces SVR without any possibility for a compensatory increase in CO, and severe hypotension typically results. This traditional paradigm was reexamined in patients with fixed, severe AS (area <1.0 cm^2) and left ventricular dysfunction (EF <0.35).[145] Nitroprusside was carefully titrated to maintain a mean arterial pressure of more than 60 mm Hg with concomitant hemodynamic monitoring. The cardiac index increased over 24 hours from a mean of 1.60 to 2.52 L/min/m^2 with no changes in heart rate and mean arterial pressure (Fig. 21.19). The pulmonary capillary wedge pressure (PCWP) and SVR decreased, whereas SV increased.

This treatment can effectively alleviate to some extent the left ventricular dysfunction component of the complete syndrome. Left ventricular dysfunction benefits derived from unloading and careful titration of the nitroprusside most likely allows SVR to decrease without changes in mean arterial pressure. Titrated unloading may benefit patients with severe AS and left ventricular dysfunction, and it may serve as a bridge to AVR or oral vasodilator therapy.[145] It is unclear whether treatment with positive inotropic agents can produce similar effects with fewer risks. Patients with AS, a depressed EF, and a low transvalvular gradient continue to pose a diagnostic and therapeutic challenge.[146] The use of nitroprusside in AS in the absence of ventricular dysfunction may not be as effective and may even be deleterious because of the prompt decrease in preload by nitroprusside.

Timing of Intervention

For asymptomatic patients with AS, it appears to be relatively safe to delay surgery until symptoms develop, but outcomes vary widely. Moderate or severe valvular calcification along with a rapid increase in aortic-jet velocity identify patients with a very poor prognosis. They should be considered for early valve replacement rather than delaying until symptoms develop.[40]

Echocardiography and exercise testing may identify asymptomatic patients who are likely to benefit from surgery.[147] In a study of 58 asymptomatic patients, 21 had symptoms for the first time during exercise testing.[148] Guidelines for AVR in patients with AS are shown in Fig. 21.20.

Functional outcome after AVR for patients older than 80 years is excellent, operative risk is limited, and late survival rates are good.[149] For patients with severe left ventricular dysfunction and a low transvalvular mean gradient, the operative mortality rate was increased, but AVR was associated with improved functional status.[150] Postoperative

BOX 21.1 AORTIC STENOSIS

- Maintain preload and diastolic filling.
- Maintain sinus rhythm.
- Maintain or increase afterload.
- Avoid myocardial depression.
- Avoid tachycardia, hypotension, and increased myocardial oxygen demand situations.

survival rates were best for younger patients and those with larger prosthetic valves, whereas medium-term survival rates were correlated with improved postoperative functional class.[150]

Anesthesia Considerations

The described pathophysiologic principles dictate anesthesia management based on avoidance of systemic hypotension, maintenance of sinus rhythm and an adequate intravascular volume, and awareness of the potential for myocardial ischemia (Box 21.1). In the absence of CHF, adequate premedication may reduce the likelihood of undue preoperative excitement, tachycardia, and exacerbation of myocardial ischemia and the transvalvular pressure gradient. In patients with critical outflow tract obstruction, however, heavy premedication with an exaggerated venodilatory response can reduce the appropriately increased LVEDV (and LVEDP) needed to overcome the systolic pressure gradient. In these patients, the additional precaution of administering supplementary oxygen may obviate the possibility of a similarly pronounced response to the sedative effects of the premedicant.

Intraoperative monitoring should include a standard five-lead electrocardiographic (ECG) system, including a V_5 lead, because of the LV's vulnerability to ischemia. A practical constraint in terms of interpretation is that these patients usually exhibit ECG changes because of preoperative LVH. The associated ST-segment abnormalities (ie, strain pattern) may be indistinguishable from or very similar to those of myocardial ischemia, making the intraoperative interpretation difficult. Lead II and possibly an esophageal electrocardiogram should be readily obtainable because for assessing the P-wave changes in the event of supraventricular arrhythmias (see Chapter 12).

Hemodynamic monitoring is controversial, and few prospective data are available on which to base an enlightened clinical decision. The central venous pressure (CVP) is a particularly poor estimate of left ventricular filling when left ventricular compliance is reduced. A normal CVP can significantly underestimate the LVEDP or PCWP. The principal risks, although minimal, of using a pulmonary artery catheter (PAC) in the patient with AS are arrhythmia-induced hypotension and ischemia. Loss of synchronous atrial contraction or a supraventricular tachyarrhythmia can compromise diastolic filling of the poorly compliant LV, resulting in hypotension and the potential for rapid hemodynamic deterioration. The threat of catheter-induced arrhythmias is significant for the patient with AS. However, accepting a low-normal CVP as evidence of good ventricular function can lead to similarly catastrophic underfilling of the LV on the basis of insufficient replenishment of surgical blood loss. To some extent, even the PCWP can underestimate the LVEDP (and LVEDV) when ventricular compliance is markedly reduced. Placement of a PAC also allows measurement of CO, derived hemodynamic parameters, mixed venous oxygen saturation (Svo_2), and possible transvenous pacing (see Chapter 13).

Intraoperative fluid management should be aimed at maintaining appropriately increased left-sided filling pressures. This is one reason why many clinicians think that the PAC is worth its small arrhythmogenic risk. Keeping up with intravascular volume losses is particularly important in noncardiac surgery, in which the shorter duration of the operation may make inhalation or potentially vasodilating regional anesthesia preferable to a narcotic technique.

Patients with symptomatic AS are usually encountered only in the setting of cardiovascular surgery because of their ominous prognosis without AVR. Few studies have specifically addressed the response of

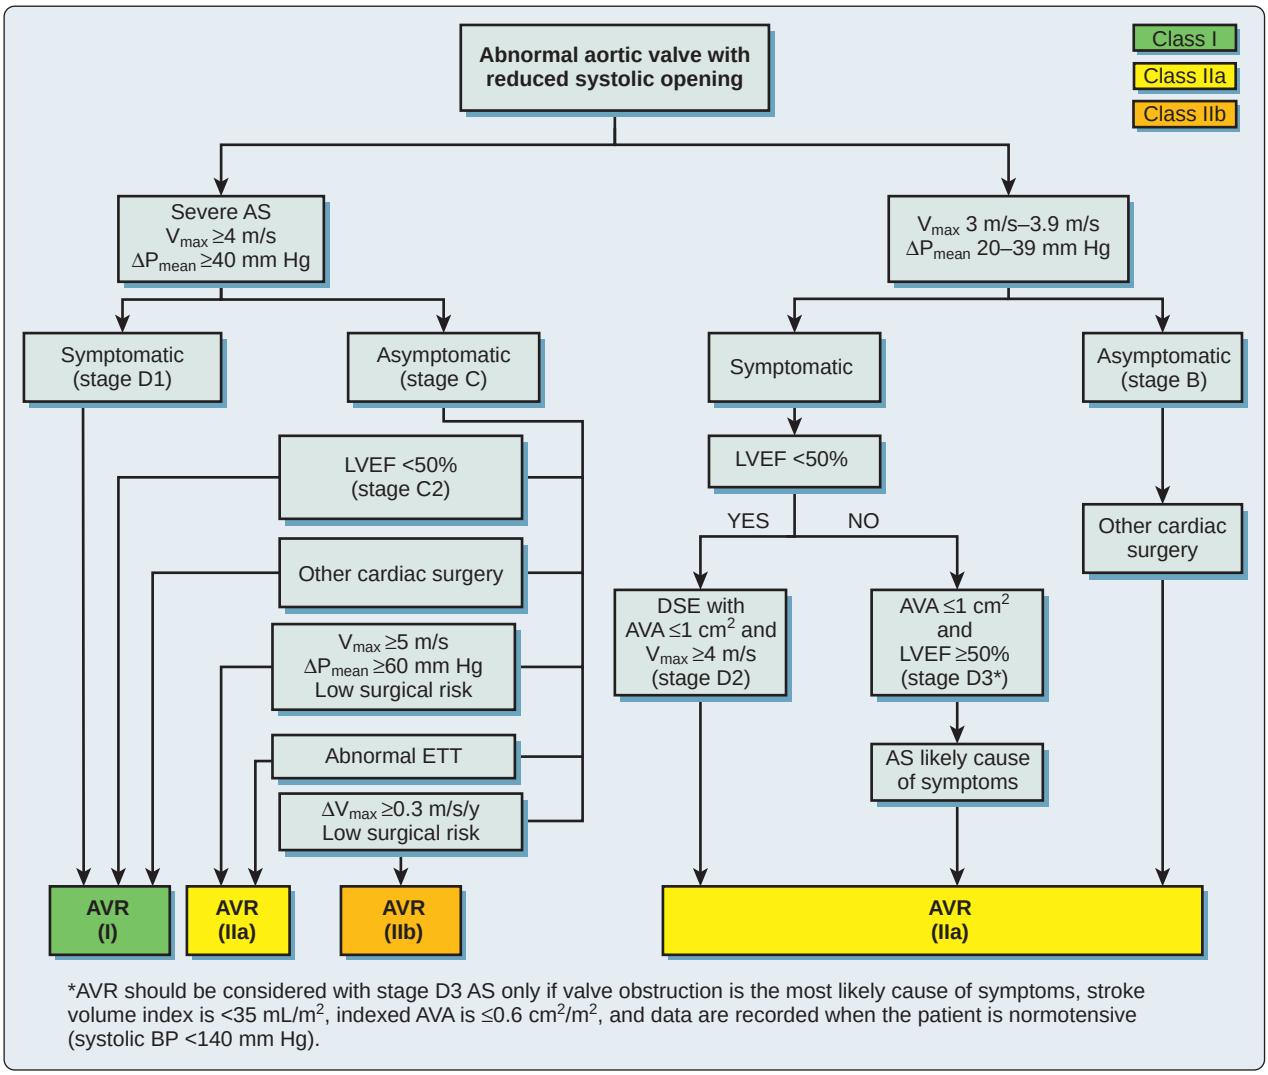

Fig. 21.20 Indications for aortic valve replacement (AVR) in patients with aortic stenosis (AS). *Arrows* show the decision pathways that result in a recommendation for AVR. Periodic monitoring is indicated for all patients in whom AVR is not yet indicated, including those with asymptomatic AS (stage D or C) and those with low-gradient AS (stage D2 or D3) who do not meet the criteria for intervention. *AVA,* Aortic valve area; *AVR,* aortic valve replacement by either surgical or transcatheter approach; *BP,* blood pressure; *DSE,* dobutamine stress echocardiography; *ETT,* exercise treadmill test; *LVEF,* left ventricular ejection fraction; ΔP_{mean}, mean pressure gradient; V_{max}, maximum velocity. *(From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC guideline for the management of patients with valvular heart disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;63[22]:2438–2488.)*

these patients to the standard intravenous and inhalation induction agents; however, the responses to narcotic[151,152] and nonnarcotic[153,154] intravenous agents are apparently not dissimilar from those of patients with other forms of VHD. The principal benefit of a narcotic induction is assurance of an adequate depth of anesthesia during intubation, which reliably blunts potentially deleterious reflex sympathetic responses capable of precipitating tachycardia and ischemia.

Many clinicians also prefer a pure narcotic technique for maintenance. The negative inotropy of inhalation anesthetics is a theoretical disadvantage for a myocardium faced with the challenge of overcoming outflow tract obstruction. A more clinically relevant drawback may be the increased risk for arrhythmia-induced hypotension, particularly that associated with nodal rhythm and resultant loss of the atrium's critical contribution to filling of the hypertrophied ventricle[155,156] (see Chapter 10).

Occasionally, surgical stimulation elicits a hypertensive response despite the impedance posed by the stenotic valve and a seemingly adequate depth of narcotic anesthesia. In these patients, a judicious trial of low concentrations of an inhalation agent, used purely for control of hypertension, may prove efficacious. The ability to concurrently monitor CO is useful in this situation. The temptation to control intraoperative hypertension with vasodilators should be resisted in most cases. Given the risk for ischemia, nitroglycerin seems to be a particularly attractive drug. Its effectiveness in relieving subendocardial ischemia in patients with AS is controversial[157,158]; however, there is always the risk for transient episodes of overshoot. The hypertrophied ventricle's critical dependence on an adequate CPP may be unforgiving of even a momentary dip in the systemic arterial pressure.

Intraoperative hypotension, regardless of the primary cause, should be treated immediately and aggressively with a direct α-adrenergic agonist such as phenylephrine.[159] The goal should be to immediately restore the CPP and then to address the underlying problem (eg, hypovolemia, arrhythmia). After the arterial pressure responds, treatment of the precipitating event should be equally aggressive, but

rapid transfusion or cardioversion should not delay the administration of a direct-acting vasoconstrictor. Patients with severe AS in whom objective signs of myocardial ischemia persist despite restoration of the blood pressure should be treated extremely aggressively. This may mean the immediate use of an inotropic agent or accelerating the institution of cardiopulmonary bypass (CPB).

Intraoperative myocardial ischemic injury in the patient with AS has been appreciated for some time, and there are several theories regarding its pathogenesis. The potential vulnerability of the hypertrophied myocardium to ischemic damage was initially speculated on by cardiac surgeons who described the phenomenon of irreversible ischemic contracture—what they called the *stone heart*—occurring after AVR in a group of patients with severe LVH.[160] The anatomic and hemodynamic bases for an unfavorable myocardial oxygen supply and demand relation have already been considered, but the possibility that these patients may be experiencing prebypass ischemic injury remains a plausible, although unproven, hypothesis.

Most attention has been focused on the potential for irreversible cellular damage occurring during the period of ischemic cardiac arrest. Although there is a consensus that improved myocardial preservation has been crucial in reducing the mortality rate after CABG, there is evidence that current cardioplegic techniques may provide suboptimal protection for patients with VHD.[161,162] Ultrastructural evidence (ie, intracellular or mitochondrial edema) suggests that the hypertrophied myocardium is uniquely susceptible to ischemic damage during the aortic cross-clamp interval despite the presumed protection. Although these changes are observed in patients whose clinical course is seemingly unremarkable, ischemic cellular damage also may underlie the frequent occurrence of postoperative low-output syndromes and the greater mortality rates associated with valvular operations.[163]

Although a detailed consideration of myocardial preservation is beyond the scope of this chapter (see C), certain aspects are peculiar to the operative management of patients with AS, and improved cardioplegic techniques likely will play an important role in reducing operative morbidity and mortality rates. Because the operation requires an ascending aortotomy, many surgeons routinely use direct coronary ostial cannulation for the delivery of the cardioplegic solution. Problems associated with this approach are uncommon but include the inherent hazard of injury to the coronary ostia and cannula-induced late stenosis of the left main coronary artery.[164] Coronary ostial delivery requires interrupting the surgical procedure for subsequent reinfusions of the cardioplegic solution. These problems are obviated by the use of cardioplegia delivery through the coronary sinus. The retrograde technique commonly is used in conjunction with an initial dose of antegrade cardioplegia; the latter provides for a more immediate electromechanical arrest.[165–167]

Noncardiac Surgery in the Patient With Aortic Stenosis

Patients with AS who undergo noncardiac surgery were identified by Goldman and coworkers[148] as being at increased risk for cardiac complications, including myocardial infarction, CHF, and supraventricular tachyarrhythmias. Likewise, the ACC Task Force on perioperative evaluation of the cardiac patient identified patients with severe or symptomatic AS as being at increased risk for serious perioperative cardiac morbidity.[168] It stated that symptomatic stenotic lesions are associated with the risk of perioperative severe CHF or shock and often require percutaneous valvotomy or valve replacement before noncardiac surgery to reduce cardiac risk.

Due to the aging of the surgical population and a peak incidence of significant AS in the fifth and sixth decades, these patients likely will be encountered with increasing frequency in the setting of noncardiac surgery. Because of the natural history of the disease and the conservative ACC guidelines cited previously, one approach is to recommend immediate elective AVR to all AS patients before noncardiac procedures. Although there is a rationale for this shotgun solution, a variety of ethical, practical, and economic constraints argue for a more selective approach.

A common clinical problem is the elderly, asymptomatic patient with a harsh systolic ejection murmur who is scheduled for noncardiac surgery. Risk assessment for the asymptomatic patient is challenging because the prognosis in the absence of AVR may be quite benign. However, symptoms correlate poorly with AS severity, which may by itself portend a more ominous natural history. For these patients, a two-dimensional Doppler echocardiographic examination allows a noninvasive assessment of the severity of stenosis[57] and some quantification of contractile function (see Chapters 14 and 15). Patients with moderate AS have a greater short-term incidence of cardiovascular complications, and this risk is further increased by symptoms or objective evidence of contractile impairment.[53]

Armed with the echocardiographic evaluation (eg, stenosis severity, contractile state), the clinician can make an initial assessment of relative risk. Depending on the overall clinical picture, some patients may warrant immediate elective AVR by a surgical or transcutaneous approach, whereas for others, it may be more appropriate to proceed with the noncardiac operation along with hemodynamic monitoring as dictated by the echocardiographic data and the nature of the operation. In the clinical setting, the overall picture often dictates that the anesthesiologist proceed with the originally planned operation, albeit at increased risk for perioperative cardiac morbidity (see Chapter 27).

Hypertrophic Cardiomyopathy

Hypertrophic Obstructive Cardiomyopathy

Obstructive hypertrophic cardiomyopathy (HCM) is a relatively common genetic malformation of the heart with a prevalence of approximately 1 case in 500 births (see Chapter 24). The hypertrophy initially develops in the septum and extends to the free walls, often giving a picture of concentric hypertrophy. Asymmetric septal hypertrophy leads to a variable pressure gradient between the apical left ventricular chamber and the LVOT. The LVOT obstruction leads to increases in left ventricular pressure, which fuels a vicious cycle of further hypertrophy and increased LVOT obstruction.[169]

Treatment modalities include β-adrenoceptor antagonists, calcium channel blockers, and surgical myectomy of the septum. For more than 40 years, the standard treatment has been the ventricular septal myotomy-myomectomy of Morrow, in which a small amount of muscle from the subaortic septum is resected.[170] Two new treatment modalities have gained popularity in recent years: dual-chamber pacing and septal reduction (ie, ablation) with ethanol.

Dual-chamber DDD pacing is based on the observation that excitation of the septum of the LV contracts it away from the apposing wall, which can reduce the LVOT gradient. The precise mechanism by which dual-chamber pacing decreases LVOT gradient or improves symptoms is uncertain. Possible mechanisms are asynchronous ventricular activation, paradoxical septal wall motion, a negative inotropic effect, an increase in ESV, decreased systolic anterior leaflet motion, altered myocardial perfusion, and regression of LVH.[171] The AV interval must be sufficiently short to guarantee early right ventricular apical activation without conduction through the His-Purkinje system. Although some studies have shown a decrease in the LVOT gradient of 25%, there are still variable results with respect to improvements in exercise capacity and symptoms.[171–174]

Patients with severe, drug-resistant symptoms of CHF, angina, or syncope are considered for nonsurgical septal reduction therapy. In one series, patients with a resting gradient of more than 40 mm Hg or a dobutamine-induced gradient of more than 60 mm Hg were included.[175] After coronary angiography to exclude significant CAD and after placement of temporary pacing wires, the LVOT gradient was measured at rest and during various interventions (eg, Valsalva, postextrasystolic, isoproterenol, amyl nitrite). The coronary septal branches were cannulated with a small balloon-equipped catheter.

The balloon was inflated to prevent overflow or spillage into the left anterior descending coronary artery. Depending on the septal branch size and area of septal hypertrophy, a dose of 2 to 5 mL of ethanol was injected slowly through the balloon catheter lumen. The LVOT gradient decreased immediately in 85% to 90% of patients. Further decreases in gradient were reported after 6 months.[171]

The septal muscle mass was not decreased adequately through alcohol injections at the time of the intervention, but ventricular remodeling continued and led to sustained symptomatic improvement, most dramatically over the first 3 to 6 months.[169] Exercise tolerance also increased, but atrioventricular block, right bundle branch block, and left bundle branch block were frequent adverse consequences. Permanent heart blocks occurred in 5% to 10% of cases.[176]

Clinical Features and Natural History

HCM is a familial disorder in which there is pronounced hypertrophy of histologically abnormal sarcomeres with characteristically disproportionate involvement of the interventricular septum.[177–179] This disease has numerous pathologic and pathophysiologic features, which vary in their relative predominance in individual patients. The cause and exact pattern of inheritance of the disease remain unknown, although it appears to be an autosomal dominant trait expressed with a high degree of penetrance.[179–181]

Many names have been applied to the disorder, including asymmetric septal hypertrophy, muscular sub-AS, and idiopathic, hypertrophic sub-AS. Each emphasizes some aspect of the disease that may or may not be a prominent feature of its manifestation in an individual patient.

The clinical presentation of patients vary widely. Echocardiography has unquestionably increased the number of asymptomatic patients who carry the diagnosis. Most patients with HCM are asymptomatic and have been seen by the echocardiographer because of relatives having clinical disease. Follow-up remains an important problem for cardiologists because sudden death or cardiac arrest may occur as the presenting symptom in slightly more than one-half of previously asymptomatic patients.[182]

Less dramatic presenting complaints include dyspnea, angina, and syncope.[179] The clinical picture is often similar to valvular AS. The symptoms may share a similar pathophysiologic basis (eg, poor diastolic compliance) in the two conditions. The prognostic implications of clinical disease, however, are less certain for patients with HCM. Although cardiac arrest may be an unheralded event, some patients may have a stable pattern of angina or intermittent syncopal episodes for many years.[183] Palpitations are frequently described and may be related to a variety of underlying arrhythmias. Of patients studied with continuous ambulatory monitoring, ventricular arrhythmias occur in more than 75%, supraventricular tachycardias in 25%, and atrial fibrillation (AF) in 5% to 10%.[184–186] The latter often precipitates clinical deterioration because of the dependence of the noncompliant LV on atrial systole for its filling.[187]

The natural history of patients with HCM varies broadly. These patients are at risk for sudden death, although those with a family history of this problem form an especially high-risk group.[188] Unfortunately, younger and previously asymptomatic patients with minimal subaortic gradients also may be at greater risk for sudden death because of their more frequent and vigorous physical activity.[182,189] It is unknown whether vigorous physical activity by patients with HCM is an independent risk factor for sudden death, but HCM is the most frequent autopsy finding in previously healthy competitive athletes who die suddenly.[190]

Although patients referred to diagnostic centers for evaluation of HCM are usually young to middle-aged, a syndrome with similar clinical and echocardiographic findings has been identified in the elderly.[93] Echocardiographically, these patients exhibit a similarly thickened and hypercontractile LV. Their most common symptoms are those of CHF and are thought to reflect severe reductions in ventricular diastolic compliance. As in younger patients with classic HCM, there is marked systolic anterior motion (SAM) of the mitral apparatus. However, in HCM of the elderly, the SAM is caused or accentuated by a severe degree of mitral annular calcification, which results in a particularly small LVOT.[191] Previously asymptomatic, these patients often experience the onset of progressively severe symptoms in the sixth decade of life, and the response to medical therapy, usually calcium channel blockers, has been poor.[191] The lack of improvement with medical therapy may reflect the fact that mitral annular calcification plays a key role in producing a physical (ie, less dynamic) subaortic obstruction. It also would explain the female predominance of the disease because mitral annular calcification is more common in elderly women. It is unclear whether this represents a true variant of classic HCM with late onset or it is etiologically linked to long-standing systemic hypertension, with secondary, unexplained, disproportionate involvement of the interventricular septum.[93]

Pathophysiology

In HCM, the principal pathophysiologic abnormality is myocardial hypertrophy. The hypertrophy is a primary event in these patients and occurs independently of outflow tract obstruction. Unlike in AS, the hypertrophy begets the pressure gradient, not the other way around. Histologically, the hypertrophy consists of myocardial fiber disarray, and anatomically, there is usually disproportionate enlargement of the interventricular septum.[192]

Controversy exists concerning the intrinsic contractile strength of the myocardium in patients with HCM. Several studies have demonstrated normal or supranormal indices of systolic function in patients with this disease.[193–195] Left ventricular ejection is rapid, with 80% of the SV ejected very early during systole.[193,196] This is true regardless of the presence, temporal location during systole, or magnitude of outflow tract obstruction. However, studies have shown that end-systolic stress is significantly reduced in relation to ESV (Fig. 21.21).[197,198] The Laplace formula for wall stress ($P \times R/2h$) shows that the degree of primary hypertrophy (ie, with increased wall thickness [h]) in HCM should minimize instantaneous left ventricular afterload. There is preservation and perhaps elevation of afterload-sensitive indices of systolic function (eg, EF).[199]

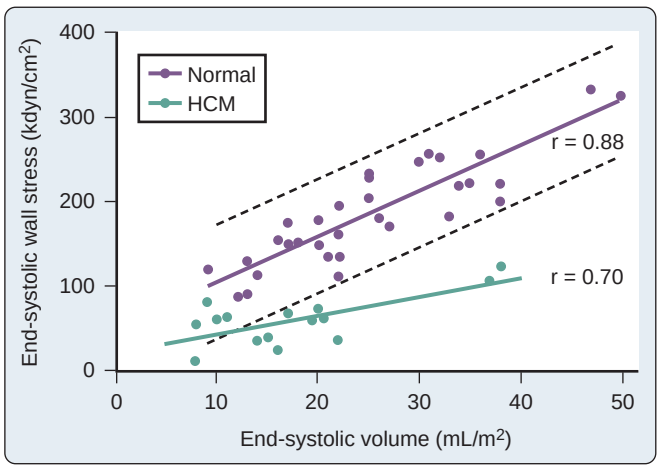

Fig. 21.21 End-systolic stress versus end-systolic volume in healthy subjects *(purple circles)* and in patients with hypertrophic cardiomyopathy *(HCM) (green circles). Dashed lines* indicate the 95% confidence limit. Stress-volume data for most patients with HCM are located downward and to the right of the confidence band (ie, decreased end-systolic stress related to volume), which indicates intrinsically depressed myocardial contractility. *(From Pouleur H, Rousseau MF, van Eyll C, et al. Force-velocity-length relations in hypertrophic cardiomyopathy: evidence of normal or depressed myocardial contractility.* Am J Cardiol. *1983;52:813.)*

Myocardial hypertrophy, particularly to the extent that it accentuates subaortic obstruction, increases the ESPVR, widening the divergence between it and the more accurate (load-insensitive) ratio of end-systolic wall stress to ESV. High peak systolic pressures (ie, subaortic obstruction), elevation of ejection phase indices, and low ESV (ie, minimal afterload) may reflect uncontrolled hypertrophy of an abnormal and perhaps intrinsically depressed myocardium. Whether overall contractility is normal, supranormal, or impaired in a patient, regional differences in a ventricle's contractile function likely correlate with the histologic heterogeneity characteristic of this disease.[200]

HCM is characterized by a broad spectrum of obstruction, which is absent in some patients and varies from mild to severe in others. The most distinctive qualities of obstruction are its dynamic nature (ie, depends on contractile state and loading conditions), its timing (ie, begins early and peaks variably), and its subaortic location.[193,201] Many think that subaortic obstruction arises from the hypertrophied septum's encroachment on the systolic outflow tract, which is bounded anteriorly by the interventricular septum and posteriorly by the anterior leaflet of the mitral valve.

In most patients with obstruction, exaggerated anterior (ie, toward the septum) motion of the anterior mitral valve leaflet during systole accentuates the obstruction.[202] The cause of SAM is unclear. One possibility is that the mitral valve is pulled toward the septum by contraction of the papillary muscles, whose orientation is abnormal because of the hypertrophic process.[203] Another theory is that vigorous contraction of the hypertrophied septum results in rapid acceleration of the blood through a simultaneously narrowed outflow tract. The generated hydraulic forces (consistent with a Venturi effect) can cause the anterior leaflet of the mitral valve to be drawn close to or in contact with the interventricular septum[204] (Fig. 21.22). After the obstruction is triggered, the mitral valve leaflet is forced against the septum by the pressure difference across the orifice. However, the pressure difference further decreases orifice size and further increases the pressure difference in a time-dependent, amplifying feedback loop.[205] This analysis is consistent with observations that the measured gradient directly correlates with the duration of mitral-septal contact. Although still controversial,[206–208] there appears to be good correlation between the degree of SAM and the magnitude of the pressure gradient.[209,210] The SAM-septal contact also underlies the severe subaortic obstruction characteristic of HCM of the elderly, although the narrowing usually is more severe and the contribution of septal movement toward the mitral valve is usually greater.[191]

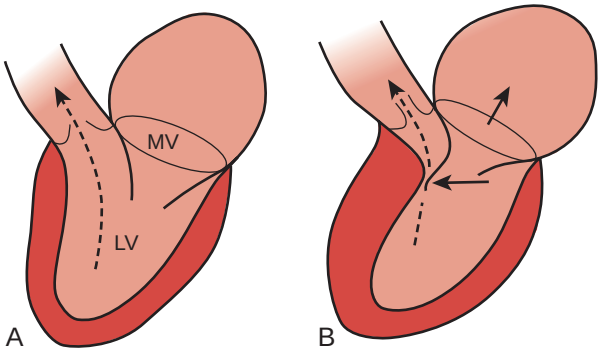

Fig. 21.22 Proposed mechanism of systolic anterior motion in hypertrophic cardiomyopathy. (A) Normally, blood is ejected from the left ventricle *(LV)* through an unimpeded outflow tract. (B) Thickening of the ventricular septum restricts the outflow tract, and the obstruction causes the blood to be ejected at a higher velocity and closer to the area of the anterior mitral valve *(MV)* leaflet. Due to its proximity to the high-velocity fluid path, the anterior MV leaflet is drawn toward the hypertrophied septum by a Venturi effect *(left arrow). (From Wigle ED, Sasson Z, Henderson MA, et al. Hypertrophic cardiomyopathy: the importance of the site and the extent of hypertrophy—a review.* Prog Cardiovasc Dis. *1985;28:1.)*

The timing of SAM-septal contact is important because the magnitude of the subaortic gradient is proportional to the fraction of forward flow ejected in the setting of anatomic obstruction.[211] Large gradients occur as a result of early and prolonged SAM-septal contact, and small gradients arise from delayed and brief SAM-septal contact.[204,209] In studies of patients with various degrees of subaortic obstruction, the proportion of flow ejected in the presence of a gradient was between 30% and 70%.[209,212,213] Patients with evidence of systolic obstruction at rest have the longest intervals of systolic contact between the anterior leaflet of the mitral valve and the septum.[214] However, if SAM-septal contact is restricted to late systole, a pressure gradient may occur on the basis of so-called cavity obliteration in the absence of functional obstruction to blood flow.[215,216] In these patients, 95% of the SV may be ejected by the halfway point in systole, when SAM-septal contact is just beginning.[193,209] Despite its seemingly critical role in producing outflow tract obstruction, SAM of the mitral valve is not a specific finding for HCM, and it may occur in patients with HCM who do not have obstruction.[206,207,214]

In addition to SAM, approximately two-thirds of patients exhibit a constellation of structural malformations of the mitral valve.[217] Malformations include increased leaflet area and elongation of the leaflets or anomalous papillary muscle insertion directly into the anterior mitral valve leaflet. HCM is not a disease process confined to cardiac muscle alone because these anatomic abnormalities of the mitral valve are unlikely to be acquired or caused by mechanical factors.

Three basic mechanisms—increased contractility, decreased afterload, and decreased preload—exacerbate the degree of SAM-septal contact and produce the dynamic obstruction characteristic of patients with HCM. The common pathway is a reduction in ventricular volume (actively by increased contractility directly or reflexively in response to vasodilation or passively by reduced preload), which increases the proximity of the anterior mitral valve leaflet to the hypertrophied septum.[179,183,218] Factors that usually impair contractile performance, such as myocardial depression, systemic vasoconstriction, and ventricular overdistention, characteristically improve systolic function in patients with HCM and outflow tract obstruction.

Diagnostically, the paradoxes are exploited by quantifying the degree of subaortic obstruction after isoproterenol (eg, increased inotropy, tachycardia, decreased volume) and the Valsalva maneuver (eg, decreased venous return, ventricular volume), both of which reliably elicit increases in the pressure gradient. In the operating room, catheter-induced ectopy or premature ventricular contractions resulting from cardiac manipulation may transiently exacerbate the gradient by increased inotropy from postextrasystolic potentiation. Therapeutically, volume loading, myocardial depression, and vasoconstriction can minimize obstruction and augment forward flow.

Patients with HCM demonstrate critical derangements in diastolic function. Although in some ways more subtle than the unique phenomenon of subaortic obstruction, they may contribute equally to the challenge posed.[219–222] Abnormalities include prolongation of the isovolumic relaxation time (ie, aortic valve closure to mitral valve opening) and reduction in the peak velocity of left ventricular filling.[91,195] Diastolic dysfunction exhibits the same heterogeneity as systolic dysfunction, probably because the underlying cause is intrinsic to the primary myopathic process and not merely caused by the associated chamber hypertrophy.[223] Diastolic filling abnormalities in HCM are largely independent of the magnitude of LVH and are seen even in patients with only mild, localized hypertrophy.[20]

Poor diastolic compliance is the most clinically apparent manifestation of the relaxation abnormalities. Left ventricular filling pressures are markedly increased despite enhanced systolic ejection and a normal or subnormal EDV. The reduced ventricular volume emphasizes the pivotal role played by the hypertrophied but intrinsically depressed myocardium. Reductions in afterload, which are mediated by hypertrophy, support the ventricle's systolic performance, resulting in increased emptying and a small diastolic volume. However, hypertrophy also impairs relaxation, resulting in poor diastolic compliance and an increased ventricular filling pressure. The high filling pressure

Hypertrophic cardiomyopathy: the importance of the site and the extent of hypertrophy—a review.* Prog Cardiovasc Dis. *1985;28:1.)*

BOX 21.2 FACTORS AFFECTING LEFT VENTRICULAR DIASTOLIC FILLING IN HYPERTROPHIC CARDIOMYOPATHY

- Chamber stiffness[a]
- Relaxation
  - Loads
    - Contraction load
      - Subaortic stenosis
    - Relaxation loads
      - Late-systolic loading
      - End-systolic deformation (ie, restoring forces)
      - Coronary filling
      - Ventricular filling
  - Inactivation
    - Myoplasmic calcium overload
      - Primary
      - Ischemic
  - Nonuniformity of load and inactivation in space and time[b]
- Pericardial constraints and ventricular interaction
- Effect of extent of hypertrophy on the preceding factors

[a]Chamber stiffness = myocardial mass × myocardial stiffness/ventricular volume.
[b]Nonuniformity of contraction and relaxation.
From Wigel ED, Wilansky S. Diastolic dysfunction in hypertrophic cardiomyopathy. *Heart Fail.* 1987;3:85.

does not reflect distention of a failing ventricle, although stress-volume relationships suggest that contractility is intrinsically depressed (Fig. 21.23 and Box 21.2). This disease is characterized by systolic and diastolic dysfunction.

As in patients with valvular AS, relatively high filling pressures reflect the LVEDV (ie, degree of preload reserve) needed to overcome the outflow obstruction. Intervention with vasodilators is therefore inappropriate. The poor ventricular compliance also means that patients with HCM depend on a large intravascular volume and the maintenance of sinus rhythm for adequate diastolic filling. The atrial contribution to ventricular filling is even more important in HCM than in valvular AS, and it may approach 75% of total SV.[132]

Another similarity between HCM and valvular AS is that the combination of myocardial hypertrophy, with or without LVOT obstruction, may precipitate imbalances in the myocardial oxygen supply and demand relationship. Angina-like discomfort is a classic symptom of patients with HCM, and its pathogenesis has been attributed to increases in $M\dot{V}O_2$, specifically the increased overall muscle mass and the high systolic wall tension generated by the ventricle's ejection against the dynamic subaortic obstruction. However, as in patients with AS, there is evidence of a compromise in myocardial oxygen supply.[224,225]

Patients with HCM suffer from several types of hypertrophy-related abnormalities of the coronary circulation; some are common to other conditions associated with pathologic hypertrophy (eg, AS), and others are unique to this distinctive form of hypertrophy.[226] Reduced capillary density in the hypertrophied myocardium prevents flow from increasing in proportion to the increase in myocardial mass.[227] It is also possible that there are primary HCM-associated abnormalities of the coronary circulation that are unrelated to myocardial hypertrophy.[228] In addition to the coronary circulatory abnormalities, there is evidence of a metabolic derangement in the hypertrophied interventricular septum, whereby there is a decreased use of adequately delivered metabolic substrates.[225]

The reduction in coronary vascular reserve is similar to that observed in patients with valvular AS, in whom $M\dot{V}O_2$ may be presumed to be uniformly increased.[118] However, angina also occurs in patients with HCM in the absence of subaortic obstruction. Although basal $M\dot{V}O_2$ is increased in proportion to the increased muscle mass, clinical studies support a greater pathogenetic role for coronary circulatory abnormalities in producing ischemia in patients with nonobstructive hypertrophy.[229]

Hemodynamic derangements peculiar to the disease may aggravate the ventricle's anatomic vulnerability to ischemia. The increased LVEDP for any LVEDV (ie, poor compliance) inevitably narrows the diastolic CPP gradient. This may precipitate subendocardial ischemia in some patients with HCM, particularly those faced with the increased oxygen demand of overcoming late-systolic obstruction.[219] There is evidence that hypertrophy-induced myocardial ischemia may underlie the diastolic dysfunction characteristic of HCM.[230] As in patients with valvular AS, ischemia-induced abnormalities of diastolic calcium sequestration may further exacerbate relaxation abnormalities, initiating a vicious cycle (Fig. 21.24).[107,122,137,160,161,231]

β-Blockers and calcium channel blockers form the basis of medical therapy for HCM. β-Blockade is most useful for preventing sympathetically mediated increases in the subaortic gradient and for the prevention of tachyarrhythmias, which can exacerbate outflow obstruction. Disopyramide also has been used to reduce contractility and for its antiarrhythmic properties.[232] Calcium channel blockers often prove clinically effective in patients with HCM, regardless of the presence or absence of systolic obstruction.[233] The mechanism of action involves improvement in diastolic relaxation, allowing an increase in LVEDV at a lower LVEDP. The negative inotropy may attenuate the subaortic pressure gradient, but in selected patients, the gradient may worsen because of pronounced and unpredictable degrees of vasodilation.[234,235]

Surgery (ie, septal myotomy or partial myomectomy by the aortic approach) is reserved for patients who remain symptomatic despite maximal pharmacologic therapy. In a long-term retrospective study, the cumulative survival rate was significantly better in surgically than in pharmacologically treated patients.[236] However, it is likely that pharmacologic therapy may be more appropriate for the patient with a dynamic component to their degree of subaortic obstruction.[237] Further improvement in the clinical outcome of surgically treated patients may be achieved with the addition of verapamil, presumably reflecting a two-pronged attack on the systolic (ie, myomectomy) and diastolic (ie, verapamil) components of the disease.

Enthusiasm continues for the therapeutic use of dual-chamber pacing in this disease, with some patients demonstrating reductions in their subaortic gradients.[171–174,238,239] It is not an option for patients with AF.

Myomectomy usually results in significant symptomatic improvement and a reduction in the subaortic gradient.[240] Intraoperative guidance and evaluation of the surgical result by an experienced

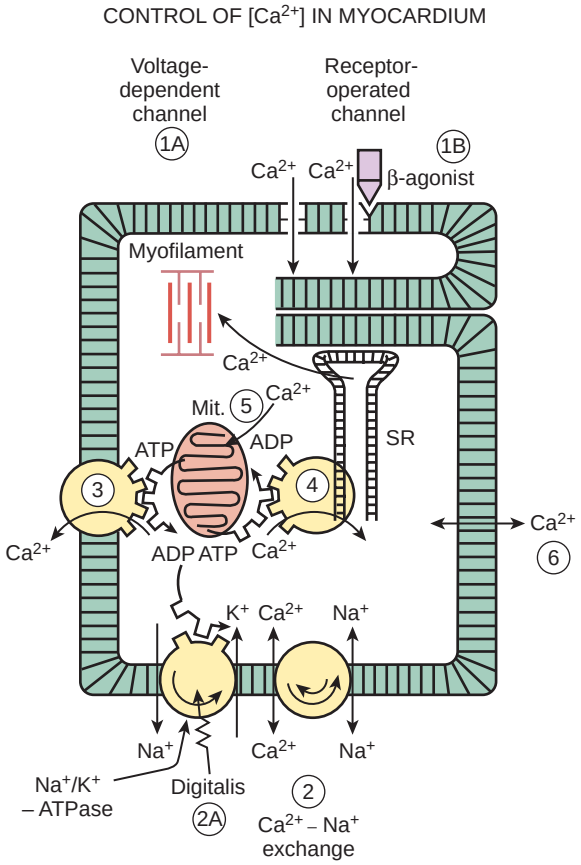

Fig. 21.24 Regulation of cytoplasmic calcium. The diastolic extrusion of calcium *(Ca^{2+})* from the myofilaments occurs at several sites. At two of the most important sites, energy *(ATP)* is required for the active reuptake of calcium by the sarcolemma *(3)* and the SR *(4)*. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *SR*, sarcoplasmic reticulum. *(From Braunwald E. Mechanisms of action of calcium channel blocking agents.* N Engl J Med. *1982;307:1618.)*

echocardiographer are essential for the success of this procedure.[241–243] In successful cases, the postmyomectomy study shows dramatic septal thinning, widening of the LVOT, and resolution of SAM and the LVOT color mosaic.

As in any disease with diverse diagnostic criteria, it is difficult to compare mortality rates among various series, but perioperative mortality rates for isolated septal myomectomy are less than 2%, although operative risks are greater when combined with other procedures.[244,245] However, clinical studies of predominantly elderly patients reported mortality rates in excess of 15%. Complications other than heart block are uncommon, although more than one-third of patients experience new, clinically insignificant AR.[246] It is unclear whether the new AR poses a long-term risk for these patients from the standpoint of CHF, but it probably warrants the continued use of endocarditis prophylaxis.

Anesthesia Considerations

Priorities in anesthesia management are to avoid aggravating the subaortic obstruction while remaining aware of the derangements in diastolic function that may be somewhat less amenable to direct pharmacologic manipulation (Box 21.3). It is necessary to maintain an appropriate intravascular volume while avoiding direct or reflex increases in contractility or heart rate. The latter goals can be achieved with a deep level of general anesthesia and the associated direct myocardial depression.

Regardless of the specific technique, preservation of an adequate CPP using vasoconstrictors rather than inotropes is necessary to avoid

BOX 21.3 HYPERTROPHIC CARDIOMYOPATHY

- Preload is increased.
- Afterload is increased.
- Goal is myocardial depression.
- Avoid tachycardia, inotropes, and vasodilators.

myocardial ischemia. Heavy premedication is advisable, with a view to avoiding anxiety-induced tachycardia or a reduction in ventricular filling. Chronic β-blockade or calcium channel blockade, or both, should be continued up to and including the day of surgery. These medications should be restarted immediately after surgery, particularly in patients undergoing noncardiac surgery.

Intraoperative monitoring should include an ECG system with the capability of monitoring a V_5 lead and each of the six limb leads. Inspection of lead II may be helpful in the accurate diagnosis of supraventricular and junctional tachyarrhythmias, which may precipitate catastrophic hemodynamic deterioration because of the potential for inadequate ventricular filling resulting from the reduction in diastolic time or loss of the atrial contribution to ventricular filling. The latter may be crucial in patients with significantly reduced diastolic compliance.[132]

Abnormal Q waves have been described on the electrocardiograms of 20% to 50% of patients with HCM.[179] These waves should not raise concern about a previous myocardial infarction; instead, they probably represent accentuation of normal septal depolarization or delay in depolarization of electrophysiologically abnormal cells.[247] Some patients exhibit a short PR interval with initial slurring of the QRS complex, and they may be at increased risk for supraventricular tachyarrhythmias due to preexcitation.[248] Although the specific predisposing factors are unknown, patients with HCM are at increased risk for any type of arrhythmia in the operative setting.[249]

Because of the pronounced abnormalities in left ventricular diastolic compliance, the CVP is likely to be an inaccurate guide to changes in left ventricular volume. However, a CVP catheter is extremely useful for the prompt administration of vasoactive drugs if they become necessary. As in valvular AS, the information provided by insertion of a PAC is worth the small arrhythmogenic risk. The potential for hypovolemia-induced exacerbation of outflow tract obstruction makes it crucial that the clinician have an accurate gauge of intravascular filling. Reduced diastolic compliance means that the PCWP overestimates the patient's true volume status, and a reasonable clinical objective is to maintain the PCWP in the high-normal to elevated range. A PAC with pacing capability is ideal because atrial overdrive pacing can effect immediate hemodynamic improvement in the event of episodes of junctional rhythm (see Chapter 13). The absolute requirement of these patients for an adequate preload cannot be overemphasized because even abrupt positioning changes have resulted in acute hemodynamic deterioration, including acute pulmonary edema.[250]

Intraoperative arrhythmias require aggressive therapy. During cardiac surgery, insertion of venous cannulas may precipitate atrial arrhythmias. Because the resultant hypotension may be severe, the surgeon should cannulate the aorta before atrial manipulation. Supraventricular or junctional tachyarrhythmias may require immediate cardioversion if they precipitate catastrophic degrees of hypotension. Although verapamil is one drug of choice for paroxysmal atrial and junctional tachycardia, it can disastrously worsen the LVOT obstruction if it elicits excessive vasodilation or it is used in the setting of severe hypotension.[235] Cardioversion is preferable when the mean arterial pressure is already very low. The concurrent administration of phenylephrine also is advisable. This drug is typically a low-risk, high-yield choice for the hypotensive patient with HCM. It augments perfusion, may ameliorate the pressure gradient, and often elicits a potentially beneficial vagal reflex when used to treat tachyarrhythmia-induced hypotension.

The inhalation anesthetics commonly are used for patients with HCM. Their dose-dependent myocardial depression is ideal because negative inotropy reduces the degree of SAM-septal contact, which reduces LVOT obstruction. Hypotension is usually the result of underlying hypovolemia, which is potentially exacerbated by anesthetic-induced vasodilation. Inotropes, β-adrenergic agonists, and calcium are contraindicated because they worsen the systolic obstruction and perpetuate the hypotension. In most cases, a beneficial response can be obtained with aggressive replenishment of intravascular volume and concurrent infusion of phenylephrine.

Several investigators have suggested that regional anesthesia, with its potential for accentuating peripheral vasodilation, may be relatively contraindicated in the management of patients with HCM.[251,252] The theoretic constraints are similar to those for patients with valvular AS, and the same clinical caveats apply. If the vascular system is kept appropriately full and "tight" with vasopressors, it is reasonable to consider these techniques in the light of other clinical advantages they can offer the patient. Catheter techniques (eg, continuous spinals, epidurals) may be preferable to the bolus administration of local anesthetics to achieve a finer degree of control of the anesthesia level.[253] There unquestionably is the potential for a cascade of iatrogenic complications if sympatholytic hypotension is treated in a knee-jerk fashion with ephedrine, epinephrine, or a variety of other equally contraindicated β-adrenergic agonists.

Although echocardiography has undoubtedly contributed to an increased frequency of diagnosis of this disease, an occasional patient escapes detection by ultrasound examination in the course of the preoperative workup. When other objective data, including the physical examination, ECG results, and chest radiograph, show only nonspecific abnormalities, it is easy to disregard vague or atypical complaints of chest pain, presyncope, and dyspnea. This is particularly true when the symptoms may reasonably be attributed to the primary condition that brought the patient to surgery (eg, CABG).[254] Other identifiable populations are said to be at high risk for occult HCM. HCM of the elderly has been discussed, and probably only a fraction of these patients arrive in the operating room with a formal diagnosis. However, it is not uncommon for the anesthesiologist to encounter an elderly patient with long-standing systemic hypertension and unexplained episodes of pulmonary congestion for whom the primary physician has prescribed a digitalis preparation.

Anesthesiologists occasionally may be presented with the opportunity to diagnose unsuspected HCM or one of its variants. Intraoperative events that can provoke or accentuate physiologic manifestations of the disease include hypovolemia, tachycardia, spontaneous or manipulative ectopy, and paradoxical responses to vasoactive drugs (eg, inotropes, vasodilators, vasoconstrictors) or anesthetic agents.[254,255] Clues such as these allow the experienced and astute clinician to recognize the phenomenon of dynamic subaortic obstruction when it occurs in less obvious clinical settings.

Aortic Regurgitation

Clinical Features and Natural History

AR may result from an abnormality of the valve itself, bicuspid anatomy, a rheumatic or infectious origin, or in association with any condition producing dilation of the aortic root and leaflet separation. Nonrheumatic valvular diseases commonly resulting in AR include infective endocarditis, trauma, and connective tissue disorders such as Marfan syndrome or cystic medial necrosis of the aortic valve.[56] Aortic dissection from trauma, hypertension, or chronic degenerative processes also can result in dilation of the root and functional incompetence (see Chapter 23).

The natural history of chronic AR is that of a long asymptomatic interval during which the valvular incompetence and secondary ventricular enlargement become progressively more severe.[3,141] When symptoms do appear, they are usually those of CHF, and chest pain, if it occurs, is often nonexertional in origin. The life expectancy for patients with significant disease has historically been about 9 years, and in contrast with AS, the onset of symptoms because of AR does not portend an immediately ominous prognosis.[256,257] In the absence of surgery, early recognition of AR and chronic use of vasodilators prolong the life span for this patient population.[141,258]

A relatively unique and problematic feature of chronic AR is that the severity of symptoms and their duration may correlate poorly with the degree of hemodynamic and contractile impairment.[141,259] The issue in surgical decision making is that many patients can remain asymptomatic, during which time they are undergoing progressive deterioration in myocardial contractility. Noninvasive diagnostic studies (ie, radionuclide cine angiography and two-dimensional and Doppler echocardiographic assessment of response to pharmacologic afterload stress) may facilitate the detection of early derangements in contractile function in relatively asymptomatic patients.[260–262] These findings are important to the cardiologist when considering surgical referral (see Chapters 1 through 3) because patients with depressed preoperative LV function have greater perioperative mortality rates and are at increased risk for persistent postoperative heart failure (HF).[96,263,264]

As in acute MR, the physiology of acute AR is quite different from chronic AR. Common causes include endocarditis, trauma, and acute aortic dissection. Because of a lack of chronic compensation, these patients usually have pulmonary edema and heart failure refractory to optimal medical therapy. Patients are often hypotensive and clinically appear to be on the verge of cardiovascular collapse.

Pathophysiology

Left ventricular volume overload is the pathognomonic feature of chronic AR. The degree of volume overload is determined by the magnitude of the regurgitant flow, which is related to the size of the regurgitant orifice, the aorta-ventricular pressure gradient, and the diastolic time. It has been suggested that the size of the regurgitant aortic orifice is constant and independent of changes in loading conditions.[265] However, in other valvular lesions (eg, AS, MR), the orifice size is not constant and depends on the hemodynamic state. An experimental model of acute AR showed that the regurgitant orifice area could change with increases or decreases in the transvalvular pressure gradient.[266] When AR occurs in the absence of valvular fibrosis or calcification (ie, valve elasticity is preserved), reduction of regurgitant area may be a beneficial effect of afterload reduction.

The hemodynamic effects of changes in heart rate are less straightforward than may be assumed.[267] Theoretically, tachycardia should maximize net forward flow by shortening the regurgitant diastolic time interval. This hypothesis, first offered by Corrigan in 1832, may be the pathophysiologic basis for the seemingly paradoxical observation that patients with AR may tolerate exercise despite having symptoms of pulmonary congestion at rest. Sympathetically mediated vasodilation, increased inotropy, and tachycardia may contribute to the increased CO achieved during isometric exercise in patients with AR.[268] Chronically, similar reflex-induced hemodynamic changes may contribute to the beneficial effects of arteriolar dilators.[269] The peripheral vasculature directly affects regurgitant volume through reflex changes in heart rate, and it can alter volume loading by effects on the diastolic time. It plays a key role in the overall pathophysiology of AR[270,271] (Fig. 21.25).

Despite these observations, the beneficial effects of shortened diastolic time alone may be less clear-cut. Angiographic study of subjects with chronic AR has shown that pacing-induced tachycardia can decrease the SV, LVEDV, and LVEDP and can increase cardiac output,[272] but the ratio of the regurgitant volume to the total SV may remain unchanged. This occurs because tachycardia shortens the diastolic period per stroke but increases the number of strokes per minute, leaving the net diastolic time per minute relatively unchanged. A similar observation has been made in radionuclide studies that demonstrated that tachycardia can increase CO and decrease LVEDV; however, pulmonary arterial pressure (PAP) and PCWP may not change with increasing heart rate.[273] The divergence between the effects of tachycardia on left ventricular volume (ie, decreased) and filling

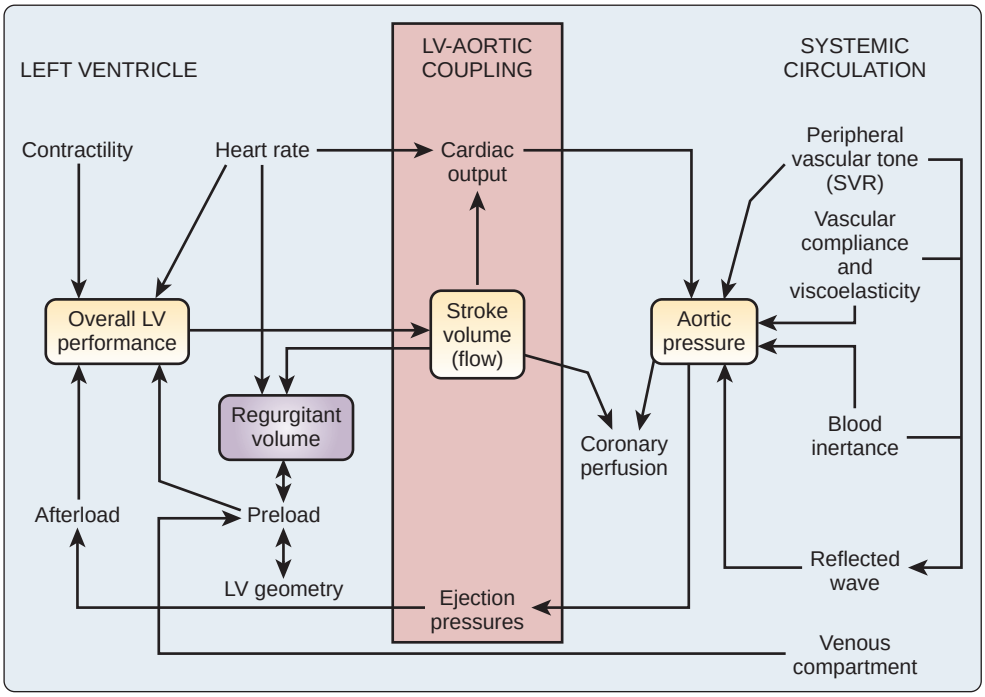

Fig. 21.25 The peripheral circulation plays a pivotal role in supporting left ventricular *(LV)* performance in the face of chronic volume overloading. *SVR*, Systemic vascular resistance. *(From Borow KM, Marcus RH. Aortic regurgitation: the need for an integrated physiologic approach.* J Am Coll Cardiol. *1991;17:898.)*

pressures (ie, unchanged) may reflect the pronounced rightward shift of the left ventricular pressure-volume loop that is characteristic of long-standing AR.

Chronically, AR results in a state of left ventricular volume and pressure overload. Progressive volume overloading from AR increases end-diastolic wall tension (ie, ventricular afterload) and stimulates the serial replication of sarcomeres, producing a pattern of eccentric ventricular hypertrophy.[97,264] In accordance with Laplace's law, dilation of the ventricle increases the systolic wall tension, stimulating some concentric hypertrophy. The result is normalization of the ratio of ventricular wall thickness to cavitary radius.[97] This process of eccentric hypertrophy results in the greatest absolute degrees of cardiomegaly seen in valve disease. EDV may be three to four times normal, and very high COs can be sustained.[274]

Fig. 21.26 shows the pressure-volume loops for acute and chronic AR. In the chronic form, the diastolic pressure-volume curve is shifted far to the right. This permits a tremendous increase in LVEDV with minimal change in filling pressure, a property frequently described as high diastolic compliance.[274] However, animal models of chronic left ventricular volume overloading instead suggest that the entire diastolic pressure-volume curve is shifted to the right (see Fig. 21.8).[11] This accounts for the apparent paradox of high ventricular volumes at relatively low filling pressures.

The parallel shifts of the entire curve relating diastolic pressure and volume are a manifestation of the physiologic process known as *creep*.[4] It refers to the time-dependent increase in dimension that occurs as a result of an applied stress, which in this case is volume overload. Because of the chronic adaptation, left ventricular filling pressures are in the low to normal range and are relatively insensitive to changes in intravascular volume. This is not true of greater filling pressures, for which increases are a reliable guide to volume overload and ventricular distention.

Because the increase in preload is compensated for by ventricular hypertrophy, CO is maintained by the Frank-Starling mechanism, and cardiac failure is not seen despite probable decreases in contractility.[258] There is virtually no isovolumic diastolic phase because the ventricle is filling throughout diastole. The isovolumic phase of systole also is brief

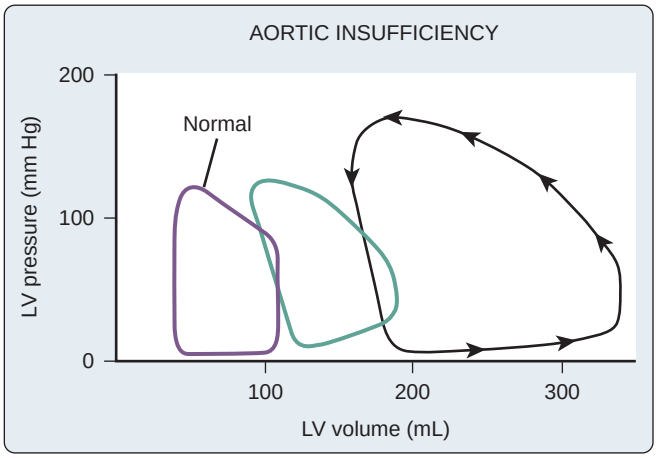

Fig. 21.26 Pressure-volume loop in aortic regurgitation (AR). Acute AR *(green loop)*; chronic AR *(black loop)*. *LV*, Left ventricular. *(Modified from Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease.* Semin Anesth. *1982;1:239.)*

because of the low aortic diastolic pressure. Minimal impedance to the forward ejection of a large SV allows performance of maximal myocardial work at a minimum of oxygen consumption. Eventually, however, progressive volume overload increases ventricular EDV to the point that compensatory hypertrophy is no longer sufficient to compensate, and a decline in systolic function occurs. As systolic function declines, the end-systolic dimension increases further, left ventricular wall stress increases, and left ventricular function is further compromised by the excessive ventricular afterload. At this point, the decline of ventricular function is progressive and can be quite rapid. As is shown in Fig. 21.27A, in the patient with compensated AR, the eccentrically dilated ventricle maintains its SV and EF by using preload reserve; wall stress is only slightly increased. In Fig. 21.27B, the limit of preload reserve has been reached and ventricular dysfunction has shifted the end-systolic wall stress relationship to the right. As a result of the higher

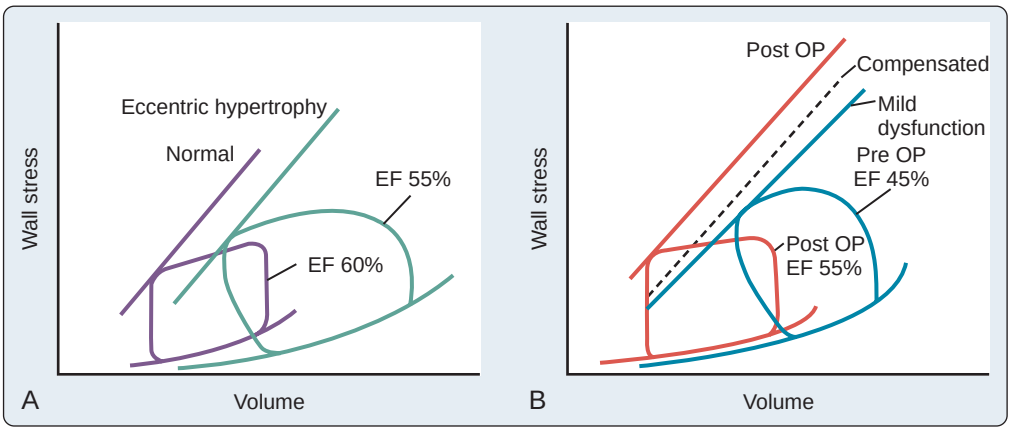

Fig. 21.27 Adaptation to volume overload. (A) Stress-volume curves and the linear end-systolic stress-volume relationship are shifted to the right in compensated aortic regurgitation compared with normal values. The stroke volume and ejection fraction *(EF)* are maintained despite slightly increased systolic wall stress. B, The same associations in a hypothetical patient with mild left ventricular dysfunction as evidenced by rightward shift of the end-systolic wall stress–volume relationship. Exhaustion of preload reserve causes wall stress to increase, resulting in reciprocal declines in the stroke volume and the EF. Valve replacement corrects afterload mismatch, allowing the end-diastolic and end-systolic volume relationships to shift to the left. Lower wall stress allows the EF to return to normal. *Post OP*, Postoperative; *Pre OP*, preoperative. *(From Ross J Jr. Afterload mismatch in aortic and mitral valve disease: implications for surgical therapy.* J Am Coll Cardiol. *1985;5:811.)*

wall stress, the SV and EF inevitably decline. In patients in whom the EF has become less than 25% or the end-systolic diameter larger than 60 mm, irreversible myocardial changes are likely to have occurred.[141]

The primary determinants of $M\dot{V}O_2$ (ie, contractility and wall tension) usually are not significantly increased with chronic AR, although calculated myocardial work may be twice normal. The $M\dot{V}O_2$ may be only minimally increased because the greater proportion of myocardial work is spent in the energy-efficient process of fiber shortening, with little increase occurring in oxygen-consuming tension development.[275]

Despite the relatively normal $M\dot{V}O_2$, angina can occur in one third of patients with severe AR, even in the absence of CAD.[276] Patients with chronic AR may be at risk for myocardial ischemia caused by hypertrophy-induced abnormalities of the coronary circulation. The increase in total myocardial mass can increase baseline $M\dot{V}O_2$, and there is evidence that total coronary blood flow, although increased, fails to keep pace with the increase in myocardial mass. Evidence suggests that the insidious development of contractile dysfunction may in part have an ischemic basis.[277]

Despite these rather favorable considerations in terms of myocardial energetics, an increase in $M\dot{V}O_2$ may pose a threat to the patient with chronic AR because of decreased coronary vascular reserve.[278] Although this phenomenon has been more thoroughly documented in patients with chronic pressure-induced hypertrophy, some studies indicate that the coronary vascular reserve is similarly compromised in patients with left ventricular volume overload.[279,280] The process of hypertrophy may be a double-edged sword from the standpoint of myocardial oxygen balance. Hypertrophy minimizes oxygen consumption as measured by wall stress, but increases basal $M\dot{V}O_2$ and may elicit derangements in the quality or quantity of the coronary vasculature.

Intraoperatively, patients with chronic AR may be at risk for acute ischemia with episodes of significant bradycardia. As bradycardia prolongs diastolic time, it increases regurgitant flow, and left ventricular diastolic pressure and wall tension increase rapidly. Simultaneously, the CPP is decreased as aortic runoff occurs during diastole and diastolic ventricular pressure is increased.[281] Under these conditions, myocardial perfusion pressure may be insufficient. Clinically, very rapid decompensation can occur. The ischemic ventricle can dilate rapidly such that progressively increased end-systolic dimensions are seen, and ischemia and ventricular failure become a positive feedback loop.

Surgical Decision Making

An accurate assessment of contractility is crucial to surgical decision making, because the clinical history of chronic AR may be an unreliable index of ventricular function. Asymptomatic patients may have ventricular dysfunction, whereas symptomatic patients may be free of myocardial depression. A variety of prognostic indicators have been used to identify early ventricular dysfunction as a trigger for surgical intervention. Clinical status, such as exercise capacity and New York Heart Association (NYHA) class, and noninvasive and invasive laboratory tests have been used. Hemodynamic parameters such as the end-systolic stress-volume relationship and estimates of the left ventricular contractile state have been evaluated as predictors of worsening left ventricular function.

Although ejection phase indices (eg, EF) are most familiar to anesthesiologists, they are inherently unreliable for quantifying ventricular function in the setting of chronic volume overloading, because the Starling mechanism continues to support increases in the SV long after the onset of intrinsic myocardial depression. Left ventricular dilation, compensatory hypertrophy, and minimal afterload may normalize the EF, even though contractility is significantly depressed.[258] Preload can be exquisitely sensitive to changes in heart rate and systemic vascular tone. Ventricular performance therefore may not be adequately reflected by the EF.[282,283] The often-reported regurgitant volume and regurgitant fraction are similarly rate and load dependent, and they may correlate poorly with the underlying inotropic state.[284]

A variety of end-systolic indices have been examined in chronic AR, and they provide a more load-independent assessment of the inotropic state. Although the left ventricular end-systolic volume (LVESV) is preload independent, it does vary with myocardial contractility and afterload. An increased ESV may reflect a depressed inotropic state, or it may increase because of an increased left ventricular afterload resulting from increased chamber size or pressure.[282] There also is evidence that the relative load independence of the LVESV is limited when ventricular hypertrophy is primarily eccentric.[25] However, with long-standing volume overload, virtually all studies have found that an increased end-systolic dimension correlates with a poor prognosis and a significantly depressed contractile state.[261,285]

When valve surgery is performed after ventricular decompensation has occurred, the immediate and long-term results are marginal. Much of the increased mortality rate is a function of postoperative deaths

from heart failure.[264,286] When valve surgery occurs before significant ventricular decompensation, ventricular recovery is remarkable, with remodeling and a reduction in left ventricular size beginning as early as 2 weeks after surgery.[141,264] Because delays in surgical intervention can be catastrophic and the response to surgery is so good, there is evidence of a shift toward earlier valve replacement, and surgery in relatively asymptomatic patients has been advocated.[264]

Based on a review of the published literature, the ACC and AHA have provided practice guidelines for surgical intervention in chronic AR.[141] Valve surgery is recommended for asymptomatic patients with left ventricular systolic dysfunction. Surgery also should be considered if ventricular dilation has occurred in the asymptomatic patient, even if the EF is normal. In patients who are symptomatic but have normal ventricular function, the ACC and AHA recommend further evaluation for an unrelated cause and observation. In these cases, serial echocardiographic assessment is appropriate. Symptomatic patients with left ventricular dysfunction should undergo surgery.[13]

Acute Aortic Regurgitation

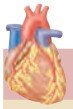
In acute AR, sudden diastolic volume overload of a nonadapted LV results in a precipitous increase in the EDP because the ventricle is operating on the steepest portion of the diastolic pressure-volume curve (see Fig. 21.26).[287] In severe acute AR, the LVEDP can equilibrate with aortic diastolic pressure and exceed the left atrial pressure in late diastole. This may be sufficient to cause closure of the mitral valve before atrial systole.[288] This is an important echocardiographic finding indicative of severe AR.[289] Although this phenomenon initially shields the pulmonary capillaries from the full force of the dramatically increased LVEDP, the protection may be short lived.[290] Severe left ventricular distention often follows and produces mitral annular enlargement and functional MR.

The inevitable decline in SV in acute decompensating AR elicits a reflex sympathetic response, making tachycardia and a high SVR common. Moderate tachycardia beneficially shortens the regurgitant time without reducing the transmitral filling volume.[291] Vasoconstriction, however, preserves CPP at the expense of increasing the aortic-ventricular gradient and regurgitation.

Patients with acute AR may be at greater risk for myocardial ischemia. As with chronic AR and bradycardia, coronary perfusion may be compromised by the combination of a low diastolic arterial pressure and the precipitously increased LVEDP. Narrowing of CPP may be so severe that the phasic epicardial blood flow may change to a predominantly systolic pattern with severe acute AR.[292] Dissection of the coronary ostia is rare but frequently causes the death of patients with acute AR. In addition to the structural impediment to myocardial oxygen delivery, catastrophic hypotension and high LVEDP combine to cause accentuated ischemia and ventricular dilation. Immediate surgical correction is the only hope for salvaging these patients, who often prove refractory to inotropes and vasodilators. Attempts at stabilizing the ischemic component of their injury with an intraaortic balloon are usually contraindicated because augmenting the diastolic pressure worsens regurgitation.

Acute AR most commonly results from infective endocarditis or aortic dissection, and intraoperative transesophageal echocardiography (TEE) has assumed increasing importance in the diagnosis of acute AR and in decisions regarding its surgical management.[293] Transesophageal echocardiographic studies are highly sensitive and specific for the diagnosis of infective endocarditis and are significantly more sensitive than transthoracic echocardiography.[294] TEE is particularly useful in the diagnosis of abscesses associated with endocarditis[295] and may detect previously unsuspected abnormalities.

Although an area of active investigation, there is currently no completely satisfactory noninvasive method for quantifying the severity of AR. Premature closure of the mitral valve, determination of the pressure half-time of AR, and color-flow estimation of the regurgitant jet's width and its size in relation to the LVOT are commonly described techniques.[296–298] (see Chapters 14, 15, and 23)



BOX 21.4 AORTIC REGURGITATION

- Preload is increased.
- Afterload is decreased.
- Goal is augmentation of forward flow.
- Avoid bradycardia.

Anesthesia Considerations

Intraoperative monitoring should include an ECG system for monitoring a lateral precordial lead because ischemia is a potential hazard (Box 21.4). For most valvular procedures, a PAC provides useful information. A PAC allows determination of basal filling pressures and CO, which is particularly useful in chronic AR given the potential unreliability of the clinical history and EF.

Equally important is the ability to accurately monitor ventricular preload and CO response to pharmacologic interventions. The aggressive use of vasodilators often is appropriate therapy perioperatively for the failing ventricle, but their use can compromise the preload to which the ventricle has chronically adjusted. Concurrent preload augmentation, guided by the diastolic PAP or PCWP, may be crucial to optimize CO when afterload is pharmacologically manipulated[299–301] (see Chapters 11, 13, 36, and 38).

The other requirement for a PAC is to allow for pacing when it is anticipated. The deleterious effects of significant bradycardia in AR have been described. In patients who arrive in the operating room with heart rates less than 70 beats per minute or patients for whom rapid epicardial pacing may be difficult to establish (eg, reoperations), placement of a pacing wire probably is indicated. Typically, only a ventricular wire is appropriate. It is more reliable than atrial pacing, and in AR, the atrial contribution to ventricular diastolic volume usually is not essential. Capturing the ventricle with a PAC-based, transvenous wire can be difficult because of the very large ventricular cavity size in patients with chronic AR.

Because patients with AR may have widely different degrees of myocardial dysfunction, anesthesia management must be appropriately individualized. For cardiac or noncardiac surgery, the hemodynamic goals are a mild tachycardia, positive inotropic state, and controlled reduction in SVR. For cardiac surgery, dopamine or dobutamine, pancuronium, ketamine, and nitroprusside infusions are excellent choices. For the patient with acute AR, the goals are the same, but urgency must be stressed. It is essential to rapidly reduce end-diastolic and end-systolic ventricular volumes with the very aggressive use of inotropes (eg, epinephrine) and vasodilators. There is sometimes concern that inotropes may exacerbate the root dissection in acute AR by increasing the shear force on the aortic wall. Despite this theoretic concern, positive inotropes should not be withheld from the patient who deteriorates in the operating room because they may provide the precious additional minutes of hemodynamic stability needed to get on CPB.

In acute and chronic forms of AR, serial measurements of CO can indicate that ventricular size and CO have been optimized, regardless of the systemic pressure. TEE is useful to look at ventricular size, but probably maximizing CO under these conditions gets closer to the therapeutic goal than looking at ventricular size alone. With acute AR and premature closure of the mitral valve, PAPs may grossly underestimate the LVEDP, which continues to increase under the influence of the diastolic regurgitant jet from the aorta. For noncardiac surgery in the patient with AR, there are advantages to epidural or other regional techniques when appropriate. Epidural anesthesia usually is preferable to spinal techniques, in which more precipitous declines in SVR can occur.

Predicting the response of the patient with AR to anesthesia can be difficult if the contractile state of the ventricle is unknown. Although reductions in functional status or EF are broad indicators of poorer outcomes, examining the medical history for *serial* measurements of

EF or ventricular ESVs may be most useful. Because patients with chronic AR are subject to a rapid, self-perpetuating decline in ventricular performance, demonstration of recent decreases in EF or increases in ventricular size may be the best indication of a challenging intraoperative course.

A few other practical points in AR surgery bear comment. The early and late phases of CPB can be a problem, particularly in reoperations. Before cross-clamp placement, the ventricle is at risk for distention if it is not ejecting or being vented. If the ventricle dilates with AR during CPB, the intraventricular pressures may equilibrate with the aortic root pressures. Under these conditions, there is no coronary perfusion, and the ventricle may dilate rapidly and become profoundly ischemic. This can occur before cross-clamp placement with bradycardia, ventricular fibrillation, or tachycardia or with a rapid supraventricular rhythm that compromises organized mechanical activity. Correcting the rhythm, pacing, cross-clamping the aorta, or venting the ventricle addresses the problem.

The problem also can occur in cardiac surgery for conditions other than AR. In patients with unknown or uncorrected AR, removal of the cross-clamp causes the same ventricular dilation and ischemia if the rhythm and ejection are not rapidly established. Ventricular venting or pacing may be essential until an organized, mechanically efficient rhythm is established. This problem must be considered in patients referred for CABG alone, in those with mild or moderate AR not having AVR, and in patients for whom intraoperative TEE is not used.

Mitral Regurgitation

Clinical Features and Natural History

Unlike mitral stenosis (MS), which is usually the result of rheumatic valve disease, MR may result from a variety of disease processes that affect the valve leaflets, chordae tendineae, papillary muscles, valve annulus, or LV. MR can be classified as organic or functional. Organic MR describes diseases that result in distortion, disruption, or destruction of the mitral leaflets or chordal structures. In Western countries, degenerative processes that lead to leaflet prolapse with or without chordal rupture are the most common cause of MR.[300] Other causes of organic MR include infective endocarditis, mitral annular calcification, rheumatic valve disease, and connective tissue disorders such as Marfan or Ehlers-Danlos syndrome. Much less common causes of organic MR include congenital mitral valve clefts, diet-drug or ergotamine toxicity, and carcinoid valve disease with metabolically active pulmonary tumors or right-to-left intracardiac shunting.[302]

Mitral valve prolapse (MVP) is a common (2.4%) disorder with a strong hereditary component. Several genes play a pivotal role in heart valve formation, including those for the calcineurin catalytic and regulatory subunits, WNT/beta-catenin signaling pathways, fibroblast growth factor 4 *(FGF4)*, a homeobox gene *(SOX4)*, and the downstream modulator of transforming growth factor-β superfamily signaling *(SMAD6)*. Genotypic linkage was found to chromosomes 11, 13, and 16. The finding of a mutation in familial MVP not related to connective tissue syndromes, an X-linked filament A mutation, suggests that MVP may be the final common outcome of multiple genetic defects.

The term *functional MR* describes MR that occurs despite structurally normal leaflets and chordae tendineae. Resulting from altered function or geometry of the LV or mitral annulus, functional MR often occurs in the setting of ischemic heart disease, and the term *ischemic MR* is sometimes used interchangeably with *functional MR*. However, the functional form can occur in patients without demonstrable CAD, such as those with idiopathic dilated cardiomyopathy and mitral annular dilation. The term *ischemic MR* probably best applies to functional cases with a known ischemic cause. Rupture of a papillary muscle with acute, severe MR is somewhat more difficult to classify. Although usually a sequela of acute myocardial infarction (AMI) with normal leaflets and chordae, there is an obvious anatomic disruption of the mitral apparatus.

The natural history of MR varies because it can be caused by a wide variety of disease processes.[302] Even among patients with acute-onset disease, the clinical course depends on the mechanism of regurgitation and the response to treatment. For instance, patients with acute, severe MR caused by a ruptured papillary muscle have a dismal outcome without surgery.[302] However, the clinical course of acute MR caused by endocarditis can be favorable if the patient responds well to antibiotic therapy.[302] Although those with chronic MR usually enter an initial, often asymptomatic, compensated phase, the time course for progression to left ventricular dysfunction and symptomatic heart failure is unpredictable.[302] The literature reflects the wide variation in the natural history of MR, with 5-year survival rates for patients with MR of 27% to 97%.[303] Selection bias, small study populations, and poorly defined degrees of MR likely explain these discrepancies.[304]

Later studies better define the clinical course of certain subgroups of patients with MR. For instance, Ling and associates[305] examined the natural history of patients with MR because of flail leaflets. Among this group, the investigators observed an annual mortality rate of 6.3%, with a combined rate of death or surgery of 90% within a 10-year period.[305] Patients with flail mitral valve leaflets also are at increased risk for sudden death.[306] Grigioni and colleagues[306] reported a 1.8% per year rate of sudden death among patients with flail mitral leaflets who were being treated medically. The rate of sudden death diminished after surgical intervention in this population.[306]

The application of quantitative Doppler echocardiography to the prospective study of MR has allowed researchers to document the progressive nature of the condition. Enriquez-Sarano and coworkers[307] found that on average, the regurgitant volume increased 7.5 mL and the effective regurgitant orifice increased 5.9 mm^2 each year. However, there was significant variation in the rate of progression among patients. Rapid progression of severity occurred among patients who developed flail leaflets, but MR regressed in 11% of those studied.[307]

Pathophysiology

MR causes left ventricular volume overload. The regurgitant volume combines with the normal left atrial volume and returns to the LV during each diastolic period. The increased preload leads to increased sarcomere stretch and, in the initial phases of the disease process, augmentation of LV ejection performance by the Frank-Starling mechanism. Systolic ejection into the relatively low-pressure left atrium (LA) further enhances the contractile appearance of the LV.

The clinical presentation of patients with MR depends on the pathophysiology of the specific condition, including the mechanism, severity, and acuity of the disease. In cases of acute, severe MR, such as in patients with a ruptured papillary muscle after AMI, the sudden increase in preload enhances left ventricular contractility by the Frank-Starling mechanism. Despite the increased preload, the size of the LV is initially normal. Normal left ventricular size combined with the ability to eject into a low-pressure circuit (ie, the LA) results in decreased afterload in the acute setting. The measured LVEF in cases of sudden, severe MR may approach 75%, although forward SV is reduced.[302] However, because the LA has not yet dilated in response to the large regurgitant volume, left atrial pressure increases acutely and may lead to pulmonary vascular congestion, pulmonary edema, and dyspnea.[302]

Many patients with MR, particularly those whose valvular incompetence develops more slowly, may enter a chronic, compensated phase. In this phase, chronic volume overload triggers left ventricular cavity enlargement by promoting eccentric hypertrophy (see Fig. 21.15). Increased preload continues to augment left ventricular systolic performance. At the same time, the LA dilates in response to the ongoing regurgitant volume. Although left atrial dilation maintains a low-pressure circuit that facilitates left ventricular systolic ejection, the increased radius of the left ventricular cavity leads to increased wall tension according to Laplace's law.

Unlike the case of sudden, acute MR, which is characterized by normal left ventricular size and reduced afterload, the afterload remains in the normal range in the chronic, compensated phase of

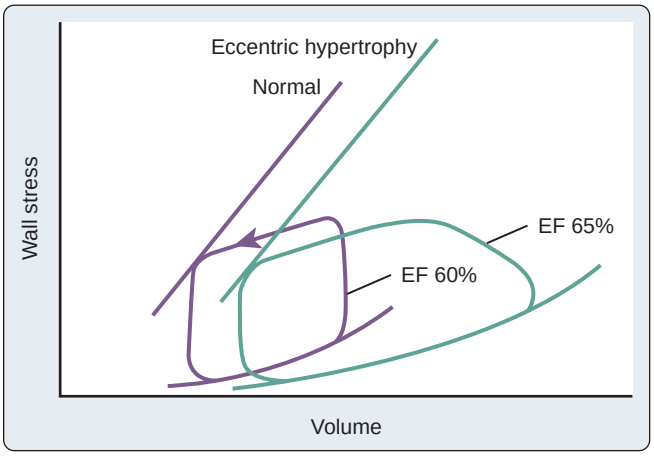


Fig. 21.28 Volume overload with mitral regurgitation (MR). As in volume overloading from aortic regurgitation, wall stress–volume loops of the eccentrically hypertrophied left ventricle are shifted to the right. However, in chronic MR, retrograde ejection into the low-pressure left atrium minimizes ventricular wall stress, supporting the ejection fraction *(EF). (From Ross J Jr. Afterload mismatch in aortic and mitral valve disease: implications for surgical therapy.* J Am Coll Cardiol. *1985;5:811.)*

MR.[308] The changes seen in chronic, compensated MR are represented graphically in Fig. 21.28. The isovolumic contraction phase is shortened as the blood is ejected into the low-pressure LA early in the cycle of ventricular systole. Because the dilated, compliant LV accepts increased diastolic volumes at low or normal filling pressures, some physicians think that left ventricular diastolic function is enhanced in patients with chronic MR.[308] Whereas dilation of the left heart chambers permits left ventricular filling at low or normal pressures, chamber enlargement progressively dilates the mitral annulus, potentially increasing the effective regurgitant orifice and regurgitant volume over time. Patients may tolerate the phase of chronic, compensated MR for many years because increased preload maintains left ventricular ejection performance. If symptoms develop during this time, they often are related to diminished forward CO because the regurgitant fraction may exceed 50%. Instead of dyspnea or signs of pulmonary congestion, fatigue and weakness predominate.

With the eventual decline in left ventricular systolic function, patients enter a decompensated phase. Progressive left ventricular dilation increases wall stress and afterload, causing further deterioration in left ventricular performance,[302] mitral annular dilation, and worsening of the MR. Left ventricular end-systolic pressure increases. The increased left ventricular filling pressures result in increased left atrial pressures and, given time, pulmonary vascular congestion, pulmonary hypertension, and right ventricular dysfunction. In addition to fatigue and weakness, patients with decompensated, chronic MR also may report dyspnea and orthopnea. It is difficult to predict when a patient with MR is likely to decompensate clinically. Progression of disease in any patient depends on the underlying cause of MR, its severity, the response of the LV to volume overload, and possibly the effect of medical management.[302,309]

Assessment of left ventricular function in patients with MR is controversial but critically important for clinical decision making.[303] As in AR, the altered loading conditions that characterize MR confound traditional, load-dependent measures of left ventricular systolic function such as EF. Although numerous methods of assessing left ventricular function have been proposed, no consensus exists.[303] Despite its limitations, EF remains the most studied variable of left ventricular function in patients with MR and the most predictive of clinical outcome. For instance, preoperative EF is the most important prognostic factor for long-term survival after surgery for MR.[310] Preoperative EF also predicts postoperative EF and the occurrence of CHF after the surgical correction of MR.[311,312]

Because of the combination of increased preload and the ability to eject into the low-pressure LA, a normally functioning LV should display an increased EF in the setting of significant MR. Conversely, an EF considered normal in a patient with competent valves may represent diminished left ventricular function in the setting of MR. In patients with severe MR, an EF in the range of 50% to 60% likely represents significant left ventricular dysfunction and is an indication for surgery.[141] Enriquez-Sarano and colleagues[310] reported that the postoperative survival rate after mitral repair or replacement declines after the preoperative EF decreases to less than 60%.

Several studies provide insight into the origin of left ventricular dysfunction in the setting of MR. In animal models of the disease, myocardial mass accumulates mainly by a decrease in the natural degradation of cellular elements, rather than by an increased rate of protein synthesis.[313–315] In contrast, myocardial protein synthesis increases within hours of the creation of simulated AS and left ventricular pressure overload.[316] Histologic preparations from animals with experimental MR and left ventricular dysfunction show a 35% reduction in contractile elements within individual myocytes.[317]

Examination of pressure-volume loops from patients with AS and MR is insightful (see Figs. 21.13 and 21.27). If the area contained within each loop is examined, it can be seen that this area, or stroke work, is similar for the two disease states. However, patients with AS usually display a greater degree of myocardial hypertrophy compared with patients with MR. Stroke work per gram of myocardium is greater in patients with MR, a finding that also may explain left ventricular dysfunction in this patient population.[308]

Ischemic Mitral Regurgitation

Ischemic MR represents MR occurring in the setting of ischemic heart disease in patients without significant abnormalities of the valve leaflets or chordal structures. Although some clinicians use the terms *ischemic MR* and *functional MR* interchangeably, ischemic MR more accurately describes cases of functional MR that occur in the setting of CAD. Papillary muscle rupture, which is almost always a sequela of AMI, also may be classified as ischemic MR, although a clear organic defect of the mitral apparatus exists.

Clinicians are increasingly recognizing the importance of ischemic MR because it is common. The incidence rate of MR after AMI as detected by echocardiography ranges from 39% to 73%.[309] Echocardiographic studies also demonstrate that in 13% to 29% of cases, the ischemic MR is at least moderate in severity.[309] Ischemic MR also portends a worse clinical outcome. For instance, patients with ischemic MR after AMI have a twofold to sixfold increase in cardiovascular mortality rates in the first year after the ischemic event.[318] Patients with severe ischemic MR have a 1-year mortality rate that approaches 50%.[319]

In evaluating patients with MR presumed to be of ischemic origin, clinicians should attempt to identify the severity of the regurgitation, the time of onset, and the likely mechanism of valvular incompetence because these factors influence prognosis and treatment. For instance, patients with mild ischemic MR in the early phase of an AMI rarely experience hemodynamic sequelae from mitral leakage, whereas those with ischemic rupture of a papillary muscle often have acute CHF and have a poor prognosis without surgical intervention.

Investigators have identified patient characteristics associated with an increased incidence of ischemic MR. Patients with advanced age, inferior or posterior AMI, spherical left ventricular geometry, and multivessel CAD tend to have greater rates of ischemic MR.[309,320] Other factors associated with increased rates of ischemic MR include left atrial enlargement, mitral annular dilatation, and decreased EF.[309] Frank rupture of a papillary muscle, which occurs in 1% of AMI cases, usually involves the posteromedial papillary muscle because its blood supply is derived from a single coronary artery.

Understanding of the pathophysiologic basis of ischemic MR continues to evolve. Early investigators proposed ischemic papillary muscle dysfunction as a primary cause of ischemic MR.[321–323] Later studies

indicated that isolated ischemia of one or both papillary muscles did not cause significant MR.[324–327] Instead, ischemia of the papillary muscle and the adjacent myocardium is necessary to produce ischemic MR.[309,324,326,327] Myocardial ischemia may result in focal or global left ventricular bulging and, with time, ventricular remodeling to a more spherical shape. Geometric changes cause outward migration of the papillary muscles. The finding most strongly correlated with chronic ischemic MR is outward papillary muscle displacement.[309,328] When the papillary muscles are displaced outward, the point of mitral leaflet coaptation moves apically and away from the mitral annulus, resulting in the appearance of valve tenting.

Besides outward bulging of the LV, scarring and retraction of the papillary muscles may produce mitral leaflet tethering, with the net effect of incomplete leaflet coaptation and valvular incompetence. Some investigators think that papillary muscle dysfunction may reduce the degree of ischemic MR in certain patients.[329,330] Komeda and associates[330] suggested that reduced contractility of the papillary muscles might counteract the tethering effect of ischemic myocardium, allowing leaflet coaptation to occur closer to the mitral annulus.

An additional potential mechanism of ischemic MR is decreased contractility of the posterior mitral annulus. During systole, annular contraction reduces the mitral orifice area by 25%.[331–333] Because the anterior portion of the mitral annulus is more fibrous, posterior annular contraction plays a greater role in reducing the size of the mitral orifice. Loss of posterior annular contraction may contribute to MR in the setting of myocardial ischemia.

The clinical approach to ischemic MR depends on its underlying mechanism. Timely surgical intervention often is warranted in cases of papillary muscle rupture. For patients with an intact mitral apparatus who have ischemic MR in the setting of AMI, early reperfusion therapy improves regional and global left ventricular function, reduces ventricular dilation, and decreases the likelihood of adverse remodeling and associated papillary muscle displacement.[329,334–337] The resultant improvements in ventricular function and geometry combine to reduce the incidence of ischemic MR.

Clinicians often prescribe angiotensin-converting enzyme inhibitors to patients with ischemic heart disease. Chronic angiotensin-converting enzyme inhibitor therapy may decrease the incidence and severity of ischemic MR by preventing left ventricular remodeling, although data to support this theory are lacking.[329]

Assessment of Mitral Regurgitation

Clinicians may suspect MR on the basis of current symptoms, medical history, or findings on physical examination. Echocardiography with the capability of two-dimensional and Doppler (including color-flow) imaging is the diagnostic modality of choice for assessment of MR. Transthoracic echocardiography (TTE) is readily available in most areas, is noninvasive, and provides detailed information about the mechanism of MR, its severity, and its impact on cardiac chamber size and function. Additional information available from TTE includes calculation of right ventricular systolic pressure based on the peak velocity of the tricuspid regurgitant signal and an estimate of right atrial pressure. Whenever possible, echocardiographers should attempt to provide a quantitative assessment of MR severity.

Techniques that allow the determination of effective regurgitant orifice, regurgitant volume, or regurgitant fraction include the proximal isovelocity surface area (PISA) method and the continuity equation. Echocardiographic findings such as pulmonary vein systolic flow reversals suggest severe MR, and they should be reported. Assessment of the size of the regurgitant jet in the LA may provide a gross estimation of MR severity, but is limited by factors such as left atrial size and pressure, machine settings such as color-flow gain and aliasing velocity, and the orientation of the regurgitant jet itself. Eccentric regurgitant jets propagating along the wall of the LA often appear smaller than a centrally directed jet of equal severity.

When TTE is suboptimal, patients may be referred for TEE. Because of the proximity of the transducer to the mitral valve, TEE often produces superior images of the mitral valve. When performing intraoperative TEE examinations, anesthesiologists should recall that altered loading conditions, such as anesthesia-induced decreases in SVR, may favor forward CO and diminish the observed amount of MR. The echocardiographic evaluation of the mitral valve is discussed in Chapters 1 and 14 through 16.

Cardiac catheterization with left ventriculography may also be used to evaluate MR. This invasive procedure often is reserved for cases in which the echocardiographic data are suboptimal, conflicting, or discordant with the clinical findings.[302] Assessment of severity by ventriculography requires analysis of the amount of contrast material that enters the LA after injection into the LV. However, the amount of contrast material appearing in the LA depends on the severity of MR, the left atrial volume, the catheter position, and the rate of contrast injection.[302] Right-heart catheterization may or may not demonstrate v waves in patients with significant MR. A high degree of left atrial compliance makes the appearance of prominent v waves less likely (see Chapter 3).

Other diagnostic tests commonly obtained for patients with MR include an electrocardiogram and chest radiograph. ECG findings such as AF, left atrial enlargement, and ST-segment abnormalities may be observed in patients with MR, but they are not specific.[301] Similarly, chest radiographs may identify enlargement of the left heart chambers and pulmonary vascular congestion, but the findings are not specific for MR.

Surgical Decision Making

The surgical approach to MR has evolved as its pathophysiology has been clarified. High operative mortality rates associated with the surgical correction of MR in the 1980s led many clinicians to treat patients conservatively.[303,304,338] Because favorable loading conditions and high left atrial compliance allow patients with significant MR to remain asymptomatic for long periods, it is likely that many patients did not undergo surgery until the onset of disabling symptoms. More severe preoperative symptoms are associated with a lower EF and a greater incidence of postoperative CHF.[304,311,312] Historically, poor outcomes after surgery for MR might have occurred because clinicians did not appreciate the true degree of left ventricular dysfunction at the time of surgery in symptomatic patients. An EF of less than 60% in the setting of severe MR represents significant left ventricular dysfunction and predicts a worse outcome with surgery or medical management.[305,310]

Surgical techniques common in the 1980s probably also contributed to unfavorable postoperative outcomes. For instance, although the mechanisms are incompletely understood, resection of the subvalvular apparatus contributes to decreased left ventricular systolic performance after mitral valve replacement.[339] In part because of improved surgical techniques, the operative mortality rate for patients with organic MR who are younger than 75 years is about 1% in some centers.[310] Besides preservation of the subvalvular apparatus, valve repair is another surgical technique associated with improved postoperative outcome.[304,340] Although not applicable to all patients, such as those with advanced rheumatic disease, the popularity of valve repairs continues to grow.

Studies indicate numerous benefits associated with mitral repair. For instance, after accounting for baseline characteristics, patients who undergo mitral repair instead of replacement have lower operative mortality rates and longer survival times, largely because of improved postoperative left ventricular function.[304,340] The survival benefit that accompanies valve repair also is observed among patients undergoing combined valve and CABG surgery.[340]

Valve repair does not increase the likelihood of reoperation compared with replacement.[340] Although originally used most often for posterior leaflet disease, surgeons now routinely repair anterior mitral leaflets with good success.[341] When repairing anterior leaflet prolapse, surgeons may insert artificial chordae.[342,343] The approach to flail or prolapsing posterior mitral leaflet segments often involves resection of a portion of the leaflet.[343] In addition to resecting a portion of the

leaflet and plicating the redundant tissue, an annuloplasty ring often is placed to reduce mitral orifice size and return the annulus to a more anatomic shape.[343] Some surgeons favor a flexible, partial, posterior annuloplasty band, which may allow improved systolic contraction of the posterior annulus and better postoperative left ventricular function.[332,343,344]

Timely and appropriate surgical referral helps improve the perioperative outcome of patients with MR. To appropriately refer patients for surgery, clinicians should have an understanding of the factors that influence surgical risk in this population.[303] Those that correlate best with increased operative risk in patients with significant MR include age older than 75 years, severe preoperative symptoms of CHF, and concomitant CAD.[310,345,346] Although they represent a high-risk group, patients with severe MR and symptoms of heart failure should be referred for surgery because valve repair or replacement offers a survival advantage compared with medical management.[303,305] Similarly, although perioperative risk remains increased, patients with evidence of left ventricular dysfunction, such as an EF less than 60% or an end-systolic left ventricular diameter greater than 45 mm, should be referred for surgery to prevent further, possibly irreversible deterioration in ventricular performance.[141,303] Asymptomatic patients without evidence of left ventricular dysfunction also should be considered for surgery if conditions such as AF, ventricular tachycardia, or pulmonary hypertension are identified or the effective regurgitant orifice is greater than 40 mm.[2,141,303] Institutional experience, particularly with techniques such as valve repair, is an important consideration for clinicians contemplating early surgical referral.[303]

Minimally Invasive Mitral Valve Surgery

Beginning in the mid-1990s, several groups adopted a minimally invasive approach to mitral valve repair.[347,348] Initially performed through lower ministernotomies or right parasternal incisions, aortic cannulation for CPB was accomplished through the chest. The venous cannula was placed in the femoral vein[347] or the right atrium.[348] Standard surgical repair techniques were used.

For a series of 707 minimally invasive mitral valve repairs, McClure and coworkers[347] reported an operative mortality rate of 0.4% and an incidence rate of stroke of 2%. Failed repair necessitating reoperation occurred in 4.8% of cases, with long-term follow-up demonstrating an 83% survival rate beyond 11 years. Compared with conventional sternotomy for mitral repair, these investigators also identified reductions in hospital length of stay, aortic cross-clamp time, and total CPB time in the minimally invasive cases.[347,349]

Additional benefits of minimally invasive approaches were reported by Svensson and associates.[348] From a cohort of patients who underwent minimally invasive mitral repair between 1995 and 2004, the study authors selected 590 cases that were matched using propensity scores with 590 patients who received mitral repair by conventional sternotomy. The study demonstrated improved pain scores and forced expiratory volume in 1 second (FEV_1) values, together with reductions in perioperative bleeding and transfusion requirements in the minimally invasive group. Procedural success was not reduced by the adoption of a minimally invasive approach, and there was a trend toward fewer patients with 3+ or 4+ residual MR at 1- and 5-year follow-up assessments for this cohort.

The trend toward even less invasive mitral repair continued in the late 1990s with the advent of thoracoscopic and robotically assisted procedures. In 1996, Carpentier[350] and colleagues performed the first video-assisted mitral valve repair by means of a minithoracotomy with fibrillatory arrest. The era of robotically assisted mitral repair began the following year, when Mohr and coworkers[351] used a voice-controlled robotic arm (ie, automated endoscopic system for optimal positioning [AESOP]) to provide thoracoscopic visualization of the mitral valve during a repair that was accomplished through a 4-cm right thoracotomy.

In 1998, Carpentier used a prototype robotic system (da Vinci, Intuitive Surgical, Mountain View, CA) to perform a mitral repair.[352]

Fig. 21.29 Close-up view of the chest incisions for a robotically assisted mitral valve repair. The surgeon has inserted his left index finger into the 4-cm primary incision located in the fourth intercostal space.

Although approved 2 years earlier for general laparoscopic surgery, the da Vinci system was given US Food and Drug Administration (FDA) approval for mitral valve surgery in the United States in 2002.[353] A review of The Society of Thoracic Surgeons Adult Cardiac Surgical Database (STS ACSD) from 2004 to 2008 showed use of minimally invasive mitral valve techniques (direct or robotic) increased from 12% to 35%[354] Within a 6-year period, more than 200 articles on robotically assisted cardiac surgery were published, including 60 from a single researcher.[355] Several centers have published series of more than 100 robotic cases.[356–358]

The concept of minimally invasive mitral surgery usually refers to valve repairs accomplished through a 3- or 4-cm right inframammary incision in the fourth or fifth intercostal space (Fig. 21.29). Several additional 1-cm incisions around the primary incision facilitate placement of robotic arms or other thoracoscopic instruments. The arterial cannula for CPB may be inserted directly or by a chimney graft into the femoral artery (Fig. 21.30) or into the ascending aorta through a thoracic incision under direct visualization.

Venous drainage is accomplished by the femoral route using TEE guidance with a multiple side hole peripheral access cannula (Fig. 21.31). Supplementary venous drainage is used in some centers by inserting either a 15- to 17-Fr right internal jugular vein cannula or specialized PAC with multiple end holes that drains to the venous reservoir during CPB.

Cardioplegia may be given antegrade into the aortic root or retrograde through the coronary sinus. Surgeons typically administer antegrade cardioplegia by one of two methods. The first involves the placement of a catheter tip into the ascending aorta through a right parasternal stab incision under thoracoscopic vision. This method is similar to standard antegrade cardioplegia administration in median sternotomy cases. A long-shafted aortic cross-clamp placed through a stab incision in the right lateral chest wall is used to occlude the aorta distal to the cardioplegia cannula. The second method of antegrade cardioplegia administration uses a specialized endoaortic cannula inserted into the femoral artery. A balloon near the distal end of this cannula is positioned in the ascending aorta using TEE guidance. Inflation of the balloon occludes the ascending aorta while antegrade cardioplegia delivery commences at the distal tip of the device.

Although the choice of antegrade cardioplegia system varies between surgeons and institutions, use of the endoaortic clamp and cardioplegia delivery system has been associated with increased morbidity, cost, cross-clamp times, and risk of aortic dissection.[359,360] Retrograde cardioplegia may be given by means of a coronary sinus catheter that has been percutaneously placed into the right internal jugular vein (see Chapters 13 and 15). When using a right minithoracotomy approach, the repair may be performed using long-handled thoracoscopic instruments (Fig. 21.32) or robotic assistance.

Although referred to as *robotic*, systems such as the da Vinci are probably more appropriately described as telemanipulators. These

devices receive direct input from the hands and feet of the surgeon who is seated at a remote console that translates these motions to end-effectors within the chest of the patient (Fig. 21.33). Proponents of robotically assisted mitral repair cite several advantages of this approach compared with minimally invasive thoracoscopic surgery.[353] When seated at the remote console of a robotic device, the surgeon has near-stereoscopic vision compared with viewing a two-dimensional image on a television screen. Robotic devices provide motion scaling and tremor filtration to smooth movements. Because the robotic arms have articulating "wrists" at their distal ends, the surgeon can achieve 7 degrees of freedom of movement within the chest, similar to open surgery. By comparison, long-handled thoracoscopic instruments, which are often oriented almost parallel to one another, afford only 4 degrees of freedom.

Both thoracoscopic and robotically assisted approaches use the same operative techniques as standard open repairs. Techniques such

as leaflet resection, chordal insertion or transfer, sliding plasties, edge-to-edge repair, and annuloplasty band insertion may be used by experienced surgeons. Adoption of robotic approaches can be hindered by longer procedure times, increased cost per case, and a significant time commitment for training all members of the surgical team.

The procedural success and operative mortality rates of robot-assisted mitral repair in larger series appear comparable with traditional surgical approaches. For their first 300 robotically assisted mitral repairs, Chitwood and associates[356] reported a 30-day mortality rate of 0.7% and a stroke rate of 0.7%. Mean CPB time was 159 minutes, with a mean aortic cross-clamp time of 122 minutes. Eighty-nine concomitant procedures such as the Maze procedure and closure of atrial level shunts were performed. At a mean follow-up of 815 days, 93% of patients had residual MR that ranged from none to mild. Technical failure, such as annuloplasty band dehiscence, led to reoperation in 3.3% of cases. Hospital length of stay averaged 5.2 days.

Cheng and collaborators[357] described the outcomes of their first 120 robot-assisted mitral repair cases. Similar to Chitwood and colleagues,[356] Cheng's group[357] reported a 30-day mortality rate of less than 1%. Mean CPB time was 157 minutes, with a mean aortic cross-clamp time of 117 minutes. Fifty-three concomitant procedures were performed in these patients. Failed repair necessitating reoperation was encountered in 5% of cases. Citing a procedural learning curve, the investigators found that all failed repairs occurred in the first 74 cases. Average hospital length of stay was 6.3 days.

Another niche for the use of minimally invasive mitral valve repair techniques is in patients who have previously undergone cardiac surgery by a median sternotomy. Repeat sternotomies have a list of life-threatening intraoperative adverse events, including injuries to bypass grafts, right-sided cardiac chambers, and great vessels. Roselli and associates[361] reviewed 1847 patients undergoing reoperative cardiac surgery and found a 7% occurrence of these events, which were associated with poor patient outcomes and increased costs.

The ability to complete mitral valve surgery and avoid the potential risks of a repeat sternotomy is desirable and has been reported by several investigators. Arciddi and colleagues[362] described 167 patients over 14 years who underwent mitral valve repair or replacement in the setting of a previous CABG or valvular procedure. The mortality rate at 30 days was 3% (ie, five patients total), with a 3% reoperation rate for bleeding. There was a trend toward lower mortality with each successive interval of experience, culminating at a 0% 30-day mortality rate during the interval between 2006 and 2010, which also had the highest (51%) surgical volume. The mean CPB and cross-clamp times were 167 and 113 minutes, respectively.

Murzi and collaborators[363] reported reoperations involving the mitral valve (ie, repair or replacement) in 173 patients with a previous sternotomy. Two patients required a conversion to sternotomy, and the overall 30-day mortality rate was 4.1%, with reoperation for bleeding occurring in 6.3% of patients. Mean CPB time was 160 minutes, with a mean cross-clamp time of 82 minutes. During the postoperative follow-up period, of the 53 patients who underwent repair, 7 had moderate MR by echocardiography, and the remainder had trivial or no MR.

Just as catheter-based techniques have been developed to treat valvular AS, efforts are underway to develop percutaneous interventions for MR (see Chapters 3 and 27). Several devices that use different approaches to correct the underlying mechanism are being investigated. A classification system proposed by Chiam and Ruiz[364] groups interventions based on anatomic targets and device action:

1. Leaflets: percutaneous plication, leaflet coaptation or leaflet ablation
2. Annulus: indirect annuloplasty through the coronary sinus or direct annuloplasty, including percutaneous and hybrid approaches
3. Chordae: percutaneous or transapical chordal insertion
4. LV: remodeling with application of external devices

The device with the largest clinical experience is the MitraClip system (Abbott Laboratories, Abbott Park, IL) (see Chapter 27). Leaflet plication is based on the open mitral repair technique reported by Alfieri and colleagues.[365] It entails the creation of a double-orifice mitral valve by suturing the free edges of the leaflets at the site of regurgitation together to improve leaflet coaptation and reduce MR. MitraClip uses a percutaneous femoral venous transseptal delivery system to deploy a cobalt-chromium clip to secure the mitral leaflets under fluoroscopic and echocardiographic guidance.

The system was evaluated in the Endovascular Valve Edge-to-Edge Repair Study (EVEREST).[366] In this safety and feasibility study, 107 patients with 3+ or greater MR with symptoms or asymptomatic patients with compromised left ventricular function (EF <60%), regurgitant jet origin of A2 to P2, and a leaflet anatomy amenable to application of the clip underwent the procedure with application of up to two clips. Acute procedural success (APS) defined as grade 2+ or less severe MR occurred in 79 patients (74%), and at 12 months, 66% of patients continued to have the severity of MR graded at 2+ or less. The in-hospital mortality rate was less than 1%, with 10 patients (9.1%) experiencing a major adverse event at 30 days, including complications from the transseptal approach, prolonged mechanical ventilation, and bleeding requiring transfusion. At the median follow-up of 680 days, 75 (70%) of patients remained surgery free. Over the follow-up period, 32 patients of the total cohort had open mitral valve surgery, 23 of whom had a clip placed previously.

EVEREST II,[367] reported in 2011, was a randomized, controlled trial that compared MitraClip treatment with conventional mitral valve surgery plus CPB in patients with severe MR. Patients were followed for major adverse events at 30 days and clinical success at 1 year. At 30 days, investigators analyzed the composite end point of major adverse events, including death, AMI, reoperation of the mitral valve, stroke, renal failure, deep wound infection, permanent AF, mechanical ventilation for more than 48 hours, and blood transfusion of more than 2 units of blood. The rates of major adverse events were 15% in the percutaneous repair group and 48% in the conventional surgery group. If transfusion was excluded, the occurrence of adverse events narrowed to 5% in the MitraClip group and 10% in the conventional surgery group. At 1 year, of patients randomized to the MitraClip, 28 (20%) had severe MR and 37 (20%) underwent surgery for mitral valve dysfunction, compared with 3 (4%) and 2 (2%) patients, respectively, who underwent reoperation in the conventional surgery group.

The mitral annulus plays an important role in the function of the mitral valve, and pathologic dilation of the annulus leads to poor leaflet coaptation and MR. Conventionally, the mitral annulus is divided into two components: the anterior fibrous portion and the posterior muscular portion. The anterior portion is relatively fixed, whereas the posterior portion is in continuity with the atrial and ventricular muscle and affected by dilation of the ventricle. Functional MR occurs as a result of altered function or geometry of the LV or mitral annulus. Most surgical procedures for functional MR are directed at reducing this portion of the annulus by placement of an annuloplasty ring to support the annulus.

Percutaneous techniques attempt to correct annular pathology by indirectly pushing the posterior annulus anteriorly[364] using devices that exploit the anatomic relationship of the coronary sinus and mitral annulus. One device is the Carillon Mitral Contour System (Fig. 21.34). It consists of self-expandable nitinol (ie, nickel-titanium alloy) proximal and distal anchors connected by a nitinol bridge. The application of tension on the system pulls the posterior mitral annulus anteriorly, reducing septal–lateral annular diameter.

The prospective, nonrandomized, multicenter TITAN trial[368] included 53 patients with dilated or nonischemic cardiomyopathy (EF <40%) and at least moderate (2+) MR. Of these patients, 36 underwent permanent implantation, whereas 17 had the device acutely recaptured for clinical reasons (eg, transient coronary compromise, <1 grade MR reduction) and served as the comparison group. Overall, the major adverse event rate for the implanted group at 30 days was 0%, with statistically significant improvement in echocardiographic assessment of MR severity and exercise performance at 12 months. Device-related limitations include coronary artery compromise due to the proximity of the circumflex artery to the CS,[369] slipping of the distal anchor, and device fracture.

Several percutaneous transcatheter mitral valve replacement devices are in preclinical and early clinical evaluation.[370] The two primary percutaneous techniques involve edge-to-edge repair and annuloplasty band insertion.[371] Edge-to-edge repair, popularized in open mitral operations by Alfieri and colleagues.[365] uses a percutaneously delivered clip to secure the anterior leaflet to the posterior leaflet, creating a double-orifice mitral valve. Although several proprietary devices are under development by different manufacturers, the MitraClip (Evalve, Menlo Park, CA) received FDA approval for use in patients deemed too high risk for surgical treatment in 2013 after completing the phase II multicenter EVEREST II trial.[372]

One-year follow-up results for this high-risk patient population continue to be reasonable, with low mortality rates and low rates of adverse events.[373,374] However, the 4-year follow-up results of the EVEREST II trial demonstrated a significantly greater requirement for late open surgical intervention in patients treated with percutaneous versus surgical repair.[375]

Anesthesia Considerations

Patients with MR may have significantly different risk factors for surgery, including duration of disease, symptoms, hemodynamic stability, ventricular function, and involvement of the right heart and pulmonary circulation (Box 21.5). For instance, a patient with severe MR caused by acute papillary muscle rupture may enter the operating

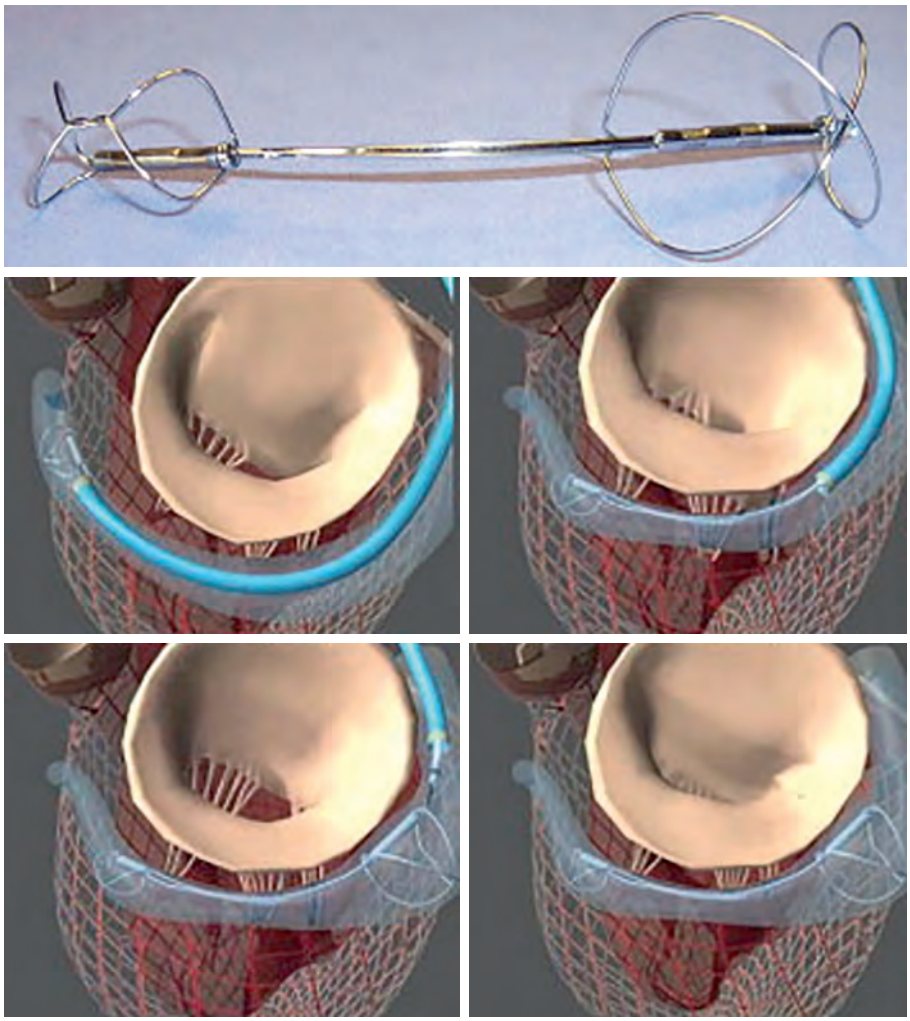

Fig. 21.34 The Carillon Mitral Contour System *(top panel)* at various steps in its deployment *(bottom panels). (From Chiam PT, Ruiz CE. Percutaneous transcatheter mitral valve repair: a classification of the technology.* JACC Cardiovasc Intv. *2011;4:1–13.)*

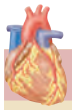

BOX 21.5 MITRAL REGURGITATION

- Preload is increased.
- Afterload isdecreased.
- Goal is mild tachycardia, vasodilation.
- Avoid myocardial depression.

room in cardiogenic shock with pulmonary congestion requiring intraaortic balloon pump augmentation. Another patient with a newly diagnosed flail posterior mitral leaflet may enter the surgical suite with relatively preserved left ventricular function and no symptoms; the compliance of the LA might have prevented pulmonary vascular congestion, pulmonary hypertension, and right ventricular dysfunction.

Despite differences in presentation, the general management goals remain similar and include maintenance of forward CO and reduction in the mitral regurgitant fraction. The anesthesiologist must optimize right ventricular function, in part by avoiding increases in pulmonary vascular congestion and pulmonary hypertension. Depending on the clinical presentation, various degrees of intervention are needed to achieve these hemodynamic management goals.

Information obtained during the preoperative interview and examination provides the anesthesiologist with important insight into the patient's degree of hemodynamic compromise. For example, a patient who reports dyspnea at rest or with minimal activity may have significant pulmonary vascular congestion and possibly compromised right ventricular function. Combined with the estimated pulmonary artery systolic pressure derived from the preoperative TTE report, this information helps the anesthesiologist prepare for potential right-heart dysfunction intraoperatively. For the patient, it is best to avoid heavy premedication with its attendant risk for obtundation, hypoventilation, and increased PAP. Auscultation of the heart may reveal rhythm disturbances such as AF and the systolic murmur of MR. However, in cases of acute, severe MR, a significant increase in left atrial pressure decreases the systolic pressure gradient between the left heart chambers, and the murmur of MR may be diminished or absent.[302]

Invasive hemodynamic monitoring provides a wealth of important information. Arterial catheters are essential for monitoring beat-to-beat changes in blood pressure that occur in response to a variety of surgical and anesthesia manipulations. PACs facilitate many aspects of intraoperative patient management. Intraoperative use of a PAC allows careful optimization of left-sided filling pressures. Although the PCWP and diastolic PAP depend on left atrial and left ventricular compliance and filling, examination of intraoperative trends in these variables helps the anesthesiologist to provide appropriate levels of preload while avoiding volume overload. Periodic determination of CO allows a more objective assessment of the patient's response to interventions such as fluid administration or inotropic infusion. The

presence or size of a v wave on a PCWP tracing does not reliably correlate with the severity of MR because this finding depends on left atrial compliance.

As in the management of patients with AR, a benefit of PAC insertion is the ability to introduce a ventricular pacing wire to rapidly counteract hemodynamically significant bradycardia. In patients with right ventricular compromise, monitoring trends in the CVP recording may be helpful. Tricuspid regurgitation (TR) detected through analysis of the CVP tracing may suggest right ventricular dilation, which may be caused by pulmonary hypertension.[376]

Intraoperative TEE provides invaluable information during the surgical correction of MR. It reliably identifies the mechanism of MR, thereby guiding the surgical approach,[377] and it objectively demonstrates the size and function of the cardiac chambers. TEE can identify the cause of hemodynamic derangements, facilitating proper intervention. For instance, the appearance of SAM of the mitral apparatus immediately after valve repair allows the anesthesiologist to intervene with volume infusion and medications such as esmolol or phenylephrine as appropriate. In rare circumstances, when hemodynamically significant SAM persists despite these interventions, the surgeon may elect to further repair or replace the mitral valve. TEE also identifies concomitant pathology that may warrant surgical attention, such as atrial-level shunts and additional valve disease (see Chapters 14 through 16).

Intraoperative TEE is essential during minimally invasive and robotically assisted mitral valve surgery. The use of a right minithoracotomy for these procedures precludes bypass cannulation in the chest. Instead, femoral arterial and venous cannulation with or without supplementary venous drainage from the superior vena cava or pulmonary artery is used. Real-time TEE imaging typically guides cannulation for CPB. If an endoaortic balloon clamp is used, the echocardiographer ensures that the balloon is correctly positioned in the ascending aorta. If a transthoracic aortic cross-clamp is chosen, the aortic cannula inserted into the femoral artery usually is not visualized with TEE. However, confirmation of guidewire placement in the descending aorta may be requested to exclude accidental passage into the contralateral iliac artery. The desired position of the tip of the femoral venous cannula varies; some prefer the tip within the superior vena cava, whereas others select the right atrium or inferior vena cava–right atrial junction.

For all positions of the venous cannula, TEE imaging can identify a malpositioned cannula or guidewire (Fig. 21.35). Tamponade after perforation of the left atrial appendage by a guidewire that was placed across a patent foramen ovale has been reported.[378] TEE also is invaluable during the percutaneous placement of coronary sinus catheters for retrograde cardioplegia delivery (Fig. 21.36A and B). Patients who may benefit from retrograde cardioplegia, such as those with significant AR, may be identified by TEE.

In addition to TEE considerations related to cannulation procedures, the selection of a minimally invasive or robotically assisted approach to mitral repair necessitates other changes in anesthesia management. Although not universally used, one-lung ventilation is preferred in many centers. This may be achieved by the usual methods, such as a double-lumen endotracheal tube or bronchial blocker. Impaired oxygenation can occur when one-lung ventilation is used during the termination of CPB during these procedures.[379]

The delivery of cardioplegia requires special attention by the surgical and anesthesia teams. If an endoaortic balloon clamp system is used, one or more methods should be used to verify its position. In addition to TEE, some centers place arterial catheters in the right and left radial arteries; dampening of the right radial arterial waveform can signify balloon migration toward the innominate artery. If retrograde cardioplegia is administered through a percutaneously placed catheter, its position should be well documented by TEE with or without fluoroscopy. Coronary sinus pressure should be monitored at baseline, during balloon inflation, and during cardioplegia administration. External patches for defibrillation are usually applied before patient positioning. A multimodal approach to analgesia may facilitate

early extubation of these patients. Some centers include a regional technique such as intrathecal opioids or paravertebral blocks as part of the anesthesia plan.

Intraoperative care of patients with MR before the institution of CPB focuses on optimizing forward CO, minimizing the mitral regurgitant volume, and preventing deleterious increases in PAPs. Maintaining adequate left ventricular preload is essential. An enlarged LV that operates on a higher portion of the Frank-Starling curve requires adequate filling. At the same time, excessive volume administration should be avoided because it may cause unwanted dilatation of the mitral annulus and worsening of the MR. Excessive fluid administration may precipitate right ventricular failure in patients with pulmonary vascular congestion and pulmonary hypertension. Optimization of preload is aided by analysis of data obtained from PAC measurements and TEE images.

Because significant left ventricular dysfunction is seen in many patients with MR, specific induction and maintenance regimens are selected to avoid further depressing left ventricular function. Large doses of narcotics have been popular in the past.[151,152] Other researchers have shown that smaller doses of narcotics combined with vasodilating inhalation anesthetics produce acceptable intraoperative hemodynamics.[380,381] By reducing the amount of narcotics administered, the addition of a vasodilating inhalation agent to the anesthetic regimen may allow for faster extubation of the trachea after surgery. With the current trend toward early referral of asymptomatic patients for mitral repair, anesthetic regimens that reduce the duration of postoperative mechanical ventilation may be advantageous.

In patients with severe left ventricular dysfunction, infusions of inotropic medications such as dopamine, dobutamine, or epinephrine may be required to maintain an adequate cardiac output. Phosphodiesterase inhibitors such as milrinone also may augment systolic ventricular performance and reduce pulmonary and peripheral vascular resistances. By reducing pulmonary and peripheral vascular resistance, forward CO is facilitated. Nitroglycerin and sodium nitroprusside represent two additional options for reducing the impedance to ventricular ejection. If patients prove refractory to inotropic and vasodilator therapy, insertion of an intraaortic balloon pump should be strongly considered (see Chapters 11, 13 through 16, 28, 36, and 38).

Manipulation of the heart rate may be necessary in some patients to optimize hemodynamics. Bradycardia usually should be avoided because slower heart rates allow larger filling volumes, potentially resulting in left ventricular distention and mitral annular dilation. Regurgitant volumes may increase at slower heart rates. Slightly increased heart rates, especially when combined with increased left ventricular contractility, favor a smaller mitral annular area and may decrease the regurgitant fraction. Sinus rhythm and preserved atrial contraction are less important in patients with MR than in patients with stenotic valves. Mitral annular dilation accompanies most cases of long-standing MR. Patients with pure MR usually have no impedance to left ventricular filling, and AF usually is better tolerated than in patients with stenotic lesions.

Because severe MR may result in pulmonary hypertension and right ventricular dysfunction, intraoperative management strategies should avoid hypercapnia, hypoxia, and acidosis. Mild hyperventilation may be beneficial in some patients. The effect of nitrous oxide on pulmonary vascular resistance (PVR) and pulmonary hypertension is controversial. Some studies show no change in PVR when nitrous oxide is administered to anesthetized patients with CAD or VHD.[382–384] Other studies of patients with MS demonstrate an increase in PVR after nitrous oxide administration, and in vitro evidence suggests that nitrous oxide increases norepinephrine release from the pulmonary artery.[385–387]

Patients with severe right ventricular dysfunction after CPB can prove exceptionally difficult to treat. Besides avoiding the factors known to increase PVR, only a few options exist for these patients. Inotropic agents with vasodilating properties such as dobutamine, isoproterenol, and milrinone augment right ventricular systolic performance and decrease PVR, but their use often is confounded by systemic hypotension. Prostaglandin E_1 (PGE_1) reliably reduces PVR and undergoes extensive first-pass metabolism in the pulmonary circulation.[388,389] Although PGE_1 reduces PAPs after CPB, systemic hypotension requiring infusions of vasoconstrictors through a left atrial catheter has occurred.[390–393]

Inhaled nitric oxide is an alternative for the treatment of right ventricular failure in the setting of pulmonary hypertension. Nitric oxide reliably relaxes the pulmonary vasculature and is then immediately bound to hemoglobin and inactivated. Studies indicate that systemic hypotension during nitric oxide therapy is unlikely[394,395] (see Chapters 11, 26, and 39).

Left ventricular dysfunction may contribute to post-CPB hemodynamic instability. With mitral competence restored, the low-pressure outlet for left ventricular ejection is removed. The enlarged LV must then eject entirely into the aorta. Because left ventricular enlargement leads to increased wall stress, a condition of increased afterload often exists after CPB. At the same time, the preload augmentation inherent to MR is removed. The systolic performance of the LV often declines after surgical correction of MR. Treatment options in the immediate post-CPB period include inotropic and vasodilator therapy and, if necessary, intraaortic balloon pump augmentation (see Chapters 26 and 39).

Mitral Stenosis

Clinical Features and Natural History

Clinically significant MS in adult patients usually is a result of rheumatic disease. Congenital abnormalities of the mitral valve are a rare cause of MS in younger patients. Other uncommon conditions that do not directly involve the mitral valve apparatus but may limit left ventricular inflow and simulate the clinical findings of MS include cor triatriatum, large left atrial neoplasms, and pulmonary vein obstruction.[396]

A decades-long asymptomatic period characterizes the initial phase of rheumatic MS. Symptoms rarely appear until the normal mitral valve area (MVA) of 4 to 6 cm^2 (Fig. 21.37) has been reduced to 2.5 cm^2 or less.[397] When the MVA reaches 1.5 to 2.5 cm^2, symptoms usually occur only in association with exercise or conditions such as fever, pregnancy, or AF that lead to increases in heart rate or cardiac output.[398,399] After the MVA decreases to less than 1.5 cm^2, symptoms may develop at rest. Some patients are able to remain asymptomatic for long periods by gradually reducing their level of activity.[396]

Patients with MS commonly report dyspnea as their initial symptom, a finding reflective of increased left atrial pressure and pulmonary congestion. In addition to dyspnea, patients may report palpitations that signal the onset of AF. Systemic thromboembolization occurs in 10% to 20% of patients with MS and does not appear to be correlated with the MVA or left atrial size.[398] Chest pain that simulates angina occurs in a small number of patients with MS and may result from RVH rather than CAD.[398]

There has been a change in the typical age at which patients are diagnosed with MS.[398] Previously, patients, often women, with MS were identified while in their 20s and 30s.[398,400,401] Since the early 1990s, perhaps because of more slowly progressive disease in the United States, patients have been diagnosed in their 40s and 50s.[398,402,403]

After symptoms develop, MS remains a slow, progressive disease. Patients often live 10 to 20 years with mild symptoms, such as dyspnea with exercise, before disabling NYHA class III and IV symptoms develop. The symptomatic state of the patient predicts the clinical outcome. For instance, the 10-year survival rate of patients with mild symptoms approaches 80%, but the 10-year survival rate of patients with disabling symptoms is only 15% without surgery.[398,403–405]

Pathophysiology

Rheumatic MS results in valve leaflet thickening and fusion of the commissures. Later in the disease process, leaflet calcification and

subvalvular chordal fusion may occur.[398] These changes combine to reduce the effective MVA and limit diastolic flow into the LV. As a result of the fixed obstruction to left ventricular inflow, left atrial pressures increase. Elevated left atrial pressures limit pulmonary venous drainage and result in increased PAPs.[310] Over time, pulmonary arteriolar hypertrophy develops in response to chronically increased pulmonary vascular pressures.[311] Pulmonary hypertension may trigger increases in right ventricular end-diastolic volume (RVEDV) and pressure (RVEDP), and some patients may have signs of right ventricular failure such as ascites or peripheral edema.[400,401] Left atrial enlargement is an almost universal finding in patients with established MS and is a risk factor for AF.

Patients with MS tolerate tachycardia particularly poorly. Left ventricular inflow, already limited by a mechanically abnormal valve, is further compromised by the disproportionate decline in the diastolic period that accompanies tachycardia. The flow rate across the stenotic valve must increase to maintain left ventricular filling in a shorter diastolic period. Because the valve area remains constant, the pressure gradient between the LA and LV increases by the square of the increase in the flow rate, according to the Gorlin formula, in which PG is the transvalvular pressure gradient:

$$\text{Valve area} = \text{Transvalvular flow rate}/\text{Constant} \times \sqrt{\text{PG}}$$

Tachycardia necessitates a significant increase in the transvalvular pressure gradient and may precipitate feelings of breathlessness in awake patients. In patients with AF, it is the increased ventricular rate that is most deleterious, rather than the loss of atrial contraction.[312] Although coordinated atrial activity is always preferable, the primary goal in treating patients with MS and AF should be control of the ventricular rate.

MS results in diminished left ventricular preload reserve. As seen in the pressure-volume loop in Fig. 21.38, LVEDV and LVEDP are reduced with an accompanying decline in SV. Controversy exists regarding the contractile state of the LV in these patients. Gash and colleagues[406] reported that almost one-third of their study population of patients with MS had an EF less than 50%. Limited preload may contribute to a reduced EF in some of these patients. However, the observation that left ventricular contractile impairment persists after surgery in some patients suggests that other causes of left ventricular dysfunction may exist. Rheumatic myocarditis has been reported, although its role in producing left ventricular contractile dysfunction is uncertain.[406] Other investigators have described posterobasal regional wall motion abnormalities, perhaps a consequence of thickening and calcification of the mitral apparatus.[314,315] Vasoconstriction occurring in response to diminished CO also may impair left ventricular ejection.[407] Afterload may be increased because of inadequate myocardial wall thickness.[406] The lack of adequate wall thickness leads to elevations in wall stress in accordance with Laplace's law.

In addition to abnormalities in systolic function, patients with MS may have impaired diastolic function. MS impairs left ventricular diastolic filling. The intrinsic compliance of the LV also may be reduced by the rheumatic disease process. Using conductance catheter and micromanometer techniques, Liu and associates[408] discovered decreased left ventricular compliance in a group of patients with MS scheduled for mitral balloon valvuloplasty. On repeat measurements taken immediately after valvuloplasty, the investigators observed a significant increase in left ventricular compliance. Because the increase in compliance occurred immediately after valvuloplasty, the physicians hypothesized that the changes associated with rheumatic MS created an internal constraint that limited left ventricular compliance.

Assessment of Mitral Stenosis

As for patients with MR, echocardiography represents the diagnostic modality of choice for patients with suspected MS.[396,409,410] Two-dimensional and Doppler echocardiographic techniques can accurately and noninvasively measure the transvalvular pressure gradient and MVA. Because the pressure gradient varies with the flow rate and diastolic period, the assessment of MS severity ideally should be based on the measured or calculated MVA.[396] Echocardiographic methods used to obtain MVA include the pressure half-time technique, the continuity equation, planimetry of the valve orifice, and PISA analysis. Other invaluable information obtained during an echocardiographic study includes the size and function of the ventricle and an estimation of the PAP.

Exercise echocardiography can be used when the patient's symptoms and the resting echocardiographic data are discordant.[409] In these cases, echocardiography may be performed while the patient exercises on a supine bicycle. If during exercise the transmitral gradient or PAP increases significantly, MS is the likely cause of the patient's symptoms.[409]

With the accuracy and widespread use of echocardiography, cardiac catheterization and invasive measurements of hemodynamics are rarely necessary.[398,410] Even patients referred for preoperative coronary angiography need not undergo invasive hemodynamic studies at the time of catheterization if adequate echocardiographic data already have been obtained.[410] Catheter-based hemodynamic assessments are reserved for situations in which echocardiographic studies are suboptimal or conflict with the clinical picture because invasive mitral valve hemodynamic studies are complex and limited.[398] For instance, a transseptal puncture is required to measure the left atrial–to–left ventricular pressure gradient directly and entails risks such as tamponade, aortic injury, and heart block.[398] If the PCWP is used in place of direct left atrial pressure measurements, the gradient derived is less accurate than that obtained with Doppler echocardiography.[319]

Similar to patients with MR, nonspecific findings commonly are seen on electrocardiograms and chest radiographs for patients with MS. Potential ECG findings include AF and left atrial enlargement. Radiographs may also reveal left atrial enlargement and pulmonary vascular congestion.

Surgical Decision Making

Appropriate referral of patients for surgical intervention requires integration of clinical and echocardiographic data. Patients with severe symptoms (ie, NYHA class III and IV) should be immediately referred for surgery because the outcome is poor if treated medically.[313,398] Patients with only mild MS and few or no symptoms may be treated conservatively with periodic evaluation. Patients who are asymptomatic but have moderate MS (ie, MVA between 1.0 and 1.5 cm^2) require careful assessment. If significant pulmonary hypertension (ie, pulmonary artery systolic pressure >50 mm Hg) is identified, surgical intervention should be considered.[313] Intervention also may be indicated if a patient becomes symptomatic or PAPs increase significantly during exercise testing.[398]

The surgical options for treating MS continue to evolve. Closed commissurotomy, in which the surgeon fractures fused mitral commissures, was first performed in the 1920s. It became popular in the 1940s and still is used to treat MS in developing countries.[409] With the advent of CPB in the 1950s, techniques of open commissurotomy developed, allowing the surgeon to directly inspect the valve before splitting the commissures.[409] The common goals of closed and open mitral commissurotomy include increasing the effective MVA and decreasing the left atrial to left ventricular pressure gradient, with a resultant relief in the patient's symptoms.

Percutaneous mitral commissurotomy (PMC) allows a less invasive, catheter-based approach to MS. It was first reported by Inoue and coworkers in 1984,[411] and clinicians worldwide perform PMC more than 10,000 times each year.[412] The technique of PMC involves directing a balloon-tipped catheter across the stenotic mitral valve. Specifically designed balloons allow sequential inflation of the distal and proximal portions of the balloon, ensuring correct positioning across the mitral valve before the middle portion of the device is inflated to split the fused commissures.[413]

Patient selection for PMC requires careful echocardiographic evaluation. Echocardiographic grading scales have been developed to evaluate mitral leaflet mobility, thickness, calcification, and subvalvular fusion.[414] Patients who score favorably on echocardiographic assessments (eg, adequate leaflet mobility with little calcification) may be referred for PMC. Success rates for PMC are similar to those achieved with surgical commissurotomy, and most patients experience a doubling in the effective MVA.[409] An increase in the amount of MR represents the most common complication associated with PMC.[409]

Not all patients are candidates for surgical commissurotomy or PMC. Those with heavily calcified valves or significant MR are likely to experience suboptimal results after commissurotomy. Mitral valve anatomy unsuitable for PMC is more commonly encountered in Western countries, where patients with MS typically are diagnosed at an older average age.[412] Mitral valve replacement commonly is recommended for these patients. The risk for mitral valve replacement depends on patient characteristics such as age, functional status, and other comorbid conditions.[409] Surgical risk in younger patients with few coexisting medical problems usually is less than 5%. Conversely, surgical risk in elderly patients with severe symptoms related to MS and multiple comorbidities may be 10% to 20%.[409]

Anesthesia Considerations

Several important goals should guide the anesthesia management of patients with significant MS. First, the anesthesiologist should prevent tachycardia or treat it promptly in the perioperative period (Box 21.6). Second, left ventricular preload should be maintained without exacerbation of pulmonary vascular congestion. Third, anesthesiologists should avoid factors that aggravate pulmonary hypertension and impair right ventricular function.

Prevention and treatment of tachycardia are central to perioperative management. Tachycardia shortens the diastolic filling period. An elevation in transvalvular flow rate is required with a resultant increase in the left atrial–to–left ventricular pressure gradient to maintain left ventricular preload with a shortened diastolic period. Avoidance of tachycardia begins in the preoperative period. Anxiety-induced tachycardia may be treated with small doses of narcotics or benzodiazepines. However, excessive sedation is counterproductive because sedative-induced hypoventilation can result in hypoxemia or hypercarbia, potentially aggravating a patient's underlying pulmonary hypertension and because large doses of premedication can jeopardize the patient's already limited left ventricular preload. Appropriate monitoring and supplemental oxygen therapy should be considered for patients receiving preoperative narcotics or benzodiazepines.

Medications taken by the patient before surgery to control heart rate, such as digitalis, β-blockers, calcium receptor antagonists, or amiodarone, should be continued in the perioperative period. Additional doses of β-blockers and calcium-receptor antagonists may be required intraoperatively, particularly to control the ventricular rate in patients with AF. Control of the ventricular rate remains the

BOX 21.6 MITRAL STENOSIS

- Preload is normal or increased.
- Afterload is normal.
- Goal is controlled ventricular response.
- Avoid tachycardia, pulmonary vasoconstriction

primary goal in managing patients with AF, although cardioversion should not be withheld from patients with atrial tachyarrhythmias who become hemodynamically unstable. Narcotic-based anesthetics often are helpful in avoiding intraoperative tachycardia. However, clinicians should realize these patients may be receiving other vagotonic drugs and that profound bradycardia is possible in response to large doses of narcotics.[326,327] The selection of a muscle relaxant such as pancuronium may help prevent the unwanted bradycardia associated with high-dose narcotics.

Maintenance of preload is an important goal for treating patients who have a fixed obstruction to left ventricular filling. Appropriate replacement of blood loss and prevention of excessive anesthetic-induced venodilation help preserve hemodynamic stability intraoperatively. Invasive hemodynamic monitoring allows the anesthesiologist to maintain adequate preload while avoiding excessive fluid administration that can aggravate pulmonary vascular congestion. Placement of an arterial catheter facilitates timely recognition of hemodynamic derangements. PACs can be invaluable in treating patients with significant MS. Although the PCWP overestimates left ventricular filling and the pulmonary artery diastolic pressure may not accurately reflect left-heart volume in patients with pulmonary hypertension, trends and responses to intervention can be more readily assessed. Tachycardia increases the pressure gradient between the LA and LV. Increased heart rates widen the discrepancy between the PCWP and the true LVEDP. Despite these limitations, the PAC remains a useful monitoring tool, providing information on CO and PAPs.

Many patients with MS have pulmonary hypertension. Anesthesia techniques that avoid increases in PVR are likely to benefit these patients and prevent additional right ventricular embarrassment. Meticulous attention to arterial blood gas results allows appropriate adjustment of ventilatory parameters. Vasodilator therapy for patients with pulmonary hypertension usually is ineffective because the venodilation produced further limits left ventricular filling and does not improve cardiac output. The only MS patients who may benefit from vasodilator therapy are those with concomitant MR or those with severe pulmonary hypertension and right ventricular dysfunction in whom pulmonary vasodilation can facilitate transpulmonary blood flow and improve left ventricular filling.[325] The treatment of right ventricular dysfunction was discussed earlier (see Chapters 26 and 38).

Tricuspid Regurgitation

Clinical Features and Natural History

The tricuspid valve is the right-sided atrioventricular valve that under normal conditions separates a low-pressure gradient from the right ventricle to the right atrium. It is possible to have a normal CO without a tricuspid valve if the PAPs and resistances are low, and because most tricuspid disease is clinically silent, it is often referred to as the *forgotten valve*.[415]

Tricuspid disease is caused by a structural defect in the valve apparatus or a functional lesion. Primary disorders of the tricuspid valve apparatus that may lead to more significant degrees of TR include congenital disease (ie, Ebstein anomaly), rheumatic valve disease, prolapse, irradiation, carcinoid syndrome, blunt chest trauma, endomyocardial biopsy–related trauma, and right ventricular pacemaker/defibrillator lead trauma.[416–419] In rheumatic disease, histologic involvement of the tricuspid valve may occur in 46% of patients, but it is rarely clinically severe, and in these cases, the valve usually is also stenotic.[56,420]

Despite numerous potential causes of primary tricuspid disease, they account for only 20% of TR cases. The remainder of TR disease is functional in nature. Left-sided valvular disease, usually MR, most commonly is responsible. Functional tricuspid incompetence also can result from MS, AR, or AS and from isolated pulmonary hypertension. Causes of functional TR include dilation of the annulus or leaflet tethering from right ventricular dilation and remodeling,[416,417] global right ventricular dysfunction from cardiomyopathy and myocarditis or segmental dysfunction due to endomyocardial fibrosis, and CAD with resulting ischemia, infarction, or rupture of the right ventricular papillary muscles.[415,421] When mitral valve disease is severe enough to warrant valve repair or replacement, TR may be identified in 30% to 50% of patients.[422-428]

Symptoms of isolated TR are usually minor in the absence of concurrent pulmonary hypertension. Intravenous drug abusers who develop tricuspid endocarditis are the classic example. In these patients, structural damage to the valve may be quite severe, but because they are free of other cardiac disease, they can tolerate complete excision of the tricuspid valve with few adverse effects.[429] Excision of the tricuspid valve in endocarditis has been common because of the undesirability of placing a valve prosthesis in a region of infection.[419] Surgical annuloplasty may be a better long-term option if the valve is structurally salvageable.

Another factor that broadly favors tricuspid repair rather than replacement is the high incidence of thrombotic complications with a valve in this position. The lower pressure and flow state on the right side of the heart are responsible for this phenomenon. Increasingly, valve replacement in the tricuspid area is relegated to patients who have unreconstructable rheumatic valve disease, totally destroyed tricuspid valves from endocarditis, or rare congenital lesions.[430–436] The literature shows improved longer-term outcomes with valve repair than with replacement.[437]

In chronic TR caused by right ventricular dilation, the clinical scenario often is much different from that of isolated tricuspid disease. The major hemodynamic derangements are usually those associated with mitral or aortic valve disease. The RV dilates in the face of the afterload stress from long-standing pulmonary hypertension, and the resultant increase in end-diastolic fiber stretch (ie, preload reserve) promotes increases in SV mediated by the Starling mechanism. These increases are negated by a concurrently increasing right ventricular afterload because of relatively inadequate RVH.[438] Regurgitation through the tricuspid valve reduces right ventricular wall tension at the price of a decrease in effective forward SV.

An important corollary to right ventricular chamber enlargement is the possibility of a leftward shift of the interventricular septum and encroachment on the left ventricular cavity.[439] This phenomenon can reduce the left ventricular chamber size and the slope of the left ventricular diastolic pressure-volume curve, rendering the LV less compliant.[440–442] Septal encroachment may mask left ventricular underfilling by decreasing left ventricular compliance, artificially increasing LVEDP. A failing RV underloads the left side by reduced effective SV and anatomic (ie, septal shift) mechanisms (see Chapter 26).

Right ventricular failure may be relatively mild early in the course of functional TR, but over time, the regurgitation worsens, with further dilation leading to further right ventricular volume overload and chamber enlargement, which may worsen the TR.[418] As in MR, the incompetent tricuspid valve serves as a pop-off circulation during right ventricular systole, and over time, the capacitance of the RA and vena cavae can increase dramatically. Untreated, this eventually leads to systemic venous congestion, hepatic congestion, severe peripheral edema, and ascites.

Because tricuspid insufficiency in the absence of pulmonary hypertension is rare, it has been difficult to demonstrate that chronic volume overload and ventricular dilation result in right ventricular cardiomyopathy. However, when right ventricular volume overload occurs in the context of pulmonic valve insufficiency, right ventricular failure results from volume overload.[443] Clinical experience also supports the presumption of right ventricular cardiomyopathy in severe TR. In late tricuspid insufficiency, right ventricular function can decline when tricuspid valve repair renders the valve competent.

The AHA/ACC guidelines classify TR in four stages (ie, A, B, C, and D). Each stage is subdivided by four defining features, including valve anatomy, valve hemodynamics, hemodynamic consequences, and symptoms.[444] Stage A patients are at risk for functional TR ad have

mild anatomic changes, including mild prolapse, rheumatic changes, early annular dilation, or an intraannular pacemaker or implantable cardioverter-defibrillator (ICD) lead with no hemodynamic or clinical symptoms. Stage B patients have progressive, asymptomatic TR with early annular dilation, moderate leaflet tethering or prolapse, and mild or moderate TR by echocardiographic parameters. Mild TR is defined as a central jet area less than 5.0 cm^2 and a soft, parabolic, and continuous-wave Doppler envelope with systolic-dominant hepatic vein flow. Moderate TR has a central jet area of 5 to 10 cm^2 with a vena contracta width greater than 0.7 cm, a continuous-wave Doppler profile that is dense, and systolic blunting of hepatic vein flow. Patients with moderate TR may have mild inferior vena cava and right atrial enlargement and normal right atrial pressure, and they are often asymptomatic.

Stages C and D are both defined as severe TR identified by echocardiography, but stage D is associated with clinical symptoms, including fatigue, palpitations, dyspnea, abdominal bloating, anorexia or edema, and reduced right ventricular function in the late phase. The echocardiographic definition of severe TR includes flail or grossly distorted leaflets, severe annular dilation (>40 mm or 21 mm/m^2), and marked leaflet tethering. The central jet area is greater than 10.0 cm^2, the vena contracta width is greater than 0.70 cm, and the dense continuous-wave Doppler signal is triangular with an early peak and systolic flow reversal in the hepatic veins.

Medical therapies for patients with severe TR are limited, and treatment should be focused on the causative lesion in patients with functional TR. However, for patients with severe TR and symptoms associated with right-sided heart failure (ie, stage D), the AHA/ACC guidelines recommend diuretic therapy to help decrease volume overload.[445] Pulmonary hypertension is an independent predictor for progression of TR. For patients with severe functional TR (ie, stages C and D), pulmonary vasodilators should be considered in cases of demonstrated responsiveness during invasive testing.[445]

Surgical Decision Making

In cases of structural tricuspid insufficiency, the decision to repair or replace the valve is straightforward. The same cannot be said of functional TR. Because most functional cases are the consequence of left-sided valve lesions with right ventricular overload, the TR usually improves significantly (typically by at least one grade) after the aortic or mitral valve is repaired or replaced. It can be unclear in the operating room whether addition of a tricuspid procedure to the left-sided valve surgery is indicated. In this situation, intraoperative TEE plays an essential role. If the TR is severe in the pre-CPB assessment, tricuspid valve surgery is usually performed.[422] The evidence is less clear when regurgitation is graded as moderate. Some surgeons choose to repair the tricuspid valve in cases of moderate TR, but others advocate observation.[422,424,446]

In the context of left-sided valve surgery, it is common with moderate or more severe TR to complete the left-sided procedure and then reassess the tricuspid valve with TEE when the heart is full and ejecting.[447,448] If the TR remains more than moderate after the left-sided valve is fixed, many surgeons perform the tricuspid procedure. If regurgitation is moderate or less severe, the appropriate surgical course may remain unclear.

A single-center, retrospective study evaluated the impact of untreated moderate or more severe functional TR on outcomes of patients undergoing mitral valve surgery. They were divided into two groups. Group A had no or mild TR ($n = 102$), and group B had moderate to severe TR ($n = 63$). Before hospital discharge, both groups had improvement in the severity of TR after left-sided valve surgery alone. However, during follow-up, the TR grade for group B returned to the preoperative severity or became worse. Moderate or more severe TR was also associated with a lower 5-year survival rate.[449]

Some patients having left-sided valve procedures must return to the operating room for tricuspid surgery, and data from the Mayo Clinic suggest that this problem may be increasing.[450] Their morbidity and mortality rates are probably significantly higher than those for patients undergoing tricuspid valve repair at the time of the aortic or mitral valve procedure.

The evidence regarding tricuspid intervention for mild to moderate functional TR at the time of left-sided heart valve surgery has been extensively developed over the past 15 to 20 years and supports the AHA/ACC guidelines.[425] The reported trials base their intraoperative decision making on TEE findings of severity of TR by Doppler analysis or tricuspid annular diameter, or both. For example, a prospective, single-center, observational trial evaluated the effect of tricuspid annuloplasty in patients undergoing surgery for severe MR.[425] Patients with a tricuspid annular diameter greater than 70 mm (ie, more than two times normal) measured by the surgeon also underwent tricuspid annuloplasty, regardless of the grade of regurgitation. Of the total 311 patients, 148 received mitral valve repair and tricuspid annuloplasty. The patients who underwent the combined procedure had significant improvement in postoperative TR and NYHA functional class. There was no significant difference between the two groups in terms of hospital mortality or 10-year actuarial survival.[425,451]

A second single-center trial evaluated the effect of tricuspid annuloplasty in patients with at least moderate MR with or without a systolic tricuspid annular diameter greater than 24 mm who underwent mitral valve surgery. Of the167 patients who had tricuspid annuloplasty ($N = 298$), 108 had moderate or more severe TR, and 59 cases were based on a systolic tricuspid annular diameter greater than 24 mm. Due to surgeon preference, tricuspid annuloplasty was not performed for 81 patients with a systolic tricuspid annular diameter greater than 24 with mild TR. Postoperatively, reduction of the severity of TR in the treated group lasted for the 1 year of follow-up. In the patients without tricuspid intervention, regression analysis demonstrated that a systolic tricuspid annular diameter greater than 24 was a risk factor for greater TR severity during follow-up.[452]

Several other trials of tricuspid intervention demonstrate a significant improvement in right ventricular remodeling,[453,454] risk of CHF,[30] 6-minute walk test,[29] and a reduction of TR severity postoperatively and for up to 3 to 5 years.[455–458] With all of these outcomes, there is still no reproducible improvement in long-term morbidity and mortality rates.[459]

Functional TR is common and clinically important for patients undergoing left ventricular assist device (LVAD) implantation. In a single center trial of LVAD implantation, the incidence of moderate or severe functional TR was 49%, which persisted after implantation of the LVAD, and was associated with increased hospital stay and inotropic support.[460] A German single-center trial reported that tricuspid annular dilation greater than 43 mm preoperatively predicted decreased survival after LVAD implantation.[461]

Early results of tricuspid procedures at the time of LVAD implantation seemed promising, with improved right ventricular reverse remodeling and significantly reduced severity of TR.[462] In later clinical trials, tricuspid valve intervention at the time of LVAD implantation had little or no positive effect on clinical outcomes.[460,463–466] One metaanalysis suggested that completion of tricuspid valve surgery prolonged CPB times, with no significant difference found for right ventricular support device (RVAD) placement, acute renal failure, or early mortality.[466] Further trials are required to resolve the question about the best management of TR in LVAD recipients.[425]

Decision making for cases of functional TR is made more complicated by the inability to rigorously quantify the severity of the regurgitation and right ventricular dysfunction.[450] As with MR and the LV, significant TR makes right ventricular function difficult to assess because the regurgitant fraction leads to a falsely increased EF. In the absence of sophisticated echocardiographic assessments, such as determination of the rate of right ventricular pressure increase with pulsed Doppler, it is common to look at enlarged right ventricular chamber size and a decrease in RVEF as indicators of decompensation.[450,467]

Clinical experience suggests that pulmonary hypertension is likely to be a marker for right ventricular failure after tricuspid surgery, but

studies of sufficient size are lacking. Like assessment of right ventricular function, grading of TR severity is at best semiquantitative. Color-flow mapping of the volume of the regurgitant jet in the RA is standard,[437] and this can be supplemented by looking for systolic flow reversal in the portal veins using pulsed-wave Doppler.[468] Although the assessment of residual TR after left-sided valve surgery is important, the tricuspid valve is sometimes difficult to examine with TEE, and the presence of an aortic or mitral mechanical prosthesis makes the assessment more difficult.

Anesthesia Considerations

Because most tricuspid surgery occurs in the context of significant aortic or mitral disease, anesthesia management primarily is determined by the left-sided valve lesion. The exception is when significant pulmonary hypertension and right ventricular failure exist. Under these conditions, the primary impediment to hemodynamic stability after surgery is right ventricular failure rather than the left-sided process.

If right ventricular dysfunction is predicted, it is useful to place a PAC, even if the tricuspid valve will be replaced. If the PAC must be removed because of tricuspid valve replacement, it still can be helpful to obtain CO and PAPs before CPB to get insight into right ventricular function and anticipate the hemodynamic support that may be required. A PAC is of greater use than CVP alone because the CVP is a poor index of intravascular filling and the degree of TR. he RA and vena cavae are highly compliant and accept large regurgitant volumes with relatively little change in pressure.

A PAC also is useful when intraoperative TEE is used. As in AR within the LV, the RV in chronic TR is volume overloaded and dilated and requires a large EDV to maintain forward flow. Because of the unreliability of the CVP as an indicator of filling, it is possible to volume overload patients with TR and right ventricular failure. Cardiac output in right ventricular failure often can be augmented with the use of vasodilators, and although right ventricular dimensions can be followed intraoperatively with TEE, maximizing CO (sometimes at the cost of systemic arterial pressure) is best done with serial CO measurements (as in AR). When there is significant right ventricular distention, the possibility of septal shift and secondary deterioration of left ventricular diastolic compliance should be carefully considered. Echocardiography is uniquely helpful for this assessment.

Post-CPB treatment of the patient undergoing an isolated tricuspid valve procedure is usually straightforward. Patients usually do not have significant right ventricular failure or pulmonary hypertension and typically require only a brief period of CPB without aortic cross-clamping. A larger group of patients, particularly those with TR related to AS, typically come off CPB with little need for support of the RV. These patients often do well because the improvement in left ventricular function after AVR for AS is usually sufficient to reduce PAPs significantly and offload the right heart. When left-sided valve surgery is for mitral disease, the improvement usually is not as marked, and greater degrees of inotropic support of the RV often are indicated. The combination of a phosphodiesterase inhibitor with a vasodilator and a catecholamine infusion is useful. Serial CO measurements to balance systemic pressure and right ventricular output and filling are critical.

A few other practical points on tricuspid valve repair and replacement should be made. First, because right-sided pressures can be chronically increased with TR, it is important to look for a patent foramen ovale and the potential for right-to-left shunting before initiation of CPB. Second, intravascular volume may be quite high in this patient population, and it is often practical to avoid red blood cell transfusion by hemofiltration during bypass. Third, if the patient has significant right ventricular dysfunction or peripheral edema or ascites, there is the potential for a coagulopathy related to liver congestion, and the patient should be treated accordingly. Fourth, central catheters, particularly PACs, should not be entrapped by right atrial suture lines.

Innovations in Valve Repair

Interventional cardiology has had a significant impact on the volume of CABG, and it can be predicted that interventional cardiology will alter surgery for VHD over time. Many less invasive approaches to mitral valve repair are being assessed in animal studies or clinical trials, and tremendous inroads have been made in percutaneous replacement of the aortic valve. Innovations also are being made in surgical valve repair, including aortic valve repair and closed- and open-chamber procedures for MR.

Aortic Valve Repair

During the past several years, there has been a major shift from valve replacement to valve repair in patients with degenerative mitral valve disease. The same has not been true of the aortic because the valve disease is different in most patients and because of the high flow and pressure conditions across the aortic valve that make repair more prone to failure. However, aortic valve repair is being increasingly done as an appropriate patient population is defined.

Although valve repair for AR has found broader use when regurgitation is associated with dissection or dilation of the aortic root,[469,470] isolated valve repair has been less common. A growing body of data suggests that aortic valve repair may offer advantages over valve replacement in younger individuals with AR due to bicuspid valves.[469,471] In contrast with AVR, aortic valve repair eliminates the need for anticoagulation for a mechanical valve and should delay the need for reoperation for a failed tissue valve.

When regurgitation occurs with a bicuspid valve, the insufficiency usually is caused by retraction or prolapse, or both, of the conjoined cusp. Repair consists of a triangular incision to shorten and elevate the cusp to improve apposition. Although very-long-term follow-up results have not been reported, in a large series from the Mayo Clinic with a mean follow-up of 4.2 years, late failure of the repair requiring reoperation occurred in 14 of 160 consecutive patients. Most of the failure was attributed to repairs done in the first decade of the 15-year experience.[469]

As a result of this experience, aortic valve repair is likely to find increasing application in this patient population. For this group, anesthesia management usually is straightforward, although the clinical indications for valve repair in AR are the same as those for valve replacement. The compelling issue for the anesthesiologist in these cases is echocardiographic assessment of the valve for suitability of repair and the adequacy of the repair after the procedure.

Sutureless Valve Replacement

Surgical aortic valve replacement continues to be the gold standard for patients with severe symptomatic aortic valve stenosis. Transcatheter aortic valve replacement (TAVR) reduced the rate of death and cardiac symptoms for patients deemed inoperable compared with medical therapy alone.[472] These procedures have been associated with a decreased mortality rate at 1 year compared with open surgery in high-risk patients.[473] However, these procedures are not without risk. A systematic review of TAVR in high-risk surgical patients reported a 30-day mortality rate between 0% and 25%, with risks of other complications, including bradyarrhythmias requiring permanent pacemaker insertion, cardiac perforation, myocardial infarction, access-related complications, and other valve-related issues such as perivalvular leak and unknown long-term durability[474] (see Chapters 3 and 27).

There is increased interest in the treatment of aortic valvular disease with sutureless AVR in patients who can benefit from a shorter cross-clamp time but are not truly inoperable.[475] In the early 1960s, Magovern and coworkers[476] described implantation of specially made sutureless aortic and mitral valve prostheses (Fig. 21.39). The goal of rapid nonsuture fixation was achieved, decreasing CPB times; however, the technique was subsequently abandoned because of paravalvular leaks and valve-related thromboembolic events.

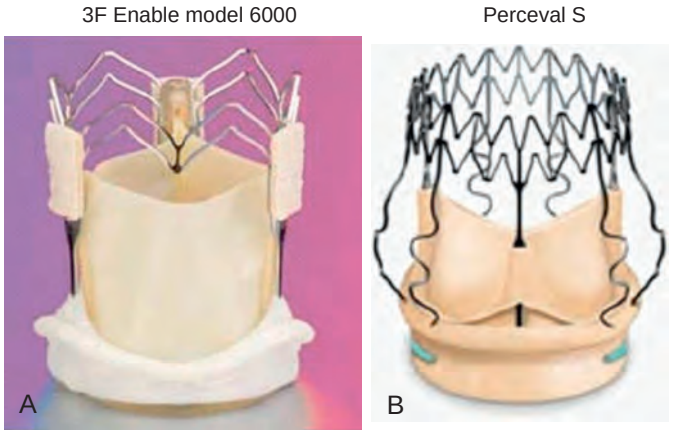

Fig. 21.39 ATS 3f Enable (A) and Perceval S (B) sutureless bioprosthetic aortic valves. *(A, Courtesy ATS Medical, Minneapolis, MN. B, Courtesy of Sorin Biomedica Cardio Srl, Saluggia, Italy.)*

With the rapid technologic progress made in transcatheter valve technology and materials, sutureless AVR has been proposed as an additional therapeutic option for high-risk patients with severe AS. Potential advantages of sutureless AVR include removal of the diseased and often calcific native aortic valve and reduction in aortic cross-clamp and CPB times in the setting of a potentially minimally invasive surgical approach.

The Perceval S (Sorin group, Arvada, CO) and the ATS 3f Enable (ATS Medical, Minneapolis, MN) valves consist of bovine or equine pericardial tissue on a self-expanding nitinol frame. After access to the aortic valve is obtained and the diseased valve excised, the appropriate valve size is selected using dedicated sizers. The 3f Enable valve is deployed by rinsing it with warm saline, and the nitinol frame expands in the annulus.[477] The Perceval S valve uses a balloon inflation to complete deployment of the valve.[478]

Early results of the use of these devices seem promising. Eichstaedt and colleagues[479] reported a retrospective, single-center analysis of 120 patients who underwent isolated AVR or combined AVR with other cardiovascular procedures using the ATS 3f Enable device. In the isolated AVR group, the mean CPB time was 62 ± 18 minutes, and the mean cross-clamp time was 37 ± 11 minutes. The researchers found that in an ideal situation, aortic cross-clamp times of less than 20 minutes were feasible. Reapplication of the aortic cross-clamp was necessary in 10 patients; causes included paravalvular leak (7 patients), acute migration of the prosthesis into the LV (2 patients), and ascending aorta (1 patient). The overall 30-day mortality rate was 6.7% (8 of 120 patients), with a reoperation rate of 4.3% (5 of 120 patients). The long-term durability has not been reported.

Folliguet and coworkers[478] described 208 high-risk patients enrolled in an international, multicenter, prospective, nonrandomized study of the Perceval S prosthesis in patients requiring AVR with or without concomitant procedures. Implantation was successful in 95.6% of patients. In the isolated AVR group, CPB time was 50 ± 22 minutes, with a cross- clamp time of 30 ± 12 minutes. During follow up, 4% (9 patients) developed a paravalvular leak requiring reoperation. Two of these patients developed an intraprosthetic leak, one due to endocarditis and the other due to pannus ingrowth on the stent causing restricted leaflet motion. Although the 30-day mortality rate was not reported, 2.4% (5 patients) died during the hospital stay with no evidence at autopsy of valve-related pathology.

Development of the sutureless aortic valve has found a specific role in the setting of minimally invasive AVR. In a retrospective, observational cohort study, Gilmanov and colleagues[480] compared a total of 515 patients who underwent surgical AVR with a right anterior minithoracotomy with placement of a sutureless ($n = 246$) or conventional ($n = 269$) aortic prosthesis. In patients who underwent sutureless valve implantation, CPB times and cross-clamp times were significantly shorter. A larger prosthesis could be implanted in the sutureless group. There were no significant differences between the groups in conversion to sternotomy, reexploration for bleeding, intensive care unit or hospital length of stay, or overall survival.

New Techniques for Mitral Valve Repair

MR frequently is associated with CHF. In dilated and ischemic cardiomyopathy, enlargement of the mitral annulus results in a failure of coaptation of the mitral leaflets and valve incompetence. Although cardiac surgery is an effective treatment, morbidity can be high. Three approaches have been developed to address MR occurring in the absence of structural mitral pathology. They address the failure of leaflet coaptation at the level of the valve leaflets or valve annulus or by altering the anatomic relationship of the septal and lateral walls of the LV.

Altering Ventricular Anatomy to Reduce Mitral Regurgitation

Valve leaflet and annulus repair techniques are described in earlier sections of this chapter and in Chapters 3 and 27. The approach to closed mitral valve repair consists of altering the geometry of the lateral and septal left ventricular walls to bring the valve leaflets together. The commercial Coapsys device has entered clinical trials. It consists of anterior and posterior epicardial pads connected by a cord. With an open chest, the cord is placed transventricularly in a subvalvular position, and the tension on the cord is adjusted before the opposing epicardial pad is fixed in place.[481] This effectively brings the ventricular walls together and improves leaflet coaptation. TEE is used to optimize cord length and pad positioning.

In contrast to the leaflet-based and annulus-based approaches, the Coapsys approach is surgical, requiring an open chest but not CPB. The position of the epicardial vessels and the relation to the submitral apparatus could pose significant risk, but the device has been used successfully in animal models.

Percutaneous Valve Replacement

Although surgery, particularly for aortic valve disease, has expanded to include a much older population, there remains a subset of patients for whom cardiac surgery may entail unacceptable risks. For them, less invasive techniques such as percutaneous valve replacement are being developed.

The first clinical percutaneous placement of an aortic valve was reported in 2002.[482] Experience and technical refinement have led to the two current strategies for transcatheter AVR: retrograde through the femoral artery and advanced into the aorta and across the aortic valve or antegrade through a limited thoracotomy, in which a valve-loaded catheter punctures the left ventricular apex and the new valve is seated antegrade (see Chapters 3 and 27).

Covello and collaboratrs[483] described management strategies and periprocedural outcomes for 18 patients in whom retrograde, percutaneous AVR was performed through the femoral artery. The treatment of 100 patients who underwent successful transapical antegrade aortic prosthesis placement was reported by Fassl and associates.[484] Although technical aspects of prosthetic valve delivery were different, common themes included the need for rigorous assessment of aortic leaflet, root, and coronary ostial anatomy; a well-coordinated, multidisciplinary approach to patient evaluation and clinical management; the use of rapid ventricular pacing to diminish CO during prosthesis deployment; and the potential for sudden hemodynamic collapse necessitating emergent intervention.

In a report of retrograde transfemoral AVR by Covello and colleagues,[483] general anesthesia was used early; however, with experience, monitored anesthesia care was selected. This contrasts with the practice

of anesthesiologists at other centers, where relatively large numbers of transfemoral, retrograde AVR procedures are performed. The advantages of general anesthesia include patient immobility during rapid ventricular pacing, valvuloplasty, and prosthesis deployment. General anesthesia facilitates surgical repair of the femoral cannulation site, which may be required. The use of general anesthesia allows prolonged TEE imaging and rapid intervention in the event that sternotomy or CPB becomes an emergent necessity (see Chapter 27).

Transapical catheter-based AVR typically is selected because of vasculopathy, small or tortuous femoral and iliac vessels, or severe aortic atheromatous disease. After general anesthesia, typically in a hybrid operating suite, a small left anterior thoracotomy is made, and the ventricular apex is exposed. Balloon aortoplasty is performed, and under a combination of fluoroscopic and echocardiographic guidance, the aortic valve is seated with deployment of a balloon.

The long-term benefits of less invasive interventions are being compared with each other or with traditional surgical approaches. Some investigators are finding use in high-risk patients as temporizing procedures, in place of reoperations, or in conjunction with percutaneous approaches for CAD. These technologies will get better, and there will be further pressure for clinical applications. The most important considerations will be case selection and long-term follow-up of outcomes.

Case Study 1: Transapical Aortic Valve Implantation

Framing

- An 89-year-old man with medical history significant for four-vessel CABG performed 11 years earlier
- Recurrent CAD with recent placement of two bare metal stents in the left internal mammary artery (LIMA) and into the left anterior descending (LAD) artery at a distal anastomosis 1 month earlier
- Dyspnea on exertion with mild chest tightness that goes away with rest
- Severe, symptomatic AS; does not wish to be considered for repeat sternotomy
- Patient's femoral anatomy not conducive to transfemoral transcutaneous aortic valve replacement; consider for transapical approach
- NYHA class II heart failure
- Society of Thoracic Surgeons risk of death is 20.9%

Medical and Surgical History

- Severe AS with a valve area of 0.73; mild to moderate AR with a mean transaortic gradient of 44 mm Hg
- CAD, four-vessel CABG 11 years earlier
- Placement of two bare metal stents 1 month earlier
- Moderate mitral regurgitation
- Atherosclerotic cerebrovascular disease, bilateral carotid endarterectomy 2 years earlier
- Mild pulmonary hypertension
- Type 2 diabetes mellitus
- Hypercholesterolemia
- Hypertension
- Chronic kidney disease
- Peripheral vascular disease
- Sleep apnea

Current Medications

- Furosemide, 40 mg once per day
- Glipizide, 10 mg bid
- Hydralazine, 25 mg tid
- Metoprolol, 25 mg bid
- Nitroglycerin (NitroQuick), 0.4 mg prn
- Rosuvastatin, 20 mg
- Timolol, 0.5% drops
- No known medication allergies

Vital Signs

- Height: 154.80 cm
- Weight: 61 kg
- Body mass index (BMI): 25.5 kg/m^2
- Body surface area (BSA): 1.64 m^2
- Afebrile
- Pulse 58/min
- Blood pressure: 156/61 mm Hg
- Chest radiograph
  - Sternotomy
  - Prominent left nipple shadow
  - Fibrotic strands in the bases
  - Calcified granulomas
  - Surgical clips on left side of the neck
  - Unchanged since previous radiograph
- Electrocardiogram
  - Ventricular rate: 56
  - Sinus bradycardia, left ventricular hypertrophy with secondary ST-T abnormalities
  - Cannot rule out anteroseptal infarct
  - No significant change was found

Laboratory Results

- Hemoglobin: 12.8 g/dL
- Platelets: 164,000/μL
- International normalized ratio (INR): 1.0
- Sodium (Na^+): 138 mmol/L
- Potassium (K^+): 4.0 mmol/L
- Glucose: 109 mg/dL
- Creatinine: 2.2 mg/dL

Data Collection and Interpretation

Computed Tomography Without Contrast of the Chest, Abdomen, and Pelvis

The aortic annulus measured 33 mm. The left main artery–to–aortic valve annulus dimension was 18 mm. The diameter at the sinus of Valsalva was 35 mm. The sinotubular junction was 31 mm. The diameter of the ascending aorta was 34 mm. The diameter of the aortic arch was 24 mm. The diameter of the aorta at the diaphragm was 24 mm. Extensive vascular disease included coronary artery calcifications. There were extensive aortic valve and mitral annular calcifications.

Bilateral renal atrophy was identified. The infrarenal aorta was 10 × 12 mm. The right common iliac artery was 10 × 11 mm. The right external iliac artery was 8 × 8 mm. The right common femoral artery was 5 × 6 mm. The left common iliac artery was 10 × 9 mm. The left external iliac artery was 9 × 9 mm, and the left common femoral artery was 5 × 5 mm.

Cardiac Catheterization and Percutaneous Transluminal Coronary Angioplasty Summary

The patient had a prior four-vessel CABG. Angiography showed patent vein grafts to the first and second obtuse marginal branches and to the diagonal branch. The free LIMA graft to the LAD artery had severe disease. The patient's native right coronary artery had severe disease, but this vessel could not be bypassed earlier when he had CABG surgery. The patient also has chronic renal insufficiency limiting the possibility of multivessel percutaneous coronary intervention because of limitation in contrast load. He had successful percutaneous transluminal coronary angioplasty (PTCA) of the middle LAD artery and

successful PTCA of the distal site of free internal mammary graft to the middle LAD artery.

Description of Operation

The patient underwent general anesthesia in the supine position, and a left inframammary incision was made in the chest entered over the top of the fifth rib. Purse-string sutures were placed just lateral to the apex of the heart. Heparin was given, and the activated coagulation time (ACT) was maintained above 300 seconds. The apex of the heart was punctured with a needle, and the wire was advanced across the aortic valve under fluoroscopic guidance. A wire was advanced up into the proximal ascending aorta, and a 23-cm, 7-Fr sheath was advanced across the aortic valve. The 7-French sheath was removed. The Ascendra sheath was inserted without difficulty. The balloon was advanced across the aortic valve. Rapid ventricular pacing was instituted and the balloon aortic valvuloplasty completed. The balloon was removed, but the patient remained hypotensive with increases in his PAPs refractory to escalating doses of epinephrine. We elected to proceed rapidly with placement of the valve.

Rapid ventricular pacing was instituted, and the valve was positioned perfectly. The balloon was deflated, and rapid ventricular pacing was stopped, but the patient remained hypotensive. The Ascendra sheath and wire were removed, and TEE showed good valvular function with no significant AR. Because there was significant PAP elevation and right-heart function was poor by TEE, the patient was prepared for femoral-femoral bypass.

A percutaneous arterial cannula was placed over a wire, the femoral artery was dilated without apparent difficulty, and a 15-Fr percutaneous arterial inflow cannula was placed. A 22-Fr percutaneous venous cannula was then inserted, and CPB was initiated. During this time, the patient was hypotensive and required initiation of external cardiac massage. The patient had recurrent ventricular fibrillation and was successfully defibrillated to a stable cardiac rhythm.

The PAPs began to decline, and the heart function appeared to improve. However, the CPB circuit volume could not be maintained, and a retrograde arteriogram identified extravasation of contrast at the bifurcation of the right common iliac artery. An attempt was made to place an endograft. A balloon was inflated in the infrarenal aorta to achieve proximal control to come off CPB. The arterial inflow line was transferred to the venous line to continue to give blood. Limited angiography confirmed disruption of the proximal right external iliac artery. Blood pressure could not be supported; the patient deteriorated and arrested. Despite cardiopulmonary resuscitation, the patient died (see Video 21.1).

Discussion

This case illustrates almost every major clinical point about the assessment and care of patients undergoing transapical AVR. There were clinical indications for a catheter-based approach:

1. The patient's desire not to undergo an open-chest approach
2. History of prior multivessel CABG
3. Perioperative risk factors, including advanced age, diffuse vasculopathy, and chronic renal insufficiency

Evaluation for a catheter-based approach demonstrated aortic valvular, sinus, and coronary anatomy suitable for catheter-based placement but severe iliac and femoral vasculopathy that excluded a transarterial approach.

A multidisciplinary approach to evaluation and preoperative optimization included participation of the cardiac surgery, echocardiography, interventional cardiology, anesthesiology, and radiology departments. The patient underwent cardiac catheterization, PTCA, and noncontrast computed tomography, and surgery was scheduled a month later to allow renal recovery.

The case was managed in a hybrid operating room with the presence of specialists in interventional cardiology and cardiovascular surgery, along with CPB standby and one-to-one coverage by a cardiovascular anesthesiologist. The technical approach to surgery was exactly as planned. Femoral vessels were wired in advance, and by a transapical approach, the valve was positioned without difficulty. However, three complications developed that are relatively common with this technique in this population: refractory hypotension after rapid ventricular pacing, difficulty in establishing rapid CPB support because of the small size and calcification of femoral and iliac vessels, and iliac artery disruption.

Although catheter-based AVR is less invasive than the open-chest approach, it probably requires more planning, complex assessment, and coordination than conventional cardiac surgery. Most patients have comorbid conditions that make them poor open surgical candidates, and untoward events during these procedures are life-threatening.

Case Study 2: Robotically Assisted Mitral Valve Repair

Framing

A 46-year-old woman had a 4-month history of decreasing tolerance for strenuous exercise. An advertising executive and amateur triathlete, she reported that increased fatigue prevented her from jogging more than 4 miles in a day. Evaluation by her physician revealed a new systolic murmur, and she was referred for echocardiography.

TTE revealed a flail posterior mitral valve leaflet with an eccentric, anteromedially directed jet of severe MR. Reliable quantification of the regurgitant volume by the PISA method was not possible. However, systolic flow reversals were identified during pulsed-wave Doppler examination of the right superior pulmonary vein. This study also demonstrated normal left ventricular dimensions in systole and diastole and a calculated EF of 67%. The LA was mildly enlarged. The right-heart chambers were of normal size, and the calculated right ventricular systolic pressure was 35 mm Hg.

During an appointment with a cardiologist, surgical consultation for possible mitral valve repair was recommended. The patient was hesitant to pursue surgery for several reasons. She worried about missing work and being unable to drive during a multiweek postoperative convalescence. She was concerned about the cosmetic implications of a median sternotomy, and she was uncertain about her need for surgical intervention at that time because she experienced symptoms only with vigorous exercise.

Data Collection and Interpretation

Although visualization of the mitral valve is superior with TEE compared with TTE, flail mitral leaflets often can be identified during transthoracic examinations. This patient had a flail leaflet that was likely caused by chordal rupture. Although quantification of the mitral regurgitant volume or effective regurgitant orifice by the PISA method was not possible during the TTE examination, the severity of the regurgitation was supported by the finding of systolic flow reversals in the right superior pulmonary vein. The right superior pulmonary vein is often the easiest pulmonary vein to visualize during TTE studies when using an apical four-chamber view. PISA analysis may be difficult in some patients with eccentrically directed regurgitant jets because of the difficulty in aligning the Doppler cursor with a significant portion of the regurgitant jet, with the resultant inability to measure the peak regurgitant velocity and obtain a complete regurgitant velocity-time integral.

In addition to detecting severe, organic MR, other important information was obtained during the TTE examination. For example, there was no evidence of left ventricular enlargement, and the calculated EF was 67%. Mild left atrial enlargement was consistent with the reported 4-month history of symptoms; severe MR of longer duration might be expected to produce a greater degree of left atrial dilation. A calculated right ventricular systolic pressure of 35 mm Hg likely corresponds to a mean PAP of less than 25 mm Hg and does not indicate pulmonary hypertension.

If surgical intervention is anticipated, additional information must be sought. Confirmation of the mechanism of MR and a thorough inspection for anterior leaflet pathology can be obtained by intraoperative TEE. The presence or absence of a patent foramen ovale can be determined by intraoperative TEE. The decision about whether to pursue preoperative coronary angiography in a 46-year-old, athletic woman depends on other risk factors for premature CAD and physician preference. The preoperative electrocardiogram should be examined for evidence of atrial tachyarrhythmias such as AF that may lead to consideration of additional surgical interventions such as the Maze procedure or exclusion of the left atrial appendage.

Decision Making and Reassessment

In deciding whether to proceed with surgery in this patient, several factors must be considered. Her MR was organic in nature, and medical management was unlikely to prevent deleterious structural changes in the heart over time such as left ventricular dilation. Progression of the severity of MR can be expected in the absence of surgical intervention.[307] A flail mitral leaflet is associated with a small but defined increase in the annual risk for sudden cardiac death; the risk can be reduced by surgical repair.[306] The patient's LVEF is currently acceptable. Postponing surgery risks the development of left ventricular systolic dysfunction. A decline in EF to less than 60% is associated with reduced survival after mitral surgery.[310] All these factors combined with a procedural mortality rate of less than 1% in many centers argue for early elective mitral valve repair.

Concerns related to cosmetic outcome and delayed return to work may be addressed by offering the patient a minimally invasive surgical approach with or without robotic assistance. A 4-cm incision in the right inframammary crease provides an excellent cosmetic result for many women. Minimally invasive techniques, including robotically assisted surgery, have been associated with decreased postoperative pain scores, earlier hospital discharge, and earlier return to work.

The patient was referred to a surgeon who was experienced in robotically assisted mitral valve repair. On the day of surgery, the anesthesiologist performed a series of right paravertebral injections before induction of anesthesia. One-lung ventilation was achieved by means of a double-lumen endotracheal tube. The intraoperative TEE confirmed the presence of a flail middle scallop of the posterior mitral leaflet with multiple ruptured chords (see Videos 21.2 and 21.3). No additional valvular pathology was found, and the atrial septum was intact. Cannulation for CPB, which was guided by intraoperative TEE, included femoral arterial and venous lines, as well as a 16-Fr superior vena cava cannula placed percutaneously through the right internal jugular vein. Cardioplegia was given antegrade through a catheter placed into the aorta by means of a right parasternal stab incision. Aortic cross-clamping was accomplished with a long-shafted clamp introducer through a stab incision in the right lateral chest wall. Mitral repair was performed with robotic assistance and consisted of a triangular resection of the middle scallop of the posterior mitral leaflet and insertion of a flexible posterior annuloplasty band.

The patient was weaned from CPB without difficulty and extubated in the operating room at the conclusion of surgery. Her postoperative course was uneventful, and she was discharged on postoperative day 3.

Case Study 3: Mitral Valve Repair With Systolic Anterior Motion After Bypass Needing Additional Repair

A 66-year-old male presented for mitral valve repair. He had a known history of moderate MR followed for 7 years. He had recently developed worsening of his chronic shortness of breath. Echo showed more LV dilatation compared to 6 months ago. His mitral regurgitant volume was 79 mL, his LA was dilated at 63mm. His LV end-diastolic and end-systolic diameters were 58 and 33mm, respectively. EF was preserved at 66%.

Video 21.4 shows a significantly prolapsed P2 segment. On CPB, the leaflets were severely myxomatous with a prolapsed P2 and a long, floppy anterior leaflet. The surgical repair consisted of a quadrangular P2 resection with extended sliding leaflet repair reinforced with a 30-mm partial annuloplasty band placed trigone to trigone. Coming off CPB, the long anterior leaflet and the patient's hyperdynamic conditions created severe MR with systolic anterior motion (SAM) of the mitral valve (see Videos 21.5 and 21.6).

A decision was made to surgically correct this phenomenon. The patient was placed back on full CPB. The heart was rearrested, the LA was reopened, and the surgeon performed a more radical sliding-leaflet resection of the entire posterior leaflet.

The patient was weaned off CPB without inotropes and under better loading conditions (see Videos 21.7 and 21.8). The patient had no residual SAM and had good valve function with no residual MR.

Congenital Heart Disease in Adults

VICTOR C. BAUM, MD | DUNCAN G. DE SOUZA, MD, FRCPC

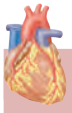
KEY POINTS

1. Because of successes in treating congenital cardiac lesions, there are currently as many or more adults than children with congenital heart disease (CHD).
2. These patients may require cardiac surgical intervention for primary cardiac repair, repair following prior palliation, revision of repair due to failure or lack of growth of prosthetic material, or conversion of a suboptimal repair to a more modern operation.
3. Noncardiac anesthesiologists will see these patients for a vast array of ailments and injuries requiring surgery.
4. If at all possible, noncardiac surgery on adult patients with moderate-to-complex CHD should be performed at an adult congenital heart center with the consultation of an anesthesiologist experienced with adult CHD.
5. Delegation of one anesthesiologist as the liaison with the cardiology service for preoperative evaluation and triage of adult CHD patients is helpful.
6. All relevant cardiac tests and evaluations should be reviewed in advance.
7. Sketching out the anatomy and path(s) of blood flow is often an easy and enlightening aid in simplifying apparently very complex lesions.

Advances in perioperative care for children with congenital heart disease (CHD) over the past several decades has resulted in an ever-increasing number of these children reaching adulthood with their cardiac lesions palliated or repaired. The first paper on adult CHD, published in 1973,[1] is of increasing interest to the medical community. A brief search for the term "adult congenital heart disease" found 51 papers published from 1995 to 2004 and 433 from 2005 to 2014. The field has grown such that several texts are now devoted to it, and a dedicated specialty society, the International Society for Adult Congenital Heart Disease (http://www.isachd.org), was formed in the 1990s. Each year an estimated 32,000 new cases of CHD occur in the United States and 1.5 million worldwide.[2] More than 85% of infants born with CHD are expected to grow to adulthood. It is estimated that there are more than 1 million adults with CHD in the United States[3] and 1.2 million in Europe,[4] and this population is growing at approximately 5% per year; 55% of these adults remain at moderate-to-high risk, and more than 115,000 in the U.S. have complex disease.[5] The increasing survival of children with complex disease has shifted the spectrum of adults with CHD. Once it was thought that adults represent milder degrees of disease, but this is now changing.[3,6,7] Annual admissions for adults with CHD have increased significantly faster than those for children, and adults now account for 37% of admissions for those with CHD.[7] As many adults as children have congenital cardiac defects considered severe.[6] As an example to support the increased life expectancy of this patient group, the leading cause of mortality in adults with acyanotic CHD in the United States is currently coronary artery disease (arrhythmia remains the leading cause of death for cyanotic patients, as it was for acyanotic patients before 1990).[8] Not surprisingly, mortality in adults with CHD is increased with increased disease severity, and in one large series 77% of deaths in this group were from cardiovascular causes.[9] These patients can be seen by anesthesiologists for primary cardiac repair, repair following a prior palliation, revision of repair due to failure or lack of growth of prosthetic material, or conversion of a suboptimal repair to a more modern operation (Box 22.1). In addition, these adults with CHD will be seen for the other common ailments of aging and trauma that require surgical intervention. Additionally, women of childbearing age with CHD will become pregnant. They must cope with the added physiologic demands of pregnancy and will require analgesia for labor and anesthesia for cesarean delivery. Although it has been suggested that teenagers and adults can have repair of congenital cardiac defects with morbidity and mortality approaching that of surgery done during childhood, these data are limited and may reflect only a relatively young and acyanotic sampling.[10] Other data suggest that, in general, adults over 50 years of age represent an excessive proportion of the early postoperative mortality encountered, and the number of previous operations and cyanosis are both risk factors.[11]

Despite the fact that congenital cardiac disease carries implications for lifelong medical problems, a significant number of patients, even those with lesions deemed severe, will not have continuing cardiology follow-up, despite ongoing general medical care.[12] These patients bring with them anatomic and physiologic complexities of which physicians accustomed to caring for adults may be unaware, as well as medical problems associated with aging or pregnancy that might not be familiar to physicians used to caring for children. This is even more complicated because a significant number of these patients will be unaware of their cardiac diagnosis, and having lived with their disease for many years, these patients will self-limit exercise or think of themselves as asymptomatic, when in fact they are not.[13] This problem has led to the establishment of the growing subspecialty of adult CHD. Two Bethesda conferences have been devoted to the issue, most recently in 2001.[14] The American College of Cardiology reviewed the available evidence and published superb guidelines for the care of these patients in 2008.[15] It is important to note that most of the current recommendations are based on Level C evidence (only consensus opinion or case studies) because prospective studies and large registries of patient outcomes are rare. A major recommendation of both Bethesda Conferences (also recommended by conferences in Canada[16] and Europe[17]) was that adult patients with moderate or complex CHD be cared for in specialized adult congenital heart centers. This recommendation, as logical as it was, was unsupported until recently, when a study from Quebec showed that mortality for adult congenital heart disease (ACHD) patients decreased following the introduction of specialized ACHD centers and that less than half die of cardiovascular diseases.[18] This

These contributions represent our best judgment and do not bind or obligate the U.S. Food and Drug Administration.



BOX 22.1 INDICATIONS FOR CARDIAC SURGERY IN ADULTS WITH CONGENITAL HEART DISEASE

- Primary repair
- Total correction following palliation
- Revision of total correction
- Conversion of suboptimal obsolescent operation into more modern repair
- Heart transplantation

is in contrast to the findings of the Dutch CONCOR registry, which found that 77% of deaths were cardiovascular in origin: chronic heart failure in 26% (mean age 51 years) and sudden death in 19% (mean age 39 years) were the most common.[9] Another review determined that among adults with CHD and cyanotic lesions, the leading cause of death was arrhythmia followed by heart failure. For patients with acyanotic disease, however, the leading cause of death until 1990 was arrhythmia; after 1990, it was myocardial infarction, consistent with the longer lifespan of these patients.[19]

An informed anesthesiologist is a critical member of the team required to care optimally for these patients. A specific recommendation of the Bethesda conference was that noncardiac surgery on adult patients with moderate-to-complex CHD be done at an adult congenital heart center (regional centers) with the consultation of an anesthesiologist experienced with ACHD.[14,20] In fact, one of the founding fathers of the subspecialty wrote, "A cardiac anesthesiologist with experience in CHD is pivotal … . The cardiac anesthesiologist and the attending cardiologist are more important than the noncardiac surgeon."[2] Despite this recommendation, the majority of adult patients with CHD having ambulatory surgery appear not to be having their surgery at ACHD centers.[21]

TABLE 22.1 Rhythm Disturbances in Adults With Congenital Heart Disease

Rhythm Disturbance	*Associated Lesions*
Tachycardias	
Wolff-Parkinson-White syndrome	Ebstein anomaly Congenitally corrected transposition
Intraatrial reentrant tachycardia (atrial flutter)	Postoperative Mustard Postoperative Senning Postoperative Fontan Tetralogy of Fallot Other
Atrial fibrillation	Mitral valve disease Aortic stenosis Tetralogy of Fallot Palliated single ventricle
Ventricular tachycardia	Tetralogy of Fallot Aortic stenosis Other
Bradycardias	
Sinus node dysfunction	Postoperative Mustard Postoperative Senning Postoperative Fontan Sinus venosus ASD Heterotaxy syndrome
Spontaneous AV block	AV septal defects Congenitally corrected transposition
Surgically induced AV block	Surgical VSD closure Subaortic stenosis relief AV valve replacement Device closure of VSD

ASD, Atrial septal defect; *AV,* atrioventricular; *VSD,* ventricular septal defect.

Noncardiac Surgery in Adults With Congenital Heart Disease

A recent study utilizing the National Surgical Quality Improvement Program database confirmed that young adults (aged 18-39 years) with a history of cardiac surgery had increased risk of a series of serious morbidities and mortality following noncardiac surgery.[22] A survey of academic anesthesiology faculty at a leading institution showed that, not unexpectedly, those with pediatric and cardiac fellowship training had better knowledge than other faculty about ACHD, whose knowledge was generally low and who had decreased levels of comfort in caring for these patients.[23] High-risk patients include, but are not limited to, those with Fontan physiology, cyanotic disease, severe pulmonary arterial hypertension, complex disease with residua such as heart failure, valve disease or the need for anticoagulation, or the potential for malignant arrhythmias (Table 22.1). Centers may find it helpful to delegate one attending anesthesiologist to be the liaison with the cardiology service to centralize preoperative evaluations and to delegate the triage of patients to an anesthesiologist with specific expertise in managing patients with CHD, rather than relying on random consultations with generalist anesthesiologists.[23]

Adults with CHD represent approximately 0.1% of admissions represented in the National Inpatient Sample, and this has increased from about 0.07% to 0.18% from 2002 to 2009.[24] The fraction of adult CHD admissions associated with noncardiac surgery also increased over this time period. Most were cared for in nonteaching hospitals. It was shown several years ago that CHD conferred an incremental mortality risk with noncardiac inpatient surgery in children.[25] This has now been confirmed for adults with CHD having inpatient noncardiac surgery. In data from the National Inpatient Sample, mortality was greater in the adult CHD cohort (odds ratio 1.3), as was a composite morbidity endpoint (odds ratio 1.44) compared with a matched cohort without CHD.[24] In both the pediatric and adult studies, mortality was highest with the most complex lesions. Risk factors for noncardiac surgery include heart failure, pulmonary hypertension, and cyanosis.[26]

The classic examination question of onset of anesthesia with right-to-left versus left-to-right shunts and with inhalational versus intravenous inductions pertains here as well. Because the lungs are bypassed by a fraction of the blood in right-to-left shunts, the onset of intravenous agents is faster, because it takes less time to enter the systemic circulation. The opposite is true for left-to-right shunts, because a fraction of an intravenous agent will recirculate from the systemic circulation to the pulmonary. The situation is opposite for inhalation inductions, where the onset is slower in right-to-left shunts. However, with the newer, low-solubility volatile anesthetic, this difference might not be clinically apparent until the degree of right-to-left shunting becomes significant, generally oxygen saturation in the upper 80% range or less. In general, patients with right-to-left shunts will have systemic oxygen saturation increases with the induction of anesthesia. With the decrease in oxygen consumption, the saturation of mixed venous blood—the blood that will be shunted—is increased, so that the "final" systemic arterial saturation will be increased.

General Noncardiac Issues With Longstanding Congenital Heart Disease

A variety of organ systems can be affected by longstanding CHD; these are summarized in Box 22.2 and Box 22.3. Because congenital cardiac disease can be one manifestation of a multiorgan genetic or dysmorphic syndrome, all patients require a full review of systems and examination.

BOX 22.2 POTENTIAL NONCARDIAC ORGAN INVOLVEMENT IN PATIENTS WITH CONGENITAL HEART DISEASE

Potential Respiratory Implications
- Decreased compliance (with increased pulmonary blood flow or impediment to pulmonary venous drainage)
- Compression of airways by large, hypertensive pulmonary arteries
- Compression of bronchioles
- Scoliosis
- Hemoptysis (with end-stage Eisenmenger syndrome)
- Phrenic nerve injury (prior thoracic surgery)
- Recurrent laryngeal nerve injury (prior thoracic surgery; very rarely from encroachment of cardiac structures)
- Blunted ventilatory response to hypoxemia (with cyanosis)
- Underestimation of $PaCO_2$ by capnometry in cyanotic patients

Potential Hematologic Implications
- Symptomatic hyperviscosity
- Bleeding diathesis
- Abnormal von Willebrand factor
- Artifactually elevated prothrombin/partial thromboplastin times with erythrocytic blood
- Artifactual thrombocytopenia with erythrocytic blood
- Gallstones

Potential Renal Implication
- Hyperuricemia and arthralgias (with cyanosis)

Potential Neurologic Implications
- Paradoxical emboli
- Brain abscess (with right-to-left shunts)
- Seizure (from old brain abscess focus)
- Intrathoracic nerve injury (iatrogenic phrenic, recurrent laryngeal, or sympathetic trunk injury)

BOX 22.3 NONCARDIAC ORGAN SYSTEMS WITH POTENTIAL INVOLVEMENT BY LONGSTANDING CONGENITAL HEART DISEASE

- Pulmonary
- Hematologic
- Renal
- Neurologic
- Vasculature
- Genitourinary (pregnancy)
- Psychosocial

Pulmonary

Any lesion that results in either increased pulmonary blood flow or pulmonary venous obstruction can cause increased pulmonary interstitial fluid with decreased pulmonary compliance and increased work of breathing.[27] Patients with cyanotic heart disease have increased minute ventilation and maintain normocarbia.[28] These patients have a normal ventilatory response to hypercapnea but a blunted response to hypoxemia that normalizes after corrective surgery and the establishment of normoxia.[29–31] End-tidal CO_2 underestimates arterial $PaCO_2$ in cyanotic patients with decreased, normal, or even increased pulmonary blood flow.[32]

Although enlarged hypertensive pulmonary arteries or an enlarged left atrium can impinge on bronchi in children, this is rare in adults. Late-stage Eisenmenger syndrome can result in hemoptysis, and patients with Eisenmenger physiology and erythrocytosis can develop thrombosis of upper lobe pulmonary arteries.[33] Prior thoracic surgery could have injured the phrenic nerve with resultant diaphragmatic paresis or paralysis.

Scoliosis can occur in up to 19% of CHD patients, most commonly in cyanotic patients. It can also develop in adolescence, years after surgical resolution of cyanosis.[34] The relative contributions of cyanosis and congenital cardiovascular defects versus early lateral thoracotomy remain unclear—scoliosis occurs more commonly with open surgical versus interventional techniques but is nevertheless increased over the general population in children with coarctation or patent ductus who had percutaneous rather than open interventions.[35] Scoliosis is rarely severe enough to impact respiratory function.

In an attempt to increase pulmonary blood flow, large collateral vessels originating from the aorta may have developed. These are sometimes embolized in the catheterization laboratory before thoracic surgery to prevent excessive intraoperative blood loss.

BOX 22.4 SYMPTOMS OF HYPERVISCOSITY

- Headache
- Faintness, dizziness, light-headedness
- Blurred or double vision
- Fatigue
- Myalgias, muscle weakness
- Paresthesias of fingers, toes, or lips
- Depressed or dissociative mentation

Hematologic

Hematologic manifestations of chronic CHD are primarily a consequence of longstanding cyanosis and incorporate abnormalities of both hemostasis and red cell regulation. Longstanding hypoxemia causes increased erythropoietin production in the kidney and resultant increased red cell mass. Because solely red cell production is affected, these patients are correctly referred to as erythrocytotic rather than polycythemic. There is, however, a fairly poor relationship among oxygen saturation, red cell mass, and 2,3-diphosphoglycerate.[36] The oxygen-hemoglobin dissociation curve is normal or minimally shifted to the right. Most patients have established an equilibrium state at which they have a stable hematocrit and are iron replete. Some patients, however, develop excessive hematocrits and are iron deficient, causing a hyperviscous state. Iron-deficient red cells are less deformable and cause increased viscosity for the same hematocrit.[37] This is a strong independent predictor of thrombosis in the setting of Eisenmenger syndrome. However, recently there is some conflicting evidence.[38] Symptoms of hyperviscosity are uncommon and typically develop only at hematocrits exceeding 65%, provided the patient is iron replete. Iron deficiency also shifts the oxygen-hemoglobin dissociation curve to the right, decreasing oxygen affinity in the lungs.[39] Symptoms of hyperviscosity are listed in Box 22.4. Iron deficiency can be the result of misguided attempts to lower the hematocrit by means of repeated phlebotomies.[40] The red cells in these patients may be hypochromic and microcytic despite the high hematocrit. Assessment of iron status is best done by measures of serum ferritin and transferrin rather than inferences from red cell indices.[40] Treatment with oral iron needs to be undertaken with care, because rapid increases in hematocrit can result.

Symptomatic hyperviscosity is the indication for treatment to temporarily relieve symptoms. It is not indicated to treat otherwise asymptomatic elevated hematocrits (generally hemoglobin >20 and hematocrit >65). Treatment is by means of a partial isovolumic exchange transfusion, and it is assumed that the increased hematocrit is not related to dehydration. Partial isovolumic exchange transfusion usually results in regression of symptoms within 24 hours. It is rare to require exchange of more than 1 unit of blood. Preoperatively, phlebotomized blood can be banked for autologous perioperative

retransfusion if required. Elective preoperative isovolumic exchange transfusion has decreased the incidence of hemorrhagic complications of surgery.[41,42]

Hyperviscosity and erythrocytosis can cause cerebral venous thrombosis in younger children, but it is not a problem in adults, regardless of the hematocrit.[33] Protracted preoperative fasts need to be avoided in erythrocytotic patients, because they can be accompanied by rapid elevations in the hematocrit.

Bleeding dyscrasias have been described in up to 20% of patients. A variety of clotting abnormalities have been described in association with cyanotic CHD, although none uniformly.[43] Bleeding dyscrasias are uncommon until the hematocrit exceeds 65%, although excessive surgical bleeding can occur at lower hematocrits. Generally, higher hematocrits are associated with a greater bleeding diathesis. Abnormalities of a variety of factors in both the intrinsic and extrinsic coagulation pathways have been described inconsistently. Both cyanotic and acyanotic patients have been reported with deficiencies of the largest von Willebrand factor multimers, which have normalized following reparative surgery.[44] Fibrinolytic pathways are normal.[45]

The decreased plasma volume in erythrocytotic blood can result in spuriously elevated measures of the prothrombin and partial thromboplastin times, and the fixed amount of anticoagulant in the collection tube will be excessive because it presumes a normal plasma volume in the blood sample. Erythrocytotic blood has more red cells and less plasma in the same volume. If informed in advance of a patient's hematocrit, the clinical laboratory can provide an appropriate sample tube. Normalizing to a hematocrit of 45%, the amount of citrate added to the tube can be calculated:

$$\text{mL citrate} = (0.1 \times \text{Blood volume collected}) \times [(100 - \text{Patient's hematocrit}) \div 55]$$

Platelet counts are typically normal or occasionally low, but bleeding is not due to thrombocytopenia. Platelets are reported per milliliter of blood, not per milliliter of plasma. When corrected for the decreased plasma fraction in erythrocytotic blood, the total plasma platelet count is closer to normal. That said, abnormalities in platelet function and life span have on occasion been reported.[46,47] Patients with low-pressure conduits (Fontan pathway) or synthetic vascular anastomoses are often maintained on antiplatelet drugs.

Cyanotic erythrocytotic patients have excessive hemoglobin turnover, and adults have an increased incidence of calcium bilirubinate gallstones. Biliary colic can develop years after cyanosis has been resolved by cardiac surgery.[33]

A variety of mechanical factors can also affect excessive surgical bleeding in patients with cyanotic CHD. These factors include increased tissue capillary density, elevated systemic venous pressure, aortopulmonary and transpleural collaterals that have developed to increase pulmonary blood flow, and prior thoracic surgery. Aprotinin and ε-aminocaproic acid improve postoperative hemostasis in patients with cyanotic CHD.[48] The results with tranexamic acid have been mixed.[49]

Renal

Some degree of renal insufficiency is not uncommon in adults with CHD, and the severity is a predictor of mortality. Moderate or severe renal dysfunction (estimated glomerular filtration rate of <60 mL/min/m^2) carries a five-fold increased risk of death at 6-year follow-up compared with patients with normal glomerular filtration rate and a three-fold increase over those with mild elevations in glomerular filtration rate [50] Renal dysfunction is particularly prevalent in cyanotic patients and those with poor cardiac function. Adult patients with cyanotic CHD can develop abnormal renal histology with hypercellular glomeruli and basement membrane thickening, focal interstitial fibrosis, tubular atrophy, and hyalinized afferent and efferent arterioles.[51] Cyanotic CHD is often accompanied by elevations in plasma uric acid levels that are due to inappropriately low fractional uric acid excretion.[52] Decreased urate reabsorption is thought to result from renal hypoperfusion with a high filtration fraction. Despite the elevated uric acid levels, urate stones and urate nephropathy are rare.[53] Although arthralgias are common, true gouty arthritis is less frequent than would be expected from the degree of hyperuricemia.[52] There appears to be an increased incidence of postcardiopulmonary bypass renal dysfunction in adults with longstanding cyanosis.[54]

Neurologic

Adults with persistent or potential intracardiac shunts remain at risk for paradoxical embolism. Paradoxical emboli can occur even through shunts that are predominantly left to right, because during the cardiac cycle there can be small transient reversals of the shunt direction. It has been said that, unlike in children, adults with cyanotic CHD are not at risk for the development of cerebral thrombosis despite the hematocrit.[33,55] However, this assertion has been challenged by Ammash and Warnes,[56] who suggested an association of stroke, not with red cell mass, but with iron deficiency and repeated venesection. Adults do, however, remain at risk for the development of brain abscess. A healed childhood brain abscess can provide the nidus for the development of seizures throughout life.

Prior thoracic surgery can result in permanent peripheral nerve damage. Surgery at the apices of the lungs is particularly associated with the risk of nerve damage. These operations would include Blalock-Taussig shunts, ligation of patent ductus arteriosus (PDA), banding of the pulmonary artery, and repair of aortic coarctation. Nerves that are susceptible to injury include the recurrent laryngeal nerve, the phrenic nerve, and the sympathetic chain. The incidence of migraine headaches is higher in adults with CHD compared with a control group with acquired heart disease (45% vs 11%) and is increased in left-to-right, right-to-left, and no-shunt groups.[57]

Vasculature

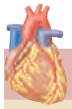
Vessel abnormalities can be congenital or iatrogenic. They can affect the suitability of vessels for cannulation by the anesthesiologist or measurement of correct pressures. These abnormalities are described in Table 22.2.

Pregnancy

The physiologic changes of pregnancy, labor, and delivery can significantly alter the physiologic status of women with CHD, and mortality and morbidity are increased in mothers with CHD.[58] There are several

TABLE 22.2 Potential Vascular Access Issues

Vessel	*Possible Problem*
Femoral vein(s)	May have been ligated if cardiac catheterization was done by cutdown. Large therapeutic catheters in infants often thrombose femoral veins.
Inferior vena cava	Some lesions, particularly when associated with heterotaxy (polysplenia) have discontinuity of the inferior vena cava; Will not be able to pass a catheter from the groin to the right atrium.
Left subclavian and pedal arteries	Distal blood pressure will be low in the presence of coarctation of the aorta or following subclavian flap repair (subclavian artery only), and variably so if postoperative recoarctation; pulses can be absent or palpable with abnormal blood pressure.
Subclavian artery	Blood pressure low with classic Blalock-Taussig shunt on that side, and variably so with modified Blalock-Taussig shunt.
Right subclavian artery	Blood pressure artifactually high with supravalvular aortic stenosis (Coanda effect).
Superior vena cava	Risk of catheter-related thrombosis with Glenn operation.



BOX 22.5 RISK FACTORS FOR PREGNANCY

- Pulmonary hypertension
- Depressed ventricular function
- Marfan syndrome with dilated aortic root
- Cyanosis
- Severe left heart obstructive lesions
- Pressure (vs volume) lesions

texts available that specifically discuss issues of the pregnant woman with CHD in more detail than is possible here.[59–61] Also, a recent review has been completed of generic cardiac surgery in the parturient.[62] Management and clinical outcomes during pregnancy and delivery for several cardiac lesions are included under the later discussions of those lesions.

Although cardiac complications, spontaneous abortions, premature delivery, thrombotic complications, peripartum endocarditis, and poor fetal outcomes can occur,[63] successful pregnancy to term with vaginal delivery is possible for most patients with congenital defects.[64] High-risk factors for mother and fetus are shown in Box 22.5. Eisenmenger physiology is a particular risk factor. Up to 47% of cyanotic women have worsening of functional capacity during pregnancy.[65] Hematocrits greater than 44% are associated with birth weights less than 50th percentile, and fetal death is about 90% or more with hemoglobin levels greater than 18 g/dL or oxygen saturation less than 85%, with most losses in the first trimester. The increases in stroke volume and cardiac output during pregnancy can stress an already pressure-overloaded ventricle. The decrease in systemic vascular resistance that accompanies pregnancy is better tolerated by women with regurgitant lesions and typically offsets the added insult of pregnancy-related hypervolemia. The decrease in systemic vascular resistance can, however, increase right-to-left shunting. Hypervolemia can be problematic in patients with poor ventricular function. Maternal cyanosis is associated with increased incidences of prematurity and intrauterine growth retardation. Profound cyanosis is associated with a high rate of spontaneous abortion.[66] Endocarditis prophylaxis is not currently recommended for vaginal deliveries.[67] The recurrence risk of any congenital cardiac defect in a newborn is 2.3% with one affected older sibling (any defect), 7.3% with two, 6.7% if the mother has a congenital cardiac defect, but only 2.1% if the father is affected.[2] However, it has become apparent that recurrence risk can be specific to the type of maternal defect and the underlying genetic basis. If possible, pregnancies in mothers with CHD should be managed in a high-risk obstetric center with cardiologists experienced with the care of ACHD, and with early consultation with the obstetric anesthesia service. Women on long-term anticoagulation will likely need peripartum modifications, and postpartum thromboembolism is a potential significant problem.

Anesthesiologists will generally encounter pregnant patients well into the last trimester. Most of the major physiologic changes associated with pregnancy occur before the third trimester, and if patients have maintained good functional status to this point, they will have demonstrated themselves to be in a relatively low-risk group. Pregnancy is a stress test, and if they have successfully arrived at the mid-to-late third trimester, it is more likely that they will successfully tolerate delivery. Also, many high-risk women will have been counseled to avoid pregnancy. There is no a priori reason to favor an instrumented or cesarean delivery over a vaginal one. This is an obstetric, not cardiologic, decision. That said, there is a common belief that women with ACHD will not tolerate the "stress" of labor, particularly bearing down in the second stage. However, a well-functioning epidural makes uterine contractions easy to tolerate. Furthermore, avoidance of second-stage pushing is an option as long as progress is being made and can be combined with a maneuver such as low-outlet vacuum or forceps to facilitate delivery. A functioning epidural makes uterine contractions easy to tolerate. Bearing down, associated with the second stage, requires close observation. The third stage can be accompanied by an autotransfusion of placental blood or potentially with hypovolemia with uterine atony and hemorrhage. If oxytocic drugs are required, the hemodynamic effects must be kept in mind. Oxytocin will decrease systemic vascular resistance and increase heart rate and pulmonary vascular resistance (PVR). Methylergonovine will increase systemic vascular resistance. These rapid changes in loading conditions can be poorly tolerated in mothers with fixed cardiac output, and pulmonary edema or heart failure can develop.

Some mothers will be taking medications for their cardiac condition, including antiarrhythmics. In general these are safe for the infant.[68] Exceptions include beta-blockers that can interfere with fetal growth and the response of the fetus to the stress of labor, and amiodarone, which can affect fetal thyroid function. Maternal cardioversion would appear to be safe for the fetus at all stages because of the low intensity of the electrical field at the uterus. However, the fetus should be monitored throughout the procedure. Women with implanted internal defibrillators have carried successfully to term.[69] Should cardiopulmonary bypass (CPB) be required during pregnancy, it carries with it increased fetal risk, particularly if hypothermia is used. Care for the obstetrical patient is presented in more detail in Chapter 50.

Psychosocial

Teenagers with CHD are certainly no different from other teenagers in that issues of denial, a sense of immortality, and risk-taking behavior can affect optimal care for these youngsters. Bodies that carry scars from prior surgery and physical limitations can complicate the body-conscious teenage years. Although most adolescents and adults with CHD function well, adults with CHD are less likely to be married or cohabitating and are more likely to be living with their parents.[70] There are several reports of the psychosocial outcomes of adolescent and adult patients, but there are no well-done controlled studies.[71–78] It has been suggested that depression is common and can exacerbate the clinical consequences of the cardiac defect.

Adolescent CHD patients have higher medical care expenses than the general population, and they can have difficulty in obtaining life and health insurance after they can no longer be covered under their parents' policies.[79–81] Life insurance is somewhat more available to adult CHD patients than in the past; however, policies vary widely among insurers.[82]

The issue of denial or lack of awareness of their cardiac condition is very relevant in teenagers and young adults. While they are children, these patients rely on their parents to ensure regular cardiac appointments are kept and surveillance echocardiograms are done. Unfortunately, young adults with ACHD often do not appreciate their physiologic limitations because they have lived with them their entire life. Many often lack basic knowledge of their cardiac condition. Sadly, this can result in ACHD patients being "lost to follow-up" until they arrive in their local emergency department with an urgent condition requiring surgery.

Cardiac Issues

The basic hemodynamic effects of an anatomic cardiac lesion can be modified by time and by the superimposed effects of chronic cyanosis, pulmonary disease, or the effects of aging. Although surgical cure is the goal, true universal cure, without residua, sequelae, or complications, is uncommon on a population-wide basis. Exceptions include closure of a nonpulmonary hypertensive PDA or atrial septal defect (ASD), probably in childhood. Although there have been reports of series of surgeries on adults with CHD, the wide variety of defects and sequelae from prior surgery make generalizations difficult, if not impossible. Poor myocardial function can be inherent in the CHD but can also be affected by longstanding cyanosis or superimposed surgical injury, including inadequate intraoperative myocardial protection.[82,83] This is particularly true of adults who had their cardiac repair several decades ago when myocardial protection may not have been as good and when

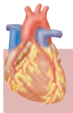
repair was undertaken at an older age. Postoperative arrhythmias are common, particularly when surgery entails long atrial suture lines, and the incidence of atrial arrhythmias increases with time, either as a primary sequela or as an indicator of diminished cardiac function.[84] Thrombi can be found in these atria precluding immediate cardioversion.[85] Bradyarrhythmias can be secondary to surgical injury to the sinus node or conducting tissue or can be a component of the cardiac defect.

The number of cardiac lesions and subtypes, together with the large number of contemporary and obsolescent palliative and corrective surgical procedures, make a complete discussion of all CHD impossible. The reader is referred to one of the current texts on pediatric cardiac anesthesia for more detailed descriptions of these lesions, the available surgical repairs, and the anesthetic implications during primary repair.[86,87] Some general perioperative guidelines to caring for these patients are offered in Box 22.6. This chapter provides a discussion of the more common and physiologically important defects that will be encountered in an adult CHD population. Defining outcome after CHD surgery is like trying to hit a continuously moving target. Both short-term and long-term results from older series can differ significantly from contemporary results.

Aortic Stenosis

Valvar aortic stenosis is the most common congenital heart defect but is often not seen in that light because it typically does not cause problems until adulthood. Most aortic stenosis in adults is due to a congenitally bicuspid valve that does not become problematic until late middle age or beyond, although endocarditis risk is lifelong. Congenital aortic stenosis can on some occasions, however, become severe enough to warrant surgical correction in adolescence or young adulthood, in addition to those severely affected valves that present in infancy. Once symptoms (angina, syncope, near-syncope, heart failure) develop, survival is markedly shortened. Median survival is 5 years after the development of angina, 3 years after syncope, and 2 years after heart failure.[88] Anesthetic management of aortic stenosis does not vary whether the stenosis is congenital (most common) or acquired (see Chapter 21).

Most mothers with aortic stenosis can successfully carry pregnancies to term and have vaginal deliveries. Severe stenosis (valve area <1.0 cm^2) can result in clinical deterioration and maternal and fetal mortality. Hemodynamic monitoring during delivery with maintenance of adequate preload and avoidance of hypotension is critical. When intervention is required during pregnancy, percutaneous balloon valvuloplasty is an attractive option compared with aortic valve replacement. A contraindication to balloon valvuloplasty is significant aortic insufficiency. Additionally, there is a risk of stroke from calcium that embolizes from the valve during balloon dilation. The quoted risk of stroke is usually higher than in surgical valve replacement; however, there is an overall benefit to the fetus in avoiding a procedure requiring CPB.



BOX 22.6 GENERAL APPROACH TO ANESTHESIA FOR PATIENTS WITH CONGENITAL HEART DISEASE

General

- The best care for both cardiac and noncardiac surgery in adult patients with congenital heart disease (CHD) is afforded in a center with a multidisciplinary team experienced in the care of adults with CHD and knowledgeable about both the anatomy and physiology of CHD and the manifestations and considerations specific to adults with CHD.

Preoperative

- Review most recent laboratory data, catheterization, and echocardiogram, and other imaging data. The most recent office letter from the cardiologist is often most helpful. Obtain and review these in advance.
- Drawing a diagram of the heart with saturations, pressures, and direction of blood flow often clarifies complex and superficially unfamiliar anatomy and physiology.
- Avoid prolonged fast if patient is erythrocytotic to avoid hemoconcentration.
- No generalized contraindication to preoperative sedation.

Intraoperative

- Large-bore intravenous access for redo sternotomy and cyanotic patients (see Table 22.2 for vascular access considerations).
- Avoid air bubbles in all intravenous catheters. There can be transient right-to-left shunting even in lesions with predominant left-to-right shunting (filters are available but will severely restrict ability to give volume and blood).
- Apply external defibrillator pads for redo sternotomies and patients with poor cardiac function.
- Appropriate endocarditis prophylaxis (orally or intravenously before skin incision).[53]
- Consider antifibrinolytic therapy, especially for patients with prior sternotomy.
- Transesophageal echocardiography for cardiac operations.
- Modulate pulmonary and systemic vascular resistances as appropriate pharmacologically and by modifications in ventilation.

Postoperative

- Appropriate pain control (cyanotic patients have normal ventilatory response to hypercarbia and narcotics).
- Maintain hematocrit appropriate for arterial saturation.
- Maintain central venous and left atrial pressures appropriate for altered ventricular diastolic compliance or presence of beneficial atrial level shunting.
- PaO_2 may not increase significantly with the application of supplemental oxygen in the face of right-to-left shunting. Similarly, neither will it decrease much with the withdrawal of oxygen (in the absence of lung pathology).

Aortopulmonary Shunts

Depending on their age, adult patients may have had one or more of several aortopulmonary shunts to palliate cyanosis during childhood. These are shown in Fig. 22.1. Although lifesaving, these shunts had considerable shortcomings in the long term. All were inherently inefficient, because some of the oxygenated blood returning through the pulmonary veins to the left atrium and ventricle would then return to the lungs through the shunt, thus volume loading the ventricle. It was difficult to quantify the size of the earlier shunts, such as the Waterston (side-to-side ascending aorta to right pulmonary artery) and Potts (side-to-side descending aorta to left pulmonary artery). If too small, the patient was left excessively cyanotic; if too large, there was pulmonary overcirculation with the risk of developing pulmonary vascular disease. The Waterston, in fact, could on occasion stream blood flow unequally, resulting in a hyperperfused, hypertensive ipsilateral (right) pulmonary artery and a hypoperfused contralateral (left) pulmonary artery. There were also surgical issues when complete repair became possible. Takedown of Waterston shunts often required a pulmonary arterioplasty to correct deformity of the pulmonary artery at the site of the anastomosis, and the posteriorly located Potts anastomoses could not be taken down from a median sternotomy. Patients with a classic Blalock-Taussig shunt almost always lack palpable pulses on the side of the shunt and arm length and strength can be mildly affected.[89] Even if there is a palpable pulse (from collateral flow around the shoulder), blood pressure obtained from that arm will be artifactually low. Even after a modified Blalock-Taussig shunt (using a piece of GORE-TEX tubing instead of an end-to-side anastomosis of the subclavian and pulmonary arteries), there can be a blood pressure disparity between the arms. To ensure a valid measurement, preoperative blood pressure should be measured in both arms (Table 22.3).

Modified Blalock-Taussig	GORE-TEX tube subclavian artery → ipsilateral pulmonary artery	Current
Central shunt	GORE-TEX tube ascending aorta → main pulmonary artery	Current

Atrial Septal Defect and Partial Anomalous Pulmonary Venous Return

There are several anatomic types of ASD. The most common type—and, if otherwise undefined, the presumptive type—is the secundum type located in the midseptum. The primum type at the lower end of the atrial septum is a component of endocardial cushion defects, the most primitive of which is the common atrioventricular canal (see later). The sinus venosus type, high in the septum near the entry of the superior vena cava, is almost always associated with partial anomalous pulmonary venous return, most frequently drainage of the right upper pulmonary vein to the low superior vena cava. An uncommon atrial septal–type defect occurs when blood passes from the left atrium to the right via an unroofed coronary sinus. For purposes of this section, only secundum defects are considered, although the natural histories of all of the defects are similar (Box 22.7).

Both the natural history and the postoperative outcome of ASDs and the physiologically related partial anomalous venous return are similar.[90–92] Because the symptoms and clinical findings of an ASD can be quite subtle and patients often remain asymptomatic until

BOX 22.7 COMPLICATIONS OF ATRIAL SEPTAL DEFECT IN ADULTHOOD

- Paradoxical emboli
- Effort dyspnea
- Atrial tachyarrhythmias
- Right-sided failure with pregnancy
- Pulmonary hypertension
- ↑ Right-sided failure with ↓ left ventricular compliance with aging
- Mitral insufficiency

adulthood, ASDs represent approximately one-third of all CHD discovered in adults. Although asymptomatic survival to adulthood is common, significant shunts ($\dot{Q}_p/\dot{Q}_s > 1.5:1$) will probably cause symptoms over time, and paradoxical emboli can occur through defects with smaller shunts. Surgical repair of restrictive lesions less than or equal to 5 mm in size does not impact the natural history. Thus surgical closure of small lesions is not indicated in the absence of paradoxical emboli. Effort dyspnea occurs in 30% by the third decade, and atrial flutter or fibrillation in about 10% by age 40.[90] The avoidance of complications developing in adulthood provides the rationale for surgical repair of asymptomatic children. The mortality for a patient with an uncorrected ASD is 6% per year over 40 years of age, and essentially all patients over 60 years of age are symptomatic.[90–92] Large unrepaired defects can cause death from atrial tachyarrhythmias or right ventricular failure in 30- to 40-year-old patients.[93] With the decreased left ventricular diastolic compliance accompanying the systemic hypertension or coronary artery disease that is common with aging, left-to-right shunting increases with age. Pulmonary vascular disease typically does not develop until after the age of 40, unlike ventricular or ductal level shunts, which can lead to it in early childhood. Mitral insufficiency can be found in adult patients and is significant in about 15% of adult patients.[94] Paradoxical emboli remain a lifelong risk.

Late closure of the defect, after 5 years of age, has been associated with incomplete resolution of right ventricular dilation.[95] Left ventricular dysfunction has been reported in some patients having defect closure in adulthood, and closure, particularly in middle age, may not prevent the development of atrial tachyarrhythmias or stroke.[96–99] Survival of patients without pulmonary vascular disease has been reported to be best if operated on before 24 years of age, intermediate if operated on between 25 and 41 years of age, and worst if operated on thereafter.[99] However, more recent series have shown that even at ages over 40, surgical repair provides an overall survival and complication-free benefit compared with medical management,[100] although pulmonary artery pressure can progress even after surgical closure if done late.[101] Surgical morbidity in these patients is primarily atrial fibrillation, atrial flutter, or junctional rhythm.[97] Current practice is to close these defects in adults in the catheterization laboratory via transvascular devices if anatomically practical (Fig. 22.2). For example, there needs to be an adequate rim of septum around the defect to which the device can attach. Device closure is inappropriate if the defect is associated with anomalous pulmonary venous drainage. The indications for closure with a transvascular device are the same as for surgical closure.[102] Surgical closure of ASD also lends itself to a thoracoscopic approach.[103]

An otherwise uncomplicated secundum ASD, unlike most congenital cardiac defects, is not associated with an increased endocarditis risk.[104] Presumably this is because the shunt, although potentially large, is low pressure and unassociated with jet lesions of the endocardium from turbulent flow.

Although some discussion is given to onset times with intravenous or inhalation induction agents, clinical differences are hard to notice with modern low-solubility volatile agents. Thermodilution cardiac output reflects pulmonary blood flow, which will be in excess

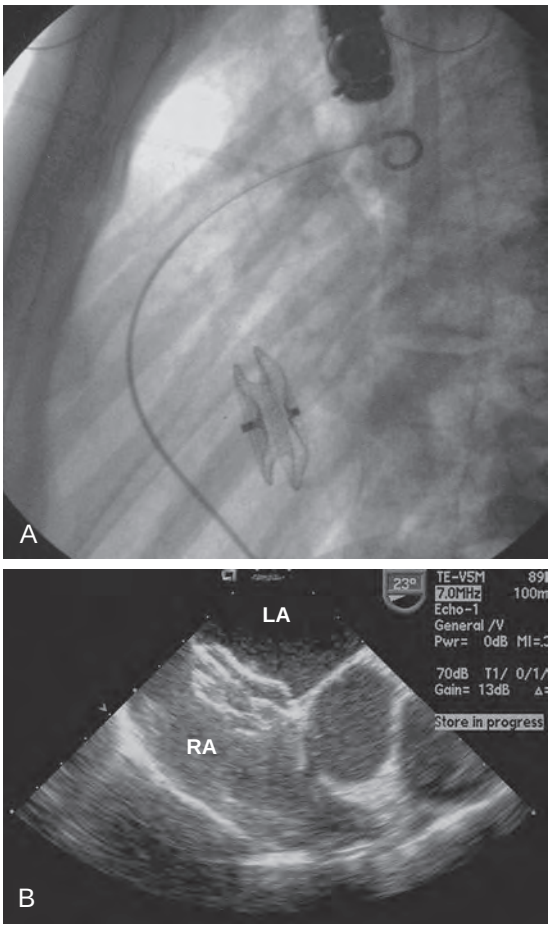

Fig. 22.2 Closure of an atrial septal defect in an adult with use of a transvascular device (the Amplatzer septal occluder). (A) Radiograph. (B) Transesophageal echocardiogram. The device is clearly visualized spanning and occluding the atrial septal defect. *RA,* Right atrium; *LA,* left atrium. *(Courtesy Dr. Scott Lim.)*

of systemic blood flow. Pulmonary arterial catheters are not routinely indicated. Patients generally do tolerate any appropriate anesthetic; however, particular care should be taken in patients with pulmonary arterial hypertension or right-sided failure.

The vast majority of women with an ASD tolerate pregnancy well. However, the normal hypervolemia associated with pregnancy can result in heart failure in women with large defects. Hypovolemia accompanying delivery can result in right-to-left shunting through the defect, and there is a risk of pulmonary thromboembolism or paradoxical embolism.

Coarctation of the Aorta

Unrepaired coarctation of the aorta in the adult brings with it significant morbidity and mortality. Mortality is 25% by age 20, 50% by age 30, 75% by age 50, and 90% by age 60.[93,105–107] Left ventricular aneurysms, rupture of cerebral aneurysms, and dissection of a postcoarctation aneurysm all contribute to the excessive mortality. Left ventricular failure can occur in patients over 40 with unrepaired lesions. If repair is not undertaken early, there is incremental risk for the development of premature coronary atherosclerosis.[108] Even with surgery, coronary artery disease remains the leading cause of death 11 to 25 years after surgery.[109] However, more recent data have questioned that assertion.[110] Coarctation is accompanied by a bicuspid aortic valve in the majority of patients. Although endocarditis of this abnormal valve is a lifelong risk, these valves often do not become stenotic until middle age or later. Coarctation can also be associated with mitral valve abnormalities (Box 22.8).

Fig. 22.3 Magnetic resonance image of a 37-year-old man showing descending thoracic aortic pseudoaneurysm at the site of a coarctation that had been repaired years earlier. This patient also has a bicuspid aortic valve and an aneurysm of the ascending aorta that was later repaired. *(Courtesy Dr. Christopher Kramer.)*

BOX 22.8 COMPLICATIONS OF AORTIC COARCTATION IN ADULTHOOD

- Left ventricular failure
- Premature coronary atherosclerosis
- Rupture of cerebral aneurysm
- Aneurysm at site of coarctation repair
- Complications of associated bicuspid aortic valve
- Exacerbation of hypertension during pregnancy

Aneurysms at the site of coarctation repair can develop years later (Fig. 22.3), and restenosis as well can develop in adolescence or adulthood. Repair includes resection of the coarctation and end-to-end anastomosis. Because this sometimes resulted in recoarctation when done in infancy, for many years a common repair was the Waldhausen or subclavian flap operation, in which the left subclavian artery is ligated and the proximal segment opened and rotated as a flap to open the area of the coarctation. Aneurysms in the area of repair are a particular concern in adolescents and adults following coarctectomy. Persistent systemic hypertension is common following coarctation repair.[111] The risk of hypertension parallels the duration of unrepaired coarctation. Adult patients require continued periodic follow-up for hypertension. A pressure gradient of 20 mm Hg or more (less in the presence of extensive collaterals) is an indication for treatment.[112] Recoarctation can be treated surgically or by balloon angioplasty with stenting.[113] Surgical repair of recoarctation or aneurysm in adults is associated with increased mortality and can be associated with significant intraoperative bleeding due to previous scar or extensive collateral vessels. It requires lung isolation for optimal surgical exposure and placement of an arterial catheter in the right arm. Endovascular repair by ballooning/stenting has proven useful for these patients.[114,115]

Half of patients operated on after age 40 have persistent hypertension, and many of the remainder have an abnormal hypertensive response to surgery. Long-term survival is worse for patients having repair later in life. Patients older than 40 undergoing repair have a 15-year survival of only 50%.[109] Pulmonary hypertension can develop secondary to longstanding restrictive left ventricular physiology.[116]

Blood pressure should be obtained in the right arm unless pressures in the left arm or legs are known to be unaffected by residual or recurrent coarctation. Postoperative hypertension is common after repair of coarctation and often requires treatment for some months. Postoperative ileus is also common, and patients should be maintained NPO for about 2 days.

Pregnancy can exacerbate preexisting hypertension in women with unrepaired lesions, increasing the risk of aortic dissection or rupture, heart failure, angina, and rupture of a circle of Willis aneurysm. Adequate blood pressure control during pregnancy is paramount in these women. Most aortic ruptures during pregnancy occur during labor and delivery. Presumably, epidural analgesia would moderate hypertension during delivery.

Congenitally Corrected Transposition of the Great Vessels (L-Transposition, Ventricular Inversion)

"Transposition" in this context refers solely to the fact that the aorta arises anterior to the pulmonary artery. It bears no reference to the origin of blood in the aorta or pulmonary artery or to the ventricle of origin of those vessels. In L-transposition, as a consequence of the embryonic heart tube rotating to the left (levo) rather than to the right, the flow of blood is through normal vena cavae to the right atrium, through a mitral valve to a right-sided morphologic left ventricle, to the pulmonary artery, through the pulmonary circulation, to the left atrium, through a tricuspid valve to a left-sided morphologic right ventricle, and thence to the aorta (Fig. 22.4) The L refers to the fact that the aorta originates anterior and to the left ("levo") of the pulmonary artery. Although anatomically altered, the physiologic flow of blood is appropriate, and there are no associated shunts. L-Transposition of the great vessels (L-TGV) is very frequently associated with other cardiac lesions, most commonly a ventricular septal defect (VSD), subpulmonic stenosis, heart block, or systemic atrioventricular (tricuspid) valve regurgitation. In the absence of any of these associated cardiac defects, L-TGV will usually be asymptomatic through infancy and childhood. When L-transposition is an isolated lesion, most patients maintain normal biventricular function through early adulthood and can attain a normal lifespan. However, the relatively thin-walled morphologic right ventricle is not well suited to eject blood against systemic pressure. Over a lifetime the right ventricle can fail, and the patient will develop heart failure. Over the past few years an alternative surgical approach has been utilized in some centers to avoid a systemic right ventricle. If an associated lesion has allowed for a hypertensive left ventricle, or if the left ventricle has been prepared by pulmonary artery banding, an anatomic repair can be undertaken by means of an atrial switch (Senning operation) + an arterial switch, or a Senning + Rastelli operation, resulting in a systemic morphologic left ventricle. There are as yet no long-term results for this approach. The goal of establishing the morphologic left ventricle as the systemic ventricle comes at the cost of a very complex operation with significant short- and long-term complications. Specifically, the atrial baffles may obstruct resulting in the physiologic equivalent of tricuspid or mitral stenosis. Also, the extensive atrial sutures make the long development of atrial arrhythmias likely.

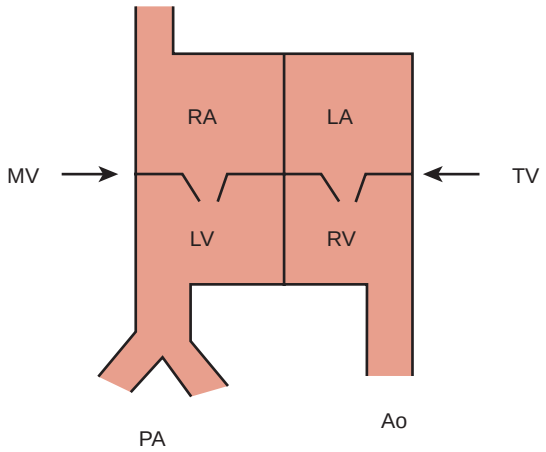

Fig. 22.4 Diagram of the anatomy of L-TGA. Note that the atrioventricular valves are associated with the "usual" ventricle. *Ao,* Aorta; *LA,* left atrium; *LV,* morphologic left ventricle; *MV,* mitral valve; *PA,* pulmonary artery; *RA,* right atrium; *RV,* morphologic right ventricle; *TV,* tricuspid valve.

Systemic atrioventricular (tricuspid) valve insufficiency may not develop until later in life, resulting in approximately 60% of patients being diagnosed as adults.[117] Dysfunction of the right (the systemic) ventricle can develop with aging, and asymptomatic aging is relatively uncommon.[118] By age 45, heart failure will be present in 67% of those patients with associated lesions and 25% of those without.[119] Resynchronization therapy for severe ventricular dysfunction can be problematic because of significant abnormal cardiac venous drainage with variations in coronary sinus anatomy.[120] These patients can be born with congenital heart block, which can progress in degree. Second- or third-degree heart block occurs at a rate of about 2% per year. More than 75% of patients develop some degree of heart block, although the intrinsic pacemaker remains above the His bundle with a narrow QRS complex. Chronic subpulmonary (left) ventricular pacing can be associated with a deterioration in systemic (right) ventricular function.[121] L-Transposition can be associated with an Ebstein-like deformity of the systemic atrioventricular (tricuspid) valve, and there can be a bundle of Kent causing the Wolff-Parkinson-White (WPW) syndrome associated with that abnormal valve. There is a significant incidence of tricuspid valve insufficiency in the systemic ventricle, and this is higher still in patients with an Ebstein deformity of the valve.[122] Anesthetic management depends on the presence of any associated lesions and the adequacy of right (systemic) ventricular function.

Although women generally do well with pregnancy,[123] the physiologic stresses of pregnancy and delivery can result in ventricular or valvar dysfunction, particularly with baseline dysfunction and/or an insufficient systemic atrioventricular valve; however, even if these develop, pregnancy can be successfully managed.[123–126] The decrease in systemic vascular resistance associated with both pregnancy and neuraxial analgesia might be advantageous to women with tricuspid (systemic) valve insufficiency. The acute autotransfusion associated with delivery could potentially cause problems for women with existing diminished systemic ventricle function. A recent study suggested that pregnancy resulted in a sustained deterioration in right (systemic) ventricular function.[127]

Ebstein Anomaly of the Tricuspid Valve

This defect,[128] one of arrested or incomplete delamination of the embryonic tricuspid valve from the right ventricular myocardium, resulting in apically displaced valve tissue, is the most common cause of congenital tricuspid insufficiency. The septal leaflet tends to be the most dysplastic. The anterior leaflet tends to be large and redundant. The defect is associated with a patent foramen ovale or a secundum ASD. There is "atrialization" of part of the right ventricle. The displacement of the tricuspid valve toward the right ventricular apex results in a portion of the right ventricle being above the tricuspid valve and becoming functionally part of the right atrium. Apicalization of the tricuspid valve results in a portion of the heart above the valve having a ventricular intracardiac electrogram (it is ventricular myocardium) but atrial pressures (it lies above the tricuspid valve). The right atrium can be massively enlarged (Fig. 22.5), and the right ventricle,

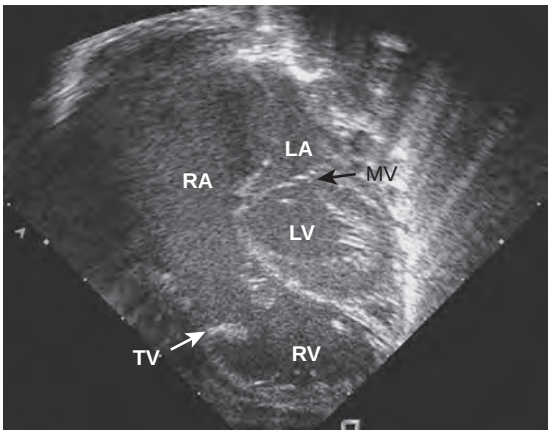

Fig. 22.5 Ebstein anomaly of the tricuspid valve. This echocardiogram shows the apically displaced redundant tricuspid valve tissue and a massively enlarged right atrium with bowing of the atrial septum to the left. *LA,* Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium, *RV,* right ventricle; *TV,* tricuspid valve. *(Reprinted with permission from Baum VC. Abnormalities of the atrioventricular valves. In: Lake CL, Booker P, eds.* Pediatric Cardiac Anesthesia, *4th ed. Philadelphia: Lippincott Williams and Wilkins; 2004.)*

lacking the inflow portion that is now part of the right atrium, is smaller than usual with varying degrees of pulmonic stenosis. Patients with L-transposition (see earlier) can have an Ebstein or Ebstein-like anomaly of a left-sided tricuspid valve, and Ebstein anomaly is on occasion associated with left ventricular noncompaction.

Symptoms will vary based on the amount of displacement of the valve and the size of the smaller-than-normal right ventricle. Cyanosis from atrial-level right-to-left shunting can be a neonatal phenomenon, resolving with the normal postnatal decrease in PVR, only to recur in adolescence or adulthood. Very mild disease is quite compatible with asymptomatic survival into adulthood, although overall earlier reports suggested a mean age at death of about 20 years with about one-third dying before 10 years of age and only 15% survival by 60 years.[129–131] About one-half develop arrhythmias, typically supraventricular tachyarrhythmias. Once symptoms develop, disability rapidly progresses.

Valve repair is currently the approach of choice, and only uncommonly will tricuspid valve replacement be required.[132] Additional intervention may be required for progressive insufficiency, stenosis, prosthetic valve failure, or valve replacement with growth. Following valve replacement, up to 25% of patients develop high-grade atrioventricular block. Surgery in older patients (>50 years of age) is associated with acceptable but not outstanding long-term survival (65% 20-year survival versus 74% for controls, plus 4% early mortality).[133] Ebstein valves are often associated with a right-sided bypass tract, causing WPW syndrome. This is of concern, because 25% to 30% of patients develop supraventricular tachyarrhythmias. The dilated right atrium is ready substrate for the development of atrial fibrillation. In addition to a decrease in cardiac performance, atrial fibrillation is also potentially very dangerous in patients with underlying WPW because very high atrial rates can be conducted to the ventricle through the bypass tract.

The major concerns when anesthetizing patients who have Ebstein anomaly include decreased cardiac output, right-to-left atrial-level shunting with cyanosis, and the propensity for atrial tachyarrhythmias. The right atria of these patients are very sensitive, and arrhythmias are easily induced by catheters or guidewires passed into the right atrium or during surgical manipulation; arrhythmias remain a concern into the postoperative period. Supraventricular arrhythmias should be treated aggressively. If associated with significant hypotension, the arrhythmia needs to be electrically cardioverted.

In the absence of marked cyanosis, pregnancy and delivery are generally well tolerated.[134] There is, however, an increased incidence of prematurity and fetal loss. Birth weights are lower in infants of cyanotic mothers.[135] and incidence of CHD is increased in offspring.

Eisenmenger Syndrome

Eisenmenger described a particular type of large VSD with dextroposition of the aorta.[136] In a general way, the term *Eisenmenger syndrome* has come to describe the clinical setting in which a large left-to-right cardiac shunt results in the development of pulmonary vascular disease and has been the subject of recent reviews.[137,138] Although early on the pulmonary vasculature remains reactive, with continued insult pulmonary hypertension becomes fixed and does not respond to pulmonary vasodilators. Ultimately, the level of PVR is so high that the shunt reverses and becomes right to left. Clinically, patients who are cyanotic from intracardiac right-to-left shunting are deemed to have Eisenmenger physiology even though their PVR may not yet truly be fixed. This is the intermediate phase of the disease before progression to a truly fixed PVR. That is, at baseline they shunt right to left but may still retain some pulmonary vascular reactivity in the presence of vasodilating agents such as oxygen or nitric oxide. The degree of reactivity can be determined in the catheterization laboratory by measuring the pulmonary blood flow on room air, pure oxygen, and pure oxygen with nitric oxide added. The development of pulmonary vascular disease is dependent on shear rate. Lesions with high shear rates, such as a large VSD or a large PDA, can result in pulmonary hypertension in early childhood. Lesions such as an ASD with high pulmonary blood flow but low pressure may not result in pulmonary vascular disease until late middle age. Pulmonary vascular disease progression is also accelerated in patients living at altitude.

The most common presenting symptom is dyspnea on exertion. Additional symptoms include palpitations, edema, hemoptysis, syncope, hyperpnea, and of course, increasing cyanosis. Hepatic synthetic function can be altered from the elevated central venous pressure. There can be CNS symptoms from increased blood viscosity from the erythrocytosis associated with cyanosis. Right ventricular ischemia is a possibility. Patients may be on chronic therapy with drugs such as intravenous prostacyclin, an oral phosphodiesterase 5 inhibitor such as sildenafil (eg, Revatio), an oral endothelin receptor antagonist such as bosentan (eg, Tracleer), a prostanoid, or a soluble guanylate cyclase stimulator such as riociguat (Adempas). Because of the risk of pulmonary thromboses,[139] patients may be on chronic anticoagulants.

Eisenmenger physiology is compatible with survival into adulthood.[140,141] However, reported rates of survival after diagnosis vary, probably based on the relatively long life expectancy and variability in the time of diagnosis. Cantor and colleagues[142] reported median survival to 53 years but with wide variation. Saha and coworkers[143] reported survival of 80% at 10 years after diagnosis and 42% at 25 years. Oya and others,[144] however, reported survival of 77% at 5 years and 58% at 10 years. A recent study, however reported worse long-term survival and challenged these other data for methodologic reasons.[145] Syncope, increased central venous pressure, and arterial desaturation to less than 85% are all associated with poor short-term outcome.[140] Other factors associated with mortality include syncope, age at presentation, functional status, supraventricular arrhythmias, elevated right atrial pressure, renal insufficiency, severe right ventricular dysfunction, and trisomy 21. Most deaths are sudden cardiac deaths. Other causes of death include heart failure, hemoptysis, brain abscess, thromboembolism, and complications of pregnancy and noncardiac surgery.[146] These patients face potentially significant perioperative risks. Findings of Eisenmenger syndrome are summarized in Box 22.9.

Surgical closure of cardiac defects with fixed pulmonary vascular hypertension is associated with very high mortality. Lung or heart-lung transplantation is a surgical alternative.[147] Although there are several surgical series reporting survival after heart-lung or single- or double-lung transplantation performed for primary pulmonary hypertension, it is unclear if this cohort of patients is similar to patients with Eisenmenger physiology.

BOX 22.9 FINDINGS IN EISENMENGER SYNDROME

- Physical examination: Loud pulmonic component of the second heart sound, single or narrowly split second heart sound, Graham-Steell murmur of pulmonary insufficiency, pulmonic ejection sound ("click")
- Chest radiography: Decreased peripheral pulmonary arterial markings with prominent central pulmonary vessels ("pruning")
- Electrocardiogram: Right ventricular hypertrophy
- Impaired exercise tolerance
- Exertional dyspnea
- Palpitations (often due to atrial fibrillation or flutter)
- Complications from erythrocytosis/hyperviscosity
- Hemoptysis from pulmonary infarction, rupture of pulmonary vessels or aortopulmonary collateral vessels
- Complications from paradoxical embolization
- Syncope from inadequate cardiac output or arrhythmias
- Heart failure (usually end stage)

When noncardiac surgery is deemed essential and time permits, a preoperative cardiac catheterization may be helpful to determine the presence of pulmonary reactivity to oxygen or nitric oxide. Fixed PVR precludes rapid adaptation to perioperative hemodynamic changes. Changes in systemic vascular resistance are mirrored by changes in intracardiac shunting. A decrease in systemic vascular resistance is accompanied by increased right-to-left shunting and a decrease in systemic oxygen saturation. In addition, an acute fall in systemic resistance can impair left ventricular filling with the right ventricular encroachment. Systemic vasodilators, including regional anesthesia, should be used with caution, and close assessment of intravascular volume is important. Epidural analgesia has been used successfully in patients with Eisenmenger physiology, but the local anesthetic must be delivered slowly and incrementally with close observation of blood pressure and oxygen saturation.[148] Postoperative postural hypotension can also increase the degree of right-to-left shunting, and these patients should change position slowly. All intravenous catheters must be maintained free of air bubbles.

Placement of pulmonary artery catheters in these patients is problematic for a variety of reasons, and they are of less utility than might be expected. Pulmonary arterial hypertension is a risk factor for pulmonary artery rupture from a pulmonary artery catheter. Rupture is particularly worrisome in these cyanotic patients, who can also have hemostatic deficits associated with erythrocytosis.[149] Abnormal intracardiac anatomy and right-to-left shunting can make successful passage into the pulmonary artery difficult without fluoroscopy. Relative resistances of the pulmonary and systemic beds are reflected in the systemic oxygen saturation, readily measured by pulse oximetry, so measures of pulmonary artery pressure are not required. In addition, in the presence of right-to-left shunting, thermodilution cardiac outputs do not accurately reflect systemic output. Thus the value of pulmonary artery catheters in these patients is minimal at best, and they essentially are never indicated. The one potential exception is the patient with an ASD who is at risk to develop right ventricular failure if suprasystemic right ventricular pressure develops.[150]

Fixed PVR is by definition unresponsive to pharmacologic or physiologic manipulation, but as previously mentioned, only patients at the true end stage of disease have fixed PVR. Thus the clinician must still avoid factors known to increase PVR, including cold, hypercarbia, acidosis, hypoxia, and α-adrenergic agonists. Although the last of these is commonly listed to be avoided, in the face of pulmonary vascular disease due to intracardiac shunting, the systemic vasoconstrictive effects predominate and systemic oxygen saturation increases.

Nerve blocks offer an attractive alternative to general anesthesia if otherwise appropriate. Although Martin and colleagues in a literature review found that the mortality in nerve block cases was less than that for general anesthesia cases (5% vs 15%), they could not differentiate the relative risk between type of anesthetic and type (complexity) of surgery.[151]

If patients have general anesthesia, consideration should be given to postoperative observation in an intensive or intermediate care unit. Because of the increased perioperative risk, patients should be observed overnight, particularly if they have not had recent surgery or anesthesia, because their responses will be unknown. Ambulatory surgery is possible for patients having uncomplicated minor surgery with sedation or nerve block.

Although the perioperative mortality risk in the past has been estimated as high as 30%,[151,152] estimates of mortality after noncardiac surgery in adulthood from more current series suggest that the mortality risk from noncardiac surgery and/or anesthetics is less than in the past. For example Ammash and colleagues in 1999 reported a mortality rate of 7% (2 of 24)[153] and Bennett and associates in 2014 reported a mortality of 3.8% (2 of 53).[154] However, all of these series suffer from being somewhat small, conducted at single institutions, and including operations and patients of varying complexity. In the series from Bennett and others, 26% of patients developed significant systemic hypotension and 17% oxygen desaturation. Not surprisingly, hypoxemia was preceded by systemic hypotension. The incidence of hypotension was worse with propofol and inhalation inductions, and the authors found that use of a vasopressor during induction was helpful. Worrisomely, the authors reported that the only two deaths in their series occurred following monitored anesthesia care: the first patient developed hypoxic respiratory failure 2 hours after TEE and cardioversion, and the second patient died on postoperative day 6 following TEE, cardioversion, and upper and lower endoscopy.

Pregnancy carries very high risks of mortality and premature delivery. From 20% to 30% of pregnancies result in spontaneous abortions, and premature delivery occurs in about half.[155] At least half of newborns have intrauterine growth retardation. From 30% to 45% of all pregnancies end in maternal death intrapartum or during the first postpartum week, and successful first pregnancy does not preclude maternal death during a subsequent pregnancy.[156] The hemodynamic changes of both pregnancy and delivery increase maternal risk. Pulmonary microembolism and macroembolism have caused peripartum maternal deaths, even days after delivery. Factors influencing mortality include thromboembolism (44%), hypovolemia (26%), and preeclampsia (18%).[155,156] Mortality is similar with cesarean section or vaginal delivery, and both carry significantly higher mortality rates than that for spontaneous abortion. In a literature review Martin and colleagues found a 24% mortality rate for laboring women who received regional anesthesia. Most of these women died several hours after delivery.[151] Of course reporting bias cannot be excluded in a report such as this. Pregnancy should be discouraged in these women. Women who do become pregnant should be closely monitored with arterial catheters during delivery. Epidural analgesia, delivered slowly and incrementally, can moderate many of the deleterious hemodynamic changes of active labor. Pulmonary arterial catheters are of little to no use during delivery. Prompt treatment of blood loss and hypotension during delivery is absolutely required. Postpartum observation should be in an intensive care setting. Pulmonary hypertension in pregnancy was reviewed in detail.[157,158]

Endocardial Cushion Defects (Atrioventricular Canal Defects)

The endocardial cushions are the embryonic cardiac tissues that form the crux of the heart—the primum (lower) atrial septum, the posterior basal part of the ventricular septum, the septal leaflet of the tricuspid valve, and the anterior leaflet of the mitral valve. The endocardial cushion defects then consist of one or more of a primum ASD, inlet VSD, cleft septal leaflet of the tricuspid valve, and/or cleft anterior leaflet of the mitral valve. The most primitive form is the complete atrioventricular canal. In this defect, there is a single large

atrioventricular valve with mitral and tricuspid components with large ASDs and VSDs. This valve is usually "balanced." In the more complex, unbalanced defects, one component of the valve can be predominant, and this large valve is not centered over the ventricular septum, leading to underfilling of one of the ventricles. Three-dimensional echocardiography can be particularly useful in delineating the specific anatomy with these lesions.[159] These defects can occur alone or can be part of more complex cardiac defects such as tetralogy of Fallot or single ventricle. Half of all children with Down syndrome have CHD; one-half of these have an endocardial cushion defect. These lesions are marked by a typical electrocardiogram (ECG) with first-degree block and a superior QRS axis with a counterclockwise QRS loop. Although adults with unrepaired complete atrioventricular canal will likely have developed inoperable pulmonary arterial hypertension, partial canal defects can sometimes be first diagnosed in adults and can be appropriate candidates for surgical repair. The AV node and bundle of His are displaced inferiorly, putting them at risk for surgical injury and the induction of heart block.

Much subtlety is required to construct two separate functional atrioventricular valves without residual stenosis or insufficiency of either component. Postoperative or residual mitral insufficiency is not uncommon, and 10% to 30% require repeat surgery.[160] The strongest predictor of postoperative mitral insufficiency is the degree of preoperative regurgitation of the common atrioventricular valve. Anesthesia for these patients depends on the degree of shunt, valve insufficiency, and pulmonary vascular disease.

Fontan Physiology

In 1968, performing the operation that now bears his name, Fontan and colleagues proved that it was possible to deliver the entire systemic venous return to the lungs without the benefit of a ventricular pump.[161] The Fontan operation was a landmark development in CHD because it established a "normal" series circulation in patients with a single ventricle. The price to be paid for a series circulation is the unique physiologic demand of passive pulmonary blood flow. Complications never envisioned at the time of the original operation have occurred, necessitating significant changes in operative technique. Fontan's original operation (Fig. 22.6) was soon modified to an atriopulmonary connection[162] (Fig. 22.7). The original strict eligibility criteria[163] have been liberalized, but patients meeting as many of the criteria as possible still have the best prognosis for good long-term survival. By the mid-1980s, it became clear that success of Fontan circulation was based on an unobstructed pathway from systemic veins to pulmonary artery, a pulmonary vasculature that was free from anatomic distortion (eg, from previous Blalock-Taussig shunt), low PVR, and good ventricular function without significant atrioventricular valve regurgitation. The incorporation of the atrium in the Fontan pathway proved disappointing. The atrium lost its contractile function, providing no assistance to pulmonary blood flow and causing serious complications. Understanding these complications and how the Fontan operation has evolved is the key to managing these challenging patients whose complex CHD has been palliated, not cured.

Complications (Box 22.10)

The dilated, noncontractile atrium serves as a reservoir of blood and a ready source of thrombus.[164–166] Pulmonary embolization will impair the passive blood flow necessary for successful Fontan circulation. Atrial thrombus could embolize paradoxically through residual right-to-left shunts. Patients are also at risk for arterial thrombosis, secondary to a mild hypercoagulable state.[167,168] Given the morbidity associated with thromboembolism, it seems reasonable to put all Fontan patients on aspirin.[169] Those who display further potential for thrombosis such as low cardiac output state, atrial arrhythmia with significant atrial dilation, or marked venous hypertension may benefit from warfarin (Coumadin).

Fontan patients show a steady increase in atrial tachyarrhythmias with an incidence of over 50% at 20 years.[170] Changes in surgical technique evolved in part to decrease the rate of atrial arrhythmias. Although initial results were promising,[171] unfortunately, much of this benefit is lost with longer-term follow-up.[172] Fontan patients tolerate tachycardia very poorly, and acute episodes usually require urgent treatment using medical therapy to control ventricular rate or cardioversion. Late-onset atrial tachyarrhythmias usually occur between 6 to 10 years post-Fontan completion.[173] The most common tachyarrhythmia

BOX 22.10 COMPLICATIONS OF FONTAN OPERATION

- Atrial thrombus
- Atrial arrhythmia (tachyarrhythmia or bradyarrhythmia)
- Ventricular dysfunction
- Chylothorax
- Protein-losing enteropathy

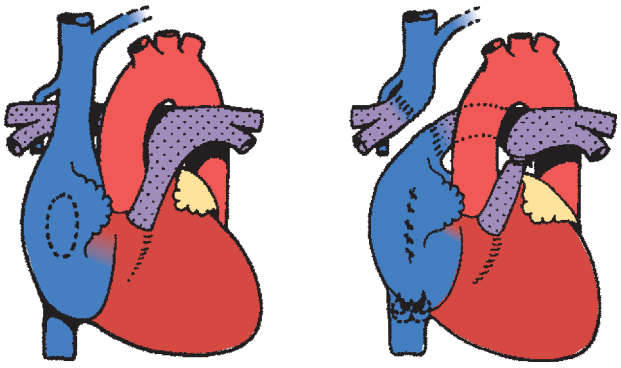

Fig. 22.6 The original Fontan operation. Fig. 22.7 The atriopulmonary modification of the Fontan operation. *(Reprinted with permission from Kreutzer G, Galindez E, Bono H, et al. An operation for the correction of tricuspid atresia.* J Thorac Cardiovasc Surg. *1973;66:613.)*

is right intraatrial reentrant tachycardia. Over time, episodic attacks of tachycardia become more frequent. Frequently, atrial fibrillation occurs, and the loss of atrioventricular synchrony results in decreased effort tolerance. The onset of atrial tachyarrhythmias mandates an evaluation of the Fontan pathway with attention turned to relieving any significant obstructions. In the setting of passive pulmonary blood flow, even small gradients can be very hemodynamically significant.[174] Therapies for chronic atrial arrhythmias consist of medication, catheter ablation, and surgery. Given the complex anatomy, dilated atrium, and atrial scar with suture lines from prior surgeries, it is not surprising that atrial arrhythmias can become refractory to standard treatment in many patients. Catheter ablation typically has high initial success rates that are not maintained.[174]

Bradyarrhythmias, caused by sinus node ischemia, are common. In a large cohort of patients with atriopulmonary connections, the incidence of bradyarrhythmias requiring pacemakers was 13%.[175] Progressive fibrosis and scar around the sinus node, caused by prior surgical dissection, eventually leads to ischemia and clinical sinus node dysfunction. If accompanied by premature atrial contractions, sinus or junctional bradycardia can precipitate an intraatrial reentry tachycardia. Thus sinus node dysfunction also serves as a risk factor for the development of atrial tachyarrhythmias. Clinically significant bradyarrhythmias require pacing. Pacemakers pose special problems in the Fontan patient because the altered anatomy precludes transvenous placement. Thus Fontan patients who require pacing will have epicardial leads placed via repeat sternotomy with all the accompanying risks. Even though atrioventricular synchrony can be achieved with pacing, it is still not as desirable as intrinsic sinus rhythm. The incidence of sinus node dysfunction is less with a cavopulmonary versus an atriopulmonary connection.[176] However, a clear benefit from an extracardiac connection (see later) when compared with the lateral tunnel approach has been difficult to prove.[177–179]

The last major complication of Fontan physiology is protein-losing enteropathy (PLE), a condition as confounding as it is serious. The incidence is quoted as high as 15%, but a large international multicenter study found a rate of 3.7%.[180] Clinically, there is an edematous state with ascites and pleural-pericardial effusions. Serum albumin is low and the diagnosis is confirmed by finding enteric protein loss with elevated levels of stool α1-antitrypsin. Most ominously, PLE is accompanied by 50% mortality 5 years from diagnosis despite treatment. It was believed that PLE constituted a straightforward situation of elevated portal pressures secondary to central venous hypertension. Elevated portal pressures lead to vascular congestion, lymphatic obstruction, and enteric protein loss from the gut. Unfortunately, there is not a good correlation between central venous pressures and PLE.[181] This has led to a broader understanding of PLE as a multifactorial phenomenon due to reduced mesenteric perfusion,[181] chronic inflammation[182] and enterocyte dysfunction.[183] Patients who present with PLE should have a complete hemodynamic evaluation. This is vital because interventions that improve cardiac output have proven successful in PLE. Any Fontan pathway obstruction should be treated and cardiac output optimized with medical therapy, fenestration, or pacing. In the absence of correctable obstructions, PLE portends a poor prognosis, despite surgery or cardiac transplantation.

The Modern Fontan Operation

The atriopulmonary connection proved an inefficient method of pulmonary blood flow. Colliding streams of blood from the superior and inferior vena cavae resulted in energy loss and turbulence within the atrium.[184] The energy required to propel blood forward into the pulmonary vasculature was lost as blood swirled sluggishly in the dilated atrium (Fig. 22.8). The modern Fontan operation is a total cavopulmonary connection (Fig. 22.9). The lateral tunnel Fontan improved pulmonary blood flow, and only the lateral wall of the atrium was exposed to central venous hypertension. There was no dilated atrium to serve as a source of thrombus. The extensive atrial suture lines, however, remained a risk for arrhythmia. The extracardiac Fontan is a further modification of the total cavopulmonary connection. The extracardiac Fontan greatly reduces the number of atrial incisions and hopefully the long-term development of atrial arrhythmias. Has the modern Fontan improved outcomes? Reductions in arrhythmia and improvements in overall survival have been noted.[185] Results for the extracardiac Fontan are even better than those of the lateral tunnel Fontan but are limited by the shorter duration of follow-up. It is not yet certain if the development of long-term complications has been truly reduced or only delayed.

Fig. 22.8 Injection of contrast into the inferior vena cava reveals a markedly dilated right atrium following an atriopulmonary Fontan operation.

Preoperative Assessment

Patients with Fontan physiology are presenting in larger numbers for the entire array of noncardiac surgery, including obstetric procedures. Preoperative assessment begins with a directed history, concentrating on functional status and the presence of major complications. Heightened suspicion is clearly needed for patients with atriopulmonary connections and for those with a systemic right ventricle. Patients with Fontan circulation have a low cardiac output state. This low output state exists despite the presence of good ventricular function, minimal atrioventricular valve regurgitation, and low PVR. A cohort of patients with an atriopulmonary Fontan performed at an older age showed striking reductions in anaerobic threshold (less 50% of controls), $\dot{V}O_2$ max (less than 33% of controls) and systemic ejection fraction both at rest and exercise.[186] Further compounding the issue is that patients' self-assessment grossly overestimates their objective exercise capacity.[187] This places the anesthesiologist in a considerable dilemma when faced with a Fontan patient who rates his or her functional status as "good." The authors believe that transthoracic echocardiography should be the initial preoperative investigation and is mandatory except in cases of very minor surgery. Further testing is guided by the results of the echocardiogram and in consultation with a cardiologist experienced in caring for adults with CHD. Normal ventricular function on echocardiogram would stratify the patient as "low risk" only within the context of patients with Fontan circulation.

A term that should immediately get the attention of the anesthesiologist is *failing Fontan*. Specific reasons for failing may differ, but the common denominator in these patients is a marked limitation of functional status. They will manifest some combination of refractory arrhythmias, PLE, liver dysfunction, hypoxemia, or congestive heart failure. Although PLE always signifies a failing Fontan, the converse is not always true. That is, patients can have severely limited function with elevated central venous pressures and even evidence of cirrhosis on liver biopsy without demonstrating PLE.[188] Patients with a "failing

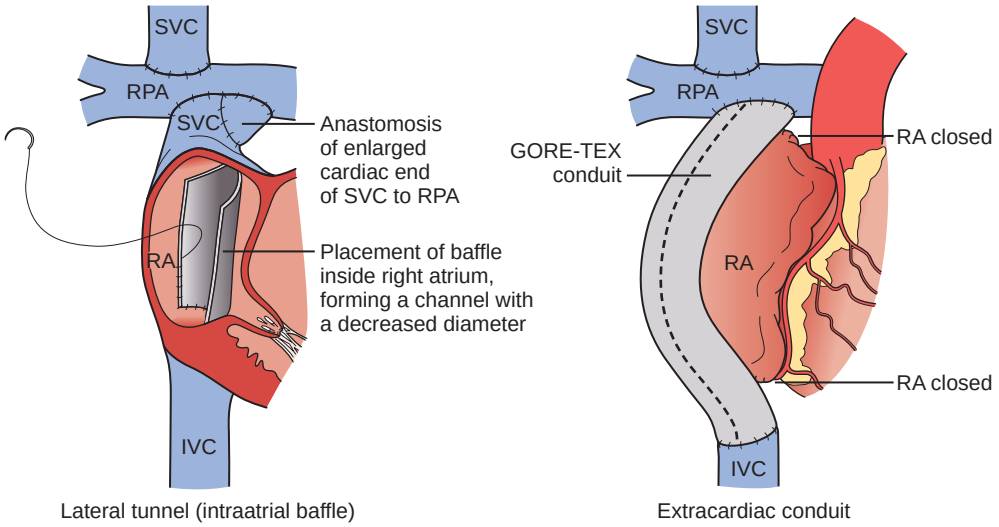

Fig. 22.9 Two variations of the modern Fontan operation, the lateral tunnel and extracardiac operations. *IVC,* Inferior vena cava; *RA,* right atrium; *RPA,* right pulmonary artery; *SVC,* superior vena cava. *(Reprinted with permission from D'Udekem Y, Iyengar AJ, Cochrane AD, et al: The Fontan procedure: contemporary techniques have improved long-term outcomes.* Circulation. *2007;116[11 Suppl]:I157.)*

Fontan" require a search for correctable lesions.[189] First, any obstructions within the Fontan pathway should be treated, preferably with percutaneous techniques of dilation and stenting. Second, loss of sinus rhythm should be treated with pacing. If loss of sinus rhythm is accompanied by severe tachyarrhythmias, Fontan conversion surgery is indicated. Third, some patients develop collateral vessels. Aortopulmonary collaterals result in a progressive volume load on the single ventricle. Collaterals from the venous system to the systemic atrium or ventricle cause hypoxemia. In both cases large collaterals should be coil occluded in the catheterization laboratory. Another option is the creation of a fenestration, which can improve cardiac output and lower central venous pressures but at the expense of a right-to-left shunt. Unfortunately, not all of these therapeutic options are indicated or successful in every patient. At this point, if no realistic hope of further improvement exists, the only option is cardiac transplantation.

The functional state of Fontan patients exists across a spectrum but generally falls into two groups. The first and largest group is made of those who report NYHA I-II level of function but have been shown to possess much less cardiorespiratory reserve than age-matched two-ventricle controls. These patients will tolerate most surgical procedures with an acceptably low risk. The second group is smaller but consists of those patients who have manifested one of more of the "failing Fontan" criteria. Surgery in these patients carries much greater risk and should only be undertaken after careful consultation with physicians experienced in ACHD. When it comes to a discussion of anesthetic technique, the same lessons learned in caring for patients with acquired coronary artery disease apply. That is, there is no right drug for these patients, nor is there a single "best" anesthetic technique. Rather, the critical issue is to gain a clear and comprehensive understanding of the patient's pathophysiology. The key is not which drugs are used, but rather how they are used. Certain principles for patients with Fontan physiology are important and need to be stressed (Box 22.11).

Ventilatory Management

In an effort to minimize PVR, functional residual capacity should be maintained by the application of small amounts of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP), and excessive lung volumes should be avoided. PEEP or CPAP will not significantly impede cardiac output if less than 6 cm H_2O. Spontaneous ventilation has been assumed to be optimal for these patients to minimize intrathoracic pressure and encourage forward flow into the pulmonary circulation; but as discussed by Steven and McGowan,[190] hard evidence for this approach is mostly lacking. Cardiac output should be optimized by limiting mean airway (intrathoracic) pressure: minimizing peak inspiratory pressure, limiting inspiratory time, using low respiratory rates, and applying judicious amounts of PEEP while using higher tidal volumes to maintain normocarbia. The

BOX 22.11 MANAGEMENT PRINCIPLES FOR PATIENTS WITH FONTAN PHYSIOLOGY

1. Maintenance of preload is essential. A prolonged NPO period without intravenous hydration should be avoided.
2. Regional and neuraxial techniques are attractive options, with appropriate attention to volume status. A neuraxial anesthetic is a poor choice if a high level of block is required. A slowly titrated epidural is preferable to a rapid-acting spinal anesthetic.
3. Airway management must be skilled to avoid hypercarbia and elevations in pulmonary vascular resistance (PVR).
4. Adequate levels of anesthesia must be established before stimulating events such as laryngoscopy. A surge of catecholamines may precipitate dangerous tachycardia.
5. Spontaneous ventilation that augments pulmonary blood flow is desirable but must not be pursued at all costs. Spontaneous ventilation under deep levels of anesthesia will result in significant hypercarbia. The benefit of spontaneous ventilation may be negated by the rise in PVR secondary to hypercarbia.
6. A plan must be in place to treat tachyarrhythmias.
7. Patients with pacemakers must have the device interrogated before surgery and a plan developed to avoid potential interference from electrocautery, particularly if the patient is pacemaker dependent.
8. If large volume shifts are anticipated, invasive monitoring with central lines and transesophageal echocardiography is recommended.
9. An appropriate plan for postoperative pain management should be established. The need for anticoagulation in many Fontan patients may preclude the use of epidural analgesia.
10. A cardiologist experienced in caring for patients with congenital heart disease should be involved perioperatively.

benefits of very early postoperative tracheal extubation (in the operating) have been considered particularly useful in these patients.[191]

Pregnancy

It was inevitable that as some of the female Fontan patients reached childbearing age they would become pregnant. Case reports first began appearing in 1989.[192,193] Unfortunately, 20 years later the body of knowledge on this important subject consists primarily of more case reports with no large registry documenting outcomes. The physiologic changes of pregnancy are well known and described in standard texts. Can a Fontan patient cope with the increased cardiovascular demands of pregnancy? The dilemma facing physicians caring for these patients is that Fontan patients are known to have decreased cardiac reserve, even those who report good functional status. Because pregnancy is a "stress test," who will pass this test and who will fail? The literature provides conflicting data. One series of 33 pregnancies found women tolerated pregnancy, labor, and delivery well but there was an increased risk of spontaneous abortion.[50] More recently, a smaller series found live birth pregnancies complicated by high rates of NYHA class deterioration, atrial arrhythmia, prematurity, and intrauterine growth retardation.[63] What can be made of these reports? They suffer from the usual problems of retrospective review and self-reporting. However, they do provide clinicians with some reassuring information. First, pregnancy is usually undertaken only in those patients with relatively good functional status, thereby removing the highest risk patients. Undoubtedly, most adult congenital cardiologists would counsel against pregnancy in any patient with evidence of a failing Fontan circulation. In patients with good functional status, pregnancy can successfully be carried to term, albeit with increased risk of miscarriage and premature delivery. A review of the case reports in the anesthetic literature shows that epidural analgesia is well tolerated and indeed recommended for the first stage of labor. The caesarian section rate approaches 50%.[64] Neuraxial anesthesia for caesarian section, in addition to its usual benefits, preserves spontaneous ventilation, which is desirable in Fontan patients. However, no increased risk from general anesthesia was identified. Perioperative complications are low, and peripartum cardiac decompensation is rare. Obstetric anesthesia care in these women has been reviewed.[194]

Fontan Conversion Surgery

There is now a large cohort of patients with atriopulmonary connections suffering from some degree of thrombosis, arrhythmia, PLE, or ventricular dysfunction. These patients are candidates for Fontan conversion surgery, which is the most commonly performed high-risk operation in the ACHD population. Case reports and small case series began to appear in the literature in the mid-1990s. At this time, interest focused on the best indications for this major surgery, outcome predictors, and optimizing the surgical technique. Nearly 15 years later there are some answers to these important questions. It was believed that conversion of an atriopulmonary Fontan to the improved hemodynamics of the modern Fontan would relieve severe atrial arrhythmias. The profile of the early patient undergoing Fontan conversion surgery was one of refractory atrial arrhythmias and poor functional state.[195] Two general trends have been identified. First, in this very-high-risk group of patients perioperative mortality was low. Second, arrhythmia control was much better in the group that underwent extracardiac connection with arrhythmia surgery. Conversion to extracardiac Fontan without an ablative procedure resulted in a high rate of arrhythmia recurrence. The largest experience came from Mavroudis, whose preferred technique was conversion to an extracardiac Fontan with intraoperative electrophysiologic mapping, arrhythmia ablation, and pacemaker placement.[196] The risk factors for death or transplantation were right or ambiguous ventricular morphology, PLE, atrioventricular valve regurgitation graded moderate or worse, and long CPB time.

These encouraging results give hope to the many patients with atriopulmonary connections and poor functional status. Patients should not have multiple failed attempts at arrhythmia ablation in the catheterization laboratory because of a fear that surgery is associated with an unacceptably high mortality. The ideal patient is one with refractory arrhythmia and poor functional status despite adequate ventricular function. The higher risk groups of patients are those with significant ventricular dysfunction, atrioventricular valve regurgitation, or PLE. Fontan conversion surgery provides myriad challenges to the anesthesiologist. Preoperatively, the important factors are the degree of arrhythmia control and the ventricular function. Most of the patients will be on at least one antiarrhythmic drug. They may be in sinus rhythm, but it is more likely they have an atrial arrhythmia with some degree of ventricular rate control. They retain the ability to become tachycardic very easily. This is almost always associated with prompt hemodynamic deterioration. The underlying ventricular function may be poor due to longstanding arrhythmia, made worse by the negative inotropic effect of antiarrhythmic medications. Transcutaneous patches for cardioversion should be placed before induction. Intravenous induction can be prolonged because blood moves sluggishly through the greatly dilated atrium. Airway management needs to be prompt and skilled, as it does for all Fontan patients. Once safely through induction and intubation, large-bore intravenous access must be established. This is usually not a problem because the central venous hypertension of Fontan patients creates dilated peripheral veins. Small central venous catheters are appropriate for delivering inotropic drugs and monitoring but some centers will prefer to place transthoracic atrial lines and completely avoid central access for fear of thrombosis. Transesophageal echocardiography is routinely used to assess volume status and ventricular function, as well as to exclude intracardiac thrombus. The repeat sternotomy, usually at least the third, can be especially bloody because of the raised central venous pressure. Maintenance of preload and the ability for large-volume transfusion is required. Also, a plan should be worked out with the surgeon and perfusionist for emergency establishment of femoral bypass if necessary. Patients with pacemakers are vulnerable to electromagnetic interference because the repeat sternotomy requires extensive use of electrocautery in close proximity to the heart and pacemaker generator. If the patient is pacemaker dependent, consideration should be given to reprogram the device to an asynchronous mode. The ability to pace using transcutaneous patches is necessary. The pre-bypass period can obviously be one of high stress.

In preparation to separate from CPB, full recruitment of the lungs and modest hyperventilation with 100% oxygen are necessary to keep PVR as low as possible. Other factors that raise PVR, such as acidosis and hypothermia, must be corrected before separation from CPB. Fontan conversion is a lengthy surgery, and the long duration of CPB can precipitate a potent inflammatory response with release of numerous mediators that raise PVR. Milrinone's pulmonary vasodilating properties make it an attractive choice. Despite long CPB times for this type of surgery, aortic cross-clamp time usually is short. Thus ventricular function after CPB is generally good but must be supported as necessary with inotropes to ensure that atrial and pulmonary venous pressures remain low. Finally, aggressive management of coagulation is required, and in this regard there is no substitute for point-of-care testing to guide transfusion products. The anesthetic considerations for Fontan conversion surgery have been reviewed in detail.[197]

Patent Ductus Arteriosus

Beyond the neonatal period, spontaneous closure of a PDA is uncommon. The risk of a longstanding moderate-to-large PDA is volume overloading of the left atrium and left ventricle with the risk of development of pulmonary vascular disease. The progression of pulmonary vascular disease is relatively accelerated when compared with patients with other types of right-to-left shunts with equivalent degrees of shunting. The development of pulmonary vascular disease is dependent on the volume and pressure of the right-to-left shunt. A PDA delivers blood at high shear stress (ie, arterial pressure) to the pulmonary vasculature and flow occurs continuously throughout the cardiac cycle. With time, the ductus can become calcified or aneurysmally dilated with a risk of rupture. Ductal calcification or aneurysm

increases the risk of surgery, which rarely requires CPB.[198] Unrepaired, the natural history is for one-third of patients to die of heart failure, pulmonary hypertension, or endocarditis by 40 years of age and two-thirds by age 60.[199] Although small PDAs are of no hemodynamic consequence, even small PDAs carry relatively high endocarditis risk. Surgical closure should be considered for all adults with PDA[198]; transvascular closure by means of one of several devices is possible and is currently the treatment of choice unless excluded by atypical anatomy. With calcification and friability of the ductus, if device closure is not practicable, it is possible to do a patch closure from inside the aorta or pulmonary artery.

Small PDAs do not carry a hemodynamic risk for pregnancy. The decrease in systemic vascular resistance accompanying pregnancy could lead to right-to-left shunting in a woman with a large PDA.

Pulmonary Valve Stenosis

Long-term asymptomatic survival is typical of patients, with the exception of neonates with critical stenosis.[200] There is a 94% survival rate 20 years after diagnosis, and adults generally do not require surgical intervention.[201] With aging, however, right ventricular fibrosis and failure can develop, and this is the most common cause of death, usually in the fourth decade. Almost all patients who have relief of stenosis either surgically or by balloon valvuloplasty have normal right ventricular function postoperatively, although surgical reintervention may be required in a significant number in the long term.[202] Percutaneous pulmonary valve implantation, done in the catheterization laboratory, is another option. However, abnormal ventricular function may not resolve after late surgical correction. The development of isolated pulmonary valvular stenosis, even of a severe degree, is usually well tolerated during pregnancy, even in the face of the volume overload that accompanies pregnancy.[203]

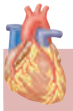
In patients with significant right ventricular hypertension, right ventricular ischemia can occur if systemic hypotension and decreased coronary perfusion occur. This is manifest on the ECG. Coronary ischemia resolves if coronary perfusion pressure is increased, as with use of phenylephrine.

Single Ventricle

See the Fontan Physiology section earlier in this chapter for a detailed discussion.

Tetralogy of Fallot

As with many things in medicine, tetralogy of Fallot was first described by someone else—probably in 1673 by Stenson. The classic description of tetralogy of Fallot includes (1) a large, nonrestrictive malaligned VSD, with (2) an overriding aorta, (3) infundibular pulmonic stenosis, and (4) consequent right ventricular hypertrophy, all derived from an embryonic anterocephalad deviation of the outlet septum. However, there is a spectrum of disease with more severe defects including stenosis of the pulmonary valve, stenosis of the pulmonary valve annulus, or stenosis and hypoplasia of the pulmonary arteries in the most severe cases. Pentalogy of Fallot refers to the addition of an ASD. With advances in genetics, up to one-third or more of cases of tetralogy have been ascribed to one of several genetic abnormalities, including trisomy 21, the 22q11 microdeletion, the genes NKX 2-5, JAG1, GATA4, and others. Tetralogy of Fallot is the most common cyanotic lesion encountered in the adult population. Unrepaired or nonpalliated, approximately 25% of patients survive to adolescence, after which the mortality is 6.6% per year. Only 3% survive to age 40.[204] Unlike children, teenagers and adults with tetralogy do not develop "tet spells." Long-term survival with a good quality of life is expected after repair. The 32- to 36-year survival has been reported to be 85% to 86%, although symptoms, primarily arrhythmias and decreased exercise tolerance, occur in 10% to 15% at 20 years after the primary repair[205–208] (Box 22.12). In the past, most children with tetralogy were managed with a preliminary palliation with an aortopulmonary shunt such as a Blalock-Taussig, followed by complete correction. Essentially all patients would eventually have come for complete repair. Currently, most children are managed with a complete repair in infancy, without preceding palliation.



BOX 22.12 RISK FACTORS FOR SUDDEN DEATH AFTER REPAIR OF TETRALOGY OF FALLOT

- Repair requiring ventriculotomy
- Older age at repair
- Severe left ventricular dysfunction
- Postoperative right ventricular hypertension (residual outflow tract obstruction)
- Wide-open pulmonary insufficiency
- Prolongation of the QRS

It is uncommon to encounter an adolescent or adult with unrepaired tetralogy. However, it can be encountered in immigrants or in patients whose anatomic variation was considered to be inoperable when they were children. In tetralogy, the right ventricle "sees" the obstruction from the pulmonic stenosis. PVR is typically normal to low. Right-to-left shunting is caused by obstruction at the level of the right ventricular outflow tract and is unaffected by attempts at modulating PVR. Shunting is minimized, however, by pharmacologically increasing systemic vascular resistance. Because there is an unrestrictive VSD, in the unrepaired adult systemic hypertension developing in adult life imposes an additional load on both ventricles, not just the left. The increase in systemic vascular resistance decreases right-to-left shunting and diminishes cyanosis but at the expense of right ventricular or biventricular failure. Increases in the inotropic state of the heart increase the dynamic obstruction at the right ventricular infundibulum and worsen right-to-left shunting. β-Blockers are often used to decrease inotropy. Although halothane was the historic anesthetic of choice in children with tetralogy due to its myocardial depressant effects and ability to maintain systemic vascular resistance, current practice is to use sevoflurane, without undue consequence from a reduction in systemic vascular resistance.[209] Anesthetic induction in adults can easily be achieved with any of the available agents, keeping in mind the principles of maintenance of systemic blood pressure, avoidance of hypovolemia, and preventing increases in inotropy.

Patients require closure of the VSD and resolution of the pulmonic stenosis. Although current practice is to repair the VSD through the right atrium in an effort to maintain competence of the pulmonary valve and limit any ventriculotomy, older patients will likely have had repair via a right ventriculotomy. A large right ventriculotomy increases the risks of arrhythmias and sudden death.[210] Patients who have had a right ventriculotomy will have an obligate right bundle-branch block pattern on the ECG. However, unlike the more usual bundle-branch block in adults, this represents disruption of the His-Purkinje system only in the right ventricular outflow, in the area of the right ventricular incision. Because the vast majority of His-Purkinje conduction is intact, it does not carry increased risk for the development of complete heart block. These patients can have an abnormal response to exercise.

Some patients require repair of pulmonic stenosis by placement of a transannular patch, with obligate residual pulmonary insufficiency. Isolated mild-to-moderate pulmonary insufficiency is generally well tolerated, but in the long term, it can contribute to right ventricular dysfunction with a risk of ventricular tachycardia and sudden death. Patients requiring pulmonary valve replacement in their late teens or early 20s after a transannular patch in early childhood are a growing proportion of the adult CHD population. Atrial tachyarrhythmias occur in about one-third of adults late after repair and can contribute to late morbidity.[211,212] The development of atrial flutter or atrial

reentrant tachycardia is often a harbinger of hemodynamic compromise. The substrate is usually an atrial surgical scar and the trigger is atrial dilation, such as from tricuspid insufficiency with right ventricular dysfunction. The mechanism for the development of ventricular arrhythmias is presumably the same, namely, dilation superimposed on surgical scar.

In some cases, the right ventricular outflow tract patch needs to be extended onto the branch pulmonary arteries to relieve obstruction. Patients with abnormal coronary arteries may have required repair using a right ventricle–to–pulmonary artery conduit to avoid doing a right ventriculotomy in the area of the coronary artery. Repair at a younger age (<12 years) results in better postoperative right ventricular function.[213]

Sudden death or ventricular tachycardia requiring treatment can occur in up to 5.5% of postoperative patients over 30 years, often years postoperatively.[206,207,214] The foci for these arrhythmias are typically in the right ventricular outflow tract in the area that has had surgery, and they can be ablated in the catheterization laboratory. Older age at repair, severe left ventricular dysfunction, postoperative right ventricular hypertension from residual or recurrent outflow tract obstruction, wide-open pulmonary insufficiency, and prolongation of the QRS (to >180 milliseconds) are all predictors of sudden death.[210,215] Premature ventricular contractions and even nonsustained ventricular tachycardia are not rare but do not seem to be associated with sudden death, making appropriate treatment options difficult.[216] QRS prolongation to longer than 180 milliseconds, although highly sensitive, has a low positive predictive value.[217] The impact of this risk factor in the current group of younger patients who have not had ventriculotomies is unclear, because their initial postoperative QRS durations are shorter than in patients who had a right ventriculotomy.

Although for many years it was thought that moderate-to-severe pulmonary insufficiency in these patients was well tolerated, it has become apparent from a number of series that right ventricular dysfunction and both atrial and ventricular arrhythmias can be common long-term sequelae. For this reason, patients with symptomatic pulmonary insufficiency from a transannular patch or aneurysm formation at the site of a right ventricular outflow tract patch can require reoperation to replace a widely incompetent pulmonary valve with a bioprosthetic valve with or without a tricuspid annuloplasty.[218] Of interest, the incidence of atrial arrhythmias may not be diminished when adult patients have a pulmonary valve placed, although the incidence of ventricular arrhythmias is decreased. Right ventricular dysfunction improves in a variable number of adults, suggesting that pulmonary valve placement be done sooner rather than later. The development of pulmonary valves that can be delivered via a vascular catheter holds much promise.[219,220]

Additional possible late-term complications include residual VSD, patch dehiscence, progressive aortic insufficiency, left ventricular dysfunction from surgical injury to an anomalous coronary artery or longstanding preoperative cyanosis, and heart block from VSD closure (uncommon today). Because patients who have had repairs using a conduit require multiple sternotomies and the valved conduit tends to lie immediately behind and in close proximity to the sternum, sternotomy carries with it significant potential risk for laceration of the conduit. On occasion, the femoral vessels are cannulated for bypass before sternotomy.

Most adult patients require reoperation to repair the right ventricular outflow tract or to insert or replace a valve in the pulmonic position. Other reasons for reoperation include repair of an outflow tract aneurysm at the site of a patch, repair of a residual VSD, or repair of an incompetent tricuspid valve.[208] These patients often have diminished right ventricular diastolic compliance and require higher-than-normal central venous pressure. Postoperative management includes minimizing PVR and maintaining central venous pressure. Patients often require treatment postbypass with an inotrope and afterload reduction.[221]

Women with good surgical results without residual defects should tolerate pregnancy and delivery well with outcomes approximating those of the general population, although there is a significant rate for CHD in the infant.[222,223] Women with uncorrected tetralogy, particularly those with significant cyanosis, have a high incidence of fetal loss (80% with hematocrit >65%). The fall in systemic vascular resistance that accompanies pregnancy and delivery can worsen cyanosis, and the physiologic volume loading of pregnancy can exaggerate failure of both ventricles.

Transposition of the Great Arteries (D-Transposition)

In D-transposition of the great arteries, there is a discordant connection of the ventricles and the great arteries. The aorta (with the coronary arteries) arises from the right ventricle, and the pulmonary artery arises from the left ventricle. Thus the two circulations are separate. Postnatal survival requires interchange of blood between the two circulations, typically via a patent foramen ovale and/or a PDA or VSD. With a 1-year mortality approximating 100%, all adults with D-transposition have had some type of surgical intervention. Older adults will have had atrial-type repairs (Mustard or Senning), whereas children born after the mid-1980s will have had repair by arterial switch (the Jatene operation). Some will also have had repair of D-transposition with a moderate-to-large VSD by means of a Rastelli operation (see later).

Atrial repairs function by redirecting systemic venous blood to the left ventricle (and thence to the transposed pulmonary artery) and pulmonary venous blood to the right ventricle (and thence to the aorta). The Mustard operation uses an intraatrial conduit of native pericardium (Fig. 22.10), whereas the Senning operation uses native atrial tissue to fashion the conduit. The arterial switch operation transposes transected aorta and pulmonary artery such that they then arise above the appropriate ventricle. This operation also requires transposing the coronary arteries from the aorta to the pulmonary root,

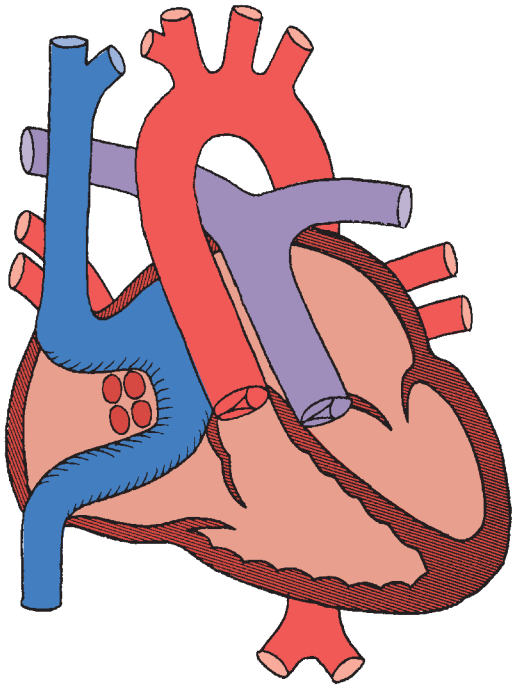


Fig. 22.10 The Mustard operation. An intraatrial baffle has directed vena caval blood across the excised atrial septum to the mitral valve and pulmonary venous blood to the tricuspid valve. The right ventricle remains as the systemic ventricle and the left ventricle as the subpulmonary ventricle. *(Reprinted with permission from Mullins C, Mayer D. Congenital Heart Disease. A Diagrammatic Atlas. New York: Wiley-Liss, Inc.; 1988.)*

which following the procedure, becomes the aortic root. The Rastelli procedure closes the VSD on a bias such that the left ventricle empties into the aorta and connects the right ventricle to the pulmonary artery by means of a valved conduit.

Atrial repairs result in a systemic right ventricle, and these patients consistently have abnormal right ventricular function that can be progressive with a right ventricular ejection fraction of about 40%.[224] Mild tricuspid insufficiency is common, but severe tricuspid insufficiency suggests the development of severe right ventricular dysfunction. There is an 85% to 90% 10-year survival with these operations, but by 20 years, survival is less than 80%.[225–227] Over 25 years, about half develop moderate right ventricular dysfunction and one-third develop severe tricuspid insufficiency.[225,226,228–230] Although function always remains abnormal, it has been suggested that earlier surgery minimizes right ventricular dysfunction.[231] Because of the incidence of right ventricular dysfunction, some patients with atrial repairs have been converted to an arterial switch, following preparation of the left ventricle by a pulmonary artery band to prepare it to tolerate systemic arterial pressure.[232]

Atrial repairs bring an incidence of late electrophysiologic sequelae including sinus node dysfunction (bradycardia), junctional escape rhythms, atrioventricular block, and supraventricular arrhythmias. Atrial flutter occurs in 20% of patients by age 20, with half of them having progressive sinus node dysfunction by that time.[225,229] On occasion these tachyarrhythmias can result in sudden death, presumably from 1:1 conduction producing ventricular fibrillation.[225,233] The loss of sinus rhythm in the face of right ventricular (the systemic ventricle) dysfunction can also contribute to late sudden death. The risk of late death after an atrial repair is almost three times higher if there is an associated VSD. The incidence of tachyarrhythmias does decrease, however, after the tenth postoperative year.

An arterial switch operation can be done after a failed atrial repair in adults, but the outcome is generally poor. It is suggested that younger patients do better.[234] Survival after an arterial switch operation, even early in the experience with this operation, is approximately 90% at 10 years.[235] Very-long-term outcome after the arterial switch procedure is still not known. It does appear that there is essentially no mortality after 5 years postoperatively, and late surgical reintervention is mostly due to supravalvular pulmonic stenosis.[236] Neoaortic root dilation, though only rarely requiring repair, has been noted as a long-term problem.[237] Although many of these children have abnormal resting myocardial perfusion, up to 9% can show evidence of exercise-induced myocardial ischemia.[238] The implication for the development of premature coronary artery disease in adulthood is not known, and there is also some concern about the ultimate function of the neoaortic valve. Patients who have had a Rastelli repair will require episodic reoperation for replacement of the prosthetic conduit valve.

Following an atrial or a Rastelli repair, pregnancy and delivery are generally well tolerated, although right ventricular failure and deterioration in functional capacity can occur. Women with an atrial repair in particular have an increased incidence of complications. There is an increased incidence of prematurity and small-for-date infants in these women.[239]

Truncus Arteriosus

Truncus arteriosus derives from lack of septation of the embryonic truncus arteriosus into aortic and pulmonary artery components, resulting in a single great vessel, the aorta, arising from the heart with a truncal (semilunar) valve. The truncal valve is an amalgamation of the aortic and pulmonary valves and therefore contains between three and six cusps. Additionally, truncal valve insufficiency is a common finding with this morphologically abnormal valve. A large malalignment-type VSD allows filling from both ventricles. The pulmonary arteries arise from the ascending aorta. Although various types have been described depending on the exact anatomy of the pulmonary artery origin, in actual experience, it is more common to see a spectrum of types I through III. Type IV, or pseudotruncus, describes the situation of pulmonary atresia with VSD and supply of the pulmonary arteries from large collaterals originating from the descending aorta. Repair is by closure of the VSD and connection of the right ventricle to the pulmonary artery (or pulmonary arteries) by a conduit containing a homograft valve.

The 1-year survival is less than 10%. Because of the very high risk of congestive heart failure followed by pulmonary vascular disease in childhood from high pulmonary blood flow from the aorta, essentially all patients who survive to adolescence have had surgical repair or will have inoperable pulmonary vascular disease. The rare exception is the patient with stenosis near the origin of the pulmonary arteries from the aorta. Patients with valved conduits placed in infancy and early childhood have requisite reoperations to replace the conduit with patient growth, even in the face of adequate valve function. Conduits placed in later childhood can suffice until adulthood. There can be ongoing problems with incompetence and stenosis of the truncal valve (postoperatively functioning as the aortic valve), and eventual dysfunction from stenosis and/or incompetence of the homograft conduit is routinely encountered, requiring replacement.[240,241] Aortic dilation in adulthood will on occasion require surgical correction, but the criteria for repair remain somewhat undefined. Some use an aortic diameter of greater than 55 mm.[242] Because these patients require multiple sternotomies and the valved conduit tends to lie immediately behind and in close proximity to the sternum, sternotomy carries with it significant potential risk for laceration of the conduit. On occasion the femoral vessels are cannulated for bypass before sternotomy.

Ventricular Septal Defects

The natural history of VSDs has been reviewed in detail.[200] More than 75% of small and moderate VSDs close spontaneously during childhood by a gradual ingrowth of surrounding septum. Of those that close spontaneously, almost all have closed by 10 years of age. Other mechanisms for natural closure include closure by tricuspid valve tissue, closure by prolapsed aortic leaflet, and closure by endocarditis. Some VSDs result in the development of aortic insufficiency in adults from prolapse of the aortic valve into the defect.[243] Although the risk of endocarditis is ongoing, there is no hemodynamic risk of a small VSD in the adult. If pulmonary vascular disease is present, it can progress if closure of a large VSD is delayed.

Although some studies have reported possible ventricular dysfunction years after surgical repair, these are older reports and patients were operated on later than by current standards.[244–246] It does appear, though, that the ventricle successfully remodels from chronic volume overload if surgical correction is done by 5 years of age and perhaps up to 10 to 12 years of age. Iatrogenic heart block is a possible surgical complication, but this was much more common in the earlier days of cardiac surgery. If significant pulmonary hypertension has developed, closure can sometimes be done by means of a unidirectional valve patch, as described by Novick and others.[247] Percutaneous closure devices for use with certain VSDs are available.

Although some discussion is given to onset times with intravenous or inhalation induction agents, clinical differences are hard to notice with modern low-solubility volatile agents. Thermodilution cardiac output reflects pulmonary blood flow, which will be in excess of systemic blood flow. Pulmonary arterial catheters are not routinely indicated. In the patient with a moderate or large left-to-right shunt, low inspired oxygen and moderate hypercarbia avoid intraoperative decreases in PVR with pulmonary overcirculation and left ventricular dilation. However, unlike children, it would be rare to encounter adults with large left-to-right shunts. Adults with unrepaired lesions would either have small shunts or have large shunts that caused Eisenmenger physiology.

Pregnancy is well tolerated in the absence of preexisting heart failure or pulmonary hypertension. Pregnancy with a naturally or surgically closed defect carries with it no additional risk in the absence of additional cardiac problems.

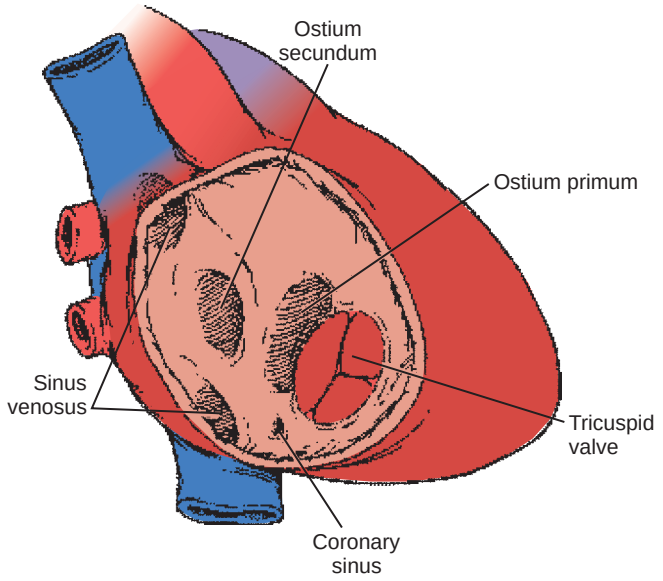

Fig. 22.11 Types of atrial septal defects. *(Reprinted with permission from Nichols DG, Cameron DE, Greeley WG, et al: eds.* Critical Heart Disease in Infants and Children. *St Louis: Mosby; 1995.)*

Case Study 1: Atrial Septal Defect

Framing

The different types of ASDs arise from problems that occur in the various embryologic structures that combine to form the atrial septum (Fig. 22.11). The echocardiographer is required to know the different types of ASD and any associated cardiac defects that accompany each lesion. Secundum ASDs are by far the most common type and are rarely associated with other cardiac defects. Those lesions requiring intervention are usually treated with percutaneous device closure providing there is an adequate rim of surrounding atrial septum for the device to "grab on to." The echocardiographer is vital in helping the interventional cardiologist "see" the atrium in three dimensions and guide placement of the device.

The primum ASD arises from an endocardial cushion defect. When combined with an inlet VSD, it becomes the atrial component of complete atrioventricular canal. As an isolated septal defect, a primum ASD is frequently associated with mitral regurgitation owing to a cleft in the anterior leaflet of the mitral valve. Sinus venosus ASD occurs at the cavoatrial junction, either superiorly or inferiorly. The superior sinus venosus ASD is usually accompanied by anomalous drainage of the right superior pulmonary vein to the superior vena cava (SVC). The inferior sinus venosus ASD is strongly associated with anomalous drainage of the right inferior pulmonary vein to the inferior vena cava (IVC). These associated defects are crucial information for the echocardiographer to incorporate into the transesophageal echocardiographic (TEE) examination.

Data Collection and Interpretation

The intraoperative TEE examination is focused on confirming the presumptive diagnosis of ASD and determining the presence of any other associated defects. The Society of Cardiovascular Anesthesiologists has published guidelines with 20 views that constitute a comprehensive intraoperative TEE examination[248] and this has recently been expanded.[249] When a more detailed examination of a specific cardiac structure is sought, we recommend focusing on the structure by using the zoom feature. The specific structure can then be carefully assessed by using the multiplane function to advance 15 to 30 degrees at a time until the structure has been visualized in multiple views from 0 to 180 degrees. In this example the echocardiographer would focus on the atrial septum in the midesophageal four-chamber view at 0 degrees and then slowly multiplane forward to 180 degrees, providing a comprehensive examination of the structure. The pulmonary veins can be difficult to identify, even for experienced echocardiographers. In the midesophageal four-chamber view with the multiplane angle at 0 degrees, the ultrasound image is focused on the left atrium. The probe is then gently turned to the patient's left to identify the left-sided pulmonary veins and to then to right to identify the right-sided pulmonary veins. Visualizing two separate pulmonary veins from each side is challenging because they arrive at a confluence as they enter the left atrium. The use of color Doppler is often helpful to identify blood flowing within the pulmonary veins.

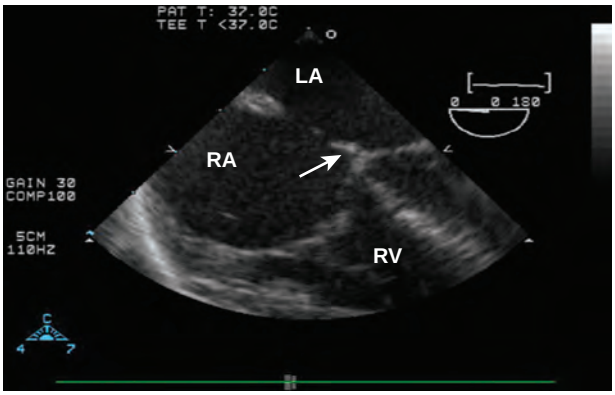

Fig. 22.12 Midesophageal four chamber view at 0 degrees focusing on the atrial septum. There is a large secundum atrial septal defect with only a small rim of inferior atrial septum *(arrow)*. *LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle.

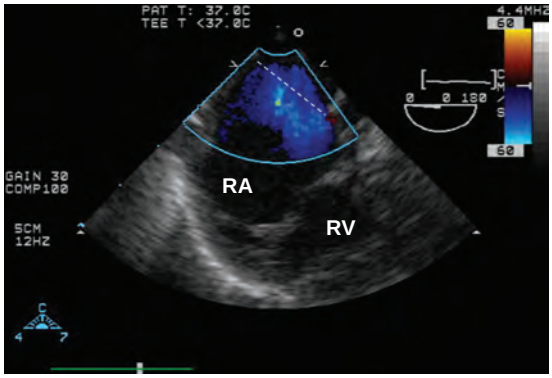

Fig. 22.13 Midesophageal four chamber view at 0 degrees with color flow Doppler. There is a large volume left-to-right shunt *(blue)* across the atrial septal defect (ASD). The *dashed line* represents the approximate location of the ASD. The *uniform blue* color confirms low velocity flow through a large defect. *RA,* Right atrium; *RV,* right ventricle.

Decision Making and Interpretation

A patient was scheduled for surgical resection of an ASD. Preoperative transthoracic echocardiography confirmed a large secundum ASD with inferior extension toward the IVC (Fig. 22.12). The size and inferior extension of the ASD precluded percutaneous device closure. The TEE examination confirmed the preoperative findings and demonstrated four pulmonary veins returning to the left atrium. The volume of left-to-right shunting was large (Fig. 22.13). Right ventricular volume overload was present with significant right ventricular dilation (Fig. 22.14). After closure of the ASD and separation from CPB, a residual ASD was seen at the inferior aspect of the ASD patch (Fig. 22.15). Comparing Figs. 22.13 and 22.15 demonstrates the echocardiographic difference in appearance between a high-volume, low-velocity shunt

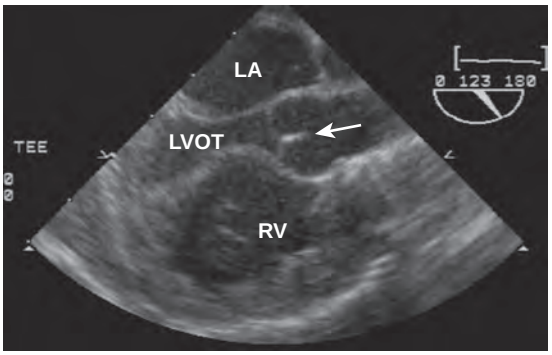

Fig. 22.14 Midesophageal aortic valve long axis view at 123 degrees. The aortic valve *(arrow)* is closed signifying diastole. The atrial septal defect has caused marked volume overload of the right ventricle. During diastolic filling of the right ventricle, the septum bulges into the left ventricle. *LA,* Left atrium; *LVOT,* left ventricular outflow tract; *RV,* right ventricle.

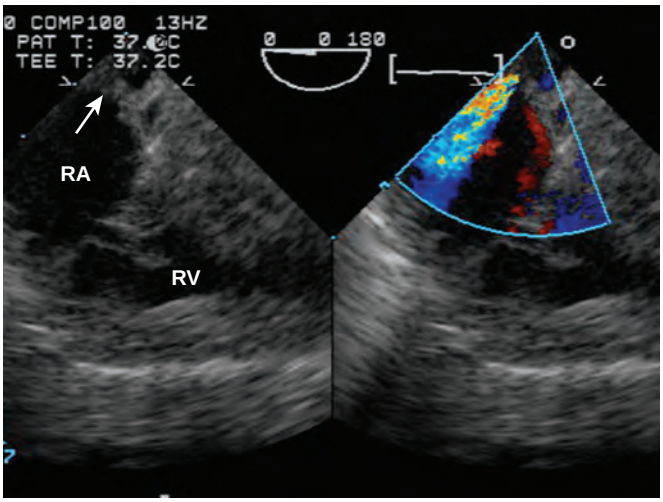

Fig. 22.15 Side-by-side images in 2D *(left image)* and with color flow Doppler *(right image).* In the 2D image there is a possible inferior residual atrial septal defect (ASD; *arrow*). With color flow Doppler the residual ASD is clearly appreciated. The *orange speckling* superimposed on the *blue* color confirms high-velocity flow. *RA,* Right atrium; *RV,* right ventricle.

and a more restrictive, higher-velocity shunt. The configuration of the TEE machine in the color Doppler mode identifies blood flow towards the transducer in red and blood flow away from the transducer in blue. There is also a threshold of velocity set, such that when blood flow exceeds the velocity threshold, speckling occurs. In Fig. 22.13 there is a uniform blue color demonstrating a significant volume shunt. The absence of color speckling confirms low-velocity blood flow. Fig. 22.15, taken after attempted repair of the ASD, shows a smaller blue area with orange speckling. The speckling confirms higher-velocity blood flow, which is to be expected because the residual defect is much smaller than the unrepaired ASD. Velocity increases as blood flows through a narrower orifice.

How is a residual septal defect assessed? The defect can be assessed qualitatively by examining the degree of shunt using color flow Doppler. After attempted surgical repair, it would be unusual to have a large residual septal defect. What other information can guide the surgeon in determining whether to return to CPB and attempt to close what appears to be a small residual defect? The residual defect results in a left-to-right shunt, which allows the measurement of the "oxygen step-up" between the SVC and pulmonary artery. To do this, the patient should be ventilated with room air. High levels of inspired oxygen result in left atrial blood having a high PaO_2, which causes an overestimation of the residual shunt. After a period of 5 minutes to allow equilibration, blood gas samples from the SVC and pulmonary artery were sent. The oxygenation saturation was 58% in the SVC and 72% in the pulmonary artery. Using a simple equation allows for an estimation of the ratio of pulmonary to systemic blood flow ($Q_p:Q_s$). The saturation at four anatomic locations is entered into the following equation. The oxygen saturations from the SVC and pulmonary artery are measured, the oxygen saturation for the aorta is taken from the peripheral pulse oximeter, and the oxygen saturation for the pulmonary vein assumed to be 100%.

$$Q_p:Q_s = \frac{\text{Aorta} - \text{SVC}}{\text{Pulmonary vein} - \text{Pulmonary artery}} = \frac{100-58}{100-72} = 1.5$$

The $Q_p:Q_s$ ratio of 1.5 was high enough that, if unrepaired, it would likely leave the patient symptomatic from excessive pulmonary blood flow. Integrating the echocardiographic images with quantitative data estimating the degree of the shunt provided the surgeon with a sound justification to return to CPB and attempt to close the residual ASD. The echocardiographic images suggested it was very unlikely the residual defect would close spontaneously. The decision to return to CPB and subject the heart to another period of aortic cross-clamp and ischemia must never be made lightly. It was the surgeon's opinion that the residual defect was not amenable to closure with a percutaneous device at some later date and the patient's underlying heart function was good enough to withstand another period of ischemia and aortic cross-clamp.

After the second attempt at repair, the patient separated easily from CPB. The ASD patch appeared intact on TEE examination, but there was an unusual color flow Doppler jet seen originating from the junction of the IVC and right atrium. What are the possible explanations? Could this simply be turbulence in the area of the ASD repair? The echocardiographer must now rely on knowledge of the lesion and the potential surgical complications associated with its repair. Fig. 22.11 clearly demonstrates the very close proximity of an inferior sinus venosus ASD to the IVC. A known, albeit rare, complication of inferior sinus venosus ASD repair is to suture the ASD patch from the IVC to the ASD, thus creating a path from the IVC to left atrium. This suspicion was bolstered by the fact the peripheral pulse oximeter reading varied between 85% and 88%. This was confirmed by arterial blood gas results. The presence of a right-to-left shunt demanded correction. The patient returned to CPB for a third time for takedown of the patch and closure of the ASD. Based on the two previous attempted repairs, the surgeon realized the secundum ASD might extend even farther into the sinus venosus region of the septum than previously imagined. The IVC venous cannula was repositioned more inferiorly, allowing greater exposure of the defect. After repair, the patient once again separated easily from CPB. The TEE examination confirmed the success of the repair with no residual shunting. This case well demonstrates the need for the intraoperative echocardiographer to be more than a "technician" and integrate supporting physiologic information with the TEE images.

Case Study 2: Anomalous Left Main Coronary Artery

Framing

Anomalous coronary arterial lesions comprise a spectrum of defects. In one variant, the left main coronary artery (LMCA) originates from the pulmonary artery. The clinical presentation is heart failure secondary to left ventricular ischemia and generally occurs in the first few months of life. A more insidious but also potentially lethal form of anomalous coronary arterial lesion occurs when both coronary arteries arise from the aorta but from abnormal locations. Most well described

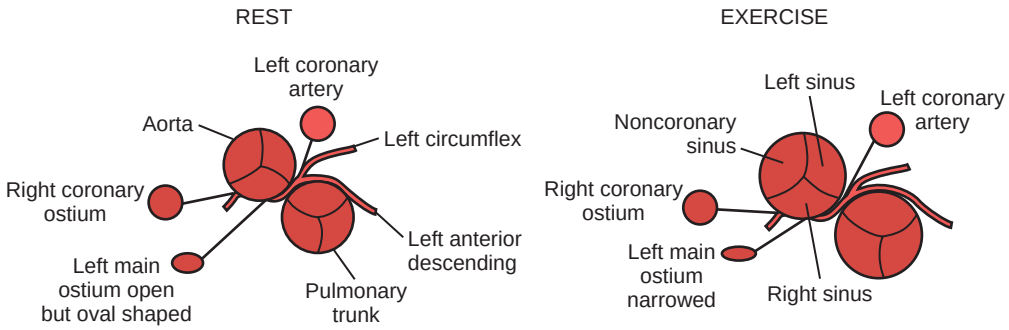

Fig. 22.16 Anomalous left main coronary artery. Compression of the left main coronary artery occurs during exercise. *(Reprinted with permission from Basilico FC. Cardiovascular disease in athletes.* Am J Sports Med. *1999;27:108–121.)*

is an anomalous LMCA that originates from the right coronary sinus. The LMCA may originate from a separate ostium or may share the same ostium as the right coronary artery (RCA) (Fig. 22.16). As the figure demonstrates, the path of the LMCA is abnormal. First, the LMCA travels within the wall of the aorta for a short distance before exiting to the epicardial surface of the heart. This is known as an intramural coronary artery. The path of LMCA then follows a path between the aorta and pulmonary artery. The abnormal path of the anomalous LMCA explains why the clinical presentation is sudden death, most often during exercise. The increased blood flow caused by exercise results in dilation of both the aorta and pulmonary artery. This dilation can compress the LMCA between the aorta and pulmonary artery. Alternatively, if the LMCA is intramural, it can be compressed within the wall of the aorta. Either case leads to ischemia in the entire territory of the LMCA with sudden cardiac death. Tragically, an anomalous LMCA is often a postmortem finding after an unexplained sudden death in an otherwise healthy young person. For reasons that are unclear, patients rarely, if ever, develop exertional chest pain. Also the amount of exertion that precipitates a cardiac event is not predictable. That is, the patient may have vigorously exercised in the past without a problem but then suffers a cardiac event during more modest exertion. For these reasons, if a diagnosis of anomalous LMCA is made, surgery is indicated for the prevention of sudden cardiac death.

Data Collection and Interpretation

The diagnosis of LMCA is most often an incidental finding when echocardiography is done for other indications. Proving the absence of a structure is difficult because it may be present but not well visualized by the particular test being used. Echocardiography, either transthoracic or transesophageal, is not the recommended test for demonstrating the origins of the coronary arteries. Therefore if the ostium of the LMCA is not seen with echocardiography, confirmatory testing is needed. Magnetic resonance imaging or computed tomography is highly specific and sensitive in accurately diagnosing coronary artery anomalies.

The preferred surgical approach is to divide the LMCA from the right coronary sinus and reimplant it in its proper location. This requires mobilization of the LMCA to allow safe reimplantation on the left coronary sinus. An anomalous LMCA does not cause chronic ischemia. The TEE examination should demonstrate normal left ventricular function. The absence of the LMCA ostium may be noted, but even in patients with normal coronary anatomy, the ostia are frequently not well visualized.

Decision Making and Interpretation

During investigations for nonspecific chest pains, an otherwise healthy patient was discovered to have an anomalous LMCA and was scheduled for coronary reimplantation. After induction of anesthesia, the

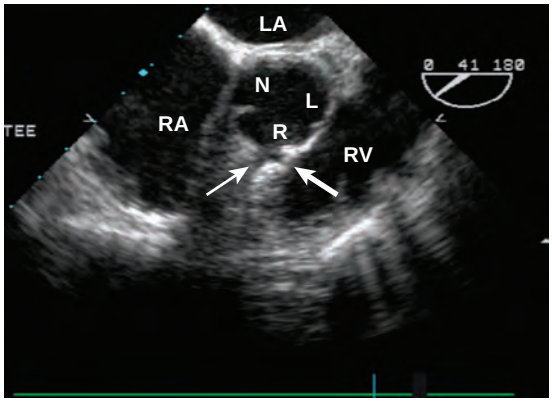

Fig. 22.17 Midesophageal aortic valve short axis view at 41 degrees. The left main coronary artery *(thick arrow)* and right coronary artery *(thin arrow)* both arise from a single ostium in the right coronary sinus. *L,* Left coronary sinus; *LA,* left atrium; *N,* noncoronary sinus; *R,* right coronary sinus; *RA,* right atrium; *RV,* right ventricle.

TEE probe was inserted, which demonstrated normal left ventricular function and the LMCA originating from the right coronary cusp, sharing a common ostium with the RCA (Fig. 22.17). After the aortic cross-clamp was applied and cardioplegia delivered, the heart was slow to arrest. The cardioplegia circuit was checked and found to be working properly. However, throughout the period of aortic cross-clamp the heart frequently recovered electrical and mechanical activity before the next scheduled dose of cardioplegia. At the conclusion of the coronary reimplantation, the surgeon felt the myocardial preservation had been poor and the patient would likely need inotropic support. Upon attempted separation from CPB, the patient was hypotensive with poor myocardial function. What is the differential diagnosis of ventricular dysfunction after CPB? The ECG showed sinus tachycardia with nonspecific S-T changes in both leads II and V5. This was confirmed in other ECG leads. The question to be answered was whether ventricular dysfunction could be due to possible poor myocardial preservation or whether the LMCA reimplantation was unsuccessful. By visual inspection, the right ventricle was contracting well. There was no S-T elevation in lead II to suggest air embolus to the RCA. What is the preferred TEE view to assess ventricular function? The transgastric short axis view at the midpapillary level is used routinely to assess preload, contractility, and regional wall motion abnormalities. Knowing the coronary artery that corresponds to the various left ventricular segments allows the echocardiographer to identify regional wall motions abnormalities caused by ischemia (Fig. 22.18). The transgastric image showed marked left ventricular dilation with akinesis of the septal, anterior, lateral, and posterior walls. There was minimal decrease in left ventricular cavity size during systole (Video 22.1). The reimplanted

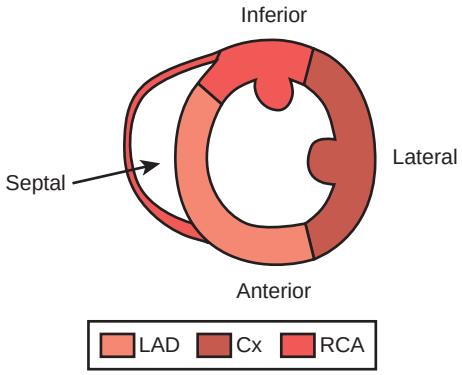

Fig. 22.18 Regional left ventricular anatomy with the corresponding coronary artery distribution. *Cx,* Circumflex artery; *LAD,* left anterior descending artery; *RCA,* right coronary artery. *(Reprinted with permission from Shanewise JS, Cheung AT, Aronson S, et al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination: recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society of Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography.* Anesth Analg. *1999;89:870–884.)*

LMCA could not be seen originating from the left coronary sinus. Global ventricular dysfunction secondary to poor myocardial preservation was unlikely because right ventricular function was good. The inferior region of the left ventricle, which is supplied by the RCA, had normal function. The findings of severe regional wall motion abnormalities in the distribution of the LMCA confirmed the suspicion of unsuccessful LMCA reimplantation. The extensive wall motion abnormalities suggested the patient had left dominant coronary circulation. By inspection the reimplanted LMCA appeared to free of tension or kinking. After consultation with the surgeon and a description of the TEE findings, it was decided that a second attempt at LMCA reimplantation was very unlikely to be successful.

A decision was made to perform a left internal mammary artery (LIMA) to proximal left anterior descending (LAD) artery graft. It was hoped that a very proximal anastomosis to the LAD would ensure flow into the circumflex artery as well. The patient separated easily from CPB. The TEE revealed normal left ventricular function with dramatic resolution of the previous regional wall motion abnormalities (Video 22.2). Specifically, the lateral and posterior regions of the left ventricle had good function, which provided strong evidence that the LIMA to proximal LAD graft was also perfusing the circumflex artery. Contrasting the two video images illustrates that the echocardiographic assessment of contractility is based on the degree of ventricular wall thickening during systole. In the first image, the ischemic regions (septal, anterior, lateral, posterior) of the left ventricle do not thicken during systole, but they do move because they are contiguous with the other regions that retain normal function. Although unlikely in this example because the findings are so dramatic, the novice echocardiographer can often confuse ventricular motion with contractility. After the LIMA to LAD graft, the previously akinetic segments increase their wall thickness by more than 50% during systole. The significant reduction in left ventricular cavity size during systole denotes a normal ejection fraction.

23 Thoracic Aorta

PRAKASH A. PATEL, MD | JOHN G.T. AUGOUSTIDES, MD, FASE, FAHA | ENRIQUE J. PANTIN, MD | ALBERT T. CHEUNG, MD

KEY POINTS

1. Diseases of the thoracic aorta can occasionally be managed with medical treatment and surveillance, whereas others require surgical intervention. Depending on the disease process, some surgeries may be performed electively, whereas others are truly emergency operations.
2. Aortic surgery is complex, and therefore it requires an anesthetic tailored to the specific goals for hemodynamics, neuromonitoring, and cerebral/spinal cord perfusion.
3. Multidisciplinary guidelines for the diagnosis and management of thoracic aortic disease summarize the evidence and expert consensus for this challenging group of important diseases.
4. Thoracic aortic aneurysms can cause compression of the trachea, left mainstem bronchus, right ventricular outflow tract, right pulmonary artery, or esophagus.
5. Deliberate hypothermia is the most important therapeutic intervention to prevent cerebral ischemia during temporary interruption of cerebral perfusion during aortic arch reconstruction.
6. Early detection and interventions to increase spinal cord perfusion pressure are effective for the treatment of delayed-onset spinal cord ischemia after thoracic or thoracoabdominal aortic aneurysm repair.
7. Severe atheromatous disease or thrombus in the thoracic or descending aorta is a risk factor for stroke.
8. Stanford type A dissection, involving the ascending aorta and aortic arch, is a surgical emergency. Stanford type B dissection, confined to the descending thoracic or abdominal aorta, should be managed medically when possible.
9. When adequate preoperative imaging is lacking, intraoperative transesophageal echocardiography can be used to diagnose type A dissection or traumatic aortic injuries that require emergency surgery.
10. Intraoperative transesophageal echocardiography and ultrasound imaging of the carotid arteries are useful for the diagnosis of aortic regurgitation, cardiac tamponade, myocardial ischemia, or cerebral malperfusion, complicating type A aortic dissection.
11. Newer endovascular approaches to the management of thoracic aortic disease continue to have a great impact on both elective and emergent aortic surgery.

Thoracic aortic diseases typically require surgical intervention (Box 23.1). Acute aortic dissections, rupturing aortic aneurysms, and traumatic aortic injuries are surgical emergencies. Subacute aortic dissection and expanding aortic aneurysms require urgent surgical intervention. Stable thoracic or thoracoabdominal aortic aneurysms (TAAAs), aortic coarctation, or atheromatous disease causing embolization may be addressed surgically on an elective basis. The volume of thoracic aortic procedures has grown steadily because of factors such as increased public awareness, an aging population, earlier diagnosis, multiple advances in imaging, and advances in surgical techniques including endovascular stenting. Medical centers have emerged that specialize in thoracic aortic diseases, resulting in improved management and survival.[1] This progress has created a set of patients who later require reoperation for long-term complications such as valve or graft failure, pseudoaneurysm at anastomotic sites, endocarditis, and/or progression of the original disease process into the residual native aorta.

The anesthetic management of thoracic aortic diseases has unique considerations, including the temporary interruption of blood flow, often resulting in ischemia of major organ systems. Critical components of anesthetic management include the maintenance of organ perfusion, protection of vital organs during ischemia, and monitoring and management of end-organ ischemia. As a result, the vigilant and skillful anesthesiologist contributes significantly to the overall success of these operations. The procedures performed by the thoracic aortic team for organ protection, such as partial left-heart bypass (PLHB) for distal aortic perfusion, cardiopulmonary bypass (CPB) with deep hypothermic circulatory arrest (DHCA), selective cerebral perfusion, and lumbar cerebrospinal fluid (CSF) drainage, are practiced routinely in no other area of medicine. Several multisociety guidelines represent a contemporary evidence-based, consensus-driven approach to thoracic aortic diseases. Their recommendations are referred to throughout this chapter, based on the well-known classification of recommendations and levels of evidence (Tables 23.1 and 23.2) by the American College of Cardiology (ACC) and American Heart Association (AHA).[2–5]

Anatomy of the Aorta

The aorta is the large artery running from the aortic valve to the iliac bifurcation. It serves both as a conducting vessel and as a secondary passive pump because of its elastic recoil. During ventricular systole, the aortic lumen distends as it receives the entire stroke volume. In diastole, after aortic valve closure, the blood is propelled forward as a result of the aorta's elastic recoil. This pulse wave is transmitted distally at approximately 5 m/second, exceeding the aortic blood flow velocity of 40 to 50 cm/second. The aortic systolic blood pressure results from the summated effects of stroke volume, aortic compliance, and peripheral vascular resistance. Isolated systolic hypertension develops with aging as the aorta loses elasticity and cannot dampen the stroke volume.

During fetal development, the ductus arteriosus diverts blood from the pulmonary artery into the distal aortic arch. After birth,

BOX 23.1 THORACIC AORTIC DISEASES AMENABLE TO SURGICAL TREATMENT

Aneurysm
Congenital or developmental
  Marfan syndrome, Ehlers-Danlos syndrome
Degenerative
  Cystic medial degeneration
  Annuloaortic ectasia
  Atherosclerotic
Traumatic
  Blunt and penetrating trauma
Inflammatory
  Takayasu arteritis, Behçet syndrome, Kawasaki disease
Microvascular diseases (polyarteritis)
Infectious (mycotic)
  Bacterial, fungal, spirochetal, viral
Mechanical
  Poststenotic, associated with an arteriovenous fistula
  Anastomotic (postarteriotomy)
Pseudoaneurysm
Aortic dissection
  Stanford type A
  Stanford type B
Intramural hematoma
Penetrating atherosclerotic ulcer
Traumatic aortic injury
Aortic coarctation

TABLE 23.1 Classification Scheme for Clinical Recommendations

Clinical Recommendations	*Definition of Recommendation Class*
Class I	The procedure/treatment should be performed (benefit far outweighs the risk).
Class IIa	It is reasonable to perform the procedure/treatment (benefit still clearly outweighs risk).
Class IIb	It is not unreasonable to perform the procedure/treatment (benefit probably outweighs the risk).
Class III	The procedure/treatment should not be performed as it is not helpful and may be harmful (risk may outweigh benefit).

lung expansion and constriction of the ductus arteriosus because of increased blood oxygen content drive the blood from the pulmonary artery into the pulmonary circulation. Typically, the ductus arteriosus is functionally closed by 48 hours and is permanently closed by 3 weeks after birth.[6] It subsequently fibroses to become the ligamentum arteriosum. Occasionally, this process fails and the ductus arteriosus remains patent. Furthermore, occasionally a ductal diverticulum may persist and be confused in later life with an aortic injury during aortic imaging. The pathogenesis of aortic coarctation may be related to residual ductal tissue that narrows the aorta as it constricts.

The aortic wall has three layers: a thin intima or inner layer lined by endothelium, a thick media or middle layer, and a thin adventitia or outermost layer.[3] The endothelium is in direct contact with blood, is easily traumatized, and is the site for atherosclerosis. The media accounts for 80% of the aortic wall thickness and consists of spirally arranged intertwining layers of elastic tissue that provide the aorta's tensile strength and elasticity. The adventitia consists mainly of collagen and contains the vasa vasorum that nourishes the outer half of the aortic wall. The fact that the vasa vasorum are absent in the infrarenal aorta may explain the frequency of infrarenal aortic aneurysms. These three aortic layers typically are indistinguishable by current clinical imaging techniques. Pathologic aortic processes can separate the aortic wall layers to make them evident on computed tomography (CT), magnetic resonance imaging (MRI), or transesophageal echocardiography (TEE).[2–4]

The thoracic aorta comprises the ascending aorta, the aortic arch, and the descending aorta.[2–4] The ascending aorta also includes the aortic root. The aorta begins at the aortic valve just to the right of midline at the left ventricular base. The aortic root and proximal ascending aorta lie within the pericardial sac. The aorta then travels superiorly and anteriorly to the left. It then turns posteriorly and continues to the left to the fourth thoracic vertebra. Thereafter, it travels inferiorly, initially anterior and to the left of the spine to cross the diaphragm, ending in front of the fourth lumbar vertebra. The aortic root includes the aortic valve annulus and the sinuses of Valsalva that terminate at the sinotubular junction.[3,4] The origin of the brachiocephalic artery marks the end of the ascending aorta and the beginning of the aortic arch. The aortic arch lies within the superior mediastinum between the ascending and descending thoracic aorta. The aortic arch ends after the origin of the left subclavian artery. The aortic isthmus is the segment of aorta where the distal aortic arch becomes the descending thoracic aorta. At the aortic isthmus, the relatively mobile ascending aorta and arch join the descending thoracic aorta that is fixed to the posterior thoracic cage by pleural reflections, the intercostal arteries, the ligamentum arteriosum, and the left subclavian artery. As a result, the aortic isthmus is vulnerable to traumatic injury because it is subjected to high shear forces after blunt trauma or rapid deceleration. Furthermore, the aortic isthmus also is the most common site for aortic coarctation.

The coronary arteries are the first branches of the aorta. The aortic arch subsequently gives origin to the brachiocephalic (innominate), left carotid, and left subclavian arteries that supply the head, neck, and arms.[2–4] The brachiocephalic artery is the first branch of the aortic arch, followed by the left common carotid artery, and finally, the left subclavian artery. There are multiple aortic arch anatomic variations, including vascular rings, right-sided aortic arch, and branching anomalies. A right-sided aortic arch is found in about 0.1% of the population. A relatively common aortic arch branch anomaly with a 4% prevalence rate is an isolated left vertebral artery, so named because it arises directly from the aortic arch.[7]

The aortic arch also modulates blood pressure via baroreceptors within its outer wall. The aortic bodies are located inferior to the aortic arch. The aortic baroreceptors respond to a greater threshold pressure and thus are less sensitive when compared with the carotid sinus receptors. These receptors send impulses to the brainstem that interact with the medullary cardiovascular center for modulation of autonomic nervous system activity.[8]

General Considerations for the Perioperative Care of Aortic Surgical Patients

Patients undergoing thoracic aortic surgery require the common considerations for the safe use of anesthesia and perioperative care that are addressed in this section (Box 23.2). The unique considerations and care that apply to specific diseases and procedures are addressed in subsequent sections devoted to their management.

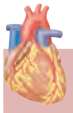
Preanesthetic Assessment

The preanesthetic assessment of the thoracic aorta surgical patient ideally begins before admission to the operating room (OR). The first consideration is whether the planned procedure is emergent, urgent, or elective. For urgent or emergent operations, it is most efficient to assign team members specific tasks for rapid and comprehensive patient and OR preparation. For example, one team member can review the patient chart and diagnostic studies to formulate an anesthetic plan. A second team member can interview the patient and obtain informed consent. The remaining team members can simultaneously prepare the OR, apply physiologic monitors, secure intravascular access, and send laboratory specimens including blood for crossmatching.

The second consideration is to determine the aortic diagnosis because its extent and physiologic consequences dictate both anesthetic management and surgical approach. Aortic diseases proximal to the left carotid artery typically are approached via a median sternotomy, whereas aortic diseases distal to this point usually are approached via a left thoracotomy or thoracoabdominal incision. Although an aortic diagnosis often is established in advance, at times a definitive diagnosis must be verified after OR admission by direct review of diagnostic studies or by subsequent TEE. In every case, a review of the operative plan with the surgical team facilitates thorough anesthetic preparation. Direct review of adequate aortic diagnostic imaging studies not only verifies the operative diagnosis but also determines the surgical possibilities (class I recommendation; level of evidence C).[2,9] The anatomic details of an aortic disease permit the anesthesiologist to anticipate potential perioperative difficulties, including likely postoperative complications.

The systematic assessment of each organ system in the aortic surgical patient should focus on how it will affect the conduct of anesthesia and surgery. The baseline functional reserve of each organ system determines the likely perioperative complications and allows ranking of organ-protective strategies. It is reasonable in nonemergent cases to obtain further tests to quantitate the functional reserve of affected organ systems, for example, neurocognitive testing, brain imaging, noninvasive carotid artery imaging, pulmonary function testing, echocardiography, and cardiac catheterization (class IIa recommendation; level of evidence C).[2] Significant cerebrovascular disease affects blood pressure management to ensure adequate cerebral perfusion. Significant cardiac compromise typically increases the risks for heart failure, myocardial ischemia, and arrhythmias. Significant lung disease often is predictive for postoperative respiratory failure, pneumonia, or both. Significant renal insufficiency affects fluid management, triggers the avoidance of nephrotoxic drugs, and customizes the dosing of renally cleared drugs. Hepatic disease and hematologic dysfunction are risk factors for perioperative bleeding and transfusion. Severe aortic atheroma is a major risk factor for atheroembolism and consequent stroke and limb ischemia.

Because myocardial ischemia is an important predictor of perioperative outcome, it has featured prominently in the guidelines for thoracic aortic diseases.[2–4] Patients with evidence of myocardial ischemia should undergo further evaluation to determine the extent and severity of coronary artery disease (CAD; class I recommendation; level of evidence C).[2] If significant CAD is responsible for an acute coronary syndrome, then coronary revascularization is indicated before or concomitant with the thoracic aortic procedure (class I recommendation; level of evidence C).[2] Concomitant coronary artery bypass grafting (CABG) is reasonable in patients who have significant CAD and are scheduled to undergo surgery for diseases of the ascending aorta or aortic arch, or both (class IIa recommendation; level of evidence C).[2] In contrast, the benefit of coronary revascularization is less clear in patients who have stable CAD and who are scheduled to undergo



BOX 23.2 ANESTHETIC CONSIDERATIONS FOR THE CARE OF THORACIC AORTIC SURGICAL PATIENTS

Preanesthetic Assessment
- Urgency of the operation (emergent, urgent, or elective)
- Pathology and anatomic extent of the disease
- Median sternotomy vs thoracotomy vs endovascular approach
- Mediastinal mass effect
- Airway compression or deviation

Preexisting or Associated Medical Conditions
- Aortic valve disease
- Cardiac tamponade
- Coronary artery stenosis
- Cardiomyopathy
- Cerebrovascular disease
- Pulmonary disease
- Renal insufficiency
- Esophageal disease (contraindications to TEE)
- Coagulopathy
- Prior aortic operations

Preoperative Medications
- Warfarin (Coumadin)
- Antiplatelet therapy
- Antihypertensive therapy

Anesthetic Management
- Hemodynamic monitoring
  - Proximal aortic pressure
  - Distal aortic pressure
  - Central venous pressure
  - Pulmonary artery pressure and cardiac output
  - TEE
- Neurophysiologic monitoring
  - Electroencephalography
  - Somatosensory-evoked potentials
  - Motor-evoked potentials
  - Jugular venous oxygen saturation
  - Lumbar cerebrospinal fluid pressure
  - Body temperature
- Single-lung ventilation for thoracotomy
  - Double-lumen endobronchial tube
  - Endobronchial blocker
- Potential for bleeding
  - Large-bore intravenous access
  - Blood product availability
  - Antifibrinolytic therapy
- Antibiotic prophylaxis

Postoperative Care Considerations and Complications
- Hypothermia
- Hypotension
- Hypertension
- Bleeding
- Spinal cord ischemia
- Stroke
- Renal insufficiency
- Respiratory insufficiency
- Phrenic nerve injury
- Diaphragmatic dysfunction
- Recurrent laryngeal nerve injury
- Pain management

surgical intervention for descending thoracic aortic disease (class IIb recommendation; level of evidence C).[2]

Preoperative Medications

Preoperative medications typically provide detailed information about concomitant medical conditions. As a general rule, all cardiac, pulmonary, and anticonvulsant medications should be continued up until the morning of surgery. Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers should be discontinued the day before surgery to minimize the risk for perioperative vasoplegia and adverse outcomes.[10,11] Occasionally, these drugs may be continued with caution in patients with hypertension that is difficult to control. All oral hypoglycemic agents should be discontinued the night before surgery to avoid hypoglycemia. If possible, metformin should be discontinued the day before surgery to minimize the risks for severe lactic acidosis associated with exposure to iodinated contrast agents or perioperative hypovolemia. If a patient is receiving insulin, up to 50% of the typical morning dose should be given the day of surgery with subsequent close glucose monitoring. Finally, the consequences of preoperative medications for anesthetic procedures must be carefully considered. For example, coagulopathy caused by organ dysfunction or concomitant medication, or both, increases the risks for hemorrhagic complications associated with neuraxial techniques such as lumbar CSF drainage and epidural analgesia.

Warfarin should be discontinued for approximately 5 days before surgery to allow for full recovery of coagulation function as verified by a normal international normalized ratio.[12,13] If this is not possible, then the patient should be admitted for heparin bridging until shortly before surgery. Patients chronically exposed to low-molecular-weight heparin, aspirin, adenosine diphosphate platelet-receptor inhibitors (clopidogrel, prasugrel, or ticagrelor), and platelet glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban) are typically at increased risk for perioperative bleeding. Aspirin may or may not be discontinued depending on a coexisting acute coronary syndrome, but ideally, agents such as clopidogrel or prasugrel will have been discontinued at least 5 to 7 days before surgery to allow adequate recovery of platelet function for perioperative hemostasis.[12,13] The new oral anticoagulants, including dabigatran, rivaroxaban, apixaban, and edoxaban, should be stopped for longer than three half-lives—ideally, for 3 to 5 days (see Chapter 35).

Anesthetic Management

Overall, the anesthetic plan, including techniques, drugs, and monitoring, should be individualized to enhance the conduct of the procedure, including perfusion technique, hemodynamic monitoring, and preservation of organ function (class I recommendation; level of evidence C).[2] Because thoracic aortic procedures may result in massive bleeding and cardiovascular collapse, it is essential to have immediate availability of packed red blood cells and clotting factors, large-bore vascular access, invasive blood pressure monitoring, and central venous access. Pulmonary artery catheterization assists in the management of cardiac dysfunction associated with CPB, DHCA, and PLHB. Intraoperative TEE is indicated in thoracic aortic procedures, including endovascular interventions, in which it assists in hemodynamic monitoring, procedural guidance, and endoleak detection (class IIa recommendation; level of evidence B).[2,9] A rationale exists for choosing to cannulate the left or right radial artery for intraarterial blood pressure monitoring. Right radial arterial pressure monitoring will often detect compromised flow into the brachiocephalic artery because of aortic cross-clamping too near its origin. Right radial arterial pressure monitoring also makes sense in procedures that require clamping of the left subclavian artery. Left radial arterial pressure monitoring is indicated when selective antegrade cerebral perfusion (ACP) is planned via the right axillary artery; however, a right-sided catheter may be preferred for ACP if direct brachiocephalic cannulation is used by the surgeon. At times, bilateral radial arterial pressure monitoring may be required. Femoral arterial pressure monitoring allows the assessment of distal aortic perfusion in procedures with PLHB. Overall, institutional practices depending on surgical techniques and preferences will also help determine the best location for monitoring.

Large-bore peripheral intravenous cannulation secures vascular access for rapid intravascular volume expansion. Rapid transfusion is desirable via an intravenous set with a fluid-warming device. Alternatively, large-bore central venous cannulation can be utilized for volume expansion. If a pulmonary artery catheter (PAC) is required, a second introducer sheath dedicated to volume expansion also can be placed in the same central vein. Central venous cannulation with ultrasound guidance often increases speed and safety, especially in emergencies.[14] Both a urinary and a nasopharyngeal temperature probe are required for monitoring the absolute temperature of the periphery and core, as well as the rates of change during deliberate hypothermia and subsequent rewarming. The rectum is an alternative site for monitoring peripheral temperature, and the PAC can provide core temperature monitoring.

The induction of general anesthesia requires careful hemodynamic monitoring with anticipation of changes because of anesthetic drugs and tracheal intubation. Appropriate vasoactive drugs should be immediately available as required. Concomitant vasodilator infusions often are discontinued before anesthetic induction. Because etomidate does not attenuate sympathetic responses and has no direct effects on myocardial contractility, it may be preferred in the setting of hemodynamic instability. Thereafter, titration of a narcotic such as fentanyl and a benzodiazepine such as midazolam will provide maintenance of general anesthesia. In elective cases, anesthetic induction can proceed with routine intravenous hypnotics, followed by narcotic titration for attenuation of the hypertensive responses to tracheal intubation and skin incision. Antibiotic therapy optimally should be completed in most cases at least 30 minutes before skin incision to achieve adequate bactericidal tissue levels.

General anesthetic maintenance is typically with a balanced intravenous and inhalation anesthetic technique, and neuromuscular blockade is achieved by titration of a nondepolarizing muscle relaxant. Anesthetics can be reduced during moderate hypothermia and then discontinued during deep hypothermia. With concomitant electroencephalographic (EEG) and/or somatosensory-evoked potential (SSEP) monitoring, anesthetic signal interference is minimized with the avoidance of barbiturates, bolus propofol, and doses of inhaled anesthetic greater than 0.5 minimum alveolar concentration. Propofol infusion, narcotics, and neuromuscular blocking drugs do not interfere with SSEP monitoring. With intraoperative motor-evoked potential (MEP) monitoring, high-quality signals are obtained when the anesthetic technique comprises total intravenous anesthesia with propofol and a narcotic such as remifentanil without neuromuscular blockade. Neuromonitoring (EEG, SSEP, MEP) in thoracic aortic procedures is not only compatible with contemporary anesthetic techniques but is also reasonable when the resulting data will guide perioperative management (class IIa recommendation; level of evidence B).[2] The decision to utilize this monitoring modality should be based on procedural urgency, institutional resources, patient needs, and planned operative technique (class IIa recommendation; level of evidence B)[2] (see Chapter 18).

In most cases, the duration of general anesthesia continues for several hours after admission to the intensive care unit (ICU) to permit a controlled anesthetic emergence. If epidural analgesia is used intraoperatively, a dilute solution of local anesthetic and narcotic is preferred to minimize postoperative hypotension from a concomitant sympathectomy and to minimize motor blockade to permit serial neurologic assessment of lower extremity function. Neuraxial anesthetic techniques are not recommended in patients at risk for neuraxial hematomas in the setting of concomitant thienopyridine antiplatelet therapy, low-molecular-weight heparins, and clinically significant anticoagulation (class III recommendation; level of evidence C).[2,13]

The potential for significant bleeding and rapid transfusion is always relevant in thoracic aortic procedures. Consequently, it is prudent to

have fresh frozen plasma and platelets available for ongoing replacement during massive red blood cell transfusion. The time delay associated with standard laboratory testing severely limits the intraoperative relevance of these data to guide transfusion; however, viscoelastic tests are being used with greater frequency to determine coagulation needs.[15] Strategies to decrease bleeding and transfusion in these procedures include timely preoperative cessation of anticoagulants and platelet blockers, antifibrinolytic therapy, intraoperative cell salvage, biologic glue, activated factor VII, and avoidance of perioperative hypertension. It is reasonable to have an institutional algorithmic approach to the management of bleeding and transfusion for thoracic aortic surgery (class IIa recommendation; level of evidence C).[2] This algorithm will depend significantly on institutional variations in point-of-care coagulation testing, blood component availability, and access to recombinant factor VII (class IIa recommendation; level of evidence C).[2]

Aprotinin, an antifibrinolytic that works by inhibiting serine proteases, has now been widely withdrawn from clinical practice after a large randomized trial demonstrated its significant mortality risk in the setting of high-risk cardiac surgery, including thoracic aortic surgery with DHCA.[16,17] However, the risk-versus-benefit discussion with aprotinin continues to be debated.[18] The antifibrinolytic lysine analogs, epsilon-aminocaproic acid or tranexamic acid, are now the commonly utilized blood conservation agents in thoracic aortic surgery with and without DHCA (class 1 recommendation; level of evidence A).[12,19] Concerns with high-dose tranexamic acid leading to an increased risk for seizures after cardiac surgery remain, and thus, further trials on drug safety are still warranted.[20,21] Recombinant activated factor VII is a synthetic agent that accelerates thrombin production leading to hemostasis, and it may be considered for the management of intractable nonsurgical bleeding after CPB that is unresponsive to routine therapy.[12] Although this agent has demonstrated efficacy in complex aortic surgery, concerns for arterial thrombotic events remain, requiring further trials to investigate perioperative safety.[22–24] Finally, the use of fibrinogen concentrates in the management of coagulopathy continue to be investigated in cardiac surgery, with recent evidence suggesting decreased intraoperative bleeding when fibrinogen concentrates are used as a first-line therapy for coagulopathy after major aortic surgery[25] (see Chapters 34 and 35).

Postoperative Care

With the exception of some endovascular aortic procedures, patients often remain intubated and sedated at the completion of the operation, when they are transported directly from the OR to the ICU. The continuation of care from the OR to the ICU should be seamless and protocol based.[26] In the absence of complications, early anesthetic emergence is preferable for early assessment of neurologic function. If delayed anesthetic emergence is indicated, then sedation and analgesia can be provided. The chest roentgenogram allows confirmation of endotracheal tube and intravascular catheter position, as well as the diagnosis of acute intrathoracic pathologies. Common early complications include hypothermia, coagulopathy, delirium, stroke, hemodynamic lability, respiratory failure, metabolic disturbances, and renal failure. Frequent clinical and laboratory assessment is essential to manage this dynamic postoperative recovery, including the safe conduct of tracheal extubation (see Chapters 38 and 39). Given the risks associated with hyperglycemia after cardiac surgery, management of blood glucose levels should be standardized, with more recent data to suggest more liberal control (glucose less than 180 mg/dL) is acceptable with good outcomes.[27,28] Antibiotic prophylaxis is typically continued for 48 hours after surgery to minimize surgical infection risk.

Thoracic Aortic Aneurysm

A thoracic aortic aneurysm is a permanent localized thoracic aortic dilatation that has at least a 50% diameter increase and three aortic wall layers.[2–4] Localized dilatation of the thoracic aorta less than 150% of normal is termed *ectasis*. Annuloaortic ectasia is defined as isolated dilatation of the ascending aorta, aortic root, and aortic valve annulus. Pseudoaneurysm or a false aneurysm is a localized dilation of the aorta that does not contain all three layers of the vessel wall and instead consists of connective tissue and clot. Pseudoaneurysms are caused by a contained rupture of the aorta or arise from intimal disruptions, penetrating atheromas, or partial dehiscence of the suture line at the site of a previous aortic prosthetic vascular graft.

BOX 23.3 COMPLICATIONS OF THORACIC AORTIC ANEURYSMS

- Aortic rupture
- Aortic regurgitation
- Tracheobronchial and esophageal compression
- Right pulmonary artery or right ventricular outflow tract obstruction
- Systemic embolism from mural thrombus

Thoracic aortic aneurysms are common and are the 15th most common cause of death in people older than 65.[29] This disease process is virulent (Box 23.3) but indolent because it typically grows slowly at an approximate rate of 0.1 cm/year.[29] The most common reason for more rapid degeneration is acute aortic dissection. Besides acquired risk factors such as hypertension, hypercholesterolemia, and smoking, current evidence points to the strong influence of genetic inheritance.[29,30] Genetic analysis suggests that thoracic aortic aneurysms divide into two groups at the level of the ligamentum arteriosum. Above the ligamentum arteriosum, the disease is not related to typical arterial risk factors and has a smooth, noncalcified wall accompanied by no debris or clot. Below the ligamentum arteriosum, the disease process primarily is atherosclerotic, with an irregular calcified wall accompanied by copious debris and clot. This freedom from atheromatous disease in patients with thoracic aortic aneurysms of the ascending aorta has been called a "silver lining."[29] Inflammatory causes for thoracic aortic aneurysm include syphilis, mycotic aneurysm from endocarditis, giant-cell arteritis, and Takayasu arteritis.[2]

The aneurysm's location and extent determine the operative strategy and related perioperative complications. Aneurysms of the aortic root and/or ascending aorta commonly are associated with a bicuspid aortic valve.[31,32] Dilation of the aortic valve annulus, aortic root, and ascending aorta pulls the aortic leaflets apart and causes central aortic regurgitation (AR).[30] Aneurysms involving the aortic arch require temporary interruption of cerebral blood flow to accomplish the operative repair. Endovascular stent repair is an established therapy for aneurysms isolated to the descending thoracic aorta; however, ascending aorta stents have been employed in certain patients considered too high-risk for open surgery.[2,33–35] Repair of descending thoracic aortic aneurysms requires the sacrifice of multiple segmental intercostal artery branches that compromise spinal cord perfusion and results in a significant risk for postoperative paraplegia from spinal cord ischemia.[36]

The shape of thoracic aortic aneurysms can be described as either fusiform or saccular. Fusiform aneurysms are more common, associated with atherosclerotic or collagen vascular disease, and usually affect a longer segment of the aorta, producing a dilation of the entire circumference of the vessel wall. Saccular aneurysms are more localized, confined to an isolated segment of the aorta, and produce a localized outpouching of the vessel wall.

Thoracic aortic aneurysms mostly are asymptomatic and frequently are discovered incidentally.[2–4,29] Common symptoms of thoracic aortic aneurysm include chest and back pain caused by aneurysmal dissection, rupture, or bony erosion. The intrathoracic "mass effect" from a large thoracic aortic aneurysm can compress local structures to cause hoarseness (recurrent laryngeal nerve), dyspnea (trachea, mainstem bronchus, pulmonary artery), central venous hypertension (superior vena cava syndrome), and/or dysphagia (esophagus).[37] Rupture of thoracic aortic aneurysms is a surgical emergency and is often

accompanied with acute pain with or without hypotension. Although rupture of an ascending aortic aneurysm may cause cardiac tamponade, rupture in the descending thoracic aorta may cause hemothorax, aortobronchial fistula, or aortoesophageal fistula.

Diagnostic Imaging for Thoracic Aortic Aneurysms

Multiple imaging modalities are available to diagnose and manage aortic aneurysms. Recent guidelines and standards on imaging diseases of the aorta review the advantages and limitations of various techniques, as well as expected normal ranges for vessel caliber.[38] Imaging begins with the basic chest radiograph, which may suggest a thoracic aortic aneurysm if features such as a widened mediastinum, enlarged aortic knob, dilated descending thoracic aorta, aortic calcifications, leftward tracheal deviation, upward deviation of the left mainstem bronchus, and/or new left pleural effusion are present. Typically, transthoracic echocardiography can provide a reasonable examination of the thoracic aorta, although the acoustic windows are limited by the lungs. The contemporary imaging modalities of choice are CT, MRI, and TEE. Computed tomographic angiography (CTA) images the thoracic aorta during the arterial phase of an intravenous radiocontrast agent injection. It defines vascular anatomy and surrounding nonvascular structures. Aneurysm leak is detected as extravascular contrast extravasation. This imaging modality has multiple advantages, such as high resolution, wide availability, rapid acquisition, imaging in patients with metallic implants, and generation of volumetric aortic images for stent design. Because CTA requires iodinated contrast agents, it carries a risk for contrast nephropathy that can be attenuated by administration of hydration, acetylcysteine, and sodium bicarbonate.[39]

Contrast-enhanced magnetic resonance angiography (MRA) with gadolinium also images the entire thoracic aorta in fine detail. Although the spatial resolution of MRA is slightly inferior to CTA, it does allow for degrees of tissue and fluid characterization. The disadvantages of MRA include its limited availability, lack of imaging in patients with metallic implants, imaging difficulty in the setting of continuous hemodynamic monitoring, and the time required for image acquisition. Its advantages are the avoidance of ionizing radiation and the lack of renal toxicity.[2,29]

TEE can image the thoracic aorta from the aortic valve to the distal ascending aorta and from the distal aortic arch to the proximal abdominal aorta. The distal ascending aorta and proximal aortic arch cannot be reliably imaged by TEE because the intervening trachea and left mainstem bronchus obstruct the acoustic window; this is known as the "blind spot" of TEE.[40] It is possible to overcome this blind spot with modalities such as imaging across the trachea temporarily filled with a saline-filled balloon (the A-view) and utilizing an expanded aortic view.[40,41] The advantages of TEE include its portability, its real-time interpretation, its compatibility at the bedside and in the OR, and its multiple imaging modalities for complete aortic and cardiac assessment. Disadvantages include the requirement for sedation or general anesthesia and the risks for upper gastrointestinal injury.[42]

Surgical Considerations for Thoracic Aortic Aneurysms

Surgical repair aims to replace the aortic aneurysm with a tube graft to prevent further aneurysmal complications (Box 23.4). The first indication for thoracic aortic aneurysm resection is whenever the aneurysm is symptomatic regardless of size (class I recommendation; level of evidence C).[2,29] Symptoms often herald the onset of rupture or dissection and should be interpreted as an urgent indication for surgery. A symptomatic presentation occurs in about 5% of patients. Unfortunately, the first symptom in the remaining 95% of patients often is death.

The second indication for resection is aortic diameter. In the ascending aorta, a diameter of 6.0 cm is the critical hinge point after which the risk for aneurysm rupture increases exponentially. Thus surgical resection is recommended in the ascending aorta when the diameter reaches 5.5 cm (class I recommendation; level of evidence B).[2,29]

BOX 23.4 INDICATIONS FOR SURGICAL REPAIR OF THORACIC AORTIC ANEURYSMS

Atherosclerotic aneurysm diameter
- Ascending aorta ≥5.5 cm
- Descending aorta ≥6.5 cm

Marfan or familial thoracic aneurysm diameter
- Ascending aorta ≥5.0 cm
- Descending aorta ≥6.0 cm

Severe aortic regurgitation
Aortoannular ectasia with aortic root aneurysm
Rupture
Refractory pain

In patients with genetically mediated aortopathies (Marfan syndrome, bicuspid aortic valve, familial thoracic aortic aneurysm, vascular Ehlers-Danlos syndrome, and Turner syndrome), surgical resection is recommended at a lower ascending aortic diameter of 5.0 cm (class I recommendation; level of evidence B); however, a lower threshold of 4.5 cm is acceptable in cases of a family history of aortic dissection.[3,29] Ascending aortic aneurysms with diameters less than 5.5 cm but with an annual growth rate in diameter greater than 0.5 cm/year qualify for surgical resection (class I recommendation; level of evidence B).[3] It is reasonable to consider prophylactic replacement of the aortic root and ascending aorta in a woman with Marfan syndrome who is planning a pregnancy and who has an aortic root or ascending aortic diameter larger than 4.0 cm (class IIa recommendation; level of evidence C).[2] In adults with the aggressive aortopathy of the Loeys-Dietz syndrome, it is reasonable to consider proximal thoracic aortic repair when the internal aortic diameter exceeds 4.2 cm (class I recommendation; level of evidence C).[3,43] The ascending aortic aneurysm diameter also must be indexed to body size.[44] For example, if the maximal cross-sectional area of the aortic root or ascending aorta (in square centimeters) divided by the patient's height (in meters) exceeds a ratio of 10, then surgical repair is a reasonable option (class IIa recommendation; level of evidence C).[2] The rationale behind indexing the aortic dimensions to body size is that shorter adults dissect and rupture their aortas at smaller diameters.[2,38] Furthermore, those patients who are undergoing open aortic valve procedures and who have an aortic root or ascending aortic diameter larger than 4.5 cm should be considered for concomitant aortic replacement (class I recommendation; level of evidence B).[3]

The hinge point for rupture in the descending thoracic aorta is a diameter of 7.0 cm.[29] Consequently, surgical resection is recommended in thoracoabdominal aneurysms when the aortic diameter exceeds 6.0 cm (or less when it is associated with a connective tissue disorder such as Marfan syndrome) (class I recommendation; level of evidence C).[2] In patients who have aneurysmal degeneration of the descending thoracic aorta associated with prior dissection and/or a connective tissue disorder, surgical resection is recommended when the aortic diameter is more than 5.5 cm (class I recommendation; level of evidence B).[2] Patients with aneurysms of the descending thoracic aorta should be considered for thoracic endovascular aortic repair (TEVAR) when technically feasible (class I recommendation; level of Evidence B).[2,33]

Aneurysms of the ascending aorta and aortic arch are approached from a median sternotomy incision. Standard CPB can be used for the repair of aneurysms limited to the aortic root and ascending aorta that do not extend into the aortic arch by cannulating the distal ascending aorta or proximal aortic arch and applying an aortic cross-clamp between the aortic cannula and the aneurysm. Aneurysms that involve the aortic arch require CPB with temporary interruption of cerebral perfusion (DHCA). Neuroprotection strategies in this setting include deep hypothermia, selective ACP, and retrograde cerebral perfusion (RCP). Aortic aneurysms of the descending thoracic aorta require lateral thoracotomy for open surgical access. Aneurysmal resection requires cross-clamping with or without distal aortic perfusion.

Surgical Repair of Ascending Aortic and Arch Aneurysms

The type of surgical repair depends on aortic valve function and the aneurysm extent. Perioperative TEE can evaluate the aortic valve structure and function to guide and assess the surgical intervention (reimplantation, repair, replacement).[9,38] Furthermore, TEE can assess the diameters of the aortic root, ascending aorta, and aortic arch to guide intervention. The most common aortic valve diseases associated with ascending aortic aneurysm are bicuspid aortic valve or AR caused by dilation of the aortic root (Fig. 23.1). If the aortic valve and aortic root are normal, a simple tube graft can be used to replace the ascending aorta. If the aortic valve is diseased but the sinuses of Valsalva are normal, an aortic valve replacement combined with a tube graft for the ascending aorta without need for reimplantation of the coronary arteries can be performed (Wheat procedure; Fig. 23.2; class I recommendation; level of evidence C).[2]

If disease involves both the aortic valve and the aortic root, the patient requires aortic root replacement and aortic valve intervention. If technically feasible, the aortic valve can be reimplanted with a modified David technique, which includes graft reconstruction of the aortic root with reimplantation of the coronary arteries (class I recommendation; level of evidence C).[2,45] If not feasible, aortic root replacement with a composite valve-graft conduit is indicated (Bentall procedure; Fig. 23.3; class I recommendation; level of evidence C).[2] Aortic root replacement requires coronary reimplantation or aortocoronary bypass grafting (Cabrol technique; Fig. 23.4).

Repairing aortic aneurysms that extend into or involve the aortic arch requires CPB with DHCA with or without perfusion adjuncts. For ascending aortic aneurysms that involve only the proximal aortic arch, partial arch replacement (hemiarch technique) is reasonable in which a tubular graft is interposed between the ascending aorta or aortic root and the lesser curve of the aortic arch (class IIa recommendation; level of evidence B).[2] Ascending aorta with hemiarch reconstruction often is performed using DHCA with or without ACP/RCP to make the distal anastomosis feasible without cross-clamping ("open technique"). In patients who have isolated aortic arch aneurysms and a low operative risk, arch replacement is reasonable when the arch diameter exceeds 5.5 cm (class IIa recommendation; level of evidence B).[2] Total aortic arch replacement is reasonable in aneurysms that involve the entire arch (class IIa recommendation; level of evidence B).[2] Ascending aortic aneurysms that extend through the aortic arch into the descending aorta can be repaired with the "elephant trunk" technique (Fig. 23.5; class IIa recommendation; level of evidence B).[2,46] Aortic arch aneurysms that extend into the aortic branch vessels may require repair with branched or trifurcated tube grafts to permit separate anastomosis to the brachiocephalic, left carotid, and left subclavian arteries.[47] In patients with aortic arch aneurysms and concomitant severe comorbidity, guidelines support an endovascular repair technique (class IIb recommendation; level of evidence C).[2,33] However, in patients who have aortic arch aneurysms and who have reasonable surgical risk, the guidelines advise against an endovascular repair technique (class III recommendation; level of evidence A).[2,33] The use of a hybrid arch approach has gained popularity as it aims to minimize (or avoid) bypass and circulatory arrest times. With this technique, patients with arch aneurysms undergo an open debranching of the great vessels with the creation of appropriate landing zones for an endovascular stent graft of the aortic arch (Fig. 23.6).[48,49]

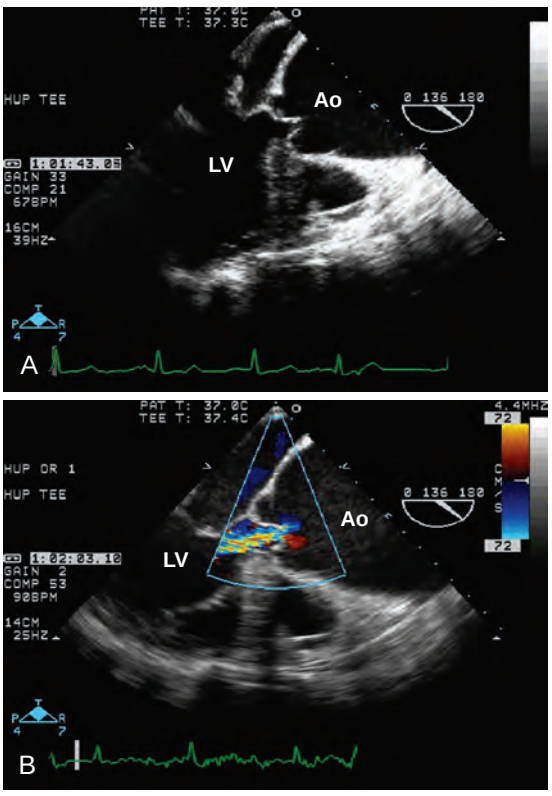


Fig. 23.1 Transesophageal echocardiographic (TEE) midesophageal long-axis images of the aortic valve demonstrating aneurysmal dilation of the aortic root and ascending aorta (A). Doppler color-flow imaging (B) demonstrating severe aortic regurgitation caused by outward tethering of the aortic valve cusps by the aortic aneurysm. *Ao,* Aorta; *LV,* left ventricle.

Anesthetic Management for Ascending Aorta and Arch Aneurysms

The conduct of general anesthesia in this setting has specific concerns. The imaging studies should be reviewed for aneurysm compression of mediastinal structures such as the right pulmonary artery and left mainstem bronchus (Fig. 23.7). Prevention of hypertension increases forward flow in AR and minimizes the risk for aneurysm rupture. As reviewed earlier, the preference for a left or right radial arterial catheter depends on the surgeon's approach to arch repair. Occasionally, bilateral radial arterial catheters can allow for simultaneous monitoring of cerebral and systemic perfusion pressures if arterial cannulation of the right axillary, subclavian, or brachiocephalic artery is planned for CPB and ACP. Nasopharyngeal, tympanic, and bladder temperatures are important for estimating brain and core temperatures for monitoring the conduct of DHCA. Monitoring of jugular bulb venous oxygen saturation and the EEG may reflect cerebral metabolic activity to guide the conduct of DHCA. Intraoperative TEE is essential to guide and assess the surgical interventions. In patients with AR, TEE can assist in the conduct of CPB by guiding placement of cannulae such as the retrograde cardioplegia cannula (coronary sinus) and by monitoring left ventricular (LV) volume to ensure that the LV drainage cannula keeps the ventricle collapsed. Intraoperative TEE is reasonable in thoracic aortic procedures, including endovascular interventions, in which it assists in hemodynamic monitoring, procedural guidance, and endoleak detection (class IIa recommendation; level of evidence B).[2]

Neuroprotection Strategies for Temporary Interruption of Cerebral Blood Flow

The risk for stroke is substantial during the cerebral ischemia that accompanies aortic arch reconstruction.[50] The first mechanism is cerebral ischemia due to hypoperfusion or temporary circulatory arrest during aortic arch repair. The second mechanism is cerebral ischemia due to embolization secondary to CPB and atheroma. Arterial embolic causes include air introduced into the circulation from open cardiac chambers, vascular cannulation sites, or arterial anastomosis. Atherosclerotic particulate debris may be released during clamping and unclamping of the aorta, the creation of anastomoses in

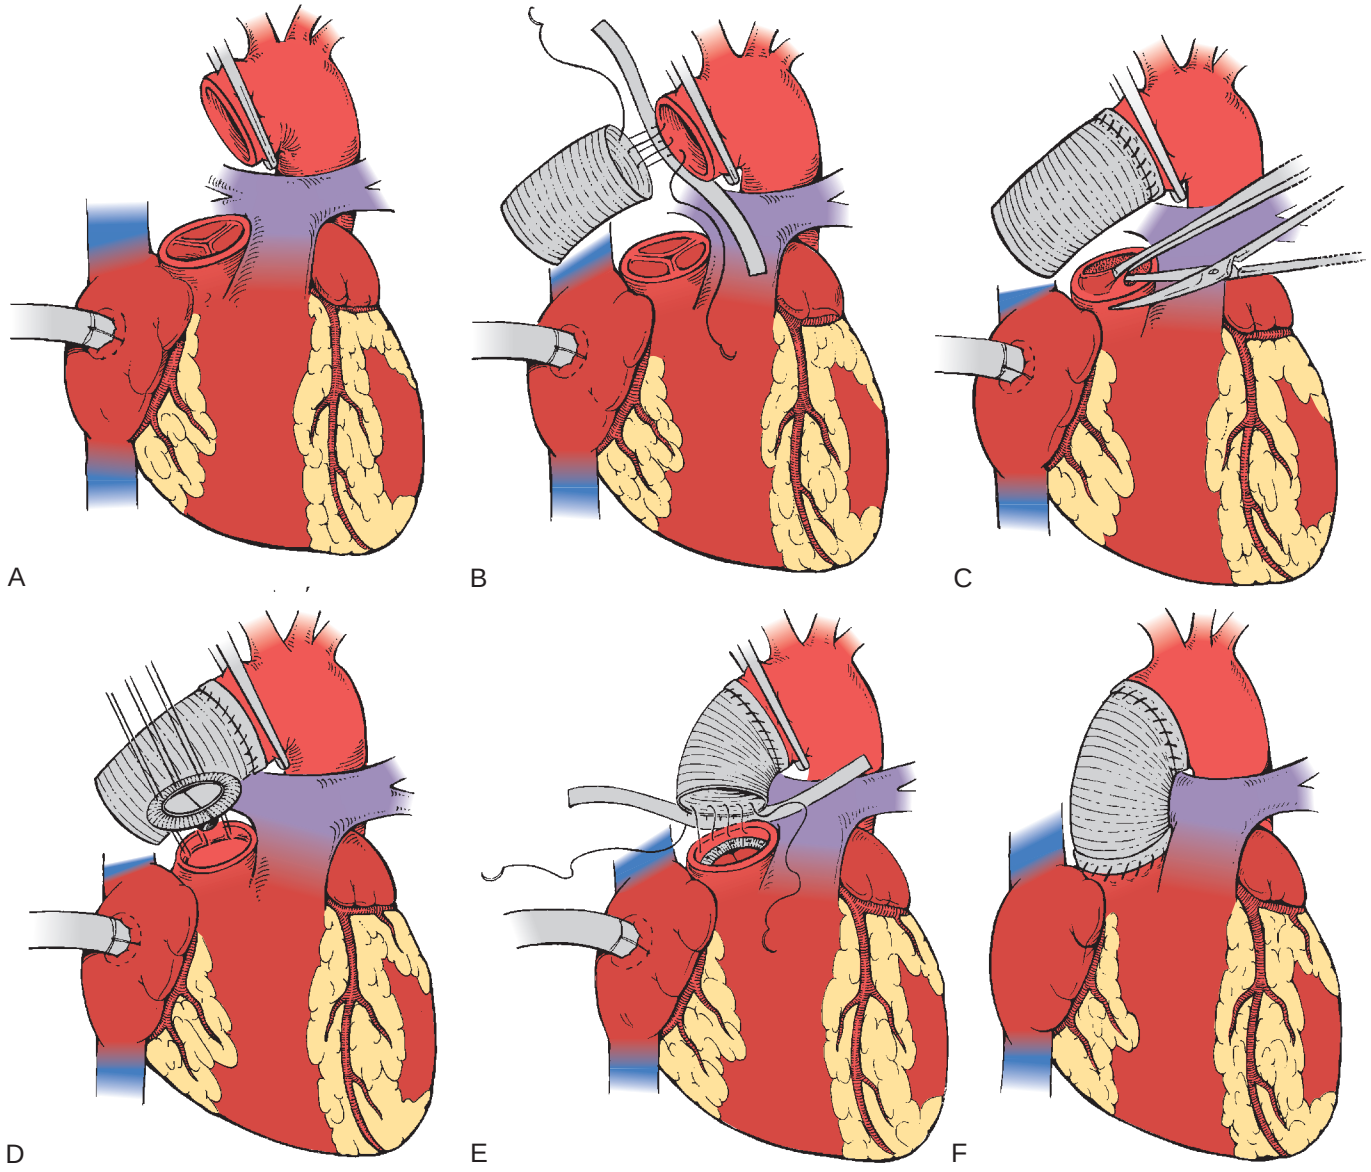

Fig. 23.2 Replacement of the ascending aorta with a prosthetic tube graft for ascending aortic aneurysm or type A aortic dissection (A, B, F). In the presence of aortic valvular disease, the aortic valve can be replaced (C–E) or repaired (not shown). Extension of the aneurysm or dissection into the aortic arch may require replacement of part or all of the aortic arch with a prosthetic tube graft (not shown). A small rim of the native aortic root containing the right and left coronary ostia was left behind in this repair. *(Reproduced with permission from Downing SW, Kouchoukos NT. Ascending aortic aneurysm. In: Edmunds LH, eds.* Cardiac Surgery in the Adult. *New York: McGraw-Hill; 1997:1176.)*

the ascending aorta and aortic arch, or the excision of severely calcified and diseased cardiac valves. CPB may result in the microparticulate aggregates of platelets and fat. The turbulent high-velocity blood flow out of the aortic cannula used for CPB also may dislodge atherosclerotic debris within the aorta. Retrograde blood flow through a diseased descending thoracic aorta as a consequence of CPB conducted with femoral artery cannulation may cause retrograde cerebral embolization. For all these reasons, strategies to provide neurologic protection are essential in thoracic aortic operations (Box 23.5), and there exists a great degree of variation in the approaches used to protect and monitor brain function.[51,52]

Deep Hypothermic Circulatory Arrest

The brain is extremely susceptible to ischemic injury within minutes after the onset of circulatory arrest because it has a high metabolic rate,

BOX 23.5 BRAIN PROTECTION FOR AORTIC ARCH RECONSTRUCTION

- Deep systemic hypothermia
- Topical cerebral cooling
- Retrograde cerebral perfusion
- Selective antegrade cerebral perfusion
- Cerebral hyperthermia prevention during rewarming

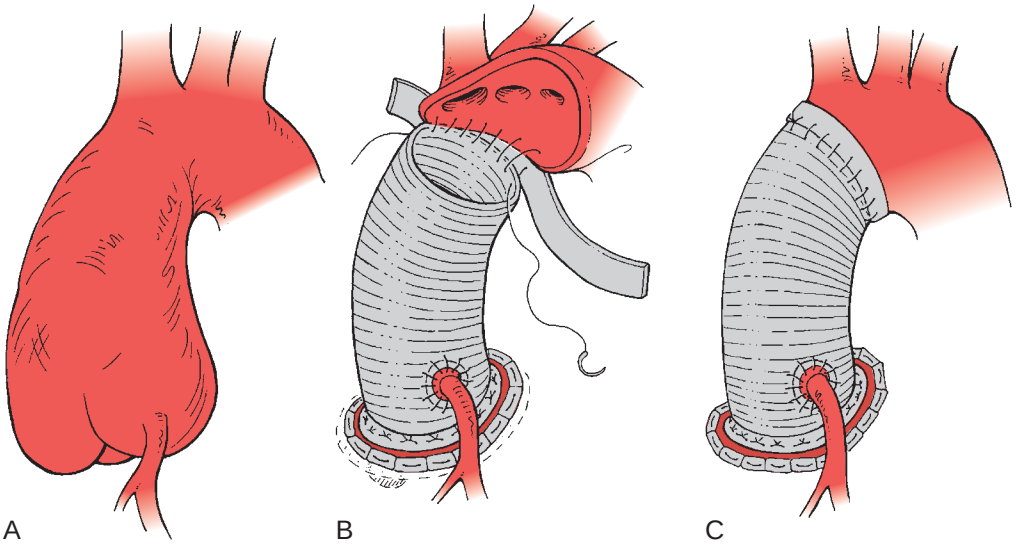

Fig. 23.3 Replacement of the entire aortic root with a composite valved conduit for ascending aortic aneurysm. The underside of the aortic arch was also incorporated into the prosthetic graft. The right and left coronary arteries were reimplanted into the graft (A–C). Alternatively, the aortic root can be replaced with a cryopreserved homograft or porcine bioprosthesis (not shown). *(Reproduced with permission from Griepp RB, Ergin A. Aneurysms of the aortic arch. In: Edmunds LH, ed.* Cardiac Surgery in the Adult. *New York, McGraw-Hill; 1997:1209.)*

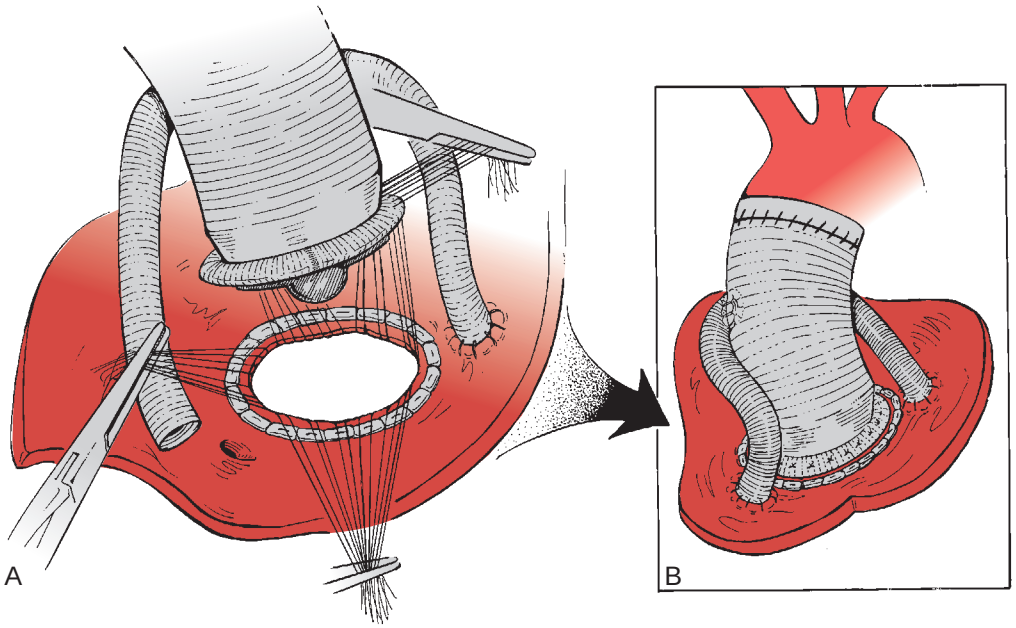

Fig. 23.4 Replacement of the entire aortic root with a composite valved conduit for ascending aortic aneurysm combined with end-to-end anastomosis of the right and left coronary arteries to an 8-mm or 10-mm prosthetic tube graft that was then anastomosed to the aortic root (A, B). *(Reproduced with permission from Downing SW, Kouchoukos NT. Ascending aortic aneurysm. In: Edmunds LH, ed.* Cardiac Surgery in the Adult. *New York, McGraw-Hill; 1997:1181.)*

continuous requirement for metabolic substrate, and limited reserves of high-energy phosphates. The physiologic basis for deep hypothermia as a neuroprotection strategy is to decrease cerebral metabolic rate and oxygen demands to increase the period that the brain can tolerate circulatory arrest.[53] Existing evidence indicates that autoregulation of cerebral blood flow is maintained during deliberate hypothermia with alpha-stat blood gas management without compromise of clinical outcome.[54] Direct measurement of cerebral metabolites and brainstem electrical activity in adults undergoing DHCA with RCP at 14°C indicated the onset of cerebral ischemia after only 18 to 20 minutes (Fig. 23.8).[55] Despite this observation, the large body of experimental evidence and clinical experience with deliberate hypothermia suggest that it is the single most important intervention for preventing neurologic injury in response to circulatory arrest.

Despite the proven efficacy of hypothermia for operations that require circulatory arrest, no consensus exists on an optimal protocol for the conduct of deliberate hypothermia for circulatory arrest.[56] A strategy to protect the brain during aortic arch surgery must be a high priority in the perioperative management of these procedures to prevent stroke and optimize cognitive function (class I recommendation; level

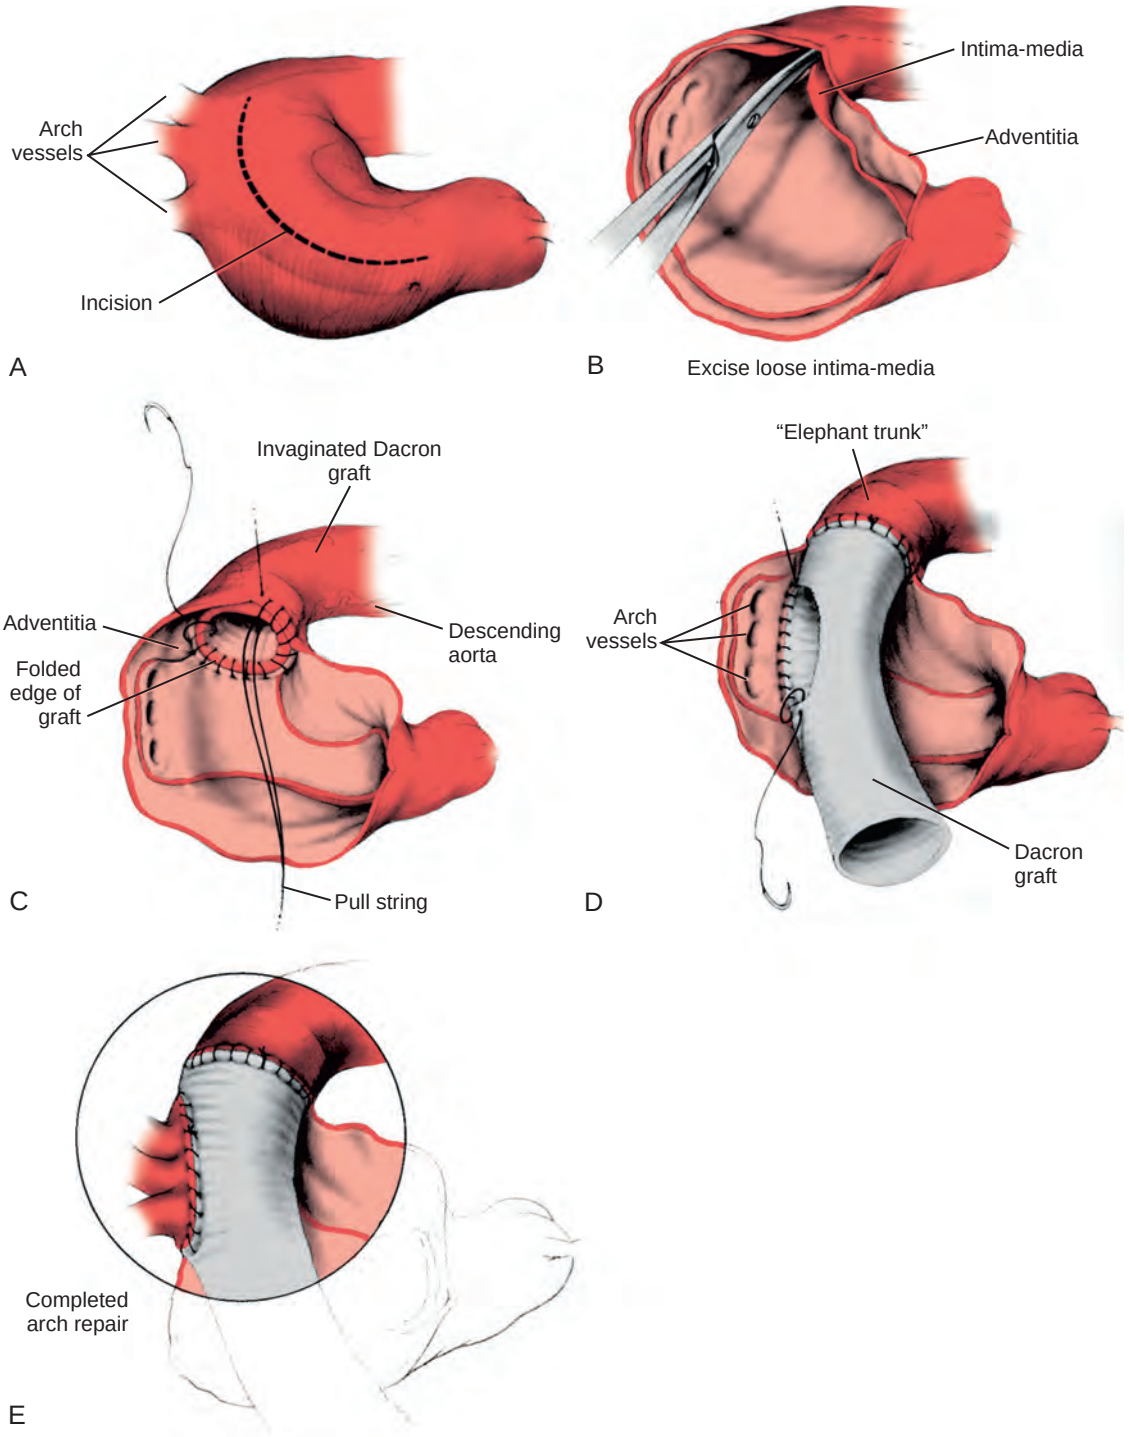

Fig. 23.5 Elephant trunk procedure for prosthetic graft replacement of the ascending aorta, aortic arch, and descending thoracic aorta. The aortic aneurysm or dissection is opened its entire length and extended through the aortic arch (A, B). The prosthetic tube graft is implanted with its distal end extending into the descending thoracic aorta, "elephant trunk" (C, D). The graft is pulled back into the arch for implantation of the arch branch vessels and construction of the proximal anastomosis (D, E). In the second stage of the procedure, the descending thoracic aorta is replaced by constructing a proximal graft-to-graft anastomosis (not shown). *(From Doty DB. Aortic aneurysm. In: Brown M, Baxter S, eds.* Cardiac Surgery: Operative Technique. *St Louis, Mosby-Year Book; 1997:324.)*

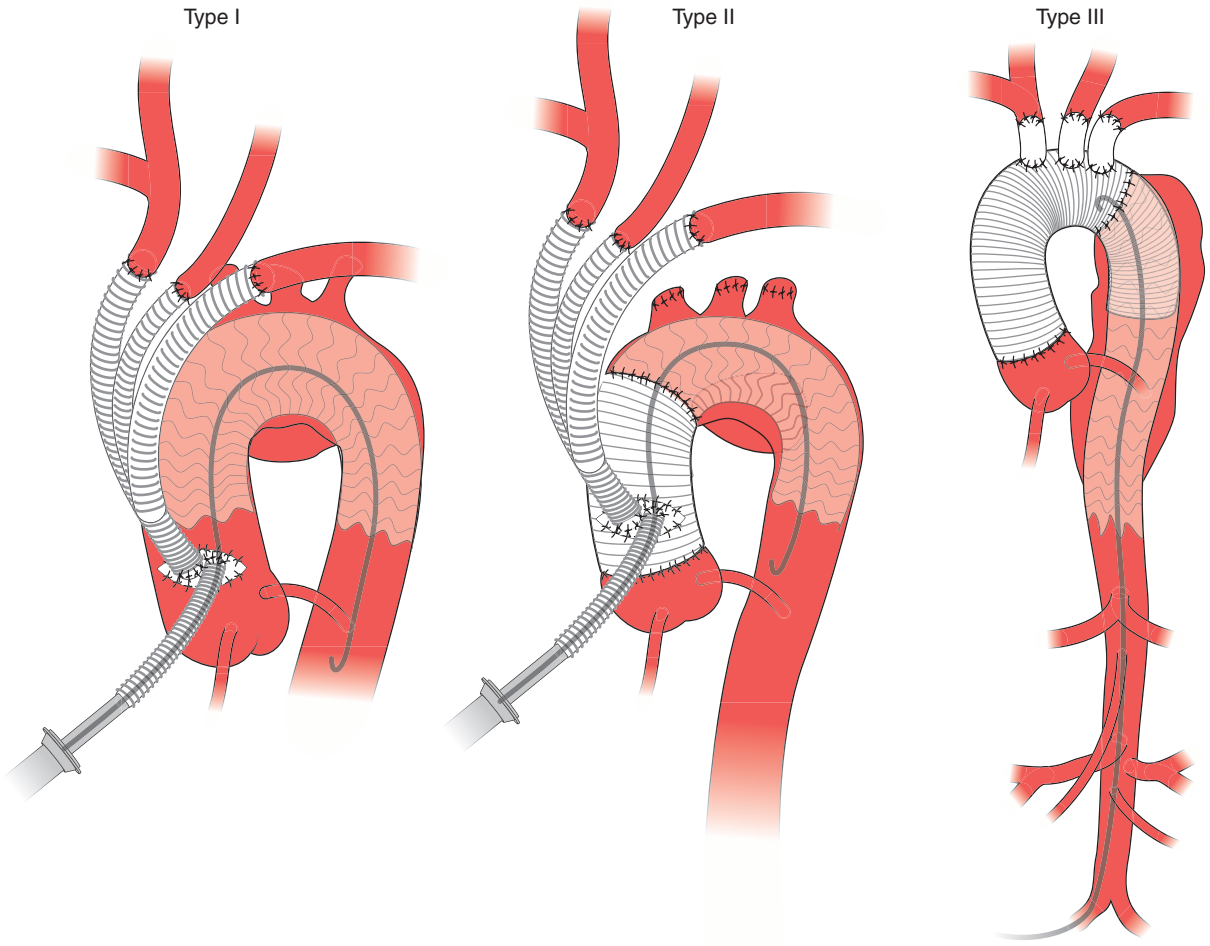

Fig. 23.6 Various debranching procedures and endovascular stent graft placement for aortic arch aneurysms, depending on the extent of ascending and/or descending aorta involvement. Adequate ascending aorta may allow an off-bypass technique. Pathology of the proximal ascending aorta warrants replacement with cardiopulmonary bypass prior to stent deployment, while the addition of diseased descending aorta may require a two-staged procedure with TEVAR performed after the initial debranching procedure. *(From Milewski RK, Szeto WY, Pochettino A, et al. Have hybrid procedures replaced open aortic arch reconstruction in high-risk patients? a comparative study of elective open arch debranching with endovascular stent graft placement and conventional elective open total and distal aortic arch reconstruction.* J Thorac Cardiovasc Surg. *2010;140:590–597.)*

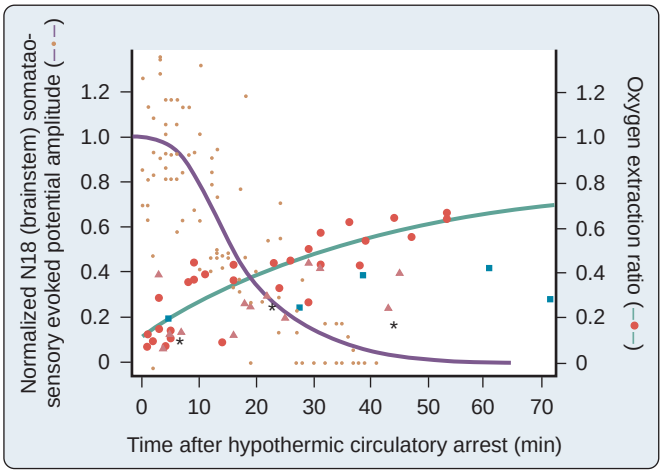

Fig. 23.8 Changes in brainstem (N18) somatosensory-evoked potential amplitudes *(dots)* after initiation of deep hypothermic circulatory arrest with retrograde cerebral perfusion superimposed on the change in brain oxygen extraction ratio (OER) in patients without strokes (*circles;* n = 19), preoperative strokes (*triangles;* n = 4), intraoperative strokes (*squares;* n = 3), and both preoperative and intraoperative strokes (*asterisks;* n = 1). The N18 somatosensory-evoked potential decayed to half its original amplitude at 16 minutes after interruption of antegrade cerebral perfusion. The OER decreased to half its maximal value of 0.66 also at 16 minutes after interruption of antegrade cerebral perfusion. *(Modified from Cheung AT, Bavaria JE, Pochettino A, et al. Oxygen delivery during retrograde cerebral perfusion in humans.* Anesth Analg. *1999;88:14.)*

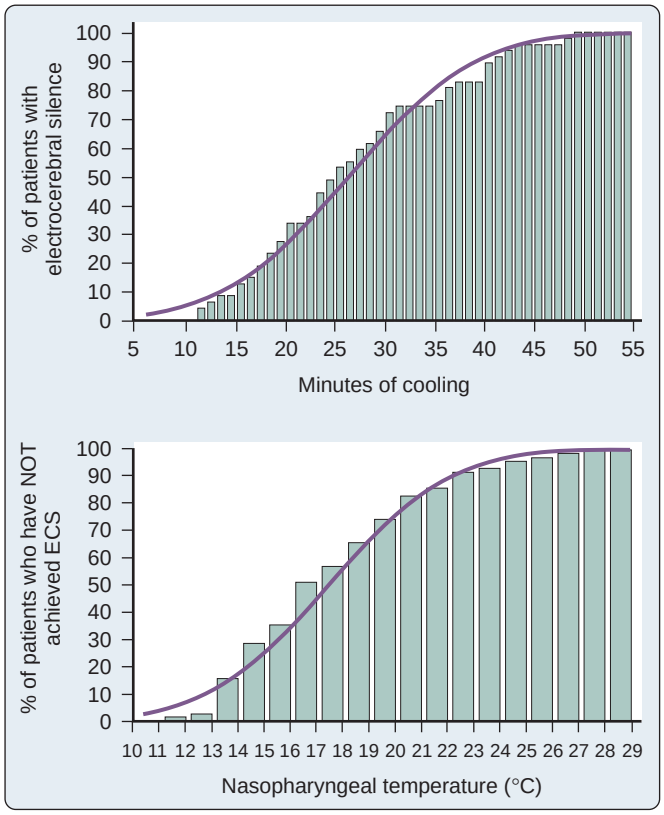

Fig. 23.9 The relation between electroencephalographic activity to minutes of cooling *(top)* and nasopharyngeal temperature *(bottom)* before deep hypothermic circulatory arrest in 109 patients undergoing thoracic aortic operations requiring circulatory arrest. Electrocortical silence (ECS) was achieved by electroencephalogram (EEG) in all patients after 50 minutes of cooling or at a nasopharyngeal temperature of 12.5°C. At a nasopharyngeal temperature of 18°C, only 50% of patients had ECS by EEG. *(Reproduced with permission from The Society of Thoracic Surgeons. Modified from Stecker MM, Cheung AT, Pochettino A, et al. Deep hypothermic circulatory arrest: I. Effects of cooling on electroencephalogram and evoked potentials.* Ann Thorac Surg. *2001;71:19.)*

of evidence C).[2] Although the average nasopharyngeal temperature for DHCA may be about 18°C, the optimal temperature for DHCA has not been established.[50,53] A challenge in the selection of the ideal temperature for DHCA is the inability to directly measure the brain temperature. In an EEG-based approach to this question, the median nasopharyngeal temperature for electrocortical silence was 18°C, although a nasopharyngeal temperature of 12.5°C or cooling on CPB for at least 50 minutes achieved electrocortical silence in 99.5% of cases (Fig. 23.9).[57] Although the EEG functions well as a physiologic endpoint for cerebral metabolic suppression during cooling for DHCA as part of an institutional protocol, its outcome benefit remains to be demonstrated in a randomized trial.[26,50,58] A jugular bulb venous oxygen saturation greater than 95% measured using an oximetric catheter represents an alternative physiologic end point to detect maximum cerebral metabolic suppression for DHCA.[59] It is important to note that deep hypothermia alone to a set temperature (mean = 19°C) as an end point for DHCA without EEG or jugular bulb venous oxygen saturation has been associated with excellent neurologic outcomes.[60,61] Therefore the technique of DHCA alone is a reasonable approach for neuroprotection during aortic arch surgery in the setting of adequate institutional experience (class IIa recommendation; level of evidence B).[2] In addition to systemic hypothermia produced by extracorporeal circulation, topical hypothermia by packing the head in ice has also been incorporated in some institutional DHCA protocols to minimize passive warming of the head.[60,61] However, the value of topical head cooling is questionable, with some evidence actually suggesting no benefit or potential harm.[62,63] Concern for interference with EEG or cerebral oximetry monitors also limits the role of topical cooling.[63]

The conduct of DHCA extends CPB duration with consequent risks for coagulopathy and embolization. Rewarming increases cerebral metabolic rate and can aggravate neuronal injury during ischemia/reperfusion. Consequently, it is important to rewarm gradually by maintaining a temperature gradient of no more than 10°C in the heat exchanger and avoiding cerebral hyperthermia (nasopharyngeal temperature >37.5°C). The current guidelines advise against cerebral hyperthermia in aortic arch procedures (class III recommendation; level of evidence B).[2]

Retrograde Cerebral Perfusion

Although clinical studies would support the practice of limiting the duration of straight DHCA to shorter than 45 minutes to avoid the associated significant increases in stroke and mortality risks, the use of adjunct perfusion techniques for neuroprotection has allowed surgeons to work for longer periods of time in a safe manner.[50,64] Similarly, these cerebral perfusion adjuncts have led to increased use of moderate degrees of hypothermia (20.1 to 28.0 degrees C).[64] RCP is a cerebral perfusion technique performed by infusing cold oxygenated blood into the superior vena cava cannula at a temperature of 8°C to 14°C via CPB (Fig. 23.10) (see Chapter 32). The internal jugular venous pressure is maintained at less than 25 mm Hg to prevent cerebral edema. Internal jugular venous pressure is measured from the introducer port of the internal jugular venous catheter at a site proximal to the superior vena cava perfusion cannula and zeroed at the level of the ear. The patient is positioned in 10 degrees of Trendelenburg to decrease the risk for cerebral air embolism and prevent trapping of air within the cerebral circulation in the presence of an open aortic arch. RCP flow rates of 200 to 600 mL/minute usually can be achieved. The potential benefits of RCP include partial supply of cerebral metabolic substrate,

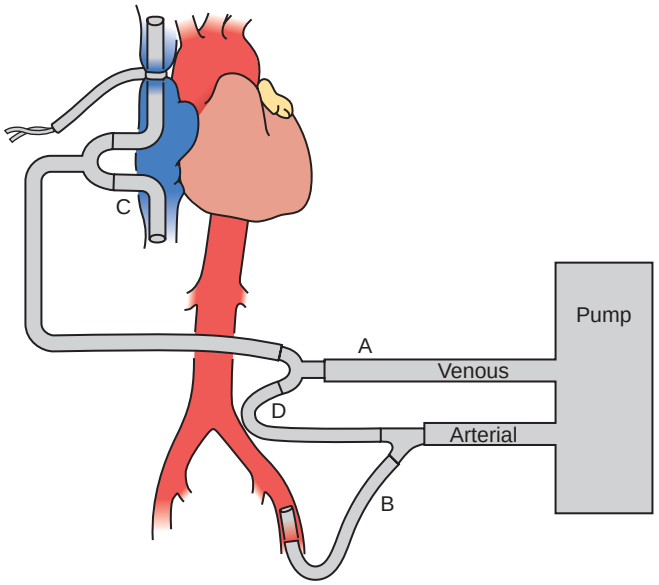

Fig. 23.10 Extracorporeal perfusion circuit used to deliver retrograde cerebral perfusion. The bridge *(D)* is clamped during cardiopulmonary bypass. After initiation of deep hypothermic circulatory arrest, clamps are placed on the venous return line *(A)*, the proximal arterial cannula *(B)*, and inferior vena caval cannula *(C)*, and the bridge *(D)* is unclamped to permit retrograde perfusion into the superior vena cava. *(Reproduced with permission from The Society of Thoracic Surgeons. After achieving deep hypothermia on cardiopulmonary bypass, individual cannulas are inserted into the coronary, innominate, and left carotid arteries for selective antegrade perfusion of the heart and brain. *(From Bachet J, Teodori G, Goudot B, et al. Replacement of the transverse aortic arch during emergency operations for type A acute aortic dissection.* J Thorac Cardiovasc Surg. *1988;96:878.)*

cerebral embolic washout, and maintenance of cerebral hypothermia.[65] Although RCP has been associated with excellent clinical results in aortic arch repair, it has not become the standard technique for neuroprotection in DHCA.[26,66] A large, single-center study (1991–2007; $N = 1107$; RCP in 82%) evaluated the role of RCP in proximal thoracic aortic repair.[67] The perioperative rates for mortality and stroke in this series were 10.4% and 2.8%, respectively. The application of RCP was significantly protective against mortality (odds ratio [OR], 0.42; 95% confidence interval [CI], 0.25–0.70; $P = 0.0009$) and stroke (OR, 0.35; 95% CI, 0.15–0.81; $P = 0.02$).[67] Therefore RCP is safe and easily implemented in aortic arch repair as an adjunct to maintain cerebral hypothermia, provide partial metabolic substrate delivery, and decrease the risk for cerebral embolization.[58–61,65–67] The technique of DHCA with RCP is a reasonable approach for neuroprotection during aortic arch surgery in the setting of adequate institutional experience (class IIa recommendation; level of evidence B).[2] A large recent metaanalysis ($N = 5060$: 15 trials) has demonstrated that with deep hypothermia RCP provides similar cerebral protection as compared with ACP.[68]Although RCP is clinically effective at deep hypothermia, the clinical movement towards moderate hypothermia with ACP in contemporary aortic arch reconstruction will likely limits its application in the future.[69]

Selective Antegrade Cerebral Perfusion

Selective ACP should be considered for aortic arch repairs longer than 45 minutes.[50] Compared with DHCA alone, the combined use of DHCA and selective ACP has been associated with superiority in terms of mortality outcomes.[70] ACP typically is initiated during DHCA by selective cannulation of the right axillary artery, right subclavian artery, brachiocephalic artery, or left common carotid artery (Fig. 23.11).[71,72] In transverse aortic arch reconstruction procedures, ACP can be accomplished by inserting individual perfusion cannulae into the open end of the aortic branch vessels after opening the aortic arch. After reattachment of the aortic arch branch vessels to the vascular graft, ACP can be provided through a separate arm of the vascular graft or by direct cannulation of the graft. A functional circle of Willis may provide contralateral brain perfusion during interruption of antegrade perfusion in the brachiocephalic or left carotid arteries during construction of the vascular anastomoses. ACP with oxygenated blood at 10°C to 14°C at flow rates in the range of 250 to 1000 mL/minute typically achieves a cerebral perfusion pressure in the range of 50 to 80 mm Hg.

Unilateral ACP via right axillary arterial cannulation is a popular technique for adult aortic repair.[71] This technique assumes an adequate circle of Willis; however, the anatomic completeness of the circle of Willis does not guarantee adequate cerebral cross-perfusion during aortic arch repair.[73,74] Consequently, it remains essential to monitor the contralateral hemisphere in unilateral ACP with modalities such as cerebral oximetry, carotid artery scanning, and transcranial Doppler.[75–77]

Given that ACP may be unilateral or bilateral, there remains controversy about which ACP technique is superior.[78] A large analysis that combined 17 studies for a total sample size of 3548 patients compared bilateral ACP (83.1%) with unilateral ACP (16.9%).[79] Although the stroke rates were less than 5% regardless of technique, the period of safe ACP was significantly prolonged with bilateral ACP (86–164 minutes) compared with unilateral ACP (30–50 minutes). The evidence favors bilateral ACP in the setting of aortic arch repair times longer than 60 minutes.[79] Further, a recent metaanalysis ($N = 5100$; 28 trials) has demonstrated that unilateral and bilateral ACP in aortic arch reconstruction achieve similar clinical outcomes for perioperative mortality, stroke, and delirium.[80]

Pilot clinical series in adult aortic arch repair also have been undertaken in the setting of ACP with moderate hypothermic circulatory arrest (MHCA; systemic temperature = 25°C).[81,82] A large, single-center study (1999–2006; $N = 501$ [36.1% emergency cases]; median age, 64 years; 63.9% male sex) evaluated perioperative outcomes with this technique.[83] With a perioperative mortality rate of 11.6%, multivariate predictors for mortality included age and CPB time. The stroke rate was 9.6% with operative time and renal dysfunction as its multivariate predictors for stroke. The rate of temporary neurologic dysfunction was 13.4%, with MHCA duration (OR, 1.015; $P = 0.01$) as a multivariate predictor. Although MHCA with cold ACP appears to be an adequate technique for adult aortic arch repair, its safety is limited in the settings of the elderly, multiple comorbidities, and extended operative time. A more recent metaanalysis of patients undergoing arch surgery actually demonstrates that the use of MHCA with selective ACP is a superior technique in terms of stroke risk.[84] However, the safety of MHCA with ACP for ischemic protection of the spinal cord and kidney are still questioned.[85,86] Overall, the technique of DHCA with ACP is a reasonable approach for neuroprotection during aortic arch surgery in the setting of adequate institutional experience (class IIa recommendation; level of evidence B).[2]

Pharmacologic Neuroprotection Strategies for Deep Hypothermic Circulatory Arrest

There are no proven pharmacologic regimens that have demonstrated effectiveness for decreasing the risk or severity of neurologic injury in the setting of thoracic aortic operations.[58] The agents that have been reported in aortic arch series include thiopental, propofol, steroids, magnesium sulfate, and lidocaine.[26,53,87] Furthermore, there is considerable variation in practice with these agents in aortic arch repair.[87] A recent analysis of a large clinical registry in surgical management for acute type A dissection ($N = 2137$ over 4 years) suggested that steroids may improve neurologic outcome by protecting against stroke (adjusted OR, 0.50; 95% CI 0.24–0.96; $P = 0.049$).[88] In general, the existing evidence suggests that pharmacologic neuroprotection should be considered as a neuroprotective adjunct and not a substitute for hypothermia to protect against cerebral ischemia in the setting of hypoperfusion. The technique of DHCA with pharmacologic adjuncts is a reasonable approach for neuroprotection during aortic arch surgery in the setting of an institutional protocol and adequate institutional experience (class IIa recommendation; level of evidence B).[2]

Descending Thoracic and Thoracoabdominal Aortic Aneurysms

Surgical therapy for descending thoracic and thoracoabdominal aortic aneurysms is to replace the aneurysmal aorta with a prosthetic tube graft. Surgical access is via lateral thoracotomy or thoracoabdominal incision. Despite recent advances, major surgical challenges remain because the typical patient is elderly with multiple significant comorbidities. The risks for spinal, mesenteric, renal, and lower extremity ischemia are significant because of thromboembolism, loss of collateral vascular networks, temporary interruption of blood flow, and reperfusion injury. The risks for wound dehiscence and respiratory failure remain significant because of the large incisions and diaphragmatic division, as well as injuries to the phrenic and recurrent laryngeal nerves. Consequently, TAAA repair is high risk (Table 23.3).[89]

Aneurysms of the descending thoracic aorta are classified by considering which third(s) of the descending thoracic aorta is (are) involved.[2] Extent A involves the proximal third, extent B involves the middle third, and extent C involves the distal third. If more than one-third is involved, then the extent is classified according to which thirds are involved; for example, an aneurysm involving the proximal two-thirds is classified as extent AB. Essentially, multisegment aneurysms can be classified as proximal or distal because these extents influence the risk for spinal cord ischemia after surgical repair, whether open or endovascular.

TABLE 23.3 Clinical Outcomes of Open Thoracoabdominal Aortic Aneurysm (TAAA) Repair (United States: 2005–2012; n = 823)

Complication	*No. of Patients (%)*
Any adverse outcome	131 (15.9%)
Operative mortality	69 (8.4%)
Permanent spinal cord deficits	42 (5.1%)
Stroke	27 (3.3%)
Acute renal dysfunction	95 (11.5%)
Cardiac complication	250 (30.4%)
Pulmonary complication	338 (41.1%)
Bleeding requiring re-exploration	48 (5.8%)

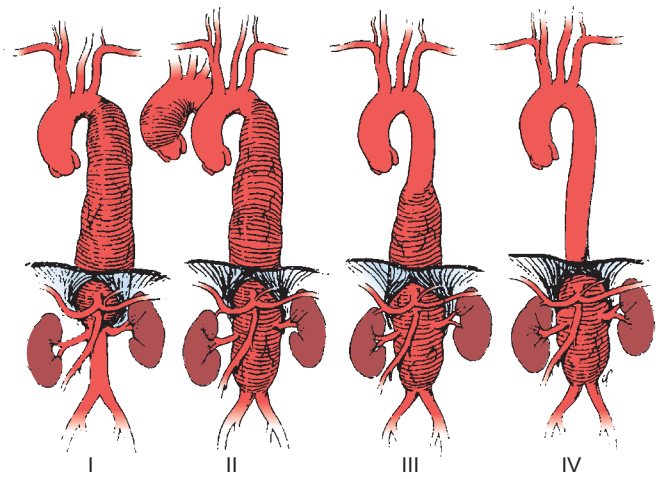

Fig. 23.12 Crawford classification of thoracoabdominal aortic aneurysm extent. *(From Coselli JS. Descending thoracoabdominal aortic aneurysms. In: Edmunds LH, ed.* Cardiac Surgery in the Adult. *New York: McGraw-Hill; 1997:1232.)*

Aneurysms of the thoracoabdominal aorta typically are defined by the Crawford classification (Fig. 23.12).[90] Extent I TAAA begins at the left subclavian artery and ends below the diaphragm, but above the renal arteries. Extent II TAAA involves the entire descending thoracic aorta and ends below the diaphragm at the aortic bifurcation. Extent III TAAA begins in the lower half of the descending thoracic aorta and ends below the diaphragm at the aortic bifurcation. Extent IV TAAA is confined to the entire abdominal aorta. If an extent I or extent II TAAA involves the distal aortic arch, its surgical replacement often requires DHCA for the proximal anastomosis. The Crawford classification stratifies operative risk and guides perioperative management (Table 23.4). Open repair of TAAA typically is accomplished by aortic cross-clamping with or without the addition of a shunt, PLHB, or partial CPB (Fig. 23.13).

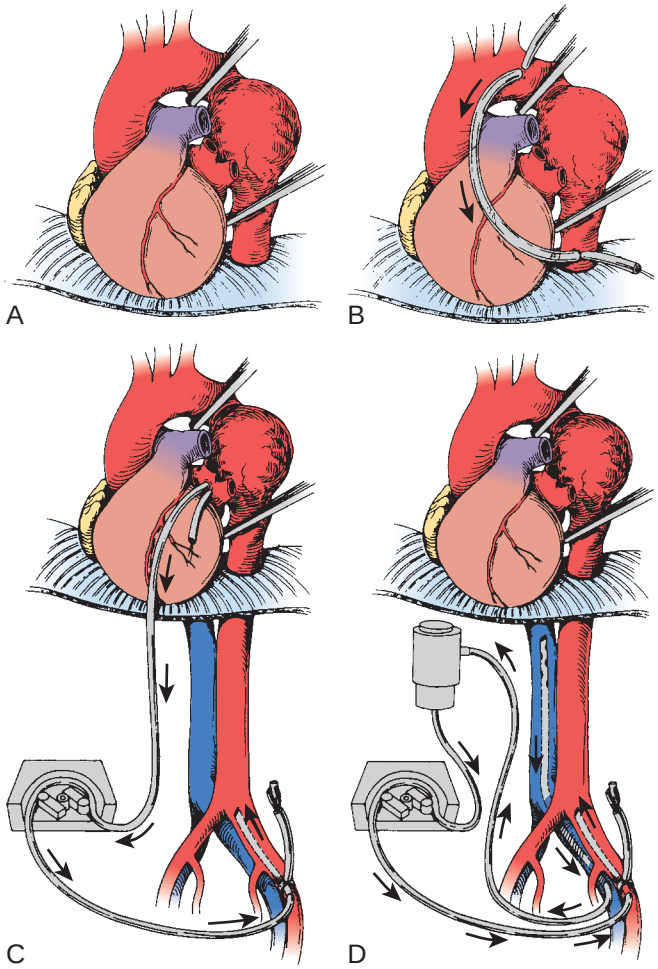

Fig. 23.13 Operative techniques for repair of thoracic or thoracoabdominal aortic aneurysms. In the clamp-and-sew technique, the distal aorta is not perfused (A). Alternatively, distal aortic perfusion during repair can be provided by a passive Gott shunt (B), partial left heart bypass (C), or partial cardiopulmonary bypass (D). Deep hypothermic circulatory arrest may be necessary if the proximal cross-clamp cannot be safely applied in aneurysms extending into the distal aortic arch (not shown). *(From O'Connor CJ, Rothenberg DM: Anesthetic considerations for descending thoracic aortic surgery: Part II.* J Cardiothorac Vasc Anesth. *1995;9:734.)*

Simple Aortic Cross-Clamp Technique

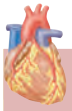
The major disadvantage of this technique, developed by Crawford, is the concomitant vital organ ischemia below the aortic clamp. Consequently, surgical speed is critical to achieve an ischemic time less than 30 minutes to limit the risk for vital organ dysfunction.[91] Its further disadvantages include proximal aortic hypertension, bleeding, and hemodynamic instability on reperfusion. Despite anesthetic interventions, this proximal aortic hypertension may induce LV ischemia.[92] Blood loss can be minimized with intraoperative red blood cell salvaging. Hemodynamic instability during reperfusion can be minimized with correction of metabolic acidosis, rapid intravascular volume expansion, vasopressor therapy, and/or gradual clamp release. Mild systemic hypothermia and selective spinal cooling protect against the ischemia associated with this technique.[93,94] Despite its physiologic consequences, this technique remains popular because it is simple and has proven clinical outcomes (Box 23.6).

Gott Shunt

Passive shunts allow for blood to be diverted from the proximal aorta to the distal aorta during aortic cross-clamping for thoracic aortic repair. One specific type is the heparin-coated Gott shunt (Fig. 23.13B).[95] Blood flow from the proximal to distal aorta through the shunt depends on proximal aortic pressure, shunt length and diameter, and distal aortic pressure. Monitoring the femoral arterial pressure facilitates assessment of distal aortic perfusion and shunt flow. The advantages of the Gott shunt are its simplicity, its low cost, and its requirement for only partial anticoagulation. Its disadvantages include vessel injury, dislodgment, bleeding, and atheroembolism.

Partial Left-Heart Bypass

The control of both proximal and distal aortic perfusion during TAAA repair can be achieved with PLHB. This technique requires left atrial cannulation, usually via a left pulmonary vein (Fig. 23.13C). Oxygenated blood from the left atrium flows through the CPB circuit into the distal aorta or a major branch via the arterial cannula.[93] The CPB circuit can include a heat exchanger, membrane oxygenator, and/or a venous reservoir. The degree of heparinization for PLHB is minimal with heparin-coated circuits without an oxygenator. Full systemic anticoagulation with ACT greater than 400 seconds is required for CPB circuits with membrane oxygenators and heat exchangers.[96] During PLHB, the proximal mean arterial pressure (MAP; radial artery) is generally maintained in the 80 to 90 mm Hg range. Flow rates in the range of 1.5 to 2.5 L/minute typically maintain a distal aortic MAP in the 60 to 70 mm Hg range, monitored via a femoral arterial catheter.[96] Sequential advancement of the aortic cross-clamp during PLHB permits segmental aortic reconstruction with a decrease in end-organ ischemia. The advantages of PLHB include control of aortic pressures and systemic temperature, reliable distal aortic perfusion, and selective antegrade perfusion of important branch vessels (Fig. 23.14).[93] Its disadvantages include increased expense, increased complexity, and requirement for systemic anticoagulation (see Box 23.6). An alternative technique uses partial CPB by femoral vein to femoral artery perfusion with or without an oxygenator. This can allow for distal perfusion without the need for cannulation of the heart or aorta. However, it does not offer the control that is achieved with proper PLHB.



BOX 23.6 ADVANTAGES AND DISADVANTAGES OF DISTAL PERFUSION TECHNIQUES

Potential Advantages

- Control of proximal hypertension
- Decrease left ventricular afterload
- Less hemodynamic perturbations with aortic clamping and unclamping
- Decrease duration of mesenteric ischemia
- Decrease risk for paraplegia from spinal cord ischemia
- Ability to control systemic temperature with heat exchanger
- Vascular access for rapid volume expansion
- Ability to oxygenate blood with extracorporeal oxygenator
- Capability to selectively perfuse mesenteric organs or aortic branch vessels
- Maintain lower extremity SSEPs and MEPs for neurophysiologic monitoring

Potential Disadvantages

- Require greater level of systemic anticoagulation
- Increase risk for vascular injury at cannulation sites
- Increase risk for thromboembolic events.
- Require perfusion team
- Need to monitor and control upper and lower body arterial pressure and flow
- Increase technical complexity of operation

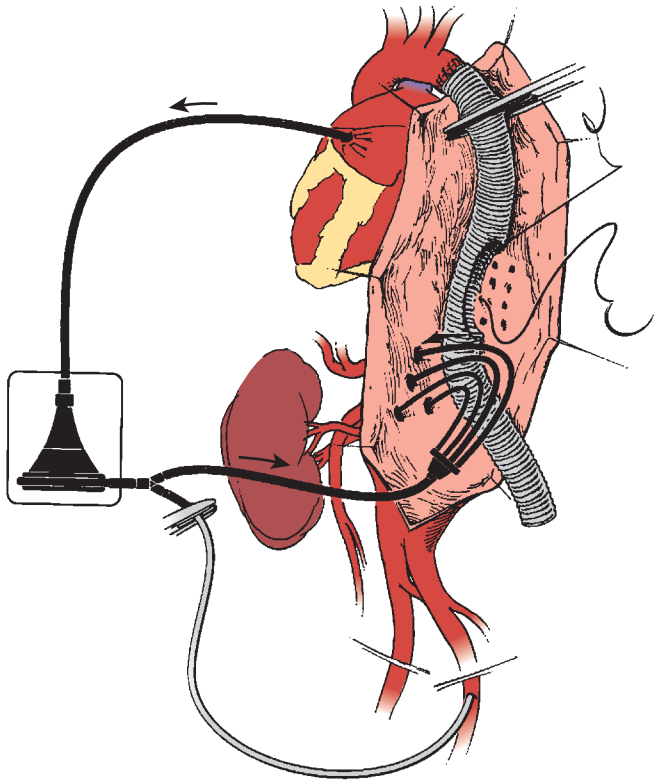


Fig. 23.14 Extracorporeal perfusion circuit for repair of an extensive thoracoabdominal aortic aneurysm. Cannulation of the left atrium and femoral artery provides distal aortic perfusion by partial left heart bypass. Visceral perfusion can be provided by selective cannulation of the celiac, superior mesenteric, and renal arteries. *(Modified from Coselli JS: Descending thoracoabdominal aortic aneurysms. In: Edmunds LH, ed.* Cardiac Surgery in the Adult. *New York: McGraw-Hill; 1997:1237.)*

Cardiopulmonary Bypass With Deep Hypothermic Circulatory Arrest

When a TAAA involves the distal aortic arch precluding an adequate cross-clamp site, CPB with DHCA is required to allow completion of the distal anastomosis. This technique has acceptable perioperative outcome for major reconstruction of the thoracoabdominal aorta because it also protects the spinal cord and mesenteric organs from ischemia.[97] If CPB with DHCA is planned for TAAA repair through a left thoracotomy incision, TEE should monitor for aortic regurgitation so that any LV distention with the onset of asystole during deliberate hypothermia can be managed with insertion of a drainage cannula. The disadvantages of CPB with DHCA include the limited safe period for DHCA, risk for stroke from retrograde aortic perfusion, increased CPB duration, and bleeding. For TAAA with extension into the distal aortic arch, a two-stage elephant-trunk procedure can be performed instead of using CPB with DHCA.[98] In the two-stage elephant-trunk procedure, the transverse aortic arch graft is performed first through a median sternotomy, leaving a short segment of graft extending into the descending aorta (see Fig. 23.5). The second stage of the repair is performed through a left thoracotomy incision to access and anastomose the distal end of the transverse arch graft to the proximal end of the descending thoracic aortic graft. This two-stage repair avoids the need for retrograde CPB perfusion through the diseased descending thoracic aorta and decreases the risk for injury to the recurrent laryngeal nerve, esophagus, and pulmonary artery located in the proximity of the distal aortic arch.

Endovascular Stent Graft Repair of Thoracic Aortic Aneurysms

TEVAR was established for the management of thoracic aortic aneurysms and now has recent management guidelines.[33] Endovascular stent grafts are tube grafts reinforced by a wire frame that are collapsed within a catheter for delivery and deployment within the aortic lumen. The principle of TEVAR is that the deployed stent complex spans the length of diseased aorta to exclude blood flow into the aneurysm cavity. TEVAR requires a landing zone for each end of the tubular graft. Endoleak is defined as blood flow within the aneurysm but outside the endovascular graft (Table 23.5).

TABLE 23.5 Classification of Endoleaks

Type	*Cause of Perigraft Flow*	*Consequences and Therapeutic Strategy*
I	Inadequate seal at proximal and/or distal landing zone	Systemic blood pressure is transmitted to aneurysm with risk for rupture: timely repair is indicated.
II	Retrograde flow from aortic branches into aneurysm	It may thrombose. If aneurysm is expanding, aortic branch embolization is indicated.
III	Structural failure of stent (eg, perforations, fractures)	Systemic blood pressure is transmitted to aneurysm with risk for rupture: timely repair is indicated.
IV	Stent graft fabric porosity	This usually occurs at implantation and disappears with anticoagulation reversal.
V	Aneurysm expansion without obvious endoleak ("endodistention")	The endovascular repair can be strengthened with a second stent.

Data from Hiratzka LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: Executive summary. A report of the American College of Cardiology Foundation, American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, and Society for Vascular Medicine. *Circulation.* 2010;121:e266–e369.

The current guidelines from The Society of Thoracic Surgeons (STS) suggest TEVAR for aneurysms of the descending thoracic aorta when the aortic diameter is larger than 5.5 cm (class IIa recommendation; level of evidence B, when the patient has significant comorbidity; class IIb recommendation; level of evidence C, when the patient has no significant comorbidity).[33] When the aortic diameter is less than 5.5 cm, the STS guidelines advise against TEVAR (class III recommendation; level of evidence C).[33] In the setting of TAAA, the STS guidelines support TEVAR in patients with severe comorbidity (class IIb recommendation; level of evidence C).[33] In patients with severe comorbidity and aortic arch aneurysm with distal extension, the STS guidelines support an endovascular repair technique (class IIb recommendation; level of evidence C).[2,33] In patients who have reasonable surgical risk and who have aortic arch aneurysms with distal extension, the STS guidelines advise against an endovascular repair technique (class III recommendation; level of evidence A).[2,33]

Endovascular stent graft repair for isolated descending thoracic aortic aneurysms with a proximal landing zone that involves the left subclavian artery can be accomplished using a two-stage procedure (Fig. 23.15). In the first stage, the left subclavian artery can be divided and anastomosed onto the left common carotid artery. This first stage of the procedure provides a proximal landing zone, allowing the deployment of the endovascular stent graft over the left subclavian artery branch in the distal aortic arch in the second stage of the procedure without compromising flow through the vessel. Multiple recent metaanalyses have demonstrated the outcome importance of not sacrificing the left subclavian artery during TEVAR to avoid the risks for stroke, paraplegia, and left upper extremity ischemia.[99–101] The recent guidelines from the Society of Vascular Surgery strongly support this principle but also recognize that in urgent TEVAR for life-threatening acute aortic syndromes, left subclavian artery coverage is unavoidable.[102]

There are currently two major options for endovascular TAAA repair, namely, total TEVAR and hybrid TEVAR. Total endovascular TAAA repair requires customized stents that preserve major aortic branches with fenestrations or side branches.[103] Multiple series have

Fig. 23.15 Intraoperative angiogram demonstrating an isolated saccular aneurysm *(double arrows)* of the thoracic aorta (A). The left subclavian artery *(single arrow)* was previously divided and transposed onto the left carotid artery to create a proximal landing site for endovascular stent repair (A). Intraoperative angiogram (B) after deployment of the endovascular stent graft (C) demonstrated exclusion of the aneurysm.

demonstrated the safety and efficacy of this TEVAR modality in high-risk TAAA patients.[104–106] In hybrid TAAA repair, the landing zone for the nonfenestrated endovascular graft is created by aortic debranching procedures, for example, the renal and mesenteric arteries are anastomosed to the iliac arteries. Multiple series and metaanalyses have demonstrated the safety and efficacy of this TEVAR modality as well in high-risk patients.[107–111] This hybrid approach also has been used in aortic arch reconstruction for high-risk patients with aortic arch aneurysms.[49,112] Furthermore, TEVAR recently has extended proximally for therapy of select aneurysms of the ascending aorta.[35,113] In summary, TEVAR for TAAA, whether entirely endovascular or hybrid, is in recent clinical development with an established niche in patients with excessive operative risk. It is likely that these technologies will mature further in the coming years. This maturation of TEVAR for

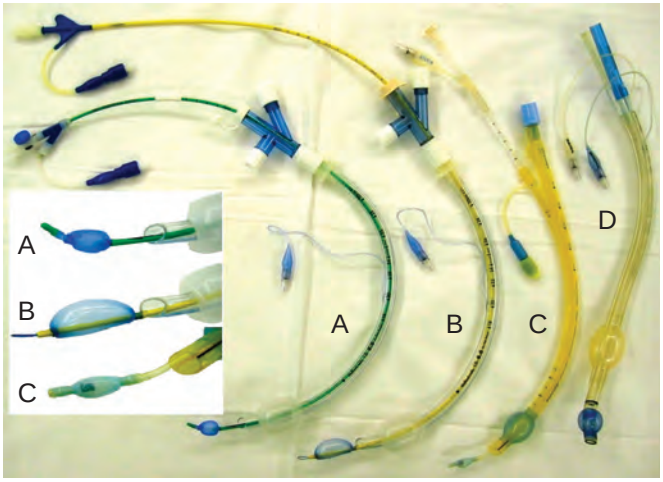

Fig. 23.16 Single-lung ventilation for thoracic or thoracoabdominal aortic aneurysm repair requiring a left thoracotomy can be accomplished using a Cohen bronchial blocker inserted through a standard endotracheal tube *(A)*, an Arndt wire-guided bronchial blocker inserted through a standard endotracheal tube *(B)*, a Univent endotracheal tube with an integrated bronchial blocker *(C)*, or a left-sided double-lumen endobronchial tube *(D)*.

diseases of the descending thoracic aorta likely will be rapid given that recent metaanalysis ($N = 5888$, 42 nonrandomized studies) demonstrated that TEVAR as compared with open aortic repair reduced perioperative mortality (OR, 0.44; 95% CI, 0.33–0.59), paraplegia (OR, 0.42; 95% CI, 0.28–0.63), pneumonia, cardiac complications, renal failure, bleeding, and transfusion, as well as length of hospital stay.[114]

Anesthetic Management for Thoracoabdominal Aortic Aneurysm Repair

The anesthetic management of patients undergoing TAAA repair often requires selective right lung ventilation in the setting of a major left thoracotomy and anesthetic interventions to prevent spinal cord ischemia. Right radial arterial pressure monitoring typically is preferred, especially if the aortic repair involves clamping the left subclavian artery or surgical endovascular access via the left brachial artery. Femoral arterial pressure monitoring is required when distal aortic perfusion is planned either with PLHB or a passive shunt. Hemodynamic monitoring with a PAC usually is helpful for the management of the concomitant specialized perfusion techniques already discussed. The anesthetic plan must allow for spinal cord monitoring with SSEPs, MEPs, or both to account for decreases in renal function and decreases in spinal cord perfusion. Finally, a strategy for postoperative analgesia should be planned.

Lung Isolation Techniques

Selective ventilation of the right lung with concomitant left lung collapse during TAAA repair enhances surgical access and protects the right lung from left lung bleeding. Collapse of the left lung typically is achieved when the left main bronchus is intubated either with a double-lumen endobronchial tube (DLT) or a bronchial blocker. Routine fiberoptic bronchoscopic guidance guarantees the effectiveness of either technique. The increased length of the left mainstem bronchus facilitates placement of a left-sided DLT and subsequently anchors it during surgery. Endobronchial blockade is achieved with one of the following devices: the Arndt blocker, the Cohen blocker, or the Univent tube (Fig. 23.16).[115] Wire-guided endobronchial blocking catheters permit the balloon-tipped catheter to be guided and positioned precisely in the left mainstem bronchus with a fiberoptic bronchoscope. The advantages of a left DLT include the ability to apply selective continuous positive airway pressure to the left lung.

BOX 23.7 FACTORS THAT CONTRIBUTE TO PARAPLEGIA AFTER THORACIC OR THORACOABDOMINAL AORTIC PROCEDURES

- Thoracoabdominal aortic aneurysm extent
- Hypotension or cardiogenic shock
- Emergency surgery
- Aortic rupture
- Presence of aortic dissection
- Duration of aortic cross-clamp
- Sacrifice of intercostal or segmental artery branches
- Prior thoracic or abdominal aortic aneurysm repair
- Prior repair of type A aortic dissection
- Occlusive peripheral vascular disease
- Anemia

BOX 23.8 MINIMIZING PARAPLEGIC RISK AFTER THORACIC OR THORACOABDOMINAL AORTIC PROCEDURES

Minimize Aortic Cross-Clamp Time
- Distal aortic perfusion
- Passive shunt (Gott)
- Partial left heart bypass
- Partial cardiopulmonary bypass

Deliberate Hypothermia
- Mild-to-moderate systemic hypothermia (32°C to 35°C)
- Deep hypothermic circulatory arrest (14°C to 18°C)
- Selective spinal cord hypothermia (epidural cooling, 25°C)

Increase Spinal Cord Perfusion Pressure
- Reimplantation of critical intercostal and segmental arterial branches
- Lumbar cerebrospinal fluid (CSF) drainage (CSF pressure ≤10 mm Hg)
- Arterial pressure augmentation (mean arterial pressure ≥85 mm Hg)

Intraoperative Monitoring of Lower Extremity Neurophysiologic Function
- Somatosensory-evoked potentials
- Motor-evoked potentials

Postoperative Neurologic Assessment for Early Detection of Delayed-Onset Paraplegia
- Serial neurologic examinations

Pharmacologic Neuroprotection
- Glucocorticoid
- Barbiturate or central nervous system depressants
- Magnesium sulfate
- Mannitol
- Naloxone
- Lidocaine
- Intrathecal papaverine

Its disadvantages include increased difficulty in difficult airways and bronchial injury in distorted endobronchial anatomy. The major advantage of endobronchial blockade is its compatibility with an existing standard 8.0-mm endotracheal tube. This is advantageous in emergencies and in difficult airways.[115] The disadvantages of endobronchial blockade include increased time for left-lung collapse and dislodgement during surgery. The majority of patients will require temporary postoperative mechanical ventilation, usually via a single-lumen endotracheal tube. ICU personnel often are unaccustomed to managing patients with DLTs with their risks for malposition, airway obstruction, and difficulty with airway secretions. Endotracheal tube exchange may be challenging if there is airway edema. An endotracheal tube exchange catheter in combination with direct laryngoscopy often facilitates safe endotracheal tube exchange.[116] It is recommended that in the setting of upper airway edema, DLTs are not routinely exchanged for single-lumen tubes (class III recommendation; level of evidence C)[2] (see Chapter 49).

Paraplegia After Thoracoabdominal Aortic Aneurysm Repair

Paraplegia after TAAA repair is a devastating complication. The temporary interruption of distal aortic perfusion and sacrifice of spinal segmental arteries during TAAA repair are central events in the pathogenesis of spinal cord ischemia and paraplegia. There are multiple contributing factors (Box 23.7).[36] The typical level of spinal cord ischemia after TAAA is midthoracic and is associated with a high perioperative mortality. There are many management strategies for prevention of this devastating complication after TAAA (Box 23.8).[2,36]

The spinal cord arterial supply provides a partial explanation for the clinical features of paraplegia after TAAA repair (Fig. 23.17).[36,117,118] The anterior spinal artery supplies the anterior two thirds of the spinal cord, and the posterior spinal arteries supply the posterior third. Branches from each vertebral artery join to form the anterior spinal artery that descends along the midline of the anterior surface of the spinal cord. The anterior spinal artery sometimes is discontinuous and fed in a variable extent by radicular arteries derived from ascending cervical, deep cervical, intercostal, lumbar, and sacral segmental arteries. The posterior spinal arteries also are derived from the vertebral arteries and receive collateral supply from posterior radicular arteries. The terminal cord segments are supplied by radicular arteries that arise from the internal iliac and sacral arterial network. The thoracolumbar spinal cord typically has multiple arterial sources with a clinical vulnerability to significant ischemia. In this watershed region, an important blood supply is derived from a large radicular artery (intercostal arteries T9–T12 in 75% of patients, T8–L3 in 15%, and L1–L2 in 10%).[119,120] This important artery is known as the arteria magna or the artery of Adamkiewicz. Ischemia in the anterior spinal artery territory classically causes motor paralysis with preservation of proprioception.[36] Clinical experience, however, has demonstrated that spinal cord ischemia after TAAA repair is variable, asymmetric, and can affect motor or sensory function, or both.[36,121]

Paraplegia is defined as lower extremity motor weakness with muscle strength weaker than gravity. Paraparesis is defined as lower extremity weakness with muscle power that allows movement at least against gravity (Table 23.6).[118,121] Spinal cord ischemia may have an immediate onset, defined as lower extremity weakness on emergence from anesthesia within 24 hours of the procedure.[36,121] Delayed-onset spinal cord ischemia is defined as lower extremity weakness that follows a normal postoperative neurologic examination after emergence from anesthesia. In the largest series of TAAA repairs ever reported ($N = 2286$; 1986–2006), the incidence rate of symptomatic spinal cord ischemia was 3.8%, with 63% of these cases having an immediate onset and 37% a delayed onset.[93] Multiple series have indicated that delayed-onset spinal cord ischemia can present days, weeks, or even months after TAAA repair.[36,93,121,122]

Immediate-onset paraplegia likely is a consequence of intraoperative spinal cord ischemia, leading to infarction that occurred during surgery. In contrast with delayed-onset paraplegia, recovery with intervention in immediate-onset paraplegia has not been consistently demonstrated. This lack of therapeutic response likely indicates that irreversible spinal cord injury has occurred. Consequently, strategies to prevent immediate-onset paraplegia are directed toward intraoperative spinal cord protection (Box 23.9). The objective of intraoperative spinal cord monitoring is to detect spinal cord ischemia for immediate intervention to improve spinal cord perfusion. Distal aortic perfusion

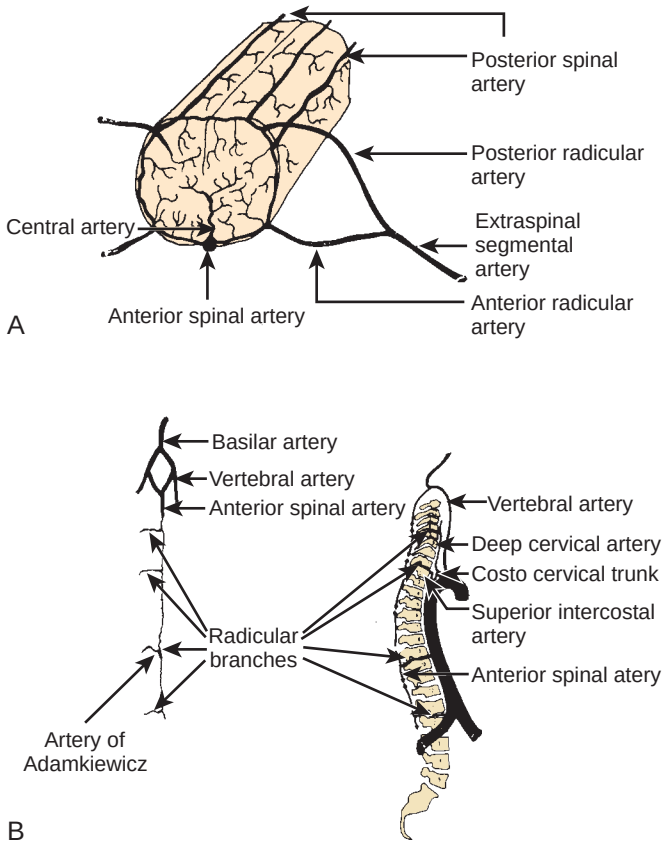

Fig. 23.17 The arterial supply to the spinal cord is provided by the anterior spinal artery and paired posterior spinal arteries that branch off the vertebral arteries (A). Radicular arterial branches off the descending thoracic aorta provide collateral arterial supply to the anterior and posterior spinal arteries (B). The arteria magna or artery of Adamkiewicz refers to a large radicular branch, located between the T9 and L2 vertebral levels, that supplies the anterior spinal artery (B).

TABLE 23.6 Description of Lower Extremity Weakness Caused by Spinal Cord Ischemia

Score	*Description*
Paraplegia	
0	No movement of lower extremity
1	Minimal movement or flicker of lower extremity
2	Movement of lower extremity but not against resistance or gravity (eg, bend knee, move leg)
Paraparesis	
3	Movement of lower extremity against resistance and gravity but without ability to stand or walk
4	Ability to stand and walk with assistance

Data from Greenberg RK, Lu Q, Roselli E, et al. Contemporary analysis of descending thoracic and thoracoabdominal aneurysm repair: a comparison of endovascular and open techniques. *Circulation.* 2008;118:808.

maintains spinal cord function during aortic cross-clamping and improves the ability to monitor spinal cord integrity during surgery with SSEP or MEPs.[118]

Delayed-onset paraplegia indicates that, although the spinal cord was protected intraoperatively, it remains vulnerable to ischemia after surgery. Although the causes of this syndrome are incompletely understood, it often is preceded by hypotension.[123] Strategies to minimize delayed-onset paraplegia include the prevention of perioperative hypotension, early anesthetic emergence for early and subsequent serial neurologic assessment, and lumbar CSF drainage (Box 23.10). Given the catastrophic sequelae of permanent paraplegia after TAAA repair, all reasonable attempts to treat delayed-onset paraplegia can be justified.[36,117]

BOX 23.9 TECHNIQUES TO DECREASE THE RISK FOR INTRAOPERATIVE SPINAL CORD ISCHEMIA

- Mild systemic hypothermia
- Lumbar cerebrospinal fluid drainage
- Selective spinal cord cooling
- Distal aortic perfusion
- Minimizing the ischemic time
- Segmental aortic reconstruction
- Intercostal artery preservation
- Pharmacologic neuroprotection
- Intraoperative motor- or somatosensory-evoked potential monitoring
- Arterial pressure augmentation

BOX 23.10 PREVENTION AND TREATMENT OF DELAYED-ONSET SPINAL CORD ISCHEMIA

- Maintain mean arterial pressure ≥85 mm Hg
- Serial neurologic assessment for lower extremity weakness or sensory loss
- Immediate treatment to augment spinal cord perfusion pressure
- Arterial pressure augmentation with vasopressor therapy
- Lumbar cerebrospinal fluid drainage
- Prevent hypotension

Lumbar Cerebrospinal Fluid Drainage

Lumbar CSF drainage is a strongly recommended spinal cord protective strategy for TAAA repair (class I recommendation; level of evidence B).[2,124–127] The physiologic rationale is that reduction of CSF pressure improves spinal cord perfusion pressure (SCPP) and also may counter CSF pressure increases caused by aortic cross-clamping, reperfusion, increased central venous pressure, and/or spinal cord edema.[36,118]

Lumbar CSF drainage is performed by the insertion of a silicon elastomer ventriculostomy catheter via a 14-gauge Tuohy needle at the L3-L4 vertebral interspace. The catheter is advanced into the subarachnoid space and securely fastened to the skin at approximately 15 cm to prevent catheter movement while the patient is anticoagulated. The open end of the catheter is attached to a sterile reservoir, and CSF is drained when the lumbar CSF pressure exceeds 10 mm Hg. The lumbar CSF pressure is measured with a pressure transducer zero-referenced to the midline of the brain. Currently, the best strategy to manage a traumatic lumbar puncture or the drainage of blood-tinged CSF has not been determined.[128,129] The lumbar CSF drainage catheter is inserted before or at the time of surgery for CSF drainage up to the first 24 hours after surgery. The lumbar drainage catheter subsequently can be capped and left in place for the next 24 hours. It then can be removed, assuming a normal neurologic examination and adequate coagulation.

The complications of lumbar CSF drainage include neuraxial hematoma, catheter fracture, meningitis, intracranial hypotension, and spinal headache.[36,96,130] Neuraxial hemorrhage after lumbar drain insertion remains a risk in patients subsequently subjected to systemic anticoagulation for CPB. Despite this risk, the overall safety of this technique has been established in multiple case series.[96,131,132] Measures to minimize neuraxial hematoma include establishing normal coagulation for both CSF catheter insertion and removal, as well as allowing a few hours between its insertion and heparinization for CPB.[36,131] In

two large contemporary series (combined $N = 2001$), the complication rate associated with CSF drainage for thoracic aortic repair was about 1% with no spinal hematomas. Both series identified excessive CSF drainage as a principal risk factor for intracranial hypotension and subsequent subdural hematoma and emphasized the outcome benefit associated with a limited CSF drainage protocol.[131,132] For routine use, CSF only should be drained, using a closed circuit reservoir, when the lumbar CSF pressure exceeds 10 mm Hg. Meningitis is characterized by high fever, altered mentation, and CSF pleocytosis often with bacteria. The risk for catheter fracture can be minimized by careful catheter removal.

Arterial Pressure Augmentation

The optimization of SCPP for spinal cord protection is recommended as part of an institutional perioperative protocol (class IIa recommendation; level of evidence B).[2] This recommendation also recognized the variety of suitable techniques such as maintenance of proximal aortic pressure and distal aortic perfusion with the caveat that technique selection often is a function of institutional experience.[2] The principles of arterial pressure augmentation and CSF drainage for prevention and management of postoperative spinal cord ischemia are in keeping with this recommendation (Fig. 23.18).[122] Spinal cord ischemia after TAAA repair is more likely in the setting of hypotension because the spinal arterial collateral network has been reduced due to factors such as intercostal artery sacrifice.[123,133,134] Surgical techniques to preserve SCPP include selective intraoperative spinal cord perfusion and intercostal artery revascularization with interposition grafts.[135,136]

SCPP is estimated as the MAP minus the lumbar CSF pressure. In general, the SCPP should be maintained greater than 70 mm Hg after TAAA repair; that is, a MAP of 80 to 100 mm Hg.[36,122,133] Because spinal cord ischemia often involves the thoracolumbar cord, it often is accompanied by a significant sympathectomy known as spinal vasodilatory shock.[2,36,122] Early intervention to treat hypotension with vasopressor therapy may counter the autonomic nervous system dysfunction accompanying spinal cord ischemia and also augment SCPP. As in the treatment of neurogenic shock, high-dose vasopressor therapy with norepinephrine, phenylephrine, epinephrine, and/or vasopressin typically is required to restore systemic vascular resistance and spinal cord perfusion, with a MAP in the 80 to 100 mm Hg range.[122] Recovery from spinal cord ischemia often is heralded by recovery of systemic vascular tone and a decreasing vasopressor requirement. Therapeutic hypertension, as discussed here, for the management of spinal cord ischemia after TAAA must be weighed against the risks for arterial bleeding.

Intraoperative Neurophysiologic Monitoring

Neurophysiologic monitoring of the spinal cord (SSEPs and/or MEPs) is recommended as a strategy for the diagnosis of spinal cord ischemia so as to allow immediate intraoperative neuroprotective interventions such as intercostal artery implantation, relative arterial hypertension, and CSF drainage (class IIb recommendation; level of evidence B)[2] (see Chapter 18). This management strategy may prevent immediate-onset postoperative paraplegia. SSEP monitoring is performed by applying electrical stimuli to peripheral nerves and recording the evoked potential that is generated at the level of the peripheral nerves, spinal cord,

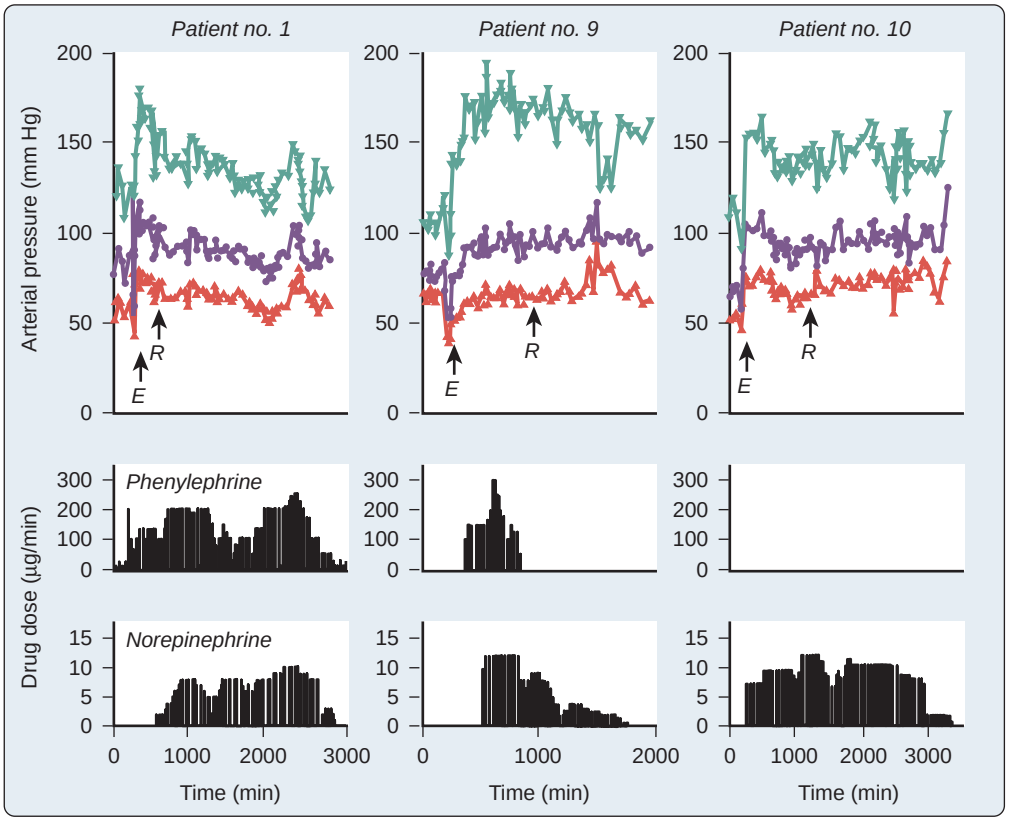

Fig. 23.18 Systolic, mean, and diastolic blood pressures in the period surrounding the onset *(E)* and recovery *(R)* from delayed-onset paraplegia in three patients after thoracoabdominal aortic aneurysm repair. Autonomic nervous system dysfunction caused by spinal cord ischemia may have contributed to the decrease in arterial pressure during the events. Arterial pressures were augmented with vasopressor therapy *(bottom)*. Vasopressor requirements decreased after recovery from spinal cord ischemia. *(Reproduced with permission from The Society of Thoracic Surgeons. From Cheung AT, Weiss SJ, McGarvey ML, et al. Interventions for reversing delayed-onset postoperative paraplegia after thoracic aortic reconstruction.* Ann Thorac Surg. *2002;74:417.)*

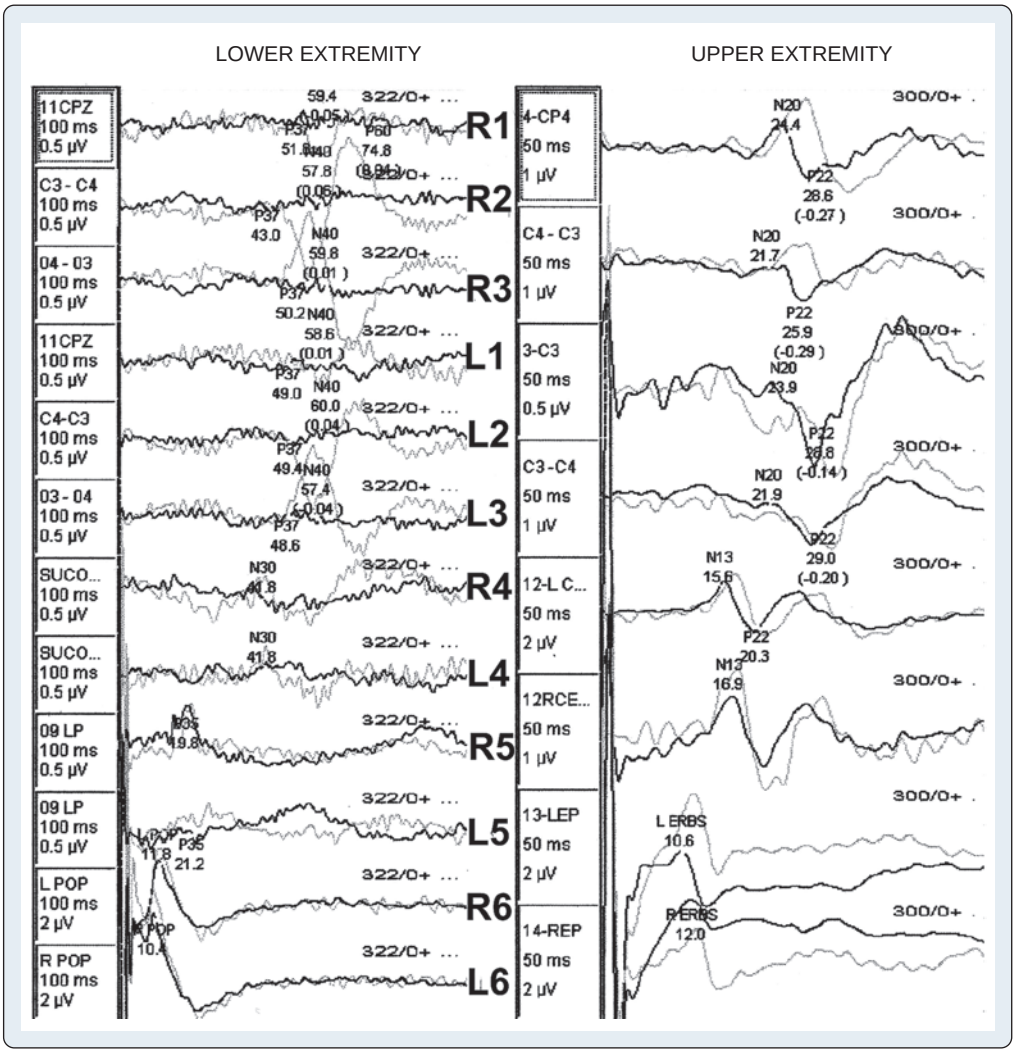

Fig. 23.19 Intraoperative somatosensory-evoked potential (SSEP) recordings from the lower *(left)* and upper *(right)* extremities that demonstrated spinal cord ischemia during thoracoabdominal aortic aneurysm repair. Disappearance of SSEP signals from the right *(R)* and left *(L)* lower extremities recorded at the cortex *(R1, R2, R3, L1, L2, L3)* and spine *(R4, L4)* with preservation of SSEP signals from the lumbar plexus (R5, L5) and popliteal nerves *(R6, L6)* indicated the acute onset of spinal cord ischemia. Upper extremity SSEP signals were maintained during the episode. The *light gray tracings* were the baseline SSEP signals used for comparison.

brainstem, thalamus, and cerebral cortex.[137] Because SSEP monitors posterior spinal column integrity, MEPs have been advocated because they monitor the anterior spinal columns that are typically at risk during TAAA repair. MEP monitoring is performed by applying paired stimuli to the scalp and recording the evoked potential that is generated in the anterior tibialis muscle.[138,139] Paraplegia caused by spinal cord ischemia significantly dampens lower extremity evoked potentials as compared with the upper extremity (Fig. 23.19). Intraoperative comparison of upper and lower extremity evoked potentials distinguishes spinal cord ischemia from the generalized effects of anesthetics, hypothermia, and/or electrical interference (see Chapter 18). As discussed earlier, the anesthetic must be designed for minimal interference with the selected neuromonitoring strategy. Although SSEPs can reliably exclude spinal cord ischemia with a negative predictive value of 99.2%, their sensitivity for its detection is only 62.5%, with no clinically useful predictive value for delayed-onset paraplegia.[140] A recent study (N = 233) compared both MEPs and SSEPs for spinal cord monitoring in extensive descending thoracic and TAAA repairs.[141] Both monitoring modalities had a nearly 90% correlation for spinal cord infarction (correlation statistic = 0.896; $P < 0.0001$), as well as a 98% negative predictive value for immediate-onset paraplegia. Furthermore, reversible changes in MEPs and SSEPs had no correlation with permanent paraplegia. In summary, despite the theoretic advantages of MEPs for monitoring the at-risk anterior spinal columns, in practice, data suggest that SSEPs alone suffice for clinical purposes, and that MEPs did not add significantly to clinical management.[141] This assessment also is reflected in the neuromonitoring recommendations of the latest thoracic aortic disease guidelines[2] (see Chapter 18).

Spinal Cord Hypothermia

Although DHCA is effective, moderate systemic hypothermia is also reasonable for spinal cord protection during TAAA repair (class IIa recommendation; level of evidence B).[2] Furthermore, topical spinal cord hypothermia is possible with cold saline epidural infusion to avoid ischemia during TAAA repair.[142,143] Although clinical experience with this technique has been limited to a few institutions, it has demonstrated clinical benefit as part of a multimodal spinal protection protocol.[127,142,143] Epidural cooling is recommended as an adjunctive technique for spinal cord protection during major distal thoracic aortic reconstructions (class IIb recommendation; level of evidence B).[2] This

technique may disseminate further, given its adjunctive benefit and the recent clinical development of a specialized countercurrent closed-lumen epidural catheter for epidural cooling during major distal aortic reconstructions.[144]

Pharmacologic Protection of the Spinal Cord

Pharmacologic spinal cord protection with agents such as high-dose systemic glucocorticoids, mannitol, intrathecal papaverine, and anesthetic agents is recommended as an adjunctive technique in a multimodal neuroprotective protocol (class IIb recommendation; level of evidence B).[2,127] Additional neuroprotective agents that have been studied in this regard include lidocaine, naloxone, and magnesium.[127,145,146] Although there are multiple agents with potential benefit, only a few are utilized routinely in clinical practice.[145]

Renal Protection During Thoracoabdominal Aortic Aneurysm Repair

Even though there has been major progress in TAAA repair, renal dysfunction remains common and still independently predicts adverse clinical outcomes.[93,147,148] The thoracic aortic guidelines recommend preoperative hydration and intraoperative mannitol administration as reasonable nephroprotective strategies in extensive distal open thoracic aortic repairs, including TAAA repair (class IIb recommendation; level of evidence C).[2] Furthermore, intraoperative cold renal perfusion with blood or crystalloid is recommended as a reasonable intraoperative nephroprotective strategy during TAAA repair (class IIb recommendation; level of evidence C).[2,149,150] The administration of furosemide, mannitol, or dopamine for the sole purpose of renal preservation is not recommended in distal thoracic aortic repairs (class IIb recommendation; level of evidence B).[2] Rhabdomyolysis from lower extremity ischemia has also been identified as a mechanism for renal dysfunction after TAAA repair.[151–153] The maintenance of lower extremity perfusion bilaterally during distal aortic perfusion has been shown to ameliorate this rhabdomyolysis with a significant nephroprotective effect.[151–153] Although these multimodal contemporary nephroprotective strategies have reduced renal complications after TAAA repair, further research is required to enhance renal preservation because renal failure remains a challenge, especially in extent II and III TAAA procedures.[154]

Postoperative Analgesia After Thoracoabdominal Aortic Aneurysm Repair

It is well recognized that the extensive thoracoabdominal incision is very painful. Because epidural analgesia has proven outcome utility in this type of extensive incision, it typically is part of the analgesic plan after TAAA repair.[155] The timing of epidural catheter placement and analgesia must take into account the perioperative anticoagulation status of the patient to minimize the risk for neuraxial hematoma.[13] Furthermore, the epidural analgesia regimen should be formulated for a predominantly sensory block to allow serial motor assessment of the lower extremities and to minimize systemic vasodilation from a sympathectomy. For example, bupivacaine (0.05%), combined with fentanyl (2 µg/mL), can be initiated at a basal rate of 4 to 8 mL/hour after the patient exhibits normal neurologic function.[122] Bolus administration of concentrated local anesthetic through the epidural catheter should be discouraged to avoid sympathetic blockade and associated hypotension. The epidural catheter can be inserted before surgery, at the time of surgery, or in the postoperative period.

Anesthetic Management for Thoracic Endovascular Aortic Repair

TEVAR has revolutionized the management of descending thoracic and TAAAs with significant clinical outcome benefit.[33,114,156] The anesthetic management is based on the principles of care for patients undergoing endovascular abdominal aortic repair, but with the additional concerns of spinal cord ischemia and stroke.[157,158] Typically, these patients undergo a balanced general anesthetic with invasive blood pressure monitoring and central venous access. Some centers have successfully performed these endovascular procedures using a local or regional anesthetic technique.[159] However, it is important to differentiate neuraxial blockade effects from the effects of spinal cord ischemia. The right radial artery is preferred for blood pressure monitoring, given that the left subclavian artery frequently may be covered and/or the left brachial artery may be accessed as part of the procedure.[99–102] PAC monitoring may be helpful in the setting of significant cardiac disease. TEE is reasonable in TEVAR in which it may assist in hemodynamic monitoring, procedural guidance, and endoleak detection (class IIa recommendation; level of evidence B).[2] As discussed earlier, if spinal cord monitoring is planned (SSEPs and/or MEPs), the anesthetic technique must be designed not to interfere with their signal quality (see Chapter 18).[160] The risk factors for stroke after TEVAR include a history of prior stroke, mobile aortic arch atheroma, and TEVAR of the proximal or entire descending thoracic aorta.[157,161] Therefore the detection of mobile atheroma in the aortic arch is an important TEE finding in TEVAR because it predicts a greater stroke risk. The risk factors for spinal cord ischemia after TEVAR include perioperative hypotension (decreased SCPP), prior abdominal/descending thoracic aortic procedures (compromised spinal collateral arterial network), and coverage of the entire descending thoracic aorta (significant loss of intercostal arteries).[157,162] Consequently, indications for CSF lumbar drainage in TEVAR include planned extensive coverage of the descending thoracic aorta, history of prior abdominal/descending thoracic aortic procedures, and postoperative paraparesis/paraplegia despite relative hypertension.[157,162] Lumbar CSF drainage is a strongly recommended for spinal cord protection strategy for TEVAR in patients with identified risk factors (class I recommendation; level of evidence B).[2,157–162]

Aortic Dissection

Aortic dissection results from an intimal tear that exposes the media to the pulsatile force of blood within the aortic lumen (Fig. 23.20).[2,163] Blood may exit the true aortic lumen and dissect the aortic wall to create a false lumen. The aortic dissection may remain localized at the primary entry site at the original intimal tear, or it may extend proximally, distally, or both. It also may extend into the aortic branch vessels to cause branch occlusion, or the intimal layer may shear at the site of branch vessels to result in intimal fenestrations. Propagation of the dissection into the aortic root can cause AR.[2,4] The weakened

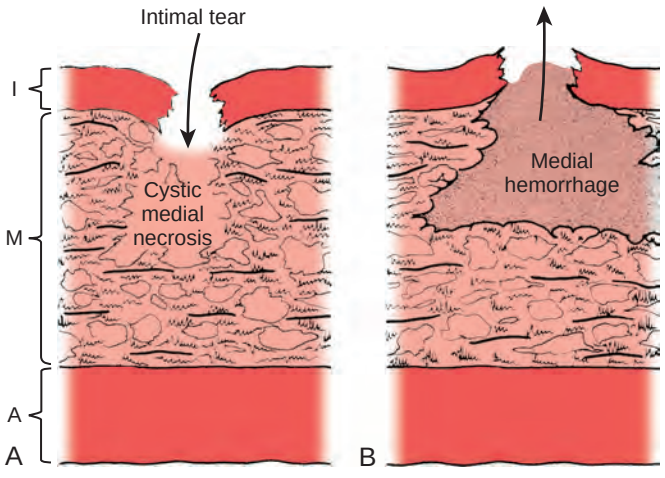

Fig. 23.20 A potential mechanism for aortic dissection is cystic medial necrosis with an intimal tear allowing blood from the aortic lumen to enter the medial layer of the aorta *(M)*, leading to separation of the intima *(I)* from the adventitia *(A)*. *(From Eagle KA, De Sanctis RW. Diseases of the aorta. In: Braunwald E, ed.* Heart disease *[4th ed]. Philadelphia; Saunders; 1992:1528.)*

BOX 23.11 CLASSIFICATION OF ACUTE AORTIC DISSECTION

DeBakey Classification

- Type I: The entire aorta is involved (ascending, arch, and descending)
- Type II: Confined to the ascending aorta
- Type III: Intimal tear originating in the descending aorta with either distal or retrograde extension
- Type IIIA: Intimal tear originating in the descending aorta with extension distally to the diaphragm or proximally into the aortic arch
- Type IIIB: Intimal tear originating in the descending aorta with extension below the diaphragm or proximally into the aortic arch

Stanford Classification

- Type A: Involvement of the ascending aorta and/or aortic arch regardless of the site of origin or distal extent
- Type B: Confined to the descending aorta distal to the origin of the left subclavian artery

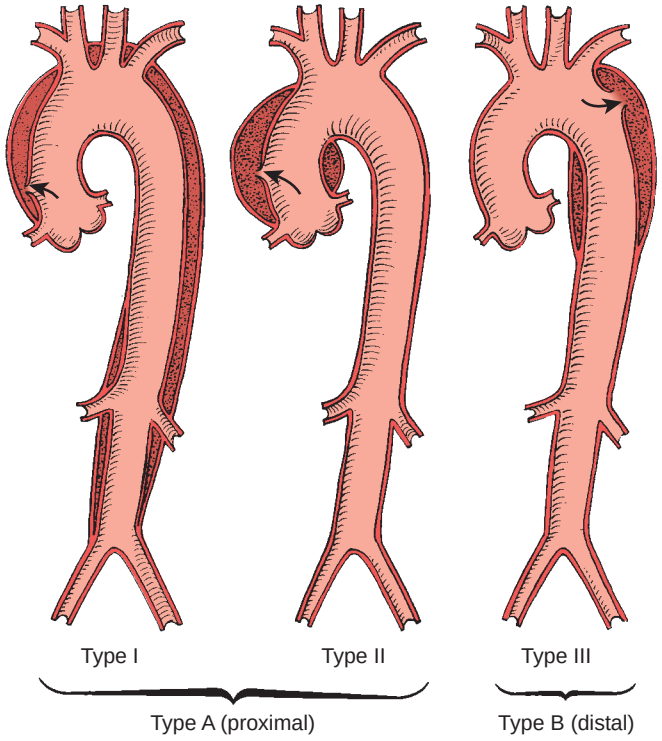

Fig. 23.21 DeBakey classification of aortic dissections. Type I: intimal tear in the ascending aorta with extension of the dissection to the descending aorta. Type II: ascending intimal tear with dissection limited to the ascending aorta. Type III: intimal tear in the descending aorta with proximal extension of the dissection to involve the ascending aorta. Type IIIB: intimal tear in the descending aorta with dissection limited to the descending aorta. *(Reprinted by permission from Excerpta Medica, Inc. From Larson EW, Edwards WD. Risk factors for aortic dissection: A necropsy study of 161 cases.* Am J Cardiol. *1984;53:849.)*

aortic wall often results in acute aortic dilation, which can progress to rupture resulting in pericardial tamponade, exsanguination, or both.

There are two generally accepted classifications of thoracic aortic dissections (Box 23.11).[2,164] The DeBakey scheme classifies aortic dissections into three groups (Fig. 23.21; Videos 23.1 to 23.5). DeBakey type I dissections originate from a primary entry site in the ascending aorta and extend to involve the entire aorta. DeBakey type II dissections originate from a primary entry site in the ascending aorta and are confined to the ascending aorta. DeBakey type III dissections originate from a primary entry site in the descending thoracic aorta and are confined to the descending thoracic aorta distal to the origin of the left subclavian artery. DeBakey type III dissections also can be subdivided into subtype IIIA that are confined to the descending thoracic aorta above the diaphragm and subtype IIIB that extend below the diaphragm into the abdominal aorta. The Stanford scheme classifies aortic dissections into two groups (Fig. 23.22).[165] Stanford type A dissections are aortic dissections that involve the ascending aorta regardless of extent, origin, or entry sites. Stanford type B dissections are confined to the descending thoracic aorta distal to the origin of the left subclavian artery regardless of the extent or entry sites (see Videos 23.1 and 23.2).

BOX 23.12 POTENTIAL COMPLICATIONS OF ACUTE TYPE A AORTIC DISSECTION

- Cardiac tamponade
- Aortic regurgitation
- Myocardial infarction
- Stroke
- Limb ischemia
- Mesenteric ischemia

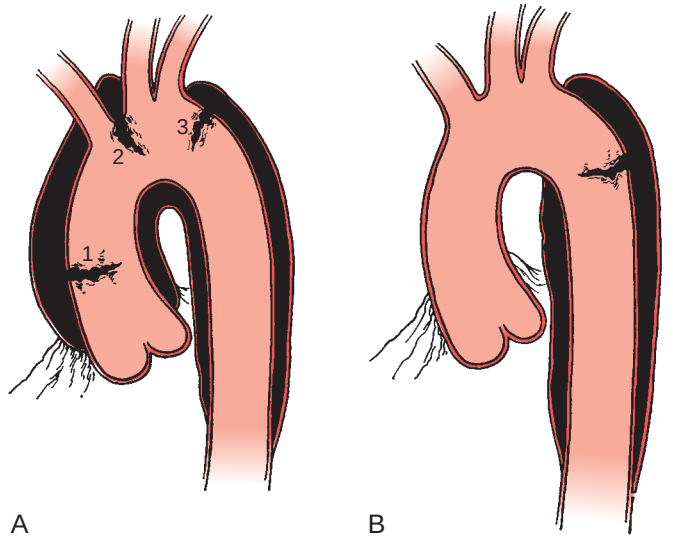

Fig. 23.22 Stanford classification of aortic dissection. In type A aortic dissection, the ascending aorta is dissected regardless of the location or number of intimal tears (A). In type B aortic dissection, the dissection is limited to the descending aorta (B) distal to the origin of the left subclavian artery. *(Reproduced with permission from The Society of Thoracic Surgeons. Type A Aortic Dissection

Aortic dissections that involve the ascending aorta (Stanford type A) are considered surgical emergencies (Box 23.12) (class I recommendation; level of evidence B).[2] The mortality rate without emergency surgery is about 1% per hour for the first 48 hours, 60% by about 1 week, 74% by 2 weeks, and 91% by 6 months (Fig. 23.23).[2,163,166] Immediate surgical intervention significantly improves the mortality rate (Table 23.7), especially in patients younger than 80 years.[2,163–167] The principal causes of mortality include rupture, cardiac tamponade, myocardial ischemia from coronary dissection, severe acute AR,

stroke caused by brachiocephalic dissection, and malperfusion syndromes including renal failure, ischemic bowel, and limb ischemia (Table 23.8).[168] An aortic dissection less than 2 weeks old is classified as acute and older than 2 weeks is classified as chronic.[169] This distinction is clinically important because after 2 weeks, mortality risk has plateaued and thus emergency surgery is not necessarily indicated. Although this time-based classification has prevailed, a recent registry analysis demonstrated four distinct time periods as follows: hyperacute (symptom onset to 24 hours), acute (2–7 days), subacute (8–30 days), and chronic (greater than 30 days).[169] Survival was progressively compromised through these four time periods in the presentation of acute type A dissection.[169] The type of preoperative presentation in type A dissection also significantly determines operative mortality, prompting a clinical classification developed at the University of Pennsylvania (Penn classification; Table 23.9).[170] The Penn classification for describing localized or generalized ischemia has been shown to serve as a useful risk assessment tool for predicting mortality, with class Abc (branch vessel malperfusion and circulatory collapse) carrying the highest mortality risk.[171–173]

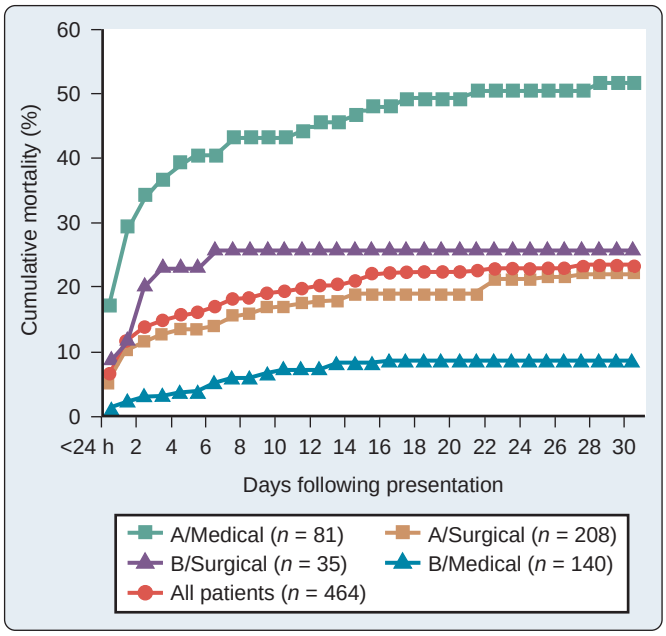

Fig. 23.23 Thirty-day mortality in 464 patients from the International Registry of Aortic Dissection (IRAD) stratified by medical and surgical treatment in both type A and type B aortic dissection. *(From Nienaber CA, Eagle KA. Aortic dissection: New frontiers in diagnosis and management. Part I: From etiology to diagnostic strategies.* Circulation. *2003;108:631.)*

TABLE 23.7 Mortality in Acute Aortic Dissection According to Dissection Type and Management

Dissection Type	*N*	*Hospital Mortality (%)*
Stanford Type A	289	101 (34.9%)
Medical management	81	47 (58%)
Surgical management	208	54 (26%)
Stanford Type B	175	26 (14.9%)
Medical management	140	15 (10.7%)
Surgical management	35	11 (31.4%)

Type B Aortic Dissection

Aortic dissections confined to the descending thoracic aorta (Stanford type B) should be managed medically unless there are life-threatening complications present such as malperfusion and aortic rupture, as well as severe pain and/or hypertension despite aggressive medical therapy (class I recommendation; level of evidence B).[2,163] Mortality with medical management in this type of aortic dissection is significantly lower than perioperative mortality (see Table 23.7).[2,163,166,174] The greater operative mortality is due to the severe complications of type B aortic dissection and the operation itself. TEVAR for the therapy of complicated acute type B dissection is highly recommended (STS guideline: class I recommendation; level of evidence A).[2,33] Similar to the newest clinical classification scheme for type A dissection, a Penn classification for type B dissection has also been introduced to distinguish complicated and uncomplicated presentations (Table 23.10).[175]

Aortic Intramural Hematoma

Aortic intramural hematoma (IMH) is a variant of the classic aortic dissection (Box 23.13).[2,163,166,176] IMH has no intimal flap with no obvious intimal tear on aortic imaging. This class of intimal tear accounts for about 17% of all dissections, with a 30-day mortality rate of 24%: 36% in type A IMH, and 12% with type B IMH ($P < 0.05$).[177] Surgical management of type A IMH reduces mortality rate by 61.1% (14% vs 36%; $P = 0.02$). Medical management for type B IMH reduced mortality fourfold (8% vs 33%; $P < 0.05$).[177] Surgical indications in type A IMH include ascending aortic diameter larger than 50 mm or IMH thickness more than 12 mm. Surgical indications in type B IMH include rapid progression, rupture, or severe clinical symptoms despite aggressive medical therapy.[1,3] It is, therefore, reasonable to

TABLE 23.9 Penn Classification of Ischemic Presentations in Acute Stanford Type A Aortic Dissection

Type A Dissection Presentation	*Definition*	*Mortality Rate*
Penn presentation a (Type Aa)	Type A dissection with **a**bsence of ischemia	3.1%
Penn presentation b (Type Ab)	Type A dissection with **b**ranch vessel malperfusion producing clinical organ ischemia (eg, stroke, renal failure, ischemic extremity, mesenteric ischemia)	25.6%
Penn presentation c (Type Ac)	Type A dissection with **c**irculatory collapse (systolic blood pressure <80 mm Hg and/or vasopressor therapy) with or without cardiac involvement	17.6%
Penn presentation b + c (Type Abc)	Types Ab and Ac together	40%

Data from Augoustides JG, Geirsson A, Szeto W, et al. Observational study of mortality risk stratification by ischemic presentation in patients with acute type A aortic dissection: the Penn classification. *Nat Clin Pract Cardiovasc Med.* 2009;6:140.

TABLE 23.10 Penn Classification of Ischemic Presentations in Acute Stanford Type B Aortic Dissection

Type B Dissection Presentation	*Definition*
Class A (uncomplicated)	Absence of branch-vessel ischemia or circulatory compromise Type I high risk for future aortic complications Type II low risk for future aortic complications
Class B (complicated)	Branch-vessel malperfusion with visceral, renal, lower-extremity, and/or spinal cord hypoperfusion based on clinical and/or laboratory and/or radiographic evidence.
Class C (complicated)	Circulatory compromise Type I aortic rupture with hemorrhage outside the aortic wall with/without cardiac arrest, shock, and hemothorax Type II threatened aortic rupture typically heralded by refractory pain and/or hypertension
Class BC (complicated)	Branch-vessel malperfusion combined with circulatory compromise

Data from Augoustides JG, Szeto WY, Woo EY, et al: The complications of uncomplicated acute type-B dissection: the introduction of the Penn classification. *J Cardiothorac Vasc Anesth.* 2012;26:1139–1144.

BOX 23.13 AORTIC INTRAMURAL HEMATOMA

Diagnostic Criteria

- Crescent-shaped or circumferential thickening of aortic wall
- Hematoma thickness >7 mm
- No dissection flap
- No intimal tear
- No blood flow within hematoma

Risk Factors for Mortality or Progression

- Ascending aorta or arch involvement (type A)
- Aortic diameter >45 mm
- Hematoma thickness >11 mm

manage IMH similar to classic aortic dissection in the corresponding thoracic aortic segment (class IIa recommendation; level of evidence C).[2] Although IMH may be caused by rupture of the vas vasorum in the aortic wall without intimal hematoma, there are frequently small intimal tears that are beyond the resolution of current aortic scanners and are only identifiable on close aortic inspection during surgery or autopsy.[2,170,177–179]

Clinical Diagnosis and Imaging Studies for Aortic Dissection

Aortic dissection is more common in men and has a peak incidence in later life.[2,163,166] It often has an earlier onset in the setting of Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome, bicuspid aortic valve, aortic coarctation, and familial aortic dissection.[2,4,163,166] It also is commonly associated with hypertension but less so with atherosclerosis.[29] Further predisposing factors include pregnancy, cocaine abuse, arteritis, aortic trauma, and aortic instrumentation.[2,4,180]

The pain of aortic dissection typically is severe, abrupt in onset, and has a ripping, tearing, or stabbing quality (class I recommendation; level of evidence B).[2] Highly suggestive physical findings include a pulse deficit, a systolic blood pressure limb differential greater than 20 mm Hg, focal neurologic deficit, and a new murmur of AR (class I recommendation; level of evidence B).[2,4] Electrocardiogram (class I recommendation; level of evidence B), along with urgent and definitive aortic imaging (TEE, CT, MRI), is strongly recommended in suspected aortic dissection (class I recommendation; level of evidence B).[2,5] A negative chest radiograph should not delay aortic imaging, especially in patients suspected of presenting with aortic dissection

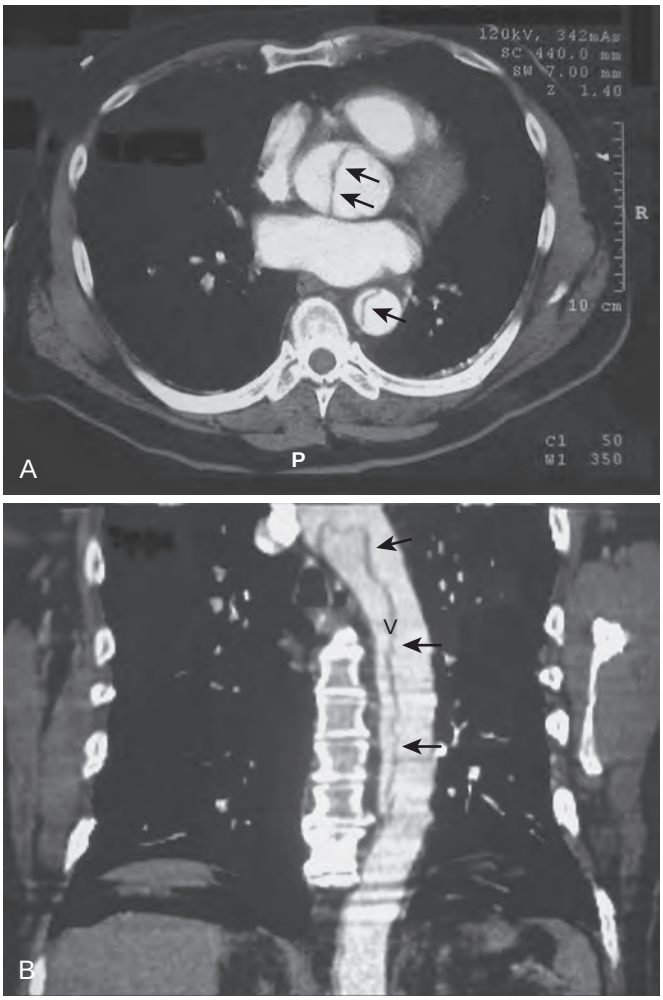

Fig. 23.24 Computed tomographic angiogram in a patient with a type A aortic dissection. Axial images of the chest (A) demonstrated an intimal flap that extended from the ascending aorta *(double arrows)* into the descending thoracic aorta *(single arrow)*. Sagittal reconstruction (B) demonstrated the presence of an intimal flap in the descending thoracic aorta *(single arrows)*.

(class I recommendation; level of evidence B).[2,4] The selection of an aortic imaging modality should be guided by patient and institutional variables, including immediate test availability (class I recommendation; level of evidence C).[2,4] If initial aortic imaging is negative in the setting of high clinical suspicion for dissection, a second imaging study should be arranged (class I recommendation; level of evidence C).[2,38]

The most common imaging study is contrast-enhanced spiral CT or CTA because it is widely available.[181] Typical findings in acute aortic dissection include an intimal flap, luminal displacement of intimal calcifications, and aortic dilation (Fig. 23.24).[163,166,169] IMH appears as a crescent-shaped high-attenuation thickening of the aortic wall in noncontrast CT (Fig. 23.25).[163,166] CT can demonstrate rupture, branch-vessel involvement, and false lumen extent. Although MRI has a near 100% sensitivity and specificity and is widely available, it also takes significantly longer than CT (Fig. 23.26).[2,38,163,166,169]

At experienced centers, TEE provides high-resolution aortic images with comparable sensitivity and specificity to MRI and CT.[2,163,166,182] Furthermore, TEE can look for complications by interrogating the aortic valve (AR severity and mechanism), assessing ventricular function including regional wall motion for coronary dissection, and diagnosing cardiac tamponade and pericardial effusion. Aortic dissection appears on TEE examination as an undulating intimal flap within the aorta separating a true and false lumen (Fig. 23.27). It is sometimes

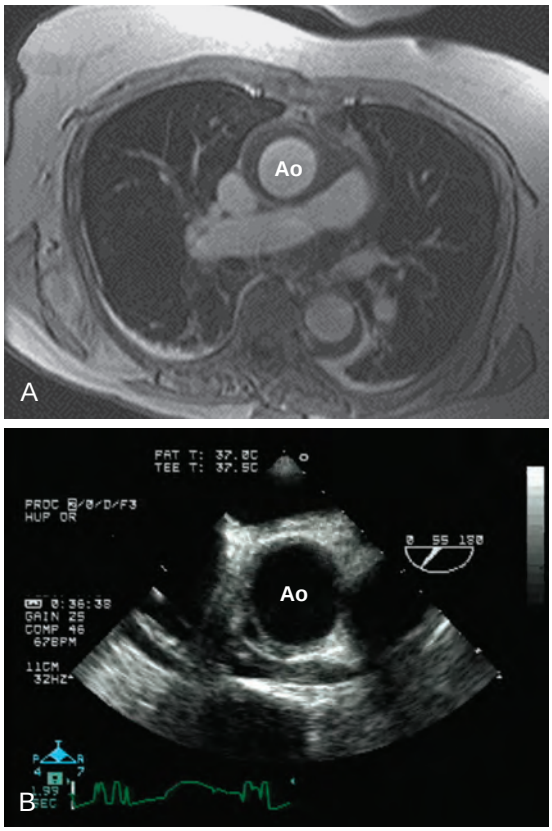

Fig. 23.25 Computed tomographic angiogram of the chest (A) and transesophageal echocardiographic upper esophageal short-axis images of the aorta (B) demonstrating an aortic intramural hematoma that extended from the ascending aorta into the descending thoracic aorta. A crescent-shaped or circumferential thickening of the aortic wall is diagnostic for aortic intramural hematoma. *Ao*, Aorta.

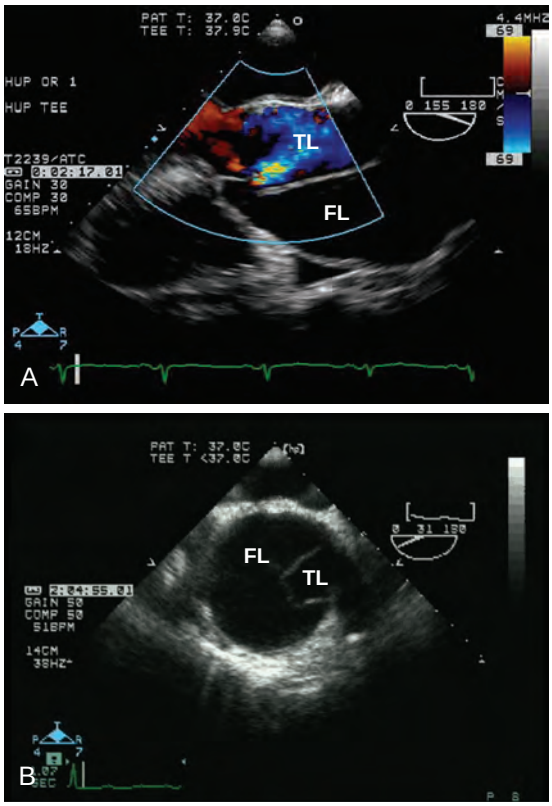

Fig. 23.27 Transesophageal echocardiographic midesophageal long-axis image of the aortic valve (A) and short-axis image of the ascending aorta (B) in a patient with a type A aortic dissection. An intimal flap separating the true lumen *(TL)* of the aorta with the false lumen *(FL)* was demonstrated in the aortic root and ascending aorta. Extension of the dissection into the aortic root may cause aortic regurgitation or coronary insufficiency.

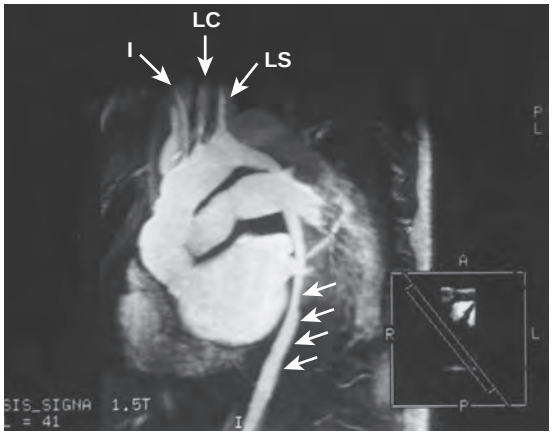

Fig. 23.26 Magnetic resonance imaging of the chest with gadolinium contrast injection in a patient with a type A aortic dissection. The dissection extended into the innominate artery *(I)*, left carotid artery *(LC)*, left subclavian artery *(LS)*, and into the descending aorta *(arrows)*.

difficult to distinguish the true lumen from the false lumen, but the true lumen tends to be smaller with pulsatile high-velocity flow in systole.[38] Doppler color-flow imaging can detect flow communication between the true and false lumens at intimal tear sites. The use of 3D-TEE can also be valuable in determining the size of the entry tear, as well as the relationship to nearby structures.[38] Aortic IMH appears as an echo-dense crescent-shaped thickening (>7 mm) of the aortic wall that may contain echolucent pockets of noncommunicating blood (see Fig. 23.25). TEE also may distinguish clinical mimickers of aortic dissection and can assess the thoracic aortic anatomy in detail to guide surgical decision making.[183,184]

Anesthetic Management for Aortic Dissection

Acute aortic dissection is a medical emergency. Initial medical management is directed at treatment of pain and decreasing the arterial pressure with antihypertensive agents. Vasodilator therapy should be initiated to decrease wall stress with control of heart rate and blood pressure (class I recommendation; level of evidence C).[2,4] In the presence of acute AR, β-blockers should be used with caution because they block the compensatory tachycardia (class I recommendation; level of evidence C).[2] In the absence of contraindications, β-blockers should be titrated to a heart rate of 60 beats/minute (class I recommendation; level of evidence C).[2] Esmolol is a particularly useful β-blocker because it has a short pharmacologic half-life and can be rapidly titrated. Esmolol can be administered as an initial bolus of 5 to 25 mg intravenously, followed by a continuous infusion of 25 to 300 μg/kg per minute. In patients with β-blocker contraindications, heart rate control should be gained with titration of nondihydropyridine calcium channel blockers such as verapamil or diltiazem (class I recommendation; level of evidence C).[2] Alternatively, labetalol, a drug that has a 1:7 ratio of β-blocker to α-blocker activity, can be administered as a 20 to 80 mg intravenous bolus followed by an infusion at 0.5 to 2.0 mg/minute. Metoprolol, a cardioselective β-blocker, may be advantageous in patients with reactive airway disease who are sensitive to β-adrenergic antagonists. Metoprolol is administered at a dose of 5

to 15 mg intravenously every 4 to 6 hours. If the systolic blood pressure remains greater than 120 mm Hg with adequate heart rate control, then vasodilators (e.g., nitroprusside at a dosage of 0.5 to 2.0 μg/kg per minute or nicardipine at a dose of 1 to 15 mg/hour) should be titrated for further reductions of blood pressure while still maintaining adequate vital organ perfusion (class I recommendation; level of evidence C).[2] Vasodilator therapy should not be initiated before heart rate control to avoid the associated reflex tachycardia that might aggravate the aortic dissection (class III recommendation; level of evidence C).[2]

In general, the anesthetic management of type A aortic dissection resembles the management of ascending aortic aneurysms that require DHCA. The anesthetic management of type B aortic dissections resembles the management of TAAA repair. Large-bore intravenous catheters are essential for intravenous medications and rapid volume expansion. A radial arterial catheter for invasive blood pressure monitoring is preferred over a femoral artery catheter to allow for CPB cannulation, depending on surgeon preference. If a pulse deficit is detected, the site for arterial pressure monitoring should be chosen to best represent the central aortic pressure. A central venous or PAC to monitor CVP, pulmonary artery pressure, and cardiac output is useful. TEE insertion is performed after anesthetic induction, and it can be used to verify the diagnosis (class IIa recommendation; level of evidence B).[3,182]

Critically unstable patients should be resuscitated by standard ACC/AHA guidelines or by securing the airway, providing mechanical ventilation, and administering drugs to support the circulation. Emergent TEE should follow to verify the diagnosis of type A aortic dissection and to detect cardiac tamponade, hypovolemia, AR, and/or heart failure.[185] If TEE detects cardiac tamponade, immediate sternotomy with preparations to institute CPB via femoral artery cannulation should be performed. Opening the pericardium and relief of cardiac tamponade can be followed by hypertension causing aortic rupture.

The induction of general anesthesia in hemodynamically stable patients with aortic dissection should proceed in a cautious manner. The dose of intravenous antihypertensive drugs may need to be reduced at the time of anesthetic induction to prevent severe hypotension when combined with anesthetic drugs. Hypotension may also occur on anesthetic induction in response to the attenuation of sympathetic nervous system tone or decreased cardiac preload caused by venodilation and positive pressure ventilation in patients with preexisting concentric left ventricular hypertrophy. The hypertensive response to endotracheal intubation, TEE probe insertion, and sternotomy should be anticipated and attenuated with narcotic analgesics.

Surgical Treatment of Stanford Type A Aortic Dissection

Surgical repair for type A aortic dissection requires resection of the proximal extent of the dissection. A partially dissected aortic root may be repaired with aortic valve resuspension.[186] A destroyed aortic root must be replaced with a composite graft or a valve-sparing root replacement.[3,4] In the setting of a DeBakey type II dissection, the entire dissected aorta merits replacement. CABG sometimes is necessary for aortic dissections that involve the coronary ostia.

Although femoral arterial cannulation is popular for CPB, recent evidence suggests that it is associated with adverse clinical outcomes including death, stroke, and malperfusion syndromes.[187,188] Cannulation of the distal ascending aorta or the axillary artery (ideally with an end-to-end graft) has been associated with significantly enhanced clinical outcome as compared with standard femoral arterial cannulation.[187,188] When central cannulation through dissected aorta is chosen, TEE is mandatory to verify initial wire placement in the true lumen (Fig. 23.28).[189] It remains important to monitor cerebral perfusion throughout the operative procedure for detection and correction of acute malperfusion.[75–77] The use of selective cerebral perfusion techniques with circulatory arrest is reasonable to complete arch reconstructions to reduce neurologic complications (class IIa recommendation; level of evidence B).[3]

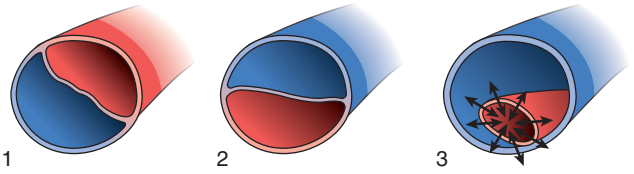

Fig. 23.28 Depiction of the increasing levels of difficulty in direct cannulation of the ascending aorta in acute type A aortic dissection, depending on the location of the true lumen. Level 1 has an anteriorly positioned true lumen, whereas Level 2 includes those patients with a posteriorly positioned true lumen. Level 3 involves cases where there is a near circumferential dissection and essentially a free-floating true lumen. Intraoperative TEE is imperative in verifying wire placement in the correct lumen prior to cannulation. *(From Frederick JR, Wang E, Trubelja A, et al. Ascending aortic cannulation in acute type A dissection repair.* Ann Thorac Surg. *2013;95:1808–1811.)*

In DeBakey type I dissections, the dissected descending thoracic aorta often undergoes aneurysmal degeneration and is responsible for significant aorta-related mortality in the long term.[190] Consequently, long-term outcomes after extensive type A dissection would be significantly improved if this distal aortic degeneration could be prevented.[190,191] Recent clinical series have demonstrated the efficacy and safety of anterograde stenting of the descending thoracic aorta during open aortic arch repair for DeBakey type 1 aortic dissection.[192–194] This technique is also known as the endovascular stented elephant-trunk technique or the frozen elephant-trunk technique.[195] The long-term aneurysmal degeneration of the descending thoracic aorta is prevented by immediate stenting in the acute dissection phase; thus, favorable long-term aortic remodeling is facilitated.

Integrated Management of Stanford Type B Aortic Dissection

Uncomplicated type B aortic dissection currently has the best clinical outcome when managed medically.[33,196] Medical therapy for type B aortic dissection is directed at control of systemic hypertension to prevent aortic aneurysm formation, aortic rupture, and extension of the aortic aneurysm (class I recommendation; level of evidence C).[2] Combination therapy with a diuretic, β-blocker, angiotensin-converting enzyme inhibitor, or other antihypertensive agents usually is necessary to achieve and maintain blood pressure less than 130/80 mm Hg. All patients after repair of type A aortic dissection also should be managed aggressively with antihypertensive therapy because many are left with a residual distal aortic dissection after repair. Serial imaging of the aorta is necessary to detect expansion of the aortic lumen and aneurysm development that may warrant surgical correction.

In the presence of life-threatening complications, TEVAR has emerged as a preferred alternative therapy to surgery.[33,114,196–199] A landmark randomized trial demonstrated that, in the short term, TEVAR added no survival advantage over medical management for uncomplicated type B aortic dissection.[200] However, because TEVAR did improve aortic remodeling in this trial, further adequately powered trials are indicated to test whether this translates into better aortic outcomes.[201] Malperfusion syndromes associated with type B dissection also can be managed with intimal fenestration.[202,203]

Penetrating Atherosclerotic Ulcer

Penetrating atherosclerotic ulcer describes an isolated disruption of the intimal layer of the aortic wall at the site of atheromatous disease (Fig. 23.29).[2,4] This class of intimal tear may occur at any aortic locus but is most common in the descending thoracic aorta. It typically is associated with severe aortic atheroma in the elderly and penetrates through to the aortic adventitia.[2,4] Penetrating atherosclerotic ulcers may be associated with IMH or pseudoaneurysm, and they have been shown to progress to aneurysm in 27.8% and rupture in 4.1% of

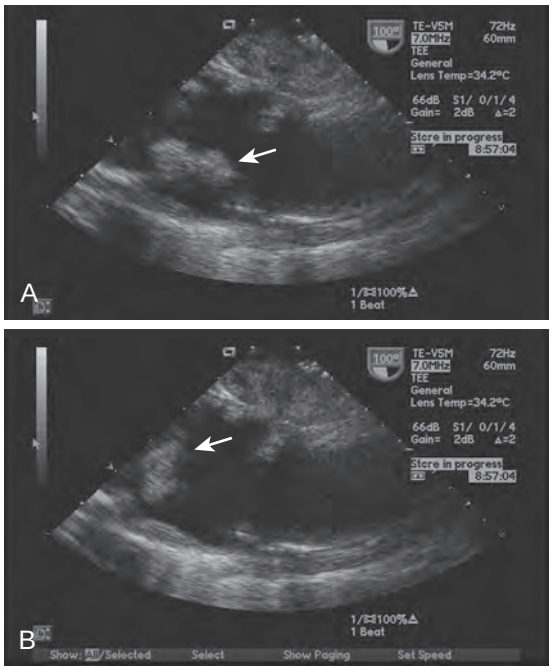

Fig. 23.29 Transesophageal echocardiographic (TEE) long-axis images of the descending thoracic aorta demonstrating severe atherosclerotic disease with atheroma protruding into the vessel lumen. Images obtained in diastole (A) and in systole (B) demonstrated a large mobile atheroma *(arrow)* that may represent an atheromatous plaque that has ruptured and detached from the aortic wall.

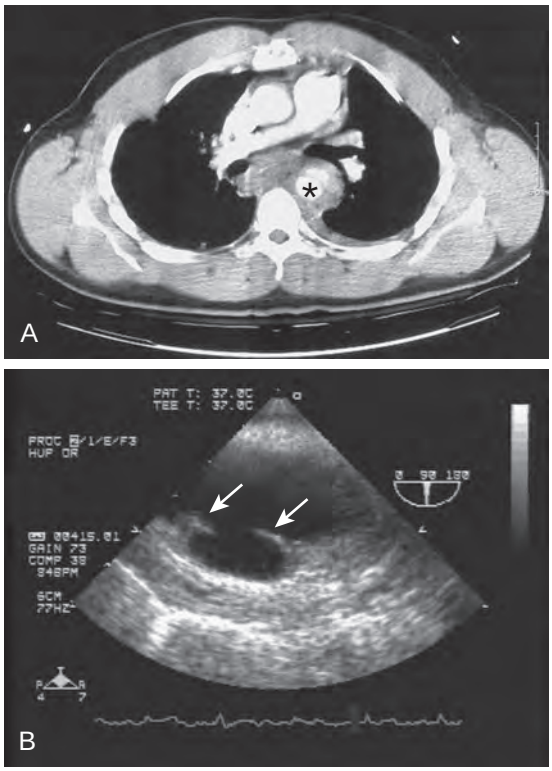

Fig. 23.30 Computed tomographic angiogram of the chest (A) in a trauma patient who presented with a widened mediastinum on the chest roentgenogram demonstrating traumatic intimal disruption of the aorta in the region of the aortic isthmus *(asterisk)*. Perivascular hematoma and extravasation of contrast agent into the mediastinum and left pleural cavity indicated a rupture of the descending aorta. Intraoperative transesophageal echocardiographic (TEE) long-axis image of the proximal descending thoracic aorta (B) demonstrated a thick mural flap *(arrows)* and surrounding hematoma at the site of the intimal disruption.

patients.[204–206] Initial symptoms include chest and back pain similar to aortic dissection.[2] Diagnosis typically is made with contrast-enhanced CT.[207,208] Although patients may be managed medically, TEVAR has emerged as a major management strategy, especially in severely symptomatic or complicated presentations (class IIa recommendation; level of evidence C).[33,209,210] Furthermore, in asymptomatic presentations of this intimal syndrome, TEVAR currently is not recommended (class IIa recommendation; level of evidence C).[33]

Traumatic Aortic Injury

The most common cause of traumatic aortic injury is blunt chest trauma or rapid deceleration injuries associated with motor vehicle accidents or falls. Although this injury may be fatal, the majority of patients have injuries in the region of the aortic isthmus.[211] Patients with traumatic aortic injury commonly will have associated significant injuries. TEE is helpful in the management of traumatic aortic injury because it is portable, is often available in the OR, provides a rapid diagnosis, and does not require aortic instrumentation or radiographic contrast injection. TEE also can detect cardiac tamponade, left pleural effusion, hypovolemia, ventricular dysfunction from myocardial contusion, or vascular injuries from penetrating chest wounds.[212] Its disadvantages include limited imaging in the setting of facial injuries, suspected cervical spine injuries, and lesions in the distal ascending aorta. The characteristic features of traumatic aortic injury detected by TEE are a mural flap at the site of intimal disruption and regional deformities of the aortic wall caused by the contained rupture (Fig. 23.30). The mural flap commonly is limited to a 1- to 2-cm aortic segment located at the aortic isthmus just distal to the origin of the left subclavian artery. This mural flap usually is thick compared with the intimal flap seen in aortic dissection and is less mobile because it usually contains several layers of the vessel wall. Contrast-enhanced CT is frequently selected for aortic imaging because these patients typically require CT scanning as part of their initial diagnostic evaluation.[213,214]

TABLE 23.11 Incidence of Postoperative Paraplegia after Surgical Repair of Traumatic Aortic Injury in Relation to Operative Technique

Operative Technique	*No. of Patients*	*Paraplegia (%)*
Clamp and sew	73	16.4[ab]
Bypass (distal aortic perfusion)	134	4.5[a]
Gott shunt	4	0
Full bypass	22	4.5
Partial bypass	39	7.7
Centrifugal pump	69	2.9[b]

[a]$P < 0.004$, bypass vs clamp and sew; [b]$P < 0.01$, centrifugal pump vs clamp and sew.
Data from Fabian TC, Richardson JD, Croce MA, et al. Prospective study of blunt aortic injury: multicenter trial of the American Association for the Surgery of Trauma. J Trauma. 1997;42:374–380.

Injuries to the ascending aorta or aortic arch typically require CPB with DHCA for repair. Injuries to the aortic isthmus can be repaired via a left thoracotomy. The descending thoracic aorta usually is repaired with an interposition graft with the aid of PLHB. The risk for perioperative spinal cord ischemia is minimal when distal aortic perfusion is provided (Table 23.11) because only a short segment of the thoracic aorta is replaced. Although open repair is possible, TEVAR has emerged as the preferred intervention whenever possible because of the well-documented outcome advantages (STS class I recommendation; level of evidence B).[33,213–217]

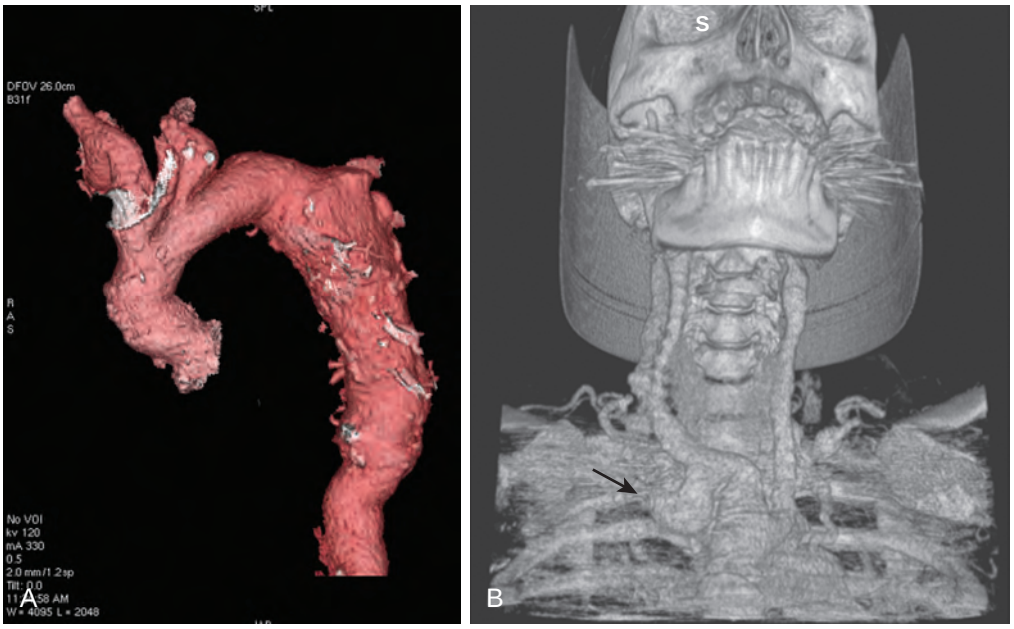

Fig. 23.31 Three-dimensional reconstruction from a computed tomographic angiogram of the aorta (A) and aortic arch branch vessels (B) from a patient with Takayasu arteritis. The reconstructions demonstrated aneurysmal dilation of the descending thoracic aorta, proximal innominate artery, and both subclavian arteries. The left and right *(arrow)* subclavian arteries were occluded distal to the aneurysm.

Aortic Atheromatous Disease

Severe aortic atheroma is a major risk factor for stroke.[2,33] Thoracic aortic replacement is indicated for serious embolism and to facilitate the conduct of concomitant cardiac procedures that require the safe cross-clamping of the aorta (see Fig. 23.29). The anesthetic management of patients undergoing thoracic aortic reconstruction for atheromatous disease resembles the management of thoracic aortic aneurysms for corresponding aortic segments. Intraoperative epiaortic ultrasound imaging is superior to manual palpation or TEE for thoracic aortic atheroma.[218,219] The epiaortic ultrasound is important for selecting the optimal site for aortic cannulation for CPB or placement of the aortic cross-clamp to minimize atheroembolic events such as stroke.[218–220]

Takayasu Arteritis

Takayasu arteritis is a chronic vasculitis that affects primarily the thoracic aorta, its branches, and even the pulmonary artery (Fig. 23.31).[2,4] Takayasu arteritis occurs most frequently in young Asian women and occurs worldwide.[221] Its onset is insidious with the gradual development of vascular insufficiency. Dilation and aneurysm formation also may occur in diseased aortic segments. Diagnostic criteria include onset of disease at age younger than 40 years, claudication of the extremities, decreased brachial pulses, a systolic blood pressure differential of 10 mm Hg between the arms, subclavian or abdominal aortic bruits, and angiographic demonstration of narrowing of the aorta and/or its primary branches.[2,4]

Initial therapy consists of high-dose corticosteroids (class I recommendation; level of evidence B).[2,4] Elective revascularization should be postponed until the acute inflammatory state has been adequately treated (class I recommendation; level of evidence B).[2,4] Once revascularization is feasible, an endovascular approach is a good option that has been shown to have a high success rate with improved quality of life.[222] Anesthetic management of Takayasu arteritis is complicated by limited sites for arterial blood pressure measurement. The femoral artery may be the only site for accurate measurement of central aortic pressure in patients with stenosis of both subclavian arteries.

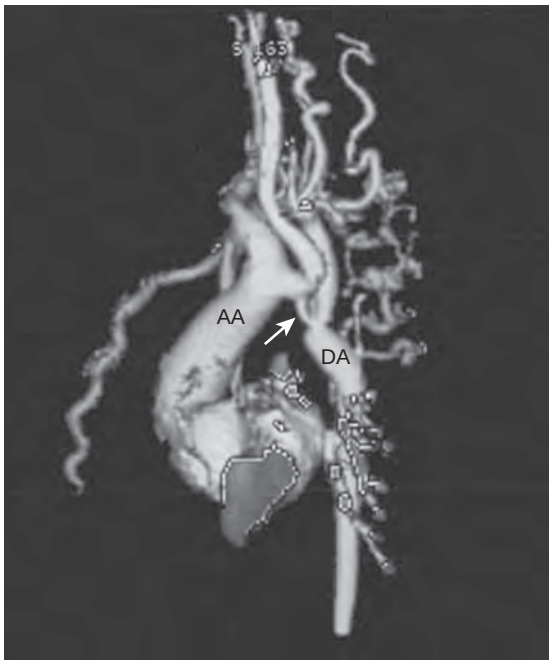

Fig. 23.32 Three-dimensional reconstruction from a computed tomographic angiogram of a patient with aortic coarctation. In this patient, the site of coarctation was located between the left carotid and left subclavian arteries *(arrow)*. Repair was performed by construction of an extra-anatomic bypass graft between the ascending *(AA)* and descending *(DA)* thoracic aorta.

Aortic Coarctation

Aortic coarctation is a common malformation that ranges from a discrete narrowing of the aorta to a long hypoplastic segment of the vessel to complete discontinuity of the aorta (Fig. 23.32).[223] The site of coarctation can be variable but is typically juxtaductal in location, affecting

the proximal descending thoracic aorta just distal to the origin of the left subclavian artery. The distal descending aorta often is hypoplastic in severe cases. Conditions associated with aortic coarctation include Turner syndrome, bicuspid aortic valve, ventricular septal defect, patent ductus arteriosus, and intracerebral aneurysm.[2,223]

Adults with coarctation may present with headache, epistaxis, heart failure, or lower extremity claudication. Its typical hemodynamic profile is upper extremity hypertension combined with lower extremity hypotension and weak pulses. If the origin of the left subclavian artery is distal to the coarctation, blood pressure in the left arm may also be diminished. The chest radiograph often shows rib notching caused by the enlarged intercostal arteries that serve as collateral vessels to supply the lower body. The electrocardiogram often shows left ventricular hypertrophy. The diagnosis is confirmed by definitive aortic imaging.[38] Cardiac catheterization, MRI, and echocardiography are useful to detect associated cardiac abnormalities.

Balloon angioplasty with stenting is the preferred treatment when coarctation is limited to a discrete segment of the aorta.[223–225] Although sedation often will suffice for the procedure, general anesthesia may be required when dilation of the coarctation is expected to be painful or when it is necessary to keep the patient immobile for the procedure. Complications of balloon angioplasty have included residual stenosis, recoarctation, paracoarctation aortic dissection or rupture, aortic aneurysm, and injury to the femoral artery. Aortic dissection or aneurysm at or near the angioplasty site may be a consequence of mechanical damage to the aortic wall or congenital defects of the aortic wall.

Operative repair in adults may involve interposition graft repair or extraanatomic bypass grafting from the proximal aorta or left subclavian artery to the descending aorta.[226] Extraanatomic bypass is advantageous for reoperations or in adults when the distal aortic arch cannot be mobilized to perform an end-to-end anastomosis. Avoiding surgical dissection in the region of the distal aortic arch also decreases the risk for injury to the recurrent laryngeal and phrenic nerves. Although perioperative mortality is low, spinal cord ischemia is possible during repair if collateral circulation is inadequate or if distal aortic perfusion pressure is too low. Preventive strategies include intraoperative monitoring of distal aortic perfusion pressure, neuromonitoring with SSEPs and/or MEPs, deliberate hypothermia, and distal aortic perfusion with PLHB.[227] Postoperative hypertension after repair may require aggressive monitoring and management.

Illustrative Transesophageal Echocardiography Cases

Case Study 1: Thoracic Aortic Atheroma

A 78-year-old man with diabetes and hypertension presents for CABG for triple-vessel disease. He has severe peripheral vascular disease. After induction of general anesthesia, a TEE is performed.

Framing

Because this patient has advanced atherosclerosis with multiple risk factors, it is likely that his thoracic aorta will have extensive atheromatous disease. Thoracic aortic atheroma is a major risk factor for stroke, especially in the setting of intraoperative aortic manipulation and instrumentation. What is the surgical plan in this case: Is this CABG on-pump or off-pump? If there is significant aortic atheroma, then the ascending aortic manipulation associated with aortic cannulation and cross-clamping for on-pump CABG would likely be associated with significant atheroembolism and a significant stroke risk. The cardiac surgeon requests an assessment of the atheroma burden in the thoracic aorta to guide the conduct of the CABG.

Questions

What is the extent of the thoracic aortic atheroma? Which aortic segments are involved? What is the severity of the aortic atheroma? Is there severe atheroma with a high embolic risk in the thoracic aortic segment involved in the planned procedure? In this case of planned CABG, the ascending aorta is the aortic segment of interest.

Data Collection

Severe thoracic aortic atheroma is characterized by atheroma protrusion larger than 5 mm into the aortic lumen or mobile atheroma, or both. Severe protruding and mobile atheroma, as depicted in Figs. 23.33 to 23.37, disseminated throughout the descending thoracic aorta and aortic arch, make it likely that the ascending aorta also is involved with severe atheroma because advanced atheroma is a disseminated arterial process. The detection of severe thoracic aortic atheroma by TEE, therefore, represents a major opportunity to modify surgical decision making to minimize stroke risk in the setting of heavy aortic atheroma burden.

Fig. 23.33 Short-axis view of the descending thoracic aorta. There is severe aortic atheroma greater than 5 mm in diameter. This large atheroma is sessile and does not appear to have any mobile components. There are no associated complications of aneurysm or dissection apparent on this view. This severe aortic atheroma predicts severe atheroma in the aortic arch and ascending aorta, as well as a high perioperative stroke risk associated with surgical aortic manipulation.

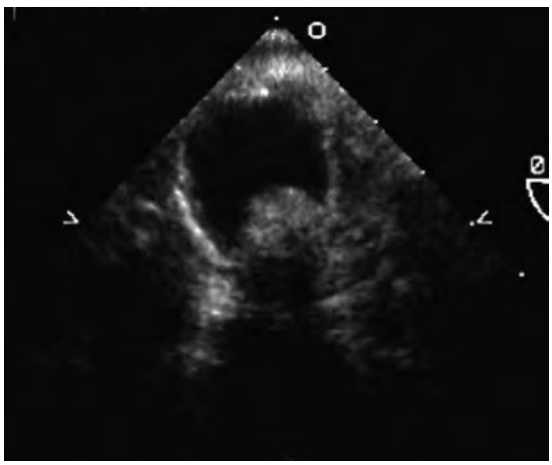

Fig. 23.34 Short-axis view of the descending thoracic aorta. In this aortic segment, there is also severe sessile aortic atheroma with a diameter greater than 5 mm. Notice the variation in morphology as compared with another descending thoracic aortic segment, as in Fig. 23.33. When severe atheroma is detected, it is important to comprehensively evaluate the entire thoracic aorta as in this patient. Multiple thoracic aortic views demonstrate severe aortic atheroma. It is clear that this patient has a severe atheroma burden based not only on the severity but also on the extent.

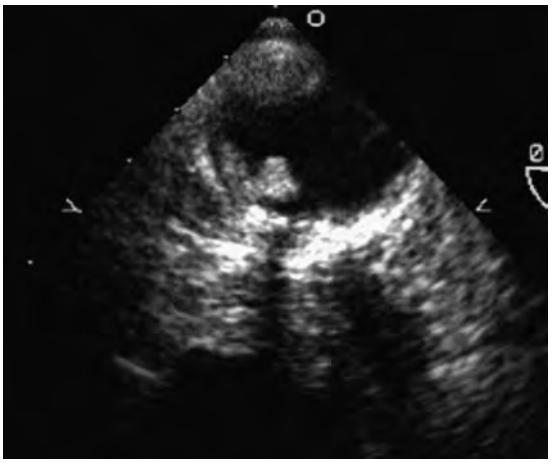

Fig. 23.35 Short-axis view of the descending thoracic aorta. Again, there is severe aortic atheroma with variations in morphology. There is a pedunculated mobile atheroma that is at high risk for embolism downstream in the aorta. Taken together, Figs. 23.33 through 23.35 show that this patient has a heavy atheroma burden throughout his descending thoracic aorta. Because atheroma is seldom a selective disease process, this atheroma burden is likely in the ascending aorta and aortic arch.

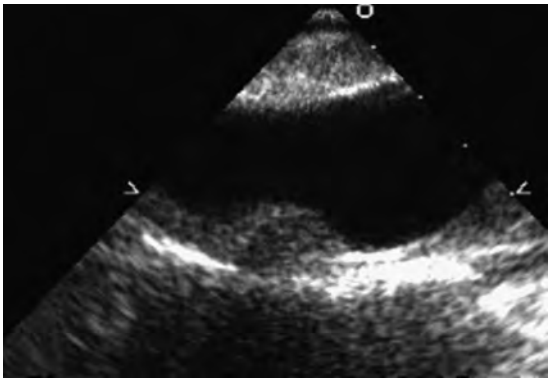

Fig. 23.36 Long-axis view of the aortic arch. There is severe focal sessile aortic atheroma evident in this view. Notice that there is relative sparing of the surrounding intima. There is no evidence of penetrating atheromatous ulceration with associated aneurysm or intramural hematoma. This severe atheromatous disease present in the aortic arch is in keeping with the atheroma burden in the descending thoracic aorta. This patient has a high perioperative stroke risk that focuses attention on the conduct of the coronary artery surgery to minimize this risk.

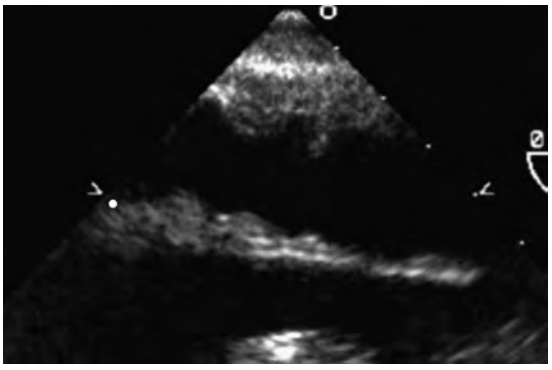

Fig. 23.37 Long-axis view of the aortic arch. There is severe aortic atheroma not only because of a thickness greater than 5 mm but also because of the presence of a mobile pedunculated atheroma. These features further highlight the heavy atheroma burden of the aortic arch and the high stroke risk in this patient associated with on-pump coronary artery bypass grafting.

Discussion

In this CABG scenario, there are at least three broad options for minimizing aortic atheroembolism and stroke:

1. Guided by epiaortic scanning, manipulate the least-diseased ascending aortic segments and proceed with on-pump CABG.
2. Avoid ascending aortic manipulation and proceed with off-pump CABG with a no-touch aortic technique.
3. Cannulate the axillary artery for CPB and replace the severely diseased ascending aorta and proximal arch under DHCA. This would not only minimize the long-term stroke risk because of massive proximal aortic atheroma burden, but would allow completion of the CABG on-pump with minimal risk for cerebral atheroembolism.

In this case, after extensive discussion with the cardiac surgeon, the joint decision was to proceed with off-pump CABG, given the high likelihood of severe ascending aortic disease and the considerable experience of the surgeon with this off-pump CABG technique.

Severe aortic arch and descending thoracic aortic atheroma also are major risk factors for stroke after TEVAR, especially with lesions of the proximal descending thoracic aorta that necessitate hardware manipulation in the aortic arch with the associated risk for arch atheromatous cerebral embolism. This principle also is applicable to the stroke risk associated with transfemoral transcatheter aortic valve implantation in which the hardware has to cross retrograde across the aortic arch to reach the aortic valve. In this scenario, the detection of severe mobile atheroma provides a strong rationale to proceed with transapical aortic valve implantation because the hardware would not cross the aortic arch.

Severe atheroma of the aortic arch and distal thoracic aorta is an important factor in procedures such as acute type A dissection in which femoral arterial cannulation commonly is performed for arterial access required for bypass. This cannulation strategy would carry a significant retrograde cerebral atheroembolic risk. The presence of severe atheroma, as demonstrated by TEE, provides a strong rationale to proceed with antegrade arterial flow via cannulation of the axillary artery. Furthermore, the atheroma burden of this patient also provides a strong rationale to avoid intraaortic balloon counterpulsation. In summary, the assessment of thoracic aortic atheroma (extent, severity, embolic risk) should be related to the operative plan to minimize the risks for vital organ atheroembolism.

Case Study 2: Acute Thoracic Aortic Dissection

A 45-year-old man with known Marfan syndrome presents to the emergency department with severe acute tearing back pain. Physical signs suggestive of acute aortic dissection include a pulse deficit, severe jugular venous distention, and a new precordial murmur. His chest radiograph shows a widened mediastinum, and his electrocardiogram is consistent with sinus tachycardia with no acute ischemia. Because of severe hemodynamic instability, he is transferred emergently to the OR before definitive aortic imaging can be undertaken. After his resuscitation and anesthetic induction, a TEE is performed.

Framing

Because this patient has multiple highly suggestive features, there is a high pre-TEE probability of acute thoracic aortic dissection. Time matters here because the mortality rate is about 1% to 2% per hour. The diagnosis needs to be confirmed. The dissection extent should be characterized to guide definitive management. The known complications of acute aortic dissection should be assessed. The TEE examination serves multiple purposes including establishing the diagnosis, characterizing the full extent of the disease process, providing the data to guide operative decision making, and assessing the results of the surgical repair. The cardiac surgeon requests a comprehensive echocardiographic assessment to guide surgical management of this hemodynamic emergency.

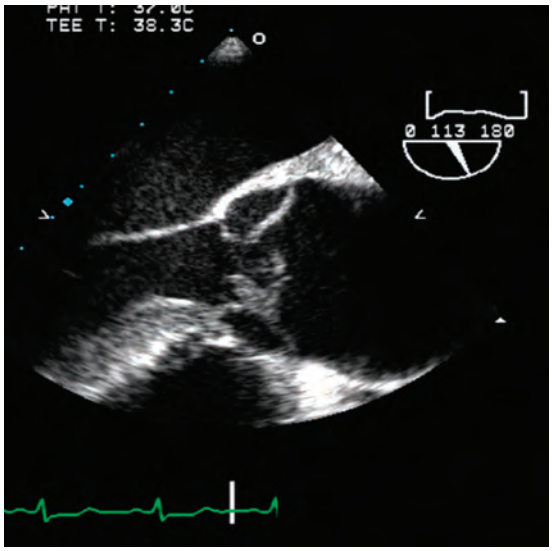

Fig. 23.38 Midesophageal long-axis view of the aortic valve and ascending aorta in systole before cardiopulmonary bypass (at 113 degrees of rotation). There is an intimal dissection flap in the ascending aorta that not only has a large fenestration but is also prolapsing into the left ventricular outflow tract. This view confirms dissection proximal to the left subclavian artery (Stanford type A); thus immediate surgical repair is indicated.

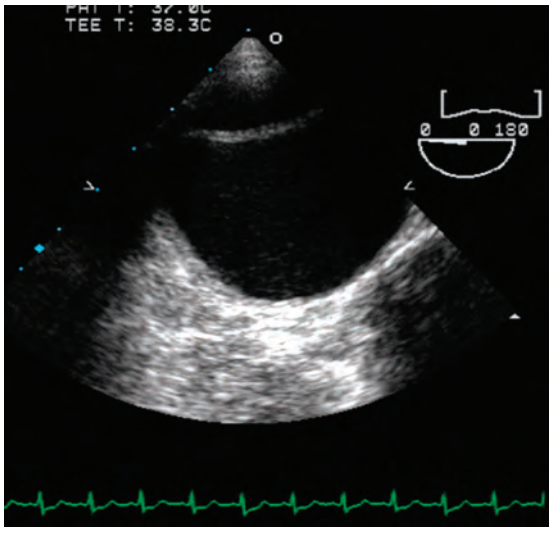

Fig. 23.39 Midesophageal short-axis view of the descending thoracic aorta (at zero degree of rotation). An intimal dissection flap is evident. This view demonstrates that the extent of this type A dissection is compatible with a DeBakey type I aortic dissection. The descending thoracic aortic dissection can be addressed during open aortic arch repair with a thoracic endovascular aortic stent deployed anterograde through the open aortic arch. This is an example of the frozen elephant trunk technique, which is designed to improve long-term aortic remodeling and thus minimize the adverse outcomes associated with aneurysmal degeneration of the dissected descending thoracic aorta.

Questions

Is there an intimal flap compatible with acute aortic dissection? Is it type A or type B aortic dissection? Are there associated complications of the dissection process? Is there a pericardial effusion with tamponade physiology? What is the status of biventricular function? Are there regional wall motion abnormalities compatible with dissection of a major coronary artery? If so, which coronary artery? Is CABG required? Is there AR? If so, what is the severity and mechanism? Can the native aortic valve be resuspended or is aortic valve replacement required? Can the aortic root be spared or is aortic root replacement required? Does the descending thoracic aorta require endovascular stenting?

Data Collection

There is a type A dissection that requires surgical intervention (Figs. 23.38 to 23.43). The aortic root is dilated and dissected. The ascending aorta is dilated and dissected with extension into the aortic arch and descending thoracic aorta (DeBakey I extent) (see Videos 23.3 and 23.4). Severe AR is caused by intimal prolapse and aortic root dilation without native aortic cusp destruction. There are no regional wall motion abnormalities to suggest myocardial ischemia from coronary dissection. There is cardiac tamponade.

Discussion

In the emergency management of acute aortic dissection, the OR can function as a diagnostic suite where TEE is promptly performed after anesthetic induction, endotracheal intubation, and hemodynamic resuscitation. TEE is ideally suited for the fast-track management of this acute aortic syndrome. TEE offers near-100% sensitivity and specificity for the diagnosis and localization of aortic dissection. There are three possibilities in this diagnostic process: (1) surgery for type A dissection or complicated type B dissection; (2) medical therapy for uncomplicated type B dissection; and (3) no acute aortic syndrome present, in which case, further diagnostic workup should proceed to identify and manage the cause.

In this case of type A dissection, the TEE examination not only provides the rationale for immediate surgical intervention but also guides the operative plan. The tense hemopericardium with clinical tamponade was managed with pericardiotomy; the immediate hemodynamic

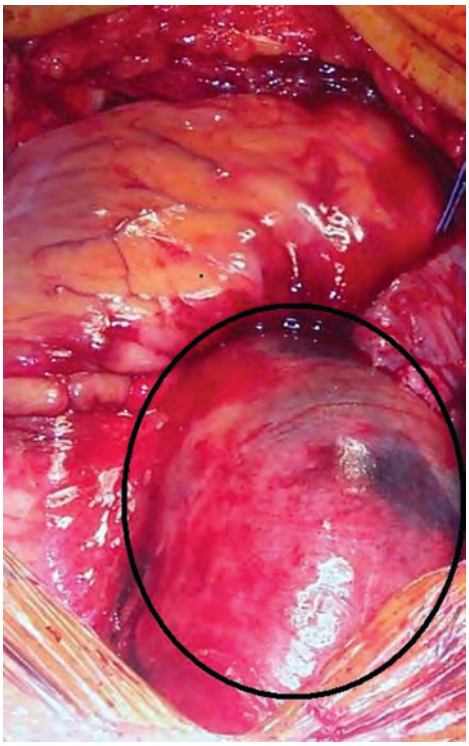

Fig. 23.40 Intraoperative photograph of the ascending aorta after sternotomy and pericardiotomy. The ascending aorta is dissected: The wall is hemorrhagic and in places transparent through the adventitia (area indicated within the *black circle*). Aortic rupture was imminent in this case. The decision to operate emergently and proceed with proximal thoracic aortic replacement on cardiopulmonary bypass with deep hypothermic circulatory arrest was based on the transesophageal echocardiographic findings, as shown in Figs. 23.38 and 23.39.

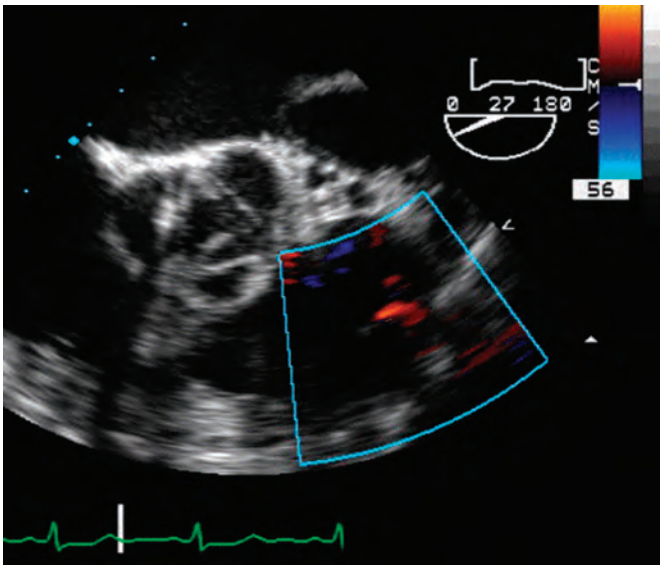

Fig. 23.41 Midesophageal short-axis view of the aortic valve in diastole (at 27 degrees of rotation). The aortic leaflets appear normal. There is prolapse of the intimal dissection flap through the aortic valve, preventing diastolic coaptation and giving the appearance of a "double aortic valve." Severe aortic regurgitation results from this mechanism, as shown in Fig. 23.43. This view also allows for assessment of right ventricular function, in particular, right ventricular hypokinesis caused by ischemia from right coronary dissection. Color-flow Doppler interrogation in this view shows trace pulmonic insufficiency, a common incidental finding. There is also a small pericardial collection evident: This is the residual from the hemopericardium that was drained at pericardiotomy. Before pericardiotomy, the hemopericardium was under tension and had resulted in severe cardiac tamponade.

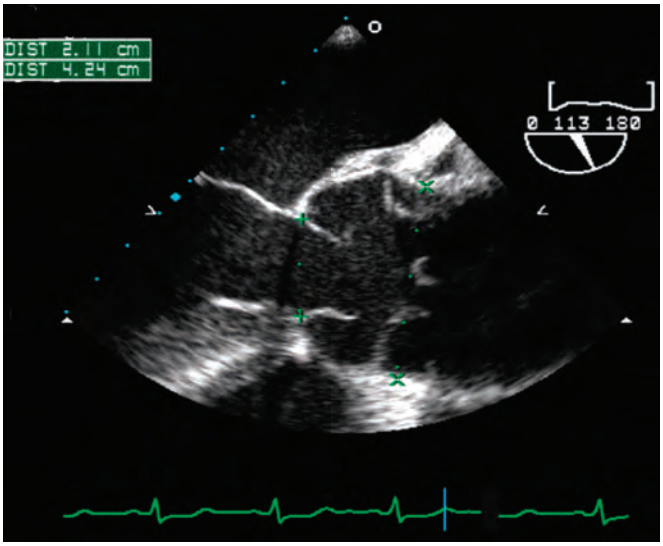

Fig. 23.42 Midesophageal long-axis view of the aortic valve and ascending aorta in systole before cardiopulmonary bypass (at 113 degrees of rotation). An intimal dissection flap in the ascending aorta has a large fenestration. The sinotubular junction is splayed and dilated because of the dissection. This is a second mechanism for aortic regurgitation, as the dilated aortic root will result in diastolic aortic cusp separation. In this case, the intimal flap is also responsible for the severe aortic insufficiency, as shown in Fig. 23.43.

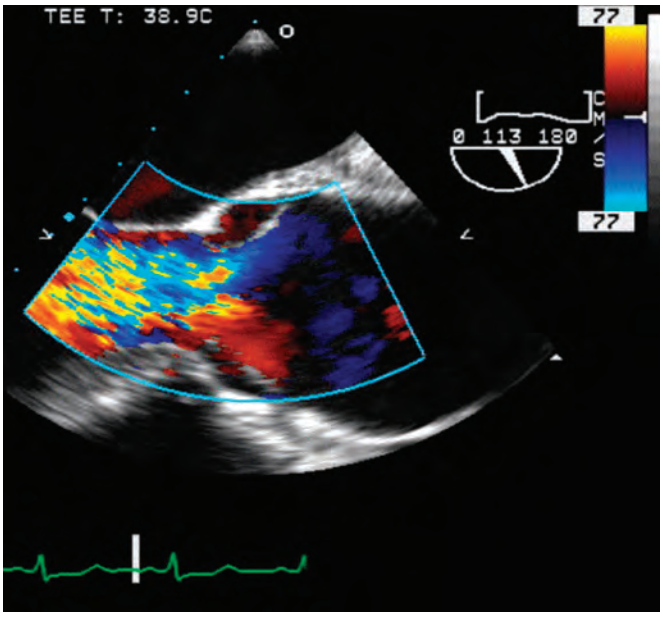

Fig. 23.43 Midesophageal long-axis view of the aortic valve and ascending aorta in systole before cardiopulmonary bypass (at 113 degrees of rotation). Color-flow Doppler interrogation reveals severe aortic regurgitation, as the diastolic jet visualized by color Doppler imaging fills the entire left ventricular outflow tract. The mechanisms of this severe aortic regurgitation, namely, intimal prolapse and aortic root dilation, are more fully explained in Figs. 23.41 and 23.42.

improvement and consequent hypertension were managed immediately to avoid aortic rupture. Because the AR was not related to native aortic cusp destruction, aortic valve resuspension was undertaken. The dissected aortic root was replaced and coronary reimplantation was by means of the button technique. The dissected ascending aorta and aortic arch were replaced. The aortic arch repair was with the hemiarch technique with DHCA. During the open aortic arch anastomosis, the dissected descending thoracic aorta was repaired by means of anterograde deployment of an endovascular stent (frozen elephant-trunk technique). After separation from CPB, TEE demonstrated normal native aortic valve function, normal biventricular function with no regional wall motion abnormalities, and an endovascular stent in the descending thoracic aorta with no flow in the false lumen.

Acute type A dissection is a life-threatening surgical emergency. TEE is a standard of care in this acute aortic syndrome at all stages of its definitive management: prompt diagnosis, detection of complications, conduct of the operative repair, and acute evaluation of surgical results.

Case Study 3: Thoracic Aortic Transection

A 42-year-old woman was involved in a motor vehicle accident. She was an unrestrained driver and sustained a side impact injury with no loss of consciousness. She had no significant medical history. She presented to the emergency department for evaluation. Her physical examination was within normal limits. Her chest radiograph showed a widened mediastinum. Although initially stable, the patient developed shock that was unresponsive to pressors and fluid resuscitation, and so she was emergently transferred to the OR for a diagnostic TEE and possible operative aortic repair. She underwent a TEE after induction of general anesthesia.

Framing

Because this patient likely has an acute aortic syndrome resulting from traumatic aortic transection, it is essential that TEE not only confirm the diagnosis but also fully characterize the aortic lesion. The location and extent of the aortic transection will determine the operative plan.

The cardiac surgeon requests a detailed echocardiographic interrogation of the thoracic aorta to plan the surgical intervention. The surgeon asks whether the incision should be a sternotomy or left thoracotomy.

Clinical Questions

Is there a thoracic aortic transection? If so, what is the extent? Which thoracic aortic segments are involved? Is endovascular aortic repair possible? If not, should the surgeon expose the thoracic aorta via sternotomy or left thoracotomy? What perfusion techniques are required? Is full CPB with DHCA required? Is PLHB required?

Data Collection

The TEE examination confirms thoracic aortic transection localized to the aortic arch with brachiocephalic involvement (Figs. 23.44 to 23.50). The ascending aorta and descending thoracic aorta, including the isthmus, are not involved. In other words, there is no extension either proximal or distal to the aortic arch. This transection and associated IMH involve most of the aortic arch. There is contained rupture of the aortic arch.

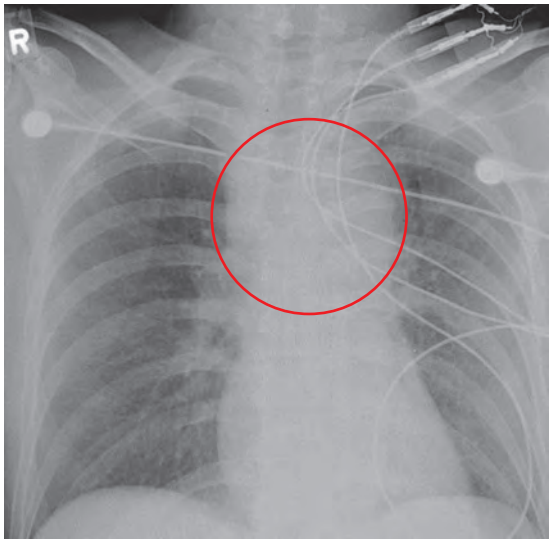

Fig. 23.44 Chest radiograph taken on hospital admission. Note the widened mediastinum (area enclosed by the *red circle*). This finding is suggestive of a thoracic aortic syndrome. Although a chest radiograph may be suggestive, it is important to remember that a normal chest radiograph does not reliably rule out major thoracic aortic pathology.

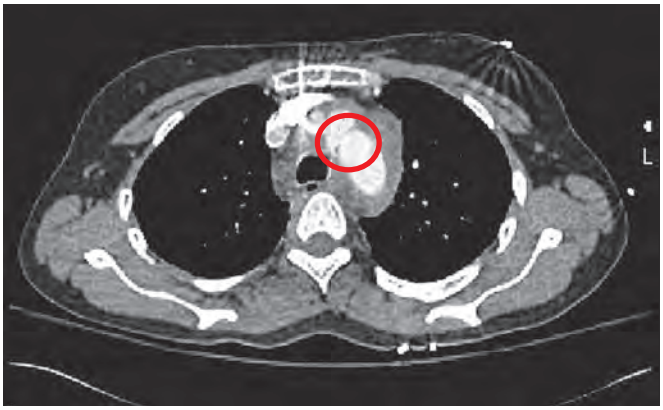

Fig. 23.45 Computed tomographic scan of the thoracic aorta done soon after hospital admission. The aortic arch is *circled in red*. This aortic arch view shows aortic arch disruption compatible with a transection, given the history of a recent automobile accident.

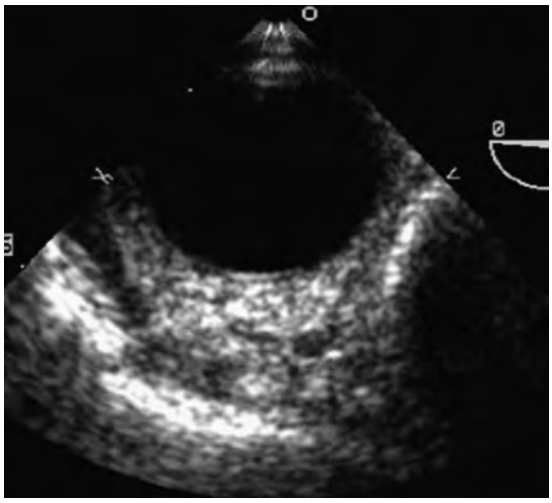

Fig. 23.46 Upper esophageal transesophageal echocardiographic short-axis view of the distal ascending aorta (at zero degree of rotation). No intimal flap is compatible with dissection. However, there is extensive anterior intramural hematoma.

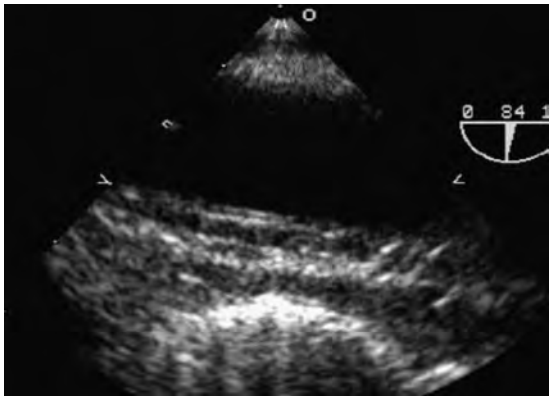

Fig. 23.47 Upper esophageal transesophageal echocardiographic (TEE) long-axis view of the midaortic arch (at 84 degrees of rotation). There is no intimal flap compatible with dissection. There is extensive anterior intramural hematoma, as evidenced by the extensive anterior aortic wall thickening.

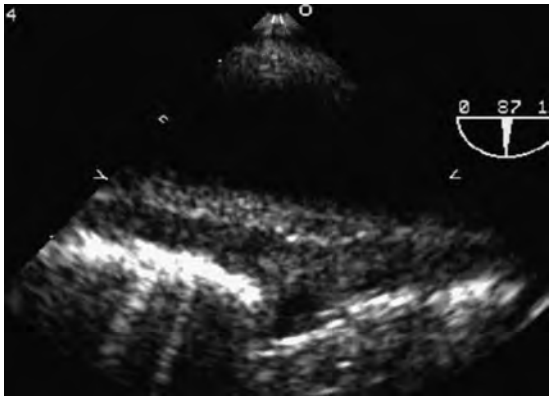

Fig. 23.48 Upper esophageal transesophageal echocardiographic (TEE) long-axis view of the midaortic arch (at 87 degrees of rotation). There is extensive anterior intramural hematoma with a break in the aortic wall, compatible with a significant near-full thickness tear in the aortic arch. This view is diagnostic of focal traumatic transection of the aortic arch.

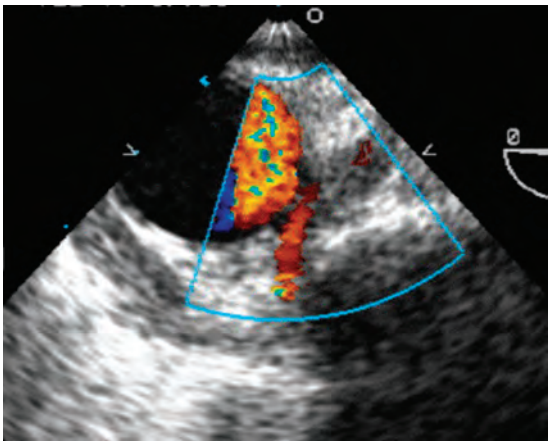

Fig. 23.49 Upper esophageal transesophageal echocardiographic (TEE) short-axis view of the distal aortic arch (at zero degree of rotation). Color-flow Doppler interrogation in this view shows flow into the site of the arch transection. This flow is still contained by periaortic hematoma evident at this aortic level. The next step in the evolution of this pathology is free aortic rupture, a lethal event.

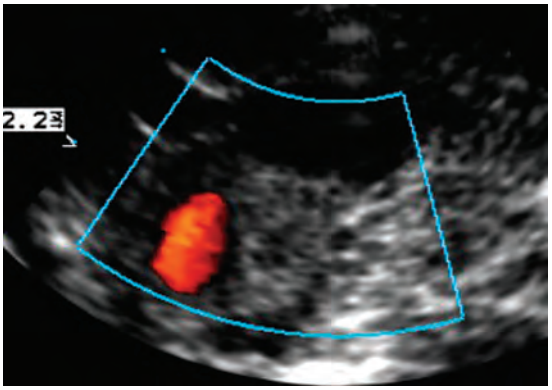

Fig. 23.50 Transcutaneous short-axis views of the right carotid artery and right internal jugular vein. There is extensive hematoma around the lumen of the carotid artery. Color-flow Doppler interrogation of the carotid artery demonstrates intact flow. There is no obvious carotid dissection. These views indicate extension of the mural hematoma into the brachiocephalic vessels. Hence the brachiocephalic vessels at the level of the aortic arch may require reconstruction. These findings suggest a total aortic arch replacement with brachiocephalic reconstruction, a major surgical procedure.

Discussion

The TEE examination suggests that the aortic arch requires extensive acute repair. Although acute endovascular aortic arch repair may be possible in the future, acute total arch endovascular repair is not currently part of standard thoracic aortic endovascular intervention. The current endovascular technology still consists mainly of tubular components with no fenestrations or branches. Given that this is a young patient with minimal comorbidities, the thoracic aorta was accessed anteriorly via sternotomy, and a total aortic arch repair with CPB and DHCA was performed (Figs. 23.51 and 23.52). If the patient was elderly with multiple comorbidities, a hybrid aortic arch repair might have been considered. In this procedure, the brachiocephalic arteries are transposed to the ascending aorta to create the landing zone for aortic arch stenting. This procedure is typically performed off-pump via sternotomy: Stent deployment can be antegrade through the ascending aorta or retrograde via the femoral artery.

This case of aortic arch transection is unusual. About 85% to 90% of aortic transactions occur at the aortic isthmus, just distal to the left subclavian artery. The remaining 10% occur in the remainder of the

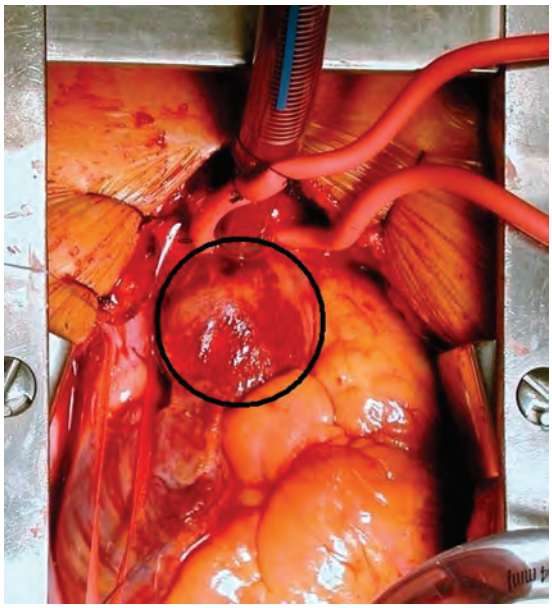

Fig. 23.51 Intraoperative photograph of the thoracic aorta after sternotomy. There is extensive intramural hematoma evident in the proximal aortic arch (area enclosed by the *black circle*).

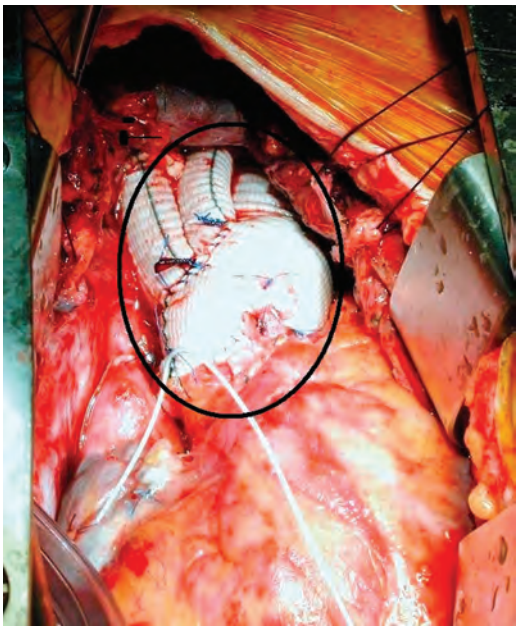

Fig. 23.52 Intraoperative photograph of the aortic arch after cardiopulmonary bypass and deep hypothermic circulatory arrest (area enclosed by the *black circle*). The entire aortic arch has been replaced with a trifurcated prosthetic graft.

thoracic aorta, including the ascending aorta, the aortic arch, and the distal descending aorta. TEE clearly images the thoracic aortic segments where the overwhelming majority of aortic transections occur. The blind spot of TEE is the distal ascending aorta and proximal aortic arch, where transections are rare. Furthermore, in the setting of chest trauma, TEE also can evaluate the heart for evidence of further traumatic injury that may significantly affect perioperative management. Traumatic myocardial contusion may be evidenced by regional wall motion abnormalities that may be severe enough to mandate inotropic support. Traumatic hemopericardium with cardiac tamponade may require surgical drainage. The tricuspid valve also is at risk for

traumatic rupture. Significant tricuspid regurgitation may mandate surgical repair or replacement.

In this case, TEE showed an acute aortic arch transection with extensive brachiocephalic vessel involvement. After total aortic arch replacement, the patient had an uncomplicated hospital course and a complete recovery.

Case Study 4: Bicuspid Aortic Valve

A 43-year-old man presented with progressive heart failure. His father had undergone aortic valve replacement at 50 years of age. His physical examination was compatible with advanced AR. Transthoracic echocardiography showed severe AR and a possible bicuspid valve. Coronary catheterization excluded significant CAD. He was referred for aortic valve surgery. The patient expressed a strong preference to avoid chronic anticoagulation after surgery. He requested aortic valve repair.

Framing

Because this patient has symptomatic AR, he has qualified for surgical intervention. In the setting of a bicuspid aortic valve and patient preference for valve repair, valve anatomy and the mechanism of AR strongly determine the feasibility of successful valve repair. Furthermore, because the bicuspid valve is associated with aortic dilation, the diameters of the aortic root and ascending aorta must be assessed for possible replacement at the time of surgery. The current thoracic aortic guidelines recommend consideration of proximal thoracic aortic replacement when the diameter exceeds 4.5 cm to avoid the future risks for rupture and dissection (class I recommendation; level of evidence B).[2]

Questions

Is there a bicuspid valve? Is the valve calcified? Is there aortic stenosis? Is there AR? If so, what are the severity and mechanism of the AR? Is the valve anatomy compatible with successful valve repair? What are the aortic root diameters? What is the diameter of the ascending aorta? Is the proximal thoracic aorta dissected? Does the patient qualify for aortic root replacement? Does the patient qualify for ascending aortic replacement?

Data Collection

The aortic valve is bicuspid (Figs. 23.53 to 23.59). There is no detectable aortic valve calcification and no aortic stenosis. There is severe eccentric AR because of anterior leaflet prolapse in the region of the raphe. Although mildly dilated, the aortic root does not qualify for replacement at this point. The ascending aorta is not dissected but has a diameter at the level of the pulmonary artery of 4.6 cm.

Discussion

Bicuspid aortic valve is common and is an established risk factor for ascending aortic aneurysm and type A aortic dissection. Although the anatomic orientation of bicuspid aortic cusps varies, the most common arrangement is anterior-posterior, as in this case. The anterior cusp has a raphe where the commissure between the right and left cusps would be in a tricuspid aortic valve. The anterior cusp usually is elongated and thus is prone to diastolic prolapse, as in this case. The posterior cusp usually is normal. The TEE examination should focus on the anatomy, orientation, and mechanism of aortic insufficiency in bicuspid aortic valve cases. As in this case, the delineation of an otherwise competent aortic valve with focal prolapse merits strong consideration for repair. The ascending aorta and not the aortic root met criteria for aortic replacement in this young patient. The aortic arch also was mildly dilated.

In this case, surgical inspection of the aortic valve confirmed the TEE findings. The aortic root, although mildly dilated, did not merit intervention. The raphe of the anterior cusp was excised. The free prolapsing edge was excised in a triangular fashion as part of the anterior aortic leaflet valvuloplasty. The ascending aorta was replaced under

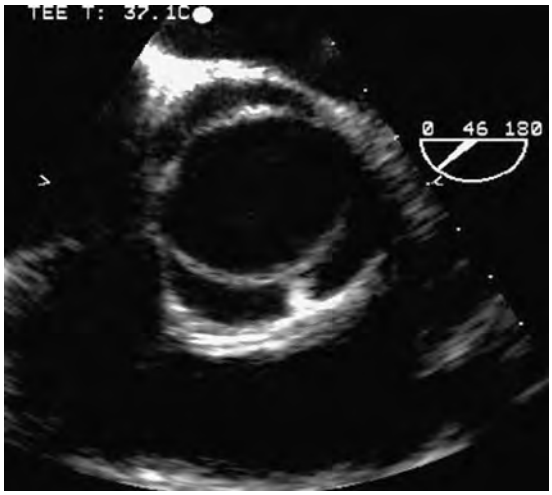

Fig. 23.53 Midesophageal short-axis view of the aortic valve in systole (imaging angle of 46 degrees). The aortic valve is bicuspid with an anterior raphe evident. The aortic cusps appear normal. There is no restricted mobility evident in systole. The cross-sectional area of this bicuspid valve measured 3.2 cm^2. This was within the normal range even when indexed for body surface area.

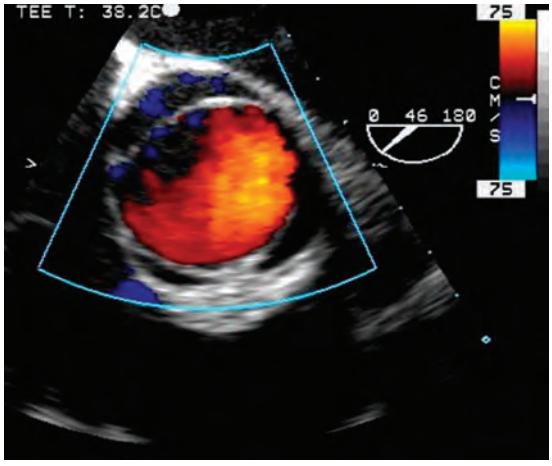

Fig. 23.54 Midesophageal short-axis view of the aortic valve in systole (imaging angle of 46 degrees). Color-flow Doppler mapping shows laminar flow through the aortic valve consistent with an adequate valve area. There is no suggestion of aortic stenosis.

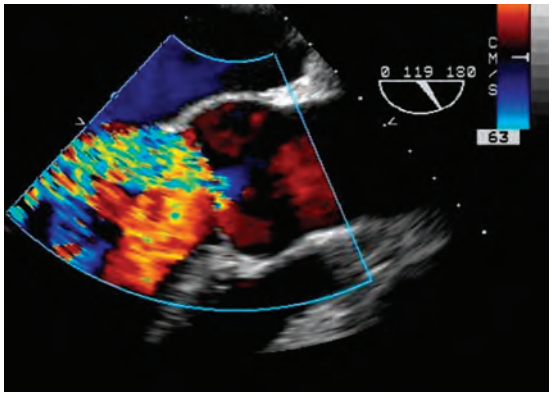

Fig. 23.55 Midesophageal long-axis view of the aortic valve (imaging angle of 119 degrees). Color-flow Doppler imaging reveals severe aortic regurgitation. The jet of aortic regurgitation almost fills the entire left ventricular outflow tract. It is partly directed posteriorly toward the anterior mitral leaflet. This posterior eccentric flow may be caused by prolapse of the anterior aortic cusp or a perforation in the posterior cusp.

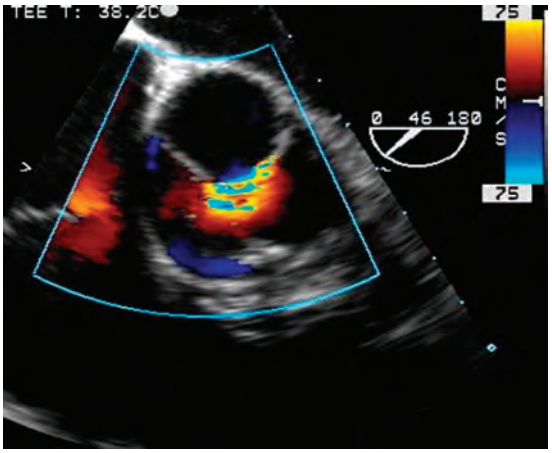

Fig. 23.56 Midesophageal short-axis view of the aortic valve in diastole (imaging angle of 46 degrees). Color-flow Doppler imaging shows central commissural aortic regurgitation at the midpoint of the anterior cusp. This location of the regurgitation suggests focal prolapse of an aortic cusp. When considered together with the posterior eccentric flow evident in Fig. 23.55, the mechanism for the aortic regurgitation in this case is focal prolapse of the anterior cusp in the region of the raphe. This identification of this focal mechanism suggests the possibility of a focal aortic valve repair.

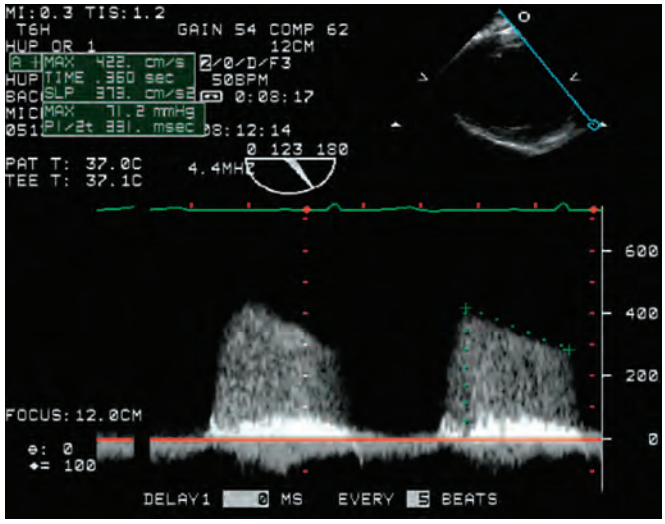

Fig. 23.57 Transgastric long-axis view of the aortic valve (imaging angle of 123 degrees). Continuous-wave Doppler interrogation of the aortic valve shows significant aortic regurgitation (flow above the baseline). The pressure half-time has been quantified at 331 milliseconds, consistent with moderate aortic insufficiency. However, the final grading of the aortic insufficiency was severe when considered together with color-flow Doppler in Fig. 23.55 and effects on the left ventricle in Fig. 23.58. Because the jet of insufficiency is eccentric, it is possible to underestimate the peak diastolic velocity with continuous-wave Doppler. This is the probable explanation for the underestimation of the aortic regurgitation by the pressure half-time method. This underlines the importance of quantifying the valve lesion by multiple methods.

DHCA with the addition of an aortic arch repair (hemiarch technique; DHCA time = 15 minutes). This complete resection of the ascending aorta was undertaken to avoid leaving the cross-clamped ascending aorta in situ because it was judged to be at a greater risk for future dissection. Furthermore, the aortic arch also was mildly dilated. This lower threshold for aggressive proximal thoracic aortic resection was undertaken because of the bicuspid aortic valve, the low operative risk of the patient, and the extensive experience of the thoracic aortic team.

Fig. 23.58 Transgastric midpapillary short-axis view of the left ventricle at end-diastole (imaging angle of zero degree). The left ventricle is severely dilated with an end-diastolic diameter of 6.5 cm. This is consistent with chronic severe aortic regurgitation.

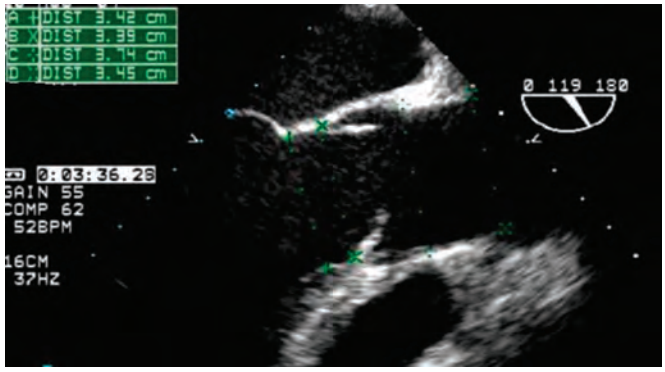

Fig. 23.59 Midesophageal long-axis view of the aortic root (imaging angle of 119 degrees). The diameters of the left ventricular outflow tract *(A)*, the aortic annulus *(B)*, the sinuses of Valsalva *(C)*, and the sinotubular junction *(D)* have been measured. These diameters are consistent with a mild degree of annular and root dilation, a common association with a bicuspid aortic valve. It is important that these diameters are accurately measured because excessive annuloaortic ectasia may dictate aortic root replacement with or without native aortic valve sparing. Furthermore, ascending aorta diameters closer to the level of the pulmonary artery (not shown) should also help determine if ascending aorta replacement is warranted.

After separation from CPB, TEE demonstrated normal aortic valve function with no AR. There was no dissection in the residual native thoracic aorta. There was improved LV function. The patient had an uneventful recovery.

TEE provides important information in the planning of proximal thoracic aortic intervention in the setting of a bicuspid aortic valve. Thorough echocardiographic interrogation of the aortic valve, the aortic root, the ascending aorta, and aortic arch typically provides all the data required for operative decision making. The bicuspid aortic valve signals the presence of an abnormal proximal thoracic aorta that should be managed as carefully as the associated aortic valve dysfunction.

24 Uncommon Cardiac Diseases

JONATHAN F. FOX, MD | MARK M. SMITH, MD | GREGORY A. NUTTALL, MD | WILLIAM C. OLIVER, Jr., MD

KEY POINTS

1. Patients with uncommon cardiac diseases frequently have complicated medical conditions, the treatment for which should take place in the context of an institution capable of providing coordinated multidisciplinary care.
2. Cardiac tumors are rare. In general, a cardiac mass is more likely a vegetation or a thrombus than a tumor. Secondary (metastatic) tumors are far more common than primary cardiac tumors. Among primary cardiac tumors, benign lesions are more common than malignant tumors. Anesthetic management for tumor resection is likely to depend more on a patient's comorbidities and tumor location than on the tumor's pathologic condition.
3. Cardiac myxomas historically have been considered the most common benign cardiac tumor. Although most commonly solitary, sporadic, and located on the left atrial side of the fossa ovalis, they may also occur as multiple, simultaneous tumors inherited in cases of Carney complex. Patients with myxomas typically exhibit signs and symptoms attributable to one of the triad of intracardiac obstruction, embolism, or constitutional symptoms.
4. Papillary fibroelastomas are the most common valvular cardiac tumor and may be the most common benign lesion as well. Typically solitary, fibroelastomas occur most frequently on the mitral and aortic valve leaflets. Once considered an incidental, benign finding, they have a high incidence of coronary and cerebral embolization.
5. Primary malignant cardiac tumors are less common than benign tumors. The overwhelming majority of primary malignant tumors are sarcomas.
6. Metastatic cardiac tumors are far more common than primary tumors. Metastatic tumors may involve the heart by direct extension (breast, lung, esophageal), by venous extension (renal cell carcinoma, hepatocellular carcinoma), or by hematogenous (melanoma) or lymphatic (lymphoma, leukemia) spread. Although metastatic cardiac tumors may affect the pericardium, epicardium, myocardium, or endocardium, pericardial involvement is the most common.
7. Carcinoid tumors are metastasizing neuroendocrine tumors. In patients with carcinoid syndrome, carcinoid heart disease is common and characterized by tricuspid regurgitation, mixed pulmonic regurgitation and stenosis, and right-sided heart failure. The management of patients with carcinoid heart disease, similar to the management of many patients with uncommon cardiac conditions, is complex and requires coordinated care at specialty referral centers. The mainstays of treatment are symptom management with somatostatin analogs, antitumor therapy, and cardiac surgical intervention. Successful perioperative management depends on optimal preoperative symptom control with long-acting somatostatin analogs.
8. Renal cell carcinomas are the most common renal tumors. Clear cell carcinomas are the most common subtype of renal cell carcinoma and tend to produce venous extension into the renal veins and the inferior vena cava. Surgical resection of tumor thrombus extending into the intrahepatic inferior vena cava (New York Heart Association [NYHA] level III tumor) or above the diaphragm (NYHA level IV tumor) may require cardiac surgical and anesthesia involvement, although some institutions are now performing resections of proximal lesions involving the right-sided heart without the assistance of cardiopulmonary bypass.
9. Cardiomyopathies are a heterogeneous group of diseases that may be acquired or genetic and may be confined to the heart (primary) or may be part of a systemic disorder (secondary). The American Heart Association classifies cardiomyopathies as primary or secondary and subclassifies primary processes as genetic, acquired, or mixed. The European Society of Cardiology, however, classifies the cardiomyopathies morphologically and functionally into hypertrophic, dilated, arrhythmogenic, restrictive, and unclassified, each of which, in turn, may be considered genetic or nongenetic.
10. Dilated cardiomyopathy is the most common of the cardiomyopathies and may be acquired, hereditary, or idiopathic. Hearts affected with dilated cardiomyopathy show four-chamber dilatation, myocyte hypertrophy, and disproportionate impairment of systolic heart function. The goals of perioperative management of patients with dilated cardiomyopathy, who most frequently require correction of tricuspid or mitral regurgitation, device implantation, or transplantation, include minimizing further myocardial depression, reducing afterload, and maintaining preload.
11. The first case series of patients with hypertrophic cardiomyopathy was published in 1957 and highlights

both the understandings and misunderstandings that continue to affect the current thinking of the disease. Contrary to common belief, hypertrophic cardiomyopathy need not be obstructive, need not be fatal, and need not entail massive left ventricular hypertrophy.

12. Hypertrophic cardiomyopathy is likely the most common inherited cardiac disease and may progress along one or more of three pathways: (1) sudden cardiac death, (2) heart failure, or (3) atrial fibrillation, with or without cardioembolic stroke. Hypertrophic cardiomyopathy is morphologically heterogeneous and includes variants with asymmetric basal septal hypertrophy, midventricular hypertrophy, and apical hypertrophy. Surgical intervention may require transaortic and/or transapical approaches. Anesthetic management requires an intimate knowledge of the patient's anatomy and physiologic characteristics and may differ considerably, depending on whether the patient has a basal lesion with dynamic obstruction or an apical lesion with significant impairment of ventricular filling.
13. The restrictive cardiomyopathies, less common than either the dilated or the hypertrophic cardiomyopathies, are heterogeneous and characterized by impaired myocardial relaxation and decreased ventricular compliance. Although diastolic dysfunction is the hallmark of restrictive cardiomyopathies, systolic function may not be normal, although gross indicators of systolic function such as ejection fraction may be unimpaired. Considering that their treatments are significantly different, restrictive cardiomyopathy and constrictive pericarditis must be distinguished. The patients with restrictive cardiomyopathy who are most likely seen in a cardiac surgical unit are patients with cardiac amyloidosis.
14. Mitral valve prolapse is a relatively common cardiac condition. Most patients remain clinically asymptomatic with normal life expectancies. Progression of mitral valve disease and the development of severe mitral regurgitation are rare; however, severe regurgitation represents a common indication for cardiac surgery. Current approaches to mitral valve prolapse are reviewed, including the range of clinical presentations from mitral valve prolapse syndrome to degenerative valve disease and severe mitral regurgitation.
15. Management of patent foramen ovale has received considerable attention with the widespread use of percutaneous closure devices. Determining the superiority of percutaneous device closure to medical management is heavily debated. The management of an incidental patent foramen ovale found during cardiac surgery via transesophageal echocardiography continues to evolve; however, few data suggest that closure offers morbidity or mortality benefit and may actually increase the risk of postoperative stroke.
16. The definitive approach to a patient with both carotid and coronary artery disease requires a large multicenter, randomized trial; however, the many approaches to the surgical management of combined procedures are described.
17. Heart disease continues to be the leading cause of maternal and fetal death during pregnancy; consequently, the important features of managing the pregnant patient who requires cardiopulmonary bypass and cardiac surgery is updated.
18. With newly developed therapies, the incubation time to develop acquired immune deficiency syndrome after infection and the life expectancy of those with human immunodeficiency virus have been extended; therefore the likelihood of cardiac surgery is greater. Consequently, the rates of exposure, types of procedures, and the precautions of the individuals are addressed.
19. The number of individuals with chronic renal failure, not necessarily dialysis dependent before surgery, are more frequently undergoing cardiac surgery and are likely to develop worsening renal function after cardiopulmonary bypass; therefore the identification of steps that may improve outcome are discussed.
20. Anesthetic concerns for patients with hematologic problems who undergo cardiac surgery are further complicated by the stress cardiopulmonary bypass places on coagulation and oxygen-carrying systems and require special considerations and techniques.

In this chapter, uncommon cardiac diseases and coexisting problems of patients undergoing cardiac surgery are reviewed. Each subsection includes a general overview of the disease or condition, followed by anesthetic considerations for cardiac surgery. Although some of the diseases discussed are quite rare and unlikely to be encountered regularly outside of large referral centers, other conditions, such as chronic kidney disease, are exceedingly common and likely to be routinely found in the patient population. Regardless of the prevalence of the disease or condition, however, optimal anesthetic management will depend both on a thorough understanding of the underlying pathologic and pathophysiologic findings, and on the recognition that the disease process may affect the anesthetic just as much as the anesthetic may exacerbate the disease process. For many conditions, preoperative evaluation and medical optimization in the context of an institution capable of providing coordinated multidisciplinary care may be as important in the intraoperative management of these patients as are the details of any particular anesthesia plan. Furthermore, provider vigilance and sound clinical judgment exercised in the context of intimate knowledge of a given patient's pathologic and pathophysiologic nature under specific clinical circumstances are likely to be more important for ensuring the optimal and safe care of the patient than is any specific combination of medications and monitors.

Cardiac Tumors

Cardiac tumors belong to the class of cardiac masses that includes vegetations and thrombi, for which tumors may be mistaken. Cardiac tumors may be classified as primary or secondary (metastatic). Primary tumors may be benign or malignant, whereas secondary tumors may involve the heart by direct extension (breast and lung), by venous extension (renal cell and hepatocellular carcinoma), or by hematogenous (melanoma, breast, and carcinoid) or lymphatic (lymphoma) spread (Table 24.1).[1]

In general, cardiac tumors are rare, and a cardiac mass encountered echocardiographically or radiographically is more likely to be a thrombus or a vegetation than a tumor. Metastatic tumors are more common than primary cardiac tumors, with an incidence at autopsy between 2.3% and 18.3%, whereas primary tumors have an incidence rate between 0.0014% and 0.33%.[2–7] Among primary tumors, benign lesions are more common than malignant masses. In adults,

the most common primary benign tumors are myxomas, although several series now suggest that papillary fibroelastomas may, in fact, be more common (Table 24.2).[1,8] In children, rhabdomyomas are the most common benign tumor. Approximately 15% to 25% of primary cardiac tumors are malignant, with sarcomas being the most common in both adults and children.[1,3,9] Tumors with high rates of cardiac metastases include pleural mesothelioma, melanoma, lung adenocarcinoma and squamous cell carcinoma, and breast carcinoma.[7,10] Although metastases may involve the pericardium, epicardium, myocardium, or endocardium, pericardial involvement is most common.[2]

Although cardiac tumors may be clinically silent and diagnosed only at autopsy, advancements in imaging have facilitated both their often-incidental antemortem diagnosis and their characterization once detected. The increasing sophistication of two-dimensional echocardiography, the advent of three-dimensional echocardiographic imaging, and the continued refinement of computed tomography (CT) and magnetic resonance imaging (MRI) have all allowed earlier, more frequent, and more complete assessment of cardiac tumors.[11–15] When tumors do produce symptoms, the symptoms are frequently nonspecific and more likely to reflect a tumor's location or size than its histopathologic characteristics (Box 24.1).[1,8] Although malignant primary lesions and metastatic tumors may produce constitutional symptoms, even histologically benign masses may cause concerning signs and symptoms associated with intracardiac obstruction and extracardiac embolization.[8] A tumor's location, however, as well as the age of the patient in whom it occurs, and its imaging characteristics may facilitate tumor diagnosis, especially when the cause of the cardiac tumor is taken into account; that is, metastatic lesions are more common than primary lesions, and benign tumors are more common than malignant tumors among primary lesions.[1,14]

Based on a recent retrospective study, the most effective treatment of primary tumors is generally surgical resection with an approximate 2% operative mortality. This study involved 323 consecutive patients who underwent surgical resection of primary cardiac tumors over a period of 48 years in one institution.[16] Recurrence rate in these tumors varied between 3% and 13% but appeared to be related to a biologic propensity rather than the surgical technique as was previously believed. The overall rate of tumor embolization was 25%, compared with previous reports of 12% to 45%. Embolic complications were seen more often in patients with minimal or no symptoms than in those with large tumors associated with hemodynamic changes. Papillary fibroelastoma and aortic valve tumors are most commonly preceded by an embolic event. Even patients who are diagnosed by an embolic event benefit greatly from surgical resection with excellent short- and long-term survival that is comparable with a cohort of patients with tumors undergoing surgery for other reasons.[12] Orthotopic cardiac transplantation has been recommended for unresectable tumors, but the benefit is indeterminate.[17] Although malignant lesions are less common, the surgical risk and outcome for their resection, compared with benign tumor resection, is usually significantly worse, especially in younger patients.[18,19]

In this section, the most common primary benign cardiac tumors in adults (myxomas and papillary fibroelastomas) are discussed, and an overview of adult primary malignant cardiac tumors and metastatic tumors is provided, followed by a review of the anesthetic management for tumor resection. Next, two frequently encountered systemic malignancies with cardiac involvement—carcinoid heart disease and renal cell carcinoma—are discussed, along with their respective anesthetic management.

Primary Benign Tumors

Myxoma

Often a diagnostic challenge, myxomas are benign, solitary, and slow-proliferating neoplasms. Microscopically, they often resemble

BOX 24.1 CLINICAL PRESENTATION OF CARDIAC TUMORS

Benign Tumors

Cardiac myxomas
- Obstructive cardiac symptoms: pulmonary edema or progressive cardiac failure
- Embolic symptoms
- Constitutional symptoms

Papillary fibroelastoma
- Embolic symptoms of obstruction of coronary or cerebral circulation
- Sudden death by prolapse into coronary ostia or occlusion of a large coronary branch

Rhabdomyoma
- Possible cardiomegaly, congestive heart failure, and cardiac arrhythmias, dependent on size
- Sudden death or stillbirth

Fibroma
- One third asymptomatic; two thirds with heart failure, cyanosis, arrhythmias, syncope, chest pain, or sudden death

Atrioventricular nodal tumours
- Asymptomatic sudden death

Cardiac lipomas
- Asymptomatic
- Rare extrinsic compression of heart, dependent on size and location

Malignant Tumors

Angiosarcoma
- Nonspecific, possible chest pain, shortness of breath, malaise, and/or fever

Osteosarcoma
- Atrial involvement with respiratory symptoms
- Ventricular involvement with recurrent ventricular tachyarrhythmia

Leiomyosarcoma
- Pulmonary lesions with dyspnea, chest pain, and nonproductive cough
- Cardiac dysfunctions, including right-sided heart failure, valve stenosis, rhythm alterations, conduction abnormalities, hemopericardial anomalies, and/or sudden death

Rhabdomyosarcoma
- Nonspecific symptoms; possible pleuropericardial symptoms and distal embolization
- Arrhythmias and obstructive symptoms

Cardiac lymphoma
- Cardiac tamponade, heart failure, exertional dyspnea, atrial fibrillation, and features of right-sided heart obstruction

Pericardial mesothelioma
- Chest pain, cough, dyspnea, and palpitations

Metastatic cardiac tumor
- Tachycardia arrhythmias, cardiomegaly, or heart failure in a patient with carcinoma, raising the suspicion of cardiac metastasis (Rarely, cardiac involvement such as pericardial effusion or incipient cardiac tamponade can be first clinical feature of malignant disease, although 90% are clinically silent.)

Reproduced with permission from Butany J, Nair V, Naseemuddin A, et al. Cardiac tumours: diagnosis and management. *Lancet Oncol.* 2005;6:220.

organized thrombi, which may obscure their identity as a primary cardiac tumor (Fig. 24.1).[20] The pedunculated mass is believed to arise from undifferentiated cells in the fossa ovalis and adjoining endocardium, projecting into the left atrium (LA) and the right atrium (RA) 75% and 20% of the time, respectively. However, myxomas appear in other locations of the heart, even occupying more than one chamber.[21] The undifferentiated cells of a myxoma may develop along a variety of cell lines, accounting for the multiple presentations and pathologic observations.[22] Besides a variable amount of stroma, myxomas include hemorrhage, hemosiderin, thrombus, and calcium. Myxomas predominate in the 30- to 60-year-old age range, but any age group may be affected.[20] More than 75% of the affected patients are women.[23] Although most cases occur sporadically, 7% to 10% of atrial myxomas will occur in a familial pattern with an autosomal dominant transmission pattern known as Carney complex.[20,24,25]

Occasionally, an incidental finding on echocardiography, myxomas may produce a variety of symptoms. The classic triad includes embolism, intracardiac obstruction, and constitutional symptoms.[26] Approximately 80%[21] of individuals will exhibit one component of the triad. Up to 10% of people may be asymptomatic, even with mitral myxomas arising from both atrial and ventricular sides of the anterior leaflet of the mitral valve.[27] The most common initial symptom, dyspnea on exertion,[23] reflects mitral valve obstruction associated with left atrial myxomas (Figs. 24.2 and 24.3). Because of the pedunculated nature of some myxomas, temporary obstruction of blood flow may cause hemolysis, hypotension, syncope, or sudden death. Other symptoms of mitral obstruction, similar to mitral stenosis, may occur, including hemoptysis, systemic embolization, fever, and weight loss. If the tumor is obstructing the mitral valve, then a *tumor plop* may be heard after the second heart sound on chest auscultation. The persistent sinus rhythm in the presence of such symptoms may help distinguish an atrial myxoma from mitral stenosis. Severe pulmonary hypertension without significant mitral valve involvement suggests recurrent pulmonary emboli, which is known to occur with a myxoma in the RA or right ventricle (RV). Occasionally, right-sided heart tumors may appear as cyanotic congenital heart lesions attributable to intracardiac shunting.[28]

Recurrent fragmentation and embolization of the gelatinous-like tumor usually appears with systemic manifestations and is characteristic of myxoma. The smaller myxoma in the LA that does not create hemodynamic complications, but can exists undiagnosed for years, is more likely to cause embolization.[12] Cerebral aneurysms often exist in persons with recurrent systemic embolization from intracardiac myxoma, probably secondary to damage by the systemic tumor emboli. The kidneys are also more susceptible to damage from myxoma emboli. Constitutional symptoms such as malaise, fever, and weight loss occur in approximately one third of patients, reflecting a possible autoimmune component to the disease process. The lack of symptoms specific to the tumor frequently delays its diagnosis. The differential diagnosis includes endocarditis, connective tissue disorders, and malignancies. In general, the anatomic type of myxoma portends the clinical presentation. The solid, ovoid tumors are more often associated with congestive heart failure (CHF), whereas papillary myxomas are linked with cerebral embolization.[29] Tumor size does not correlate with symptoms.[23]

Findings on a chest roentgenogram of a myxoma may be absent in approximately one third of persons. Calcification on the chest roentgenogram is more diagnostic of right atrial myxoma but may occasionally be present with left atrial myxomas. Before the availability of echocardiography, angiography was used to identify myxomas; currently, however, angiography is probably only useful to determine coronary anatomy, if considered necessary.[18,30] CT and MRI can help delineate the extent of a tumor and its relation to surrounding cardiac and thoracic structures.[31] MRI is especially valuable in the diagnosis of myxoma when masses are equivocal or suboptimal with echocardiography or if the tumor is atypical in presentation.[21] Difficulty may arise in differentiating a thrombus from a myxoma, because both are so heterogeneous.

Transthoracic echocardiography (TTE) is excellent for identifying intracavitary tumors, because it is noninvasive, identifies tumor type, and permits complete visualization of each cardiac chamber. TTE is the predominate imaging modality for screening.[18] Transesophageal echocardiography (TEE) allows for better definition of tumor size and location and can be used to identify the site of tumor attachment and the presence of multiple lesions.[1,14,32]

Myxomas have a typical echocardiographic appearance and are often irregular in shape with protruding fronds of tissue. Areas of

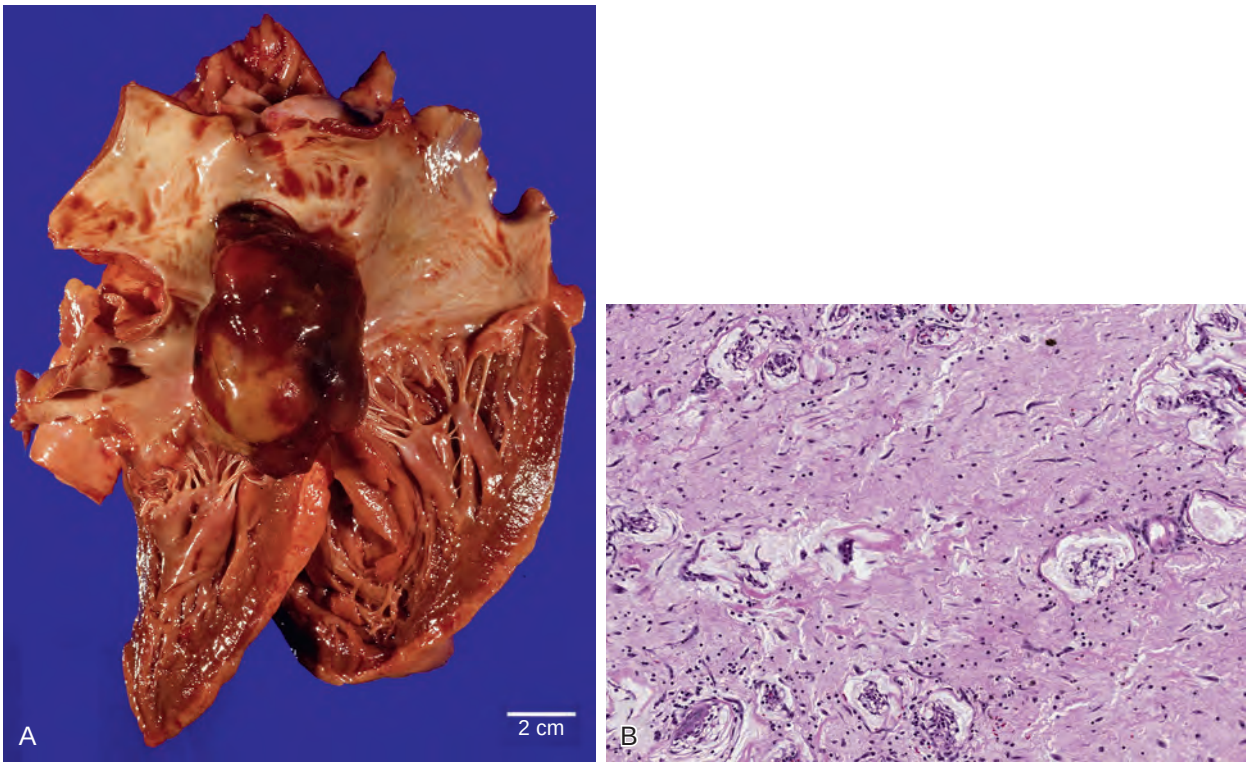

Fig. 24.1 Cardiac myxoma. (A) Gross specimen, solid type, with a typical smooth, lobular, mucoid appearance and location in the fossa ovalis. (B) Microscopic specimen, with small, stellate myxoma or lepidic cells forming rings and strands around vascular structures set against a myxoid background. *(Reproduced with permission from Jain D, Maleszewski JJ, Halushka MK. Benign cardiac tumors and tumorlike conditions.* Ann Diagn Pathol. *2010;14:217.)*

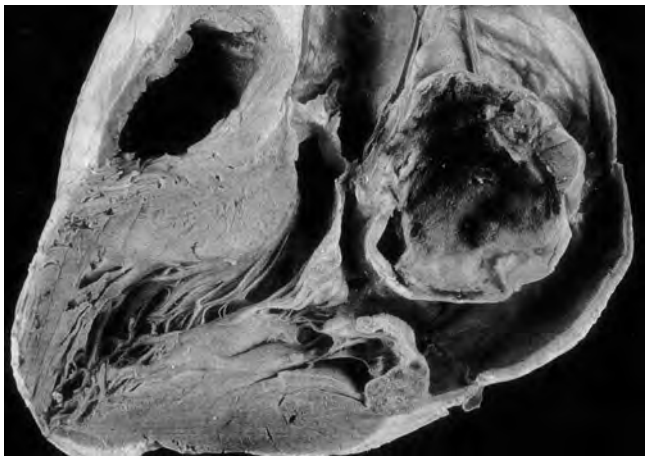

Fig. 24.2 Postmortem specimen of a large left atrial myxoma prolapsing into the orifice of the mitral valve. *(Reproduced with permission from Schaff HV, Mullany CJ. Surgery for cardiac myxomas.* Semin Thorac Cardiovasc Surg. *2000;12:81.)*

calcification may be evident, and the echogenicity of the mass may not be homogeneous.[1,14,15] The presence of a large mass in the LA with an attachment to the interatrial septum is highly suggestive of myxoma; however, echocardiography cannot, of course, provide a definitive tissue diagnosis. Rarely is a thrombus attached to the atrial septum.[33] The degree of obstruction to ventricular filling caused by the tumor may be evaluated with Doppler echocardiography (see Fig. 24.3). Qualitatively, color-Doppler imaging will show aliasing and flow acceleration through the atrioventricular valve when obstruction is present. Continuous-wave Doppler imaging is able to quantify the gradient between the atrium and the ventricle. Preoperatively, the goal of echocardiographic evaluation is to determine the site of tumor attachment, to characterize a tumor's relationship, in particular, to the cardiac valves and their leaflets, and to assess for the presence of multiple masses as in the case of Carney complex.[34] If this cannot be accomplished with TTE, then TEE should be performed to aid in surgical planning.

Although professional societies have specified appropriate use criteria for TEE, most are based on opinion rather than on evidence.[35–37] Whereas TEE may be appropriate to evaluate for a cardiac source of embolus when no noncardiac source has been identified, it may be inappropriate when a noncardiac source has already been located or when the results of the examination are unlikely to change patient management.[35] When the primary reason for cardiac surgery is the removal of an intracardiac mass, an intraoperative transesophageal echocardiographic evaluation should take place before the surgical incision to ensure that the mass is still present and has not embolized or even dissolved, as in the case of intracardiac thrombus. In the case of myxoma, an intraoperative examination in the presence of the surgeon can aid in finalizing the surgical plan and in detecting previously unseen tumors. After tumor removal, the goal of TEE is to ensure that all visible mass was removed and that no damage occurred to adjacent structures. Specifically, in the case of a myxoma attached to the atrial septum, ensuring that no interatrial shunting has occurred after resection is important. If the tumor was attached on or adjacent to the valvular apparatus, then the examiner must determine whether the valve is competent after removing the tumor.

The first surgical resection of an atrial myxoma was performed in 1954.[30] Subsequently, surgical resection has been recommended even if the myxoma is discovered incidentally, primarily because the risk of embolization to the central nervous system may be 30% to 40%.

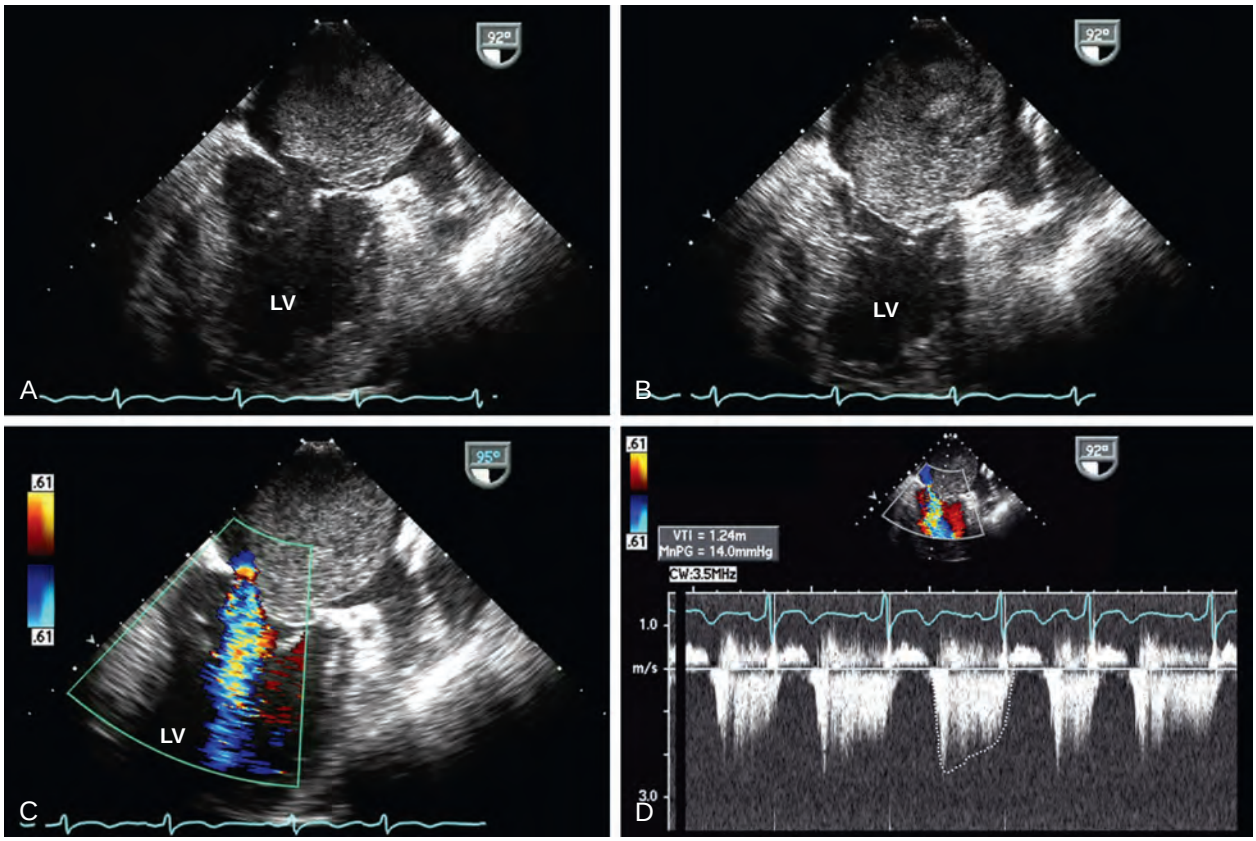

Fig. 24.3 Transesophageal echocardiographic characteristics of a large left atrial myxoma. (A) Midesophageal two-chamber view during systole shows a 5 × 7 cm mass located in the left atrium. (B) Two-dimensional and (C) color-flow Doppler images show that during diastole, the mass obstructs flow across the mitral valve, creating severe functional mitral stenosis. (D) Continuous-wave Doppler across the mitral valve demonstrates a mean gradient of 14 mm Hg. *LV,* Left ventricle. *(Reproduced with permission from Otto CM, ed.* Practice of Clinical Echocardiography. *4th ed. Philadelphia: Saunders/Elsevier; 2012.)*

Generally, the time interval between the onset of symptoms and surgical resection is approximately 4 months, although surgery has been delayed for as long as 10 years in some cases.[23] Surgery is associated with a mortality rate between 0% and 7%.[4,12] More importantly, recent studies show that the long-term survival of an individual who has undergone myxoma resection is no different from age- and gender-matched populations.[16]

Papillary Fibroelastoma

Papillomas (papillary fibroelastoma) are rare, benign tumors that tend to affect the cardiac valves. Although large surgical series count them as the second most common primary cardiac tumor, several series now suggest that papillary fibroelastomas may, in fact, be more common than myxomas.[1,8] Initially thought to be incidental findings during autopsies, most papillary fibroelastomas are currently discovered in living patients.[38] Mostly singular (90%), 1 to 4 cm in size, highly papillary, pedunculated, and avascular, papillomas are covered by a single layer of endothelium containing fine elastic fibrils in a hyaline stroma.[20,39,40] Macroscopically, they resemble sea anemones (Fig. 24.4). They originate most commonly from valvular endocardium,[41] usually involving the ventricular surface of the aortic valve or the atrial surface of the mitral valve, but they only infrequently render the involved valve incompetent. Papillary fibroelastomas account for 75% of all primary cardiac valvular tumors.[16,42] Adults between the ages of 40 and 80 years are primarily affected, with a mean age of 60 years at the time of detection.[43] Many patients are asymptomatic; therefore it is not surprising that 47% of these tumors are discovered incidentally during echocardiography, catheterization, or even cardiac surgery. Echocardiographically, fibroelastomas have a typical appearance (Figs. 24.5 and 24.6; see also Fig. 24.4).[40,44] They are usually small (mean size 12 × 9 mm), and their motion is independent of that of the attached valve leaflet.[45] They may appear similar to vegetations seen in endocarditis or they may be confused with Lambl excrescences, which tend to be more nodular in appearance.[1,14]

Currently, many tumors are detected during the search to find the cause of embolic symptoms. These symptoms are most common when the aortic valve is involved.[12] Although papillary fibroelastomas were previously believed to be harmless, postmortem studies have shown a high incidence of embolization to the cerebral and coronary circulations.[9] Not surprisingly, symptoms are often related to stroke or transient ischemic attack and myocardial infarction (MI). Although embolization may be a tumor, it may be a thrombus because tumors are excellent sites for thrombus formation.[43] Making the diagnosis is very important, because acute valvular dysfunction and even sudden death may occur.[41] Surgical resection is curative but may require valvular repair or replacement in one-third of cases.[38] Recurrence is very rare.

Primary Malignant Tumors

Approximately 25% of primary cardiac tumors are malignant,[43] and 95% of these are sarcomas (Fig. 24.7). They are found infiltrating the RA and causing cavitary obstruction but may have variable clinical presentations based on the location, causing the diagnosis to be elusive. Primary malignant tumors usually occur between the ages of 30 and 50 years and are preceded by vague symptoms such as dyspnea, rapidly

progressing to death. Angiosarcomas, the most common sarcoma,[9] are rapidly spreading vascular tumors that arise most often from the RA and appear near the inferior vena cava (IVC) with extension to the mediastinum. They occur most commonly in adults and men.[43] Presenting symptoms include chest pain and dyspnea, progressive CHF, and bloody pericardial effusion.[46] There are two clinicopathologic forms of the tumor. The first type deposits a small tumor in the pericardium or epicardium and is associated with skin lesions or risk factors for Kaposi sarcoma. The second involves a large tumor in the RA. Treatment is palliative, because the response to chemotherapy and radiation is poor. Resection may be possible, but survival is less than 2 years. Rhabdomyosarcomas are aggressive tumors that have cellular elements that resemble striated muscle. These tumors occur equally in both sexes. They may originate in any chamber of the heart but, in contrast to angiosarcomas, rarely become diffusely involved with the pericardium. They are bulky and invasive, growing rapidly. Surgical resection is possible, but distant metastasis reduces the chances of success. Chemotherapy and radiation are ineffective.[43]

Echocardiography tends to be less helpful in the management of these patients than it is in patients with benign tumors. It may reveal physiologic complications of the tumor such as cavity obliteration or valvular regurgitation, and it is helpful in finding associated pericardial effusions and physiologic tamponade. However, these tumors have complex anatomy, and the perimeters of the tumor and their involvement in valve apparatuses and coronary anatomy can be difficult to determine even with TEE. In addition, echocardiography does not image adjacent cardiac structures such as the lung and mediastinum in detail. When echocardiography is combined with other imaging modalities such as CT and MRI, the clinician may obtain both the anatomic information needed (from the CT or MRI), as well as the physiologic consequences from echocardiography.[15]

Other primary malignant tumors of the heart include malignant fibrous histiocytoma, fibrosarcomas, osteosarcoma, leiomyosarcoma (the rarest malignant cardiac tumor), undifferentiated sarcoma, neurogenic sarcoma, and lymphomas. Primary cardiac lymphoma is defined as a non-Hodgkin lymphoma and accounts for approximately 1% of primary cardiac tumors.[47] Prevalence of these tumors has been increasing attributable, in part, to acquired immunodeficiency syndrome (AIDS) and to earlier detection with improvements in imaging technology. Lymphomas are generally large masses with extensive infiltration into adjacent areas of the heart from the point of tumor origin and are commonly located in the RA and RV. These primary tumors are very rare, representing less than 2% of all cardiac tumors.[48] Treatment involves a combination of chemotherapy and radiation, occasionally extending survival up to 5 years, but the median survival is 1 year. Malignant fibrous histiocytoma, in contrast to other sarcomas, is generally found in the LA. Despite resection, local recurrence and metastasis are common. Surgical excision may be useful to ameliorate symptoms but ultimately does not improve the poor survival.[49]

In general, malignant primary cardiac tumors may require a combination of surgery, radiation, and chemotherapy to limit cavitary obstruction to blood flow because of rapid growth and metastasis. Local recurrence is more likely to cause death than metastasis.[50] More aggressive approaches for malignant tumors with extensive local disease before metastasis include autotransplantation, during which the heart is removed from the chest cavity and inverted to provide better exposure.[51] Its value is still indeterminate, but no intraoperative deaths have occurred. Although still controversial, orthotopic heart transplantation may be considered for unresectable tumors that involve only the heart, but survival is not extended beyond 1 to 2 years.[18] The rate of intraoperative death with malignant tumor resection is seven times that of benign resection, and the morbidity rate is twice as high.

Metastatic Tumors

Although rare in general, secondary or metastatic cardiac tumors are far more common than primary tumors with an incidence at autopsy between 2.3% and 18.3%.[2,3,6,7,10] Metastatic tumors may involve the heart by direct extension, by venous extension, or by hematogenous or lymphatic spread.[2] These tumors may affect primarily the pericardium, the epicardium, the myocardium, or the endocardium, although one large autopsy series found that the pericardium was involved in approximately two thirds of the cases of metastatic disease (Figs. 24.8 through 24.11).[2] The site of metastasis frequently provides clues to the means of metastasis. Pericardial involvement, for example, often occurs via the direct extension from surrounding intrathoracic structures or from lymphatic spread, whereas endocardial lesions typically reflect hematogenous spread, and epicardial and myocardial lesions tend to arise from lymphatic extension.[2]

Tumors exhibiting high rates of cardiac metastases include mesothelioma (48.4%), melanoma (27.8%), pulmonary adenocarcinoma (21%), undifferentiated lung carcinoma (19.5%), pulmonary squamous cell carcinoma (18.5%), and breast carcinoma (15.5%), although other autopsy series suggest that esophageal carcinoma may also be commonly found in cases of cardiac metastases.[2,6] When considered by means of extension, direct extension is most likely to occur with tumors of the lung, breast, and esophagus, whereas hematogenous seeding is more likely with melanomas, and lymphatic spread is associated with lymphomas and leukemias. Venous extension, primarily involving right-sided cardiac structures, occurs with tumors of the kidneys (renal cell carcinoma), liver (hepatocellular carcinoma), and uterus (uterine leiomyosarcoma).[3,14]

In general, as is the case with most primary cardiac tumors, tumor location determines an individual's clinical presentation.[3] Although cardiac metastasis may be an incidental finding at autopsy, other lesions may exhibit the signs and symptoms of intracardiac or extracardiac obstruction, embolization, or arrhythmia.[52] Left-sided tumors involving the mitral or aortic valves may mimic stenotic lesions, producing angina, syncope, or heart failure with progressive pulmonary venous hypertension, whereas right-sided masses may affect all the manifestations of right-sided heart failure with hepatic congestion, ascites, abdominal distention, and worsening renal function in the face of venous hypertension.[2,52] With lesions affecting the pericardium or epicardium, a large pericardial effusion may develop with the manifestations of tamponade and obstructive shock, depending on the rate of pericardial fluid accumulation.[2] Embolization of right-sided lesions may be clinically silent or may be similar to thrombotic pulmonary emboli with tachycardia, chest pain, dyspnea, or hypoxemia. Embolization of left-sided tumors classically exhibit neurologic manifestations, although systemic embolization may affect the ischemia of any end organ, including the kidneys and abdominal viscera, or produce cutaneous manifestations. When the myocardium is involved, progressive tumor infiltration has the potential to produce any number of atrial and ventricular arrhythmias or conduction abnormalities, depending on tumor location.[2]

Although TTE or TEE may be useful in detecting and localizing metastatic disease, multimodal imaging with CT or MRI may be necessary to determine the extent of cardiac involvement and to facilitate tissue characterization and diagnosis, particularly in cases where the primary lesion is unknown.[14] Unsurprisingly, the prognosis with a diagnosis of metastatic cardiac disease is poor. In one recent small series, 53.4% of patients diagnosed with metastatic lesions were deceased at 1 year.[53] Although surgical intervention is not typically contemplated, 53.5% of the patients with metastatic disease in that series underwent surgical resection. Of those who underwent resection, 56.5% were alive at 1 year.[53]

Anesthetic Considerations

In general, anesthetic management of patients with cardiac tumors is likely guided first by the patient's comorbidities and second by tumor location. Clearly, a patient with an invasive right-sided lesion and the stigmata of right-sided heart failure undergoing a palliative resection will warrant different management than a young, otherwise healthy individual undergoing a minimally invasive papillary fibroelastoma resection.

At the current time, tumor resection is an invasive procedure requiring general anesthesia. However, it is easy to imagine a time in

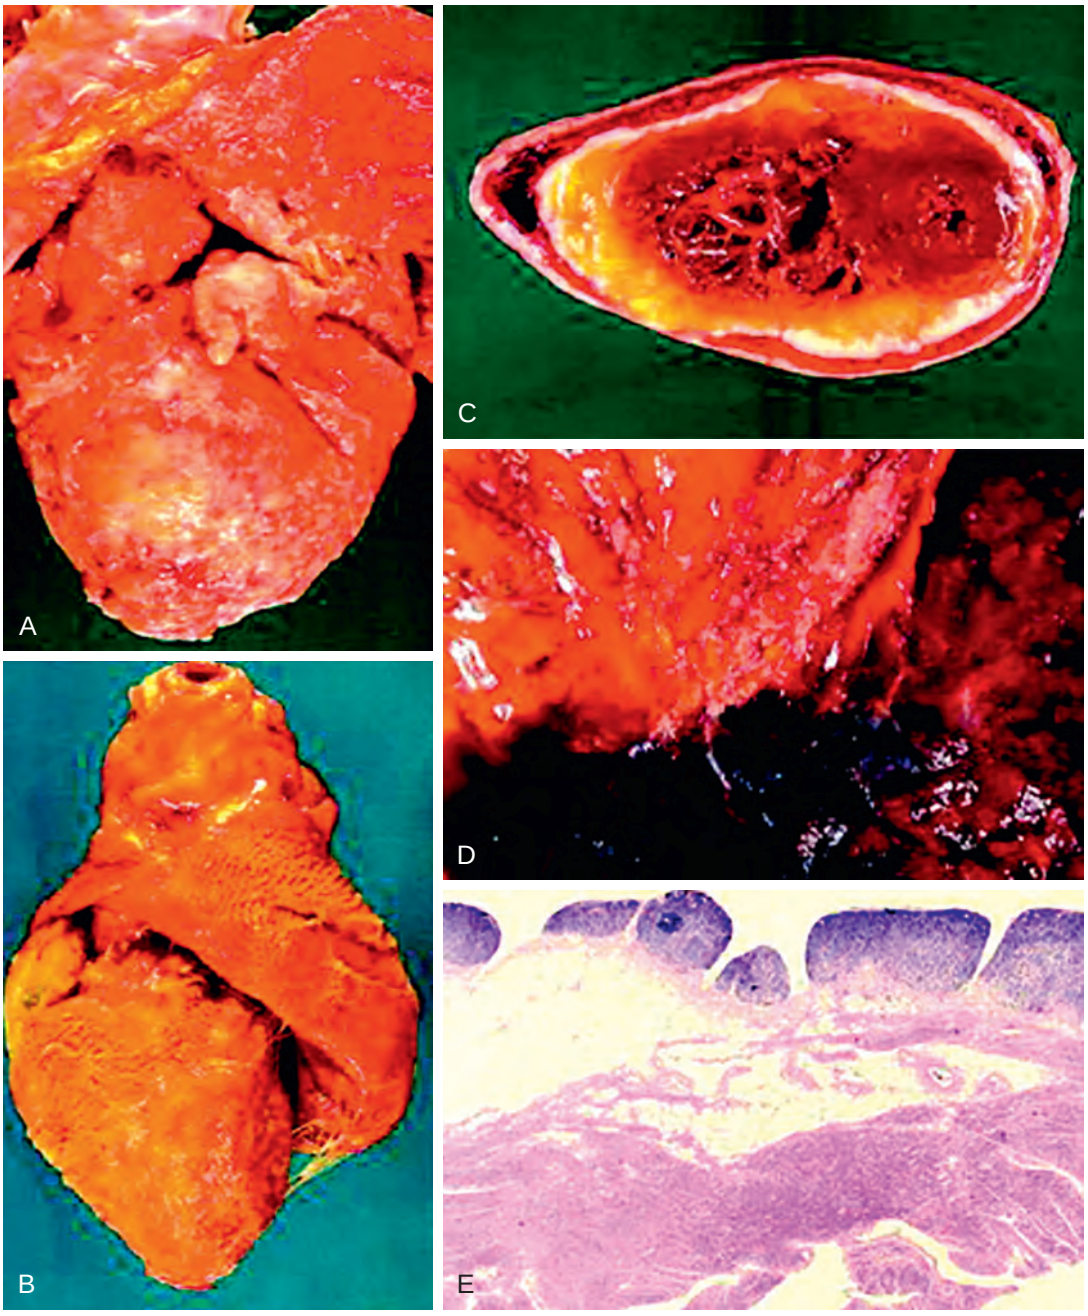

Fig. 24.8 Patterns of tumors metastatic to the heart. Pericardial metastases of esophageal squamous cell carcinoma with fibrinohemorrhagic pericarditis. *(Reproduced with permission from Bussani R, De-Giorgio F, Abbate A, Silvestri F. Cardiac metastases.* J Clin Pathol. *2007;60:29.)*

the not-too-distant future when small, uncomplicated lesions could be resected using catheter-based approaches performed in a cardiac catheterization suite or a hybrid surgical unit under monitored anesthesia care, similar to some transfemoral aortic valve insertions or percutaneous mitral valve repairs that are performed today. At present, however, general anesthesia with an airway secured with an endotracheal tube is required. For minimally invasive or robotic-assisted procedures using limited thoracotomies, lung isolation is required with either a double-lumen endotracheal tube or a bronchial blocker.[54,55]

In addition to the American Society of Anesthesiologists standard monitors providing continual evaluation of oxygenation, ventilation, circulation, and temperature, anesthesia for resectioning a cardiac tumor will undoubtedly involve placing an arterial line for continuous hemodynamic monitoring and establishing central venous access for vasoactive drug administration, volume infusion, and pressure monitoring. For patients with depressed cardiac function in whom mechanical circulatory support may be anticipated at the conclusion of the bypass run or for patients whose surgical resection may be complicated, involving a prolonged bypass run, after which a discrepancy between central and peripheral blood pressures may be significant, consideration may be given to placing a second arterial line in either a femoral or a brachial location. The timing of arterial line placement with respect to anesthetic induction should be guided by the patient's comorbidities and provider experience. Similarly, the choice of catheters and their placement locations for central venous access should be guided by the patient's pathologic condition and the surgical skill

of the provider. A healthy 20 year old undergoing resection of a small atrial myxoma may require no more than a triple- or quadruple-lumen infusion catheter, whereas a debilitated 70 year old undergoing resection of a tumor with myocardial involvement and ventricular reconstruction may merit more than one central venous catheter, as well as a pulmonary artery catheter (PAC). Tumors with extensive right-sided involvement and superior vena cava (SVC) compromise may call for the avoidance or delayed (postresection) placement of PACs or the placement of catheters in the femoral vessels rather than in the neck. A skilled surgeon who can resect a tumor with a 20-minute pump run may require different monitoring than a less facile surgeon whose shortest pump times may never be less than an hour.

The choice of induction drugs, again, likely depends less on the tumor's pathologic nature than on patient comorbidity and personal preference. In general, the choice of drug is likely to matter less than how the drug is used. A patient with an effectively stenotic left-sided lesion can just as safely be managed with judicious doses of propofol as with etomidate, ketamine, or barbiturate. The requirement for pharmacologic support with the separation from cardiopulmonary bypass (CPB) will be guided more by patient comorbidity and the details of surgical resection than by the pathologic nature of the tumor.

Anesthetic management is guided by tumor location in addition to patient comorbidity. Left atrial myxomas, for example, will most likely cause mitral valve obstruction, often in conjunction with pulmonary venous hypertension. Anesthetic management will closely resemble that of a patient with mitral stenosis. In contrast, right atrial myxomas may produce signs of right-sided heart failure that correspond to tricuspid valve obstruction. Positioning the patient for surgery must be carefully performed to detect severe restriction of venous return that may often be quickly followed with profound hypotension and arrhythmias. A large tumor may increase the likelihood of hemodynamic instability, whereas small tumors may be associated with increased risk of embolization.[12] Perioperative arrhythmias, especially atrial fibrillation or atrial flutter, may arise in 25% of these patients and may require immediate treatment.

Although median sternotomy may be required for many procedures, others involving isolated, superficial lesions may be performed through an anterior thoracotomy or similar minimally invasive techniques.[18,54–56] Femoral cannulation for the initiation of CPB may minimize the risk of tumor dislodgment or fragmentation. If bicaval venous cannulation is required, then a second venous cannula may be placed in the SVC, often using a small 5 or 6 French sheath placed by the cardiac anesthesia team that is subsequently upsized using the Seldinger technique to an appropriate venous cannula. Cardiac arrest is required for open-chambered procedures. With a prohibitive aorta, ventricular fibrillatory arrest may be used to prevent ejection of blood and embolization of tumor fragments after initiating CPB. For malignant tumors with significant myocardial invasion, deep hypothermic circulatory arrest may be required.

Tumors With Systemic Cardiac Manifestations

Carcinoid Tumors

Carcinoid tumors are metastasizing neuroendocrine tumors that arise primarily from the small bowel, occurring in 1 to 2 per 100,000 people in the population.[57,58] Upon diagnosis, 20% to 30% of individuals with carcinoid tumors exhibit the symptoms of carcinoid syndrome, characterized by episodic vasomotor symptoms, bronchospasm, hypotension, diarrhea, and right-sided heart disease attributed to the release of serotonin, histamine, bradykinins, and prostaglandins, often in response to manipulation or pharmacologic stimulation. Manifestations of carcinoid syndrome occur primarily in patients with liver metastasis that impair the ability of the liver to inactivate large amounts of vasoactive substances.

Initially described in 1952,[57] carcinoid heart disease may occur in 20% to 50% of patients with carcinoid syndrome.[59,60] Carcinoid heart disease may be the initial feature of metastatic carcinoid disease in 20% of patients. The prognosis has improved substantially in the last 20 years for individuals with malignant carcinoid tumors and carcinoid heart disease, but it still causes considerable morbidity and

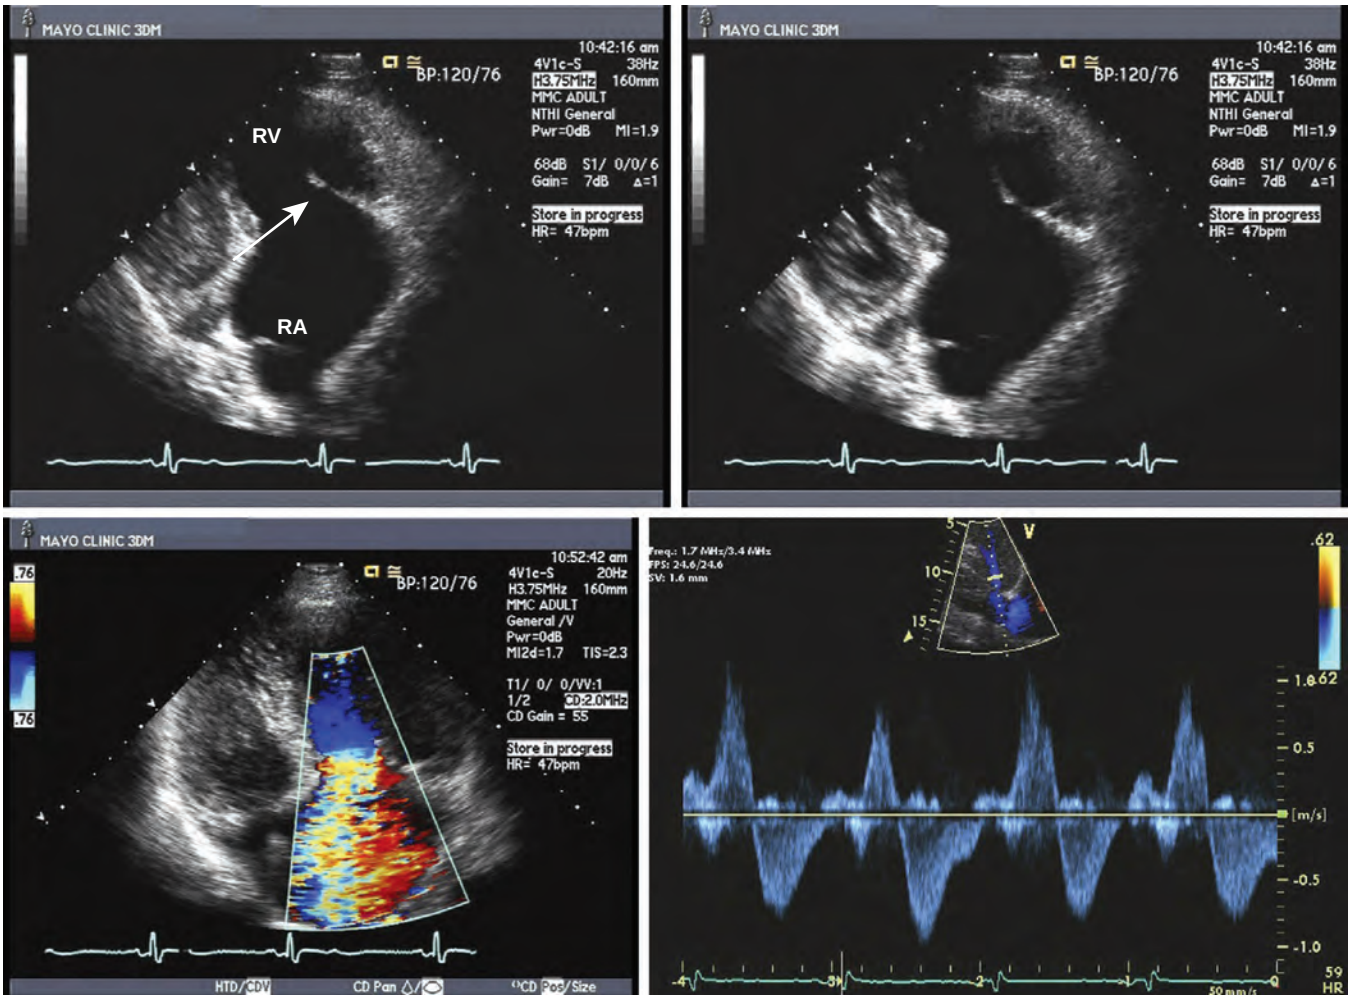

Fig. 24.12 Transthoracic imaging using an apical view in a patient with carcinoid heart disease. The *upper left and right panels* show the tricuspid valve *(arrow)* in both systole and diastole, respectively. The thickened tricuspid leaflets move little between systole and diastole and demonstrate an enormous coaptation defect during systole *(upper left panel)*. Color-flow Doppler imaging *(lower left panel)* reveals massive tricuspid regurgitation that fills the entire right atrium, which is severely dilated. In the *lower right panel*, continuous-wave Doppler imaging of the hepatic veins reveals systolic flow reversals (deflection of Doppler signal above the baseline during systole), which is indicative of severe tricuspid regurgitation. *RA*, Right atrium; *RV*, right ventricle. *(Reproduced with permission from Oliver WC, Mauermann WJ, Nuttall GA. mortality. The median life expectancy is 5.9 years without carcinoid heart disease but falls to 2.6 years if it is present.[60] Circulating serotonin levels had once been found to be more than twice as high in persons with carcinoid syndrome who develop carcinoid heart disease,[61] but this is no longer true because most patients receive somatostatin analogs.[60]

Carcinoid heart disease characteristically produces tricuspid regurgitation and mixed pulmonic stenosis and regurgitation resulting in severe right-sided heart failure (Fig. 24.12). Tumor growth in the liver permits large amounts of tumor products to reach the RV without the benefit of first-pass hepatic metabolism (Fig. 24.13). Carcinoid plaques composed of myofibroblasts, collagen, and myxoid matrix[62] are deposited primarily on the tricuspid and pulmonary valves, bringing about immobility and thickening of the valve leaflets, causing the distinctive valvular changes (Figs. 24.14 through 24.16). At the time of surgery, 80% of tricuspid valves are observed to be incompetent with only 20% with stenosis, whereas the affected pulmonary valves tend to be equally divided between incompetence and stenosis.[62] The exact mechanism that causes valve injury is unknown, but high levels of serotonin are sometimes found in patients with carcinoid heart disease.[57] Fewer than 10% of those with carcinoid heart disease have left-sided heart involvement, possibly attributable to inactivation of serotonin in the lungs,[62,63] but either the mitral or aortic valve may be affected in the presence of a bronchial carcinoid, a right-to-left intracardiac shunt, or poorly controlled disease with high levels of circulating vasoactive substances.[58,63,64]

Echocardiographic features of carcinoid heart disease, particularly of the tricuspid valve, are practically diagnostic of the underlying disease process. The leaflets are thickened and retracted. The appearance of the tricuspid leaflets often appears as if the leaflets are curled under. The thickening and retraction of the leaflets result in a large coaptation defect and severe valvular regurgitation. The pulmonic valve may be difficult to image with TTE, but the midesophageal echocardiographic view at 70 to 90 degrees often shows the valve well. With severe tricuspid regurgitation, the RV will dilate and abnormal ventricular septal motion may be noted. Ventricular wall thickness is usually normal. Doppler imaging of the hepatic veins will show systolic flow reversals consistent with severe tricuspid regurgitation.

A careful search for a patent foramen ovale (PFO) should be undertaken, because its presence raises the possibility of left-sided valvular involvement.[58,64]

Historically, the prognosis of patients with carcinoid syndrome has been poor. In the absence of treatment, median survival was 38 months from the time of development of systemic symptoms.[65] With the development of cardiac involvement and frank carcinoid heart disease, median survival has dropped to a dismal 11 months.[57,65] Improvements in medical management and surgical technique, however, have led to improved symptom control and a lower mortality rate.[57,60] In a retrospective review of 200 patients with carcinoid syndrome referred to the Mayo Clinic, Møller and colleagues[60] found that median survival improved from 1.3 years in the 1980s to longer than 4 years in the late 1990s.[60] Of the 200 patients in the study, 87 underwent cardiac surgery; in addition, when cardiac surgery was included in a multivariate analysis, it was associated with a significant risk reduction. Although the introduction of somatostatin analogues in the mid-1980s was associated with improved symptom control, no evidence suggested that their use was associated with improved survival.[57,60]

The management of patients with carcinoid disease, in general, and carcinoid heart disease, in particular, is complex, requiring a multidisciplinary team of gastroenterologists, endocrinologists, oncologists, general and hepatic surgeons, cardiologists, cardiac surgeons, cardiac anesthesiologists, and surgical intensivists.[58,66] The mainstays of treatment are symptom management with somatostatin analogues and medical management of right-sided heart failure; antitumor therapy with chemotherapy, vascular embolization and surgical debulking; and surgical treatment of carcinoid heart disease.[57,58,66]

First reported in 1985 for the rapid reversal of carcinoid crisis, somatostatin analogues bind somatostatin receptors on carcinoid cells and prevent the release of the vasoactive mediators responsible for the carcinoid syndrome.[67,68] Currently, two somatostatin analogues are available for treatment, octreotide and lanreotide.[69] Octreotide, itself, may be administered as an immediate-release subcutaneous injection, administered two to three times daily at doses between 100 and 500 μg; or it may be administered as a long-acting depot formulation given intramuscularly every 4 weeks at doses between 10 and 60 mg.[69] Although the somatostatin analogues provide symptom relief, their use has not been associated with any demonstrated mortality benefit.[57,66]

A large percentage of patients with carcinoid heart disease are asymptomatic, because the disease is mild. Early detection can affect prognosis as the progression of cardiac disease, especially to right ventricular failure, increases mortality.[59] Treatment of the tumor and the malignant carcinoid syndrome does not result in regression of carcinoid heart disease.[60] The surgical replacement of both the tricuspid and pulmonary valves with either bioprosthetic or mechanical valves is the only viable therapeutic option.[70] The decision regarding mechanical or bioprosthetic valves depends on individual risks and concerns.[57,64,71] The optimal timing of surgical intervention is uncertain but should be considered when signs of right-sided heart failure appear if not before.[64,72] With improvements in surgical technique and perioperative care, postoperative mortality in the large cohort from the

Mayo Clinic improved from 25% in the mid-1980s to 9% in the late 1990s, although this change was not statistically significant.[60]

Anesthetic Considerations

Patients who have carcinoid heart disease and require cardiac surgical intervention pose an anesthetic challenge.[72–77] A carcinoid crisis with exuberant vasoactive-mediator release is a life-threatening event that may be precipitated by endogenous and exogenous stimuli alike. Patient anxiety and fear in anticipation of surgical intervention may provoke a crisis. A variety of pharmacologic agents, including thiopental, meperidine, morphine, atracurium, and succinylcholine, as well as catecholamines such as epinephrine, norepinephrine, dopamine, and dobutamine, have all been implicated, often anecdotally, in crisis precipitation. Furthermore, physical stimulation that may occur with laryngoscopy and endotracheal intubation, vascular access placement and the placement of urinary catheters, and tumor manipulation that may occur during tumor resection may also elicit a brisk release of vasoactive mediators.

Preoperative control of carcinoid activity is a critical aspect of perioperative management.[58,72,77] The importance of a multidisciplinary team coordinating patient care, ensuring optimal preoperative symptom control and anticipating perioperative problems, cannot be overestimated. The perioperative management of a patient with severe disease, although with minimal symptoms, who is maintained on a long-acting somatostatin analogue formulation supplemented preoperatively with additional subcutaneous injections of short-acting drug, is entirely different from that of a severely symptomatic patient who only recently was begun on low doses of short-acting medications. Although the former may be a candidate for a rapid recovery postoperative protocol and may spend only a single night in the intensive care unit, the latter may incur significant morbidity and even mortality.

Perioperative patient management is facilitated with optimal preoperative symptom control with carefully monitored administration and up-titration of a long-acting somatostatin analogue formulation, supplemented preoperatively with additional subcutaneous injections of short-acting medications. Some institutions initiate an octreotide infusion at doses between 50 and 100 μg per hour the night before surgery or the day of surgery in the preoperative holding area, while providing additional intravenous doses of 20 to 100 μg as indicated clinically during anesthetic management.[72,77,78] In the absence of any randomized clinical trials, it remains unclear whether any data, other than institutional experience, can guide the decisions regarding the need for preoperative infusion therapy, the timing of its initiation, the dosing regimen, and the strategy for intraoperative bolusing. It may well be the case that the presence of a well-reasoned institutional protocol designed and monitored by a multidisciplinary team is at least as important, if not more important, than the details of pharmacologic dosing.[72,77] Incidentally, it should be noted that severe hyperglycemia may occur with octreotide because of its inhibition of insulin secretion, especially in combination with steroids. Consequently, regimented glucose monitoring is recommended, especially in an era when hospital reimbursements are tied, in part, to perioperative glycemic control.[68,71]

Because patient anxiety and stress may provoke a carcinoid crisis, consideration should be given to judicious administration of preoperative anxiolytic agents.[73,77] The emphasis, however, should be on judicious, and the dosing should be guided by clinical judgment rather than simply by diagnosis. Liberal preoperative administration of benzodiazepines, especially in conjunction with opioids, to an already sedate patient may result not in the intended plane of hemodynamic stability but in progressive hypoxemia and hypercarbia, leading to right ventricular compromise and the very cardiovascular collapse one meant to avoid. A variety of strategies have been recommended for the induction and maintenance of general anesthesia: use etomidate rather than thiopental; use fentanyl or sufentanil rather than morphine and meperidine; avoid atracurium and succinylcholine, considering vecuronium or cisatracurium; and maintain the patient with isoflurane.[77,78] Without exception, these are anecdotal recommendations. For a patient, even a patient with severe disease, whose symptoms are well-controlled preoperatively on a regimen of long- and short-acting octreotide or its equivalent, it is likely the case that the drugs used matter less than how they are used and matter less than the vigilance of the anesthesiologist directing the patient's care.

One particular challenge with cardiac surgical patients in general and with carcinoid cardiac surgical patients in particular is determining the cause of intraoperative hypotension and thus its appropriate treatment.[72] Clearly, a carcinoid crisis should be at the top of a differential diagnosis, but making that diagnosis with speed and certainty may be difficult, especially when surgical drapes may mask the cutaneous manifestations of a crisis and volatile anesthetics may minimize attendant bronchospasm. Even in the absence of diagnostic certainty, some practitioners may treat each such episode of apparently unprovoked hypotension with a bolus of intravenous octreotide in doses of 20 to 100 μg. Some anesthesiologists may simultaneously administer a subcutaneous dose of 50 to 100 μg with the intention of providing an additional depot of drug to smooth further hemodynamic oscillations. In the face of repeated episodes of apparently unprovoked hypotension, an anesthesiologist may start an octreotide infusion, if he or she has not done so already, at rates of 50 to 100 micrograms per hour, up-titrating it as necessary to a rate of 300 μg/hr. Once started, such infusions are typically continued into the postoperative period. Once the patient is clinically stable, he or she may be weaned and the infusions discontinued, often in accordance with the recommendations of a cardiac surgical critical care pharmacist, over the succeeding 24 to 48 hours. As has been stated repeatedly, evidence-based data for such interventions are absent, and the choice of drug administration, dosing, route, and timing are based largely on institutional protocol and individual provider preference and experience.

In carcinoid patients, acute right ventricular heart failure should also be considered as a potential cause of intraoperative hypotension.[72] Carcinoid heart disease is preferentially a disease of the right-sided heart valves, and it is typically right-sided heart failure that prompts surgical intervention.[57,58] The development of intraoperative hypoxemia, hypercarbia, and acidemia may be sufficient to cause acute right-sided heart failure in an already compromised ventricle. Intraoperative TEE is key for monitoring changes in biventricular function.

When intraoperative hypotension arises, as it inevitably will in patients with carcinoid heart disease, it should be treated promptly even if its cause is unclear. Early and judicious administration of octreotide has been discussed. Previously, certain catecholamines (epinephrine, norepinephrine, dopamine, and isoproterenol) were considered to provoke mediator release in carcinoid syndrome, but a retrospective study of 100 consecutive patients with carcinoid heart disease who underwent cardiac surgery did not show a significant increase in intraoperative octreotide use or mortality with the administration of such vasoactive and inotropic medications.[76] Because nearly 75% of patients with carcinoid heart disease scheduled for cardiac surgical intervention will be in New York Heart Association (NYHA) class III or higher and will require multiple-valve replacement, vasoactive and inotropic medication should be administered according to hemodynamic indices and clinical judgment.[72,77]

Finally, surgical intervention on multiple valves inevitably entails longer aortic cross-clamp and CPB times. In the setting of increased duration of exposure to extracorporeal circulation and hepatic dysfunction associated with liver metastases, coagulopathy and excessive hemorrhage after bypass are anticipated.[77,78] Although malignancy may be associated with a hypercoagulable state, the use of an antifibrinolytic medication is routine in many centers during carcinoid surgery to reduce blood loss and transfusion requirements associated with cardiac surgery.[76,77,79]

Renal Cell Carcinoma

Although renal cell carcinoma may not normally be considered a topic in cardiac anesthesia, cardiac anesthesia team members may increasingly find themselves caring for patients with renal cell carcinoma with significant venous extension.[80] Renal cell cancers represent 2%

to 3% of adult malignancies but are the most common and most deadly of renal neoplasms, accounting for approximately 90% of all renal cancers and conferring historic mortality rates between 30% and 40%.[81–83] Renal cell carcinoma is a disease of the aging, occurring most commonly in patients in their 60s and 70s, with a slight male-to-female predominance (1.5:1).[81,84] Although classically diagnosed by a combination of flank pain, hematuria, and a palpable mass, most renal cell cancers are now found incidentally during radiographic evaluation for other reasons.[81] Largely as a result of the increased frequency of abdominal imaging, the incidence of renal cell cancers has increased in the United States between 3% and 4% annually since the 1970s.[82] A small (2–3%) proportion of the cancers may be associated with familial syndromes, such as von Hippel-Lindau disease, although smoking, obesity, and hypertension are considered the three primary modifiable risk factors.[81–83]

Renal cell malignancies do not represent a single tumor type but, in fact, comprise a number of tumor subtypes, the most common of which are clear cell carcinoma (70–80% of all renal cell tumors), papillary renal cell carcinoma (10–15% of all renal cell tumors), and chromophobe renal cell carcinoma (3–5% of all renal cell tumors).[81–83] Notably, the most common variant of clear cell tumors is that they are highly vascular, confer a worse prognosis than their papillary or chromophobe counterparts, and tend to produce venous tumor extension into the renal veins and the IVC.[82] According to the American Joint Committee on Cancer Staging, a T1 lesion is 7 cm or less and confined to the kidney, whereas a T2 lesion is greater than 7 cm but still confined to the kidney, a T3 lesion extends into major veins and perinephric tissue, and a T4 lesion extends beyond the Gerota fascia.[82] Although the pathologic stage, incorporating tumor size, vascular involvement, and extension, is the most important prognostic factor, an individual's clinical and performance status, tumor histologic anatomy, and tumor molecular markers all combine to influence survival.[81,82] For patients most likely encountered in a cardiac surgical unit with tumor invasion of the IVC extending above the diaphragm (stage T3c), the 5-year survival is between 20% and 40%.[82]

Particularly pertinent to cardiac anesthesiologists is the propensity of clear cell renal cell carcinomas to invade venous vascular structures and produce venous tumor thrombus in 4% to 10% of cases.[82] According to a classification system developed at the Mayo Clinic in the 1980s, level I tumor thrombus is confined to the ipsilateral renal vein or extends 2 cm or less into the IVC. A level II tumor thrombus extends more than 2 cm into the IVC but remains below the hepatic veins, whereas a level III mass involves the intrahepatic IVC but remains below the diaphragm. A level IV thrombus extends above the diaphragm and may involve the RA and right-sided heart structures (Fig. 24.17).[85,86] Tumors demonstrating caval extension are considered locally advanced and curiously may not be associated with metastatic lesions.[82] As such, a combination of radical nephrectomy and IVC tumor thrombectomy may be curative in 45% to 70% of cases, and more cephalad venous extension may not necessarily portend a worse prognosis.[82,84,86]

Historically, surgery for levels III and IV tumors has been performed on CPB, often using deep hypothermic circulatory arrest.[82,86–92] As discussed in other chapters, exposure to extracorporeal circulation and to profound hypothermia is far from benign. In the context of concomitant radical nephrectomy and tumor thrombus resection, procedures performed on CPB, with or without hypothermic arrest, may be associated with a profound hypocoagulable state, requiring transfusion of a significant volume of blood and blood products.[82,86] In an attempt to avoid exposure to extracorporeal circulation, to avoid the neurologic morbidity associated with profound hypothermia and circulatory arrest, and to avoid the ravages of massive transfusion, surgeons have developed strategies for both on-pump resection without hypothermic arrest and off-pump resection, even in the case of lesions extending into the RA (Fig. 24.18).[82,86–89,93–95] Regardless of the surgical technique used, most medical professionals recommend that the care of these complex patients, as the care of other patients with complicated and unusual medical problems discussed in this chapter (carcinoid heart disease, hypertrophic cardiomyopathy [HCM]), be coordinated by a multidisciplinary team, including oncologists; nephrologists; urologic, hepatic, and vascular surgeons; cardiothoracic surgeons; cardiac anesthesiologists; and surgical intensivists.[80,87,95–97]

Anesthetic Considerations

Anesthetically, the most important concerns in caring for patients undergoing radical nephrectomy and tumor thrombectomy will be establishing sufficient venous access and performing a thorough intraoperative transesophageal echocardiogram. All patients will have arterial access for continuous hemodynamic monitoring and for the frequent blood draws that will occur late in the procedure to monitor the adequacy of resuscitation. Central venous access is imperative for volume resuscitation, for monitoring of right-sided heart filling pressures, and for the infusion of vasoactive and inotropic medications. Placement of a PAC may be unnecessary in patients with normal preoperative biventricular function and may be contraindicated in patients with tumor thrombus extending high into the supradiaphragmatic IVC and RA (Figs. 24.19 and 24.20). If monitoring pulmonary pressures after thrombus removal is desired, then a PAC may be placed with its tip just beyond the introducer sheath (approximately 20 cm) and subsequently floated carefully into position once the tumor has been removed, perhaps with direct manual surgical assistance. Placement of femoral venous catheters for volume use intraoperatively may be of little use, considering the need to interrupt IVC blood flow for surgical resection. As indicated, the need for volume resuscitation may be greater than the need for infusion of vasoactive or inotropic medications. Given such, one or two 9 French introducers accompanied by a clip-in infusion catheter may be more useful than a triple- or quadruple-lumen infusion catheter. An upper extremity 8.5 French Rapid Infusion Catheter (Teleflex, Morrisville, NC) may also be used to supplement a central venous line. Depending on the surgical technique and the anticipated volume of blood loss, a rapid infusion device (Belmont Rapid Infuser, Belmont Instrument Corp., Billerica, MA) may be considered. The choice of induction and maintenance medications and the need for vasoactive and inotropic medications will depend on patient comorbidities and provider preference. As has been stated previously, the specific drugs used likely matter less than their means of use. For on-pump procedures, consideration should be given to avoiding the use of antifibrinolytic agents, considering a patient's clear hypercoagulable state, although data to guide a rational choice are practically nonexistent.

Intraoperative TEE will be important for most cases, regardless of the need for CPB.[80,95,98] Although TEE may be used to guide central line placement in patients with tumor extension high in the IVC and RA and to monitor biventricular function, especially during the time of hepatic reperfusion, TEE is particularly useful for reconfirming the proximal extent of tumor burden and for monitoring the adequacy of surgical resection in real time.[80,95,98] Most patients will have undergone high-resolution imaging with either MRI or multiplanar CT before surgery to define the extent of caval tumor burden.[82] However, TEE performed at the time of surgery still has the potential to alter surgical management.[80,99] In one small series from the Mayo Clinic describing concomitant nephrectomy and pulmonary tumor thrombectomy, two of the nine patients developed pulmonary artery tumor embolism intraoperatively that was diagnosed by TEE (see Figs. 24.19 and 24.20).[100]

To date, Fukazawa, Ciancio, and colleagues[80] have recently presented the largest case series, detailing the anesthetic management of patients undergoing radical nephrectomy and tumor thrombectomy. In their report, the authors describe 70 patients (58 with level III thrombus and 12 with level IV thrombus) who underwent surgical resection at the University of Miami between 1997 and 2010.[80] Of the patients with level III lesions, only 2 (3.5%) required the use of CPB for surgical resection, whereas 3 (25%) of those with level IV disease required extracorporeal support. No patients required venovenous bypass. Patients undergoing resection for level IV disease experienced a significantly greater blood loss than those with level III disease (mean

Stage II: Extends more than 2 cm into the IVC but remains below the hepatic veins. Stage III: Involves the intrahepatic IVC but remains below the diaphragm. Stage IV: Extends above the diaphragm and may involve the heart structures. *IVC*, Inferior vena cava. *(Reproduced with permission from Fukazawa K, Gologorsky E, Naguit K, et al. Invasive renal cell carcinoma with inferior vena cava tumor thrombus: cardiac anesthesia in liver transplant settings.* J Cardiothorac Vasc Anesth. *2014;28:641.)*

6978 vs 1540 mL) and received significantly more fluid, blood, and blood products, and were more likely to require a vasopressor infusion.[80] Additionally, patients with level IV disease had longer intensive care unit (ICU) (mean 9.8 vs 4.8 days) and hospital (mean 18.8 vs 8.1 days) lengths of stay.[80] The authors do not provide the details of the anesthetic technique, although all patients had arterial lines placed for hemodynamic monitoring. Of those with level III tumors, 62.1% had central venous cannulas placed, whereas 83.3% of those with level IV tumors had them placed. A second central line was placed in 31% of those with level III disease and in 16.7% of those with level IV disease. PAC placement was uncommon, occurring in only 8.6% of those with level III tumors and 16.7% of those with level IV tumors. Using intraoperative TEE was common, occurring in 77.6% of patients with level III tumors and 100% of patients with level IV tumors and led to significant alteration of the surgical approach in 3 of the 57 patients in whom it was used (5.2%).[80]

In conclusion, as Fukazawa's paper suggests, the optimal anesthetic management of these patients with uncommon diseases should take place in the context of an institution capable of providing a patient with coordinated multidisciplinary support. Although infrequently

recognized, the anesthetic plan for many patients with uncommon conditions, whether locally advanced renal cell carcinoma with caval tumor thrombus or carcinoid heart disease or HCM, will depend as much on the level and quality of institutional support and the skill of a surgical team as it will on the specific pathologic condition of the patient.

Cardiomyopathy

Previously, the World Health Organization (WHO) and the International Society of Cardiology (ISC) defined cardiomyopathy as heart muscle disease of unknown cause, unlike heart muscle disease attributed to a specific cause or associated with a disease process. With more knowledge concerning pathogenetic and etiologic factors, the difference between seemingly idiopathic cardiomyopathy and specific heart diseases has become less distinct. Previously, cardiomyopathy was classified as dilated, hypertrophic, or restrictive. Over time, each classification has become a recognized clinical condition. In 1995 WHO and ISC redefined the cardiomyopathies according to dominant pathophysiologic considerations or, if possible, by "etiological/pathogenetic factors."[101] Cardiomyopathies were then defined as "diseases of the myocardium associated with cardiac dysfunction."

The original cardiomyopathies classified as dilated cardiomyopathy (DCM), restrictive cardiomyopathy (RCM), and HCM were preserved, and arrhythmogenic right ventricular cardiomyopathy (ARVC) was added.

In an attempt to incorporate knowledge gleaned in the succeeding decade and the numerous new insights into cardiac molecular genetics, the American Heart Association (AHA) issued a scientific statement in 2006 that proposed to redefine and classify cardiomyopathies.[102] In their words:

> *Cardiomyopathies are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that are frequently genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure-related disability.*[102]

Based on this definition, cardiomyopathies may then be divided into primary and secondary classifications, depending upon the primary organ involvement. Whereas primary cardiomyopathies are confined generally to the myocardium, secondary cardiomyopathies reflect myocardial involvement in the context of a systemic disorder.[102] Primary cardiomyopathies primarily affecting the heart may, in turn, be classified as genetic (eg, HCM, ARVC/dysplasia, left ventricular noncompaction, conduction system disease, ion channelopathies), mixed (DCM, RCM), or acquired (eg, inflammatory, stress-provoked [Takotsubo], peripartum, tachycardia-induced) (Fig. 24.21).[102] Secondary cardiomyopathies, in which cardiac involvement occurs in the context of a systemic disorder, are more numerous and include infiltrative (amyloidosis, Gaucher disease) and storage (hemochromatosis, Fabry disease) diseases, drug toxicities (heavy metals, alcohol, cocaine), chemoradiation side effects (doxorubicin, cyclophosphamide, Adriamycin), nutritional deficiencies (beriberi, scurvy), endocrine abnormalities (diabetes mellitus, hypothyroidism and hyperthyroidism, acromegaly), inflammatory conditions (sarcoidosis, viral), and autoimmune disorders (systemic lupus erythematosus, scleroderma, rheumatoid arthritis), among others (Box 24.2).[102]

As if to confuse the subject further and to take issue with the AHA's proposal, the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases presented its own classification scheme in 2008.[103] Reasoning that distinguishing between primary and secondary cardiomyopathies is not always easy, as many primary disorders may be associated with systemic manifestations and many secondary disorders may almost exclusively affect the heart, The European Society proposed retaining a taxonomy based on ventricular morphologic structure and function.[103] According to the European scheme, cardiomyopathies were divided much as they had been by WHO and the International Society and Federation of Cardiology into hypertrophic, dilated, arrhythmogenic right ventricular, restrictive, and unclassified; and each category, in turn, could be subdivided into familial and genetic or nonfamilial and nongenetic (Fig. 24.22).[101,103]

With the lack of a consensus on a definition of cardiomyopathy and with its numerous subtypes, it is difficult, if not impossible, to speak of its epidemiologic factors, although likely not uncommon. DCM alone, of whatever cause, has been estimated to have an annual incidence of 5 to 8 cases per 100,000 population and a prevalence in the United States of 36 cases per 100,000 population, leading to approximately 10,000 deaths annually.[104] HCM is even more common, if not the most common inherited cardiomyopathy, with an estimated prevalence between 1:500 and 1:200 and an estimated prevalence of at least 700,000 in the United States alone.[105–107] Given this burden of disease, anesthesia providers are likely to encounter patients with a cardiomyopathy in both cardiac and noncardiac surgical units.

In the sections that follow, this text adheres to the WHO and European Society classification, presenting overviews of DCM, HCM, RCM, and ARVC and followed, in turn, by a discussion of the salient points of their anesthetic management (Table 24.3).

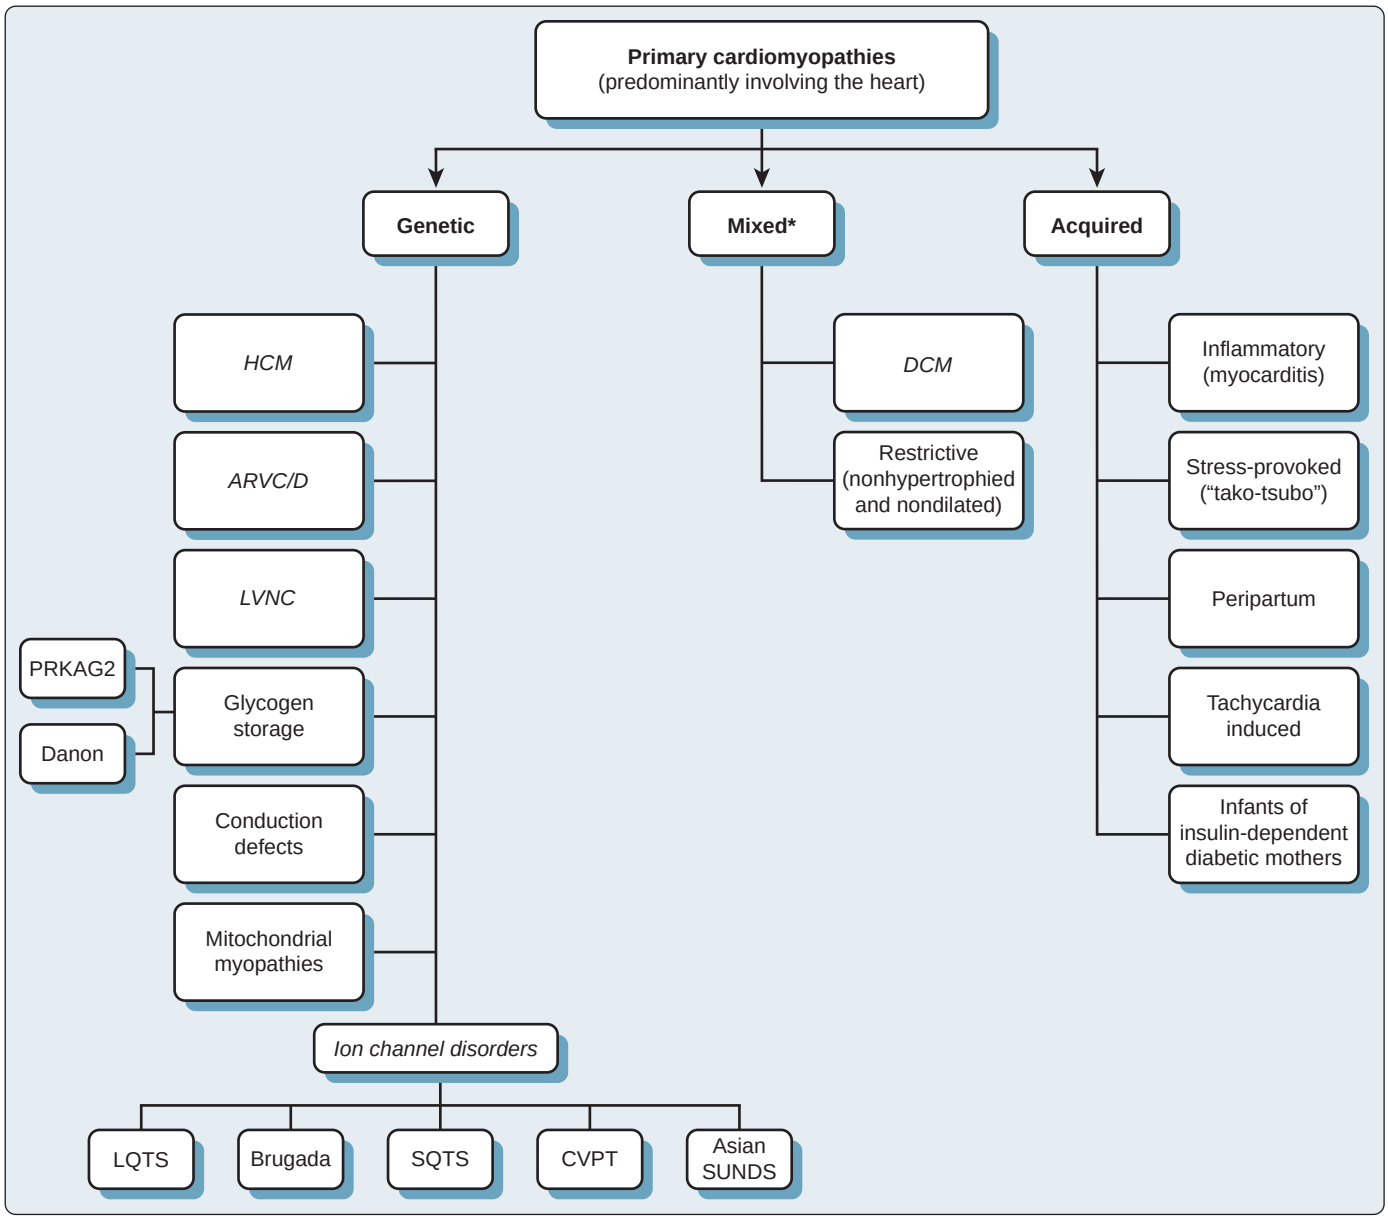

Fig. 24.21 American Heart Association classification of primary cardiomyopathies. Predominantly nongenetic causes, although rare cases of primary cardiomyopathy with a genetic origin, have been reported (see text for details). *ARVC/D,* Arrhythmogenic right ventricular cardiomyopathy/dysplasia; *CVPT,* catecholaminergic polymorphic ventricular tachycardia; *DCM,* dilated cardiomyopathy; *HCM,* hypertrophic cardiomyopathy; *LQTS,* long QT syndrome; *LVNC,* left ventricular noncompaction; *PRKAG2,* adenosine monophosphate–activated protein kinase, subunit gamma-2; *SQTS,* short QT syndrome; *SUNDS,* sudden unexplained nocturnal death. *(Reproduced with permission from Maron BJ, Towbin JA, Thiene G, et al; American Heart Association; Council on Clinical Cardiology, Heart Failure and Transplantation Committee; Quality of Care and Outcomes Research and Functional Genomics and Translational Biology Interdisciplinary Working Groups; Council on Epidemiology and Prevention. Dilated Cardiomyopathy

Formerly referred to as congestive cardiomyopathy or idiopathic cardiomyopathy, DCM is by far the most common of the four cardiomyopathies in adults in the WHO and European Society classification. As developments in molecular biology and genetics have provided better insight into the pathogenesis of DCMs, the term, *idiopathic*, has become less applicable. As suggested earlier, the term, *dilated cardiomyopathy*, should likely be replaced with *dilated cardiomyopathies*, because although the end-stage phenotype may be similar with four-chamber dilatation, the insults leading to that phenotype are both numerous and heterogeneous.[102–104,108]

BOX 24.2 AMERICAN HEART ASSOCIATION CLASSIFICATION OF SECONDARY CARDIOMYOPATHIES

- Infiltrative[a]
  - Amyloidosis (primary, familial autosomal dominant,[b] senile, secondary forms)
  - Gaucher disease[b]
  - Hurler disease[b]
  - Hunter disease[b]
- Storage[c]
  - Hemochromatosis
  - Fabry disease[b]
  - Glycogen storage disease[b] (type II, Pompe disease)
  - Niemann-Pick disease[b]
- Toxicity
  - Drugs, heavy metals, chemical agents
- Endomyocardial
  - Endomyocardial fibrosis
  - Hypereosinophilic syndrome (Löffler endocarditis)
- Inflammatory (granulomatous)
  - Sarcoidosis
- Endocrine
  - Diabetes mellitus[b]
  - Hyperthyroidism
  - Hypothyroidism
  - Hyperparathyroidism
  - Pheochromocytoma
  - Acromegaly
- Cardiofacial
  - Noonan syndrome[b]
  - Lentiginosis[b]
- Neuromuscular and neurologic
  - Friedreich ataxia[b]
  - Duchenne muscular dystrophy[b]
  - Becker muscular dystrophy[b]
  - Emery-Dreifuss muscular dystrophy[b]
  - Myotonic dystrophy[b]
  - Neurofibromatosis[b]
  - Tuberous sclerosis[b]
- Nutritional deficiencies
  - Beriberi (thiamine), pellagra, scurvy, selenium, carnitine, kwashiorkor
- Autoimmune and collagen
  - Systemic lupus erythematosus
  - Dermatomyositis
  - Rheumatoid arthritis
  - Scleroderma
  - Polyarteritis nodosa
- Electrolyte imbalance
- Consequence of cancer therapy
  - Anthracyclines: doxorubicin (Adriamycin), daunorubicin
  - Cyclophosphamide
  - Radiation

TABLE 24.3 Characteristics of Cardiomyopathies

Characteristics	*Hypertrophic Cardiomyopathy*	*Dilated Cardiomyopathy*	*Arrhythmogenic Right Ventricular Cardiomyopathy*	*Restrictive Cardiomyopathy*
Clinical				
Heart failure	Occasional (LV)	Frequent (LV or BV)	Frequent (RV)	Frequent (BV)
Arrhythmias	Atrial and ventricular arrhythmias	Atrial and ventricular arrhythmias, conduction defects	Ventricular tachycardia (RV), conduction defects	Atrial fibrillation
Sudden Death	0.7–11% per year	Frequent (ND)	Frequent (ND)	1–5% per year
Hemodynamically				
Systolic function	Hyperdynamic, outflow tract obstruction (occasionally)	Reduced	Normal-reduced	Near normal
Diastolic function	Reduced	Reduced	Reduced	Severely reduced
Morphologic				
Cavity size				
Ventricle	Reduced (LV)	Enlarged (LV or BA)	Enlarged (RV)	Normal or reduced (BV)
Atrium	Normal-enlarged (LA)	Enlarged (LA or BA)	Enlarged (RV)	Enlarged (BA)
Wall thickness	Enlarged, asymmetric (LV)	Normal-reduced (LV or BV)	Normal-reduced (RV)	Normal (BV)

BA, Both atria; *BV,* both ventricles; *LA,* left atrium; *LV,* left ventricle; *ND,* not determined; *RA,* right atrium; *RV,* right ventricle.

Acknowledging the limitations of any taxonomy, the DCMs run a spectrum from genetic to acquired with an overlap in the middle.[102] The genetics of DCMs and the genetics of familial DCM are complicated.[108] For example, if the family members of individuals with apparently idiopathic DCM are screened, as many as 35% will be found to have evidence of DCM, thus suggesting a previously unrecognized familial or genetic basis for the apparently idiopathic presentation of the index individual.[108–110] Although many cases of familial DCM are transmitted in autosomal dominant fashion, the phenotype may not become apparent until later decades in life.[102,103,110] The combination of such age-dependent penetrance with incomplete penetrance and the variable expression of any given mutation makes genealogic analysis difficult.[108] The causes of acquired DCMs are diverse and include toxins, such as ethanol, cocaine, lithium, and chemotherapeutic agents, such as Adriamycin and cyclophosphamide; infectious agents, such as coxsackievirus, human immunodeficiency virus (HIV), syphilis, and Chagas disease; inflammatory and autoimmune conditions, such as lupus erythematosus, sarcoidosis, and rheumatoid arthritis; endocrinopathies, such as diabetes mellitus, hypothyroidism, hyperthyroidism, and acromegaly; metabolic abnormalities, such as thiamine deficiency and scurvy; and a host of miscellaneous causes, such as pregnancy, stress, radiation, and tachycardia (Box 24.3).[102,104]

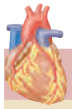
The epidemiologic factors of DCM have already been mentioned. Interestingly, even after controlling for differences in rates of tobacco and alcohol use, hypertension, and socioeconomic disparity, African Americans have three times the risk for developing DCM than do Caucasian Americans. Once they develop DCM, African Americans have a mortality rate almost two times higher.[104] As with many other aspects of the DCMs, their natural history is unclear. In general, the development of symptoms portends a poor prognosis, with 1- and 5-year mortality rates of 25% and 50%, respectively, although as many as one quarter of those with new-onset symptoms will improve without intervention.[104] In an era before the use of ß-blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers (ARBs), and cardiac implantable cardioverter-defibrillators (ICDs), the mortality rate with the DCMs was due largely to decompensated systolic heart failure (70%) and sudden cardiac death (30%), presumably from malignant arrhythmia.[104]

Phenotypically, the end-stage cardiomyopathies are similar, regardless of the inciting event. There is gross dilatation of all four cardiac chambers, modest thinning of the ventricular walls, and significant hypertrophy of the myocytes and the heart globally, reflecting a myocardium subjected to chronic volume overload (Fig. 24.23).[104,110] At autopsy, these dilated hearts may weigh two to three times normal, exceeding 1000 g.[110] Although valve leaflets may be normal, dilatation of the heart has been associated with regurgitant lesions, secondary to papillary muscle displacement and leaflet malcoaptation, producing the frequently encountered mitral and/or tricuspid regurgitation.[108] Histologic changes are nonspecific and typically shed little insight on the cause. Microscopically, a patchy and diffuse loss of tissue with interstitial fibrosis and scarring is demonstrated. Encroachment on the conduction system produces the bundle branch pattern frequently seen on the electrocardiogram (ECG).[108,110]

With the dilated cardiomyopathies, systolic function is disproportionately impaired, although as systolic functions worsens, diastolic function is compromised as well.[108] As contractile function diminishes, stroke volume is initially maintained by augmentation of end-diastolic volume. Despite a severely decreased ejection fraction, stroke volume may remain almost normal. Eventually, both increased wall stress attributable to significant left ventricular dilatation and normal or thin left ventricular wall thickness occur.[109] Increasing left atrial size may indicate worsening diastolic dysfunction in these patients, contributing significantly to functional mitral regurgitation.[111] Ventricular dilatation, combined with valvular regurgitation, compromises the metabolic capabilities of the heart muscle and produces overt circulatory failure. Compensatory mechanisms may allow symptoms of myocardial dysfunction to go unnoticed for an extended period. However, the onset of mitral regurgitation signals a poor prognosis, because ventricular function progressively worsens without intervention.

Although DCM occurs in children, its presentation is generally in the fourth and fifth decades of life.[110] The clinical picture of DCM typically includes signs and symptoms of CHF often corresponding to months of fatigue, weakness, and reduced exercise tolerance before diagnosis.[112] One third of individuals complain of chest pain.[109] However, the first indication of DCM may be a stroke, arrhythmia, or even sudden death. Increasingly, individuals after routine medical screening are informed of cardiomegaly on a routine chest roentgenogram. Insidious symptoms may appear over a period of years or evolve rapidly after an unrelated illness. Physical signs of DCM, depending on the disease's progression, include pulsus alternans, jugular venous distention, murmurs of atrioventricular valvular regurgitation, tachycardia, and gallop heart sounds.

A chest roentgenogram demonstrates variable degrees of cardiomegaly and pulmonary venous congestion. An ECG may be surprisingly normal or depict low QRS voltage, abnormal axis, nonspecific ST-segment abnormalities, left ventricular hypertrophy, conduction defects, and evidence of atrial enlargement. Atrial fibrillation is common, and approximately one fourth of patients have nonsustained ventricular tachycardia.[112] Although the left ventricle (LV) is affected, the RV may be spared in some patients, and this finding has been associated with improved survival.[113] Coronary catheterization usually reveals normal coronary vessels. Coronary angiography



BOX 24.3 CAUSES OF DILATED CARDIOMYOPATHY

Idiopathic Causes
- Idiopathic dilated cardiomyopathy
- Idiopathic arrhythmogenic right ventricular dysplasia

Familial (Hereditary) Causes
- Autosomal dominant
- X-chromosomal
- Polymorphism
- Other

Toxic Causes
- Ethanol
- Cocaine
- Adriamycin
- Catecholamine excess
- Phenothiazines, antidepressants
- Cobalt
- Carbon monoxide
- Lead
- Lithium
- Cyclophosphamide
- Methysergide
- Amphetamine
- Pseudoephedrine or Ephedrine

Inflammatory: Infectious Causes
- Viral (coxsackievirus, parvovirus, adenovirus, echovirus, influenza virus, HIV)
- Spirochete (leptospirosis, syphilis)
- Protozoal (Chagas disease, toxoplasmosis, trichinosis)

Inflammatory: Noninfectious Causes
- Collagen vascular disease (scleroderma, lupus erythematosus, dermatomyositis, rheumatoid arthritis, sarcoidosis)
- Kawasaki disease
- Hypersensitivity myocarditis

Causes of Miscellaneous Acquired Cardiomyopathies
- Postpartum cardiomyopathy
- Obesity

Metabolic and Nutritional Causes
- Thiamine
- Kwashiorkor, pellagra
- Scurvy
- Selenium deficiency
- Carnitine deficiency

Endocrine Causes
- Diabetes mellitus
- Acromegaly
- Thyrotoxicosis
- Myxedema
- Uremia
- Cushing disease
- Pheochromocytoma

Electrolyte Imbalance
- Hypophosphatemia
- Hypocalcemia

Physiologic Causes
- Tachycardia
- Heat stroke
- Hypothermia
- Radiation

Autoimmune Disorders

Infiltrative cardiomyopathies (dilated cardiomyopathy usually after progression from restrictive cardiomyopathy; in end-stage)
- Cardiac amyloidosis
- Hemochromatosis

Stress- and Catecholamine-Induced Cardiomyopathies

Reproduced with permission from Bozkurt B. Heart failure as a consequence of dilated cardiomyopathy. In: Mann DL, Felker GM, eds. *Heart Failure: A Companion to Braunwald's Heart Disease*, 3rd ed. Philadelphia: Elsevier; 2016:301.

will also distinguish between ischemic and idiopathic DCM, a finding that has therapeutic and prognostic implications. An endomyocardial biopsy is rarely valuable to identify the cause of DCM but may be useful to rule out other pathologic abnormalities that have a similar presentation to DCM.[110] The biopsy has no prognostic value or correlation with ventricular function.

Echocardiography is extremely useful in the outpatient management of patients with DCM. The characteristic two-dimensional findings are a dilated LV with globally decreased systolic function. Indeed, all markers of systolic function (ejection fraction, fractional shortening, stroke volume, cardiac output [CO]) are uniformly decreased.[114] Other associated findings may include a dilated mitral annulus with incomplete mitral leaflet coaptation, dilated atria, right ventricular enlargement, and thrombus in the left ventricular apex (Fig. 24.24). In some instances, regional wall motion abnormalities will be present. Color-Doppler imaging is useful in assessing the presence or absence of valvular regurgitation. Pulsed-wave and continuous-wave Doppler imaging are used to quantify CO and evaluate filling pressures. Well-compensated patients with DCM may have only mild impairment of diastolic function. As the disease progresses and patients become less well compensated, the left ventricular diastolic filling pattern changes to that of restricted filling. Although systolic function may not change in these patients, the increased filling pressures associated with restrictive left ventricular filling will often worsen the symptoms of CHF.

Management of acute decompensated CHF continues to evolve, but the onset of overt CHF is a poor prognostic indicator for persons with DCM.[115] However, compared with ischemic CHF, patients with nonischemic DCM show greater improvement in symptoms, left ventricular function, and remodeling during more contemporary therapy than in the past.[116] In general, treatment of patients with DCM is similar to the treatment of patients with heart failure with reduced ejection fraction and is aimed at improving symptoms, survival, and quality of life while preventing disease progression.[117] Treatment includes medication regimens and device intervention based on symptom class (Table 24.4). Pharmacologically, medications are directed at the management of fluid retention and prevention of disease progression.[117] Although diuretics of various classes are used to treat volume overload, ACE inhibitors, ARBs, ß-blockers, and aldosterone antagonists work to stabilize if not reverse the detrimental effects of cardiac remodeling that accompany DCM.[117] ACE inhibitors work to reduce symptoms, improve exercise tolerance, and reduce cardiovascular mortality without a direct myocardial effect.[112,118,119] Perhaps more important than the hemodynamic effects, ACE inhibitors suppress ventricular remodeling and endothelial dysfunction, accounting for the improvement in mortality noted with this medication in DCM.[120] Other afterload-reducing agents such as selective phosphodiesterase-3 inhibitors may improve quality of life but do not affect mortality; consequently, they are rarely administered in chronic situations. More recently, spironolactone has assumed a greater role in treatment; with the addition of spironolactone in a large double-blind randomized trial,[121] mortality was reduced by 30% from all causes in patients receiving standard ACE inhibitors for DCM. Although aldosterone increases sodium retention and reduces potassium loss, it has also been shown to cause myocardial and vascular fibrosis, impair baroreceptor function, and prevent catecholamine reuptake by the myocardium.

Historically, ß-blockers were contraindicated in DCM. In 1982, Bristow and associates[122] found a decreased catecholamine sensitivity and ß-receptor density in the failing human myocardium, leading to loss of contractility. The association between excess sympathetic activity and the failing heart has been demonstrated.[123] Recently, the dobutamine stress test has been shown to identify changes in the ventricle of patients with asymptomatic to mildly symptomatic DCM that reflect increased sympathetic stimulation.[124] This finding may aid in the initiation of ß-blockers in patients with normal resting parameters. The use of ß-blockers in DCM has provided not only symptomatic improvement, but its use has also provided substantial reductions in sudden and progressive death with NYHA functional class II and III heart failure.[125] This finding is especially significant because almost 50% of deaths are sudden.[126]

High-grade ventricular arrhythmias are common with DCM. Approximately 12% of all patients with DCM die suddenly,[127] but overall prediction of sudden death in an individual with DCM is poor.[126] Electrophysiologic testing has a poor negative predictive value that limits its usefulness. The best predictor of sudden death remains the degree of left ventricular dysfunction. Patients who have sustained ventricular tachycardia or out-of-hospital ventricular fibrillation are at increased risk for sudden death, but more than 70% of patients with DCM have nonsustained ventricular tachycardia during ambulatory monitoring.[119] Furthermore, the prognostic significance of ventricular arrhythmias and the response to prophylactic antiarrhythmic therapy in patients with DCM is not well established.

Antiarrhythmic medications are hazardous in patients with poor ventricular function because of their negative inotropic and sometimes proarrhythmic properties. Antiarrhythmic therapy may only be considered in DCM if inducible ventricular tachycardia or symptomatic arrhythmias are present. Class I agents (sodium-channel blockers) are not indicated, because they have clearly demonstrated increased mortality in patients with advanced CHF.[112] Amiodarone is the preferred antiarrhythmic agent in DCM, because its negative inotropic effect is less than other antiarrhythmic medications[126] and its proarrhythmic potential is the lowest.[128] Counter to most trials of antiarrhythmic prophylaxis, results of a large multicenter trial of antiarrhythmic therapy in patients with CHF[128] demonstrated that amiodarone was associated with a significantly lower mortality rate of 38%, compared with 62% without therapy in persons with a high resting heart rate. Notwithstanding these results, ICDs reduce the risk of sudden death and improve mortality.[126,127] Recent evidence has indicated that with previous cardiac arrest or sustained ventricular tachycardia, more benefit is gained from an implantable defibrillator.[129] This conclusion is based on a 27% reduction in the relative risk of death attributed to a 50% reduction in arrhythmia-related mortality, compared with treatment with amiodarone.

Other treatments for DCM include digoxin, which has been reaffirmed as clinically beneficial in two large trials of adults.[113] The risk of thromboembolic complications is significant in DCM for adults. Patients with moderate ventricular dilation and moderate-to-severe systolic dysfunction have intracavitary stasis and a decreased ejection of blood; consequently, they are likely to receive anticoagulant agents if any history of stroke, atrial fibrillation, or intracardiac thrombus exists.

Patients who are resistant to pharmacologic therapy for CHF have received dual-chamber pacing, cardiomyoplasty, left ventricular

TABLE 24.4 Pharmacologic and Device Therapy for Chronic Heart Failure

Indication	*ACE Inhibitor*	*ARB*	*Diuretic Agent*	*Beta Blocker*	*Aldosterone Antagonist*	*Cardiac Glycosides*	*CRT*	*ICD*
Asymptomatic LV dysfunction (NYHA class I)	Indicated	If patient is ACE-intolerant	Not indicated	Post-MI Indicated[a]	Recent MI	(1) For rate control with atrial fibrillation or (2) When improved from more severe HF and in sinus rhythm	May be considered[a]	Indicated
Symptomatic HF (NYHA class II)	Indicated	Indicated with or without ACE inhibitor	Indicated if fluid retention is present	Indicated	Indicated	(1) With atrial fibrillation (2) When improved from more severe HF in sinus rhythm	Indicated[b]	
Worsening HF (NYHA classes III–IV)	Indicated	Indicated with or without ACE inhibitor	Combination of diuretic agents indicated	Indicated (under specialist care)	Indicated	Indicated	Indicated[c]	Indicated
End-stage HF (NYHA class IV)	Indicated	Indicated with or without ACE inhibitor	Combination of diuretic agents indicated	Indicated (under specialist care)	Indicated	Indicated	Indicated[c]	Not indicated[d]

[a]May be considered in patients with LVEF 30% or less, of ischemic cause, in sinus rhythm with a QRS of 150 milliseconds or longer, and with morphologic LBBB.
[b]Indicated with QRS of 130 milliseconds or longer with morphologic LBBB or QRS of 150 milliseconds or longer with nonmorphologic LBBB and EF of 30% or less.
[c]Indicated with QRS of 120 milliseconds or more with LBBB or QRS of 150 milliseconds or longer, nonmorphologic LBBB, and EF of 35% or less.
[d]Use of an ICD may be considered in patients with NYHA class IV HF who are undergoing implantation of a CRT device.

assist devices (LVADs), cardiac surgical procedures (nontransplantation), and transplantation in recent years. Cardiac resynchronization therapy with dual ventricular pacing improves the NYHA functional class and ejection fraction 6 months after implantation.[130] Placement of implantable LVADs has enabled end-stage patients to reach transplantation or has become destination therapy for those for whom transplantation is not an option.[131] If mitral regurgitation develops in patients with DCM, then mitral valve repair or replacement is recommended. Surgical intervention in this high-risk population is safe and improves NYHA classification and survival.[132] Transplantation can substantially prolong lives with current survival at 15 years of 50% if younger than 55 years of age.[133] However, limited organ availability and drug-related morbidity suggest that improvements in device therapy, either with LVADs or artificial hearts, may provide the best opportunity for increased survival.

Anesthetic Considerations

The most common cardiac procedures for patients with DCM are correction of mitral and tricuspid regurgitation, placement of an ICD for refractory ventricular arrhythmias, and device (LVAD, total artificial heart) placement or orthotopic heart transplantation. Anesthetic management is predicated on minimizing further myocardial depression, optimizing preload, and judiciously reducing afterload.

Individuals with DCM may be extremely sensitive to cardiodepressant anesthetic drugs. Historically, high-dose intravenous opioids, such as fentanyl (30 µg/kg), were considered to provide excellent analgesia and hemodynamic stability in patients with ejection fractions less than 30%,[134] but opioids will likely contribute to prolonged respiratory depression that may delay extubation. Short-acting narcotics such as remifentanil may be unsuitable for patients undergoing cardiac surgery who have poor left ventricular function attributable to a high incidence of bradycardia and severe hypotension.[135] A comparison of the remifentanil-sevoflurane anesthetic with fentanyl-etomidate-isoflurane found significantly greater reduction in mean arterial pressure and greater incidence of bradycardia with the remifentanil anesthetic.[136] Although etomidate has been shown to have little effect on the contractility of the cardiac muscle in patients undergoing cardiac transplantation,[137] ketamine has been recommended often for induction in critically ill patients[138,139] because of its cardiovascular actions attributed primarily to a sympathomimetic effect from the central nervous system. Ketamine is a positive inotrope in the isolated rat papillary muscle and, more importantly, in a model of cardiomyopathic hamsters; it did not display a negative inotropic effect.[140] These findings make ketamine (less than 0.5 mg/kg) an excellent choice to use in combination with fentanyl for induction in patients with severe myocardial dysfunction, secondary to cardiomyopathy. The use of propofol with cardiomyopathy may be a concern, because cardiovascular depression has been observed, possibly attributable to an inhibition of sympathetic activity and a vasodilatory property. However, in a cardiomyopathic hamster model, no direct effect on myocardial contractility was observed with propofol.[141] Caution is still prudent with propofol, as it is with any drug, because of its indirect inhibitory effects on the sympathetic activity on which many patients with cardiomyopathy and reduced left ventricular function may depend for hemodynamic stability. As has been stated previously, however, the choice of a particular drug or drug combination is likely less important than how the drugs are used. If the anesthesiologist is vigilant and judicious with his or her drug dosing, and if he or she anticipates and treats hypotension before it occurs, then induction can likely proceed safely with a variety of pharmacologic regimens, including propofol.

Volatile agents have long been a theoretical concern in persons with failing hearts because of their known depressant effects on myocardial contractility. The effect of currently used volatile anesthetic agents on intrinsic myocardial contractility is difficult to assess. Animal data indicate halogenated volatile agents may have more profound negative inotropic effects in cardiomyopathic muscle than in healthy cardiac muscle.[142] Although an anesthetic technique that minimizes myocardial depression is desirable, there is little support from an evidence-based cardiovascular standpoint for the selection of one agent over another in adults. Although the failing myocardium has been thought to be more sensitive to the depressant effects of volatile agents, synergistic myocardial depression in the presence of moderate left ventricular dysfunction and volatile agents has not been demonstrated.[143] Desflurane, which possesses the lowest blood-gas partition coefficient of the volatile agents and allows for rapid induction and emergence, would appear to have some theoretical benefit for early extubation in patients undergoing cardiac surgery. In healthy hamster papillary muscles, desflurane did not appear to have a negative inotropic effect, although a profound negative inotropic effect was demonstrated in cardiomyopathic papillary muscles.[144] Conversely, sevoflurane and desflurane were not shown to adversely affect the ability of the LV to

respond to increased work, despite their negative inotropic properties, in patients undergoing cardiac surgery and placed on CPB.[145]

Invasive monitoring is commonly used for patients with DCM undergoing surgical procedures during which abrupt hemodynamic changes may be of clinical significance. The use of more aggressive monitoring, however, will depend not only on the patient but also on the procedure that he or she is undergoing. Patients receiving ICDs, for example, although usually having severely depressed left ventricular function, are routinely managed with a peripheral intravenous lines and a noninvasive blood pressure cuff. Echocardiography may be useful for patients undergoing both cardiac and noncardiac surgical procedures, because it can offer real-time information that may be used in conjunction with other data to assess the adequacy of cardiac function for supporting the metabolic needs of the body.

Hypertrophic Cardiomyopathy

Although Brock[146] published a case of functional left ventricular outflow track obstruction, or what he called "acquired aortic subvalvular stenosis" in 1957, Robert Donald Teare, a British pathologist and specialist in forensic medicine who would later perform the autopsy of Jimi Hendrix, presented the first case series of eight patients with HCM under the title of *Asymmetrical Hypertrophy of the Heart in Young Adults* in 1958.[147,148] For those with an interest in the history of medicine and in the evolution in our understanding of what we now call HCM, Teare's publications in 1958 and the succeeding years are fascinating.[147,149–151] More than 50 years later, Teare's original 1958 publication highlights both the understanding and the misunderstandings that continue to affect the thinking of the disease today.[106,152] To begin to understand something of the genetics, the clinical diagnosis, and the natural history of the disease, returning to Teare's 1958 piece is worthwhile.

Teare's first case is that of an apparently healthy 14-year-old boy who first suffers a "blackout" while riding his bike; 5 months later, he collapses suddenly on the playground at school. He is dead when he arrives at the hospital 20 minutes later. At autopsy, he is found to have a heart with "localized and diffuse hypertrophy of the interventricular septum" (Fig. 24.25). Microscopically, the myofibrils are arranged in "bizarre" fashion, "running in divers[e] directions" (Fig. 24.26).[147] Cases two and three appear to have been otherwise healthy young men, each 25 years of age, one of whom is found on a preemployment physical to have a "soft high-pitched systolic murmur just internal to the apex of the heart." An ECG was "grossly abnormal," with T-wave inversions in the anterior precordial leads and Q waves in the anterolateral leads (Fig. 24.27). Although one develops "auricular fibrillation," both develop signs and symptoms of CHF and die suddenly and unexpectedly. On autopsy, their hearts appear similar to that of the 14-year-old boy. Cases four and five are young women, both bearing the stigmata of CHF, both troubled by paroxysmal "auricular fibrillation," in one case complicated by a presumed cardioembolic cerebral infarct. One dies suddenly after collapsing while running to catch a bus, whereas the other dies after an attempt at surgical intervention for decompensated heart failure. Cases six, seven, and eight are but variations on the same theme: three young men, ages 33, 28, and 29 years old, respectively, all previously healthy, and all dead after a sudden collapse under benign circumstances. In each case, "localized hypertrophy of the interventricular septum with a complete absence of vascular, coronary, or aortic disease" is demonstrated.

In closing his series, Teare leaves an Addendum at least as fascinating and provocative as the cases he had just presented: "On December 13, 1956, K. C., aged 16, a brother of Case No. 5, collapsed and died while riding his bicycle. No previous medical history was available." On autopsy, his "heart was virtually identical in appearance with that of his sister, showing localized hypertrophy affecting the anterior wall and interventricular septum." The final line of Teare's report then points in the direction of what the study will come to be known as HCM and followed over the next 50 years: "By coincidence on the day of his death his younger sister attended the outpatient department of

Hammersmith hospital and was found to have signs identical with her sister. This family will be the subject of another paper."[147] That other paper appears 2 years later in the *British Heart Journal* under the title "A Family with Obstructive Cardiomyopathy (Asymmetrical Hypertrophy)."[150] The findings of the paper are worth reviewing, not

only for its historical significance, but also for its insights, however incipient, into issues still relevant today: the genetics of HCM and the role of genetic testing; the natural history of HCM; and the major sources of morbidity and mortality associated with HCM—sudden death, progressive heart failure, and atrial fibrillation and stroke.[106,152]

In their 1960 publication, Hollman, Teare, and colleagues[150] report on the extended family of case five from his 1957 cases series: a young woman, dead suddenly at age 21 years old, after a prodrome of what was surely progressive heart failure punctuated by atrial fibrillation complicated by a cardioembolic cerebrovascular accident. Having examined two generations of family members, Teare found a striking pattern: all three of the siblings of the young woman and her suddenly deceased brother (whose age had been given as 16 years old in the 1957 publication but as 18 in the 1960 piece) had evidence of a similar cardiomyopathy (Fig. 24.28). Furthermore, their father died suddenly at 40 years of age, also of cardiac causes, and one of their father's brothers, their uncle, had an "abnormal heart" that appeared to affect two of his children, the proband's cousins. Of the 23 individuals who Teare examined, 9, if not as many as 12, had evidence of heart disease, providing strong evidence of an underlying genetic disorder with an autosomal dominant pattern of inheritance.[147] When looking at the age and severity of disease onset, Teare noted that in the proband's generation, the disease was expressed earlier and in more severe fashion than it had in the preceding generation, consistent with what 50 subsequent years of investigation have found; that is, that sudden death is common among the young and less so among the old.[106,152] Finally, Teare found that the histories of the affected individuals were notable for symptomatic themes: atrial fibrillation, progressive exertional dyspnea, and frank heart failure. In closing his sentinel work, Teare, for all his prescient insight, plants the seed of a misunderstanding that has continued in the 5 decades since. Seeking a name to facilitate rather than confuse understanding, Teare writes, "the title *obstructive cardiomyopathy* [italics in the original] is proposed for these and similar cases."[147]

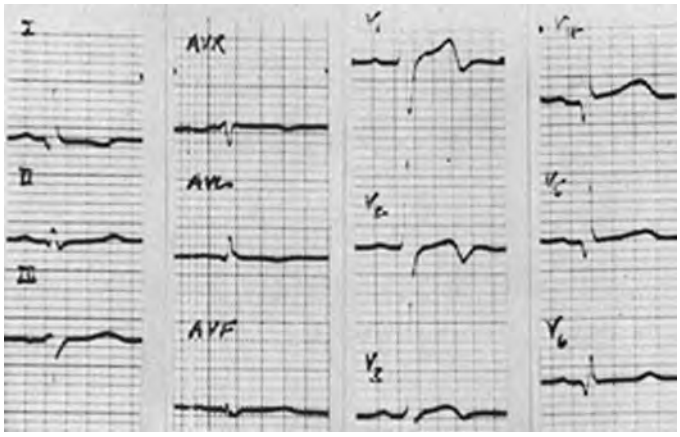

Fig. 24.27 Electrocardiogram from a patient with hypertrophic cardiomyopathy shows anterior and lateral precordial T-wave inversions in V1, V2, V3, and I, as well as Q waves in V4, V5, and V6, consistent with abnormal myocardial function and fibrosis. *(Reproduced with permission from Teare D. Asymmetrical hypertrophy of the heart in young adults.* Br Heart J. *1958;20:2.)*

Now, almost 60 years later, the sudden deaths of young, apparently otherwise healthy athletes has made HCM a seemingly familiar topic, even to the nonmedically trained, but it remains misunderstood. Among the myths, some evident even in Teare's work, that have yet to be dispelled are that HCM is necessarily obstructive (it is not); that the diagnosis is a death sentence and incompatible with a normal life expectancy (it is not); and that the diagnosis requires massive left ventricular hypertrophy that clearly distinguishes it from the physiologic hypertrophy of a performance athlete (it does not).[106,152]

So what is this disease that has been variously named and misnamed *obstructive cardiomyopathy*, *hypertrophic obstructive cardiomyopathy*, *idiopathic hypertrophic subaortic stenosis*, *muscular subaortic stenosis*, and *asymmetric septal hypertrophy*?[153] According to the most recent joint American College of Cardiology (ACC) and AHA guidelines, HCM, the preferred term, is a "disease state characterized by

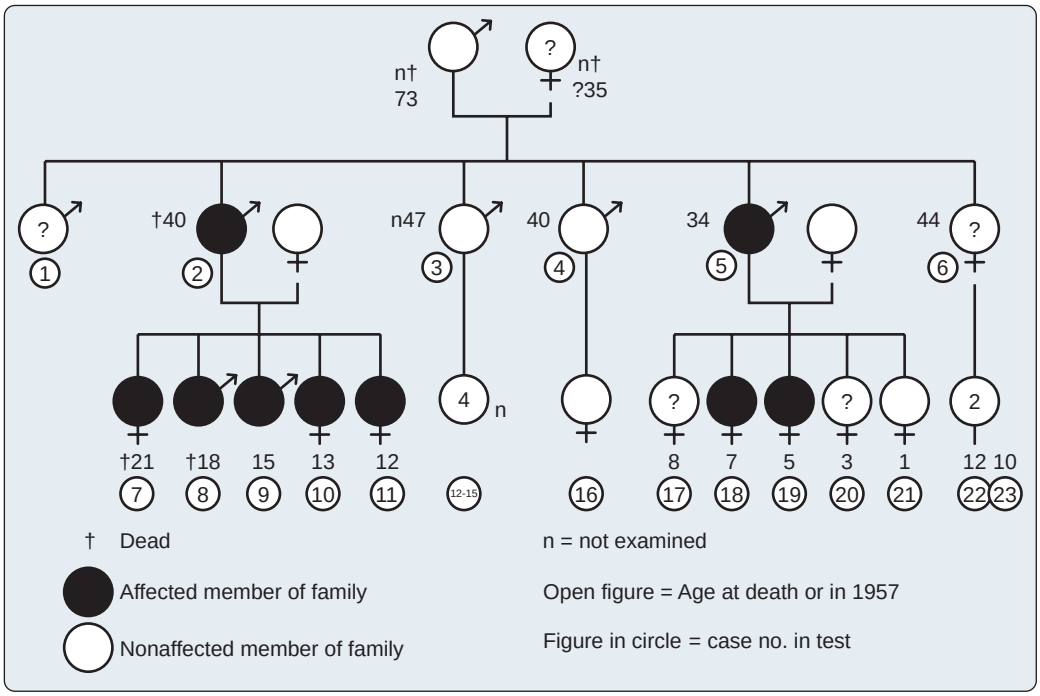

Fig. 24.28 Family tree of a patient with hypertrophic cardiomyopathy is consistent with an autosomal dominant pattern of inheritance. *(Reproduced with permission from Hollman A, Goodwin JF, Teare D, Renwick JW. Fig. 24.29 The cardiac sarcomere and the location of genes are known to cause hypertrophic cardiomyopathy. Prevalence of the mutations is shown in parentheses. *(Reproduced with permission from Maron BJ, Maron MS. Hypertrophic cardiomyopathy.* Lancet. *2013;381:24.)*

unexplained left ventricular hypertrophy associated with nondilated ventricular chambers in the absence of another cardiac or systemic disease that itself would be capable of producing the magnitude of hypertrophy evident in a given patient."[154] Although the left ventricular hypertrophy, typically quantified with TTE but increasingly assessed with cardiac MRI, may be asymmetric, it need not be nor need it show a preference for the basal septum.[154,155] Furthermore, although the clinical diagnosis is often made in the context of a left ventricular wall thickness of at least 15 mm in adults, virtually any wall thickness, even measurements within the normal range, may be compatible with the disease.[154,155] On a microscopic level, as Teare's histopathologic descriptions clearly state, HCM is a primary myocardial abnormality with sarcomeric disarray and asymmetric left ventricular hypertrophy (see Fig. 24.26).[151] The hypertrophied muscle is composed of myocytes with bizarre shapes and multiple intercellular connections arranged in a chaotic pattern.[156] Increased connective tissue, combined with significantly disorganized and hypertrophied myocytes, contributes to the diastolic abnormalities of the disease that exhibit increased chamber stiffness, impaired relaxation, and an unstable electrophysiologic substrate causing complex arrhythmias and sudden death.

HCM is both global and common, perhaps the most common inherited cardiac disease, with a prevalence of at least 1:500 if not closer to 1:200. It is estimated to affect 700,000 Americans if not more.[106,107,153] As Teare correctly inferred, HCM is inherited in autosomal dominant fashion, although with variable expressivity and age-related penetrance.[106,152,153,157] The molecular genetic basis for the disease began to be unraveled in 1989, when HCM was mapped to a locus on chromosome 14.[157–159] A year later, in 1990, the same Harvard laboratory identified in one family a missense mutation in the ß-cardiac myosin heavy chain, leading to the substitution of glutamine for arginine, and in another family an α/β-cardiac myosin heavy chain hybrid gene, thereby discovering the first two genetic bases for HCM.[157,159–161] It is now known that mutations in at least 11 different genes cause HCM and that these genes encode proteins in both the thick and thin myofilaments, as well as the associated terminal Z-disc (Fig. 24.29).[106,152,153,157] The most common of these mutations occur in the ß-myosin heavy chain (40%) and the myosin-binding protein C (40%).[106,152,153,157]

Although genetic testing for individuals with or suspected of having HCM is increasingly common, the interpretation of the results of such tests is complicated. Currently, the results of genetic testing do not predict outcome, do not allow for risk stratification, and do not determine treatment.[106,152–154,157] Genetic testing is, however, useful for identifying family members who may not meet criteria for HCM clinically but who may, nonetheless, be at risk for developing the disease on a genetic basis; that is, gene testing may identify relatives who are genetically positive but phenotypically negative (genotype positive–phenotype negative).[106,152–154,157] The significance of a positive genetic marker in an individual who does not exhibit the disease clinically is unclear. Although such individuals may be at risk of developing the hypertrophic phenotype, quantifying that risk is not currently possible, and the presence of the mutation in the absence of characteristic morphologic changes does not predict outcomes such as sudden cardiac death.[106,152–155,157] Genetic testing is useful, however, to exclude other causes of cardiomyopathy, such as Fabry disease or Danon disease, both of which have a different natural history and a require different treatment.[106,152,153,157] According to current ACC/AHA guidelines, genetic counseling should be offered to individuals with HCM, and screening should be performed in first-degree relatives, even if the prognostic value of such testing is uncertain (both Level of Evidence: B).[154] Genotype positive–phenotype negative individuals should have serial ECGs and clinical evaluations approximately every 5 years for adults and every 12 to 18 months for children and adolescents.[154]

Clinically, HCM is diagnosed most commonly with TTE but also increasingly with cardiac MRI.[106,152–155,162] The characteristic morphologic findings are those of a hypertrophied, nondilated ventricle in the

absence of alternative causes. Although guidelines reference a left ventricular wall thickness 15 mm or greater, any wall thickness, even those in the normal range, may be compatible with the diagnosis in the appropriate clinical context.[106,152–155] In cases in which TTE is inconclusive, cardiac MRI is indicated. Not only does cardiac MRI offer spatial resolution, but it also offers the potential to detect and characterize other morphologic changes that conventional echocardiography may miss: apical-variant hypertrophy, apical aneurysms and thrombus, midventricular cavity obstruction, and anomalous papillary muscle insertions contributing to either midventricular or outflow tract obstruction.[106,152–155] Furthermore, the presence of significant late gadolinium enhancement has predictive value in that its presence in 15% or more of left ventricular mass confers an increased risk of sudden cardiac death and is an indication to consider prophylactic ICD placement.[106,152,153]

In the most familiar manifestation of HCM, asymmetric hypertrophy of the basal left ventricular septum produces dynamic left ventricular outflow tract (LVOT) obstruction. More than 50 years of clinical investigation has taught, however, that there are, in fact, multiple patterns of hypertrophy, and the absence of basal hypertrophy, systolic anterior motion (SAM) of the mitral valve, and associated dynamic LVOT obstruction does not exclude the diagnosis of HCM.[163,164] Other common morphologic types, frequently visualized more clearly with cardiac MRI than with TTE, include a midventricular variant and an apical variant (Figs. 24.30 and 24.31). Defining the location and extent of hypertrophy and the site of obstruction, if any, is important for surgical planning. Although asymmetric hypertrophy of the basal septum can be treated with a standard transaortic extended left ventricular septal myectomy, midventricular and apical variants may require a transapical approach or a combination of transapical and transaortic approaches.[165–172]

As Teare's cases might suggest, the initial investigations of HCM have led many to believe that the diagnosis was the equivalent of a death sentence and the prognosis was uniformly poor. It is now known that both beliefs are clearly not the case.[106,152,153,173,174] With appropriate evaluation, treatment, and surveillance at an institution capable of providing coordinated, multidisciplinary care, HCM is compatible with a normal life expectancy, and mortality in individuals with HCM is most commonly due not to the disease itself but to other causes (Fig. 24.32).[106,152–154,173]

If Teare's early descriptions of HCM led us to believe mistakenly in the disease's poor prognosis, then they presciently and correctly illustrate its untreated and natural history.[147,150] Clinically, patients tend to progress along one or more of three pathways: sudden cardiac death, heart failure, and atrial fibrillation with or without cardioembolic stroke (Fig. 24.33).[106,152–154]

Sudden cardiac death, usually from ventricular tachycardia or ventricular fibrillation, is rare (approximately 1% per year in HCM patients), and the rate is decreasing with the increased placement of ICDs as a primary or secondary prevention.[106,152–155] As Teare's cases again illustrate, sudden cardiac death is more common among the young than the old.[106,147,150,152–154,175] Placement of an ICD is the only treatment proven to improve mortality in HCM patients, but deciding in whom and when to place such a device is complicated.[106,152–155] As the ACC/AHA guidelines make clear, any decision to place a device should take into consideration sound clinical judgment and the preferences of the patient while explicitly acknowledging the risks, benefits, and uncertainties of implantation.[154,155] Clearly, ICDs are recommended as secondary prevention for those HCM patients with a personal history of cardiac arrest, ventricular fibrillation, or ventricular tachycardia (Fig. 24.34).[106,152–155] For patients without such a history in whom placement is contemplated for primary prevention, the decision should take into account the presence of the major proven risk factors for sudden cardiac death, which include a family history of sudden death attributable to HCM in a first-degree relative, unexplained syncope, massive left ventricular hypertrophy with wall thickness 30 mm or greater, repeated episodes of nonsustained ventricular tachycardia, an inappropriate systemic systolic blood pressure response during exercise testing, and, more recently, the presence of significant late gadolinium enhancement (≥15% of left ventricular mass) on cardiac MRI.[106,152–155,176] Other potential sudden cardiac death risk modifiers whose presence or absence may help in the decision of whether to place an ICD include significant resting LVOT obstruction (≥0 mm Hg), the presence of a left ventricular apical aneurysm, end-stage disease with systolic heart failure, and a left ventricular ejection fraction less than 50%, participation in strenuous competitive sports, obstructive coronary artery disease, and age 60 years or older, the latter recognizing that sudden cardiac death is less common among older individuals than it is among the young.[106,152–155,175]

As stated previously, ICD placement is the only intervention proven to prolong life in patients with HCM. Pharmacologic therapy with ß-blockers or calcium-channel blockers may offer symptom relief, but it does not improve mortality.[106,152–153] Defibrillators are not without complications, however, which occur at an estimated annual rate of 4% to 5% and include inappropriate device discharge, lead fracture or dislodgement, device-related infection, and device-associated bleeding or thrombosis.[106,152–154]

When the subject of sudden cardiac death is mentioned, the affected population that comes most frequently to mind is the young, apparently otherwise healthy, competitive, frequently high-performance athletes. In this population, HCM is the most common cause of sudden cardiac death.[106,152–154,177,178] Both American and European cardiology societies recognize that participation in strenuous competitive sports by patients with HCM increases the risk of sudden cardiac death and that refraining from participation can decrease it.[179,180] Patients with HCM are encouraged not to participate in strenuous sports, regardless of the presence of an ICD, regardless of previous septal reduction, and regardless of the presence of LVOT obstruction (Level of Evidence: C).[154] Screening programs have met with mixed success, and American cardiology societies currently do not endorse mandatory electrocardiographic screening of young athletes.[106,153,181]

The second pathway along which HCM may progress is that of heart failure, initially diastolic and subsequently systolic.[106,152–155] Although many patients with HCM will remain asymptomatic and enjoy a normal life expectancy, others will become symptomatic, complaining of dyspnea on exertion, palpitations, and chest pain. Almost one half of HCM patients will develop signs and symptoms of heart failure.[106,152–155] Although the symptoms of heart failure frequently reflect dynamic LVOT obstruction and compromise of forward flow, especially under the conditions of hypovolemia, tachycardia, and increased contractility as may occur during exercise or stress, they may occur in the absence of obstruction, reflecting instead an imbalance of myocardial oxygen supply and demand in the context of a grossly hypertrophied heart with an endocardium constantly on the brink of ischemia; impaired left ventricular diastolic function with compromised relaxation and compliance; and the presence of often dynamic mitral regurgitation.[105,105,152–155]

For patients with the classic asymmetric hypertrophy of the basal left ventricular septum, as opposed to those with either the midventricular or apical variant HCM, obstruction occurs as blood ejects from the apex of the LV through the outflow tract and across the aortic valve, passing through a channel of changing caliber created by the hypertrophied basal septum and SAM of the mitral valve apparatus. The outflow tract diameter and thus the obstruction are dynamic and dependent on loading condition. Hypovolemia, decreased systemic vascular resistance (SVR), tachycardia, and increased contractility, all of which may occur with exercise, stress, and surgical intervention under anesthesia, act in concert to exacerbate outflow tract obstruction. For clinical decision-making purposes, it is the peak (or maximum) instantaneous gradient that influences treatment decisions. A resting gradient 30 mm Hg or greater across the LVOT is consistent with basal obstruction and is an independent predictor of heart failure and death, whereas a gradient 50 mm Hg or greater, either with rest or provocation, is considered sufficient to prompt consideration of surgical or percutaneous septal reduction in a severely symptomatic patient.[106,152–154,182]

TTE is the modality of choice for the evaluation of HCM. Two-dimensional echocardiography usually allows the clinician to analyze the morphologic characteristics of the disease and determine the location

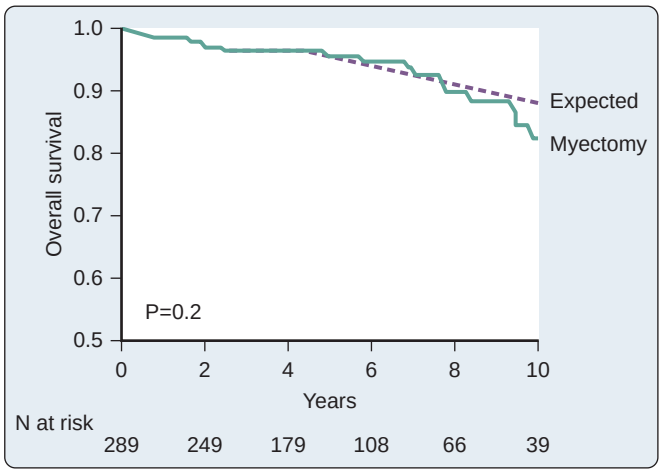

Fig. 24.32 Overall survival after surgical myectomy for obstructive hypertrophic cardiomyopathy is compared with age- and gender-matched general populations. *(Reproduced with permission from Ommen SR, Maron BJ, Olivotto I, et al. Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy.* J Am Coll Cardiol. *2005;46:473.)*

of the hypertrophy. Doppler and color-flow imaging have characteristic appearances in HCM. Continuous-wave Doppler is used to quantify the gradient across the LVOT. The Doppler signal has a unique "dagger-shaped" appearance (Fig. 24.35). The LVOT Doppler signal is typically obtained with an apical position of the transducer during TTE or from a deep transgastric view when TEE is used. If the LVOT gradient is less than expected, then provocative maneuvers should be used in an effort to demonstrate an increased gradient. Decreasing preload and ventricular filling with a Valsalva maneuver or inhalation of amyl nitrite are noninvasive techniques that can be used in the conscious patient (see Fig. 24.35). With severe obstruction, mitral regurgitation usually accompanies LVOT obstruction, in a classic pattern of EJECTION → OBSTRUCTION → REGURGITATION. With the anterior leaflet likely both pushed and drawn into the outflow tract, the jet of mitral regurgitation is typically directed posteriorly (Figs. 24.36 and 24.37).[183] If the jet is not directed posteriorly or if there are multiple jets, then another cause for the regurgitation is likely, and the valve should be interrogated in greater detail. Although posteriorly directed, mitral regurgitation associated with dynamic LVOT obstruction, even when severe, rarely requires surgical intervention and will largely resolve after the cause is addressed (specifically, LVOT obstruction secondary to basal septal hypertrophy). However, mitral regurgitation caused by organic lesions, such as mitral valve prolapse (MVP) or a flail leaflet, will not.[166,168–170,184] An unfortunately common mistake made at institutions unfamiliar with the pathophysiologic implications of basal septal hypertrophy and dynamic

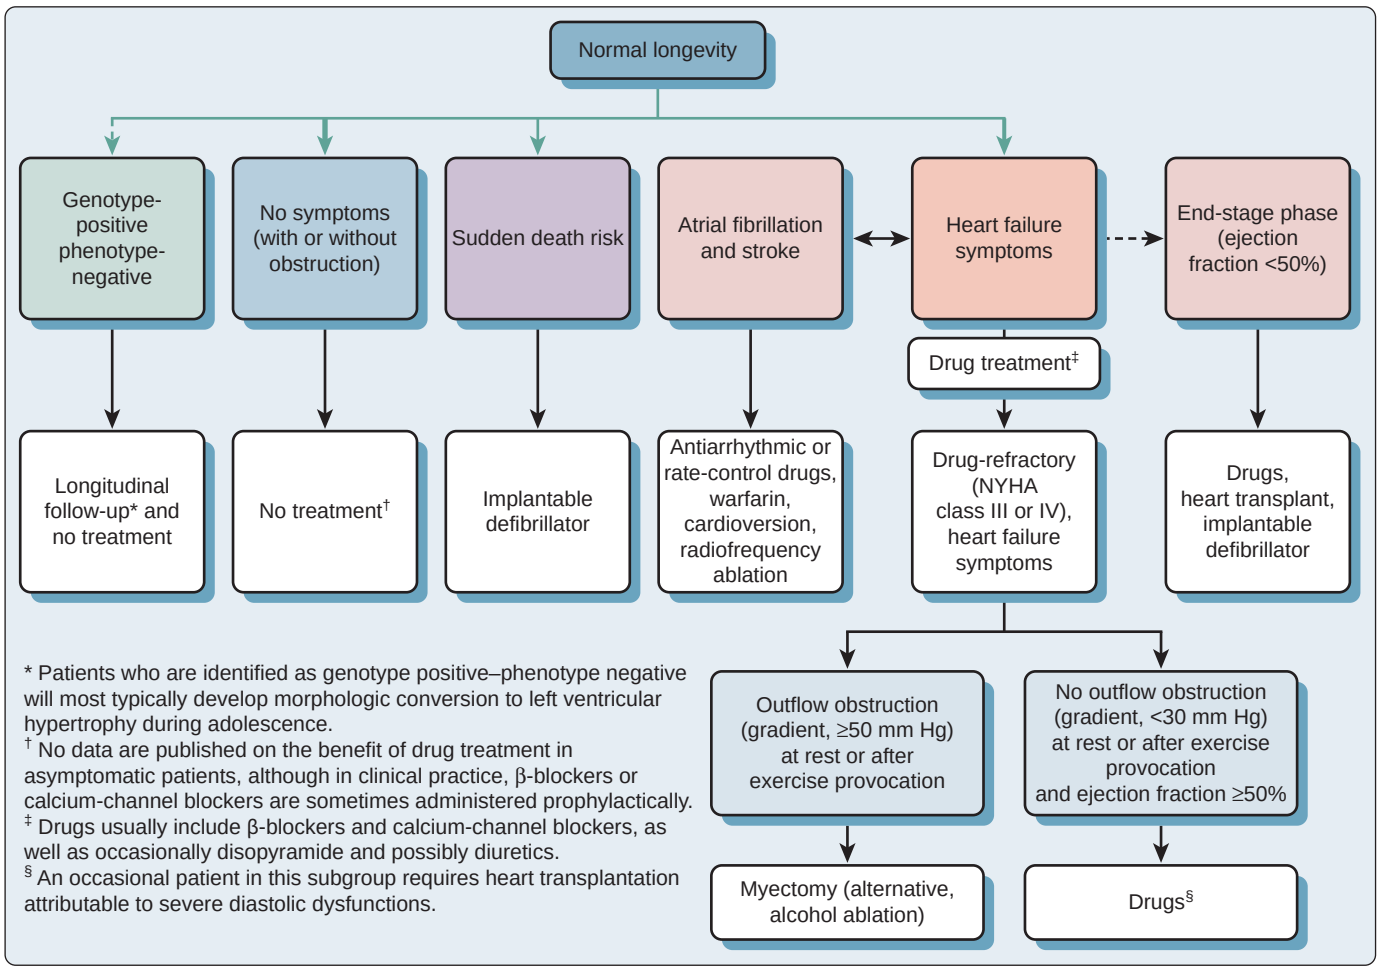

Fig. 24.33 Prognostic pathways and treatment strategies for various presentations of hypertrophic cardiomyopathy. Pathways are not necessarily mutually exclusive. *Colored arrow thickness* represents the proportion of patients affected for every pathway. *NYHA,* New York Heart Association. *(Reproduced with permission from Maron BJ, Maron MS. outflow tract obstruction is offering a patient with progressive heart failure from severe mitral regurgitation, secondary to SAM, a mitral valve repair or even replacement without addressing the culprit septal hypertrophy. Almost inevitably, symptoms in these patients will recur, and the patients will return, now for a secondary sternotomy and the indicated procedure that would have likely obviated any intervention on the mitral valve, specifically, a septal myectomy.

The mechanism of outflow tract obstruction and mitral regurgitation in cases of basal septal hypertrophy is complicated and frequently misunderstood.[183] Conventional wisdom would state that flow

acceleration during systolic ejection across a narrowed outflow tract is associated with a region of low pressure that then "sucks" the anterior leaflet of the mitral valve into the outflow tract, producing dynamic obstruction in accordance with Bernoulli principle and the Venturi effect. Whereas early surgical descriptions suggested that outflow tract narrowing was due to a muscular ring or sphincter that contracted during systole, current consensus suggests that the obstruction reflects the interactions of a hypertrophied septum, abnormal anatomy of the mitral valve and its associated apparatus, and abnormal patterns of blood flow in the LV (see Fig. 24.37).[183] An elongated anterior valve leaflet, anterior displacement of the papillary muscles, and a more anterior coaptation margin conspire to create anterior motion of the mitral valve even before aortic valve opening. As blood then courses from the apex across a bulging basal septum, it pushes against the atrial side of the anterior mitral valve leaflet, displacing it into the outflow tract as the aortic valve begins to open. With aortic valve opening and incipient ejection, the Venturi effect may then act in concert to exacerbate outflow tract obstruction, with the anterior leaflet of the mitral valve first pushed and then pulled across the LVOT, resulting in SAM of the anterior mitral leaflet.[183]

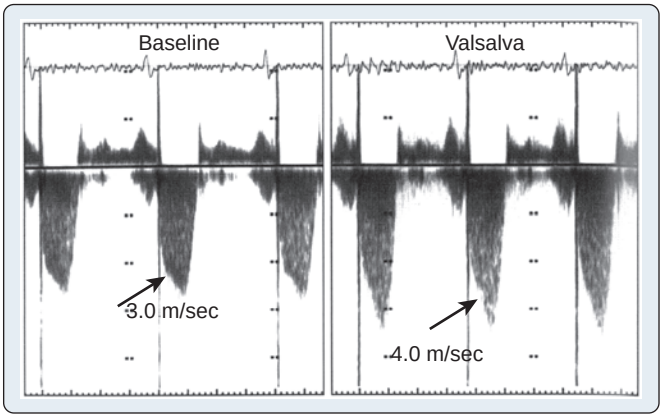

Fig. 24.35 Continuous-wave Doppler spectra obtained from the apex demonstrates dynamic left ventricular (LV) outflow tract obstruction. Note the typical late-peaking configuration resembling a dagger or ski slope *(arrows)*. The baseline *(left)* velocity is 2.8 m/sec, corresponding to the peak LV outflow tract of 31 mm Hg. With the Valsalva maneuver *(right)*, the velocity increases to 3.5 m/sec, corresponding to a gradient of 55 mm Hg. *(From Oh JK, Seward JB, Tajik AJ:* The echo manual*, ed 3, 2006. For patients with symptoms of heart failure attributable to outflow obstruction, the first-line treatment is pharmacologic therapy with ß-blockers with the express purpose of providing symptom relief. As has been stated previously, pharmacologic therapy has not been shown to improve mortality or to alter the morphologic substrate.[105,106,152–155] ß-Blockers are designed to target the exacerbators of outflow tract obstruction: increased contractility, tachycardia, and hypovolemia with decreased end-diastolic volume and stroke volume. ß-Blockers are negative inotropes and chronotropes, and by slowing the heart rate, they allow for longer diastolic filling and increased stroke volume. For patients unable to tolerate ß-blockers, nondihydropyridine calcium channel blockers such as verapamil and diltiazem are second-line agents, although they may exacerbate outflow tract obstruction by lowering mean arterial pressure, especially in patients with significant resting outflow tract gradients and patients with depressed systolic function. For patients who remain symptomatic, despite treatment with either or both ß-blockers and calcium channel blockers, both of which may lower exercise-induced but not basal gradients, disopyramide can reduce resting outflow tract gradients and afford a degree of symptom relief.[105,106,152–155]

For patients with persistent symptoms despite pharmacologic therapy, interventional therapy with either alcohol septal ablation or surgical myectomy is the next option. For patients with severe symptoms (NYHA functional class III or IV) and severe resting or provoked LVOT obstruction (≥50 mm Hg), despite maximal medical

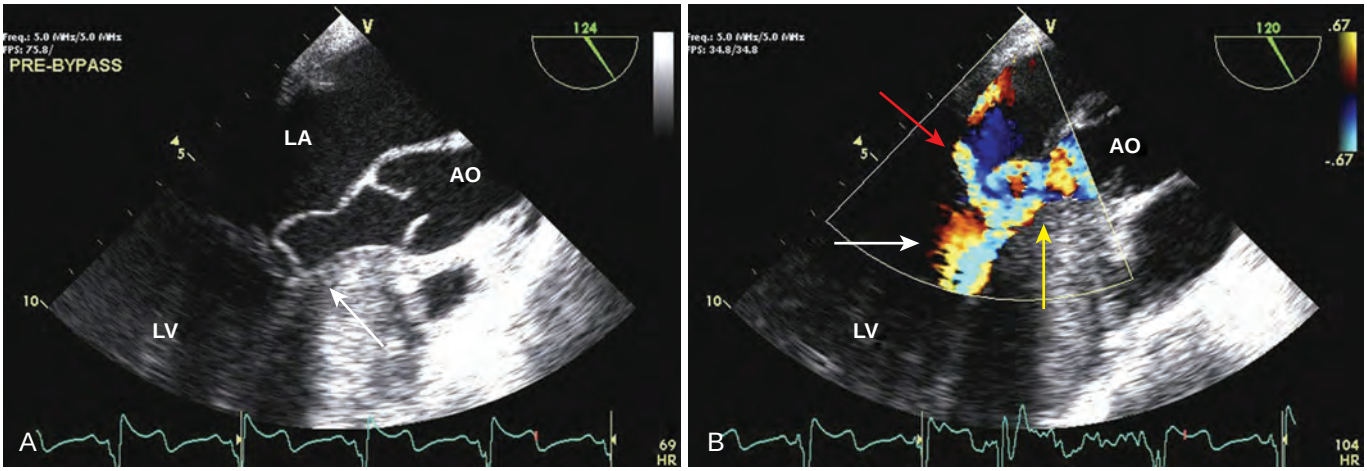

Fig. 24.36 Transesophageal midesophageal long-axis view of the aortic valve and left ventricular outflow tract (LVOT) in a patient with hypertrophic obstructive cardiomyopathy. (A) Two-dimensional echocardiography during systole shows a thickened basal septum *(white arrow)* and systolic anterior motion (SAM) of the anterior leaflet of the mitral valve, creating dynamic LVOT obstruction. (B) Color-flow Doppler shows flow acceleration beginning at the site of the septal hypertrophy *(white arrow)* and becoming more severe in the narrowed LVOT *(yellow arrow)*. Mitral regurgitation associated with SAM is typically directed posterolaterally *(red arrow)* and will typically improve if not resolve after myectomy. Jets of mitral regurgitation directed centrally or anteriorly suggest an additional cause for the regurgitation that may persist after myectomy and may need to be addressed with a separate surgical intervention on the mitral valve. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle. *(Reproduced with permission from Oliver WC, Mauermann WJ, Nuttall GA. Fig. 24.38 Surgical technique for transaortic extended left ventricular septal myectomy for isolated basal septal hypertrophy. The incision begins at the nadir of the right aortic cusp and continues to the anterior leaflet of the mitral valve. The incision should extend apically past the point of contact between the anterior mitral valve leaflet and the hypertrophied basal septum to the base of the papillary muscles. In the classic technique, the incision is extended only up to 3 cm ventricularly from the aortic valve, whereas in the technique described by Schaff at the Mayo Clinic, the incision extends up to 7 cm ventricularly from the aortic valve, creating an *extended* left ventricular septal myectomy. The surgeon can frequently visualize the point of contact between the anterior mitral valve leaflet and the hypertrophied basal septum as whitish scar tissue discoloring the normally red endocardium. *(Reproduced with permission from Mayo Foundation for Medical Education and Research. treatment, surgical septal myectomy is a class I indication, provided that it can be performed by an experienced surgeon working at a facility capable of offering patients specialized, multidisciplinary, coordinated care.[106,152–155,185] Surgical intervention has repeatedly been shown to offer durable relief from outflow tract obstruction, thereby decreasing if not abolishing resting and provoked outflow tract gradients, normalizing left ventricular filling pressures, reversing mitral regurgitation, and relieving the symptoms that had been associated with progressive diastolic heart failure.* With operative mortality now less than 1% at major medical centers that specialize in surgical resection, septal myectomy has the potential to normalize life expectancy for affected individuals.[173]

Surgical septal myectomy is both complicated and misunderstood. It is misunderstood, because the surgical technique will vary considerably, depending on the location of the ventricular hypertrophy and the obstruction, if there is any. The most common and familiar phenotype of HCM is asymmetric hypertrophy of the basal septum, producing dynamic LVOT obstruction. When basal septal hypertrophy is the diagnosis, the indicated procedure is a transaortic septal myectomy (Fig. 24.38).[166,168,170] After the initiation of CPB, the application of the aortic cross-clamp, and the administration of cardioplegia, a low transverse aortotomy is made and the subaortic septum is exposed. The prominent basal septum is excised with an excision extending from the nadir of the right aortic sinus leftward to the anterior leaflet of the mitral valve using a meticulous technique to avoid incurring complete heart block, a membranous ventricular septal defect (VSD), or injury to the mitral or aortic valves (Fig. 24.39).[166,168,170] In the classic technique described by Morrow, tissue is removed up to 3 centimeters apically from the aortic valve, whereas the current technique described by Schaff uses an extended resection up to 7 centimeters from the valve.[166,168,170,187,188]

With a midventricular variant of HCM, obstruction occurs at the midventricular level, attributable to the apposition of the ventricular septum and the papillary muscles. Because outflow tract obstruction is not present, at least in the pure form of the midventricular variant, SAM of the mitral valve and associated mitral regurgitation are unlikely. Additionally, the pressure gradient occurs not across the outflow tract but across the cavity of the ventricle, from apex to base. The elevated apical pressures, secondary to midcavitary obstruction, may favor the formation of an apical pouch (Fig. 24.40). Stagnant blood in the pouch may then predispose to apical thrombus formation. Given the location of the obstruction, a transaortic approach may not allow for sufficient exposure for adequate surgical resection; therefore a transapical approach is required (Figs. 24.41 and 24.42).[165,166,171,172] For patients with obstruction at both the base and midventricular levels, the surgeon may need to perform sequential resections from transaortic and transapical approaches, thereby lengthening the surgical procedure.[165,166]

For patients with apical variant HCM, left ventricular hypertrophy occurs predominantly at the apex, producing a small chamber size. The combination of a small volume chamber, a hypertrophied and stiff myocardium, and abnormal diastolic relaxation produces a significant impairment in diastolic filling and results in abnormally low

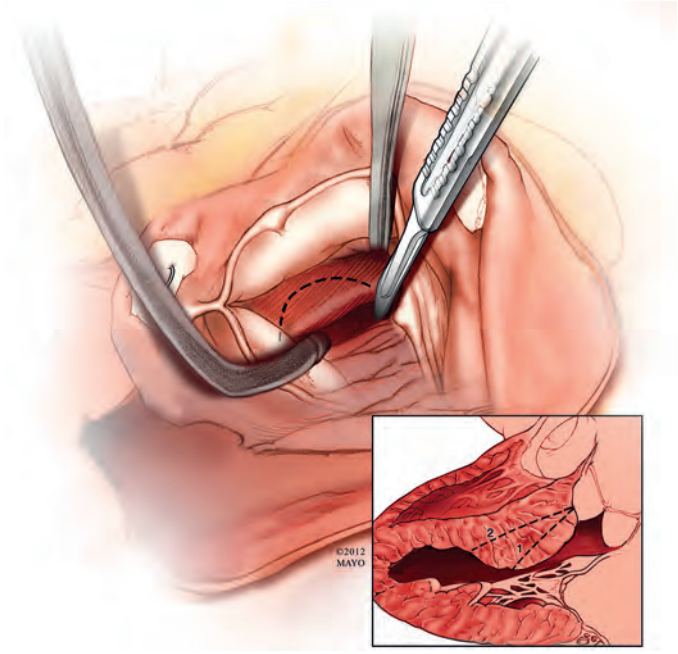

Fig. 24.39 Surgical technique for transaortic extended left ventricular septal myectomy for isolated basal septal hypertrophy. A surgeon's view of the transaortic approach looks from the proximal ascending aorta across the opened aortic valve and apically into the left ventricular cavity. With the patient in the supine position, the right coronary cusp sits anteriorly. The incision begins at the nadir of the right cusp and continues leftward to the anterior leaflet of the mitral valve. Incisions that are begun more rightward than the nadir of the right coronary cusp would risk injury to the membranous ventricular septum and its contained conduction tissue and would result in complete heart block. *(Inset)* The incision is successively deepened and extended apically past the point of contact between the anterior mitral valve leaflet and the hypertrophied basal septum to the base of the papillary muscles. *(Reproduced with permission from Mayo Foundation for Medical Education and Research. All rights reserved. Illustration No. e3151794-00.)*

stroke volumes. Although the left ventricular ejection fraction may be normal or even supranormal, the low stroke volume leads to a low CO and index and all the classic stigmata of heart failure. Typically, patients with the apical variant do not exhibit LVOT obstruction and do not have SAM of the mitral valve. The resection, itself, is performed transapically, as it is for midventricular variant cases (Figs. 24.43, 24.44 and 24.45).[166,167,172]

Intraoperative TEE is essential in the care of patient undergoing septal myectomy.[189] Before incision, TEE can identify both the location of hypertrophy in relation to the aortic annulus and the thickness of

the ventricular septum, which assists the surgeon in planning the location and depth of the myectomy. The mitral valve should be closely evaluated for abnormalities that may contribute to mitral regurgitation, particularly if the regurgitant jet is directed centrally or anteriorly. After the myectomy, TEE is used to assess the degree of residual mitral regurgitation and evidence of continued SAM and LVOT obstruction. The ventricular septum must also be closely evaluated for evidence of shunting via an iatrogenic VSD. It is common to see small shunts into the area of the LVOT from transection of coronary vessels at the site of the myectomy (Fig. 24.46). It is important that these shunts are not confused with shunting from a VSD. When an iatrogenic VSD occurs, the expected shunt would be from the LV into the RV, as opposed to the flow observed into the LV from transection of septal coronary artery branches. In addition, shunting through a VSD would be expected to occur predominantly during systole, whereas flow into the LV from septal perforators is predominantly during diastole.

At the Mayo Clinic, surgeons record simultaneous pressure measurements across the level of obstruction both before and after surgical resection to reconfirm and document the degree of obstruction and to ensure the adequacy of the surgical result (Fig. 24.47).[170,184] For patients with asymmetric basal septal hypertrophy and dynamic LVOT obstruction, pressure measurements are made simultaneously in the LV, proximal to the obstruction, and in the ascending aorta, distal to the obstruction (Fig. 24.48). Typically, resting and provocative gradients are recorded. For the latter, the surgeons will tap the ventricle, producing a premature ventricular contraction (PVC) and a post-PVC exacerbation of the outflow tract obstruction and gradient (Brockenbrough-Braunwald-Morrow sign) (Fig. 24.49).[184,190] In cases of gradients that are difficult to elicit, the surgeons may ask the anesthesiologists to administer isoproterenol in increments of 4 µg to produce the hyperdynamic state known to exacerbate outflow tract obstruction. If the latter maneuver is performed, then the patient should be heparinized and cannulated and ready to be placed on bypass emergently in case of profound hemodynamic deterioration. Esmolol should be readily available.

For patients with severe symptoms, despite optimal medical management, and those who are poor surgical candidates or show a strong desire to avoid open-heart surgery, alcohol septal ablation is an alternative to septal myectomy.[106,152–153,185,191] Performed in the cardiac catheterization laboratory under fluoroscopic and echocardiographic guidance, the procedure's objective is to identify a prominent

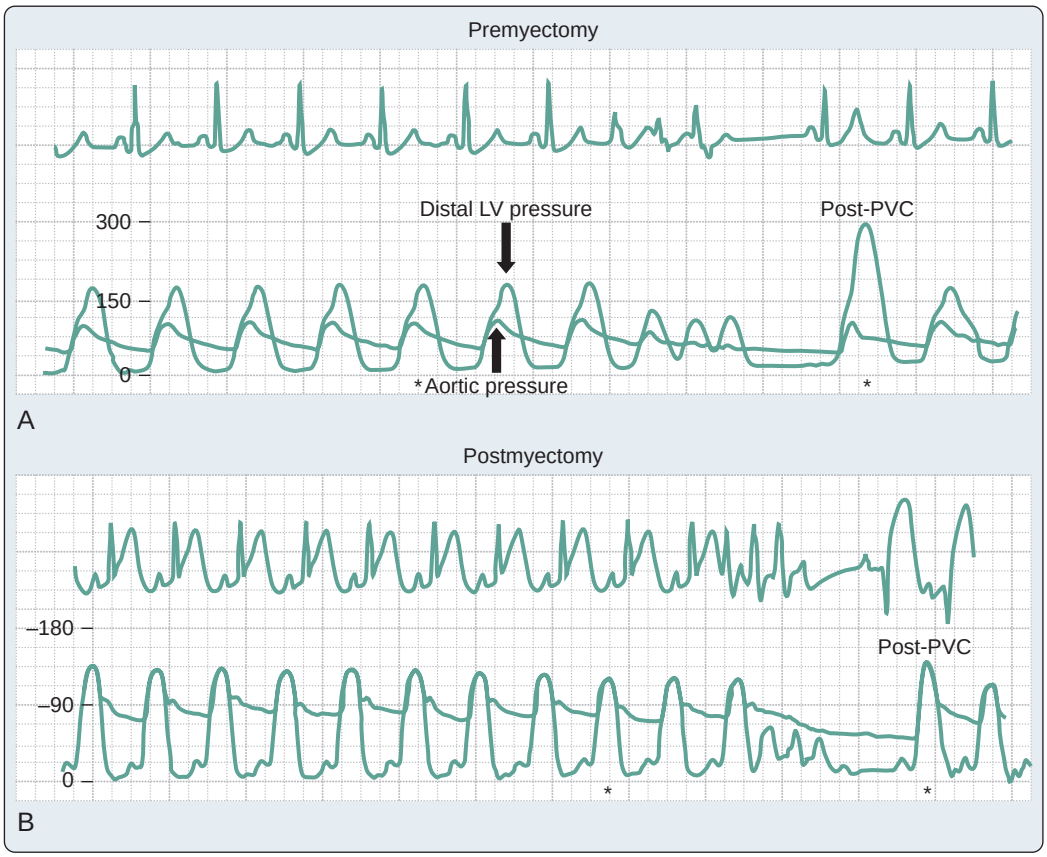

Fig. 24.47 Intraoperative pressure recordings of a patient with hypertrophic cardiomyopathy and midventricular obstruction undergoing transapical resection. (A) Preoperative pressure recording is made with simultaneous measurements in the distal left ventricular cavity and the aortic root. At rest, the left ventricular pressure was 173/8 mm Hg and the aortic pressure 98/38 mm Hg, indicating an obstructive gradient of 75 mm Hg. After a provocative premature ventricular contraction (PVC), the left ventricular pressure rose to 278/8 mm Hg, and the aortic pressure decreased to 90/38 mm Hg, producing an intraventricular gradient of 188 mm Hg. (B) Postoperative pressure recordings were made. At rest, the left ventricular pressure was 139/13 mm Hg and the aortic pressure 138/85 mm Hg, indicating trivial obstruction. After a PVC, the left ventricular pressure was 157/9 mm Hg and the aortic pressure 153/81 mm Hg, consistent with a gradient of only 4 mm Hg across the ventricular chamber. In panel B, typical electrocardiographic ST segment changes are demonstrated. A left bundle branch block pattern is common after resection along the interventricular septum. *LV*, left ventricular. *(Reproduced with permission from Kunkala MR, Schaff HV, Nishimura RA, et al. Transapical approach to myectomy for midventricular obstruction in hypertrophic cardiomyopathy.* Ann Thorac Surg. *2013;96:565.)*

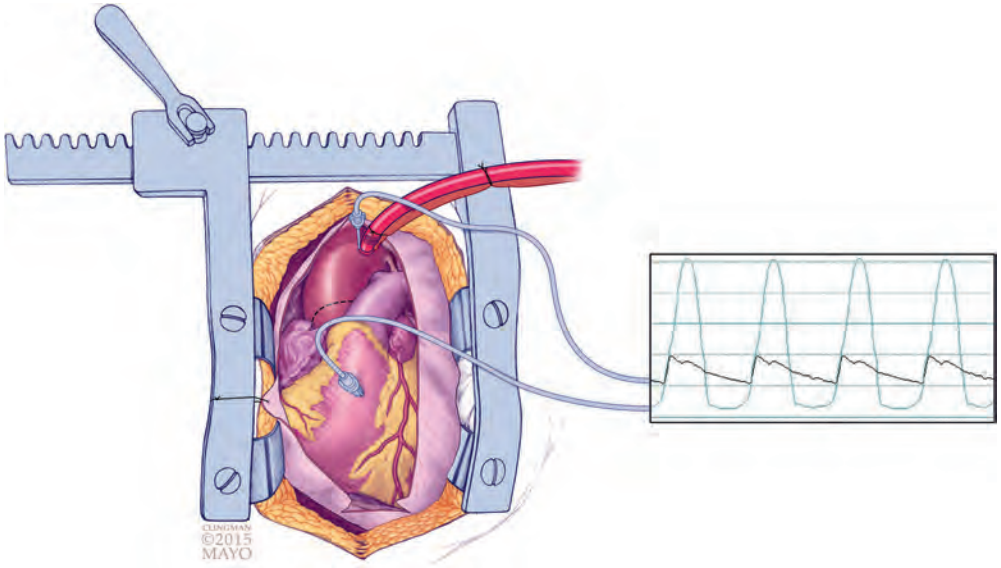

Fig. 24.48 Illustration depicts the needle placement for simultaneous pressure recordings from the left ventricle, proximal to the obstruction, and the ascending aorta, distal to the obstruction. Peak-to-peak gradients are determined by subtracting the peak aortic pressure in systole from the peak left ventricular chamber pressure in systole. *(Reproduced with permission from Mayo Foundation for Medical Education and Research. All rights reserved. Illustration No. 3397674-001.)*

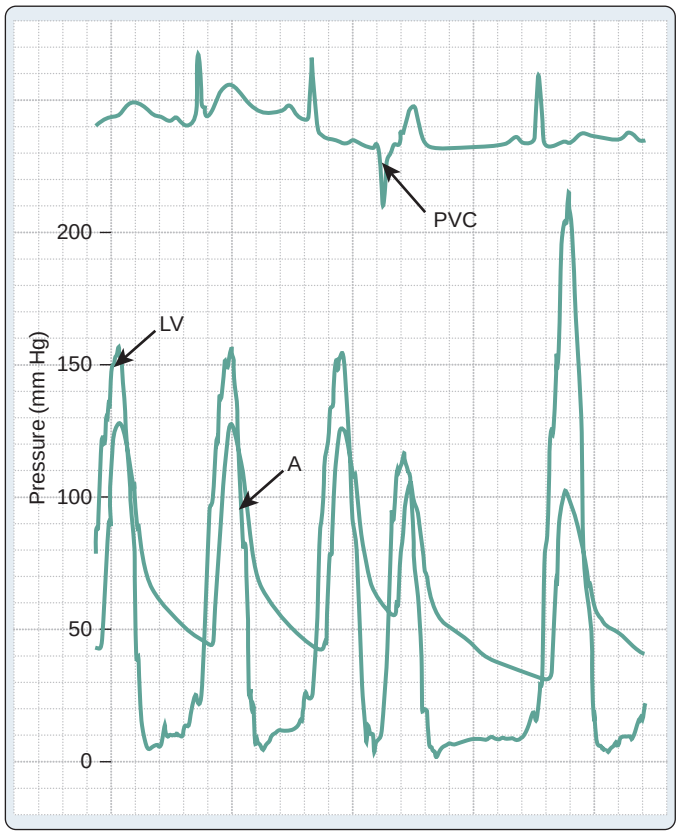

Fig. 24.49 The Brockenbrough-Braunwald-Morrow sign. After a premature ventricular contraction (PVC), the peak systolic pressure gradient increases while the systemic pulse pressure decreases, reflecting decreased stroke volume in the face of increased dynamic left ventricular outflow tract obstruction. The increased outflow tract obstruction, in turn, reflects postextrasystolic potentiation and increased contractility. In contrast, in patients with a fixed obstruction, such as aortic stenosis, the increased contractility with postextrasystolic potentiation after a PVC increases rather than decreases the systemic pulse pressure. *(Reproduced with permission from Pollock SG. Images in clinical medicine. Pressure tracings in obstructive cardiomyopathy.* N Engl J Med. *1994;331:238.)*

anteroseptal-perforating branch of the left anterior descending coronary artery that is supplying the hypertrophied, culprit portion of the basal septum. Once such a vessel is identified, 1 to 3 mL of ethanol alcohol is infused to create a localized infarction, leading to subsequent necrosis and regression of the area of the basal septum contributing to outflow tract obstruction. Although remodeling takes place over the succeeding months, the injection can affect an immediate decrease in gradient as a result of myocardial stunning.[106,152–155,185,191] The advantages of alcohol ablation are that it is minimally invasive, entails a short hospital stay, and may be more appropriate for older patients with more comorbidities. It is, however, associated with a higher risk of need for permanent pacemaker placement; a greater need for repeat procedures, secondary to recurrent or persistent obstruction; and the risk of malignant ventricular arrhythmias attributable to the transmural infarction that is produced. Furthermore, the procedure may offer little benefit to patients with the most severe symptoms and the thickest ventricles (≥30 mm), to patients whose obstruction is not due to a well-localized lesion, or to patients who need concomitant procedures, such as mitral valve intervention or coronary artery bypass grafting.[106,152–155,185,192]

The third and final pathway along which HCM may progress, again illustrated in Teare's cases, is that of atrial fibrillation, the most common arrhythmia in HCM.[106,147,152–155,193] Associated with advanced age and left atrial enlargement, atrial fibrillation occurs in as many as 25% of individuals with HCM, a rate four times greater than that for a similar general population.[106,152–155,193] Expectedly, patients with atrial fibrillation incur significant morbidity, but atrial fibrillation is not an independent risk factor for sudden cardiac death.[106,152–155,193] No strong data support rate versus rhythm control in patients with HCM. For rate control, ß-blockers and nondihydropyridine calcium channel blockers are recommended, whereas amiodarone and disopyramide are acceptable antiarrhythmic agents.[106,152–155] The annual rate of thromboembolic phenomenon has been estimated to be approximately 0.8%; therefore anticoagulation is indicated for those with chronic or paroxysmal, persistent atrial fibrillation. The CHADS (congestive heart failure, hypertension, age of 75 years, diabetes mellitus, stroke) score has not been validated in individuals with hypertrophic disease.[106,152–155]

Anesthetic Considerations

As has been stated, HCM has multiple morphologic variants, the most commonly encountered of which in the surgical unit are the basal septal variant, the midventricular variant, and the apical variant. The pathophysiologic nature and hemodynamics of the three are different. Although the strategies for anesthetic management may be similar, they are not identical.

In general, patients with basal and midventricular hypertrophy in the surgical unit have impaired diastolic and preserved systolic function. There are "burned-out" hypertrophs with severe systolic and diastolic heart failure who will require device implantation or transplantation, but they are rare and can be managed largely as any other patient with end-stage cardiac disease. Both basal and midventricular hypertrophs are physiologically obstructive, the former occurring across the LVOT and the latter occurring across the midventricular cavity, although patients with predominantly midcavitary obstruction may have outflow tract obstruction as well and vice versa. For the cardiac anesthesiologist, reviewing the preoperative ECGs is imperative to know at which level or levels, if at all, ventricular obstruction occurs and its severity.

The patients most challenging to manage hemodynamically are those with asymmetric hypertrophy of the basal septum and dynamic outflow tract obstruction. Frequently, the preoperative ECGs will document maximal instantaneous gradients across the LVOT of more than 50 mm Hg at rest and at times in excess of 100 mm Hg with provocative maneuvers. The conditions that favor obstruction, and thus hypotension, are the conditions to be avoided and treated quickly should they occur: tachycardia, increased contractility, decreased SVR, and hypovolemia.

Essentially, no evidence-based data are available to guide the choice of induction agents and maintenance medications. As mentioned previously, the choice of specific drugs or drug combinations is likely less important than how the drugs are used. Regardless of the drugs chosen, they should be used with the express goal of avoiding the conditions favoring hemodynamic decompensation. As in patients with severe aortic stenosis, hypotension may be poorly tolerated and should be treated quickly with the standard interventions.

Patients who have been followed at large referral centers should arrive to the surgical unit for a myectomy optimally medically managed. ß-Blockers or calcium channel blockers may have been uptitrated to the point of bradycardia, so that with hypotension, phenylephrine may not be the first choice of treatment. A judicious dose of ephedrine (5 mg) or a unit of vasopressin may be more effective and may not risk the loss of atrial kick that could occur as a consequence of aggressive phenylephrine administration. Although surgical myectomy is an elective procedure, for which patients should have been physiologically and pharmacologically prepared, patients with HCM may require emergent noncardiac surgery. Under conditions of pain, stress, and hypovolemia, as may occur with bowel obstruction requiring laparotomy, hemodynamic management during induction may be far more challenging. The management principles should be the same, however, although the choice of drugs and their dosing may be quite different.

Patients undergoing surgical myectomy will require an arterial line for continuous hemodynamic monitoring and will require central venous access for drug infusion and right-sided heart pressure monitoring. Although many would state unequivocally, as they would for patients with severe aortic stenosis, that arterial access needs to be obtained before induction, it does not. With vigilance, sound clinical judgment and an understanding of a given patient's physiologic condition under a given set of conditions, an arterial line may be placed safely before induction, during induction if resources are available to permit such, or after induction. Central venous access typically consists of an introducer and a PAC. The requirement for the latter is not based on evidence. In a young, otherwise healthy individual with preserved biventricular systolic and diastolic heart function undergoing basal resection with a skilled surgeon while being monitored with intraoperative TEE, a PAC may be unnecessary. Some practitioners, however, may feel uncomfortable managing a patient intraoperatively or postoperatively without its data. Intraoperative TEE, however, is essential. TEE should be used to reconfirm the location of hypertrophy and obstruction (if there is any), to characterize the mechanism of associated mitral regurgitation (if there is any), to assess the adequacy of the surgical intervention after bypass, and to look for inadvertent iatrogenic injury, such as a VSD or damage to the mitral or aortic valves.

As was mentioned previously, simultaneous pressure measurements across the level of obstruction both before and after surgical resection are recorded to reconfirm and document the degree of obstruction and to ensure the adequacy of the surgical result (see Figs. 24.47 and 24.48).[170,184] Typically, resting and provocative gradients are recorded (Figs. 24.50 and 24.51). For patients whose gradients are difficult to elicit, surgeons may ask for the administration of isoproterenol in increments of 4 μg to produce the hyperdynamic state known to exacerbate outflow tract obstruction. If the latter maneuver is performed, then the patient should be heparinized and cannulated and ready to be placed on bypass emergently in case of profound hemodynamic deterioration. Esmolol should be readily available.

With removal of the aortic cross-clamp, the myocardium may be quite irritable and the incidence of ventricular fibrillation high.[194] Amiodarone (300 mg) given before cross-clamp removal may decrease the number of defibrillations required to restore a regular, perfusing rhythm, although it does not decrease the incidence of ventricular fibrillation.[194] After myectomy, a left bundle branch block or a partial left bundle branch block is common. Preoperative right bundle branch block increases the risk of postoperative complete heart block.[166,168] Finally, with bypass separation, many patients are found clinically to have a low SVR and require repeated boluses of vasopressin and/or phenylephrine to achieve an acceptable mean arterial pressure. Such vasoplegia usually improves thereafter and typically resolves before the patient leaves the surgical unit.

Patients with apical variant HCM deserve separate mention.[165–167] In these patients, apical hypertrophy is not associated with obstruction or SAM but produces a small chamber size, which, in combination with a hypertrophied and stiff myocardium and abnormal diastolic relaxation, produces a significant impairment in diastolic filling and results in abnormally low stroke volumes. Although their calculated left ventricular ejection fraction may be normal or even supranormal, they have a depressed cardiac index in the context of their low stroke volume. Because outflow tract and even midcavitary obstruction are absent, these patients do not require the considerations of their counterparts with basal or midventricular hypertrophy. Similar to petite female octogenarians with severe aortic stenosis and long-standing hypertension, patients with apical hypertrophy may be very sensitive to

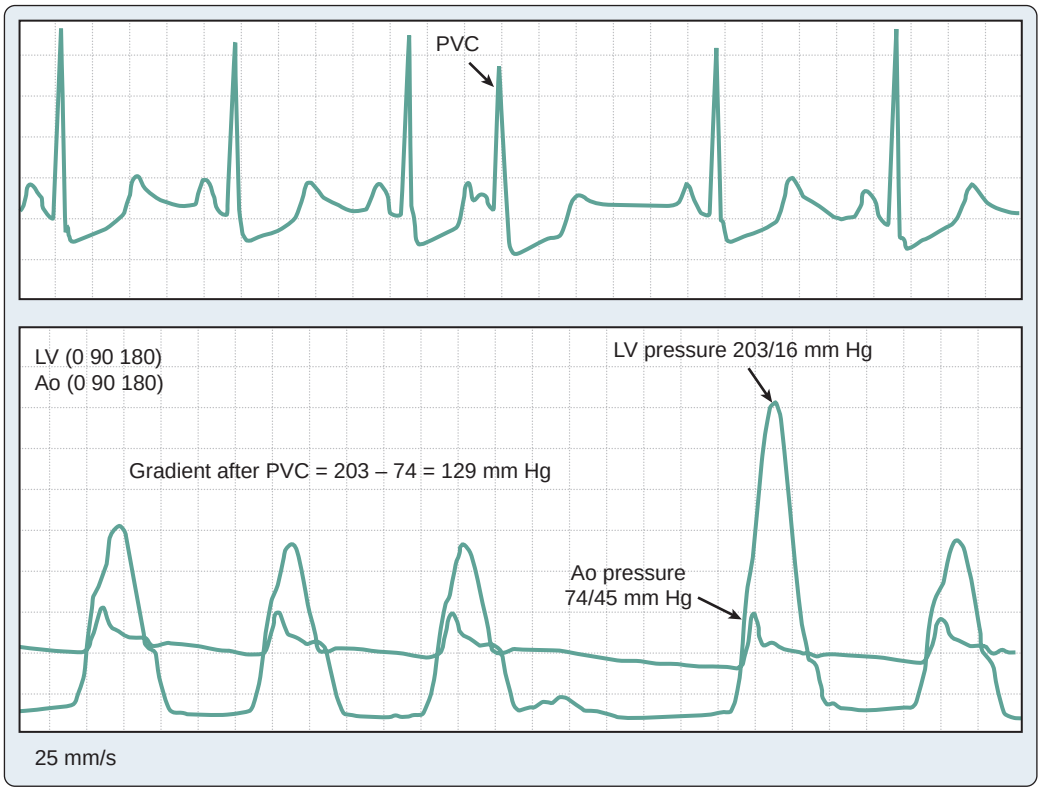

Fig. 24.50 Intraoperative pressure recordings for a patient with hypertrophic cardiomyopathy and dynamic left ventricular outflow tract obstruction. The increase in gradient after a premature ventricular contraction (a positive Brockenbrough-Braunwald-Morrow sign) is noted. *Ao,* Aorta; *LV,* left ventricle; *PVC,* premature ventricular contraction. *(Reproduced with permission from Ashikhmina EA, Schaff HV, Ommen SR, et al. Intraoperative direct measurement of left ventricular outflow tract gradients to guide surgical myectomy for hypertrophic cardiomyopathy.* J Thorac Cardiovasc Surg. *2011;142:55.)*

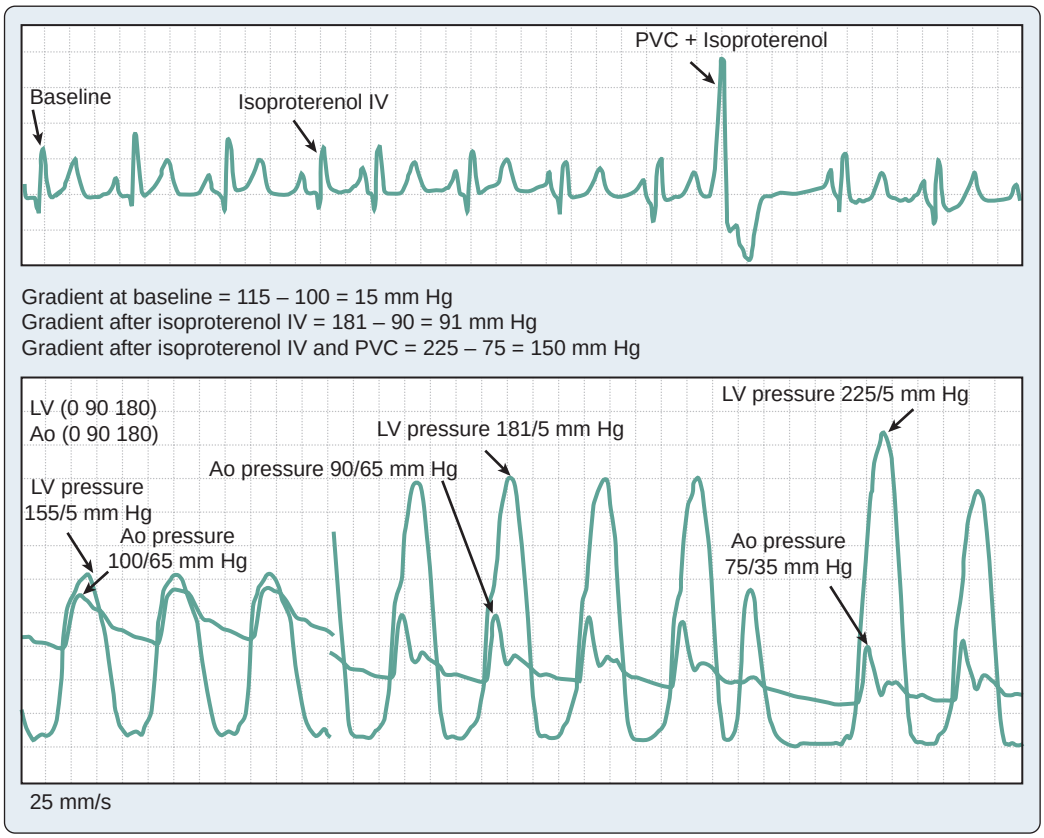

Fig. 24.51 Resting and provocative gradients in a patient with hypertrophic cardiomyopathy and dynamic left ventricular outflow tract obstruction. At baseline, the gradient between the left ventricle and aorta is 15 mm Hg. With isoproterenol infusion, the gradient increased to 91 mm Hg, whereas isoproterenol infusion and a subsequent premature ventricular contraction increased the gradient to 150 mm Hg. *AO,* Aorta; *IV,* intravenous; *LV,* left ventricle; *PVC,* premature ventricular contraction. *(Reproduced with permission from Ashikhmina EA, Schaff HV, Ommen SR, et al. Intraoperative direct measurement of left ventricular outflow tract gradients to guide surgical myectomy for hypertrophic cardiomyopathy.* J Thorac Cardiovasc Surg. *2011;142:56.)*

changes in preload and afterload. It frequently takes very little change in stroke volume to fall from normotensive to uncomfortably hypotensive or to push left-sided filling pressures to the point of pulmonary venous hypertension. As before, drug choice is likely less important than a thorough understanding of a given patient's pathophysiologic condition. Surgically, the resection for a transapical lesion is performed similar to that for midventricular variants through a transapical incision.[166,167,171,172] As is the case with a transaortic resection, transapical resection may be associated with repeated episodes of ventricular fibrillation after cross-clamp removal.

Finally, patients with midventricular obstruction may have components of basal and/or apical hypertrophy. Their intraoperative management will depend on the location of their lesion(s), which must be appreciated by a thorough review of their preoperative imaging studies. Surgical resection may require both transapical and transaortic exposure, thus prolonging modestly the aortic cross-clamp time and the duration of CPB.

Restrictive Cardiomyopathy

Primary RCM is a rare myocardial disease characterized, in the words of the AHA and in concordance with the European Society of Cardiology, "by normal or decreased volume of both ventricles associated with biatrial enlargement, normal LV wall thickness and AV valves, impaired ventricular filling with restrictive physiology, and normal (or near normal) systolic function" (Fig. 24.52).[102,103] Whereas DCM is a morphologic definition, RCM is a pathophysiologic one, characterized by impaired myocardial relaxation and decreased ventricular compliance combining to produce elevated filling pressures.[103,108,195,196]

Given the breadth of RCM's definition and its heterogeneous causes, its prevalence is unknown, although it is likely less common than either DCM or HCM.[103,195] RCM may be familial, although not always with an autosomal dominant pattern of inheritance; acquired in the course of a variety of systemic disorders (eg, amyloidosis, hemochromatosis, Fabry disease); or idiopathic.[103,108,195,196] Although its causes are varied, they may be classified as primarily myocardial or endomyocardial. Myocardial disorders are subclassified as noninfiltrative (familial, scleroderma, idiopathic), infiltrative (amyloidosis, sarcoidosis, Gaucher disease), or storage (hemochromatosis, Fabry disease). Endomyocardial disorders may be distinguished by the presence or absence of eosinophilia and include hypereosinophilic syndrome (Löffler endocarditis), endomyocardial fibrosis, and radiation-induced disorders (Box 24.4).[103,108,195,196]

Classically, systolic function is considered normal in RCM, at least by gross indices such as ejection fraction, although some have questioned whether contractile function is completely normal.[103] It may be the case that when myocardial function is interrogated more closely, as it needs to be in patients with the so-called *paradoxic* low-flow, low-gradient severe aortic stenosis, despite preserved ejection fraction, then contractile function in restrictive disease will also be found abnormal.[197,198] Diastolic dysfunction is the hallmark of RCM and is associated with impaired relaxation and compliance. Echocardiographically, RCM is characterized by biatrial enlargement, the absence of ventricular dilatation, and normal ventricular wall thickness, with grossly preserved

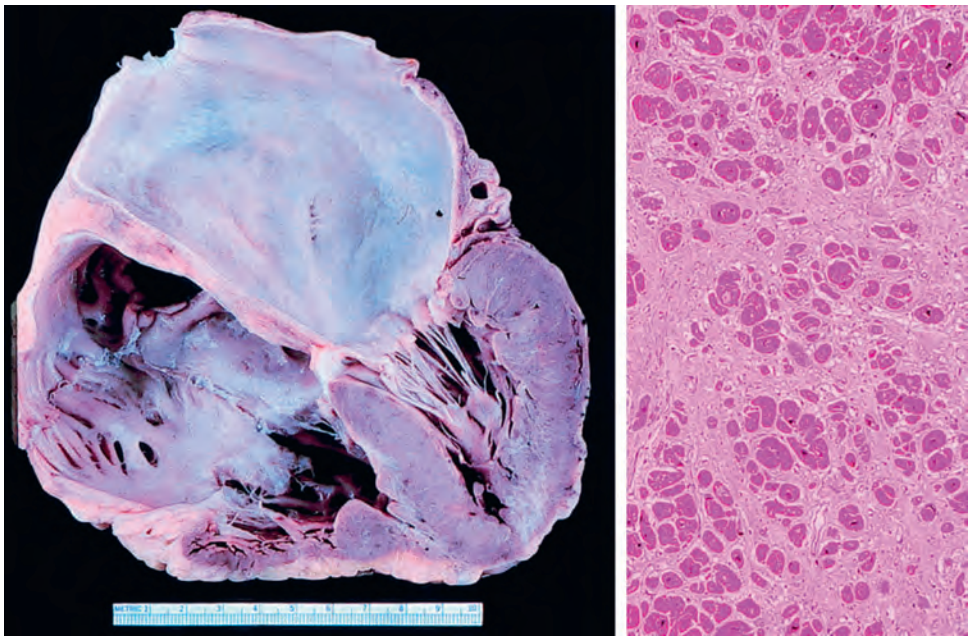

Fig. 24.52 Postmortem specimen of a patient with idiopathic restrictive cardiomyopathy. *(Left)* Gross specimen shows massive biatrial enlargement with normal ventricular size. *(Right)* Histologic section demonstrates significant interstitial fibrosis. *(Reproduced with permission from Ammash NM, Seward JB, Bailey KR, et al. Clinical profile and outcome of idiopathic restrictive cardiomyopathy.* Circulation. *2000;101:2493.)*

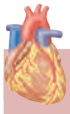

BOX 24.4 CLASSIFICATION OF TYPES OF RESTRICTIVE CARDIOMYOPATHY ACCORDING TO CAUSE

Myocardial Causes
Noninfiltrative
- Idiopathic cardiomyopathy[a]
- Familial cardiomyopathy
- Hypertrophic cardiomyopathy
- Scleroderma
- Pseudoxanthoma elasticum
- Diabetic cardiomyopathy

Infiltrative
- Amyloidosis[a]
- Sarcoidosis[a]
- Gaucher disease
- Hurler disease
- Fatty infiltration

Storage diseases
- Hemochromatosis
- Fabry disease
- Glycogen storage disease

Endomyocardial Causes
Endomyocardial fibrosis[a]
Hypereosinophilic syndrome
Carcinoid heart disease
Metastatic cancers
Radiation[a]
Toxic effects of anthracycline[a]
Drugs causing fibrous endocarditis (serotonin, methysergide, ergotamine, mercurial agents, busulfan)

[a]Conditions more likely to be encountered in clinical practice.
Reproduced with permission from Oliver WC, Mauermann WJ, Nuttall GA. Uncommon cardiac diseases. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*, 6th ed. Philadelphia: Saunders; 2011:693.

systolic function. Diastology is notable for a high E wave, driven by progressively higher left atrial pressures; a shortened deceleration time (less than 160 milliseconds), reflecting a poorly compliant LV and the rapid equalization of left atrial and ventricular pressures; a small A wave of short duration because of the rapid rise in ventricular pressure with filling during atrial kick; and an E/A ratio that frequently exceeds 2.[114,199] In addition to two-dimensional echocardiography and mitral inflow pulsed-wave Doppler, pulmonary vein pulsed-wave Doppler, tissue-Doppler imaging of the mitral annulus, M-mode imaging, and speckle tracking can all be used to establish the diagnosis of RCM and to attempt to determine its cause in a given patient (Fig. 24.53).[199]

With cardiac catheterization, right and left atrial pressures are elevated, and left-sided filling pressures frequently exceed right ventricular diastolic pressures by at least 5 mm Hg.[196] A rapid dip and subsequent early plateau in diastolic ventricular pressure, reflecting filling of a poorly compliant ventricle and rapid equalization of left atrial and ventricular pressures, may produce a characteristic ventricular diastolic waveform, the so-called "square root sign," although it may be absent in up to 50% of affected individuals, because it depends on both the degree of impaired ventricular relaxation and the atrial driving pressure (Fig. 24.54).[200] The atrial pressure waveform may take the appearance of an M or a W, reflecting prominent *a* and *v* waves and rapid *x* and *y* descents, the latter driven by increasingly elevated left atrial pressures. Furthermore, elevation in left-sided filling pressures produce pulmonary venous hypertension and pulmonary artery systolic pressures that may exceed 50 mm Hg.[196]

Diagnostically, distinguishing RCM from constrictive pericarditis (CP) is important, considering that their treatments are quite different (Table 24.5). In both disorders, filling pressures are elevated; although in restrictive disease, elevated pressures reflect a stiffened myocardium, whereas in constrictive disease, they reflect the constraint of a stiff pericardium.[199] With cardiac catheterization, as has been mentioned, left ventricular end-diastolic pressure typically exceeds its right ventricular counterpart by 5 mm Hg or more in RCM, attributable to differences in respective ventricular compliance. In CP, however, ventricular end-diastolic pressures are elevated and equal.[201,202] Additionally, because a

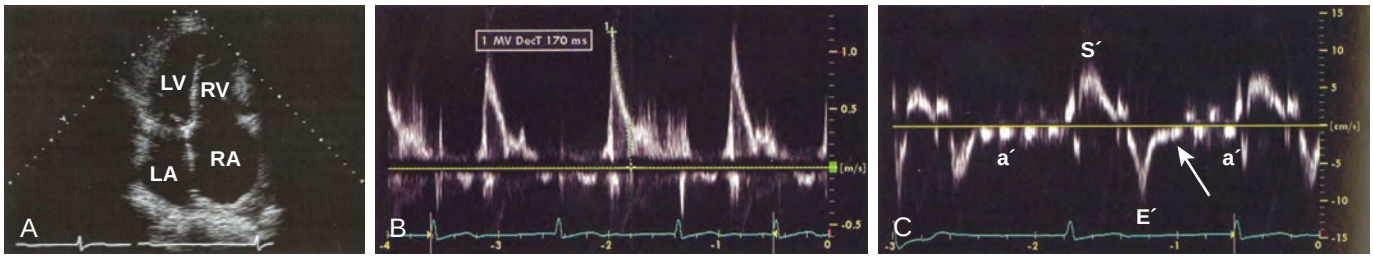

Fig. 24.53 Characteristic echocardiographic findings in a patient with restrictive cardiomyopathy. (A) Transthoracic apical four-chamber view shows significant biatrial enlargement, normal biventricular size, and grossly preserved systolic function *(not shown)*. (B) Mitral inflow pulsed-wave Doppler recording shows a deceleration time of 170 milliseconds and mild variation in E velocities. (C) Mitral annulus tissue velocity recording demonstrates E′ of 8 cm/sec and delayed relaxation *(arrow)*. An a′ reflects atrial fluttering or fibrillating motion. An E/E′ ratio of 100/8 = 13 is consistent with a mild increase in filling pressures. *a′,* Mitral annulus late diastolic velocity (atrial contraction); *DecT,* deceleration time; *E′,* mitral annulus early diastolic velocity; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *S′,* systolic velocity of the mitral annulus. *(Reproduced with permission from Oliver WC, Mauermann WJ, Nuttall GA. stiff, often thickened pericardium constrains the total cardiac volume in CP, ventricular interdependence is exaggerated. Since a pericardial *shell* affects a dissociation between intrathoracic and intracardiac pressures, decreased filling of the LV during inspiration is matched by enhanced right-sided filling. These respiratory variations, exaggerated in pericardial constriction and indicative of ventricular discordance, are not found in RCM, in which inspiration is met with concordant drops in both right and left ventricular pressures reflective of decreased intrathoracic pressure (Fig. 24.55).[203–205] Echocardiography may also be used to attempt to distinguish between RCM and pericardial constriction. In CP, two-dimensional echocardiography may show a thickened pericardium and may demonstrate a septal bounce consistent with ventricular interdependence and the dissociation of intracardiac and intrathoracic pressures.[199] Mitral inflow pulsed-wave Doppler will show increased E/A ratios in both RCM and CP; however, in the latter case, there should be significant respiratory variation in the E velocity, with at least a 25% increase during expiration (Table 24.6).[199] Radiographically, both CT and cardiac MRI may also be used to distinguish RCM and pericardial constriction. Once a tentative diagnosis of restriction is made, some attempt must be made to determine its cause. Although both CT and cardiac MRI may be useful, definitive diagnosis frequently requires an endomyocardial biopsy.[108,195,196]

Clinically, because either or both ventricles may be involved in RCM, patients may exhibit signs and symptoms of right-sided heart failure (elevated jugular venous pressure, peripheral edema, ascites, cirrhosis, renal failure), left-sided heart failure (dyspnea, orthopnea, exertional chest pain), or both.[108,196] With impaired right ventricular filling, jugular venous pressure is expected to fall during inspiration with decreased intrathoracic pressures, and enhanced right-sided filling may not occur and may, in fact, increase, giving rise to Kussmaul sign.[196,206,207]

Treatment for RCM should be based on the underlying disease process, if it is known (eg, enzyme-replacement therapy for Gaucher and Fabry diseases, steroids for sarcoidosis); otherwise, pharmacotherapy is tailored toward heart failure symptom relief (Table 24.7).[195] With biatrial enlargement, patients with RCM are prone to atrial fibrillation, for which rate therapy and anticoagulation should be used if persistent.[108,195,196]

Prognosis, similar to treatment, depends largely on the cause. For patients with idiopathic disease, 5- and 10-year survival rates of 64% and 37%, respectively, have been observed, which are less than would be expected for age- and sex-matched control subjects.[108,201] Age greater than 70 years, male gender, increasing NYHA functional class, and left atrial diameter greater than 60 mm were independent risk factors for a worse survival.[201]

TABLE 24.5 Differentiation of Pericardial Constriction and Myocardial Restriction

Characteristic	*Constrictive Pericarditis*	*Restrictive Cardiomyopathy*
Jugular venous waveform	Elevated with less rapid *y* descent	Elevated with, more rapid *y* descent Large A waves
LAP > RAP	Absent	Almost always
Auscultation	Early S_3 high pitched; no S_4	Late S_3 low pitched; S_4 in some cases
Mitral or tricuspid regurgitation	Frequently absent	Frequently present
Chest roentgenogram	Calcification of pericardium (20–30%)	Pericardial calcification rare
Heart size	Normal to increased	Normal to increased
Electrocardiogram	Conduction abnormalities rare	Conduction abnormalities common
Echocardiogram	Slight enlargement of atria	Major enlargement of atria
Right ventricular pressure waveform	Square-root pattern	Square-root pattern; dip and plateau often less prominent
Right- and left-sided heart diastolic pressures	Within 5 mm Hg of each other in almost all cases	Seldom within 5 mm Hg of each other
Peak right ventricular systolic pressure	Almost always <60 mm Hg, sometimes <40 mm Hg	Usually >40 mm Hg, sometimes >60 mm Hg
Discordant respiratory variation of peak ventricular systolic pressures	Right and left ventricular systolic pressures are out of phase with respiration	In phase with respiration
Paradoxic pulse	Often present	Rare
CT and MRI imaging	Thickened pericardium	Rarely thickened pericardium
Endomyocardial biopsy	Normal or nonspecific changes	Nonspecific abnormalities

TABLE 24.6 Echocardiographic Features of Restrictive Cardiomyopathy and Constrictive Pericarditis

	Restrictive Cardiomyopathy	*Constrictive Pericarditis*
Pericardium	Normal	Thickened
Left ventricle	Small May show systolic dysfunction No septal bounce	Small Usually intact, may be abnormal, particularly after CABG or radiation Septal bounce
Atria	Usually dilated	Usually nondilated
Mitral inflow	Increase E/A ratio, short DT No significant respiratory variation of E velocity Diastolic MR	Increase E/A ratio, short DT Expiratory increase of >25% in E velocity Diastolic MR
Tissue Doppler long velocities	Significantly reduced	Normal
Circumferential strain	Normal	Reduced
Peak radial strain class IV base	Normal	Reduced
Net twist	Normal	Reduced
Basal longitudinal strain	Reduced	Normal
Apical untwisting velocities	Normal	Reduced
Pulmonary vein inflow	Decreased (0.5) S/D ratio Prominent atrial reversal No significant respiratory change	S/D ratio = 1 Decrease in S and D[a] wave and TR velocity
Tricuspid inflow	Mild respiratory variation	Inspiratory increase of >25% in E wave and TR velocity
Inferior vena cava	Dilated	Dilated
Hepatic veins	Blunted S/D ratio	Inspiration: minimal increase in S and D velocities Expiration: decreased diastolic flow and increase in reversals Increase in atrial reversal of >25% in expiration, compared with inspiration
Peak PA pressure	>40 mm Hg	<40 mm Hg
Color M-mode	Decreased Vp <45 cm/sec	Normal or increase >100 cm/sec
Mitral annular Doppler	Low velocity <8 cm/sec	High velocity >8 cm/sec

[a]One study found significantly greater decrease of D wave only with respiration in constriction.

TABLE 24.7 Treatment Strategies in Restrictive Cardiomyopathy

Cause	*Specific Symptom*	*Treatment*
Idiopathic	To relieve congestion	Diuretics
	Control of heart rate	ß-Blockers, amiodarone, heart rate–regulating CCBs
	Atrial fibrillation: to maintain sinus rhythm paroxysmal or persistent	Amiodarone, dofetilide Long-term anticoagulation
	To control ventricular rate	ß-Blockers, heart rate–regulating calcium channel blockers, amiodarone, digoxin, atrioventricular node ablation, and pacemaker
	Atrioventricular block	Dual-chamber pacing
	To enhance myocardial relaxation	Calcium channel blockers (unproven), angiotensin inhibition (unproven)
	Refractory heart failure	Cardiac transplantation
Amyloidosis		Melphalan, prednisone, and colchicine; stem cell implant (under investigation); heart and liver transplant (in rare instances)
Hemochromatosis		Phlebotomy, desferrioxamine
Carcinoid heart disease		Somatostatin analogs; serotonin antagonists; valvuloplasty for severe tricuspid and pulmonary stenosis; valve replacement for severe tricuspid and pulmonary regurgitation
Sarcoidosis		Corticosteroids; pacemaker for heart block; implantable cardioverter-defibrillator for ventricular arrhythmias; cardiac transplantation for refractory heart failure
Eosinophilic endocarditis		Initial stage: corticosteroids, hydroxyurea, vincristine
Endomyocardial fibrosis		Endocardectomy with repair or replacement of tricuspid and mitral valves

CCBs, Calcium channel blockers.

Reproduced with permission from Oliver WC, Mauermann WJ, Nuttall GA. Uncommon cardiac diseases. In: Kaplan JA, Reich DL, Savino JS, eds. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. Philadelphia: Saunders; 2011:695

Anesthetic Considerations

Individuals with RCM only infrequently undergo cardiac surgery. One exception, however, are patients with amyloidosis, who may undergo circulatory-assist device placement, orthotopic heart transplantation, or combined heart and liver transplantation.

The amyloidoses are a family of diseases in which insoluble proteinaceous material is deposited in the extracellular tissues. Amyloid deposition may occur systemically or locally, and cardiac involvement may occur with either phenomenon.[108,196,208–211] Although amyloidosis may be reactive, with increased production and deposition of serum amyloid A (SAA) protein in the context of chronic inflammatory conditions, cardiac involvement in such cases is rare. More commonly encountered variants with cardiac involvement include primary, or systemic (coded as AL), wherein AL fibrils from monoclonal immunoglobulin light chains are overproduced and deposited in the setting of B-cell dyscrasias; hereditary systemic amyloidosis, wherein variants of transthyretin (TTR), amyloid apolipoprotein A1 (AApoA1), and others are produced and deposited systemically; and senile systemic amyloidosis (SSA), in which wild-type rather than mutant TRR is deposited. In addition to these systemic amyloidoses with cardiac involvement, there is also a localized variant, isolated atrial amyloid (IAA) (Table 24.8).[108,196,208–211] AL amyloidosis is the most common

TABLE 24.8 Common Cardiac Amyloidosis[a]

Nomenclature	*Precursor of Amyloid Fiber*	*Type*	*Prevalence*	*Prognosis*
AL (26)	Immunoglobulin light chain	Primary amyloid cardiomyopathy	50% in patients with AL amyloidosis	Median survival –11 mo
ATTR (28, 46, 79, 101)	Mutant transthyretin Wild-type transthyretin	Familial amyloid cardiomyopathy Senile systemic amyloid (SSA) cardiomyopathy	30% in patients with familial amyloidosis In most patients with senile amyloidosis	Median survival 9–13 yr Median survival –75 mo
AA (28)	Serum amyloid A	Secondary amyloid cardiomyopathy	Rare, only 2% in patients with AA amyloidosis	Good
AANF (48, 49)	Atrial natriuretic factor	Isolated atrial amyloidosis	Very common More than 40% in people older than 50	Good

[a]Other cardiac amyloidosis include: AH (24), AApoAI (40, 41, 1, 69), AApoAIV (7, 8), AFib (99), and AGel (12, 60). However, these are rarely occurring with limited literature.
Reproduced with permission from Guan J, Mishra S, Falk RH, Liao R. Current perspectives on cardiac amyloidosis. *Am J Physiol Heart Circ Physiol*. 2012;302:H546.

of the systemic amyloidoses and entails cardiac involvement in 50% of the cases. Median survival is poor at 11 months. ATTR is the next most common form of the disease and involves the heart in approximately 30% of cases. Median survival exceeds 10 years. The clinical manifestation of cardiac amyloidosis is that of restrictive heart disease with signs and symptoms of left-sided heart failure, right-sided heart failure, or biventricular heart failure. With time, diastolic heart failure progresses to systolic heart failure. With infiltration of the conduction system, a variety of arrhythmias and forms of heart block may arise. With compromise of left ventricular filling and CO and with infiltration of the autonomic nervous system, orthostatic hypotension occurs in at least 10% of those with cardiac disease.[196,208] Treatment of cardiac amyloid depends on the variant. Whereas IAA does not affect survival and does not require intervention, secondary amyloidosis relies on treatment of the underlying inflammatory condition. Although treatment of SSA attributable to the deposition of wild-type TTR is confined primarily to investigational drugs, patients with systemic AL amyloidosis and familial amyloidosis with mutant TTR may be candidates for orthotopic heart transplantation or for combined heart and liver transplantation in the case of the latter disease.[196,208–211]

Clearly, patients scheduled for heart transplantation or combined heart and liver transplantation will require full, invasive hemodynamic monitoring, with one if not two arterial lines (one monitoring peripheral pressures and one monitoring central pressures), one if not two introducers (especially in the case of a combined procedure or a *redo* procedure, when large volume blood loss and significant coagulopathy can be expected), perhaps a high-flow peripheral venous cannula, a PAC, and intraoperative TEE. The choice of induction and maintenance drugs may certainly be based on theoretical concerns related to patient physiologic considerations, but no evidenced-based data exist to support a given pharmacologic regimen clinically. The vigilance of the anesthesiologist, his or her understanding of a given patient's physiologic nature under a specific set of clinical conditions, and sound clinical judgment are important. That being said, patients with cardiac amyloid scheduled for transplantation may prove to have particularly labile if not frankly unstable hemodynamics at the time of induction. The combination of severely compromised diastolic function and impaired ventricular filling, likely systolic heart failure, and autonomic instability with amyloid infiltration of the nervous system, can conspire to make the effects of even the most judicious doses of drugs unpredictable.

Arrhythmogenic Right Ventricular Cardiomyopathy

Formerly called *arrhythmogenic right ventricular dysplasia*, arrhythmogenic right ventricular cardiomyopathy (ARVC) is defined by the 1995 WHO as "progressive fibrofatty replacement of RV myocardium, initially with typical regional and later global RV and some LV involvement, with relative sparing of the septum."[101] Evidence of a more progressive involvement of not only the RV but also the LV with long-term follow-up convinced the WHO to classify ARVC as a "disease of the myocardium" that incorporates the many different clinical presentations and aspects of this condition.

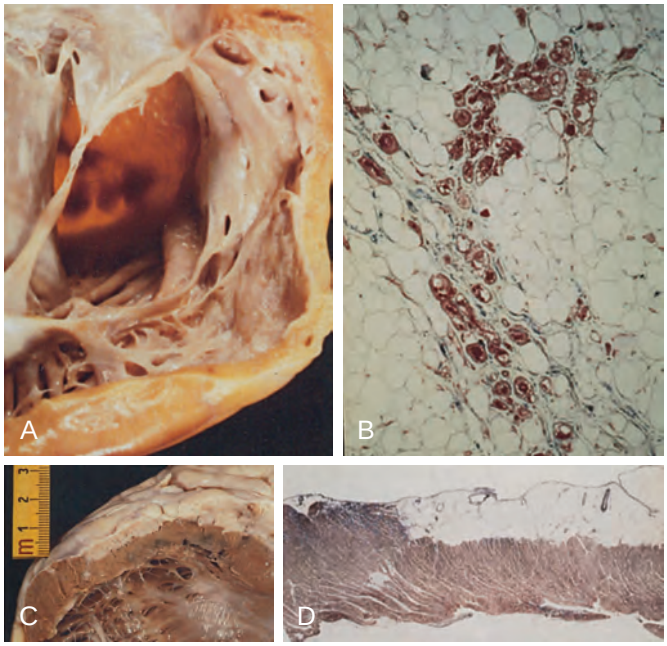

Fig. 24.56 (A) Histologic view at high magnification shows surviving degenerated right ventricular myocytes in the setting of extensive fatty replacement and tiny interstitial fibrosis. (B) Gross (A and C) and histologic (B and D) sections of the anterior left ventricular wall shows striking subepicardial fatty infiltration and fibrosis. *(Reproduced with permission from Corrado D, Basso C, Thiene G, et al. Spectrum of clinicopathologic manifestations of arrhythmogenic right ventricular cardiomyopathy/dysplasia: a multicenter study.* J Am Coll Cardiol. *1997;30;1517.)*

ARVC is familial in 30% to 50% of persons with primarily autosomal dominant inheritance, variable expressivity, and reduced penetrance.[212] The prevalence of ARVC has been estimated between 1:2000 and 1:5000 with men affected at a ratio of 3:1.[213] The initial presentation is often during adolescence, although it may occur in younger individuals. Its presentation most commonly begins with the onset of arrhythmias ranging from premature ventricular contractions to ventricular fibrillation originating from the RV. The disease is now known to proceed through three phases: (1) concealed phase without symptoms but some electrophysiologic changes that place one at risk for sudden death; (2) overt dysrhythmias; (3) advanced stage with myocardial loss, biventricular involvement, and CHF.[214] Diagnosis is rare in the early stages[215] but not at autopsy.[216] Standard diagnostic criteria have continued to be revised.[217] Postmortem examination reveals diffuse or segmental loss of the myocardium, primarily in the RV, replaced with fat and fibrous tissue; right ventricular dilation; and thinning of the right ventricular free wall (Fig. 24.56). Right ventricular involvement commonly occurs near the right ventricular outflow tract, infundibulum, and/or the right ventricular apex with reported progression to right ventricular aneurysms in this region,

Echocardiographic findings in patients meeting task force criteria for arrhythmogenic right ventricular dysplasia: new insights from the multidisciplinary study of right ventricular dysplasia.* J Am Coll Cardiol. *2005;45.)*

which are considered pathognomonic.[218] The diagnosis also includes the functional changes associated with the RV beyond the structural alterations. These changes are believed to occur by three possible mechanisms: myoblasts differentiating to (1) adipoblasts, (2) apoptosis, or (3) inflammation.[215] An inflammatory process is evident within the myocardial tissue. The replacement of myocardium with fat and fibrous tissue creates an excellent environment for a fatal arrhythmia, possibly the first sign of ARVC.[214] Although considered a disease of the RV, left ventricular involvement can also occur and even precede right ventricular presentation.[219] Sudden death occurs in up to 75% of patients, although accurately stating the percentage is difficult in view of the number of patients who go undiagnosed. Sudden death occurs most often during sports-related exercise, primarily from ventricular tachycardia and fibrillation.[220] Although a rare disease, ARVC accounts for 20% of sudden death in the young.[221]

The electrical instability, characteristic of ARVC, is not solely responsible for the natural history of the disease. Its clinical presentation may range from asymptomatic myopathic involvement to overt clinical disease with diffuse biventricular involvement.[214,220] Progressive right and left ventricular dysfunction can be appreciated with serial echocardiographic examinations. Echocardiographic findings from 29 patients with ARVC have been described (Fig. 24.57).[222] The systolic and diastolic right ventricular outflow tract dimensions are increased on a two-dimensional ECG. Regional wall motion abnormalities of the

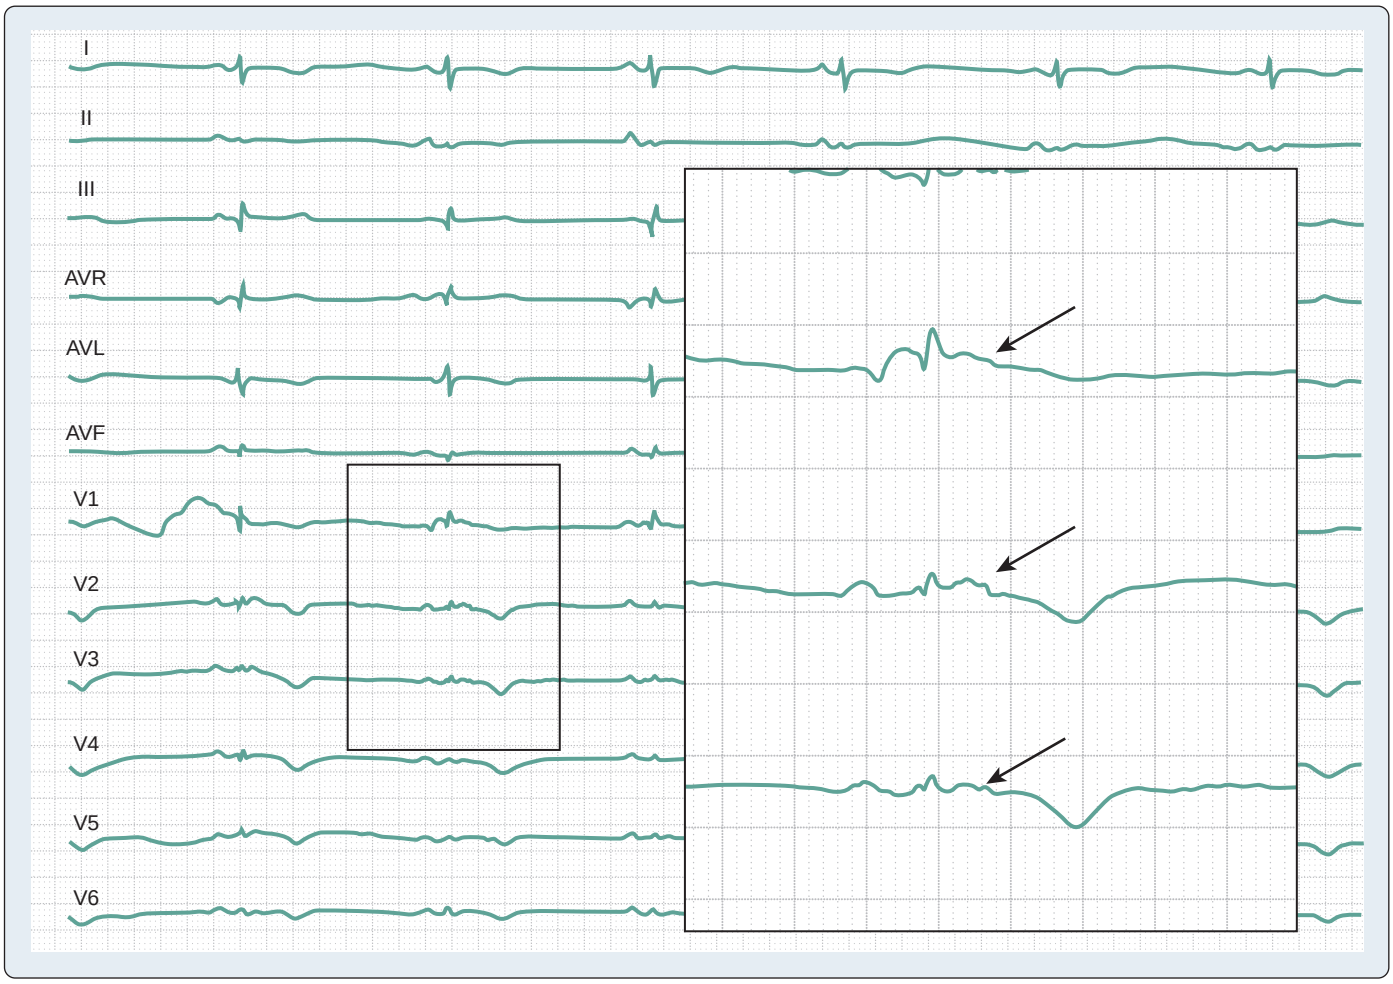

Fig. 24.58 Electrocardiogram demonstrates epsilon waves *(inset; arrows)* between the QRS complex and ST segment. *AVR*, Augmented vector right; *AVL*, augmented vector left; *AVF*, augmented vector foot. *(Reproduced with permission from Rotondi F, Amoroso G, Manganelli F. "Epsilon waves" in peripheral and precordial leads in arrhythmogenic right ventricular cardiomyopathy with severe right ventricular involvement.* J Electrocardiol. *2015;48:210–212.)*

RV were common, and over one half of patients had abnormal right ventricular systolic function. Right ventricular trabeculations were also commonly found. Although typical echocardiographic features are revealed in ARVC, the clinical disease manifestations may precede the appearance of these morphologic features. Recently, it has been shown that significant ventricular mechanical dyssynchrony is present in 50% of patients, which can lead to right ventricular dilatation and impaired systolic function.[223] Myocardial loss with progressive ventricular dysfunction progresses ultimately to CHF, accounting for 20% of deaths. End-stage ARVC may be difficult to distinguish from DCM, because the extent of left ventricular involvement has only recently been appreciated.

Diagnosis based on Revised Task Force Criteria graded aberrations (major and minor) include structural alterations (diagnosed by echocardiography, MRI, and/or right ventricular angiography), histologic evaluation, echocardiographic abnormalities, arrhythmias, genetic studies, and family history.[215,224,225] The characteristic echocardiographic findings include epsilon waves most commonly in precordial leads V1 through V3 (Fig. 24.58), right bundle branch block, inverted T waves in the right precordial leads, QRS prolongation greater than 110 to 120 ms, and extrasystoles with left bundle branch block.[221,224,226] Diagnosis may depend on endomyocardial biopsy to reveal the distinctive changes of ARVC, yet be unrewarding if the biopsy is obtained from the septal area of the myocardium known for its lack of characteristic features.[109] A new immunohistochemical analysis of a biopsy sample has proven to be highly sensitive and specific for the identification of ARVC.[227] The importance of this test is that it has been used to differentiate those patients in the early stages of the disease from those in the more advanced state. A prospective longitudinal study examined 108 newly diagnosed patients over a 2-year period and found that their clinical profile differed from the patient with the more advanced disease. This finding may offer some options for future treatments.[221]

Anesthetic Considerations

A retrospective review of forensic autopsies by the American Society of Anesthesiologists in 50 patients with intraoperative sudden cardiac death related to surgery or anesthesia revealed the presence of ARVC in 18 of the 50 cases.[228] Two adolescents undergoing routine surgical procedures were reported to develop refractory arrhythmias and sudden death after general anesthesia, with the autopsy revealing typical features of ARVC.[216] A family history of sudden death or syncope at an early age should heighten the awareness for the diagnosis of ARVC and merits further evaluation.[215] During the course of ARVC, arrhythmias of both a supraventricular and ventricular nature may occur. Because arrhythmias are more likely in the perioperative period, noxious stimuli, hypovolemia, hypercarbia, and light anesthesia must be minimized intraoperatively and during recovery. However, general

anesthesia, alone, does not appear to be arrhythmogenic. Houfani and colleagues[216] reported that over 200 patients with ARVC underwent general anesthesia without a single cardiac arrest. Anesthesia has been successfully conducted with propofol, midazolam, and alfentanil.[215] Acidosis may be especially detrimental because of its effect on arrhythmia generation and myocardial function.

The prevention of sudden cardiac death and malignant arrhythmias is paramount in the management of ARVC. Consideration for ICD implantation is commonly given in patients surviving sudden cardiac arrest or those with sustained ventricular arrhythmias, nonsustained ventricular tachycardia, syncope, and/or a family history of sudden cardiac death.[229,230] Antiarrhythmic therapy, along with radiofrequency ablation techniques, have also been described for patients with ARVC and underlying electrophysiologic aberrations.[231] Amiodarone and Sotalol have been shown in separate trials to help prevent ventricular arrhythmias in patients with ARVC.[232,233] Management of perioperative malignant dysrhythmias in patients with ARVC targets reversible causes (eg, light anesthesia, pain, electrolyte disturbances) with amiodarone and potentially ß-blockers as antiarrhythmic options.[232,234] TEE is a useful monitoring modality in patients with ARVC undergoing cardiac and other high-risk surgical procedures.[234] Extreme caution should be used if inserting a PAC in patients with ARVC; such intervention may trigger dysrhythmias or potentially cause right ventricular perforation.[234]

Mitral Valve Prolapse

MVP with severe mitral regurgitation is a common reason for cardiac surgery today. MVP is most likely a genetically inherited disease with an autosomal dominant manner. As the most commonly diagnosed cardiac valve abnormality, MVP occurs in adults who are otherwise healthy or in association with many pathologic conditions (Box 24.5) and is equally distributed between men and women.[235]

BOX 24.5 CONDITIONS ASSOCIATED WITH MITRAL VALVE PROLAPSE

Connective Tissue Disorders—Genetic
Mitral valve prolapse—isolated
Marfan syndrome
Ehlers-Danlos syndrome—types I, II, and IV
Pseudoxanthoma elasticum
Osteogenesis imperfecta
Polycystic kidney disease

Other Genetic Disorders
Duchenne muscular dystrophy
Myotonic dystrophy
Fragile X syndrome
Mucopolysaccharidoses

Acquired Collagen—Vascular Disorders
Systemic lupus erythematosus
Relapsing polychondritis
Rheumatic endocarditis
Polyarteritis nodosa

Other Associated Disorders
Atrial septal defect—secundum
Hypertrophic obstructive cardiomyopathy
Wolff-Parkinson-White syndrome
Papillary muscle dysfunction
  Ischemic heart disease
  Myocarditis
Cardiac trauma
Post–mitral valve surgery
von Willebrand disease

From Fontana ME, Sparks EA, Boudoulas H, Wooley CF. Mitral valve prolapse and the mitral valve prolapse syndrome. *Curr Probl Cardiol.* 1991;16(5):309–375.

Knowledge about MVP has evolved significantly over the last 40 years. Unrecognized as a part of the midsystolic click and systolic murmur known as Barlow disease until 1961, the finding of mitral regurgitation in conjunction with the ballooning of the posterior mitral leaflet on angiography resulted in the condition called Barlow syndrome or floppy-valve syndrome.[236] It was during this time that the true cause of MVP was understood to be a degenerative condition with myxoid found on histologic examination that caused thickening, elongation, and a change in the chordae. With the advent of echocardiography in 1970, a diagnosis based on echocardiographic parameters of the normal mitral valve was derived in 1987 for MVP.[237] In essence, only the valve that displayed prolapse in the long-axis view had *true* MVP,[238] which allowed the *true* prevalence of MVP to be determined, as well as the specific process associated with the corresponding mitral regurgitation. Carpentier was further able to differentiate the degenerative changes of MVP from another cause that did not cause billowing of the valve or excess tissue, now referred to as *fibroelastic deficiency*.[239] Currently, MVP is known to be a spectrum of structural and functional valve anomalies affecting 1% to 2% of the population, depending on accepted criteria for diagnosis.[240]

In patients with degenerative mitral valve disease, a spectrum of disease is appreciated, ranging from fibroelastic deficiency to Barlow disease (Fig. 24.59).[240] Fibroelastic deficiency was first identified by Carpentier as a form of MVP without billowing or excess valve tissue as was initially described by Barlow.[239,240] In this situation, the chordae were thin and possibly ruptured, often involving a segment of the posterior leaflet. The mechanism is impaired connective tissue production attributable to a deficiency of collagens, elastins, and proteoglycans, but the cause is unknown. Unlike Barlow disease, symptoms of fibroelastic deficiency generally arrive with chordal rupture, are frequently observed with advancing age, and include a significantly less pronounced, generalized degeneration of the mitral valve than Barlow disease. Surgical repair is also less complex.

Barlow disease is believed to result from myxomatous degeneration of the mitral valve, elongation and thinning of the chordae tendineae, and the presence of redundant and excessive valve tissue. The mechanism is unknown, but regulation of the extracellular matrix components appears to be a primary issue. Normal mitral valve leaflets may billow slightly with closure, but in MVP, redundant mitral leaflets prolapse into the LA during mid-to-late systole (Fig. 24.60). Superior arching of the mitral leaflets above the level of the atrioventricular ring is diagnostic for MVP. Distortion or malfunction of any of the component structures of the mitral valve may cause prolapse and generate audible clicks or regurgitation associated with a murmur. If the chordae tendineae are lengthened, then the valves may billow even more and progress to prolapse when valve leaflets fail to oppose each other. The degree of these changes will determine the presence of mitral regurgitation. The degenerative valve changes that are responsible for

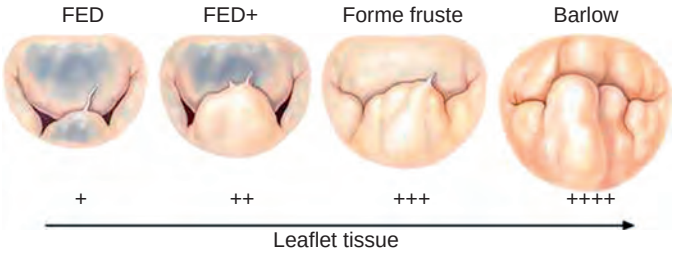

Fig. 24.59 Spectrum of degenerative mitral disease. Degenerative disease spectrum includes: fibroelastic deficiency *(FED)* with thin leaflets and a ruptured chordae *(+)*, long-standing FED leading to myxomatous changes of the prolapsing segment *(++)*, forme frusate with myxomatous disease and excessive tissue in one or more leaflet segments *(+++)*, and Barlow disease with myxomatous changes, excessive leaflet tissue, and large valve size *(++++)*. *(Reproduced with permission from Adams DH, Rosenhek R, Falk V: Degenerative mitral valve regurgitation: best practice revolution.* Eur Heart J. *2010;31:1958–1966.)*

progression from an asymptomatic state with murmurs and systolic clicks to dyspnea with severe mitral regurgitation occur over an average of 25 years.[241] Three-dimensional echocardiography has provided new insight into the characterization of mitral valve disease, as seen in Fig. 24.61, which shows Barlow disease and fibroelastic deficiency with a flail segment.[242]

Finally, even histologically, normal mitral valves may prolapse.[235] Normal mitral valve function depends on a number of factors, including the size of the LV and the mitral leaflets. Changes in these components may cause *innocent* MVP.

No universal criteria for diagnosis of MVP are available. Physical examination and echocardiographic findings are essential for the diagnosis of MVP. Auscultatory criteria that are strictly applied are highly sensitive for the diagnosis but lack specificity. Typical auscultatory features are midsystolic click and late-systolic murmur. The click is related to a deceleration of blood on the undersurface of the valve, prolapsing into the LA. The murmur is late, with progressively increasing regurgitation that results in a crescendo systolic murmur. Certain maneuvers aid with the auscultatory diagnosis of MVP such as Valsalva, squatting, or leg raises that change the left ventricular end-diastolic volume to move the timing of the click within systole.[235] Auscultatory findings may be absent, despite echocardiographic determination of MVP. Currently, MVP is diagnosed more often with two-dimensional echocardiography, because recognition and assessment of the severity is superior. Given the saddle-shaped nature of the mitral annulus, the diagnosis of MVP is typically made from the parasternal long-axis view using TTE. MVP is defined as greater than 2 mm displacement of one or both mitral leaflets into the LA during systole. If the mitral leaflets appear thickened or myxomatous, then the diagnosis is more certain. Color-Doppler and continuous-wave Doppler imaging can quantify the degree of mitral regurgitation when it is present.

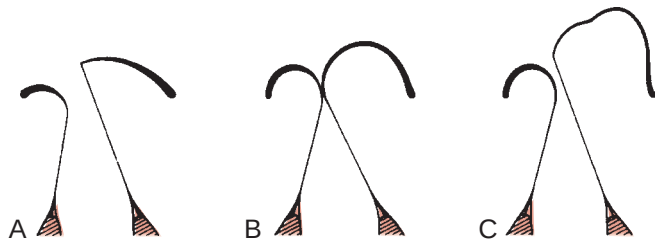

Fig. 24.60 Diagrammatic representation of the pathologic functioning of the mitral valve mechanism. (A) Regurgitation is present with mitral valve prolapse. (B) Billowing mitral valve is demonstrated without prolapse or regurgitation. (C) Billowing and prolapsed mitral leaflets are revealed with regurgitation. *(Reproduced with permission of American Heart Association. From Barlow JB, Pocock WA. Mitral valve prolapse enigma—two decades later.* Mod Concepts Cardiovasc Dis. *1984;53:13.)*

Most patients with MVP are asymptomatic; however, controlled studies have reported the presence of palpitations in 50% of patients.[243] Altered autonomic function, catecholamine responsiveness, or possibly a combination of the two may account for complaints of chest pain, fatigue, palpitations, dyspnea, dizziness, syncope, and panic attacks, among others. These symptoms and some clinical findings of thin body type, low blood pressure, and electrocardiographic repolarization abnormalities have been associated with MVP and are termed *MVP syndrome.*[235] Neuropsychiatric symptoms are no longer considered part of MVP. The possibility of a complex of unexplained cardiovascular symptoms associated with MVP has not been completely eliminated and may exist in a few patients. The cause may be abnormal autonomic activity that leads to symptoms of vasoconstriction, enhanced β-receptor activity, and decreased plasma volume; however, a relationship with MVP remains undefined.

The prognosis for most patients with MVP is excellent with a normal life expectancy.[235] The development of severe echocardiographic abnormalities is rare in patients with MVP. Although a benign course is typical for many patients with MVP, serious complications such as severe mitral regurgitation, infective endocarditis, sudden death, and cerebral ischemia may occur. The incidence of cardiovascular morbidity and mortality in MVP is just under 1% per year.[244] It is a subset of patients who appear to be at increased risk for serious complications who may be defined by echocardiography and clinical findings. These risk factors include reduced left ventricular systolic function and valve thickening greater than 5 mm, among others.[235]

Mitral valve regurgitation is the most serious complication associated with MVP. Severe mitral regurgitation develops in approximately 2% to 4% of patients with MVP, two thirds of whom are male patients.[243] Most patients will have mild-to-moderate mitral regurgitation that does not require surgery. MVP is the most common cause of severe mitral regurgitation, and its onset signals the need for therapeutic intervention. Irrespective of symptoms, the onset of severe mitral regurgitation can result in reduced life expectancy. Patients are usually younger than 60 years of age with the Barlow form of MVP and mitral regurgitation, in contrast, to older than 60 years of age for fibroelastic deficiency. Mitral regurgitation in Barlow disease is not due to the billowing of the leaflet body; rather, it is from the marginal prolapse (Fig. 24.62) and severe annulus dilation.[239] The posterior leaflet is affected more frequently than the anterior leaflet. Changes are often observed

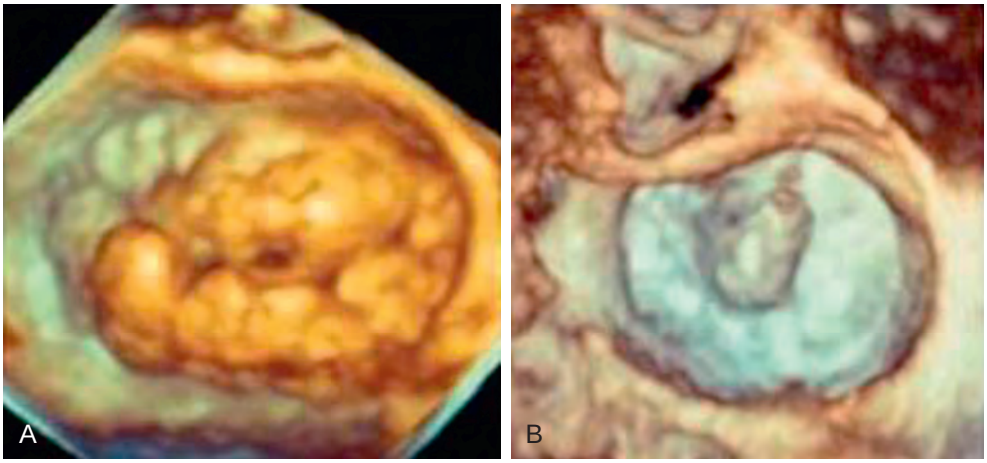

Fig. 24.61 Three-dimensional transesophageal echocardiographic views depict (A) a patient with Barlow disease and (B) fibroelastic deficiency with flail P2 segment. *(Reproduced with permission from Lang RM, Badano LP, Tsang W, et al. at the site of chordal insertion, leading to rupture of the chordae and a tethering of the valve leaflet. With the development of severe mitral regurgitation, pulmonary hypertension, left atrial enlargement, and atrial fibrillation frequently emerge. Early repair is recommended to preserve left ventricular function and to reduce the likelihood of atrial fibrillation.

The management of MVP and mitral regurgitation without symptoms continues to be reconsidered in terms of the timing for cardiac surgical intervention, especially in view of the risk of mitral valve repair and the improved outcomes associated with earlier surgery. Without overt symptoms, the degree of ventricular dysfunction may be worsening unknowingly, placing the patient at increased risk for permanent dysfunction and a worse surgical outcome.[235] Men are three times more likely to require surgical intervention, because the progression to severe mitral regurgitation is more common in men with MVP than in women, despite similar overall gender incidence of MVP. Noninvasive monitoring of mitral regurgitation and developing left ventricular dysfunction may help evaluate the optimal time for surgery. Flail mitral leaflet is an especially important risk for a poor surgical outcome if not addressed immediately.

Mitral valve repair is widely recommended for treatment of MVP, compared with replacement. Mitral valve repair confers a significantly improved surgical survival, as well as 5- and 10-year survival, compared with mitral valve replacement.[245] The Cox maze procedure may be added to mitral valve repair safely to effectively reduce late complications of mitral valve disease (eg, atrial fibrillation).[246] Advantages of mitral valve repair, compared with replacement, include a lower risk of thromboembolism, bleeding, infectious endocarditis, and better ventricular function because the valve structure is preserved.[247] Most patients with degenerative mitral disease (90%)[248] are candidates for mitral valve repair, which has been associated with low morbidity and mortality and with excellent long-term outcomes.[249] A prospective, observational study comparing mitral valve repair with mitral valve replacement in patients with mitral valve regurgitation (ischemic and degenerative causes) found a statistically significant survival benefit in patients who underwent repair.[250] Notably, repair of the valve returns the patient to a similar life expectancy as a comparable person who has not undergone a cardiac surgical procedure.

Posterior leaflet prolapse is the most common defect in mitral regurgitation.[235] The posterior leaflet repair is historically low risk, with bileaflet repairs presenting greater technical difficulty. The anterior prolapse repair has a higher rate of reoperation and decreased survival.[249] The use of robotic technology has advanced to a point that allows safe and feasible mitral repair with similar 30-day outcomes to traditional techniques in select patient populations; however, long-term follow-up data in this cohort are not yet available.[251,252] Recently, endovascular mitral valve repair via MitraClip devices (Abbott Vascular, Santa Clara, CA) has emerged as a viable treatment option for select nonoperable candidates with mitral valve regurgitation (Fig. 24.63).[253] All valves unfortunately cannot be successfully repaired, whereupon less than 10% with prolapse of a degenerative mitral posterior leaflet require mitral valve replacement.

The association of arrhythmias and sudden death with MVP is a long-held observation. Premature atrial and ventricular beats, atrioventricular block, and supraventricular or ventricular tachyarrhythmias are common during ambulatory monitoring in adults with MVP.[254] The causes of these arrhythmias are multifactorial, probably combining an anatomic substrate with some form of dysautonomia.[255] Mechanisms that have been proposed for arrhythmias include ventricular enlargement, hyperadrenergic states, electrolyte imbalances, and mechanical irritation of the ventricle because of traction of the chordae tendineae. Arrhythmias may be secondary to mitral regurgitation, not MVP. According to a study of individuals with nonischemic mitral regurgitation, complex arrhythmias were common and equally prevalent whether or not the patient had MVP.[256] Ventricular tachycardia occurred in 35% of those study participants with mitral regurgitation, in contrast to only 5% with MVP alone. Similarly, the risk of sudden death for patients with MVP may be related to mitral regurgitation in view of a reduction in ventricular arrhythmias that occurred with mitral valve repair or replacement.

The occurrence of sudden death with MVP in adults has been debated for years. The risk is low with an estimated yearly rate of 40 in 10,000, but this number is twice the expected rate in the population.[235] Sudden death does occur within families of MVP patients.[254] The ECG is abnormal in approximately two thirds of persons with MVP, but ambulatory electrocardiographic monitoring does not show an excess of atrial or ventricular arrhythmias unless accompanied by severe mitral regurgitation.[235] Electrophysiologic testing has been unable to identify an arrhythmogenic focus or reliably identify those at increased risk but is useful in the pharmacologic management of patients with ongoing complex sustainable arrhythmias. Patients with severe mitral regurgitation, flail segment, and a depressed LV appear to be at greater risk of sudden death. Prophylaxis has not averted sudden death in high-risk patients with severe mitral regurgitation. An ICD is a consideration in patients with inducible ventricular tachycardia or

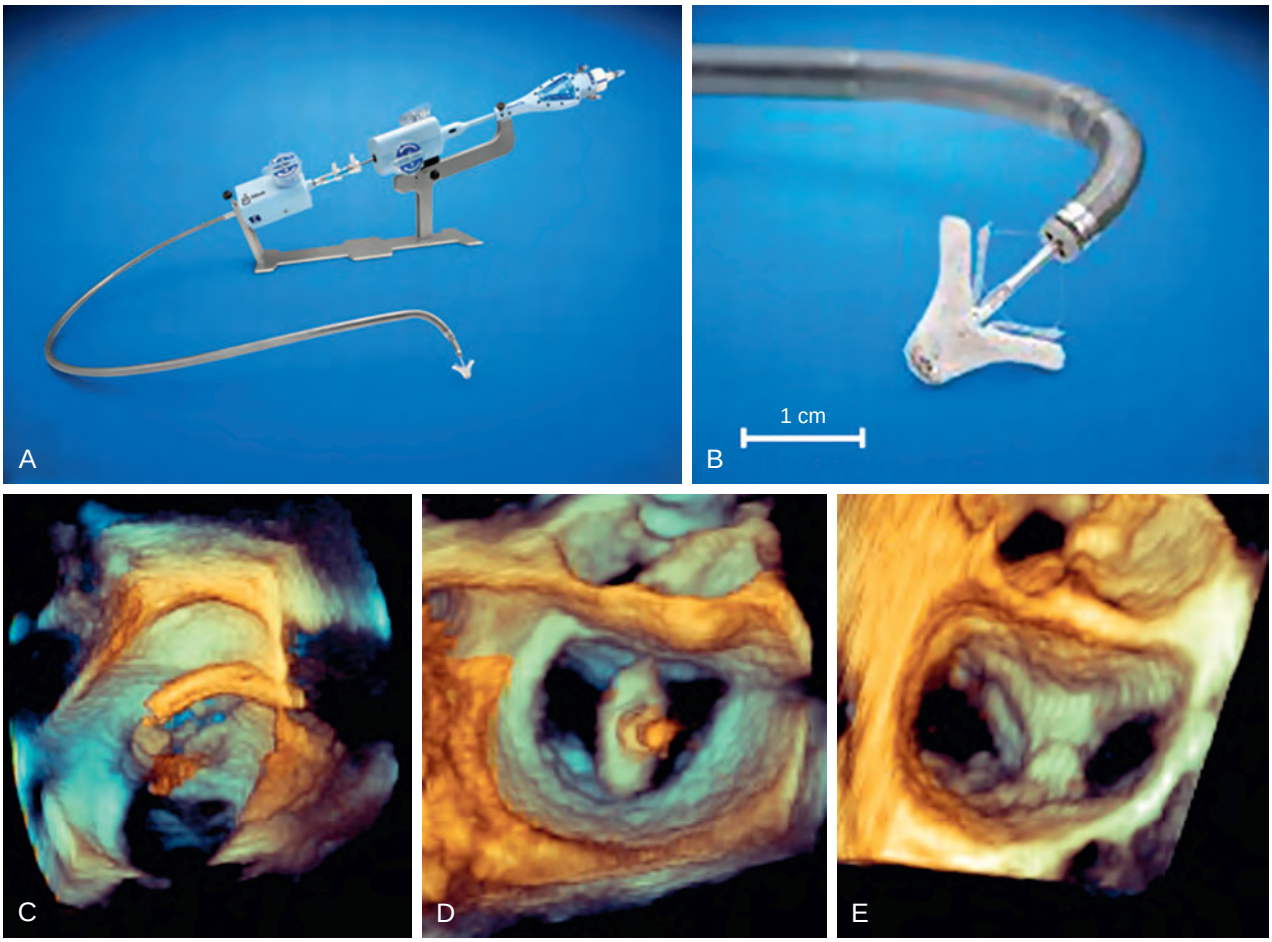

Fig. 24.63 (A) MitraClip delivery system. (B) Enlarged view of MitraClip delivery system with the clip inserted. (C) Three-dimensional transesophageal echocardiographic image shows the delivery system crossing the interatrial septum. (D) MitraClip orientation is perpendicular to the valve coaptation plane. (E) Mitral valve is shown after MitraClip placement at the anterior leaflet (A) and the posterior leaflet (P) interface with the generation of a double-orifice valve. *(Reproduced with permission from Rogers JH, Franzen O. Percutaneous edge-to-edge MitraClip therapy in the management of mitral regurgitation.* Eur Heart J. *2011;32:2350–2357.)*

ventricular fibrillation, but these patients are rare.[257] In general, most low-risk patients do not require treatment for either their symptoms or to prevent sudden death.

MVP has been reported to be associated with cerebral ischemic events, especially in the young. Mitral cusp elongation and expansion that occur with MVP may generate thrombus, vegetation, and calcification of the mitral valve. Mobile masses have been found in conjunction with cerebral events. However, a population-based cohort study involving 1079 patients found no difference in the incidence of strokes in patients under 45 years of age with MVP unless another cardiac disease process was present.[258] In contrast, a study of individuals in Olmsted County of Rochester, Minnesota, found the incidence of stroke was 0.07% per year, almost twice the normal rate.[259] The strongest factors associated with increased risk in these patients with MVP included thick valves, mitral valve surgery, atrial fibrillation, and an age 50 years and older. Factors that were independently associated with stroke were advanced age, coronary artery disease, CHF, and diabetes.

Bacterial endocarditis is an infrequent complication of MVP, but its incidence is three to eight times greater in these individuals than in the general population.[243] Male individuals are three times more likely to develop endocarditis. Current guidelines from the AHA are very specific and do not recommend antibiotic prophylaxis for individuals without a prosthetic cardiac valve, complex congenital heart disease (CHD), postcardiac transplant valvular lesions, or a history of bacterial endocarditis.[260] Patients with isolated clicks probably do not benefit from antibiotic prophylaxis, but cost effectiveness with MVP has been proven nonetheless.[261] Patients at high risk of developing endocarditis (previous bacterial endocarditis, systolic murmurs, thickened leaflets, or mitral regurgitation) should receive antibiotics before undergoing procedures commonly associated with bacteremia, because the risk increases to approximately 0.05% per year.[235] The turbulent flow from the mitral regurgitation and the thickened valve tissue may cause the increased risk of infection. Patients who may require oral endotracheal intubation or fiberoptic bronchoscopy do not require antibiotic prophylaxis.[241] Unfortunately, as recommendations regarding antibiotic prophylaxis have continued to be modified over the years, evidence to guide the physician on the issue of prophylaxis and MVP remains insufficient.

Anesthetic Considerations

Understanding the broad nature of the condition called MVP with respect to anesthetic considerations is important. Most individuals with MVP have an uncomplicated general anesthetic, because they have MVP without serious complications, often referred to as MVP syndrome. These patients are usually younger than 45 years of age with few risk factors for anesthesia. Invasive monitoring is usually unnecessary. Patients may be taking ß-blockers. Preoperative sedation

is useful to suppress a possible increased sensitivity to catecholamines. Painful stimuli may exacerbate the autonomic system, possibly causing arrhythmias, although rarely malignant in nature. Significant decreases in left ventricular end-diastolic volume and SVR or increased contractility and tachycardia should be minimized, because MVP may be enhanced such that CO and coronary perfusion are decreased. Intraoperative arrhythmias usually resolve spontaneously or respond to standard therapy. If an arrhythmia occurs, then adequate oxygenation should be confirmed and other causes of intraoperative arrhythmias investigated. If ß-blockers are required perioperatively, then esmolol will avoid the potential for prolonged blockade that might cause hemodynamically significant bradycardia.

Anticholinergic preoperative medications are best avoided, despite an increased vagal tone in MVP. A moderate anesthetic depth is desirable to minimize catecholamine levels and potential arrhythmias. Ketamine or drugs that have sympathomimetic effects must be cautiously administered. Volatile anesthetics sensitize the heart to catecholamines and thus potentially promote arrhythmias. Isoflurane is probably less sensitizing than halothane, but autonomic imbalance may actually be more important in arrhythmogenesis than any direct effect of volatile agents in patients with MVP. Patients with the MVP syndrome have been shown to possess good left ventricular function if mitral regurgitation or coronary artery disease is absent[262]; therefore myocardial depression from volatile agents will be well tolerated. Narcotics such as fentanyl will block sympathetic responses and promote hemodynamic stability; however, prolonged postoperative respiratory depression is a disadvantage with higher doses. Short-acting narcotics such as alfentanil and remifentanil, as well as other intravenous agents such as propofol, are available to facilitate rapid extubation.[263] Hypercapnia, hypoxia, and electrolyte disturbances increase ventricular excitability and should be corrected. If muscle relaxation is desired, then vecuronium is an excellent choice, because it does not cause tachycardia.

Patients with MVP who have mitral regurgitation are at greater risk for complications and warrant a different anesthetic approach, compared with those with MVP syndrome. Patients with more severe forms of MVP may rapidly progress to CHF and require cardiac surgery. The severity of mitral regurgitation will strongly influence anesthetic management. Invasive monitoring is routinely used during cardiac surgery for such patients and may even be necessary during noncardiac surgical procedures. Intraoperative TEE use is standard for mitral valve repair or replacement procedures. Opioid agents provide excellent hemodynamic stability without depressing myocardial function.[134] Although avoiding ketamine has been recommended by some for patients with the MVP syndrome, doses of ketamine below 0.5 mg/kg preserves hemodynamic stability in patients who are severely ill, especially when used in combination with opioids such as fentanyl. Unique aspects of anesthetic management for robotic mitral valve surgery involve peripheral bypass cannulation, single-lung ventilation, and often regional anesthetic techniques (eg, paravertebral block) to facilitate immediate postoperative extubation.[264,265] Anesthetic management for endovascular mitral valve repair (MitraClip, Abbott Vascular, Santa Clara, CA) typically requires general anesthesia to facilitate frequent transesophageal echocardiographic manipulation for proper device placement. A more extensive review of anesthetic management of valvular disease is found in Chapters 21 and 27.

Case Study 1: Mitral Valve Regurgitation and Septal Hypertrophy

The patient was an otherwise healthy 48-year-old woman referred for mitral valve surgery for severe mitral regurgitation. She was thin and fit. Chest auscultation revealed regular rate and rhythm with a 3/6 systolic murmur. Her preoperative transesophageal echocardiogram was remarkable for bileaflet prolapse and a left ventricular ejection fraction of 68%. The surgeon reviewed the transesophageal echocardiogram and noted that the basal ventricular septum appeared hypertrophied. The surgeon was experienced in complex valve repair and believed the valve was repairable but was concerned that the septal hypertrophy would result in significant postoperative SAM of the mitral leaflet. He requested further evaluation with TEE before CPB was initiated.

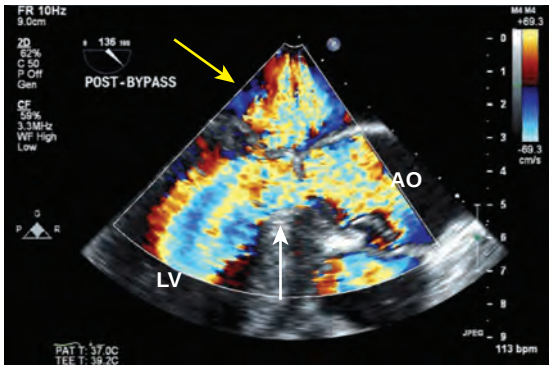

Fig. 24.64 Midesophageal long-axis view reveals the left ventricular outflow tract (LVOT) after the administration of isoproterenol. The heart rate is increased, and the blood pressure is decreased. The mitral regurgitation *(yellow arrow)* worsens, and aliasing of the color-Doppler signal in the LVOT *(white arrow)* now indicates turbulence of blood flow. *AO,* Aorta; *LV,* left ventricle.

Prebypass TEE confirmed the transthoracic echocardiographic findings with the basal ventricular septum measuring 21 mm. At rest, no evidence of SAM or LVOT obstruction was observed. The decision was made to challenge the patient with isoproterenol. With 4 µg of isoproterenol, the heart rate increased from 70 bpm to 135 bpm and the aortic blood pressure decreased from 126/52 to 77/45. Under these conditions, TEE revealed a significant amount of SAM and turbulent flow in the LVOT obstruction (Fig. 24.64). Needles placed in the aorta and LV were transduced and revealed a gradient across the LVOT of 67 mm Hg. Based on these findings, the surgical plan was altered.

CPB was instituted, and the heart arrested. The aorta was opened, and myectomy was performed through the aortic valve. The mitral valve was repaired with a posterior leaflet resection, and neochordae were placed to the anterior leaflet. The patient was weaned from CPB. A residual shelf of septal hypertrophy was seen with TEE. In addition, mild-to-moderate mitral regurgitation was posteriorly directed and assumed to be due to tethering of the anterior leaflet by the neochordae. CPB was reinstituted. A second myectomy was performed, and the neochordae removed. After weaning the patient from CPB, no mitral regurgitation was observed, and the ventricular septum appeared adequately myectomized. With an isoproterenol challenge achieving similar increase in heart rate to those seen before CPB, no evidence of SAM or LVOT obstruction was revealed with TEE. No gradient was demonstrated when needles were placed in the aorta and LV. The patient had an uneventful postoperative course.

In this instance, TEE was absolutely essential in guiding this complex mitral repair. It was able to determine the hemodynamic significance of the septal hypertrophy, the inadequacy of the initial myectomy, and the need to release the neochordae to the anterior leaflet. An alternative surgical procedure would have been mitral valve replacement. However, mitral valve repair is to replacement for the reasons previously indicated.

Patent Foramen Ovale

A PFO is the most common congenital defect involving the atrial septum.[266] It was first recognized as a causal relationship with stroke in 1877[267] and has since been proven one of the mechanisms of stroke.[268] Air, thrombus, or fat may travel from the RA to the LA into the systemic circulation causing a paradoxic embolus that may affect cerebral or coronary circulations. For years, a PFO was identified only in the catheterization laboratory, during surgery, or at autopsy. The availability of noninvasive two-dimensional echocardiography has

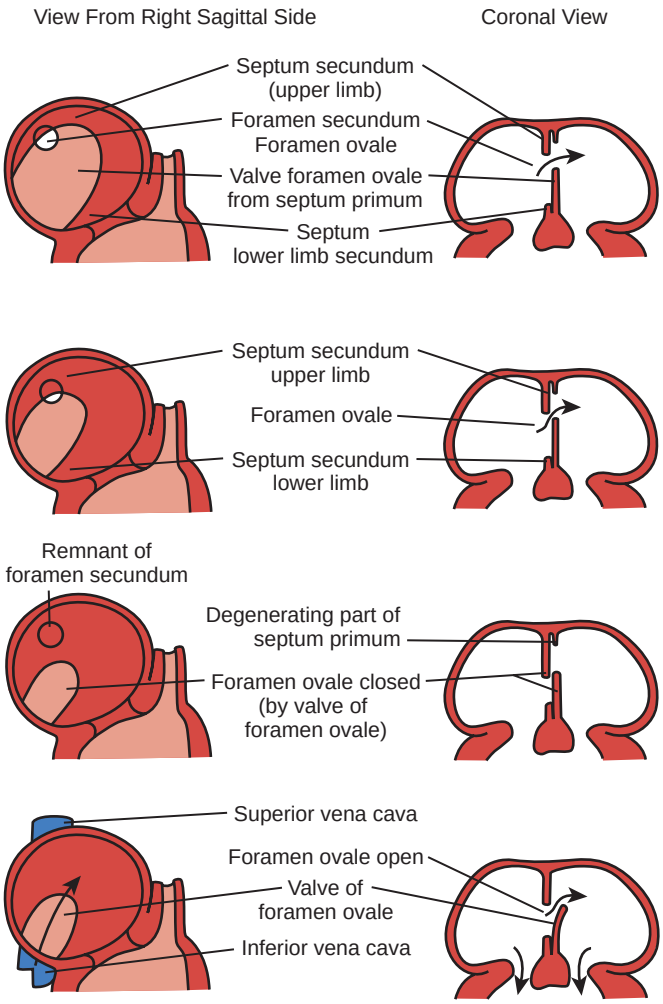

Fig. 24.65 Embryologic development of the interatrial septum. *(Reproduced with permission from Hara H, Virmani R, Ladich E, et al. Patent foramen ovale: current pathology, pathophysiology, and clinical status.* J Am Coll Cardiol. *2005;46:1768–1776.)*

considerably increased the annual number of diagnoses of PFO. The ability to so readily and safely close a PFO with minimally invasive techniques has created the need to develop guidelines to address the management of PFO.[269]

The foramen ovale is present during fetal circulation to improve the transport of maternal-oxygenated blood from the umbilical veins across the Eustachian valve selectively into the LA. With birth and the onset of respiration, pulmonary vascular resistance decreases, facilitating functional closure of the foramen ovale. If the flaplike covering from the septum primum does not fuse with the septum secundum over a period of a year, then there is anatomic failure of closure forming a PFO (Fig. 24.65). In patients with a PFO, any condition resulting in right atrial pressures exceeding left atrial pressures will facilitate right-to-left shunting. In contrast, left-sided heart conditions that result in left atrial pressures greatly exceeding right atrial pressures will cause left-to-right shunting. An individual may remain asymptomatic for years with a PFO, depending on the size of the shunt.

The incidence of PFO in the population has varied, depending on the study and diagnostic technique. Hagen and associates[270] reported a 27% incidence of PFO in nearly 1000 autopsies, considered by many, the definitive study on incidence of PFO. Subsequent studies involving various modes of echocardiography have reported the incidence of PFO in the population between 3% and 45%.[271] A recent retrospective study examining over 10 years of cardiac surgery in 13,000

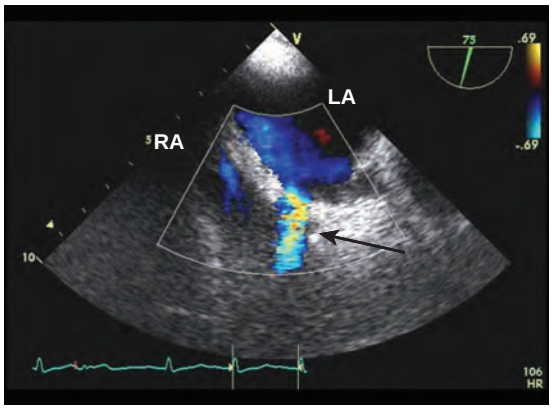

Fig. 24.66 Transesophageal image from the midesophagus at 75 degrees focusing on the interatrial septum. Color-Doppler imaging readily reveals a moderately sized shunt from the left atrium *(LA)* to the right atrium *(RA)* through a patent foramen ovale.

BOX 24.6 DISEASES AND RISKS ASSOCIATED WITH PATENT FORAMEN OVALE

Proved Causal Relationship
Stroke
Transient ischemic attack
Myocardial infarction
Eye infarction
Visceral infarction
Arterial limb embolism
Economy-class stroke syndrome
Platypnea orthodeoxia
Fat embolism in major orthopedic surgery
Air embolism in brain surgery in the sitting position
Decompression illness

Presumed Casual Relationship
Migraine (particularly with aura)
Transitory global amnesia
High-altitude pulmonary edema
Sleep apnea syndrome
Excessive snoring
Increased risk of systemic embolism in:
- Deep sea divers
- Brass musicians
- Glass blowers
- Professionals working in squatting position
- Supersonic jet pilots
- Astronauts

patients reported an incidence of PFO as 17% with TEE.[272] TTE is now recognized as less sensitive than TEE, possibly accounting for such variation in previous studies regarding the incidence of PFO. TEE has become the gold standard for diagnosing PFO with its higher image resolution than other methods and 100% sensitivity and specificity with autopsy findings (Fig. 24.66).[271] Because TEE is more invasive, additional technical advances in both TTE and transcranial Doppler have improved their sensitivity and, when combined, may be adequate for PFO screening purposes.[273]

Although a number of conditions are associated with PFO (Box 24.6) and may merit consideration for therapy, stroke receives the most attention. Approximately 700,000 strokes occur each year in the United States with 20% considered cryptogenic (ie, without an identifiable cause). In those individuals with a history of cerebral events, the

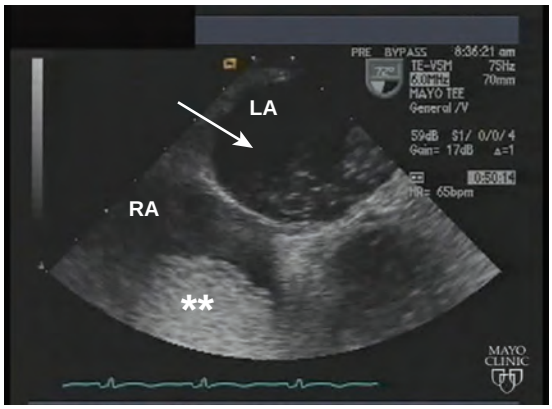

Fig. 24.67 Transesophageal image from the midesophagus at 72 degrees focusing on the interatrial septum. Agitated saline *(double asterisks)* is being used for contrast and can be seen in the right atrium *(RA)*. With the release of a Valsalva maneuver, the contrast is seen to enter the left atrium *(LA)* through a small patent foramen ovale.

prevalence of PFO ranges from 7% to 40%, depending on the diagnostic technique.[274] Several studies show a strong relationship between cryptogenic stroke and PFO, based on epidemiologic evidence,[268] but others dispute it. Petty and colleagues[275] conducted a population-based study looking at TEE in patients with cerebral ischemic events, compared with control subjects who had TEE but did not have cerebral ischemic events to eliminate bias present in other studies regarding PFO. They found that PFO was not an independent risk factor for stroke even when considering the size of the shunt. Although some recognize the PFO as an increased risk for cryptogenic stroke, it remains inconclusive.

The decision to close a PFO will include individual risk factors for stroke or other complications such as migraine headaches and platypnea orthodeoxia syndrome that may occur in the context of a PFO. Paradoxic embolus is more common if an atrial septal aneurysm, a large Eustachian valve, migraines, and an age of 50 years or older are present. Medium-to-large shunts, in combination with coagulation disorders, are highly correlated with paradoxic embolus.[269] In contrast, another study found no relationship to the size of the shunt with PFO and stroke.[275]

To diagnose paradoxic embolus, performing a correct provocative measure to ensure right-to-left movement of air or contrast is essential (Fig. 24.67). Agitated saline directed through an intravenous line with the Valsalva maneuver is most commonly used to confirm the diagnosis. The increased intrathoracic pressure from the Valsalva maneuver will lead to a temporary increased return of venous blood after the maneuver has ended; therefore the right atrial pressure will briefly exceed left atrial pressure to allow contrast administered into the right internal jugular vein to pass to the LA.[273] False-negative results may occur if the left atrial pressure is elevated to such an extent that the provocative measure does not cause right-to-left shunting.

Management of a PFO is dependent on several variables and has been largely debated because of the mixed results of several recent large studies and metaanalyses. Traditional medical therapy consists of various anticoagulation regimens and has been previously believed to be inferior to percutaneous device closure in patients with known PFO.[276] Percutaneous device closure of PFOs has been found to reduce the risk of recurrent strokes in several large studies and metaanalyses, but a recent metaanalysis has challenged the finding that the reduction of recurrent stroke risk is small with complications such as atrial dysthymias not uncommon.[266,277,278] Device closure for patients with PFO has been believed to benefit most those with recurrent stroke who have large PFOs, PFO and failed medical therapy, or who are young and without other contributable risk factors for atherosclerotic disease.[266]

Closure of PFOs can be performed either surgically or percutaneously. Although available in the late 1980s, percutaneous closure of PFOs became popular in the 1990s after a report described the successful closure of PFOs in 36 patients with known right-to-left shunt and presumed paradoxic emboli.[279] Percutaneous closure is generally performed in a catheterization laboratory with conscious sedation. Success rates (incidence of no residual shunting) have been initially very good, but the methods used to evaluate success may have been flawed, accounting for the wide range of success rates between 50% and 100%.[274] With use of transcranial Doppler to assess PFO closure, 9% of patients were found to have significant shunting after only 1 year after percutaneous closure.[280] Although percutaneous closure is routinely performed, it is not free of complications, which include dysrhythmias, cardiac perforation, air embolism, thrombus formation, and even death.[278,280]

Currently, surgically closing an isolated PFO with the safety and availability of percutaneous closure is rare. However, the use of intraoperative TEE during cardiac surgical procedures has increased the number of incidentally diagnosed PFOs. A retrospective review of cardiac surgeries in 13,000 patients found 17% with PFO.[272] The incidence of PFOs was believed to remain relatively static each year; however, the percentage of PFOs that were closed surgically increased to a maximum of 39% over the period. Not only are more PFOs closed as a percentage, but, over time, more surgeons as a percentage are choosing to close them.[269] The cause for these trends is not certain, but a PFO diagnosed incidentally during surgery creates a dilemma for the surgeon.

The decision to close an incidental PFO during cardiac surgery is not always evident, based on short- and long-term risks to the patient. When the finding has been incidental, recurrent paradoxic embolus and neurologic injury have not usually occurred. Certain conditions would almost mandate the closure of the PFO, such as the insertion of LVAD that would promote paradoxic embolus[273] or the onset of severe hypoxia attributable to increased right-sided pressures that cause a large right-to-left shunt. Little evidence suggests that incidentally discovered PFOs in patients without respective history increase morbidity or mortality.[281] In fact, one study demonstrated that an alteration in the surgical plan to include the closure of an incidental PFO actually increased the risk of stroke.[272] Surgical PFO closure when performed is routinely accomplished through a sternotomy, although new techniques of minimally invasive surgery also allow the incision to be a right thoracotomy. Closure requires CPB and cardioplegic arrest. Certain surgical procedures such as tricuspid or mitral valve repair or replacement that includes CPB and atriotomy, require minimal deviation from the originally planned procedure to close the PFO and thus incur little risk. In contrast, coronary artery bypass graft (CABG) surgery performed without CPB would entail the risk of going on CPB, aortic cross-clamping, and other complications associated with extracorporeal circulation. The decision to close an incidental PFO in such circumstances must include careful examination of the perceived risk and benefit for each individual patient.

Based on a survey of cardiac surgeons, 27.9% of respondents always close a PFO if detected during CABG surgery.[273] However, no evidence really indicates that all PFO found incidentally during cardiac surgery merit closure.[272] A retrospective study looking at those with and without PFO showed no differences between stroke, hospital and ICU lengths of stay, MIs, and death when propensity matching was applied for the comparison.[272] Long-term follow-up for 10 years also did not demonstrate any difference between those with a PFO and those without PFO. The outcomes for those who had PFO repaired versus not repaired found no differences except for a slight but significantly increased incidence of stroke postoperatively in the repaired group. In addition to the concern of paradoxic embolism, the risk of severe desaturation postoperatively is possible in patients with unrepaired PFO, but a case series of 11 off-bypass CABG surgeries with incidental PFOs that were not closed showed no adverse desaturation events perioperatively.[282]

Anesthesia Considerations

Anesthesia management for percutaneous PFO closure typically involves conscious sedation. Intraoperative management for the closure of an incidental PFO during cardiac surgery requires very little deviation from the anesthetic management of the scheduled procedure. However, certain precautions should be undertaken once the PFO has been identified.

Routine care for preventing venous air should be standard for cardiac surgery, including careful injection of medications to remove extraneous air from entering the venous system. Some providers use inline air filters on all intravenous lines once the presence of the PFO has been identified, but such practice is not widespread. Appreciating the potential for paradoxic embolus with any patient that requires mechanical ventilation is important. In situations during which the pulmonary vascular resistance may rise, such as during hypercapnia or with positive end-expiratory pressure (PEEP) greater than 15 mm Hg, the potential for right-to-left shunting increases.[283] The choice of anesthetic seems to have very little impact on the management of PFOs.

Case Study 2: Incidental Patent Foramen Ovale Found During Coronary Artery Bypass Graft Surgery

A 60-year-old man with a medical history of hypertension experienced angina on exertion. Specifically, he had bouts of recurring chest pain after jogging for 15 minutes on a treadmill. Previously, he had been able to jog for 30 minutes without difficulty. On physical examination, he appeared thin and fit. The heart was regular in rate and rhythm without a murmur, and the lungs were clear to auscultation. A stress ECG was positive for ischemia with coronary angiography revealing severe three vessel disease. The patient was scheduled for CABG surgery.

In the surgical unit, a transesophageal echocardiographic probe was placed for the purposes of monitoring ventricular function and evaluating regional wall motion abnormalities. The pre–bypass examination revealed an ejection fraction of 65%, normal valve function, and no regional wall motion abnormalities. The interatrial septum appeared redundant. Agitated saline was injected into the central line. After the release of sustained positive pressure ventilation, contrast was seen to enter the LA via a small PFO. No shunt was detected by color-Doppler imaging.

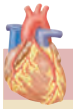
The surgeon was informed of the previously undiagnosed PFO. A discussion ensued regarding the implications of repairing the PFO, compared with leaving it undisturbed. The surgeon had not repaired a small PFO during a previous CABG surgery but learned that the patient had suffered a stroke 2 years later, presumably attributable to paradoxic embolism. Given the patient's young age and previous experience, the surgeon elected to repair the PFO that altered the surgical planning. The cannulation strategy was changed from a single right atrial venous cannula to bicaval cannulation. A right atriotomy was performed, and the PFO was closed with two stitches. The patient was easily weaned from CPB and had an uneventful postoperative course.

Pulmonary Hemorrhage

Pulmonary hemorrhage occurs in approximately 1.5% of patients with hemoptysis[284]; but mortality may reach 85%.[285] The definition of massive hemoptysis varies but is commonly characterized as more than 600 mL of expectorated blood over 24 hours or recurrent bleeding greater than 100 mL per day for several days. Four hundred milliliters of blood in the alveolar space seriously impairs oxygenation. Pulmonary hemorrhage may stabilize, only to worsen again without an obvious explanation, reflecting its unpredictable nature. Notably, death is not attributable to hemodynamic instability with hemorrhage but to excessive blood in the alveoli that causes hypoventilation and refractory hypoxia. Clot formation may lead to occlusion of bronchial segments or even the mainstem bronchus. Mortality is related to the quantity of blood loss within a given period.[285,286] For example, blood loss greater than 600 mL of blood over 16 hours has a mortality rate of 45%, whereas mortality is 5% if blood loss is 600 mL over 48 hours. A delay in initiating treatment because of difficulty in isolating the location of bleeding contributes greatly to the high mortality of pulmonary hemorrhage.

Hemoptysis may occur with various diseases and circumstances (Box 24.7). In the United States, chronic inflammatory lung disease and bronchogenic carcinoma are the most common causes of hemoptysis.[287] Of these causes, bronchitis (26%), lung cancer (23%), pneumonia (10%), and tuberculosis (8%) are most frequent. The inflammatory response is an important factor in the occurrence of bleeding.[288] The combination of chronic infection, inflammation, and vascular growth result in hypervascularization of the bronchial circulation that ultimately erodes into the alveoli.[289] Pulmonary hemorrhage may also result from vigorous suctioning of the lungs, surgery, and improper positioning of a PAC.[290] Massive hemoptysis is usually an emergency, because the underlying pulmonary disorder minimizes the patient's physiologic reserve.

To understand the pathogenesis of pulmonary hemorrhage, appreciating the anatomy of the pulmonary circulation is helpful. The lungs



BOX 24.7 CAUSES OF MASSIVE HEMOPTYSIS

Tracheobronchial Disorders
Amyloidosis
Bronchial adenoma
Bronchiectasis[a]
Bronchogenic carcinoma
Broncholithiasis
Bronchovascular fistula
Cystic fibrosis
Foreign body aspiration
Tracheobronchial trauma

Cardiovascular Disorders
Congenital heart disease
Mitral stenosis
Pulmonary arteriovenous fistula
Septic pulmonary emboli
Ruptured thoracic aneurysm
Arteriovenous malformation

Localized Parenchymal Diseases
Amebiasis
Aspergilloma[a]
Atypical mycobacterial infection[a]
Coccidioidomycosis
Lung abscess
Mucormycosis
Pulmonary tuberculosis[a]

Diffuse Parenchymal Diseases
Goodpasture syndrome
Idiopathic pulmonary hemosiderosis
Polyarteritis nodosa
Systemic lupus erythematosus
Wegener granulomatosis

Other Causes
Pulmonary artery rupture from a pulmonary artery catheter
Iatrogenic (eg, bronchoscopy, cardiac catheterization)
Pulmonary hypertension
Pulmonary edema
Pulmonary infarction

[a]Most common causes.

have a dual blood supply. The pulmonary arterial circuit is a high-flow, low-pressure circuit. The nutritive supply of the pulmonary structures is the bronchial arteries that originate from the aorta. Bronchial arteries extend into many areas around the lymph nodes, esophagus, and lungs, ultimately penetrating the bronchial wall to supply the bronchial mucosa. The bronchial and pulmonary circulations anastomose at several locations. Massive pulmonary hemorrhage usually involves bleeding attributable to a disruption of the high-pressure bronchial circulation.[284] These high-pressure, tortuous bronchial arteries are found throughout the thoracic cage. The bronchial circulation accounts for 98% of pulmonary hemorrhage, and the pulmonary circulation accounts for the remaining 2%.[286]

Diagnosis of hemoptysis requires a few simple tests. Visual inspection can usually distinguish gastrointestinal bleeding from pulmonary hemorrhage. Hemoptysis is often bright red with some sputum. Hemoptysis attributable to pulmonary artery rupture is usually copious (200 to 2000 mL).[290] Treatment begins with conservative management and simultaneous efforts to locate the bleeding site. A chest roentgenogram may reveal an infiltrate, but neither a chest roentgenogram nor a physical examination has been reliable in localizing the affected lung. Recently, better noninvasive technology such as the multidetector row CT is capable of rapidly and accurately determining the site of bleeding.[287] Flexible fiberoptic bronchoscopy of the airways may be limited by severe bleeding that obscures the view, and persistent attempts should not delay other therapies. Rigid bronchoscopy is better suited for the identification of bleeding during massive hemoptysis and the removal of any large clot that may be obstructing the airway. However, the view of the upper lobes is limited, and the procedure requires general anesthesia. Instillation of epinephrine in the bronchi may facilitate better visualization by slowing the bleeding. Ultimately, angiography of the pulmonary and bronchial arteries may be necessary to localize the source of the bleeding.[285] Imaging for bronchial artery bleeding begins with a thoracic aortogram to localize all the primary systemic arteries to the lungs that may be bronchial or nonbronchial. Once the feeding arteries are localized, selective bronchial arteriography is then used to identify the bleeding vessels.[291]

Therapeutic options for bleeding depend on the extent of bleeding. Flexible bronchoscopy may be able to identify the source of bleeding and perform techniques, such as epinephrine flush and cold-saline lavage to minimize hemorrhage and possible balloon bronchial blockers to tamponade any bleeding.[292] Advancements in bronchoscopy have seen success with the use of topically applied agents consisting of oxidized regenerated cellulose mesh injected at the site of bleeding.[287] Additionally, the use of topically applied factor VIIa (FVIIa) has been reported with success in massive hemolysis, secondary to a medical cause, although its use in this manner is off label.[289] FVIIa has been anecdotally reported beneficial with massive hemoptysis, despite low platelet count, trauma, vasculitis, and bone marrow transplantation. Other medications used to reduce bleeding include Premarin, desmopressin, vasopressin, and tranexamic acid.[293]

With rapid or persistent bleeding, a double-lumen endotracheal tube (ETT) may be necessary to isolate the bleeding from the unaffected lung. Misplacement of a double-lumen ETT occurs in 45% of patients after the initial attempt and 54% after patient positioning.[294] If the patient was administered an anticoagulant drug, then airway manipulation in connection with double-lumen ETT placement may incite further mucosal damage and bleeding. A Fogarty catheter, as described by Larsen and Gasior,[295] may be passed within an existing ETT under bronchoscopic guidance to the affected bronchus, thereby minimizing additional trauma to the airway caused by reintubation and protecting the uninvolved lung. The Univent ETT is an alternative to a double-lumen ETT but requires exchanging the existing ETT for the Univent ETT. A single-lumen ETT should not be advanced into the right main bronchus if bleeding is believed to be in the right lung because of the proximal location of the right upper lobe bronchus. Insertion of a bronchial blocker is another lung isolation strategy, but placement may again be challenging during active bleeding.

Continued bleeding after stabilization and conservative therapy necessitates bronchial artery embolization, which is considered first-line therapy for massive hemoptysis. Although success rates of 75% to 98% have been reported, 16% to 20% of patients rebleed within 1 year.[296–298] Bronchial artery embolization is often performed in conjunction with the thoracic aortogram after identifying the bleeding vessels with polyvinyl alcohol particles, Gelfoam, and/or dextran microspheres. A study found 88% of patients who underwent bronchial artery embolization had immediate control of bleeding, whereas another group of patients (81%) had bleeding cessation within 48 hours.[299] Bronchial artery embolization has greatly advanced treatment success for pulmonary hemorrhage. Immediate recurrence of hemoptysis after embolization may signal that additional contributing vessels were not identified and embolized. Latent hemoptysis is often due to recanalization or collateralization. Although it has proven effective, recanalization is not without complications, especially vascular complications such as coronary artery syndrome, spinal cord ischemia, and esophageal wall necrosis.[291]

The ability to use an array of treatment options in a multidisciplinary approach to this life-threatening condition will increase survival and reduce complications.[292] Efforts to control bleeding for at least 48 hours with nonsurgical alternatives have reduced perioperative morbidity and mortality, compared with early surgical therapy for massive hemoptysis. If bleeding persists and/or nonoperative therapies have either failed or are not feasible, then surgical treatment may be required. A localized bleeding site and sufficient lung function are ideally determined before surgical resection, as total pneumonectomy may be required. Postoperative mortality rates vary tremendously from 1% to 50%.[284] Surgery is contraindicated in those with lung carcinoma invading the trachea, mediastinum, heart or great vessels, terminal malignancy, and progressive pulmonary fibrosis.

The introduction of the PAC in 1970 allowed physicians to obtain CO, SVR, and estimates of left ventricular performance, as well as to detect perioperative myocardial ischemia. As PAC use increased, a rare but often fatal cause of pulmonary hemorrhage—the rupture of the pulmonary artery in patients undergoing cardiac surgery—emerged.[290] The incidence ranges from 0.06% to 0.2% of cases, with a corresponding mortality rate of 45% to 64%.[300] With respect to cardiac surgical patients, death may occur within minutes of pulmonary artery rupture or over a period of 1 to 14 days postoperatively.[301] The diagnosis may be initially missed because patients may be asymptomatic or only mildly symptomatic. A small amount of hemoptysis may herald the onset of severe pulmonary hemorrhage.[302] Other signs of pulmonary artery rupture are hypotension, decreased arterial oxygenation, bronchospasm, pleural effusion, hemothorax, and pneumothorax. Pulmonary hemorrhage rarely occurs during cardiac surgery; however, when present, it is a life-threatening emergency.

Certain factors predispose a patient to pulmonary artery rupture such as age older than 60 years, anticoagulation, and distal migration of PAC.[290] Although pulmonary arterial hypertension (PAH) is often present with pulmonary artery rupture, it is not a risk factor,[301] but PAH may simply promote distal migration of the PAC. Chronic PAH weakens the pulmonary artery and veins; thus a patient's susceptibility to rupture is increased. The mechanism of pulmonary artery rupture is multifactorial, but the catheter balloon is believed to be instrumental.[303] Maximal pressures for balloon inflation are approximately 1700 mm Hg and can easily reach 1000 mm Hg with the start of inflation. PACs that reside distally will lower the inflation pressures necessary to rupture the pulmonary artery, particularly in the older adult. Distal migration of the PAC also occurs more easily in patients undergoing hypothermic CPB, because hypothermia stiffens the PAC. Eccentric inflation of the PAC balloon contributes to pulmonary artery rupture, as evidenced in both cadavers and patients.[304] Inflation that distorts the balloon drives the catheter tip through the vessel wall (Fig. 24.68). Manipulation of the heart may also perforate the pulmonary artery.

The extent of bleeding after pulmonary artery rupture will determine treatment. If the rupture occurs during CPB, then extracorporeal

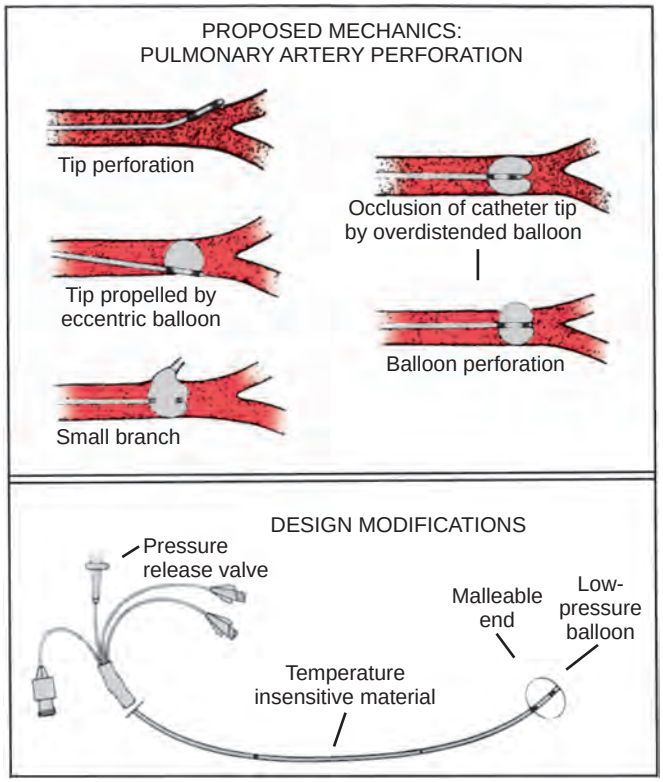

Fig. 24.68 Possible mechanisms of pulmonary artery perforation with balloon-tipped flow-guided catheter are illustrated. These problems require modifications in catheter design. *(Reproduced with permission from Barash PG, Nardi D, Hammond G, et al. Catheter-induced pulmonary artery perforation. Mechanisms, management, and modifications.* J Thorac Cardiovasc Surg. *1981;82:5.)*

support should be maintained to ensure adequate oxygenation and optimal conditions for pulmonary artery repair. If pulmonary artery rupture occurs before CPB, then the use of PEEP and maintaining PAC position with the balloon inflated may provide temporary tamponade effect until more definitive therapies ensue.[301,305] If anticoagulation has been neutralized, then blood loss of 1000 mL or more over 24 hours should merit consideration for surgical intervention, taking into account the patients underlying pulmonary function and tolerance for lobectomy or potentially pneumonectomy.[285,286]

To reduce the risk for pulmonary artery rupture, the placement of a PAC distally in the pulmonary artery should be avoided. Advancing the PAC more than 5 cm beyond the pulmonary valve is not advisable. The balloon should not be inflated against increased resistance, particularly if the patient has been given an anticoagulant drug or after separation from CPB. The pulmonary artery waveform should always be carefully observed with inflation and deflation of the balloon. Retracting the PAC into the RV on the initiation of CPB or withdrawing the PAC 5 cm immediately before CPB is advisable.

Pericardial Heart Disease

The pericardium is a two-layer sac that encloses the heart and great vessels. The inner layer is a serous membrane (visceral pericardium) covering the surface of the heart. The outer layer is a fibrinous sac (parietal pericardium), which is attached to the great vessels, diaphragm, and sternum. The parietal pericardium is a stiff collagenous membrane that is resistant to acute expansion. The space between the two layers is the pericardial space, normally containing up to 50 mL of clear fluid that is an ultrafiltrate of plasma. It can gradually dilate to accept large volumes of fluid if slowly accumulated; however, rapid

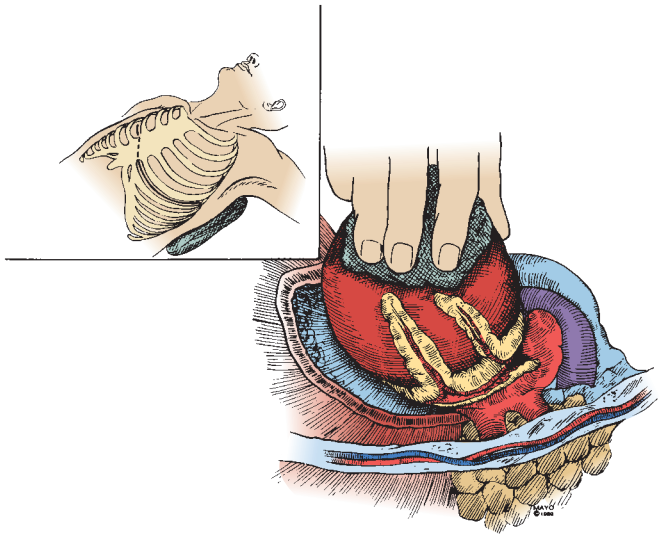

Fig. 24.69 Approach for pericardiectomy through a fifth left intercostal space for anterolateral thoracotomy. The phrenic nerves are preserved on pedicles. The lateral course of the phrenic nerves and the pericardial attachment make the phrenic nerves easily damaged during the removal of the pericardium. *(Reproduced with permission from Tuna IC, Danielson GK. Surgical management of pericardial disease.* Cardiol Clin. *1990;8:683.)*

fluid accumulation leads to cardiac tamponade. The two layers of the pericardium are joined at the level of the great vessels and at the central tendon of the diaphragm caudally, and a serous layer extends past these junctions to line the inside of the fibrinous sac (parietal pericardium). The vagus nerve, left recurrent laryngeal nerve, and esophageal plexus innervate the pericardium, along with sympathetic contributions from the stellate ganglion, first dorsal ganglion, and other ganglia. The lateral course of the phrenic nerve on either side of the heart is an important anatomic relationship because this nerve is encapsulated in the pericardium and thus can easily be damaged during pericardiectomy (Fig. 24.69). The pericardium is not essential for life, and pericardiectomy causes no apparent disability, but it has many subtle functions that are advantageous. Foremost, it acts to minimize torsion of the heart and reduces the friction from surrounding organs. In addition, the pericardium has also shown immunologic, vasomotor, paracrine, metabolic, and fibrinolytic activities.[306]

Acute Pericarditis

Acute pericarditis is common, but the actual incidence is unknown because it often goes unrecognized. It is generally self-limited with symptoms lasting 6 weeks. Acute pericarditis has many causes (Box 24.8), the most common of which is viral (30–50%).[307] Unfortunately, only 25% of cases are diagnosed with a defined cause.[308] Anesthesiologists encounter patients with acute pericarditis in the context of malignancy, MI, postcardiotomy syndrome, uremia, or infection when surgery is required, because symptoms are incapacitating and medical therapy has failed.

Acute pericarditis is characterized by fibrin deposits localized on the pericardial surface. A serous effusion may accompany the fibrinous inflammation. Consequently, the mesothelial cell layer is replaced by a fibrin membrane that has white blood cells scattered throughout. Pericardial fluid may suggest an infectious, neoplastic, or inflammatory cause.[307] Pericarditis occurs in approximately 20% of patients who suffer an MI, primarily within the first week.[309] A distinction is made between pericarditis that occurs during the first week and the Dressler syndrome, which usually appears 2 to 3 months after an MI. With acute pericarditis, pleuritic chest pain is described in the center of the chest, radiating to the back and left trapezius muscle. This

pain is more continuous than the intermittent pain of myocardial ischemia. Some degree of dyspnea may be present with acute pericarditis. Occasionally, the presentation of pericarditis may be right-sided heart failure because large and rapid accumulations of pericardial fluid will sufficiently increase intrapericardial pressure to obstruct right ventricular filling through the SVC and IVC, resulting in tamponade. Atrial arrhythmias may also occur.

In general, acute pericarditis can be differentiated from MI by the measurement of serum cardiac enzymes, but myocardial enzymes are sometimes found in the serum of patients with pericarditis. It is also common to observe the early onset of a low-grade fever that lasts for days to weeks and the presence of a friction rub after the onset of chest pain. Pericardial friction rub is pathognomonic of pericarditis but may be heard only intermittently. Early electrocardiographic changes typical of pericarditis are ST-segment elevation in two or three standard limb leads and in most of the precordial leads. ST-T wave elevation is often present but may be confused with MI (Fig. 24.70). Acute pericarditis generally results in diffuse ST-T changes, whereas an MI usually is associated with more localized ST-T changes. T-wave inversions follow the acute ST-segment abnormalities as pericarditis enters the subacute phase. Q waves usually do not appear during progression of electrocardiographic changes. The echocardiographic findings in a patient with suspected acute pericarditis are variable. A pericardial effusion may be present, the pericardium may be thickened, or it may appear completely normal. If an effusion is present, then cardiac tamponade must be excluded. If the pericardium appears thickened, then additional constrictive physiologic evidence should be sought (see later discussion). The chest roentgenogram may reveal a slightly enlarged cardiac silhouette with a pericardial effusion that indicates the effusion is at least 250 mL. A rapid accumulation of a small volume of pericardial fluid may also cause tamponade. Gradual fluid accumulation may lead to a liter or more of pericardial fluid without symptoms of cardiac tamponade. Pericardial fluid may also be found with CHF, valvular disease, or endocarditis. Pericardiocentesis may be performed in acute pericarditis, either to confirm the diagnosis or to relieve symptoms of cardiac tamponade. Pericardiocentesis is not without risk of complications, including but not limited to coronary artery or ventricular puncture. Echocardiographic evaluation of ventricular contractile function should occur before performing pericardiocentesis. If repeated aspirations are required for relief of tamponade, then a pericardial window or pericardiectomy may be necessary.

Detection of myocardial-directed serum antibodies in the Dressler syndrome and in postpericardiotomy syndrome suggests that these syndromes are immune-related responses. Postpericardiotomy syndrome

consists of acute nonspecific pericarditis that usually begins between 10 days and 3 months after cardiac surgery or trauma. In a prospective study of 944 adult patients who underwent cardiac surgery, the incidence of postpericardiotomy syndrome was 17.8%, although the incidence has been reported as high as 50% of patients after cardiac surgery.[310]

Treatment of acute pericarditis consists of symptomatic relief and treating the underlying systemic illness. Symptomatic relief involves support, bed rest, and nonsteroidal antiinflammatory agents for analgesia. Left stellate ganglion block has been used to relieve unremitting pain.

Constrictive Pericarditis

CP is a dense fusion of the parietal and visceral pericardium that limits diastolic filling of the heart, irrespective of the cause. The changes in the pericardium can be due to scarring, induced by a single episode of acute pericarditis, or caused by a prolonged exposure to a recurrent or chronic inflammatory process. Historically, tuberculosis was a major cause of CP, but currently most cases (33%) are believed to be idiopathic.[311] The leading identifiable causes of CP are previous acute pericarditis, cardiac surgery, and mediastinal irradiation in developing countries.[312] Table 24.9 lists some of the causes of chronic CP. Idiopathic, neoplastic, postirradiation, or uremic pericarditis account for most cases of CP that require surgical intervention. Up to 18% of pericardiectomies are attributed to previous cardiac surgeries,[311] which may explain the increase in the number of cases of CP over the last 15 years.[313]

CP clinically resembles the congestive states of myocardial failure and chronic liver disease.[306] The most frequent physical signs are jugular venous distention, hepatomegaly, and ascites. Symptoms are nonspecific and progress over years unless the cause is radiation, cardiac surgery, or trauma that can, instead, develop over a period of months. The normal filling phases of the jugular venous pulse are shown in Fig. 24.71. Venous pressure waves in pericardial constriction are characterized by a prominent Y descent. Kussmaul sign (a paradoxic increase in venous pressure with inspiration) may be present. The elevation of systemic venous pressure accounts for some of the classic symptoms of CP, such as hepatic congestion and peripheral edema.[200] A significant paradoxic pulse occurs in only one third of patients with chronic CP.

Characteristic electrocardiographic changes are P mitrale (broadened P-wave), low QRS voltage, and T-wave inversion.[313] One fourth of patients have atrial fibrillation. Cardiomegaly demonstrated on chest roentgenogram is nonspecific, whereas pericardial calcification is sometimes appreciated (<30%),[312] although it is less common than in the past with the decreased incidence of tuberculosis. Although calcification is very specific for CP, it is not very sensitive. CT and MRI may demonstrate the typically thickened pericardium of CP; however, patients with surgically proven CP may have a normal-appearing pericardium with imaging tests in 28% of individuals.[314]

A comprehensive echocardiographic examination including two-dimensional and Doppler imaging is an essential part of the diagnostic workup and is often adequate for diagnosis. The two-dimensional findings may include a thickened pericardium, abnormal motion of the ventricular septum, IVC dilation, and flattening of the left ventricular posterior wall during diastole.[114] A key diagnostic finding in constriction is ventricular interdependence. Diastolic filling of the ventricles is reliant on each other, because the overall cardiac volume is fixed by the stiffened pericardium. With inspiration, intrathoracic pressure falls, as does the pressure in the pulmonary vasculature. The thickened pericardium prevents the transmission of this pressure decrease to the ventricles. Thus filling of the LV decreases just after inspiration and is due to the fall in pressure within the pulmonary vasculature. Because the intracardiac space is fixed, a decrease in filling pressure to the LV allows increased filling in the RV. The result is a shift in the ventricular septum into the LV during inspiration and an increase in hepatic vein diastolic flow.[114] With expiration, intrathoracic pressure increases, the pressure in the pulmonary vasculature increases, and left ventricular filling is augmented with a shift of the ventricular septum into the RV during diastole. Right ventricular filling is now decreased because of the positive intrathoracic pressure and flow reversals that occur during diastole in the hepatic veins. When several cardiac cycles are viewed consecutively, the ventricular septum appears to *bounce* between the LV and RV.

Fig. 24.71 Schematic depiction of normal jugular venous pressure waves in relationship to the electrocardiogram. The A wave is a result of atrial contraction; the prominent negative X descent occurs during ventricular systole and is a result of downward displacement of the base of the heart and tricuspid valve, as well as continued atrial relaxation. The small C wave, which interrupts the X descent, is probably due to the bulging of the tricuspid valve into the right atrium. The V wave represents right atrial filling while the tricuspid valve is closed. Finally, the Y descent occurs after opening of the tricuspid valve and during rapid inflow of blood from the right atrium into the ventricle. *(Reproduced with permission from Legler D. Uncommon diseases and cardiac anesthesia. In: Kaplan JA, ed.* Cardiac Anesthesia. *2nd ed. Philadelphia: Saunders; 1987:785.)*

Echocardiographic findings suggestive of CP include a respiratory variation of 25% or more of early mitral inflow velocity (E velocity), accompanied by expiratory diastolic flow reversals within the hepatic veins (Fig. 24.72).[315,316] These findings, however, are present in only approximately 50% of patients with constriction.[317,318] Respiratory variation of ventricular septal motion is also appreciated with M-mode imaging modality.[315,316] Tissue-Doppler imaging of the mitral annulus has become a valuable tool in the diagnosis of constriction. Under normal conditions, early diastolic mitral annular velocity (e′) is greater at the lateral annulus than the medial annulus. In CP, the medial annular velocity (e′) is often normal or increased (>8 cm/sec) and in excess of lateral annular velocity and has thus been termed *annulus reversus*.[315,316] In myocardial disease such as RCM, relaxation is impaired and the diastolic mitral annular velocity (e′) is low (<6 cm/sec).[315,316] Tissue-Doppler imaging can be a valuable tool in differentiating between restrictive and constrictive diseases, but no uniform acceptance of indices differentiates CP from RCM.[306] Even with Doppler echocardiography, one must be aware of the loading

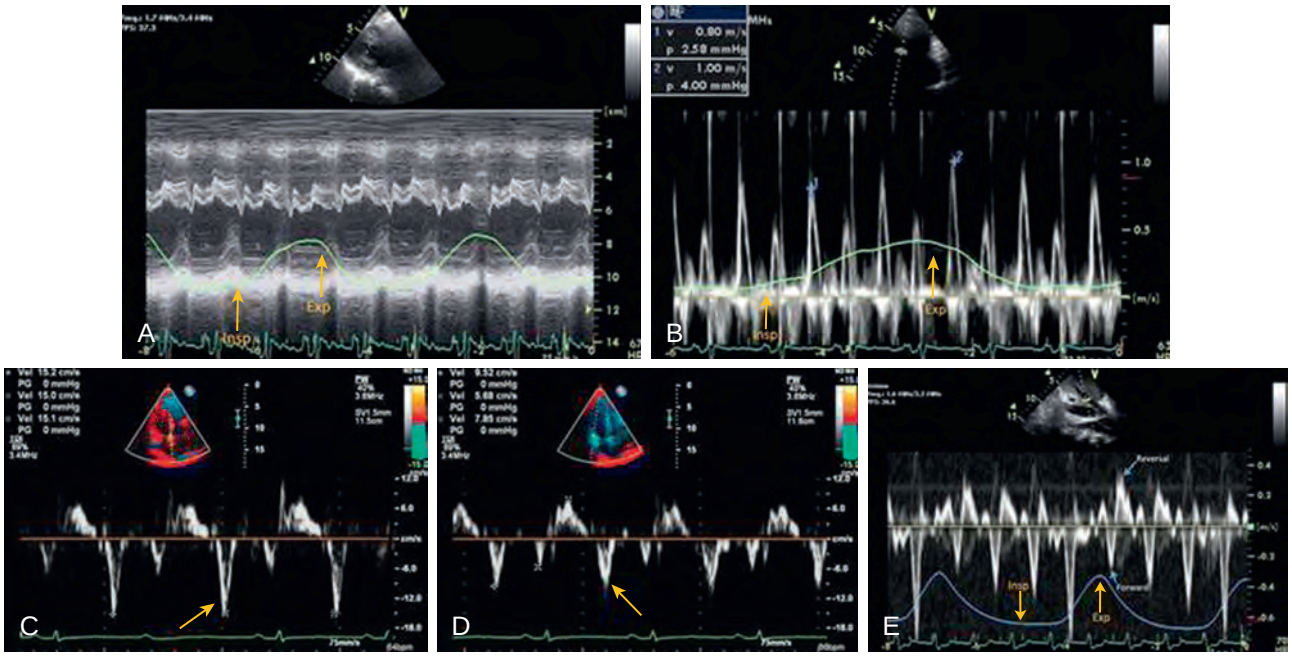

Fig. 24.72 Echocardiographic findings associated with constrictive pericarditis. (A) Transthoracic echocardiography parasternal long-axis M-mode demonstrates leftward septal motion with inspiration. (B) Pulsed-wave Doppler imaging at the mitral valve leaflets demonstrates inspiratory decrease and expiratory increase of early inflow velocity. (C) Medial and (D) lateral mitral annular tissue-Doppler images record increased early relaxation velocity (*e'*) with medial velocity exceeding lateral velocity. conditions and respiratory effort of the patient during the Doppler examination. Gated cardiac MRI is also often used in the workup for CP and allows for an assessment of pericardial inflammation and thickening, along with the characteristic abnormalities in septal motion and mitral inflow.[316] Invasive cardiac catheterization is still regarded as the gold standard for diagnosing CP; however, noninvasive techniques previously described often provide adequate diagnostic data.[316]

TEE is not tremendously helpful in patients undergoing pericardiectomy. When it is used, right ventricular function and the degree of tricuspid regurgitation can be evaluated before and after the procedure. However, remembering that the diagnosis of constriction relies on the Doppler findings in spontaneously breathing individuals is important. These findings are not validated in patients undergoing positive pressure ventilation, thus the surgical unit is not the correct place to confirm or refute a suspected diagnosis of constriction.

The hemodynamic changes of CP are primarily related to the isolation of the cardiac chambers from respiratory effects on thoracic pressure and a fixed end-diastolic ventricular volume.[312] The pericardium limits the filling of the LV during inspiration, which leads to increased filling in the RV because the pericardium is so noncompliant. With expiration, the opposite is observed as the LV is overfilled and the RV is limited. The limitation of right ventricular diastolic filling occurs when the cardiac volume approximates the pericardial volume, usually in mid and late diastole, and is characterized by the square root or dip-and-plateau sign of the right ventricular waveform (Fig. 24.73). Filling is limited by the noncompliant pericardium. The square root sign occurs because the constricting pericardium is essentially part of the ventricular wall. When the ventricle contracts, the pericardium is deformed similar to a spring. As diastole begins, the spring is released and the ventricle fills rapidly, decreasing the ventricular pressure and creating the dip of the dip-and-plateau wave. As cardiac filling approaches the limit set by the fixed pericardium, the plateau of the ventricular filling curve arrives. There is significant elevation of right atrial, left atrial, and ventricular filling pressures. Pulmonary artery

diastolic pressure, pulmonary capillary wedge pressure, and right atrial pressure are equal and elevated (*pressure plateau*) in CP and attributable to the limitation of the pericardium. Pulmonary artery systolic and right ventricular systolic pressures range from 35 to 45 mm Hg, although PAH is rare. Differences between CP and RCM have been previously reviewed.

Surgical Considerations for Pericardial Disease

Pericardiectomy is performed for recurrent pericardial effusion and CP refractory to conservative therapies. Pericardial dissection for effusive pericarditis is straightforward; however, pericardiectomy for CP is often a surgical challenge with an operative mortality of 5.9% to 11.9%[319] and 5-year survival rate of 78%.[320,321] The occurrence of tricuspid regurgitation may occur, similar to CP with signs of right-sided heart failure and volume overload. In fact, one fifth of patients undergoing surgical intervention for CP have significant tricuspid

regurgitation.[319] Unfortunately, surgical treatment of tricuspid regurgitation with CP has had no effect on long-term survival but also has not increased the risk of surgery. The presence of tricuspid regurgitation may identify a subset of patients with CP who have more advanced disease.

Persistent low CO immediately after pericardiectomy is a major cause of morbidity and mortality occurring in 14% to 28% of patients in the immediate postoperative period.[322] Examination of patients after pericardiectomy for CP found that a significant number of patients had abnormal left ventricular contractility and relaxation abnormalities, based on high-fidelity manometer measurements.[322] More importantly, this group was at a higher risk of operative and long-term mortality. These finding were in contrast to the accepted belief that the pericardium is the problem in these patients and the myocardium is normal. Determination of myocardial function is important as a marker of patient outcome and the need for inotropic support. Although patients with cardiac tamponade usually improve clinically once the pericardium is opened, improvement is not always apparent immediately after pericardiectomy for patients with CP. Noticeable improvement in cardiac function may take weeks; however, 90% of patients will experience relief of symptoms postoperatively.[311]

Median sternotomy provides excellent exposure and access for pericardiectomy, but thoracotomy in the left anterolateral position is also used. Opinions vary regarding the extent of pericardial resection for alleviation of cardiac constriction and the need for CPB. Total pericardiectomy was found to result in superior outcomes, compared with partial pericardiectomy in a retrospective review.[323] Removal of adherent and scarred pericardium to release both the RV and LV involves extensive manipulation of the heart and hemodynamic instability. The decision to use CPB is influenced by the surgeon's confidence in being able to achieve complete pericardial excision with acceptable hemodynamic stability. A more aggressive approach to pericardiectomy with CPB has increased over the years as survival has improved, and this trend may continue.[319] However, good results have been reported with and without CPB.[323] The use of CPB entails full heparinization and may exacerbate blood loss from the many exposed cardiac surfaces. Furthermore, prolonged CPB in debilitated patients contributes to early mortality associated with pericardiectomy. An especially high-risk group of patients undergoing pericardiectomy are those with postradiation CP. They not only suffer from the effects of radiation on the myocardium that may create a more sustained restrictive effect even after pericardiectomy, but they also suffer from radiation-induced pulmonary dysfunction.[319]

Anesthetic Considerations

Anesthetic goals for managing patients with CP for pericardiectomy include minimizing bradycardia, myocardial depression, and decreases in preload and afterload. Monitoring considerations include arterial and central venous pressure catheters. One femoral site should be reserved for femoral cannulation, if necessary, to emergently initiate CPB. PAC monitoring is often used because of the risk of low CO syndrome postoperatively. Low CO syndrome develops in a subset of patients with CP, irrespective of the approach or extent of pericardiectomy.[323] Low CO, hypotension, and arrhythmias (atrial and ventricular) are common during chest dissection. Because of limited and relatively fixed ventricular diastolic filling, CO becomes rate dependent. If myocardial function or heart rate is depressed, then ß-agonists or pacing will improve CO. Catastrophic hemorrhage can occur suddenly if the atrium or ventricle is perforated, necessitating adequate central venous access. Damage to coronary arteries may also occur during dissection; so careful monitoring of the ECG for signs of ischemia is prudent. Pericardiectomy via left anterior thoracotomy requires close monitoring of oxygenation because the left lung is severely compressed during dissection. Currently, the anesthetic technique is based on achieving early extubation similar to other cardiac surgical cases, assuming acceptable hemostasis and hemodynamic parameters.

Cardiac Tamponade

Cardiac tamponade occurs in a variety of clinical situations, most commonly secondary to malignancies or postpericardiocentesis in nonsurgical patients.[324] It is a continuum of physiologic changes that necessitate rapid diagnosis and treatment. Cardiac tamponade may be easily missed in the early stages as the signs and symptoms are often subtle until reaching a critical state. Decompensated cardiac tamponade is an emergency, requiring either immediate pericardiocentesis or surgical intervention.

Tamponade exists when fluid accumulation in the pericardial space dramatically increases intrapericardial pressure and limits filling of the heart. The rate of pericardial fluid accumulation, rather than the absolute fluid volume, is the determinate of tamponade sequelae. Patients with mild tamponade often remain relatively asymptomatic. One of the reasons for delay in the appreciation of tamponade is the tendency of clinicians to overestimate the sensitivity of clinical signs such as hypotension, pulsus paradoxus, and jugular venous distension.[325] In several studies, dyspnea is the earliest and most sensitive of symptoms to indicate tamponade,[325] and severe tamponade is accompanied by both dyspnea and chest discomfort.[306] If an ECG is obtained, then tamponade may show low-voltage QRS complex, electrical alternans (Fig. 24.74), and T-wave abnormalities. Sinus rhythm is usually present in tamponade. A chest roentogram requires at least 200 mL of fluid to accumulate in the pericardium before the silhouette, known as the *water bottle effect*, is seen.[327] The classic Beck triad of acute tamponade, consisting of (1) decreasing arterial pressure, (2) increasing venous pressure, and (3) a small, quiet heart, is only observed in 10% to 40% of patients.[327] Pulsus paradoxus (Fig. 24.75) may also be observed, which is a fall in systolic blood pressure of more than 10 mm Hg during inspiration, caused by a reduced left ventricular stroke volume that is generated by increased filling of the right-sided heart during inspiration. Pulsus paradoxus is not sensitive or specific for tamponade, because it may be present in those with obstructive pulmonary disease, right ventricular infarction, or CP. Pulsus paradoxus may be absent when left ventricular dysfunction, positive pressure breathing, atrial septal defect, or severe aortic regurgitation are present.

Hemodynamic monitoring may aid in the diagnosis of cardiac tamponade. As diastolic filling begins to disappear, the jugular venous pulse loses a prominent Y descent. A prominent X descent remains by the decrease in intrapericardial pressure that occurs during ventricular ejection. Eventually, the pericardial pressure-volume curve becomes almost vertical, causing any additional pericardial fluid to greatly restrict cardiac filling and to reduce diastolic compliance.[328] Ultimately, the right atrial pressure, pulmonary artery diastolic pressure, and pulmonary capillary wedge pressure equilibrate (Fig. 24.76). Equilibration of these pressures (within 5 mm Hg of each other) merit immediate action to rule out acute tamponade. Echocardiography is the current method of choice and the most reliable noninvasive method to detect pericardial effusion and exclude tamponade.

The major hemodynamic changes and compensatory mechanisms of tamponade are outlined in Fig. 24.77. Elevated intrapericardial pressure on the heart during the cardiac cycle is responsible for the hemodynamic changes of cardiac tamponade. Hemodynamic manifestations are primarily due to atrial rather than ventricular compression. Initially with mild tamponade, increased atrial and pericardial pressures limit diastolic filling. Although the intracardiac pressures are elevated with tamponade, the effective preload is greatly reduced, causing lower stroke volume and CO. To maintain CO, sympathetic reflexes are stimulated to increase heart rate and contractility.[313] The rising right atrial pressure also reflexively stimulates tachycardia and peripheral vasoconstriction. Blood pressure is initially maintained by systemic vasoconstriction, but CO begins to fall along with systemic blood pressure as tamponade progresses. Once venous pressure falls below pericardial pressure, the drop in systemic blood pressure is profound and risks inadequate coronary perfusion pressure.[328] This drop in pressure resembles hypovolemic shock and will respond to fluid

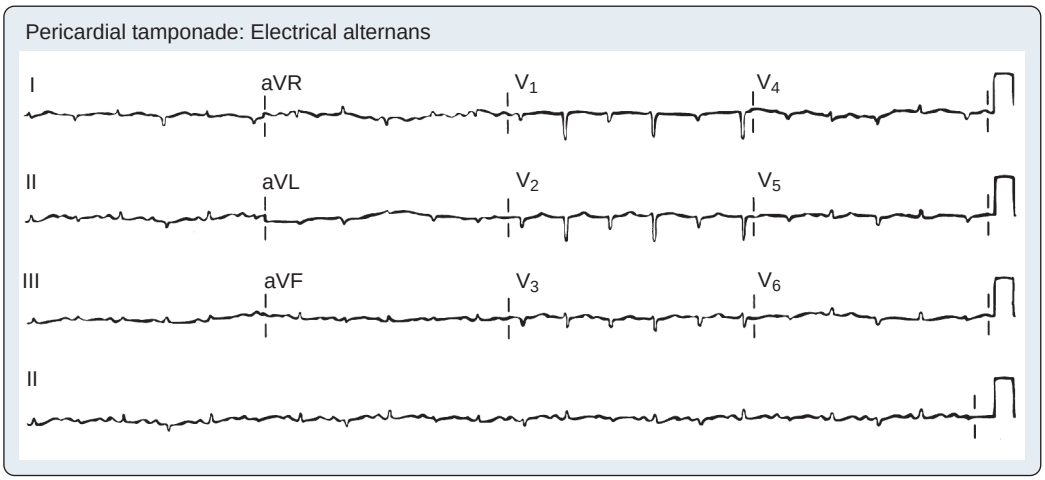

Fig. 24.74 Electrical alternans in pericardial tamponade is due to the swinging of the heart within the pericardial space. *(Reproduced with permission from Aikat S, Ghaffari S. resuscitation initially, further confusing the diagnosis, but deterioration will soon occur if tamponade is not treated and can become fatal.[306]

Echocardiographic features of tamponade include an exaggerated motion of the heart within the pericardial sac in conjunction with atrial and ventricular collapse (Fig. 24.78).[313] Fluid accumulation greater than 25 mL will result in an anechoic and hypoechoic pericardial space throughout the cardiac cycle.[114] Specific two-dimensional echocardiographic findings that support cardiac tamponade include diastolic collapse of the RV, inversion of the RA during diastole, abnormal ventricular septal motion, and variation of ventricular size with the respiratory cycle.[329] Diastolic collapse of the right-sided chambers occurs because of pericardial pressure exceeding intracardiac pressure during diastole. Right atrial collapse is a specific finding during echocardiographic examination if it is present for more than one third of the cardiac cycle.

Normally, a decrease in intrathoracic pressure during inspiration is transmitted to the pulmonary vasculature and the intrapericardial and intracardiac spaces. In tamponade, this decrease in pressure during inspiration does not occur within the pericardium because of the presence of fluid. Thus the gradient for left-sided filling is decreased, and the early mitral inflow velocity (E velocity) will decrease with inspiration. In addition, right and left ventricular filling display interdependence, similar to that observed in constrictive pericarditis.

Echocardiography can also be used to direct needle or catheter placement for pericardiocentesis. Indeed, the bulk of pericardiocentesis is performed under echocardiographic guidance in some centers.[330] Removal of no more than 50 mL of fluid may be therapeutic for severe tamponade attributable to the steepness of the pericardial pressure volume curve. Typically, a pigtail catheter is left in the pericardial space for several days until drainage becomes minimal. Failure to recognize the insidious nature of tamponade and to anticipate the progression of hemodynamic changes may lead to a delay in using echocardiography to confirm the diagnosis and begin treatment. Examples include unstable hemodynamics after a penetrating chest injury or an abrupt change in chest tube drainage after cardiac surgery, which should prompt rapid assessment for tamponade and possibly emergency sternal opening.

Hemorrhagic tamponade in excessively bleeding patients after CPB is increasingly common and may be fatal. Depending on the diagnostic techniques, cardiac tamponade occurs in up to 8.8% of patients after cardiac surgery. However, almost 75% of postcardiac surgical tamponade occurs late (5–7 days) especially with patients who have undergone valve procedures in contrast to CABG surgery.[331] The causes of early tamponade are due primarily to coagulopathy, secondary to CPB, whereas the cause of late tamponade is multifactorial with aspirin and anticoagulant drugs increasing the risk of bleeding.[331] Persistently poor CO and hypotension with increased and equalized right and left atrial pressures strongly suggest tamponade. However, the multiple causes of hypotension in the postoperative cardiac surgical patient often complicate the diagnosis. The classic features of tamponade may be absent or blunted postoperatively.[332] Arterial hypotension, pulsus paradoxus, and elevated jugular venous pressures were absent in one series of cardiac surgical patients—30%, 40%, and 50%, respectively.[333] A delay in diagnosis contributes greatly to mortality in late cardiac tamponade.

After cardiac surgery, no single clinical, hemodynamic, or echocardiographic finding is sufficient to make a diagnosis of tamponade but requires consideration of the entire clinical picture.[334] Although echocardiography is capable of identifying the size of pericardial effusions postoperatively, it does not necessarily reflect their likelihood of causing tamponade. Most patients after cardiac surgery will have evidence of pericardial effusions, but fewer than 1% will develop

hemodynamically significant tamponade.[331] TTE may be inadequate in the postoperative cardiac surgical patient, secondary to interference from chest tubes, patient positioning, and other factors necessitating transesophageal echocardiographic consideration.

Pericardiocentesis is indicated for life-threatening cardiac tamponade in conjunction with fluid resuscitation to maintain adequate filling pressures. Hemodynamics improvement should ensue after pericardiocentesis. Although pericardiocentesis relieves the symptoms of tamponade, definitive therapy directed at the underlying cause should be pursued. Major complications of pericardiocentesis include coronary artery laceration, cardiac puncture, and pneumothorax. Tamponade attributable to hemorrhage in the patient after cardiac surgery requires immediate mediastinal exploration to determine the source of bleeding and to stabilize hemodynamics.

Anesthesia Considerations

Severe hypotension or cardiac arrest has followed the induction of general anesthesia in patients with tamponade. The causes include myocardial depression, sympatholysis, decreased venous return, and changes in heart rate that often accompany anesthetic medications and positive pressure ventilation. Resuscitation requires immediate drainage of pericardial fluid. Pericardiotomy via a subxiphoid incision with only local anesthetic infiltration or light sedation is an option. If intrapericardial injury is confirmed, then general anesthesia can be induced after decompression of the pericardial space.[335] Ketamine (0.5 mg/kg) and 100% oxygen have been used with local anesthetic infiltration of the preexisting sternotomy to drain severe pericardial tamponade.[336] Spontaneous respirations, instead of positive-pressure ventilation, will

support CO more effectively until tamponade is relieved. Correction of metabolic derangements is mandatory. Volume expansion is likely warranted in hypotensive patients.[337,338] Similar to CP, patients with tamponade have a relatively low and fixed stroke volume and thus rely on heart rate and adequate filling to maintain CO. Catecholamine infusions or pacing may be used to avoid bradycardia. In a dog model of pericardial tamponade, dobutamine infusion delayed the onset of lactic acidosis by maintaining CO and tissue oxygen delivery.[339]

Case Study 3: Tamponade Case Report

A 65-year-old man with a history of chronic venous insufficiency was hospitalized for a venous stasis ulcer that ultimately required skin grafting. On the day of his planned discharge, he was found to have multiple pulmonary emboli and a large lower extremity deep venous thrombosis. Anticoagulation was initiated, a filter was placed in the IVC, and lower extremity venous catheters were placed for catheter-directed thrombolytic therapy. Two days later, mechanical extraction of the lower extremity thrombus was undertaken without any known complications.

On return to his hospital room after the thrombus extraction, the patient quickly became hemodynamically unstable. He received intravenous fluid administration, however, quickly requiring intubation with mechanical ventilation for respiratory distress. Cardiac arrest resulted, necessitating cardiopulmonary resuscitation and epinephrine administration. An emergent TTE revealed a large pericardial effusion (Fig. 24.79).

Because of the urgency of the situation, a bedside pericardiocentesis was undertaken using echocardiographic guidance (Fig. 24.80). A large amount of blood was removed from the pericardium, and the effusion appeared to resolve (Fig. 24.81). The patient's hemodynamics rapidly improved. He required a period of mechanical ventilation but was ultimately discharged from the hospital in good condition.

Combined Carotid and Coronary Artery Disease

Patients with concomitant symptomatic coronary and carotid disease are few but a significantly higher risk group than either group of patients with carotid or coronary disease alone.[340–342] CABG is proven therapy for ischemic heart disease.[343,344] Advancements in myocardial preservation, CPB technology, and perioperative care over the last three decades have reduced morbidity and mortality associated with cardiac surgery. However, stroke remains the major noncardiac complication of CABG affecting the quality of life, economic well-being,

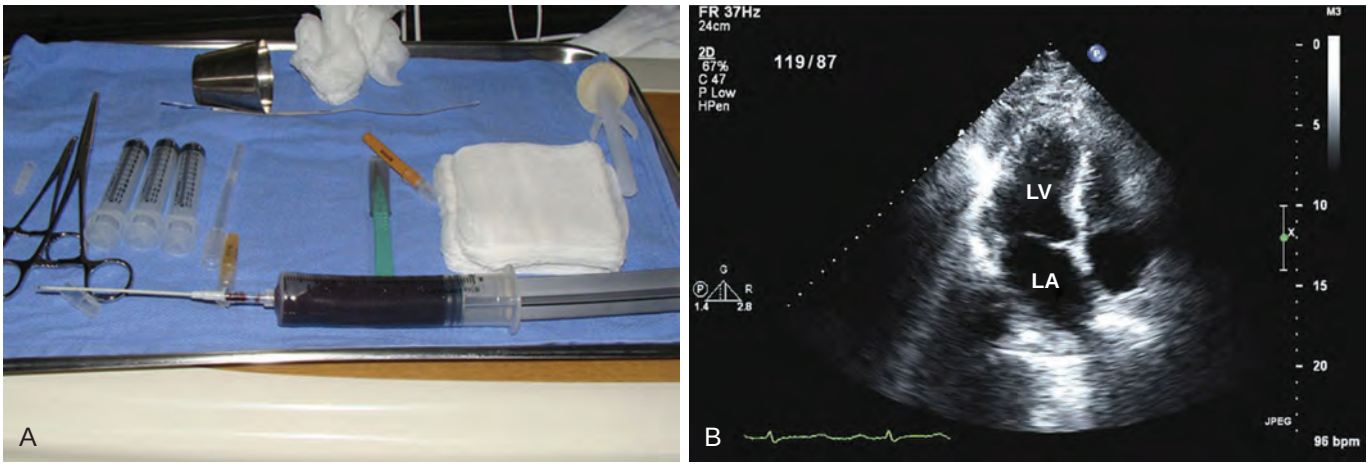

Fig. 24.81 (A) The catheter and syringe that are used for the pericardiocentesis are shown. (B) Transthoracic echocardiogram parasternal four-chamber view shows resolution of the pericardial effusion. The right side of the heart is now well filled in diastole. *LA*, left atrium; *LV*, left ventricle.

and survival. Although the overall incidence of stroke associated with CABG is approximately 2%, the role of extracranial carotid disease to the occurrence of stroke remains indeterminate.

The combination of carotid endarterectomy (CEA) and CABG surgery was first proposed by Bernhard and associates[345] in 1972 to reduce morbidity and mortality from coexistent carotid and coronary disease. Renewed interest in this approach now stems from recent controlled trials that demonstrate the benefits of isolated CEA for both symptomatic and asymptomatic severe carotid stenosis.[346] From 2000 to the end of 2004, 27,084 the combined CEA-CABG procedure was performed according to the Nationwide Inpatient Sample database.[347] According to the same database, the proportion of combined CABG and CEA procedures rose from 1.1% to 1.58% of all CABG surgeries performed from 1993 to 2002.[348] As the population ages, the number of patients with carotid bifurcation stenosis greater than 70% will continue to increase. The result is more patients with combined carotid and coronary disease[346] but with no consensus regarding their treatment. A large multicenter, randomized trial will be necessary to resolve the management of these patients. Unfortunately, the complexities of such a study with the heterogeneity of patients, varying degrees of coronary and carotid disease, and differing institutional preferences for carotid revascularization decrease its likelihood.

Neurologic injury associated with CPB is largely embolic in origin,[349] causing cerebral hypoperfusion and ischemia. Emboli originate primarily from aortic cannulation, aortic cross-clamp release, and cardiac manipulation based on transcranial Doppler ultrasonography. Less common causes of cerebral emboli are left ventricular thrombus and air. However, the cause of stroke after CABG surgery is multifactorial. Univariate analysis of systematic review of stroke associated with the CABG procedure has identified the following risk factors for stroke: carotid stenosis of 80% or more, carotid occlusion, prior stroke or transient ischemic attack, peripheral vascular disease, postinfarction angina, female, prolonged duration of CPB, age (older), previous CEA, diabetes, smoking, hypertension, left main disease, and carotid bruit.[350–352] Carotid bruits may be present in 9.93% of patients undergoing CABG surgery and increases the risk of stroke by a factor of four. Differentiating significant stenosis by auscultation is unreliable.[353] Carotid bruits may be audible with minimal carotid stenosis and silent with a carotid lumen of 1 to 2 mm in diameter. The preexisting presence of subclinical ischemia and cerebral atherosclerosis on MRI or angiography are independent predictors of stroke in CABG patients.[354,355] Atheroma of the arch and ascending aorta were another independent risk factor for stroke in CABG patients.[356] The combination of ultrasonography of the carotid arteries and risk factors are very predictive of patients likely to have a stroke in association with CABG surgery (Fig. 24.82).

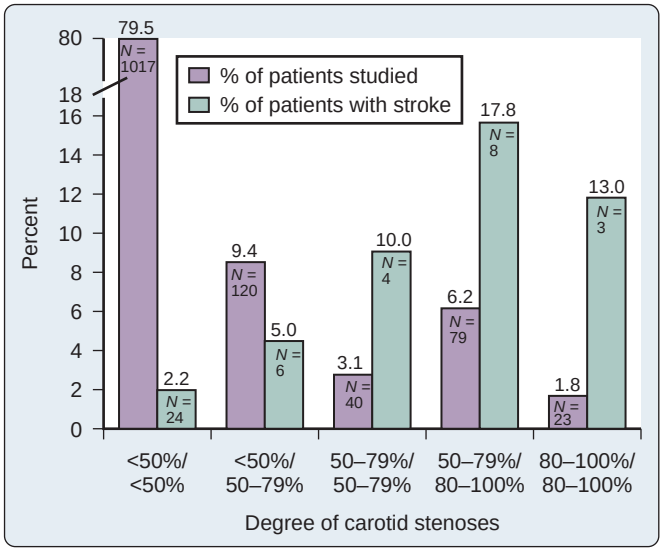

Fig. 24.82 Both the prevalence of carotid stenoses in patients undergoing noninvasive carotid screening and the occurrence of stroke by degree of carotid stenosis are illustrated. *(Reproduced with permission from D'Agostino RS, Svensson LG, Neumann DJ, et al. Screening carotid ultrasonography and risk factors for stroke in coronary artery surgery patients.* Ann Thorac Surg. *1996;62:1714–1723.)*

Carotid artery disease should be considered in all individuals with ischemic heart disease. Severe carotid disease increases the risk of stroke with CABG surgery by a factor of four.[350,357] Early estimates of the incidence of hemodynamically significant carotid stenosis in patients needing the CABG procedure varied between 2% and 16%.[358] Faggioli and associates[359] confirmed the occurrence of severe carotid disease, defined as carotid stenosis greater than 75% in patients more than 60 years of age, to be 11% in patients that underwent CABG surgery. More recently, noninvasive ultrasonography has shown the percentage of persons with severe carotid and coronary disease to be higher than prior studies.[352] Patients undergoing CABG surgery were prospectively evaluated for carotid disease with ultrasonography, and approximately 20% had significant carotid stenosis unilaterally or bilaterally. Large systematic reviews of stroke and the CABG procedure point to a relationship between an increased incidence of stroke with higher degree of carotid stenosis.[350,357,360] The frequency of stroke with cardiac surgery was less than 2% in those with no carotid disease

(0–49% stenosis), increased to 3% with asymptomatic disease (unilateral stenosis 50–99%), 5% in those with bilateral stenosis (50–99%) and 7% to 11% in those with carotid occlusion. These data would support the potential benefit of CEA in either a staged or combined manner with CABG surgery to reduce the chance of stroke in these patients.

It is generally accepted that patients with symptomatic carotid disease undergoing CABG surgery are at a significantly increased risk for stroke and merit revascularization of the carotid and coronary disease as a combined or staged procedure.[352] However, the management of unilateral or bilateral *asymptomatic* carotid stenosis continues to evolve. Asymptomatic severe carotid stenosis is a risk for ipsilateral hemispheric stroke with cardiac surgery and CPB,[342,352,361] but identifying it in the asymptomatic patient hinders determination of this *true* risk assessment. This is important, because isolated CEA was shown to not only reduce the risk of stroke in patients with symptomatic carotid stenosis greater than 70%,[348] but it also was shown to reduce the risk of stroke in asymptomatic patients with severe high-grade carotid stenosis.[346] With the incidence of neurologic injury ipsilateral to the carotid artery encompassing 40% to 50% of strokes associated with cardiac surgery,[362] prophylactic measures to prevent strokes merit consideration.[347]

In most patients, the degree of either carotid or coronary disease will not limit the ability of the patient to undergo the higher priority procedure, CEA or CABG surgery, safely. In contrast, treatment options for those with active concomitant carotid disease and ischemic heart disease are a combined, synchronous, or staged approach. The staged approach does not include CEA and CABG surgery in one anesthetic event but two separate ones. Many surgeons support the combined CABG-CEA procedure, whereas others believe the risk exceeds the benefit.[360,363]

The sequence of CEA and CABG surgery is important regarding the outcome with either the combined or staged approach. Since 1989 when Hertzer and colleagues[340] found a lower incidence of stroke when CEA was performed before rather than after the CABG procedure as a combined approach in one of the few randomized, prospective trial involving this issue, CEA has been commonly performed first. Rizzo and associates[342] confirmed the benefit of performing CEA before CABG surgery by reporting the risk of stroke may reach 14% if the CABG procedure is performed before CEA. More recently, a systematic review of synchronous and staged CEA and CAGB procedures demonstrated that reverse staged procedures (CABG surgery first and then CEA) were associated with the highest ipsilateral and global stroke rate, compared with staged or combined procedures performed with CEA first.[360] Less than 10% of staged procedures are currently performed as CABG surgery and then CEA.

The sequence of performing CEA and CABG surgery is more common than the reverse order but is not without its disadvantages. Myocardial morbidity may reach 20% if CEA is performed before CABG surgery in a staged approach.[342] MI has been recognized for years as the major cause of mortality with isolated CEA. Surgically incorrectable coronary disease may exist in 40% of those undergoing CEA.[358] CEA in patients with severe, symptomatic coronary disease has been associated with a 17% and 20% incidence of MI and mortality, respectively. Most importantly, 20% of the MIs accounted for 60% of deaths.[351] A recent systematic literature review of the combined and staged CEA and CABG procedures confirmed that the incidence of MI was highest if the CEA was performed before the CABG surgery (6.5%) rather than after the CABG procedure (0.9%).[360] Differences in the standards for reporting MI over the last 30 years challenge the accuracy of the incidence of MI after CEA being 6.5%. Without well-defined cardiovascular risks for either the staged or combined approach, the correct decision for the patient is difficult.

The recommendation to perform a combined or staged CEA and CABG surgery for those with concomitant carotid and coronary disease continues to evolve. In a prospective trial, Hertzer and colleagues[340] found a lower incidence of perioperative stroke in with combined rather than staged CABG surgery and CEA. A comparative analysis of studies that included 50 patients or more that underwent the CABG surgery with unoperated major carotid disease found the risk of stroke averaged 5.5% for patients with unoperated carotid disease and the CABG surgery versus 3.1% for patients who underwent combined procedures. However, the role of carotid disease as a direct cause of perioperative stroke after an isolated CABG procedure is not always clear. It is relatively simply to diagnose the likely cause of a perioperative stroke associated with isolated CEA.
