KAPLAN'S CARDIAC ANESTHESIA: FOR CARDIAC AND NONCARDIAC SURGERY: SEVENTH EDITION ISBN: 978-0-323-39378-2

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods, they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

The seventh edition of *Kaplan's Cardiac Anesthesia* has been written to further enhance the perioperative management of the patient with cardiac disease undergoing either cardiac or noncardiac surgery. The first edition was published in 1979 during the early years of modern cardiac surgery when our focus was primarily on anesthetizing cardiac surgical patients. Continued advances in the care of patients with heart disease have expanded the role of cardiac anesthesiologists into preoperative evaluation, advanced cardiac imaging and other monitoring devices, postoperative critical care, and pain management. Today, we are also being asked to care for or help "rescue" the sickest cardiac patients undergoing noncardiac surgery and to participate as a member of the cardiac care team by performing procedures in locations distant from cardiac operating rooms. This edition focuses on the current issues associated with advanced cardiopulmonary assist devices, procedures in hybrid operating rooms, and new anticoagulants and coagulants, as well as being members of the heart team deciding on the best options for our sick patients.

This edition is subtitled "For Cardiac and Noncardiac Surgery" to emphasize the expanded role of all anesthesiologists in the perioperative medical care of high-risk cardiac patients undergoing all types of procedures. Ten chapters have been added as the final section of this book and deal specifically with these patients, the complex care and procedures they require, and the techniques used to reduce the incidence of major adverse cardiac events. This contrasts with only one chapter in the first edition that pointed out that some cardiac patients undergoing noncardiac surgery could be just as sick or sicker than those having cardiac surgery and that their cardiovascular complications could carry a high mortality rate after noncardiac surgery. That chapter, from 1979, stated that "the anesthesiologist should be experienced in modern cardiac anesthesia skills…able to insert the monitoring devices, interpret the data, utilize new pharmacotherapy, and understand the patient's basic pathophysiology." Certainly this is even more important today, with patients presenting for noncardiac surgery and having drug-eluting stents, multiple antiplatelet drugs, ventricular assist devices, multiple drugs for end-stage heart failure, and implanted electrical devices that produce cardiac resynchronization therapy. These advanced levels of cardiac care, no longer rare, are seen routinely in noncardiac surgery performed in operating rooms, outlying areas of the hospital, and even in outpatient surgical settings. In addition, many patients undergoing vascular or thoracic surgery, some cardiac patients with complicated obstetric problems, and many other noncardiac surgical patients may have significant cardiovascular issues requiring that all anesthesiologists have the skills needed (eg, basic cardiac echocardiography) to diagnose and treat these perioperative problems so as to reduce complications.

The content of the seventh edition ranges from the basic sciences to translational medicine and the latest evidence-based clinical care of the sickest and most complex cardiac patients. To maintain its place as the standard reference textbook in the field, this edition has been completely revised, expanded, and updated to reflect the ongoing changes in cardiovascular care, especially the rapid growth and use of new monitoring techniques, minimally invasive cardiac surgical procedures performed with or without cardiopulmonary bypass, advances in postoperative care, and renewed emphasis on patient safety and reductions in postoperative complications. Significant contributions to the text have been made by leading experts in anesthesiology, cardiology, cardiac surgery, and critical care medicine from around the world. The emphasis throughout the book is on using the latest scientific developments to guide proper therapeutic interventions in the perioperative period. In addition, some chapters include expert guidelines published by leading national and international scientific specialty organizations.

Due to the success of the educational aids used in the previous edition, the Key Points of each chapter appear first in the chapter and Teaching Boxes are highlighted with many of the important take-home messages. The content of the book is enhanced by full-color presentations of the text, multicolor echo and Doppler images, cine clips, and supplementary video material on the ExpertConsult website that accompanies the print version of the text. The website also will be used to update the book on a regular basis as new material appears before the next edition.

In preparing this edition, I have been helped enormously by the four associate editors. They have helped recruit new authors, worked with them on timely production and coordination of their chapters, and expanded the educational opportunities with unique contributions. Dr. Augoustides serves as the liason editor between the book and the *Journal of Cardiothoracic and Vascular Anesthesia,* providing updates on the book's website from new material (eg, new oral anticoagulants) appearing in the journal, as well as selected highlights of the previous year in cardiothoracic and vascular anesthesia. Dr. Maus serves as the editor of the *Transesophageal Echocardiography Video Atlas* (ie, 2D and 3D views, Doppler, and hemodynamic videos) and the Pathologic View Library (eg, perivalvular leaks, aortic dissection, and obstructive cardiomyopathy) found on the book's website. This allows the reader of the book to move seamlessly from the text to the echocardiography video supplementary material. Using the ExpertConsult. Inkling platform, the interested reader can further expand his or her reading on advanced echocardiography by moving to the companion textbook entitled *Perioperative Transesophageal Echocardiography* and edited by Dr. Reich. Finally, Dr. Manecke has coordinated the noncardiac surgery section of the book and introduced the new concepts of goal-directed therapy, enhanced recovery from anesthesia, and the perioperative anesthetic/surgical home for cardiac patients. As we transition from volume-based practices by independent experts to value-based care by a team of experts, these new approaches will allow us as cardiac anesthesiologists to position ourselves as participants in the entire episode of care and the success of the entire team.

Kaplan's Cardiac Anesthesia was written by acknowledged experts in each specific area or related specialties. It is the most authoritative and up-to-date collection of material in the field. Each chapter aims to provide the scientific foundation of the subject matter, the clinical basis for practice, and (when available) outcome information. All of the chapters have been coordinated in an effort to maximize their clinical utility. Whenever possible, material has been integrated from anesthesiology, critical care medicine, cardiology, cardiac surgery, physiology, and pharmacology to present a complete clinical picture. Thus this edition should continue to serve as the definitive text for cardiac anesthesia residents, fellows, faculty, practitioners, cardiologists, cardiac surgeons, intensivists, and others interested in the management of the patient with cardiac disease for either cardiac or noncardiac surgery.

This edition should further facilitate the application of the techniques and procedures that have been learned in the cardiac surgical operating rooms to cardiac patients undergoing noncardiac surgery. These patients compose a much larger group than those undergoing cardiac surgery, and they are often sicker and at higher risk because their underlying cardiac disease is not being corrected by the operative procedure. All of our learning and experience dealing with cardiac surgery should be used to improve the outcomes of these noncardiac surgical patients. It is our overall experience and skill demonstrated while caring for the sickest cardiac patients undergoing new and innovative operations that led J. Willis Hurst, MD, one of the world's leading cardiologists, to state in his Foreword to the first edition of this book that "this cardiologist views the modern cardiac anesthesiologist

with awe." If he thought we were good in 1979, he must be amazed to see our care today guided by the latest monitoring techniques in patients who never would have been operated on in the past.

The editors gratefully acknowledge the contributions made by the authors of each of the chapters. They are the dedicated experts who have made the field of cardiac anesthesia what it is today and are the teachers of our young colleagues practicing anesthesiology around the world. This book would not have been possible without their hard work and expertise.

Joel A. Kaplan, MD, CPE, FACC
Editor

A Textbook for All Anesthesiologists

Patients with cardiac disease undergoing noncardiac surgery should be evaluated … and managed … in a similar manner to patients having cardiac surgery. In order to be able to care for these sick patients … the anesthesiologist and his assistants should be experienced in modern cardiac anesthesia skills. The anesthesiologist must be able to insert monitoring devices … interpret the ECG, utilize the new pharmacotherapy, and understand the patients basic pathophysiology.

Joel A. Kaplan and Ronald W. Dunbar
Cardiac Anesthesia, 1979

The first textbook on anesthesia for surgery of the heart was written by Kenneth K. Keown, who provided anesthesia for Charles Bailey (first successful mitral commisurotomy in 1948), and was published in 1956. This single-author text was 109 pages and had 115 references. Although many different textbooks on this subspecialty have appeared since then, the earliest and now longest and most up to date is this one edited by Joel A. Kaplan, which first appeared in 1979. It is justifiably regarded as the definitive standard reference textbook of cardiac anesthesia.

I first became acquainted with Dr. Kaplan during my second decade as a cardiac surgeon at the University of Washington when I heard him speak at a cardiac surgical meeting extolling and reviewing the role cardiac anesthesiologists can play in improving the outcomes of our patients. Shortly thereafter a team consisting of a cardiac anesthesiologist, a perfusionist, and me were sent by our chairmen to see how the experts in the eastern United States practiced cardiac surgery, and one of those sites was Emory University, where Dr. Kaplan practiced. A few years later as an anesthesia resident and then as a cardiac anesthesia fellow, the first edition of his textbook was a major resource for us, as documented by the profuse highlighting and underlining of text in that book (which still sits in my bookshelf), and then guided our initiation of the cardiac anesthesia program at the University of Kentucky more than 30 years ago.

Cardiac Anesthesia has made many contributions to the practice of anesthesia, cardiovascular medicine, and critical care. The first edition emphasized the importance of a firm understanding of cardiovascular and pulmonary physiology and pharmacology and the interaction of drugs on these two systems. *Cardiac Anesthesia* introduced routine monitoring of electrocardiography (ECG) and invasive monitoring of arterial, central venous, and pulmonary artery pressure, venous saturations, and cardiac output. It identified the discrepancy between central venous pressure and left atrial pressure by introducing the direct measurement of left atrial pressure and the subsequent use of monitoring of pulmonary artery occlusion (wedge) pressure. *Cardiac Anesthesia* also introduced the use of ECG to detect perioperative myocardial ischemia (eg, V_5 lead) and the treatment of it with intravenous nitroglycerin.

Cardiac anesthesiologists have revolutionized the evaluation and perioperative management of cardiac patients undergoing cardiac and noncardiac surgery. They were instrumental in the adoption of monitoring of arterial blood gases, the development of the surgical intensive care unit (ICU), and the incorporation of advanced respiratory and hemodynamic monitoring and management (including aggressive pharmacologic therapy with inotropes and others vasoactive drugs) in the ICU and the noncardiac operating room. Cardiac anesthesiologists collaborated with the American Heart Association/American College of Cardiology in developing various guidelines for management of such patients. They called attention to the frequent occurrence and adverse consequences of perioperative myocardial ischemia during noncardiac surgery. They initiated the use of invasive monitoring—first with the pulmonary artery catheter (PAC) and then with transesophageal echocardiography (TEE)—in the perioperative management of cardiac patients and the participation of anesthesiologists in their management in postsurgical ICUs. They introduced narcotic anesthesia (Lowenstein, Stanley) for these patients and the use of newer pharmacologic agents to treat severe heart failure, hypertension, and arrhythmias. Cardiac anesthesiologists were responsible for introducing TEE to cardiology practice in the United States and since that time have collaborated closely in the application of echocardiography to cardiac care, education, and certification.

Perhaps the greatest contribution has been the recognition very early in the history of cardiac surgery of the importance of a team (surgeon, anesthesiologist, perfusionist, nurse) in the successful management of patients. This concept has now been embedded as an important component of enhanced recovery after surgery and the perioperative surgical/anesthesia home. The Society of Cardiovascular Anesthesiologists has been a leader in improving the functioning of these teams and its safety implications, as discussed in the new chapter on patient safety and avoiding errors. All of this has led to the dramatic improvement of the care of patients with cardiac disease, those undergoing not only cardiac surgery but also noncardiac surgery and nonsurgical care, and likely has contributed to the dramatic improvement in outcomes of these sick patients over the last 40 years.

The first edition of this textbook emphasized the importance of a firm knowledge of the physiology, pharmacology, and pathophysiology of cardiac disease and the importance of management guided by detailed hemodynamic monitoring, including the use of the PAC. Subsequent editions reflected advances in cardiac surgery and anesthesia over the last 4 decades. The second edition (1987) introduced echocardiography, cardiac transplantation, circulatory assistance beyond intraaortic balloon pumping, and central nervous system monitoring and devoted more attention to myocardial protection and postoperative care. The third edition (1993) added chapters on noncardiac surgery in patients with cardiac disease and more on echocardiography (including color flow) and devoted more attention to coagulation and bleeding, central nervous system dysfunction, and the importance of outcome studies after cardiac and noncardiac surgery in patients with heart diseases. The fourth edition (1999) included new chapters on systemic inflammatory response and practice management. The fifth edition (2006) provided chapters that discussed the history of cardiac surgery and anesthesia and predictions of future developments, as well as chapters on molecular cardiovascular medicine, minimally invasive cardiac surgery, and surgical approaches to heart failure, including more advanced ventricular assist devices, pain management, strategies to reduce medical errors, and training in cardiac anesthesia. The sixth edition (2011) subtitled, "The Echo Era," emphasized the maturation of echocardiography and integrated its use into various other chapters throughout that edition.

The present edition advances a theme from the first edition of this text, as reflected in the quote at the start of this forward: the application of the principles of cardiac anesthesia to the management of patients

with cardiac disease outside of the cardiac surgery operating room. Many of its chapters provide essential information, but most relevant are those in the last section, which cover the everyday issues of patients with coronary stents, implantable electronic devices, and implantable ventricular assist devices; the benefits of the use of echocardiography outside the cardiac surgery rooms; and what can be done postoperatively to decrease the incidence of major adverse cardiac events and mortality following noncardiac surgery. I believe that this new edition points out that nearly every site where anesthesiologists practice is potentially a "heart room" and therefore, nearly all anesthesiologists must become cardiac anesthesiologists.

1 Assessment of Cardiac Risk and the Cardiology Consultation[1]

MANISH BANSAL, MD, DNB CARDIOLOGY, FACC, FASE | VALENTIN FUSTER, MD, PhD, MACC | JAGAT NARULA, MD, PhD, MACC | PARTHO P. SENGUPTA, MD, DM, FACC, FASE

KEY POINTS

1. Perioperative cardiac morbidity is multifactorial, and understanding the predictive risk factors helps define the risk for individual patients.
2. Assessment of myocardial injury is based on the integration of information from myocardial imaging (eg, echocardiography), electrocardiography (ECG), and serum biomarkers, with significant variability in the diagnosis depending on the criteria selected.
3. Multivariate modeling has been used to develop risk indices that focus on preoperative variables, intraoperative variables, or both.
4. Key predictors of perioperative risk are dependent on the type of cardiac operation and the outcome of interest.
5. New risk models have become available for valvular heart surgery and for combined coronary and valvular cardiac procedures.
6. For patients undergoing noncardiac surgery, the objectives and approach to cardiac evaluation are entirely different. The nature of the noncardiac surgery and the urgency of the surgical procedure are the primary determinants of the extent of cardiac evaluation in these patients.
7. For most patients undergoing noncardiac surgery, preoperative coronary revascularization is not required unless the patient presents with an unstable cardiac condition or has significant myocardial ischemia and the noncardiac surgery is not urgent.

In the early 1980s, coronary artery bypass graft surgery (CABG) was characterized by operative mortality rates in the range of 1% to 2%. Over the ensuing years, urgent and emergent operations and "redo" procedures became common, and greater morbidity and mortality rates were observed. Percutaneous coronary interventions (PCIs) absorbed low-risk patients from the surgery pool, with the net result that the operative mortality rate increased to the range of 5% to 6%. The trend toward PCI has continued, with trials demonstrating the safety of stenting even in left main coronary artery disease (CAD).[1–3] This demographic shift has led governmental health oversight agencies to ask for justification of the observed increase in CABG mortality, often prompting a time-consuming and expensive chart review to identify the differences in patient populations that led to the greater morbidity. Even with this information, however, it has been difficult to *objectively* determine the impact of these new and compelling factors on mortality. The impetus for the development of a risk-adjusted outcome assessment and appropriate risk adjustment scoring system was the need to compare adult cardiac surgery results in different institutions and to benchmark the observed complication rates.[4] With the recent passage of health care reform legislation and interest in controlling health care expenditures, there is increased interest in public reporting of perioperative outcomes with optimal risk adjustment.

The first risk-scoring scheme for cardiac surgery was introduced by Paiement and colleagues at the Montreal Heart Institute in 1983.[5] Since then, many preoperative cardiac surgery risk indices have been developed. The patient characteristics that affected the probability of specific adverse outcomes were identified and weighed, and the resultant risk indices have been used to adjust for case-mix differences among surgeons and centers where performance profiles have been compiled. In addition to comparisons among centers, the preoperative cardiac risk indices have been used to counsel patients and their families in resource planning, to identify high-risk groups for special care or research, to determine cost-effectiveness, to determine effectiveness of interventions, to improve provider practice, and to assess costs related to severity of disease.[6,7]

In contrast, the objectives of cardiac evaluation in a patient undergoing noncardiac surgery are entirely different. In contrast to patients undergoing cardiac surgery, for whom extensive cardiac evaluation is part of the workup, the cardiac status of patients undergoing noncardiac surgery is often unknown (see Chapter 43). In such patients, the benefit of performing cardiac assessment with its inherent time and resource implications needs to be weighed against the impact such information could have on perioperative planning and the potential risks associated with any delay in the noncardiac surgery. The main goal in this setting is to identify a high-risk group of patients who would benefit from either noninvasive or invasive cardiac evaluation and appropriate perioperative medical management or interventional therapy (see Chapters 2 and 3).

Sources of Perioperative Myocardial Injury in Cardiac Surgery

Myocardial injury, manifested as transient cardiac contractile dysfunction ("stunning") or acute myocardial infarction (AMI) or both, is the most frequent complication after cardiac surgery and the most important cause of hospital complications and death. Furthermore, patients who experience a perioperative myocardial infarction (MI) have a poor long-term prognosis; only 51% of such patients remain free from adverse cardiac events after 2 years, compared with 96% of patients without perioperative MI.[8]

It is important to understand the pathogenesis of this morbidity and mortality to clarify the determinants of perioperative risk. This is particularly important with respect to cardiac outcomes because the definition of *cardiac morbidity* represents a continuum rather than

[1]The editors and the publisher would like to thank Drs. Jiri Horak, Emile R. Mohler, and Lee A. Fleisher for contributing a chapter on this topic to the prior edition of this work. It has served as the foundation for the current chapter.

BOX 1.1 DETERMINATIONS OF PERIOPERATIVE MYOCARDIAL INJURY

Disruption of blood flow
Reperfusion of ischemic myocardium
Adverse systemic effects of cardiopulmonary bypass

a discrete event. This understanding can help target the biologically significant risk factors and interventions that may decrease irreversible myocardial necrosis.

Myocardial necrosis is the result of progressive pathologic ischemic changes that start to occur in the myocardium within minutes after interruption of its blood flow (eg, during cardiac surgery) (Box 1.1). The duration of the interruption of blood flow, either partial or complete, determines the extent of myocardial necrosis, and both the duration of the period of aortic cross-clamping (AXC) and the duration of cardiopulmonary bypass (CPB) have consistently been shown to be the main determinants of postoperative outcomes. In a study with an average follow-up of 10 years after complex cardiac surgery, Khuri[9] observed a direct relation between the lowest mean myocardial pH recorded during or after the period of AXC and long-term patient survival. Patients who experienced acidosis (pH <6.5) had decreased survival compared with those who did not. Because myocardial acidosis reflects both myocardial ischemia and poor myocardial protection during CPB, this study demonstrated the relation of the adequacy of intraoperative myocardial protection to long-term outcome (see Chapters 3, 7, 20, and 31).

Reperfusion of Ischemic Myocardium

Surgical interventions requiring interruption of blood flow to the heart must be followed by restoration of perfusion. Numerous experimental studies have provided compelling evidence that reperfusion, although essential for tissue and organ survival, is not without risk because of the potential extension of cell damage as a result of reperfusion itself. Myocardial ischemia of limited duration (<20 min) that is followed by reperfusion leads to functional recovery without evidence of structural injury or biochemical evidence of tissue injury.[10,11] However, reperfusion of cardiac tissue that has been subjected to an extended period of ischemia results in a phenomenon known as *myocardial reperfusion injury.*[12–14] Thus, a paradox exists in that tissue viability can be maintained only if reperfusion is instituted within a reasonable period, but doing so risks extending the injury beyond that caused by the ischemic insult itself. This finding is supported by the observation that ventricular fibrillation was prominent when regionally ischemic canine hearts were subjected to reperfusion.[15] Jennings and associates[16] reported adverse structural and electrophysiologic changes associated with reperfusion of the ischemic canine heart, and Hearse[17] introduced the concept of an oxygen paradox based on cardiac muscle enzyme release and alterations in ultrastructure when isolated hearts were reoxygenated after a period of hypoxic perfusion.

Myocardial reperfusion injury is defined as the death of myocytes, which were alive at the time of reperfusion, as a direct result of one or more events initiated by reperfusion. Myocardial cell damage results from restoration of blood flow to the previously ischemic heart and extends the region of irreversible injury beyond that caused by the ischemic insult alone. The cellular damage that results from reperfusion can be reversible or irreversible, depending on the duration of the ischemic insult. If reperfusion is initiated within 20 minutes after the onset of ischemia, the resulting myocardial injury is reversible and is characterized functionally by depressed myocardial contractility, which eventually recovers completely. Myocardial tissue necrosis is not detectable in the previously ischemic region, although functional impairment of contractility may persist for a variable period, a phenomenon known as *myocardial stunning.* Initiation of reperfusion after longer than 20 minutes, however, results in escalating degrees of irreversible myocardial injury or cellular necrosis. The extent of tissue necrosis that develops during reperfusion is directly related to the duration of the ischemic event. Tissue necrosis originates in the subendocardial region of the ischemic myocardium and extends to the subepicardial region of the area at risk; this is often referred to as the *wavefront phenomenon.* The cell death that occurs during reperfusion can be characterized microscopically by explosive swelling, which includes disruption of the tissue lattice, contraction bands, mitochondrial swelling, and calcium phosphate deposition within mitochondria.[15]

The magnitude of reperfusion injury is directly related to the magnitude of the ischemic injury that precedes it. In its most severe form, it manifests as a "no-reflow" phenomenon. In cardiac surgery, prevention of myocardial injury after release of the AXC, including prevention of no-reflow, is directly dependent on the adequacy of myocardial protection during the period of AXC. The combination of ischemic and reperfusion injury is probably the most frequent and most serious type of injury leading to poor outcomes in cardiac surgery today (see Chapters 2, 3, 7, 13–16, 20, and 31).

Basic science investigations (in mouse, human, and porcine hearts) have implicated acidosis as a primary trigger of apoptosis. Acidosis, reoxygenation, and reperfusion—but not hypoxia (or ischemia) alone—are strong stimuli for programmed cell death, and cardiac apoptosis has been demonstrated to lead to heart failure.[18,19] This suggests that apoptotic changes might be triggered in the course of a cardiac operation, initiating an injurious cascade of adverse clinical events that manifest late in the postoperative course.

Based on the previous discussion, it is clear that a significant portion of perioperative cardiac morbidity is related primarily to intraoperative factors. However, preoperative risk factors also influence ischemic and reperfusion injury.

Adverse Systemic Effects of Cardiopulmonary Bypass

In addition to the effects of disruption and restoration of myocardial blood flow, cardiac morbidity may result from systemic insults due to CPB circuit-induced contact activation. Inflammation in cardiac surgical patients is produced by complex humoral and cellular interactions, including activation, generation, or expression of thrombin, complement, cytokines, neutrophils, adhesion molecules, mast cells, and multiple inflammatory mediators.[20] Because of the redundancy of the inflammatory cascades, profound amplification occurs to produce multiorgan system dysfunction that can manifest as coagulopathy, respiratory failure, myocardial dysfunction, renal insufficiency, and neurocognitive defects. Coagulation and inflammation also are linked closely through networks of both humoral and cellular components, including tissue factor and proteases of the clotting and fibrinolytic cascades. Vascular endothelial cells mediate inflammation and the cross-talk between coagulation and inflammation. Surgery alone activates specific hemostatic responses, immune mechanisms, and inflammatory responses mediated by the release of various cytokines and chemokines (see Chapters 9, and 31–35). This complex inflammatory reaction can lead to death from nonischemic causes and suggests that preoperative risk factors may not predict morbidity. The ability to risk-adjust populations is critical for the study of interventions that may influence these responses to CPB.

Assessment of Perioperative Myocardial Injury in Cardiac Surgery

The current clinical armamentarium is devoid of a means by which perioperative cardiac injury can be reliably monitored in real time, and this has led to the use of indicators of AMI after the event occurs. There is a lack of consensus regarding how to measure myocardial injury in cardiac surgery because of the continuum of cardiac injury. Electrocardiographic changes, biomarker elevations, and measures

BOX 1.2 ASSESSMENT OF PERIOPERATIVE MYOCARDIAL INJURY

Assessment of cardiac function
- Echocardiography

Nuclear imaging

Electrocardiography
- Q waves
- ST-T wave changes

Serum biomarkers
- Myoglobin
- Creatine kinase
- CK-MB isoenzyme
- Troponin
- Lactate dehydrogenase

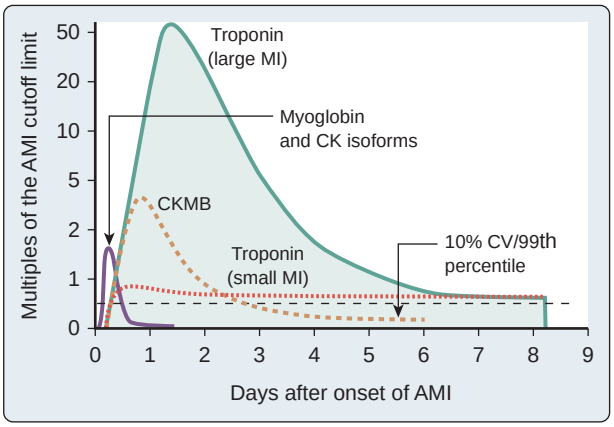

Fig. 1.1 Time course of the appearance of various markers in the blood after acute myocardial infarction *(AMI)*. Shown are the time concentrations/activity curves for myoglobin and creatine kinase *(CK)* isoforms, troponin after large and small infarctions, and CKMB. Note that with cardiac troponin some patients have a second peak in addition. *CKMB,* Creatine kinase, myocardial bound; *CV,* coefficient of variation. *(From Jaffe AS, Babuin L, Apple FS: Biomarkers in acute cardiac disease: the present and the future.* J Am Coll Cardiol. *2006;48[1]:1–11.)*

of cardiac function have all been used (Box 1.2), but all assessment modalities are affected by the direct myocardial trauma of surgery. In 2000, the American College of Cardiology/European Society of Cardiology (ACC/ESC) published a definition of MI that included a characteristic rise and fall in blood concentrations of cardiac troponins or creatine kinase (CK)-MB, or both, in the context of a coronary intervention; other modalities are less sensitive and specific (Fig. 1.1).[21]

The Joint ESC/ACC Foundation (ACCF)/American Heart Association (AHA)/World Heart Federation Task Force published a new Universal Definition of Myocardial Infarction in 2007[22] and revised it in 2012.[23] According to this most recent version of the definition, MI can be diagnosed based on detection of a rise and fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit, together with evidence of myocardial ischemia in the form of any of the following: symptoms of ischemia, ECG changes indicative of new ischemia (new ST-T changes or new left bundle branch block), development of pathologic Q waves on ECG, or imaging evidence of new loss of viable myocardium or new regional wall motion abnormality (RWMA). Because CABG itself is associated with cardiac trauma resulting in an increase in the serum levels of cardiac enzymes, an arbitrary cutoff level for elevation of cardiac biomarker values of more than 10 times the 99th percentile of the upper reference limit has been recommended for diagnosing MI during the immediate period after cardiac surgery. However, this threshold is more robust for diagnosing MI after an isolated on-pump CABG; cardiac biomarker release is typically considerably higher after combined valve replacement and CABG and considerably lower after an off-pump CABG.[24]

Assessment of Cardiac Function

Cardiac contractile dysfunction is the most prominent feature of myocardial injury, despite the fact that there are no perfect measures of postoperative cardiac function. The need for inotropic support, low cardiac output (CO) diagnosed with the use of CO measurement technologies, and assessment of abnormal ventricular function by transesophageal echocardiography (TEE) are practical intraoperative options for evaluation of cardiac contractility. Use of inotropic support and CO measurements are not reliable measures, however, because they depend on loading conditions and interpractitioner variability. Failure to wean from CPB, in the absence of systemic factors such as hyperkalemia and acidosis, is the best evidence of intraoperative myocardial injury or cardiac dysfunction, but it also may be multifactorial and therefore is a less robust outcome measure.

Because RWMAs on TEE follow the onset of ischemia within 10 to 15 seconds, echocardiography can be a sensitive and rapid monitor for cardiac ischemia/injury.[25] An irreversible RWMA indicates irreversible myocardial necrosis (see Chapters 12–16). The importance of echocardiographic assessment of cardiac function is further enhanced by its value as a predictor of long-term survival.[26] For patients undergoing CABG, a postoperative decrease in left ventricular (LV) ejection fraction (LVEF) compared with the preoperative baseline predicts decreased long-term survival.[27]

Nevertheless, the use of echocardiography for detecting postoperative LV systolic dysfunction has some challenges. Echocardiographic and Doppler systems have the limitation of being sensitive to alterations in loading conditions, similar need for inotropic support and CO determinations,[28] and the interpretation of TEE images is also operator dependent.[29] Additionally, myocardial stunning (postischemic transient ventricular dysfunction) is a common cause of new postoperative RWMAs, and the resulting wall motion abnormalities and LV systolic dysfunction are often transient. However, the appearance of a new LV RWMA in the postoperative period, whether caused by irreversible AMI or by reversible myocardial stunning, is an indication of some form of inadequate myocardial protection during the intraoperative period and therefore is of interest for assessment of the need for new interventions. At the same time, there are nonischemic causes of RWMAs, such as conduction abnormalities, ventricular pacing, and myocarditis, that confound the use of this measure for assessment of ischemic morbidity.

Electrocardiography Monitoring

The presence of new persistent Q waves of at least 0.03-s duration, broadening of preexisting Q waves, or new QS deflections on the postoperative ECG have been considered evidence of perioperative AMI.[30] However, new Q waves also may be caused by unmasking of an old MI and therefore are not indicative of a new AMI. Crescenzi and colleagues[31] demonstrated that the presence of a new Q wave together with high levels of biomarkers was strongly associated with postoperative cardiac events, whereas the isolated appearance of a new Q wave had no impact on postoperative cardiac outcome. Additionally, new Q waves may actually disappear over time.[32] Signs of non–Q-wave MI, such as ST-T wave changes, are even less reliable signs of AMI after cardiac surgery in the absence of biochemical evidence. ST-segment changes are less specific for perioperative MI because they can also be caused by changes in body position, hypothermia, transient conduction abnormalities, pericarditis, and electrolyte imbalances (see Chapter 12).

Serum Biochemical Markers to Detect Myocardial Injury

Serum biomarkers have become the primary means of assessing the presence and extent of AMI after cardiac surgery. Serum biomarkers that are indicative of myocardial damage include the following (with postinsult peak time given in parentheses): myoglobin (4 h), total CK (16 h), CK-MB isoenzyme (24 h), troponins I and T (24 h), and lactate dehydrogenase (LDH) (76 h). CK-MB isoenzyme has been used most widely, but studies have suggested that troponin I is the most sensitive and most specific marker for depicting myocardial ischemia and infarction.[33–37] Accordingly, cardiac troponin I is the current biomarker of choice for diagnosing myocardial injury.[23]

Numerous studies have demonstrated the value of cardiac biomarkers in predicting short- and long-term outcomes in patients undergoing cardiac surgery. For example, Klatte and coworkers reported on the implications of CK-MB level in 2918 high-risk CABG patients enrolled in a clinical trial of an antiischemic agent.[38] They calculated the postoperative peak CK-MB ratio (ie, the peak CK-MB value divided by the upper limit of normal for the laboratory test) for each patient. The unadjusted 6-month mortality rates were 3.4%, 5.8%, 7.8%, and 20.2% for patients with CK-MB ratios of less than 5, between 5 and 10, between 10 and 20, and greater than 20, respectively.[38] The relation remained statistically significant after adjustment for LVEF, congestive heart failure (CHF), cerebrovascular disease, peripheral vascular disease, cardiac arrhythmias, and the method of cardioplegia delivery.

In the Arterial Revascularization Therapies Study (ARTS), 496 patients with multivessel coronary artery disease undergoing CABG were evaluated by CK-MB testing after surgery and at 30 days and 1 year of follow-up.[39] Patients with increased cardiac enzyme levels after CABG were at increased risk for both death and repeat AMI within the first 30 days. CK-MB increase also was independently related to late adverse outcome. Other studies have similarly documented the prognostic value of cardiac troponin I. Increased cardiac-specific troponin I or T after CABG has been associated with a cardiac cause of death and with major postoperative complications within 2 years after CABG.[40,41]

A few new biomarkers of perioperative cardiac injury or ischemia are under development. Brain natriuretic peptide (BNP) can be detected in the early stages of ischemia and decreases shortly after ischemic insult, allowing better detection of reinjury.[42] BNP concentrations after CABG in patients who experienced cardiac events within 2 years after surgery were significantly greater than those in patients free of cardiac events.[43] Soluble CD40 ligand (sCD40L) is another early biomarker of myocardial ischemia,[44] and CPB causes an increase in the concentration of plasma sCD40L. A corresponding decrease in platelet CD40L suggests that this prothrombotic and proinflammatory protein is derived primarily from platelets and may contribute to the thrombotic and inflammatory complications associated with CPB.[45] Future research will be required to determine how these biomarkers may be used to assess outcome after cardiac surgery.

Variability in Diagnosis of Perioperative Myocardial Infarction

The variability in diagnosis of perioperative AMI was studied by Jain and colleagues,[46] who evaluated data from 566 patients at 20 clinical sites. Twenty-five percent of the patients met Q-wave, CK-MB, or autopsy criteria for AMI. Among them, 19% had increased CK-MB concentrations and ECG changes. Four percent met either Q-wave plus CK-MB or autopsy criteria. Multicenter data collection showed a substantial variation in the incidence of AMI and an overall incidence rate of up to 25%. The determination of perioperative AMI was highly variable depending on the definitions used.

Clinicians are still searching for a gold standard approach to diagnose perioperative AMI. Perioperative myocardial necrosis or injury ranges from mild to severe and can have an ischemic or nonischemic origin in patients undergoing cardiac surgery. Perioperative ECG changes, including Q waves, and new RWMAs on TEE are less reliable than in the nonperioperative arena. As mentioned earlier, troponin I or T is currently the best indicator of myocardial damage after cardiac surgery.

Cardiac Risk Assessment and Cardiac Risk Stratification Models in Patients Undergoing Cardiac Surgery

In defining important risk factors and developing risk indices, each of the studies has used different primary outcomes. Postoperative mortality remains the most definitive outcome that is reflective of patient injury in the perioperative period. Death can be cardiac and noncardiac related, and if cardiac related, it may be ischemic or nonischemic in origin. Postoperative mortality rate is reported as either the in-hospital rate or the 30-day rate. The latter represents a more standardized definition, although it is more difficult to capture because of the difficulty inherent in assessing death rates of discharged patients who may die at home or another facility. Risk-adjusted postoperative mortality models permit assessment of the comparative efficacy of various techniques in preventing myocardial damage, but they do not provide information that is useful in preventing the injury in real time.[47] The postoperative mortality rate also has been used as a comparative measure of quality of cardiac surgical care.[48,49]

Postoperative morbidity includes AMI and reversible events such as CHF and need for inotropic support. The problems of using AMI as an outcome of interest were described earlier. Because resource utilization has become such an important financial consideration for hospitals, the length of stay in the intensive care unit (ICU) increasingly has been used as a factor in the development of risk indices (see Chapters 37 and 38).

Predictors of Perioperative and Postoperative Morbidity and Mortality

Clinical and angiographic predictors of operative mortality were initially defined from the results of the Coronary Artery Surgery Study (CASS).[50,51] A total of 6630 patients underwent isolated CABG between 1975 and 1978. Women had a significantly greater mortality rate than men; mortality increased with advancing age in men, but this was not a significant factor in women. Increasing severity of angina, manifestations of heart failure, and number and extent of coronary artery stenoses all correlated with greater mortality, whereas LVEF was not a predictor. Urgency of surgery was a strong predictor of outcome, and those patients requiring emergency surgery in the presence of a 90% left main coronary artery stenosis sustained a 40% mortality rate.

A risk-scoring scheme for cardiac surgery (CABG and valve) was introduced by Paiement and associates[5] at the Montreal Heart Institute in 1983. Eight risk factors were identified: (1) poor LV function, (2) CHF, (3) unstable angina or recent MI (within 6 wk), (4) age greater than 65 years, (5) severe obesity (body mass index >30 kg/m^2), (6) reoperation, (7) emergency surgery, and (8) other significant or uncontrolled systemic disturbances. The investigators identified three classes of patients: those with none of the listed risk factors (normal), those presenting with one risk factor (increased risk), and those with more than one factor (high risk). In a study of 500 consecutive patients undergoing cardiac surgery, it was found that operative mortality increased with increasing risk score (confirming the scoring system).

zzzOne of the most commonly used scoring systems for CABG was developed by Parsonnet and colleagues[52] (Table 1.1). Fourteen risk factors were identified for in-hospital or 30-day mortality after univariate regression analysis of 3500 consecutive operations. An additive model was constructed and prospectively evaluated in 1332 cardiac procedures. Five categories of risk were identified with increasing mortality rates, complication rates, and length of stay at the Newark Beth Israel Medical Center. The Parsonnet Index frequently is used as a benchmark for comparisons among institutions. However, it was created earlier than the other models and may not be representative

TABLE 1.1 Components of the Additive Model

Risk Factor	*Assigned Weight*
Female sex	1
Morbid obesity (≥1.5 × ideal weight)	3
Diabetes (unspecified type)	3
Hypertension (systolic BP >140 mm Hg)	3
Ejection fraction (%):	
Good >50)	0
Fair (30–49)	2
Poor (<30)	4
Age (y):	
70–74	7
75–79	12
≥80	20
Reoperation	
First	5
Second	10
Preoperative IABP	2
Left ventricular aneurysm	5
Emergency surgery after PTCA or catheterization complications	10
Dialysis dependency (PD or Hemo)	10
Catastrophic states (eg, acute structural defect, cardiogenic shock, acute renal failure)[a]	10–50[b]
Other rare circumstances (eg, paraplegia, pacemaker dependency, congenital HD in adult, severe asthma)[a]	2–10[b]
Valve surgery	
Mitral	5
PA pressure ≥60 mm Hg	8
Aortic	5
Pressure gradient >120 mm Hg	7
CABG at the time of valve surgery	2

[a]On the actual worksheet, these risk factors require justification.
[b]Values were predictive of increased risk for operative mortality in univariate analysis.

TABLE 1.2 Risk Model Results

Variable	*Odds Ratio*
Age (in 10-y increments)	1.640
Female sex	1.157
Race other than white	1.249
Ejection fraction	0.988
Diabetes	1.188
Renal failure	1.533
Serum creatinine (if renal failure is present)	1.080
Dialysis dependence (if renal failure is present)	1.381
Pulmonary hypertension	1.185
Cerebrovascular accident timing	1.198
Chronic obstructive pulmonary disease	1.296
Peripheral vascular disease	1.487
Cerebrovascular disease	1.244
Acute evolving, extending myocardial infarction	1.282
Myocardial infarction timing	1.117
Cardiogenic shock	2.211
Use of diuretics	1.122
Hemodynamic instability	1.747
Triple-vessel disease	1.155
Left main disease >50%	1.119
Preoperative intraaortic balloon pump	1.480
Status	
Urgent or emergent	1.189
Emergent salvage	3.654
First reoperation	2.738
Multiple reoperations	4.282
Arrhythmias	1.099
Body surface area	0.488
Obesity	1.242
New York Heart Association class IV	1.098
Use of steroids	1.214
Congestive heart failure	1.191
PTCA within 6 h of surgery	1.332
Angiographic accident with hemodynamic instability	1.203
Use of digitalis	1.168
Use of intravenous nitrates	1.088

PTCA, Percutaneous transluminal coronary angioplasty.
From Shroyer AL, Plomondon ME, Grover FL, et al: The 1996 coronary artery bypass risk model: the Society of Thoracic Surgeons Adult Cardiac National Database. *Ann Thorac Surg.* 1999;67:1205, by permission of Society of Thoracic Surgeons.

of the current practice of CABG. Since publication of the Parsonnet model, numerous technical advances now in routine use have diminished CABG mortality rates.

Bernstein and Parsonnet[53] simplified the risk-adjusted scoring system in 2000 to provide a handy tool in preoperative discussions with patients and their families and for preoperative risk calculation and stratification. The authors developed a logistic regression model, in which 47 potential risk factors were considered, and a method requiring only simple addition and graphic interpretation was designed for relatively easy approximation of the estimated risk. The final estimates provided by the simplified model correlated well with the observed mortality (Fig. 1.2).

The Society of Thoracic Surgeons (STS) National Adult Cardiac Surgery Database (NCD) represents the most robust source of data for calculating risk-adjusted scoring systems. Established in 1989, the database included 892 participating hospitals in 2008 and has continued to grow. This provider-supported database, one of the largest in the world, allows participants to benchmark their risk-adjusted results against regional and national standards. New patient data are brought into the STS database on a semiannual basis. These new data are analyzed, modeled, and tested using a variety of statistical algorithms.

Since 1990, when more complete data collection was achieved, risk stratification models have been developed for both CABG and valve replacement surgery. Models developed in 1995 and 1996 were shown to have good predictive value[54,55] (Table 1.2 and Fig. 1.3). In 1999, the STS analyzed the database for valve replacement with and without CABG to determine trends in risk stratification. Between 1986 and 1995, 86,580 patients were analyzed. The model evaluated the influence of 51 preoperative variables on operative mortality by univariate and multivariate analyses for the overall population and for each subset. After the significant risk factors were determined by univariate analysis, a standard logistic regression analysis was performed using the training-set population to develop a formal model. The test-set population then was used to determine the validity of the model. The preoperative risk factors associated with greatest operative mortality rates were salvage status, renal failure (dialysis dependent and nondialysis dependent), emergent status, multiple reoperations, and New York Heart Association class IV status. The multivariate logistic regression analysis identified 30 independent preoperative risk factors among the six valvular models that represented isolated valvular surgery or valvular surgery in combination with CABG. The addition of CABG increased the mortality rate significantly for all age groups and for all subset models.[56]

There are currently three general STS risk models: CABG, valve (aortic or mitral), and valve plus CABG. These three models comprise seven specific, precisely defined procedures: the CABG model refers to an isolated CABG; the valve model includes isolated aortic or mitral valve replacement and mitral valve repair; and the valve plus CABG model includes aortic valve replacement with CABG, mitral valve replacement with CABG, and mitral valve repair with CABG. Besides operative mortality, these models were developed for eight additional end points: reoperation, permanent stroke, renal failure, deep sternal wound infection, prolonged (>24 h) ventilation, composite major

INSTRUCTIONS:

Step 1. Fill in the blanks for existing risk factors, using the scores provided. (Note: Scores shown are in arbitrary units, and are not, by themselves, estimates of percent risk.)

Step 2. Add the scores to obtain a total score. (Include common risk factors on this side of the page and less common risk factors on the other side.)

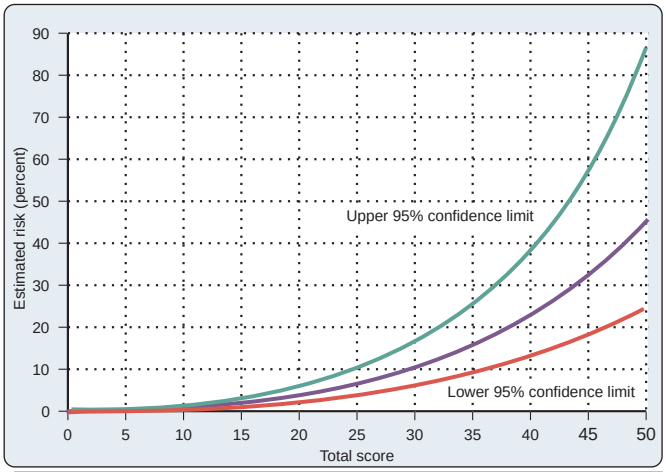
Step 3. See reverse side to interpret the total score.

RISK FACTOR	*SCORING (APPROXIMATE SYSTEM 97)*		*VALUE*
Female gender		6	6
Age	70–75 76–79 80+	2.5 7 11	7
Congestive failure		2.5	
COPD, severe		6	
Diabetes		3	
Ejection fraction	30–42% <30%	6.5 8	
Hypertension	Over 140/90, or history of hypertension, or currently taking anti-hypertension medication	3	3
Left-main disease	Left-main stenosis is 50%	2.5	
Morbid obesity	Over 1.5 times ideal weight	1	1
Preoperative IABP	IABP present at time of surgery	4	
Reoperation	First reoperation Second or subsequent reoperation	10 20	
One valve, aortic	Procedure proposed	0	
One valve, mitral	Procedure proposed	4.5	
Valve + ACB	Combination valve procedure and ACB proposed	6	
Special conditions	*(see reverse side)*		
		TOTAL SCORE:	17

(See reverse side for risk estimation.)

RISK VALUES FOR SPECIAL CONDITIONS

Cardiac	
Cardiogenic shock (urinary output <10 cc/hr)	12
Endocarditis, active	5.5
Endocarditis, treated	0
LV aneurysm resected	1.5
One valve, incuspid: procedure proposed	5
Pacemaker dependency	0
Transmural acute MI within 48 hr	4
Ventricular septal defect, acute	12
Ventricular tachycardia, ventricular fibrillation, aborted sudden death	1
Pulmonary	
Asthma	1
Endotracheal tube, preoperative	4
Idiopathic thrombocytopenic purpura	12
Pulmonary hypertension (mean pressure >30)	11
Hepato-renal	
Cirrhosis	12.5
Dialysis dependency	13.5
Renal failure, acute or chronic	3.5
Vascular	
Abdominal aortic aneurysm, asymptomatic	0.5
Cartoid disease (bilateral or 100% unilateral occlusion)	2
Peripheral vascular disease, severe	3.5
Miscellaneous	
Blood products refused	11
Severe neurologic disorder (healed CVA, paraplegia, muscular dystrophy, hemiparesis)	5
PTCA or cathaterization failure	5.5
Substance abuse	4.5



Use the total score to read the estimated preoperative-risk range from this plot, which shows the estimated risk of mortality together with 95% confidence limits.

Fig. 1.2 Preoperative Risk-Estimation Worksheet. *(From Bernstein AD, Parsonnet V. Bedside estimation of risk as an aid for decision-making in cardiac surgery.* Ann Thorac Surg. *2000;69:823, by permission from the Society of Thoracic Surgeons.)*

morbidity or mortality, prolonged length of stay (>14 days), and short length of stay (<6 days and alive).[57–59] These models are updated every few years and are calibrated annually to provide an immediate and accurate tool for regional and national benchmarking, and they have been proposed for public reporting. The calibration of the risk factors is based on the ratio between observed and expected results (O/E ratio), and calibration factors are updated quarterly. The expected mortality (E) is calibrated to obtain a national O/E ratio.

The European System for Cardiac Operative Risk Evaluation (EuroSCORE) is another widely used model for cardiac operative risk evaluation. It was constructed from an analysis of 19,030 patients undergoing a diverse group of cardiac surgical procedures from 128 centers across Europe[60,61] (Tables 1.3 and 1.4). The following risk factors were associated with increased mortality: age, female sex, elevated serum creatinine level, extracardiac arteriopathy, chronic airway disease, severe neurologic dysfunction, previous cardiac surgery, recent MI, reduced LVEF, chronic CHF, pulmonary hypertension, active endocarditis, unstable angina, procedure urgency, critical preoperative condition, ventricular septal rupture, noncoronary surgery, and thoracic aortic surgery. For a given individual, each of these risk factors is assigned a score, and the sum total of these is used to predict surgical risk. In 2003, a more sophisticated, logistic version of EuroSCORE was released to permit more accurate risk assessment in individuals deemed to be at very high risk.[62]

The additive EuroSCORE has been used widely and validated across various centers in Europe and around the world, making it a primary tool for risk stratification in cardiac surgery.[63–74] Although its accuracy has been well established for CABG and isolated valve procedures, its predictive ability in combined CABG and valve procedures has been less well studied. Karthik and associates[65] showed that, in patients undergoing combined procedures, the additive EuroSCORE significantly underpredicted the risk when compared with the observed mortality. The logistic EuroSCORE[62] performed better in this setting.

In 2011, the EuroSCORE was recalibrated to keep up with new evidence. The revised EuroSCORE, known as EuroSCORE II,[75] permits more accurate risk estimation yet preserves the powerful discrimination of the original model. The EuroSCORE II is currently the recommended model for assessment of cardiac surgical risk. It can be accessed online (www.euroscore.org/calc.html) or downloaded as a Smartphone application.

Many other investigators have developed risk assessment models using data representing different populations and different surgical

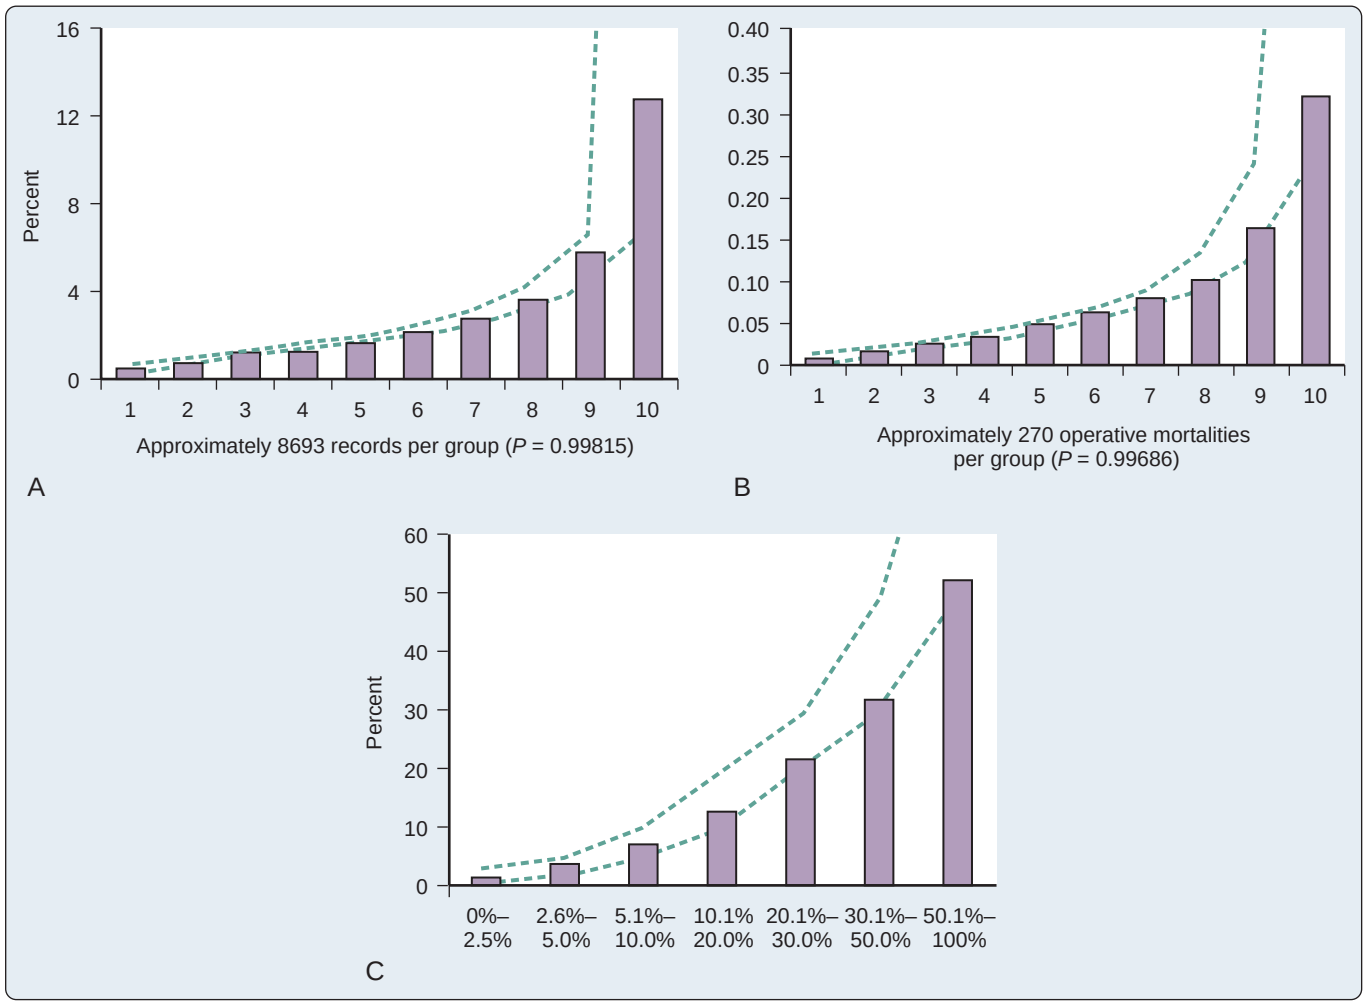


Fig. 1.3 After the predicted risk for each patient in the test set was determined, the patient records were arranged sequentially in order of predicted risk. The population was divided into 10 groups with an equal number of records in each group (A), 10 groups with an equal number of deaths in each group (B), or 7 groups by clinically relevant risk category (C). The predicted mortality rate was compared with the actual mortality for each of the groups. *Dashed lines* represent the range of predicted mortality for a group of patients; *bars* represent actual mortality for that group. *(From Shroyer AL, Plomondon ME, Grover FL, et al. The 1996 coronary artery bypass risk model: the Society of Thoracic Surgeons Adult Cardiac National Database.* Ann Thorac Surg. *1999;67:1205, by permission of the Society of Thoracic Surgeons.)*

practices.[76–84] Hannan and colleagues[82] evaluated predictors of mortality after valve surgery using data from 14,190 patients in New York state. A total of 18 independent risk factors were identified in the six models of differing combinations of valve surgery and CABG. Shock and dialysis-dependent renal failure were among the most significant risk factors in all models. The risk factors and odds ratios are shown in Tables 1.5–1.7. They also studied which risk factors were associated with early readmission (≤30 d) after CABG. Of the 16,325 total patients, 2111 (12.9%) were readmitted within 30 days for reasons related to CABG. Eleven risk factors were found to be independently associated with greater readmission rates: older age, female sex, African American race, greater body surface area, previous AMI within 1 week, and six comorbidities. After controlling for these preoperative patient-level risk factors, two provider characteristics (annual surgeon CABG volume <100 and hospital risk-adjusted mortality rate in the highest decile) and two postoperative factors (discharge to nursing home or rehabilitation/acute care facility and length of stay during index CABG admission ≥5 d) also were related to greater readmission rates.

Dupuis and associates[84] attempted to simplify the approach to evaluating the risk of cardiac surgical procedures in a manner similar to the original American Society of Anesthesiologists (ASA) physical status classification. They developed a score that uses a simple categorization of five classes plus an emergency status (Table 1.8). The Cardiac Anesthesia Risk Evaluation (CARE) score model collected data from 1996 to 1999 and included 3548 patients to predict both in-hospital mortality and a diverse group of major morbidities. It combined clinical judgment and the recognition of three risk factors previously identified by multifactorial risk indices: comorbid conditions categorized as controlled or uncontrolled, the complexity of the surgery, and the urgency of the procedure. The CARE score demonstrated predictive characteristics similar or superior to those of the more complex indices. The development of these several excellent risk models for cardiac valve surgery provides a powerful new tool to improve patient care, select procedures, counsel patients, and compare outcomes (see Chapter 21).

Consistency Among Risk Indices

Many different variables have been found to be associated with the increased risk during cardiac surgery, but only a few have consistently

TABLE 1.3 Risk Factors, Definitions, and Weights (Score)

Risk Factors	*Definition*	*Score*
Patient-Related Factors		
Age	Per 5 y or part thereof over 60 y	1
Sex	Female	1
Chronic pulmonary disease	Long-term use of bronchodilators or steroids for lung disease	1
Extracardiac arteriopathy	One or more of the following: claudication; carotid occlusion or >50% stenosis; previous or planned intervention on the abdominal aorta, limb arteries, or carotids	2
Neurologic dysfunction	Disease severely affecting ambulation or day-to-day functioning	2
Previous cardiac surgery	Requiring opening of the pericardium	3
Serum creatinine	>200 µmol/L before surgery	2
Active endocarditis	Patient still under antibiotic treatment for endocarditis at the time of surgery	3
Critical preoperative state	One or more of the following: ventricular tachycardia or fibrillation or aborted sudden death, preoperative cardiac massage, preoperative ventilation before arrival in the anesthesia room, preoperative inotropic support, intraaortic balloon counterpulsation or preoperative acute renal failure (anuria or oliguria <10 mL/h)	3
Cardiac-Related Factors		
Unstable angina	Rest angina requiring IV nitrates until arrival in the anesthesia room	2
Left ventricular dysfunction	Moderate or LVEF 30–50% Poor or LVEF <30% Recent myocardial infarct (<90 d)	1 3 2
Pulmonary hypertension	Systolic pulmonary artery pressure >60 mm Hg	2
Surgery-Related Factors		
Emergency	Carried out on referral before the beginning of the next working day	2
Other than isolated CABG	Major cardiac procedure other than or in addition to CABG	2
Surgery on thoracic aorta	For disorder of the ascending aorta, arch, or descending aorta	3
Postinfarct septal rupture		4

been found to be major risk factors across multiple and very diverse study settings. Age, female sex, LV function, body habitus, reoperation, type of surgery, and urgency of surgery were among the variables consistently present in most of the models (Box 1.3).

Although a variety of investigators have found various comorbid diseases to be significant risk factors, no diseases have been shown to be consistent risk factors, with the possible exception of renal dysfunction and diabetes. These two comorbidities were shown to be important risk factors in a majority of the studies (Box 1.4).

Applicability of Risk Indices to a Given Population

It is critical to appreciate how these indices were created so as to understand how best to apply a given risk index to a specific patient or population. The application of these risk models to a specific population must be done with caution and after careful study. One issue is that the profile of patients undergoing cardiac surgery is constantly changing, and patients who previously would not have been included in the development data set because they were not considered surgical candidates are now undergoing surgery. Therefore, the models require continuous updating and revision. In addition, cardiac surgery itself is changing with the increasing use of off-pump and less invasive procedures, and this may alter the influence of preexisting conditions.

One critical factor in the choice of model for a given practice is to understand the clinical goals used in the original development process. Additionally, despite extensive research and widespread use of risk models in cardiac surgery, there are methodologic problems. The extent of the details in the reports varies greatly. Different conclusions can be reached depending on the risk model used. Processes critical to the development of risk models are shown in Fig. 1.4.

The underlying assumption in the development of any risk index is that specific factors (eg, disease history, physical findings, laboratory data, nature of surgery) cannot be modified with respect to their influence on outcome. For example, the urgency of the planned surgical procedure and the baseline comorbidities cannot be changed. However, the models themselves depend on the appropriate selection

TABLE 1.5 Significant Independent Risk Factors for in-Hospital Mortality: Aortic Valve Surgery With or Without CABG

of baseline variables or risk factors to study, and their prevalence in the population of interest is critical for them to affect outcome. For example, referral patterns to a given institution may result in an absence of certain patient populations, in which case some risk factors may not appear in the model or their influence may be different than in the population on which the model was based. Also, the use of multivariate logistic regression may eliminate biologically important risk factors that are not present in sufficient numbers to achieve statistical significance.

In developing a risk index, it is important to validate the model and to benchmark it against other known means of assessing risks. It is important to determine whether the index predicts morbidity,

TABLE 1.8 Cardiac Anesthesia Risk Evaluation (CARE) Score

1 = Patient with stable cardiac disease and no other medical problem (a noncomplex surgery is undertaken)
2 = Patient with stable cardiac disease and one or more controlled medical problems[a] (a noncomplex surgery is undertaken)
3 = Patient with any uncontrolled medical problem[b] or any patient in whom a complex surgery is undertaken[c]
4 = Patient with any uncontrolled medical problem *and* in whom a complex surgery is undertaken
5 = Patient with chronic or advanced cardiac disease for whom cardiac surgery is undertaken as a last hope to save or improve life
E = Emergency: surgery as soon as diagnosis is made and operating room is available

[a]Examples: controlled hypertension, diabetes mellitus, peripheral vascular disease, chronic obstructive pulmonary disease, controlled systemic diseases, others as judged by clinicians

[b]Examples: unstable angina treated with intravenous heparin or nitroglycerin, preoperative intraaortic balloon pump, heart failure with pulmonary or peripheral edema, uncontrolled hypertension, renal insufficiency (creatinine level >140 µmol/L), debilitating systemic diseases, others as judged by clinicians

[c]Examples: reoperation, combined valve and coronary artery surgery, multiple valve surgery, left ventricular aneurysmectomy, repair of ventricular septal defect after myocardial infarction, coronary artery bypass of diffuse or heavily calcified vessels, others as judged by clinicians

From Dupuis JY, Wang F, Nathan H, et al. The cardiac anesthesia risk evaluation score: a clinically useful predictor of mortality and morbidity after cardiac surgery. *Anesthesiology.* 2001;94:194, by permission.

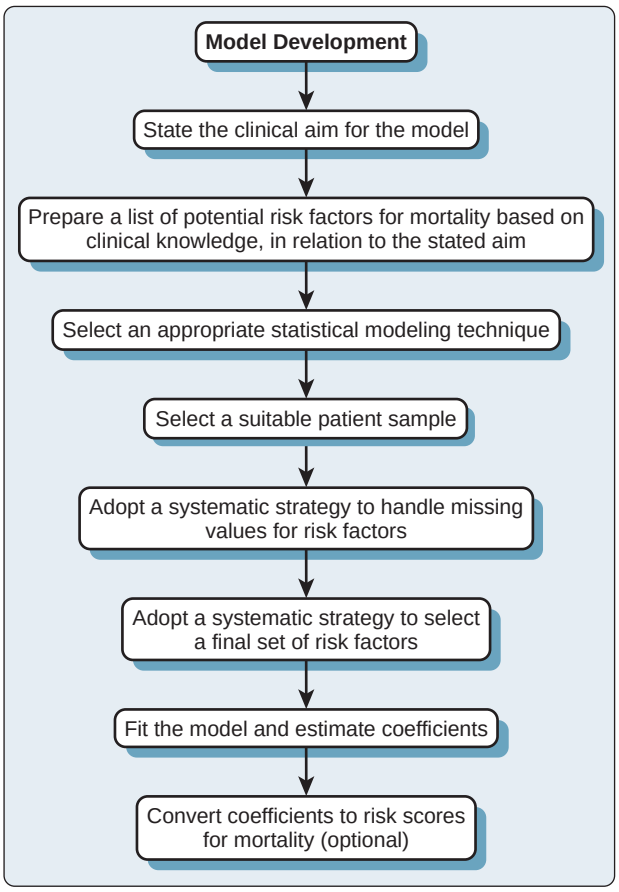

Fig. 1.4 Risk model development. *(From Omar RZ, Ambler G, Royston P, et al. Cardiac surgery risk modeling for mortality: a review of current practice and suggestions for improvement.* Ann Thorac Surg. *2004;77:2232, by permission of the Society of Thoracic Surgeons.)*

mortality, or both. Typically, a model's performance is first evaluated on its goodness of fit to the developmental data (*validation*). Alternatively, the original data can be split and the model can be built on half of the data and validated on the other half. Because this method reduces the total number of patients and outcomes available to create the model, it is best suited to situations in which data on tens of thousands of patients are available. This internal validation does not provide the practitioner with information on the generalizability of the model. External validation on a large, completely independent test data set is the best approach to satisfying this requirement.

Calibration refers to a model's ability to predict mortality accurately. Numerous tests can be applied, the most common being the Hosmer-Lemeshow test. If the *P* value from a Hosmer-Lemeshow test is greater than .05, the current practice of investigators is to claim that the model predicts mortality accurately.

Discrimination is the ability of a model to distinguish patients who die from those who survive. The area under the receiver operating characteristic (ROC) curve is the common method of assessing this facet of the model. In brief, the test is determined by evaluating all possible pairs of patients, determining whether the predicted probability of death should ideally be greater for the patient who died than for the one who survived. The ROC area is the percentage of pairs for which this is true, graphed as the sensitivity versus 1 – the specificity. The current practice in cardiac surgery is to conclude that a model discriminates well if the ROC area is greater than .7. If predictions are used to identify surgical centers or surgeons with unexpectedly high or low rates, achieving a high ROC area alone is not adequate, but good calibration is also critical. A poorly calibrated model may indicate that large numbers of institutions or surgeons have excessively high or low rates of mortality, when in fact the fault lies with the model, not the clinical performance. If predictions are used to stratify patients according to disease severity, to compare treatments, or to decide questions of patient management, both calibration and discrimination are important aspects to consider.

A key problem in the development of cardiac surgery risk stratification models is the evolving practice of surgery. New procedures or variations on older procedures may affect perioperative risk yet not be accounted for in the data used to develop the model. Despite these limitations, the calibrated and validated risk model remains the most objective tool currently available. Clinicians need to understand the specific model they are using, its strengths and weaknesses, to appropriately apply the model in academic research, patient counseling, benchmarking, and management of resources.

Specific Risk Conditions

Renal Dysfunction

Renal dysfunction has been shown to be an important risk factor for surgical mortality in patients undergoing cardiac surgery.[85–87] However, the spectrum of what constitutes renal dysfunction is broad, with some models defining it as increased creatinine levels and others defining it as dialysis dependency.

The Northern New England Cardiovascular Study Group reported a 12.2% in-hospital mortality rate after CABG in patients on chronic dialysis versus a 3.0% mortality rate in patients not on dialysis.[88] However, the incidence of dialysis dependency in the cardiac surgical population is sufficiently low (eg, 0.5% in New York state) that it may not enter into many of the models developed.

Acute kidney injury (AKI) after cardiac surgery carries significant morbidity and mortality. Patients who developed severe renal dysfunction (defined as a glomerular filtration rate [GFR] of <30 mL/min) after CABG had a mortality rate of almost 10%, compared with 1% for patients with normal renal function.[89] Poor outcomes associated with perioperative AKI have led to development of predictive models of AKI to identify patients at risk. One of these models predicts the need for renal replacement therapy (RRT) after cardiac surgery. Wijeysundera and coworkers[90] retrospectively studied a cohort of 20,131 cardiac surgery patients at two hospitals in Ontario, Canada. The multivariate preoperative predictors of RRT were estimated GFR, diabetes mellitus requiring medication, LVEF status (ie, ≤40%), previous cardiac surgery, procedure other than CABG, urgency of surgery (ie, nonelective case), and preoperative use of an intraaortic balloon pump (IABP).

An estimated GFR of 30 mL/min or less was assigned 2 points; a GFR of 31 to 60 mL/min and each of the other components were assigned 1 point each. Among the 53% of patients with low risk scores (≤1 point), the risk for RRT was 0.4%; among the 6% of patients with high-risk scores (≥4 points), it was 10%. Another group developed a robust prediction rule to assist clinicians in identifying patients with normal or near-normal preoperative renal function who are at high risk for development of severe renal insufficiency.[91] In a multivariate model, the preoperative patient characteristics most strongly associated with postoperative severe renal insufficiency included age, sex, white blood cell count greater than 12,000/μL, prior CABG, CHF, peripheral vascular disease, diabetes, hypertension, and preoperative IABP.

A major issue with respect to the development of indices to predict perioperative renal failure is that the pathophysiology of perioperative AKI includes inflammatory, nephrotoxic, and hemodynamic insults. This multifactorial nature of AKI might be one of the reasons that a limited single-strategy approach has not been successful.[92] Contrast agents used for angiography before cardiac surgery represent one of the modifiable nephrotoxic factors. Delaying cardiac surgery beyond 24 hours after the exposure and minimizing the contrast agent load can decrease the incidence of AKI in elective cardiac surgery cases.[93]

Uniformity of AKI definition, achieved by using the RIFLE criteria (risk of renal dysfunction, injury to the kidney, failure of kidney function, loss of kidney function, and end-stage kidney disease), has improved risk stratification models, and use of early biomarkers of AKI should provide additional tools to design clinical trials addressing this important issue.[94,95]

Diabetes

The association between diabetes mellitus and mortality in cardiac surgery has been inconsistent; some studies support the association, but others do not.[96–103] Several randomized trials have evaluated outcome with CABG versus PCI in patients with diabetes. In the Coronary Artery Revascularization in Diabetes (CARDia) trial,[104] a total of 510 patients who had diabetes with multivessel or complex single-vessel CAD from 24 centers were randomized to PCI plus stenting (and routine abciximab) or CABG. After 1 year, the composite rate of death, MI, and stroke was 10.5% in the CABG group and 13.0% in the PCI group (hazard ratio [HR], 1.25; 95% confidence interval [CI], 0.75 to 2.09; $P = .39$); the all-cause mortality rates were 3.2% and 3.2%, respectively; and the rates of death, MI, stroke, or repeat revascularization were 11.3% and 19.3% (HR, 1.77; 95% CI, 1.11 to 2.82; $P = .02$), respectively.

In the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trial, 2368 patients with both type 2 diabetes and heart disease were randomly assigned to undergo either prompt revascularization along with intensive medical therapy or intensive medical therapy alone, and to undergo either insulin-sensitization or insulin-provision therapy. After a mean follow-up interval of 5.3 years, all-cause mortality, cardiac mortality, MI, and other end points were assessed.[105] The mortality rates did not differ between prompt revascularization versus intensive medical therapy alone or between the two insulin strategies. However, patients in the CABG stratum had significantly fewer MI events with prompt revascularization, and their composite end point of MI plus cardiac death was significantly reduced with insulin-sensitization therapy. The researchers concluded that for patients similar to those in the PCI group, intensive medical therapy alone was an excellent first-line strategy, but for patients with more extensive CAD, similar to those enrolled in the CABG stratum, prompt CABG (in the absence of contraindications), intensive medical therapy, and insulin-sensitization therapy appeared to be a preferred strategy to reduce the incidence of MI.[106]

More recent studies have directly compared CABG with PCI in diabetic patients with multivessel CAD. The Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial randomized 1900 diabetic subjects to either PCI or CABG. After 5 years of follow-up, CABG was shown to result in lower rates of death and MI, although the stroke rate was higher in the CABG group.[107] A metaanalysis including eight studies comparing CABG with PCI in diabetic subjects reaffirmed the superiority of CABG in these patients.[108]

Acute Coronary Syndrome

Patients with a recent episode of any non–ST-segment elevation acute coronary syndrome before CABG have greater rates of operative morbidity and mortality than do patients with stable coronary syndromes.[109] However, the American College of Cardiology Foundation, in collaboration with numerous other societies, has published appropriate use criteria for coronary revascularization.[110] Because there are numerous class A recommendations for revascularization, many patients come to the operating room directly after coronary angiography or after attempted stent placement with antiplatelet agents. There is evidence to suggest that it is beneficial to delay CABG for 3 to 7 days in selected stable patients with contraindications to PCI who have experienced ST-elevation myocardial infarction (STEMI) or non–ST-elevation myocardial infarction (NSTEMI).[111] In addition, patients with a hemodynamically significant right ventricular MI should be allowed a period of time for the injured ventricle to recover.[112]

Assessment of Cardiac Risk in Patients Undergoing Noncardiac Surgery

The approach to preoperative cardiac risk assessment and stratification in patients undergoing noncardiac surgery is distinct from that in patients undergoing cardiac surgery. In the latter group, extensive cardiac evaluation is part of the routine preoperative workup, and the patient undergoes corrective therapy for the underlying disease. In contrast, although the presence of a cardiac illness is an added, and often powerful, risk factor for perioperative morbidity and mortality in patients undergoing a noncardiac surgery, the underlying cardiac status in most cases is either inadequately known or not known at all. This necessitates some form of cardiac evaluation in these patients. However, several factors need to be taken into consideration, including overall functional status of the patient, the surgical risk entailed by the proposed noncardiac surgery, the urgency of the noncardiac surgery and the potential risk associated with any delay, the availability of necessary resources for cardiac evaluation, and the impact that the information derived from cardiac evaluation is likely to have on perioperative planning and management (see Chapter 43).

Stepwise Approach to Cardiac Risk Assessment in Patients Undergoing Noncardiac Surgery

Both the ACC/AHA and the ESC recommend a stepwise approach to cardiac risk assessment in patients undergoing a noncardiac surgery (Fig. 1.5).[113,114] Their approaches are based on similar principles and are almost identical.

Step 1: Determine the Urgency of the Noncardiac Surgery

If the noncardiac surgery is emergent (ie, one in which life or limb will be threatened if the surgery is not performed promptly, typically within 6 h), no further cardiac evaluation is warranted in most instances. The clinical risk factors should be assessed, and knowledge about preexisting cardiac illness, if available, should be incorporated to help determine the surgical strategy and optimize perioperative monitoring and management.

Step 2: Identify Any Unstable Cardiac Condition

If the surgery is not emergent, then it should be determined whether the patient has any unstable cardiac condition (Box 1.5). If the patient is diagnosed as having an unstable cardiac condition, a multidisciplinary approach is required, including the patient, the family, and all stakeholders in the patient's caregiver team. A decision needs to be reached about how to stabilize the underlying cardiac condition,

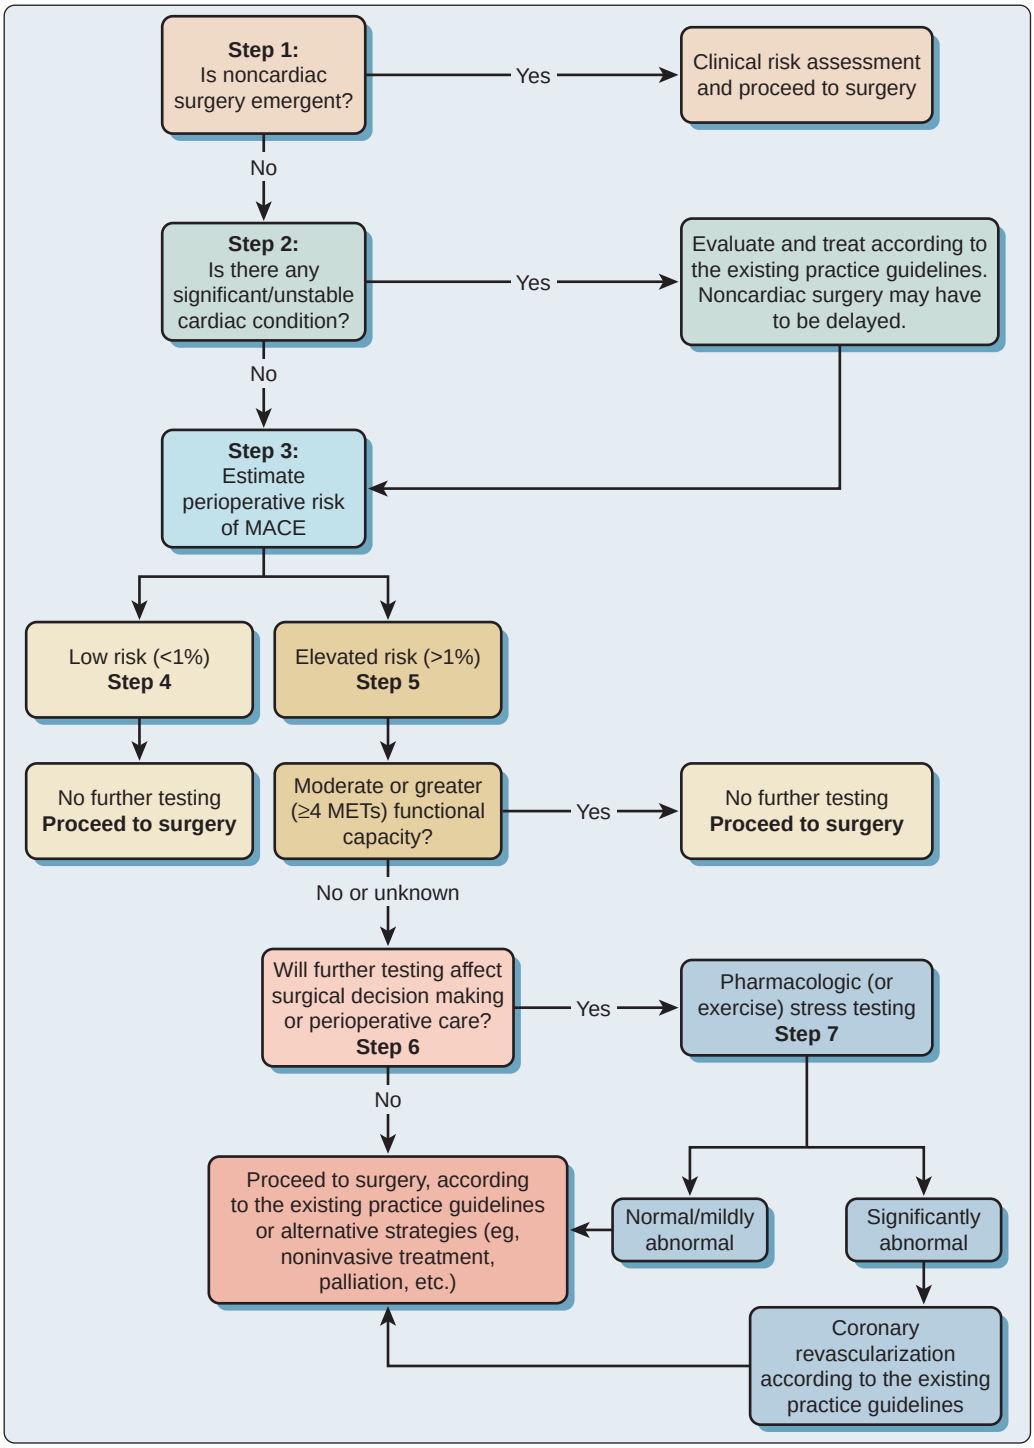

Fig. 1.5 Stepwise approach to perioperative cardiac risk assessment in patients undergoing noncardiac surgery. *MACE*, Major adverse cardiovascular event; *MET*, metabolic equivalent. BOX 1.5 UNSTABLE CARDIAC CONDITIONS

Acute coronary event
Recent myocardial infarction with residual myocardial ischemia
Acute heart failure
Significant cardiac arrhythmias
Symptomatic valvular heart disease

keeping in mind the priority of cardiac versus noncardiac interventions, the risks involved in either approach, and the impact of cardiac treatment (eg, use of antiplatelet or anticoagulant agents) on the subsequent noncardiac surgery. Depending on the outcome of this discussion, patients may either proceed for cardiac intervention if the index surgical procedure can be delayed or proceed directly to the noncardiac surgery with optimal medical therapy if the delay is incompatible.

Step 3: Assess Cardiac Risk of the Noncardiac Surgery

In patients who do not have an unstable heart disease, the next step is to assess the cardiac risk involved in the proposed noncardiac surgery. There are a number of methods to derive this risk estimate, but the most practical approach is to use risk scores or algorithms. The most validated risk indices for this purpose are the Revised Cardiac Risk Index (RCRI)[115] and the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) surgical risk calculator (http://www.surgicalriskcalculator.com)[116] (Table 1.9). The RCRI considers six major risk factors, each of which is assigned a score of 1. Patients who have a score of 0 or 1 are expected to have a low risk of major adverse cardiac events (MACE), whereas those with a score of 2 or higher are likely to have an elevated risk. Although the RCRI is simple to use and has been validated in populations outside the original cohort, it does not provide surgery-specific cardiac risk estimates, and it also tends to underestimate risk in patients undergoing major vascular surgery.[117] The NSQIP surgical risk calculator, which is based on the data derived from more than 1 million surgeries, provides more comprehensive assessment of the surgery-specific risk of a number of clinical outcomes, including MACE and death, and is the preferred approach for this purpose.[116] However, it is more complex to use, requires a Web-based calculator, and has not been validated in populations outside the original cohort.

Based on the anticipated cardiac risk, the surgical interventions can be broadly divided into three groups based on the estimated 30-day rate of cardiac events (ie, cardiac death and MI): low risk (<1%), intermediate risk (1–5%), and high risk (>5%).

Step 4: If the patient Has a Low Cardiac Risk

If the patient is estimated to have a low perioperative risk of an adverse cardiac event, no further cardiac evaluation is required, and the patient may proceed with the planned surgery. However, appropriate guideline-recommended risk-reduction pharmacotherapies should be instituted depending on the clinical condition of the patient.[113,114] Initiation of a beta-blocker regimen may be considered before surgery in patients with known CAD or myocardial ischemia. Treatment should ideally be initiated at least 2 days (and up to 30 days) before surgery, starting with a low dose and gradually titrating the dose to achieve a resting heart rate between 60 and 70 bpm with a systolic blood pressure greater than100 mm Hg. In most patients with atherosclerotic vascular disease, particularly those undergoing vascular surgery, initiation of statin therapy should be strongly considered. In addition, in patients who have heart failure due to LV systolic dysfunction, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers should also be considered before surgery. However, care should be taken to avoid hypotension during the perioperative period. A decision also needs to be reached about discontinuation of antiplatelet and/or anticoagulant agents in those who are already receiving these therapies, and alternative therapies, if any, should be recommended as appropriate.

TABLE 1.9 Risk Factors in Commonly Used Models for Assessment of Cardiac Risk in Patients Undergoing Noncardiac Surgery

Risk Factor	*Revised Cardiac Risk Index*	*American College of Surgeons NSQIP Surgical Risk Calculator*
Ischemic heart disease	Yes	Yes (previous cardiac event)
Cerebrovascular disease	Yes (history of cerebrovascular accident or transient ischemic attack)	No
Type of surgery	Yes (intrathoracic, intraabdominal, or suprainguinal vascular surgery)	Yes (uses Current Procedural Terminology codes)
Renal dysfunction	Yes (creatinine ≥2 mg/dL)	Yes (acute renal failure, need for dialysis)
Diabetes mellitus	Yes (insulin-dependent diabetes mellitus)	Yes
Heart failure	Yes	Yes
Age	No	Yes
Sex	No	Yes
Hypertension	No	Yes
Body mass index	No	Yes
Dyspnea	No	Yes
Smoker	No	Yes
COPD	No	Yes
Functional status	No	Yes
Physical status		Yes (uses ASA Physical Status classification system)
Wound class	No	Yes
Ascites	No	Yes
Systemic sepsis	No	Yes
Ventilator dependency	No	Yes
Disseminated cancer	No	Yes
Steroid use	No	Yes
Emergency surgery	No	Yes

ASA, American Society of Anesthesiologists; *COPD,* chronic obstructive pulmonary disease; *NSQIP,* National Surgical Quality Improvement Program.

Step 5: If the Patient Has an Elevated Cardiac Risk

In patients who are estimated to have an elevated risk of MACE, an assessment of functional capacity is required. Functional capacity is usually expressed in terms of metabolic equivalents (METs) and classified as excellent (>10 METs), good (7–10 METs), moderate (4–6 METs), poor (<4 METs), or unknown.

If the patient has not had a recent exercise test, functional status can usually be estimated from activities of daily living (Fig. 1.6) or, more formally, by using an activity scale such as the Duke Activity Status Index[118] or the Specific Activity Scale.[119] Examples of activities associated with greater than 4 METs include climbing two flights of stairs, walking up a hill, running a short distance, walking on level ground at 4 mph, and performing heavy work around the house. If the patient is able to easily perform 4 METs or more physical activity, he or she can proceed to the planned noncardiac surgery without the need for any further cardiac evaluation.

Step 6: If the Patient Has Poor or Unknown Functional Capacity

In patients with elevated cardiac risk whose functional capacity is poor or unknown, one must determine whether further testing will affect patient decision making (eg, a decision to perform the original surgery or willingness to undergo a cardiac intervention might change depending on the results of the test) or perioperative care. If it will, stress

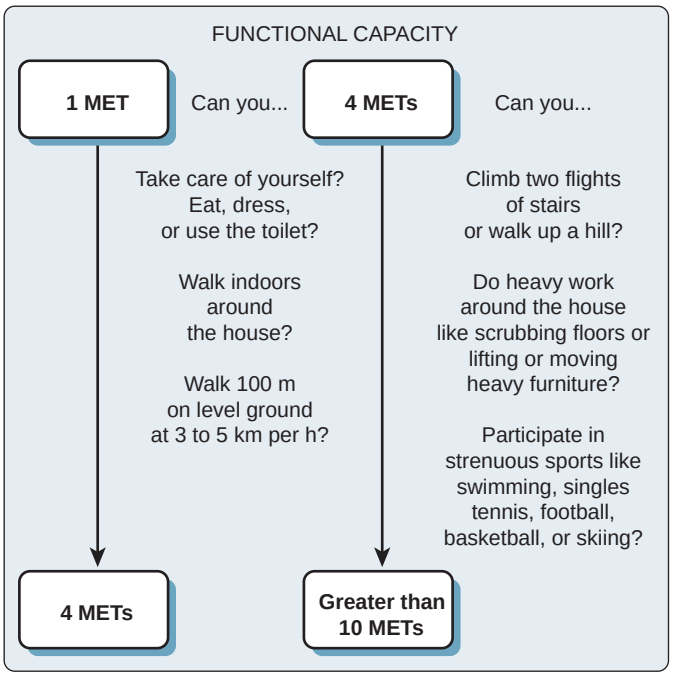

Fig. 1.6 Estimated energy requirements for various activities during daily life. *km per h*, kilometers per hour; *MET*, metabolic equivalent. *(Data from Hlatky MA, Boineau RE, Higginbotham MB, et al. A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index).* Am J Cardiol. *1989;64:651–654. and Fletcher GF, Balady GJ, Amsterdam EA, et al. Exercise standards for testing and training: a statement for healthcare professionals from the American Heart Association.* Circulation. *2001;104:1694–1740.)*

testing should be performed, and if the stress test result is normal, the patient can proceed to noncardiac surgery according to the guideline-directed medical therapy (GDMT). However, if the stress test result is abnormal, then depending on the extent of the abnormality, coronary angiography and revascularization should be considered. The patient can then proceed to surgery with GDMT or explore alternative, less invasive or noninvasive therapeutic options for the underlying noncardiac illness.

Although there are no randomized trials on the use of preoperative stress testing, a large number of single-site studies and their metaanalyses have demonstrated its clinical utility in the preoperative evaluation of patients undergoing noncardiac surgery.[120–124] These studies have shown that a normal stress test result has a very high negative predictive value for perioperative cardiac events, whereas the presence of moderate-to-large areas of myocardial ischemia is associated with increased risk of perioperative MI and/or death. In contrast, the presence of RWMAs (unless extensive) on rest imaging has little predictive value.

Most data on the impact of inducible myocardial ischemia on perioperative outcomes are based on pharmacologic stress testing.[120–124] Therefore, it remains the modality of choice in these patients, more so because many are not able to perform adequate exercise. However, in patients who are able to exercise adequately, it seems reasonable that exercise stress testing, when combined with echocardiography or myocardial perfusion scintigraphy, would perform similarly to pharmacologic stress testing.[125–127] Exercise-induced electrocardiographic changes alone are not as predictive and cannot be relied on.[125–128]

There are no randomized trials comparing different imaging modalities (eg, echocardiography vs myocardial perfusion imaging) for predictive accuracy as part of preoperative pharmacologic stress testing. However, a retrospective metaanalysis comparing thallium imaging with stress echocardiography in patients scheduled for elective noncardiac surgery showed that a moderate-to-large defect (present in 14% of the population) detected by either method predicted postoperative cardiac events, with stress echocardiography being slightly superior.[120] Given the lack of adequate evidence, it is recommended that the choice of imaging modality should be guided by the available local expertise in performing pharmacologic stress testing.

Step 7: If Testing Is Unlikely to Affect Decision Making or Care

If a patient with elevated cardiac risk has poor or unknown functional capacity but stress testing is unlikely to affect decision making or care, it is reasonable to proceed to surgery according to the GDMT or to consider alternative, less invasive or noninvasive therapeutic options for the underlying noncardiac illness.

Role of Handheld and Pocket Ultrasound

As outlined earlier, the current guidelines do not recommend routine cardiac imaging in most patients undergoing noncardiac surgery if the surgery is emergent or if the patient is physically active and does not have any overt manifestations of a cardiac illness. These recommendations are based on the assumptions that clinical evaluation is generally sufficient to identify most of the clinically relevant cardiac conditions, that the necessary resources required for cardiac imaging may not be readily available, and that in most instances recognition of a cardiac lesion during preoperative testing would not lead to a cardiac intervention. However, each of these assumptions has an important caveat.

Although a good physical examination remains an integral component of any form of medical assessment and cannot be substituted because of the wealth of information it provides, it has its limitations. It is subjective; it depends heavily on the clinical skills of the examining physician; and even with the most experienced clinicians, it has a diagnostic accuracy that is, at best, suboptimal.[129] There are several cardiac conditions that may be inherently silent (eg, asymptomatic LV systolic dysfunction) and cannot be recognized based on clinical evaluation alone. Further, accurate assessment of lesion severity on clinical examination, even for valvular lesions, remains challenging, especially when the patient has a combination of cardiac lesions. Handheld and pocket ultrasound devices offer an attractive option in these circumstances. Numerous studies have demonstrated that the addition of a screening, bedside echocardiographic examination to clinical assessment significantly increases diagnostic accuracy, reduces unwarranted diagnostic and treatment referrals, facilitates optimal use of health care resources, and is cost-effective[129–133] (see Chapter 46).

The current generation of pocket ultrasound devices offer two-dimensional and color Doppler imaging but lack spectral Doppler. Still, the image quality is usually excellent, which allows a diagnostic accuracy comparable to that achieved with full-scale echocardiography equipment.[131,134–136] At the same time, limited functionalities available on these devices serve to simply their use by physicians. Studies have shown that physicians can quickly be trained in the use of pocket ultrasound devices for rapid screening of patients to recognize major cardiac abnormalities.[137] When required, bedside imaging can also be combined with remote, Web-based interpretation to enhance the diagnostic accuracy of the screening echocardiographic examination and to ensure quality control.[137,138]

Although it is true that a cardiac lesion recognized at the time of preoperative evaluation in patients scheduled to undergo a noncardiac surgery does not necessarily require immediate cardiac intervention, studies have demonstrated that the presence of unrecognized LV systolic dysfunction or valvular heart disease is associated with worse outcomes.[115,137–141] For example, Flu and colleagues studied the value of preoperative echocardiography in 1005 consecutive patients undergoing elective vascular surgery at a single center.[139] LV dysfunction (LVEF <50%) was present in 50% of the patients, 80% of whom were asymptomatic.[58] The 30-day cardiovascular event rate was highest in patients with symptomatic HF (49%), followed by those with asymptomatic systolic LV dysfunction (23%), asymptomatic diastolic LV dysfunction (18%), and normal LV function (10%).

BOX 1.6 HANDHELD OR POCKET ULTRASOUND FOR CARDIAC EVALUATION

Enhances diagnostic accuracy of clinical examination
Can be combined with remote interpretation of acquired images to ensure optimum diagnostic accuracy
Allows recognition of major cardiac lesions
Provides information that may have incremental value in optimizing perioperative outcomes of patients undergoing a noncardiac surgery
Is simple to use and easy to incorporate into the preoperative evaluation
Has been shown to be cost-effective compared with physical examination alone

Bedside echocardiographic examination using a handheld or pocket ultrasound device can have great incremental value in these circumstances (Box 1.6). It permits easy and prompt recognition of significant cardiac lesions, and such information provides the operating team an opportunity to incorporate measures to optimize perioperative outcomes. For example, a less invasive surgical approach can be adopted, regional anesthesia can be used preferentially in certain circumstances, greater caution can be exercised with regard to perioperative fluid and hemodynamic monitoring and management, appropriate cardiac pharmacotherapies can be instituted if circumstances allow; and, importantly, the patient and family can be alerted about the possibility of a cardiac event during the perioperative period. In a recent study of patients undergoing cataract surgery in a community setting, pocket echocardiography allowed recognition of a major cardiac lesion in 14.2% of those patients considered to be free of any major cardiac illness based on clinical examination alone. Of these, roughly one-fourth (3.3% of the entire study population) had cardiac lesions deemed prohibitive for cataract surgery in an unmonitored setting. As a result, these surgeries were rescheduled to be performed later in a hospital under more intensive monitoring.[137] Although this study does not imply that every patient undergoing noncardiac surgery needs to have an echocardiographic examination, it does show that the availability of handheld and pocket ultrasound devices permits easy incorporation of an echocardiographic examination in the preoperative evaluation and may help optimize cardiac outcomes.

Conclusions

Preoperative cardiac risk assessment and stratification of patients undergoing cardiac or noncardiac surgery are pivotal in optimizing perioperative outcomes. In cardiac surgery patients, the main goal of cardiac risk assessment, from the anesthesiologist's perspective, is to provide risk-adjusted mortality rates for preoperative counseling of the patient and family and to identify the group at high risk for a perioperative cardiac event. Based on individual risk factors, perioperative care can be modified to improve the patient's outcome. Various complex or simplified risk-adjusted morbidity and mortality models can serve as tools for facilitating perioperative risk assessment. However, even a well-calibrated model with good discrimination has to be used with caution when applied to individual counseling. First, it is difficult for any model to predict morbidity or mortality, which occur with a low incidence. Second, it has to be clear that the scoring system provides only the probability of death or a major complication and that the individual patient and family members may have difficulty understanding how an adverse outcome could have occurred if the predicted incidence was low in their understanding preoperatively.

In contrast, the underlying cardiac status of noncardiac surgical patients is often unknown or inadequately known. The main goal in this setting is to define an optimal cardiac evaluation strategy considering various patient-related and surgery-related factors and, based on the findings of such evaluation, to provide recommendations for optimal perioperative management to achieve the best possible outcomes. In most such patients, noninvasive cardiac evaluation with optimization of cardiac medications and care to minimize hemodynamic perturbations during the perioperative period are all that is required to ensure cardiac safety. Invasive cardiac evaluation and coronary revascularization usually are not required unless the patient presents with an unstable cardiac condition or has significant myocardial ischemia and the noncardiac surgery is not urgent.

2 Cardiovascular Imaging

MANISH BANSAL, MD, DNB CARDIOLOGY, FACC, FASE | VALENTIN FUSTER, MD, PhD, MACC | JAGAT NARULA, MD, PhD, MACC | PARTHO P. SENGUPTA, MD, DM, FACC, FASE

KEY POINTS

1. Echocardiography is the most widely used modality for cardiac imaging in almost any form of cardiac disease.
2. Echocardiography is noninvasive, safe, readily available, and portable, and it has the ability to provide vast amounts of information about cardiac structure and function. Additionally, echocardiography is the only modality available for imaging during the intraoperative period.
3. A combination of transthoracic and transesophageal imaging permits comprehensive evaluation of most cardiac pathologies. The advent of three-dimensional transesophageal echocardiography has further enhanced the utility of this modality, especially in the evaluation of mitral valve disease.
4. Stress echocardiography is helpful in the assessment of inducible myocardial ischemia, myocardial viability, and certain valve disorders.
5. Myocardial perfusion imaging can be performed using SPECT or PET and is useful in the evaluation of myocardial ischemia and viability.
6. Cardiac computed tomography and cardiac magnetic resonance are increasingly used when there are conflicting results or when further information is required in the preoperative phase of care.
7. Cardiac magnetic resonance is the gold standard for quantitative assessment of ventricular volumes, ejection fraction, and mass. It is also able to evaluate ventricular and valvular function, atherosclerosis, and plaque composition.
8. Computed tomographic aortography is the best modality for the evaluation of aortic aneurysms and dissections. Additionally, computed tomographic coronary angiography offers an alternative to invasive coronary angiography for excluding significant coronary artery disease in patients undergoing noncoronary surgery.

Imaging is fundamental to perioperative evaluation and management of patients undergoing cardiac surgery. Even for those presenting with a noncardiac illness, cardiac imaging is often required to supplement the preoperative evaluation.

For many years, cardiac catheterization and nuclear imaging were the only modalities available for clinical use. The introduction of echocardiography in the early 1970s heralded a revolution in the field of cardiovascular imaging, and echocardiography soon surpassed all other modalities to become the cornerstone of cardiac imaging. Because of its noninvasive nature, safety, easy availability, portability, repeatability, and capacity to provide vast amounts of clinically relevant information, echocardiography has remained the most useful modality for cardiac imaging.

The last several decades have witnessed yet another explosion in imaging techniques with the evolution of cardiac computed tomography (CCT), cardiac magnetic resonance (CMR), and positron emission tomography (PET) as routine clinical evaluation tools. In the field of perioperative evaluation, these alternative imaging modalities have complemented more than supplemented traditional imaging. This chapter provides a brief overview of the roles of these different imaging modalities in the evaluation and management of various cardiac conditions.

Echocardiography

Transthoracic echocardiography (TTE) is required in all patients scheduled for cardiac surgery and is often the basis for surgical decision making itself. In contrast to the nonsurgical setting, in which TTE is usually sufficient to provide most of the information needed to meet the clinical objectives, transesophageal echocardiography (TEE) is also frequently required for patients for whom surgery is being considered. Preoperatively, TEE helps provide information that is critical for surgical planning (eg, valve repair vs valve replacement, coronary artery bypass surgery alone or with concomitant mitral valve repair). During the intraoperative period, TEE is the only modality available for cardiac imaging. In the immediate postoperative period, TEE is often called for because the presence of tissue edema, surgical dressings, and drains and the reduced ability to change the patient's position render transthoracic imaging extremely challenging.

Assessment of Left Ventricular Systolic Function

Left ventricular (LV) systolic function is one of the most important predictors of outcome in all cardiac conditions, and almost all therapeutic decisions in these patients are influenced by the status of LV systolic function. For cardiac anesthesiologists, preoperative knowledge of LV systolic dysfunction is crucial for anticipating and preparing for perioperative complications, whereas subsequent assessments are required for diagnosing and managing the cause of hemodynamic instability. Patients with LV systolic dysfunction who undergo coronary artery bypass graft surgery (CABG) are known to require more inotropic support after cardiopulmonary bypass (CPB).[1,2] Additionally, systolic dysfunction is a reliable prognosticator for surgical mortality.[3–5]

LV ejection fraction (LVEF) is the simplest and the most widely used measure of global LV systolic function. A number of echocardiographic methods are currently available for estimation of LVEF, but the biplane modified Simpson method is the most accurate and is also the method recommended by the American Society of Echocardiography (ASE).[6] In practice, however, LVEF is often estimated semiquantitatively by visual inspection alone, and this technique has been shown to have a reasonably high degree of accuracy when performed by an experienced echocardiographer.[7,8]

The Simpson method considers the LV cavity as a stack of disks of equal height; LV volume is calculated by summing the volumes of all the disks (Fig. 2.1). This is accomplished by manually tracing the LV

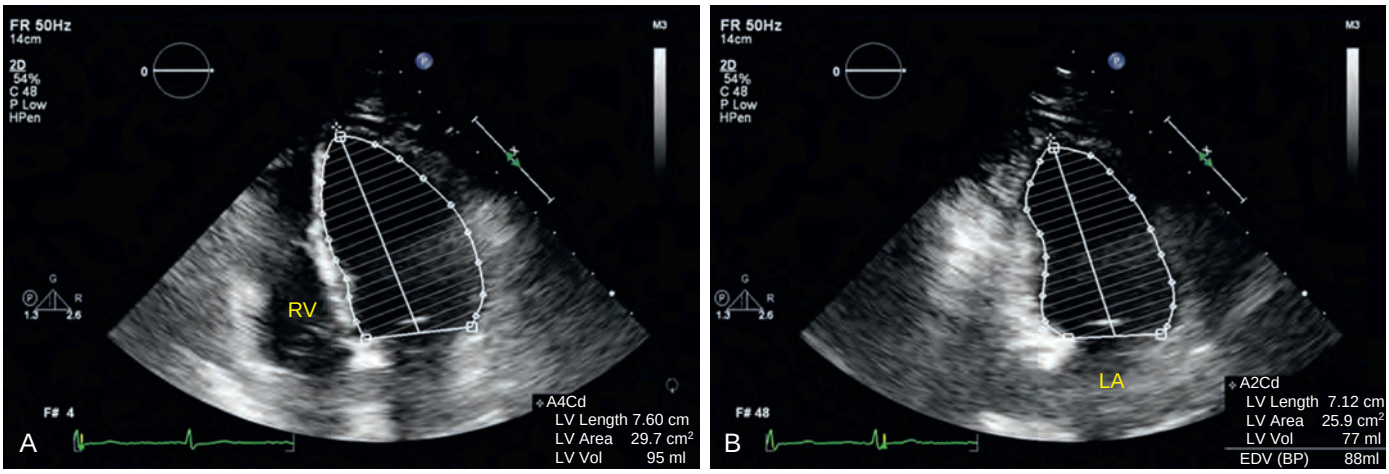

Fig. 2.1 Measurement of left ventricular volumes and ejection fraction using the Simpson summation-of-disks method. A, Apical four-chamber view in end-diastole. B, Same view in end-systole. *LA*, Left atrium; *RV*, right ventricle.

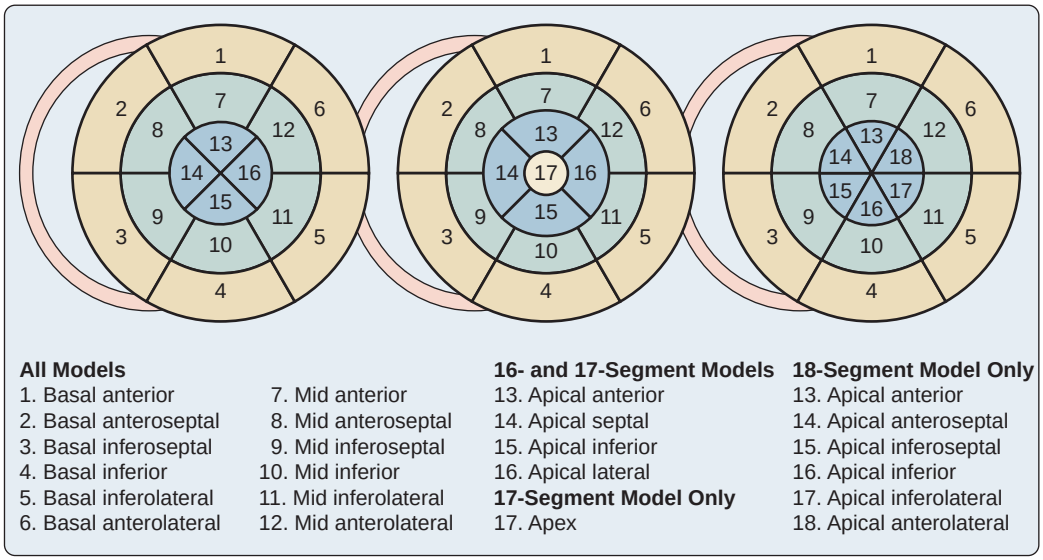

Fig. 2.2 Schematic diagram of the various left ventricular segmentation models: the 16-segment model *(left)*, the 17-segment model *(center)*, and the 18-segment model *(right)*. *(With permission from Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging.* J Am Soc Echocardiogr. *2015;28:1–39 e14.)*

endocardial border in the apical four- and two-chamber views, both at end-diastole and at end-systole. These data are then processed by the internal software of the equipment to provide LV volumes and LVEF. The main advantage of this method is that it remains applicable even when the ventricle is distorted, but its accuracy depends heavily on adequate visualization of the blood-endocardial interface. Currently, harmonic imaging is routinely used to improve endocardial border recognition, and in difficult cases LV cavity contrast can also be used.

Three-dimensional echocardiography (3DE) is the most accurate method for estimation of LVEF by echocardiography.[6] Unlike the two-dimensional (2D) methods, it does not make any assumptions about LV cavity shape and therefore is not influenced by the LV geometry. However, it requires considerable expertise, it has lower temporal resolution, and, as with 2D methods, its accuracy is dependent on image quality. For LVEF estimation by 3DE, a full volume dataset that includes the entire left ventricle is acquired. The image is then analyzed, either online or offline, using quantitation software. The endocardial border is semiautomatically identified in the end-diastolic and the end-systolic frames and adjusted manually to correct for any errors introduced by automatic border recognition. The software then calculates LV volumes and LVEF.

Regional Left Ventricular Systolic Function

In cardiac patients, assessment of regional LV systolic function has considerable clinical relevance. Coronary artery disease (CAD) is the prototype cardiac illness that affects the left ventricle regionally, and the presence of regional LV systolic dysfunction is virtually diagnostic of underlying CAD. The assessment of regional LV systolic function also provides an estimate of the overall extent of myocardial damage, permits recognition of the affected coronary arteries, and facilitates assessment of myocardial viability and inducible myocardial ischemia.

During echocardiography, LV regional function assessment is performed by visual inspection of the extent of *wall thickening* in each myocardial segment. The ventricle is traditionally divided into 16 segments, as recommended by the ASE (Fig. 2.2). A 17-segment model, with the apical cap being the 17th segment, has been proposed for use

when the objective of the examination is to compare the findings with those of nuclear imaging or radiology (CCT or CMR).[6]

Depending on the extent of wall thickening, the wall motion can be classified as normal, hypokinetic, akinetic, or dyskinetic, or it can be formally scored as 1 (normal), 2 (hypokinetic), 3 (akinetic), or 4 (dyskinetic/aneurysmal). Averaging the scores of all the evaluated segments provides a wall motion score index, which can be used as a surrogate for global LVEF. In the assessment of regional wall motion, distinction must be made between actual wall thickening and endocardial motion, which is affected by tethering effects from adjacent myocardial segments and by the translational movement of the heart. The inferior and posterior LV segments are often classified erroneously as hypokinetic by less experienced clinicians who do not appreciate that wall thickening is the gold standard for assessing regional LV function.

Role of Speckle-Tracking Echocardiography

Although LVEF is the most validated measure of LV systolic function, it is operator dependent, load dependent, and relatively insensitive to subtle changes in myocardial contractile function. Additionally, it represents an oversimplification of LV myocardial deformation, which is a complex, multidimensional process. Speckle-tracking echocardiography (STE) offers a potential solution to some of these limitations and serves to complement the information conveyed by assessments of LVEF.[9,10]

STE is a gray-scale–based technique that measures myocardial deformation using frame-by-frame tracking of the acoustic "speckles" present within the gray-scale ultrasound image.[10] The magnitude of the myocardial deformation is expressed as strain, which is the percentage change in length of the myocardial segment. The rate at which this deformation occurs is expressed as the strain rate, which has the unit of sec^{-1}. For clinical purposes, LV myocardial strain is measured in three principal directions: longitudinal, radial, and circumferential. Additionally, LV rotation and twist around the long axis can be measured. The longitudinal strain is derived from the apical four-chamber, two-chamber, and long-axis images; short-axis images are used for estimating radial strain, circumferential strain, rotation, and twist (Fig. 2.3).

Currently, it is feasible to measure global longitudinal strain, which is the average of peak longitudinal strain of all LV myocardial segments, with a high degree of reproducibility that is sufficient for regular clinical use. Accordingly, the ASE recommends measuring global longitudinal strain, along with LVEF, as an estimate of global LV systolic function.[6] The main clinical application of global longitudinal strain is in early recognition of subclinical LV systolic dysfunction in various clinical situations, such as patients receiving potentially cardiotoxic cancer chemotherapies and patients with valvular heart disease and cardiomyopathy. Other components of strain (ie, radial, circumferential) and segmental strain are currently not ready for regular clinical use.

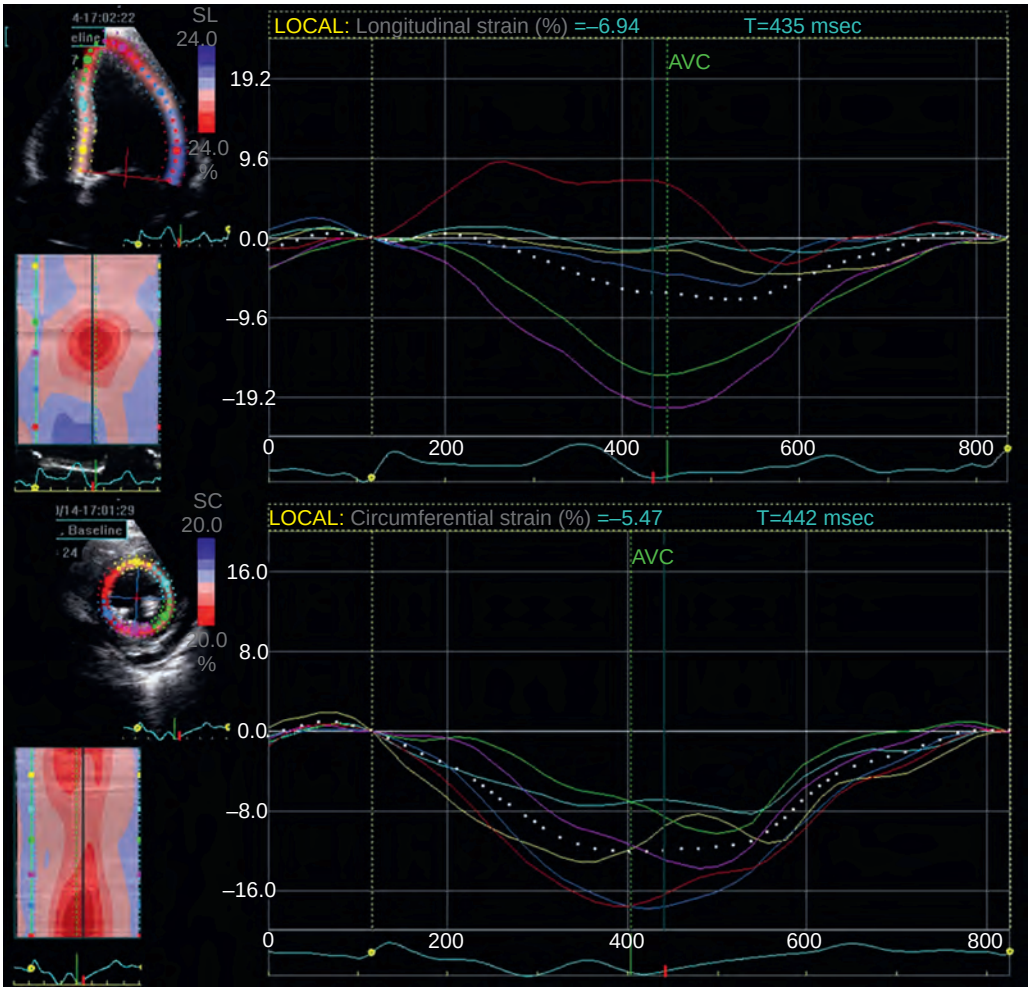

Fig. 2.3 Speckle-tracking echocardiography–based measurement of left ventricular longitudinal strain *(upper panel)* and circumferential strain *(lower panel)*. Colored traces depict segmental strain for corresponding myocardial segments. The dotted white line depicts the average of the six segments visualized in the particular view. *AVC*, Aortic valve closure.

The initial experience with STE has shown great promise; however, because it is a gray-scale–based technique, it is highly dependent on image quality. Additionally, a major limitation of STE at present is intervendor variability, which precludes comparison among measurements obtained on different STE platforms.[11,12] A joint ASE and European Association of Cardiovascular Imaging (EACVI) task force, in collaboration with industry partners, is working toward standardization of all elements involved in STE technology to minimize, and possibly eliminate, this vendor dependence.[12]

Assessment of Left Ventricular Diastolic Function

Abnormalities of LV diastolic function are common in patients undergoing cardiac surgery and have diagnostic and prognostic relevance.[13] Diastolic dysfunction during and after CABG is associated with greater time on CPB and with greater inotropic support up to 12 hours postoperatively.[14] This may be due to deterioration of diastolic dysfunction after CABG, which may persist for several hours.[15–17] Diastolic dysfunction increases the risk of perioperative morbidity and mortality.[18] Assessment of LV diastolic dysfunction permits a more accurate estimation of LV filling pressure (LVFP), information that is crucial to optimal management of critically ill patients. Goal-directed therapy using intravenous fluids, diuretics, vasopressors, and vasodilators requires knowledge of the LVFP.

Echocardiography is currently the best modality for assessing LV diastolic function in clinical practice. Several echocardiographic measures of LV diastolic function are available.[19] The examination usually begins with interrogation of the mitral inflow pattern and measurement of mitral annular velocities. The specific mitral inflow measurements include the mitral inflow early diastolic (E) and late diastolic (A) velocities, the ratio of the two (E/A), and the deceleration time of the E wave (dtE). Mitral annular early diastolic velocity (e′) is measured using tissue Doppler imaging. The ratio of mitral E to e′. (E/e′) provides an accurate and relatively load-independent measure of LVFP. Left atrial (LA) volume and tricuspid regurgitation (TR) jet velocity (a surrogate for pulmonary artery systolic pressure) are other useful measurements. Integrating all this information provides a quick assessment of LV diastolic function in most patients. When required, additional information can be obtained by evaluating pulmonary vein flow patterns, mitral inflow propagation velocity, isovolumic relaxation time, and so on. The ASE has recently published guidelines outlining a stepwise approach to assessment of LV diastolic function and estimation of LVFP or LA pressure in patients with and without LV systolic dysfunction (Fig. 2.4).[19a]

Right Heart Evaluation

Dysfunction of the right side of the heart, in the absence of congenital heart disease, is most often secondary to left heart pathologies, especially MV disease and severe LV systolic dysfunction. Additionally, obstructive airway disease and pulmonary thromboembolism are common in cardiac surgical patients. Primary right heart pathology is encountered less frequently and includes right ventricular (RV) myocardial infarction and organic tricuspid valve disease.

Unlike the left ventricle, the right ventricle has complex anatomy. The RV inflow portion, main body, and outflow tract (RVOT) do not lie in the same anatomic plane, rendering it impossible to image the entire right ventricle from one echocardiographic window. Accordingly, different acoustic windows must be used, including the RV inflow view, the RV outflow view, the RV-focused apical four-chamber view, and the subcostal view. Abnormalities of RV size and shape and global and regional contractility are qualitatively assessed, and various RV and right atrial (RA) dimensions are obtained from these windows[20] (Table 2.1). Additionally, tricuspid valve function, the presence of any intracardiac masses, and so on can be evaluated.

Because of the complex shape of the right ventricle, the RV ejection fraction generally cannot be measured by echocardiography. As a result, RV systolic function is indirectly assessed using alternative parameters, such as M-mode–derived tricuspid annular plane systolic excursion, tricuspid annular systolic velocity on tissue Doppler imaging, RV cavity fractional area change on 2D echocardiography, and myocardial performance index obtained from pulsed-wave Doppler or tissue Doppler imaging[20] (see Table 2.1). Additionally, RV free wall longitudinal strain can be measured with the use of STE.[6] Although it has now become feasible to measure RV ejection fraction by 3DE, the method is cumbersome and not yet ready for regular clinical use.[6]

In contrast, the assessment of RV diastolic function is simpler than that of LV diastolic function. The easy accessibility of the inferior vena cava (IVC) for imaging permits direct estimation of RA pressure, which in the absence of any tricuspid inflow obstruction is the same as RV filling pressure (RVFP).[20] If the IVC is normal in size (≤21 mm) and collapses by more than 50% on deep inspiration, the RA pressure is considered to be normal (ie, ~3 mm Hg; range, 0–5 mm Hg).

TABLE 2.1 Echocardiographic Measures of Right Ventricular Size and Systolic Function

Measurement	*Transthoracic Echocardiographic View*	*Normal Value*
RV Size		
RV basal diameter	RV focused apical four-chamber view	25–41 mm
RV mid-diameter	RV focused apical four-chamber view	19–35 mm
RV longitudinal diameter	RV focused apical four-chamber view	59–83 mm
RV outflow tract proximal	Parasternal long-axis view	21–35 mm
RV outflow tract distal	Parasternal short-axis view	17–27 mm
RV free wall thickness	Subcostal view	1–5 mm
RV Systolic Function		
Fractional area change	RV focused apical four-chamber view	≥35%
Tricuspid annular plane systolic excursion	Apical four-chamber view (providing best alignment of ultrasound beam with annulus motion)	>16 mm
Tricuspid annular peak systolic velocity	Apical four-chamber view (providing best alignment of ultrasound beam with annulus motion)	>10 cm/s
Pulsed Doppler myocardial performance index	A combination of parasternal short-axis view and apical four-chamber view	≤0.43
Tissue Doppler myocardial performance index	Apical four-chamber view (providing best alignment of ultrasound beam with annulus motion)	≤0.54
RV ejection fraction by 3DE	Full volume dataset from apical window	≥45%
RV free wall strain	RV focused apical four-chamber view	–20% or more

However, a dilated IVC (>21 mm) that collapses by less than 50% on inspiration indicates significantly elevated RA pressure (~15 mm Hg; range, 10–20 mm Hg). When IVC size and collapsibility are discrepant with one another, the RA pressure is assumed to be in the intermediate range (~8 mm Hg; range, 5–10 mm Hg). In such cases, additional parameters can be obtained to more accurately define the RA pressure, such as tricuspid inflow E/A and E/e′ ratios, E-wave deceleration time, and hepatic vein flow pattern. Because both IVC size and collapsibility are affected by positive-pressure ventilation, this approach cannot be used for estimating RA pressure in patients who are mechanically ventilated, which is quite common in the perioperative setting. Interrogation of the hepatic vein flow pattern can provide valuable information about RA pressure in this setting.

RV systolic pressure and pulmonary vascular resistance can also be estimated by echocardiography (see later discussion).

Assessment of Valve Lesions

Valvular heart disease is the second most common primary indication, after CAD, for cardiac surgery. Valve lesions also frequently coexist in patients undergoing surgery for other cardiac and noncardiac indications.

Echocardiography is currently the best modality available for evaluation of valvular heart disease. A combination of TTE and TEE permits comprehensive assessment of valve anatomy and function and provides all the relevant information required to determine the need for and type of valve intervention. Additionally, intraoperative TEE is useful in assessing the adequacy of valve surgery and in recognizing any surgery-related complications (eg, LV outflow tract obstruction, paravalvular regurgitation).

Mitral Valve Lesions

Rheumatic heart disease is, by far, the most common cause of mitral stenosis (MS), even in developed nations. Mitral annular calcification, which is common in elderly persons and in those undergoing hemodialysis, can also produce mitral inflow obstruction, although mitral regurgitation (MR) is more frequent.

In patients with rheumatic MS, echocardiography typically reveals mitral leaflet thickening with doming of the anterior mitral leaflet, restriction of posterior mitral leaflet motion, and variable amounts

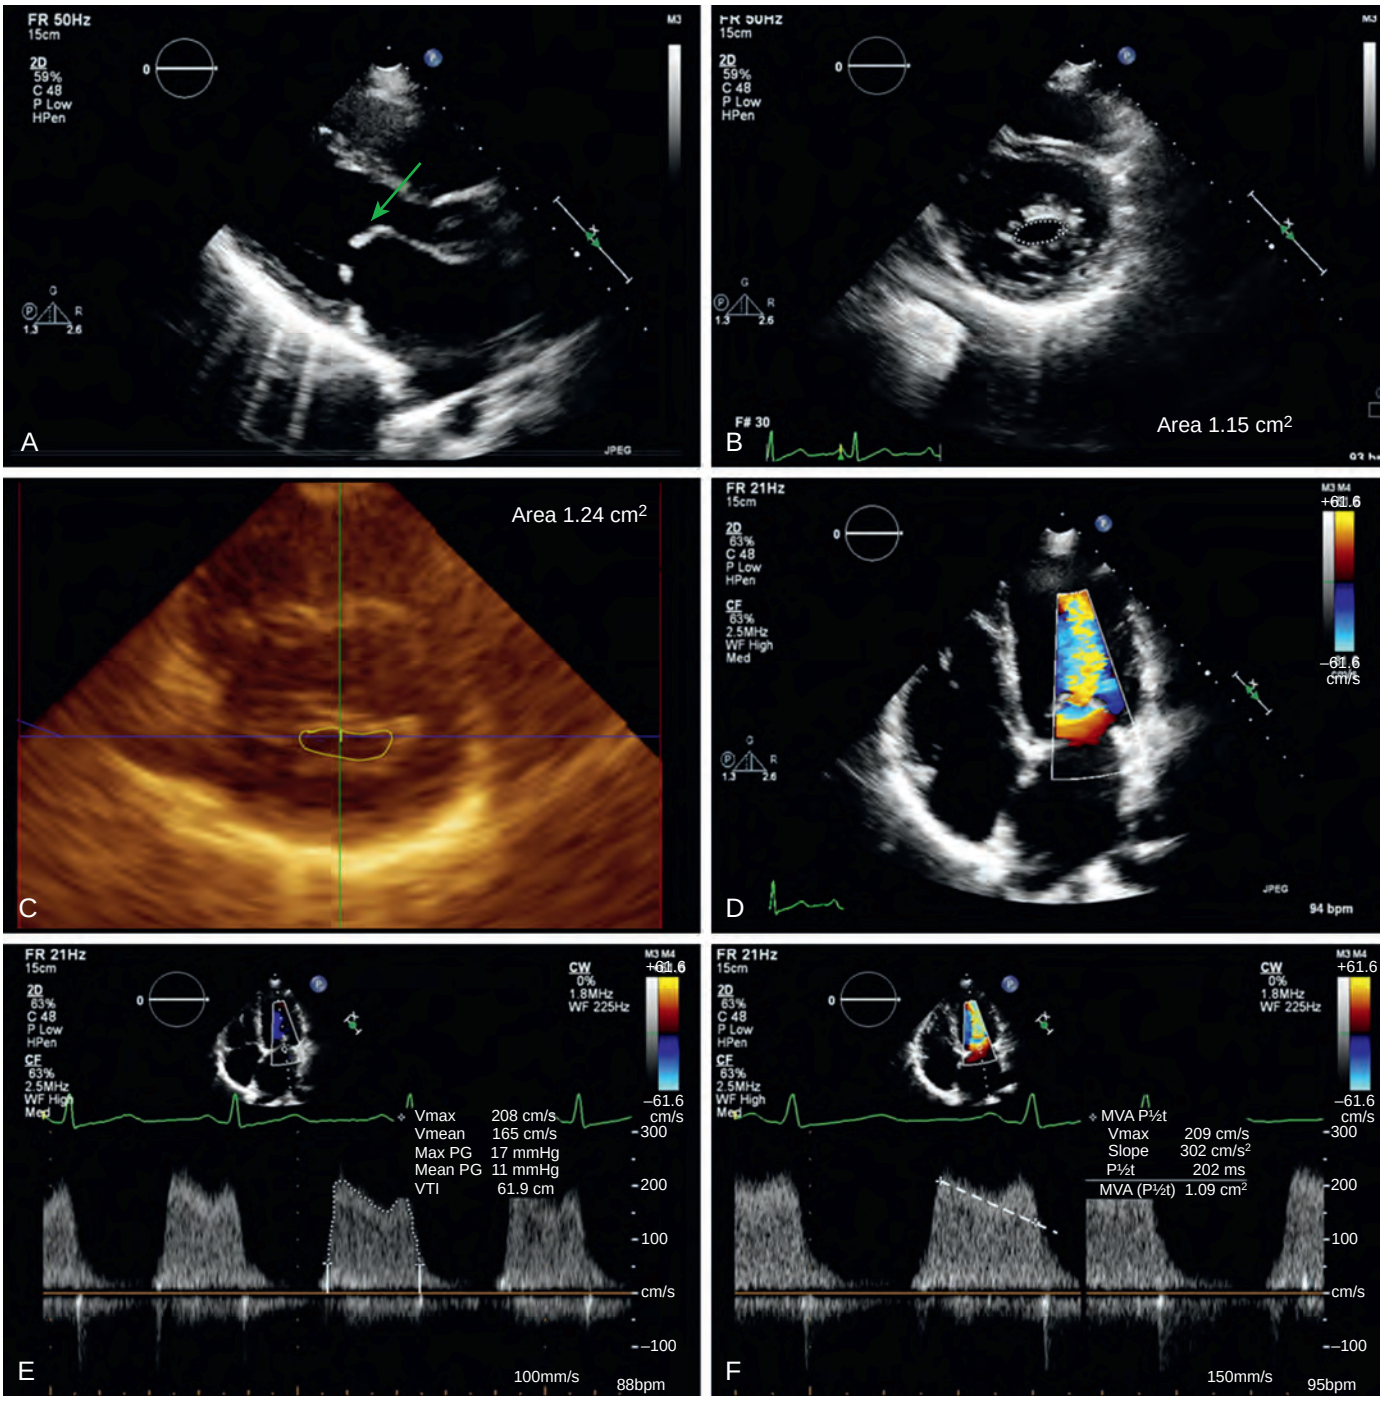

Fig. 2.5 Typical echocardiographic findings in a patient with rheumatic mitral stenosis. A, Parasternal long-axis view demonstrates restricted mitral leaflet opening with doming of anterior mitral leaflet *(arrow)*. Estimation of mitral valve area by planimetry from the parasternal short-axis view using two-dimensional (B) and three-dimensional (C) echocardiography is shown. D, Apical four-chamber view with color Doppler shows turbulent forward blood flow jet through the narrowed mitral orifice. Continuous wave Doppler is shown for estimation of transmitral gradients (E) and mitral valve area (F) by the pressure half-time method.

of leaflet calcification, fusion, and calcification of commissures. Thickening, shortening, and calcification of the subvalvular apparatus are also typically present (Fig. 2.5). These abnormalities can be formally graded with one of the various scoring systems available.[21–25] The severity of MS can be determined by measuring the transmitral gradient or by estimating the MV area, using either planimetry or the pressure half-time method[26] (Table 2.2; see Fig. 2.5). Of these, MV planimetry is the most accurate method (unless the predominant obstruction is at the level of chordae) because it is not influenced by heart rate and hemodynamics. However, its accuracy depends on gray-scale image quality and on ensuring that the measurement is performed exactly at the tips of the MV leaflets. 3DE is the best modality for this purpose because it allows the operator to optimally position the imaging plane for planimetry.[27,28] In addition to assessment of MV

TABLE 2.2 Echocardiographic Criteria for Severity of Mitral Valve Lesions

Parameter	*Mild*	*Moderate*	*Severe*
Mitral Stenosis			
Specific Findings			
Mitral valve area (cm^2)	>1.5	1.0–1.5	<1.0
Supportive Findings			
Mitral valve mean gradient (mm Hg)[a]	<5	5–10	>10
Pulmonary artery systolic pressure (mm Hg)	<30	30–50	>50
Mitral Regurgitation			
Structural Parameters			
Left atrial size	Normal[b]	Normal or dilated	Usually dilated[c]
Left ventricular size	Normal[b]	Normal or dilated	Usually dilated[c]
Mitral valve apparatus	Normal or abnormal	Normal or abnormal	Abnormal
Doppler Parameters			
Color flow jet area (cm^2)[d]	Small, central jet (usually <4 cm^2, or <20% of left atrial area)	Variable	Large central jet (usually >10 cm^2, or >40% of left atrial area) or variable-size wall-hugging jet in left atrium
Mitral inflow (pulsed wave)	A-wave dominance[e]	Variable	E wave dominance (E usually >1.2 m/s)[e]
Jet density (continuous wave)	Incomplete or faint	Dense	Dense
Jet contour (continuous wave)	Parabolic	Usually parabolic	Early peaking triangular
Pulmonary vein flow	Systolic dominance[f]	Systolic blunting[f]	Systolic flow reversal[g]
Quantitative Parameters[h]			
Vena contracta width (cm)	<0.3	0.3–0.69	≥0.7
Regurgitant volume (mL/beat)[i]	<30	30–44 (mild to moderate) 45–59 (moderate to severe)	≥60
Regurgitant fraction (%)	<30	30–39 (mild to moderate) 40–49 (moderate to severe)	≥50
Effective regurgitant orifice area (cm^2)[j]	<0.20	0.20–0.29 (mild to moderate) 0.30–0.39 (moderate to severe)	≥0.40

[a]At heart rates between 60 and 80 beats/minute.
[b]Unless there are other causes of left atrial or left ventricular dilatation.
[c]Acute mitral regurgitation is an exception.
[d]At a Nyquist limit of 50 to 60 cm/s.
[e]Usually in patients older than 50 years of age or in conditions of impaired relaxation, in the absence of mitral stenosis or other causes of elevated left atrial pressure.
[f]Unless other reasons for systolic blunting (eg, atrial fibrillation, elevated left atrial pressure) are present.
[g]Pulmonary venous systolic flow reversal is specific but not sensitive for severe mitral regurgitation.
[h]Quantitative parameters can help subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe subgroups, as shown.
[i]For functional mitral regurgitation due to left ventricular systolic dysfunction, ≥30 mL is used as the cutoff point for defining severity.
[j]For functional mitral regurgitation due to left ventricular systolic dysfunction, ≥0.20 cm^2 is used as the cutoff point for defining severity.
From Baumgartner H, Hung J, Bermejo J, et al. Echocardiographic assessment of valve stenosis: EAE/ASE recommendations for clinical practice. *J Am Soc Echocardiogr.* 2009;22:1–23; quiz 101–102; Zoghbi WA, Enriquez-Sarano M, Foster E, et al. Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. *J Am Soc Echocardiogr.* 2003;16:777–802.

morphology and MS severity, echocardiography aids in the evaluation of concomitant valve lesions, if any, and in detection of LA or LA appendage thromboses.

In comparison to MS, MR is a more complex entity with a multitude of etiologies and pathogenic mechanisms. MR can be organic, caused by direct pathologic involvement of one or more components of the MV apparatus; examples include rheumatic heart disease, degenerative diseases, systemic inflammatory diseases, infective endocarditis, ischemic heart disease (chordal or papillary muscle rupture), and congenital malformations (Fig. 2.6). Alternatively, MR can be of functional origin: The MV apparatus itself is normal, but leaflet coaptation during systole is impaired as a result of regional or global dilatation and dysfunction of the LV. Functional MR is common in patients with LV systolic dysfunction undergoing CABG and is an independent predictor of morbidity and mortality in these patients.[29–31]

TEE provides excellent visualization of the MV because of its proximity to the transducer. The exact pathology, the extent of the pathology, mitral annulus size, and papillary muscle and chordal geometry can all be delineated in great detail. Additionally, in patients with functional MR, tenting height, tenting area, and coaptation length can be assessed. When available, 3D TEE provides incremental information regarding MV pathology. One major advantage of 3D TEE is that it provides the "surgeon's view" of the MV, facilitating easy appreciation of the MV pathology preoperatively (Fig. 2.7).

For assessment of MR severity, a number of measures combining 2D and Doppler data are available, as outlined in Table 2.2.[32] Lower thresholds are used for defining the severity of functional MR compared with organic MR.[33]

Aortic Valve Lesions

Senile degeneration, bicuspid aortic valve (AV) disease, and rheumatic heart disease are the most common causes of aortic stenosis (AS). The same conditions can also result in aortic regurgitation (AR). AR can also result from aortic root pathologies, infective endocarditis, systemic inflammatory diseases, and other causes.

The echocardiographic assessment of AV lesions is based on principles similar to those for MV lesions (Table 2.3).[26,32] Compared with the MV, however, adequate visualization of the AV is often difficult, even on TEE. Inability to align the Doppler beam with the direction of blood flow in the conventional TEE views offers further challenges to the assessment of AS severity. Deep transgastric views are required to measure the AS gradient with TEE, but they may not always result in a satisfactory evaluation. An additional challenge in the assessment of AS severity is the frequent occurrence of inappropriately low transaortic gradients despite a significantly reduced AV area.[26,33–35] This discrepancy is common in the setting of LV systolic dysfunction. Dobutamine echocardiography may help in further evaluation of these patients, as described later. However, a paradoxically low gradient may also be seen in the presence of a normal LVEF. The exact pathogenesis underlying this entity, its prognostic significance, and the optimum management strategies remain debatable.[33–35]

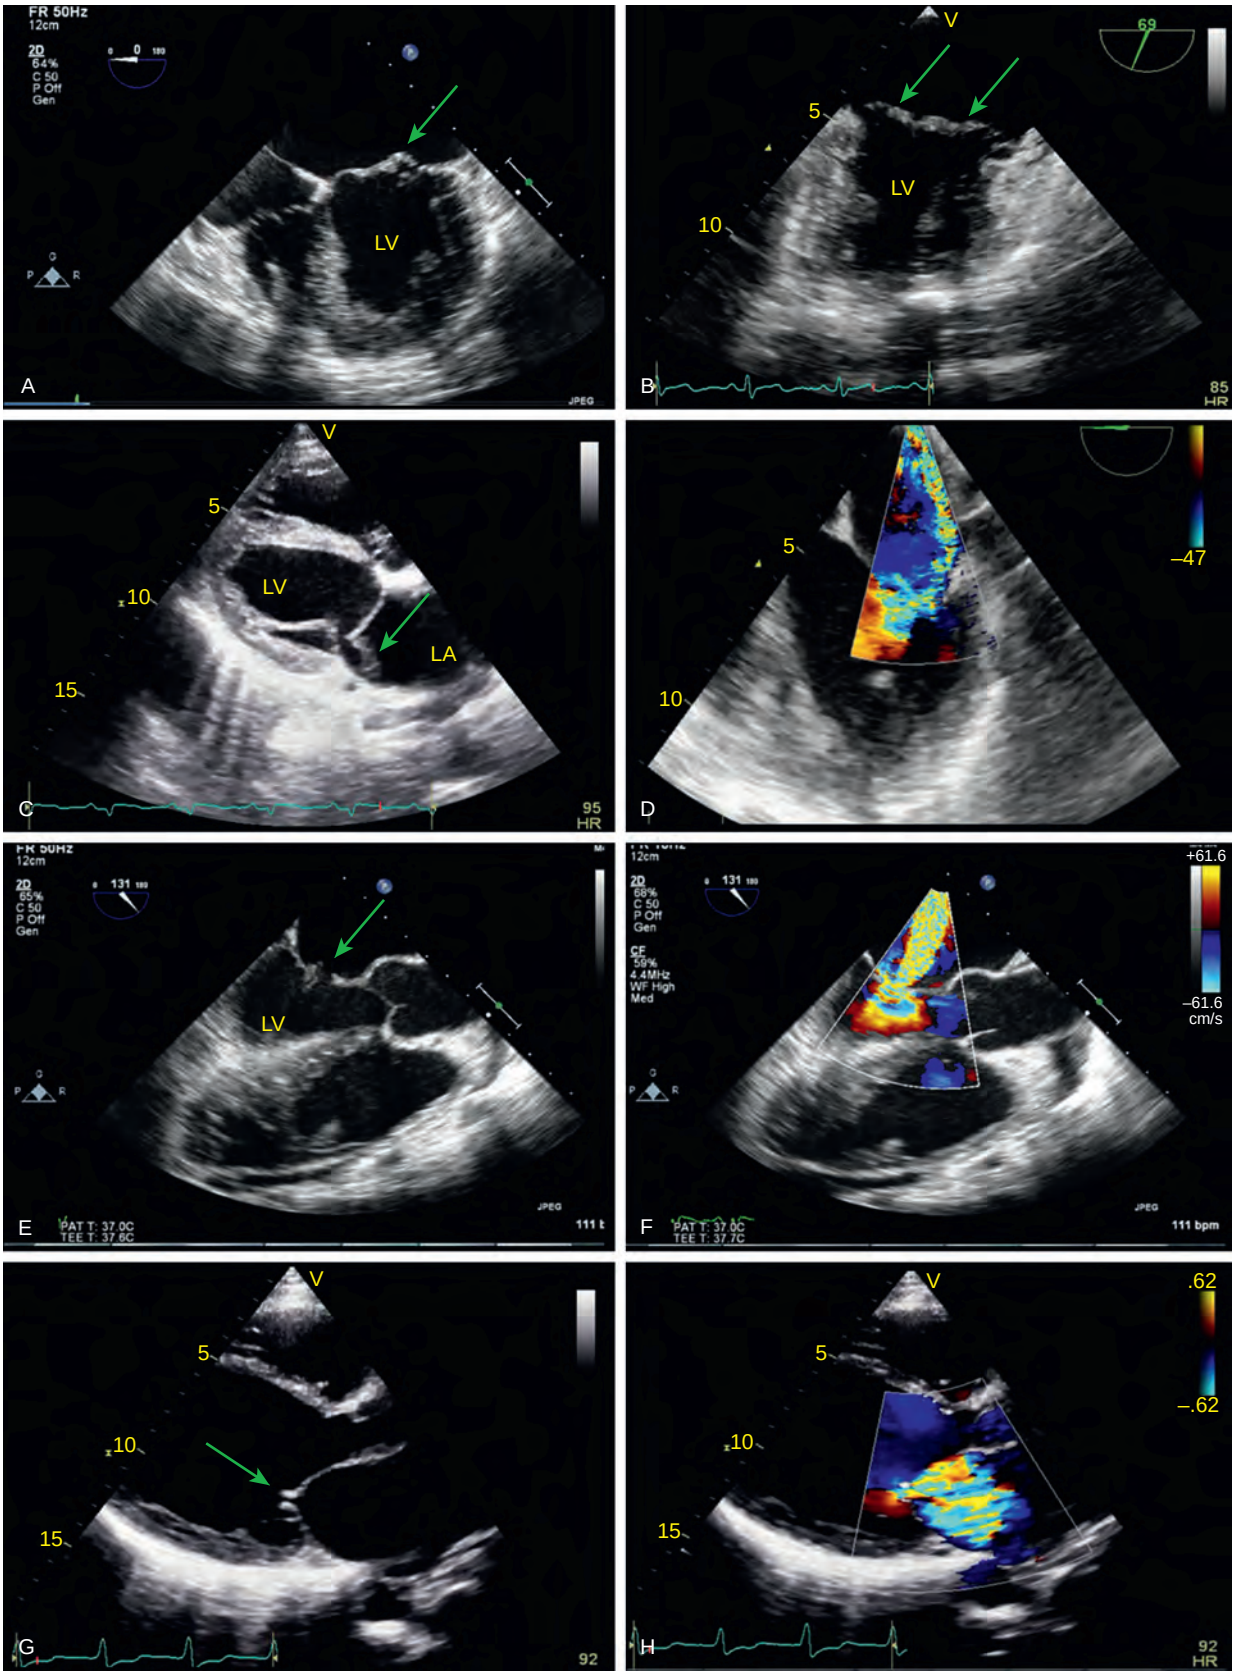

Fig. 2.6 Illustrative examples of mitral regurgitation from various causes. A and B, Bileaflet mitral valve prolapse (*arrows*). C and D, Papillary muscle rupture secondary to acute myocardial infarction. The torn papillary muscle is seen prolapsing into the left atrium (C, *arrow*), resulting in posteriorly directed severe mitral regurgitation (D). E and F, Infective endocarditis with perforation of the anterior mitral leaflet (E, *arrow*) results in severe mitral regurgitation through the perforation (F); G and H, Functional severe mitral regurgitation secondary to left ventricular systolic dysfunction and dilatation. Mitral valve leaflets are markedly tented resulting in noncoaptation (*arrow* in G). *LA*, Left atrium; *LV*, left ventricle.

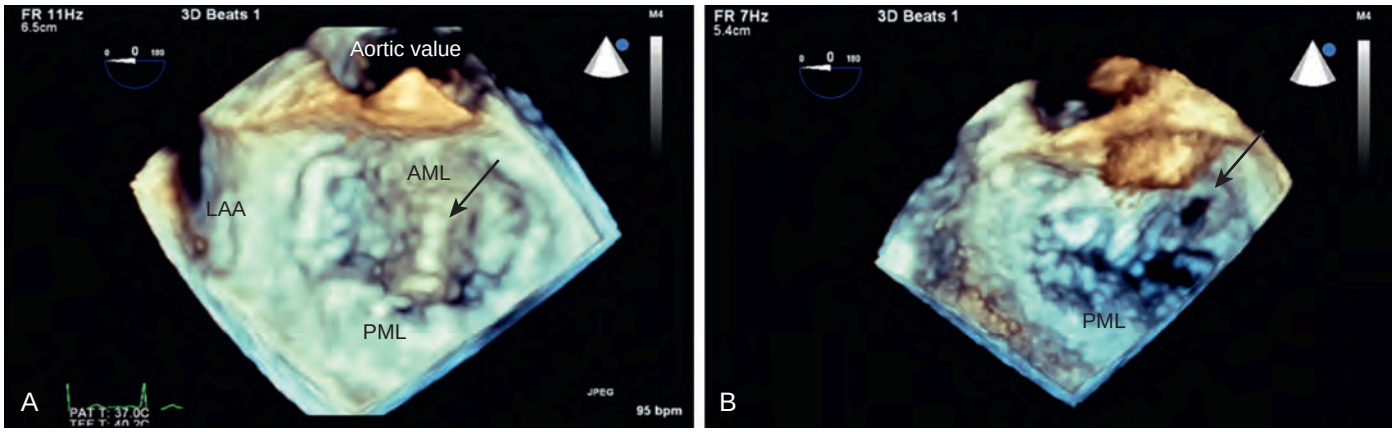

Fig. 2.7 Three-dimensional transesophageal echocardiography shows the mitral valve from the left atrial aspect, with the aortic valve in the 12 o'clock position (the "surgeon's view"). A, Prolapse of the A2 scallop of the anterior mitral leaflet *(arrow)*. B, Perforation in the A3 scallop of the anterior mitral leaflet *(arrow)*. *AML*, Anterior mitral leaflet; *LAA*, left atrial appendage; *PML*, posterior mitral leaflet.

TABLE 2.3 Echocardiographic Criteria for Severity of Aortic Valve Lesions

Parameter	*Mild*	*Moderate*	*Severe*
Aortic Stenosis			
Aortic jet peak velocity (m/s)	2.6–2.9	3.0–4.0	>4.0
Aortic valve mean gradient (mm Hg)[a]	<20	20–40	>40
Aortic valve area (cm^2)	>1.5	1.0–1.5	<1.0
Indexed aortic valve area (cm^2/m^2)	>0.85	0.60–0.85	<0.60
Velocity ratio	>0.50	0.25–0.50	<0.25
Aortic Regurgitation			
Structural Parameters			
Left ventricular size	Normal[b]	Normal or dilated	Usually dilated[c]
Aortic leaflets	Normal or abnormal	Normal or abnormal	Abnormal/ flail, or wide coaptation defect
Doppler Parameters			
Jet width in LVOT (color flow)[d]	Small in central jets	Intermediate	Large in central jets; variable in eccentric jets
Jet density (continuous wave)	Incomplete or faint	Dense	Dense
Jet deceleration rate (continuous wave) (pressure half-time, ms)[c]	Slow, >500	Medium, 500–200	Steep, <200
Diastolic flow reversal in descending aorta (pulsed wave)	Brief, early diastolic reversal	Intermediate	Prominent holodiastolic reversal
Quantitative Parameters[f]			
Vena contracta width (cm)[d]	<0.3	0.3–0.60	≥0.6
Jet width/LVOT width ratio (%)[d]	<25	25–45 (mild to moderate) 46–64 (moderate to severe)	≥65
Jet CSA/LVOT CSA ratio (%)[d]	<5	5–20 (mild to moderate) 21–59 (moderate to severe)	≥60
Regurgitant volume (mL/beat)	<30	30–44 (mild to moderate) 45–59 (moderate to severe)	≥60
Regurgitant fraction (%)	<30	30–39 (mild to moderate) 40–49 (moderate to severe)	≥50
Effective regurgitant orifice area (cm^2)	<0.10	0.10–0.19 (mild to moderate) 0.20–0.29 (moderate to severe)	≥0.30

CSA, Cross-sectional area; *LVOT*, left ventricular outflow tract.
[a]At heart rates between 60 and 80 beats/minute.
[b]Unless there are other causes of left ventricular dilatation
[c]Acute aortic regurgitation is an exception.
[d]At a Nyquist limit of 50 to 60 cm/s.
[e]Pressure half-time is shortened with increasing left ventricular diastolic pressure and vasodilator therapy and may be lengthened with chronic adaptation to severe aortic regurgitation.
[f]Quantitative parameters can help subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe subgroups, as shown.

Other Valve Lesions

Functional TR is another common valve lesion encountered in the surgical setting. Any condition resulting in severe pulmonary hypertension can cause TR. In cardiac patients, the most common causes are severe LV systolic dysfunction and significant MV disease. Significant TR in the absence of pulmonary hypertension occurs much less frequently and may be a consequence of previous RV myocardial infarction, atrial septal defect, or direct organic involvement of tricuspid valve leaflets in rheumatic heart disease, carcinoid disease, trauma, infective endocarditis, or the Ebstein anomaly. Organic, significant TR usually requires surgical correction, but the optimum management strategy for functional TR remains controversial. Although correction of the primary

pathology can often lead to partial or complete resolution of TR, it is less likely to regress, and may even progress, if tricuspid annulus dilation is present. In patients undergoing MV surgery, a maximum tricuspid annulus diameter greater than 4 cm (or >21 mm/m^2) on preoperative echocardiography is generally considered to indicate the need for surgical correction of TR at the time of MV surgery.[33,36–37]

Tricuspid valve pathology is best imaged by TTE and TEE, but on occasion the patient may have poor TTE windows, or the TEE study may be insufficient. Morphology of the valve, size of the annulus, TR gradient, status of RV systolic function, and RA pressure are the important data that need to be obtained from echocardiography.

Tricuspid stenosis is very rare and is usually congenital, associated with carcinoid tumor, or rheumatic in origin. Significant pulmonary regurgitation is also rare and typically occurs secondary to pulmonary hypertension or previous repair of congenital pulmonary stenosis. Pulmonary stenosis, however, is not uncommon. It is almost always congenital in origin and usually occurs as an isolated valvular, subvalvular, or supravalvular stenosis. The pulmonic valve is not well visualized on either TTE or TEE, especially in adults, but the transpulmonary gradient can be estimated in most patients.

Apart from native valve disease, patients can present with a wide variety of prosthetic heart valve (PHV)-related complications. Although echocardiography remains the primary modality for the evaluation of PHV function, adequate visualization of mechanical prosthetic valves, especially prosthetic AVs, is difficult because of acoustic shadowing and other artifacts caused by prosthetic materials. Mitral PHVs, however, can be imaged reasonably well, especially with TEE. The mobility of occluders, thickening of the leaflets in cases of tissue valves, valve dehiscence, paraprosthetic leaks, and presence of pannus, thrombus, or vegetation can be diagnosed effectively. Additionally, a reasonable amount of hemodynamic information can be obtained and can be corroborated with the anatomic findings to ascertain the actual mechanisms and severity of PHV malfunction.

Infective endocarditis is another common indication for valve surgery in patients with either native or prosthetic valves. It can be a life-threatening disease, with mortality rates reported to be as high as 40%.[38] The diagnosis is usually based on visualization of vegetations by echocardiography, which is the primary modality for diagnosing infective endocarditis. In severe cases, valve perforations, paravalvular abscesses, and PHV dehiscence can also be seen. With current-generation technologies, the sensitivity of TTE for detection of native valve endocarditis is in the range of 82% to 89%, and the specificity is 70% to 90%.[38–41] For prosthetic valve endocarditis, however, the sensitivity of TTE is rather poor (<50%). TEE is clearly the imaging modality of choice for infective endocarditis. For native valve endocarditis, TEE has a sensitivity of 90% to 100% and a specificity greater than 90%. Even for prosthetic valve endocarditis, TEE is highly accurate, with sensitivity in the range of 80% to 90% and specificity greater than 90%.[38–44]

Hemodynamic Assessment

Although invasive hemodynamic monitoring is routine in patients undergoing cardiac surgery, echocardiography offers an excellent alternative if invasive monitoring is not feasible. Typically, echocardiography is the best option for hemodynamic assessment during the preoperative period, or in the late postoperative period after discharge from the intensive care unit, and also in noncardiac surgery. An added advantage of echocardiography is that it allows hemodynamic data to be directly correlated with cardiac anatomy and function. Vast amounts of hemodynamic information can be obtained from echocardiography, including intracardiac pressures, cardiac output, and vascular resistance.

Intracardiac Pressures

A wide range of intracardiac pressures can be derived using the simplified Bernoulli equation, which states that the pressure gradient (ΔP) driving a blood flow jet within the cardiovascular system is equal to $4v^2$, where v is the peak jet velocity. If the pressure within the upstream or downstream chamber is known, the pressure in the other chamber can be calculated by measuring the peak jet velocity between the two chambers. The most common application of this formula is in estimation of RV systolic pressure or pulmonary artery systolic pressure from a TR jet. The RV systolic pressure is derived by adding mean RA pressure (estimated from IVC measurements as described earlier or from jugular venous observations with head elevation) to the peak TR jet gradient. In the absence of any RVOT obstruction, RV systolic pressure is identical to the pulmonary artery systolic pressure. The same principle can be applied for estimating other intracardiac pressures using other jets (eg, pulmonary artery end-diastolic pressure from a pulmonary regurgitant jet, RV systolic pressure from the jet crossing a ventricular septal defect, LA pressure from the mitral regurgitation jet).

A number of equations are also available for the estimation of peak systolic and mean pulmonary pressure from RVOT acceleration time and from pulmonary regurgitation jet velocity.[45–48] However, these formulas involve certain assumptions, and their accuracy is affected by several hemodynamic factors.

Cardiac Output and Vascular Resistance

During echocardiography, flow through any cardiac structure can easily be estimated by multiplying the cross-sectional area of the structure by the velocity-time integral (VTI) of the blood flow through that structure. This provides stroke volume, which is then multiplied by the heart rate to calculate cardiac output (CO).

In clinical practice, LV outflow tract (LVOT) is the site most commonly used for measurement of CO (Fig. 2.8). LVOT is easy to visualize, it is almost circular in shape, and its size does not change much during the cardiac cycle. Additionally, the blood flow through the LVOT is mostly laminar, which minimizes the chance of inadvertently sampling velocities that are not truly representative of the actual blood flow at that point. The LVOT diameter is measured from the parasternal or TEE long-axis view and the VTI from the apical five-chamber or TEE deep transgastric view (using pulsed-wave Doppler ultrasonography). Precision should be maintained while obtaining these measurements, because any errors will become magnified when the calculations are performed.[49]

There are several circumstances in which the CO measured at the LVOT may not be accurate or representative of true CO, including significant LVOT obstruction and AR. In such cases, the measurements can be performed at the MV or at the RVOT, provided there is no significant MR or intracardiac shunt, respectively.

Once the CO has been determined, systemic vascular resistance (SVR) can be estimated using the principle of Ohm's law, which states that the resistance across any vascular circuit is equal to the pressure gradient across the circuit divided by the flow:

$$\text{SVR} = (\text{Mean aortic pressure} - \text{Mean RA pressure}) / \text{Systemic blood flow}$$

Mean systemic blood pressure is used as a surrogate for mean aortic pressure; all the other values can be obtained by echocardiography, as described earlier. When the pressure gradient is measured in mm Hg and CO in L/min, the derived vascular resistance is described in Wood units, which can be converted to metric units (dynes·s·cm^{-5}) by multiplying by 80.

Although a similar equation can be applied for the estimation of pulmonary vascular resistance (PVR), it is generally not used because of the difficulties in obtaining transpulmonary gradients by echocardiography. An alternate, simpler method has been proposed for measuring the PVR (in Wood units); it relies on the TR jet velocity (in m/s) and the RVOT-VTI (in cm):

$$\text{PVR} = (\text{Peak TR velocity} / \text{RVOT} - \text{VTI}) \times 10 + 0.16$$

Pericardial Diseases

Bleeding into the pericardial space is a common occurrence during the immediate postoperative period after cardiac surgery and an important

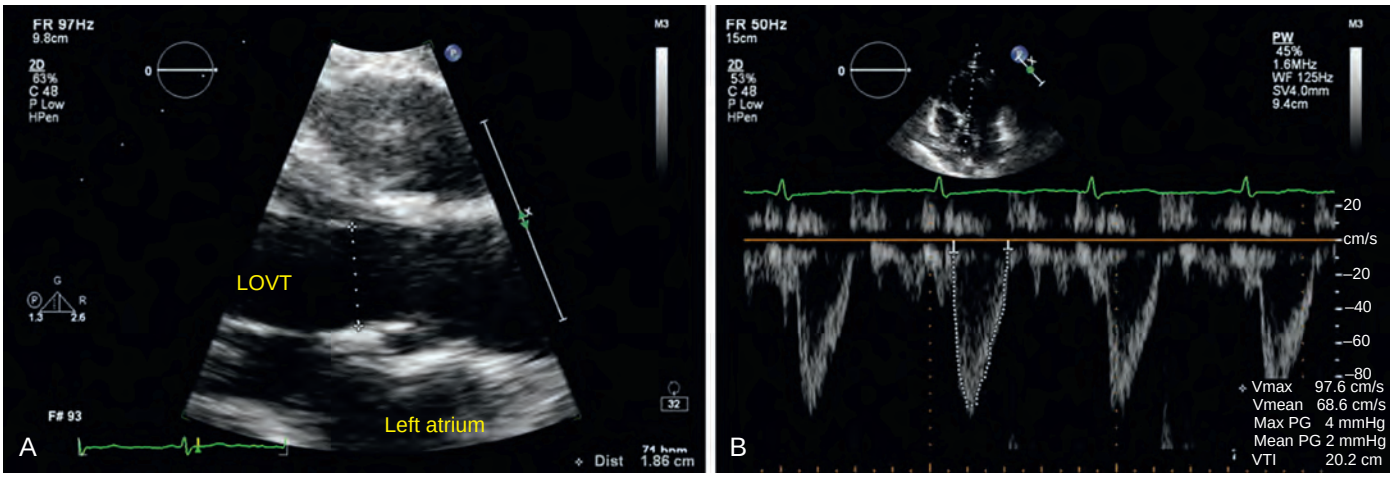

Fig. 2.8 Echocardiographic estimation of cardiac output at the left ventricular outflow tract (LVOT). A, LVOT diameter is measured from the parasternal long-axis view in midsystole. B, Measurement of the LVOT velocity-time integral (VTI) using pulsed-wave Doppler ultrasonography in apical five-chamber view. See text for details.

cause of hemodynamic compromise in this setting. Pericardial effusions can also occur secondary to a number of cardiac and noncardiac conditions; for example, it can occur as an immune reaction after myocardial infarction or cardiac surgery. Echocardiography not only allows detection and quantification of pericardial collections but also permits assessment of the hemodynamic significance of the phenomenon.

The pericardial fluid or blood collection can be circumferential or localized, and it usually appears as an echolucent space outside the heart. When bleeding is the cause, however, the fluid is more echogenic, and even frank clots may be seen. Additionally, fibrinous bands, septa, and pericardial echogenic deposits are commonly visualized in cases of exudative effusions. When a pericardial collection is localized posterior to the LV, it can be difficult to distinguish from a pleural collection. Extension of the collection posterior to the descending thoracic aorta suggests a pleural origin, rather than pericardial.

When a pericardial effusion is visualized, an important clinical question is whether there is any evidence of cardiac tamponade. Evidence of diastolic RA and RV collapse, a restrictive-type mitral inflow pattern with significant respiratory variation in mitral and tricuspid inflow velocities, and a dilated, noncollapsing IVC indicate the presence of cardiac tamponade (Fig. 2.9). The size of the effusion itself is not a reliable indicator because the rapidity of fluid accumulation is more important than the actual quantity of fluid in the causation of cardiac tamponade.

Apart from pericardial collections, constrictive pericarditis is another common pericardial pathology and is itself an indication for cardiac surgery. In patients with suspected chronic constrictive pericarditis, pericardial thickening and calcification may be visualized on echocardiography. More often, however, it is the hemodynamic abnormalities that draw attention to the possibility of constriction physiology. The echocardiographic findings suggestive of constriction include (1) exaggerated ventricular interdependence, as evidenced by septal bounce, deviation of septal position with respiration, and significant respiratory variation in mitral and tricuspid inflow velocities; (2) a restrictive-type mitral inflow pattern with a relatively preserved or exaggerated mitral e′ (known as annulus paradoxus) or a medial mitral e′ that is taller than the lateral e′ (known as annulus reversus); and (3) a dilated, noncollapsing IVC. In uncertain cases, assessment of myocardial strain and torsion abnormalities may provide further clues to help reach an accurate diagnosis.[50–51]

In patients with various pericardial pathologies, echocardiography helps not only in diagnostic evaluation but also in guiding therapeutic interventions (eg, pericardiocentesis, pericardiectomy) and in assessing the adequacy of those procedures.

Diseases of the Aorta

Aortic aneurysm and aortic dissection are commonly encountered cardiac pathologies. Despite advances in endovascular repair, surgery remains the primary treatment modality for most patients. Although CCT is the modality of choice for imaging the aorta, echocardiography is a good modality for initial evaluation, especially in acutely ill or hemodynamically unstable patients.

Ascending aortic aneurysms usually occur because of cystic medial degeneration; they frequently involve the aortic root and cause AR. These aneurysms are more common in patients with hypertension, bicuspid AV, or connective tissue diseases such as Marfan or Ehlers-Danlos syndrome (see Chapter 23).[52] In contrast, descending aortic aneurysms are mostly caused by atherosclerosis and are associated with the same risk factors as for CAD. Among descending aortic aneurysms, abdominal aneurysms are more common than thoracic aortic aneurysms.

Although TTE can provide clear visualization of the aortic root and the proximal segment of the ascending aorta, imaging of the arch and the descending thoracic aorta is usually challenging. In contrast, TEE can image the entire length of the descending thoracic aorta, in addition to aortic root and the proximal segment of ascending aorta, but the aortic arch, especially the proximal portion, is not visualized because of the interposition of the left main bronchus in the path of the ultrasound beam. An aortic aneurysm appears as a localized dilatation of a segment of the aorta to more than 1.5 times its normal size. Echocardiography can be used to measure both the width and the longitudinal extent of the aneurysm, as well as its relationship to major anatomic landmarks. Additionally, mural thrombi are frequently seen, especially in large aneurysms.

Ascending aortic dissection is a true cardiac surgical emergency that needs to be diagnosed urgently and treated surgically. In aortic dissections, there is a tear in the intima that forms a communication with the aortic true lumen. The media is exposed to blood flow, and a false lumen typically forms. The dissection extends in either an anterograde or a retrograde fashion, often involving the branch arteries.[53] Aortic dissections most commonly originate in one of two locations that experience greatest stress: the ascending aorta just above the sinuses of Valsalva (65%) or the descending aorta just distal to the subclavian artery (20%). Other, less common sites include the aortic arch (10%) and the abdominal aorta (5%).

Echocardiography is an excellent modality for the initial assessment of patients with aortic dissection, particularly those with proximal aortic dissection. TTE has a sensitivity of 77% to 80% and a specificity of 93% to 96% for the diagnosis of proximal aortic

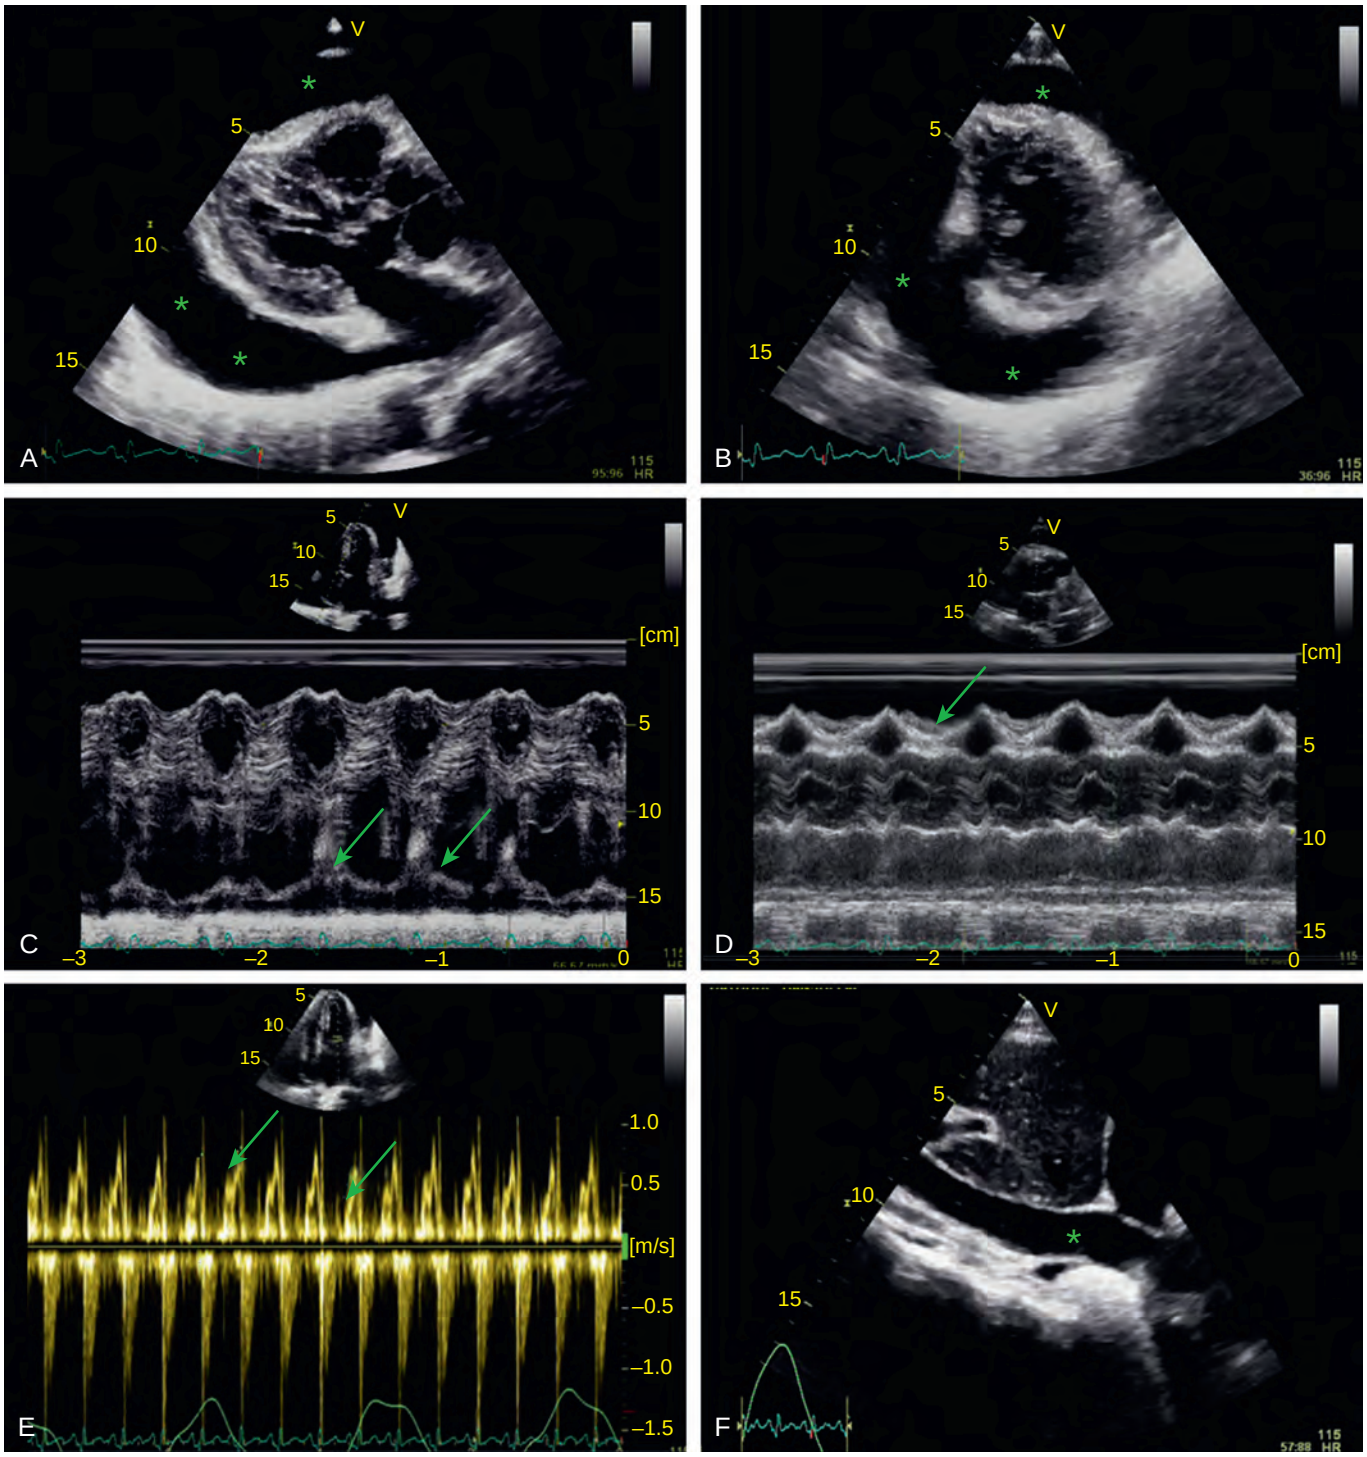

Fig. 2.9 A patient with cardiac tamponade. Parasternal long-axis view (A) and short-axis view (B) show a large circumferential pericardial effusion *(asterisks)*. dissection, whereas the sensitivity and specificity of TEE in this application are 98% and 95%, respectively.[54,55] The sensitivity of TTE for detecting distal aortic dissection is much lower, for the reasons mentioned earlier, but TEE can diagnose most dissections involving the descending thoracic aorta. TEE can also demonstrate intimal tears in most cases, and it permits recognition of true and false lumina. Additionally, both TTE and TEE are helpful in defining the mechanism of AR if present, in assessing the underlying primary AV pathology if present, and in recognizing pericardial extension of the dissection (Fig. 2.10).

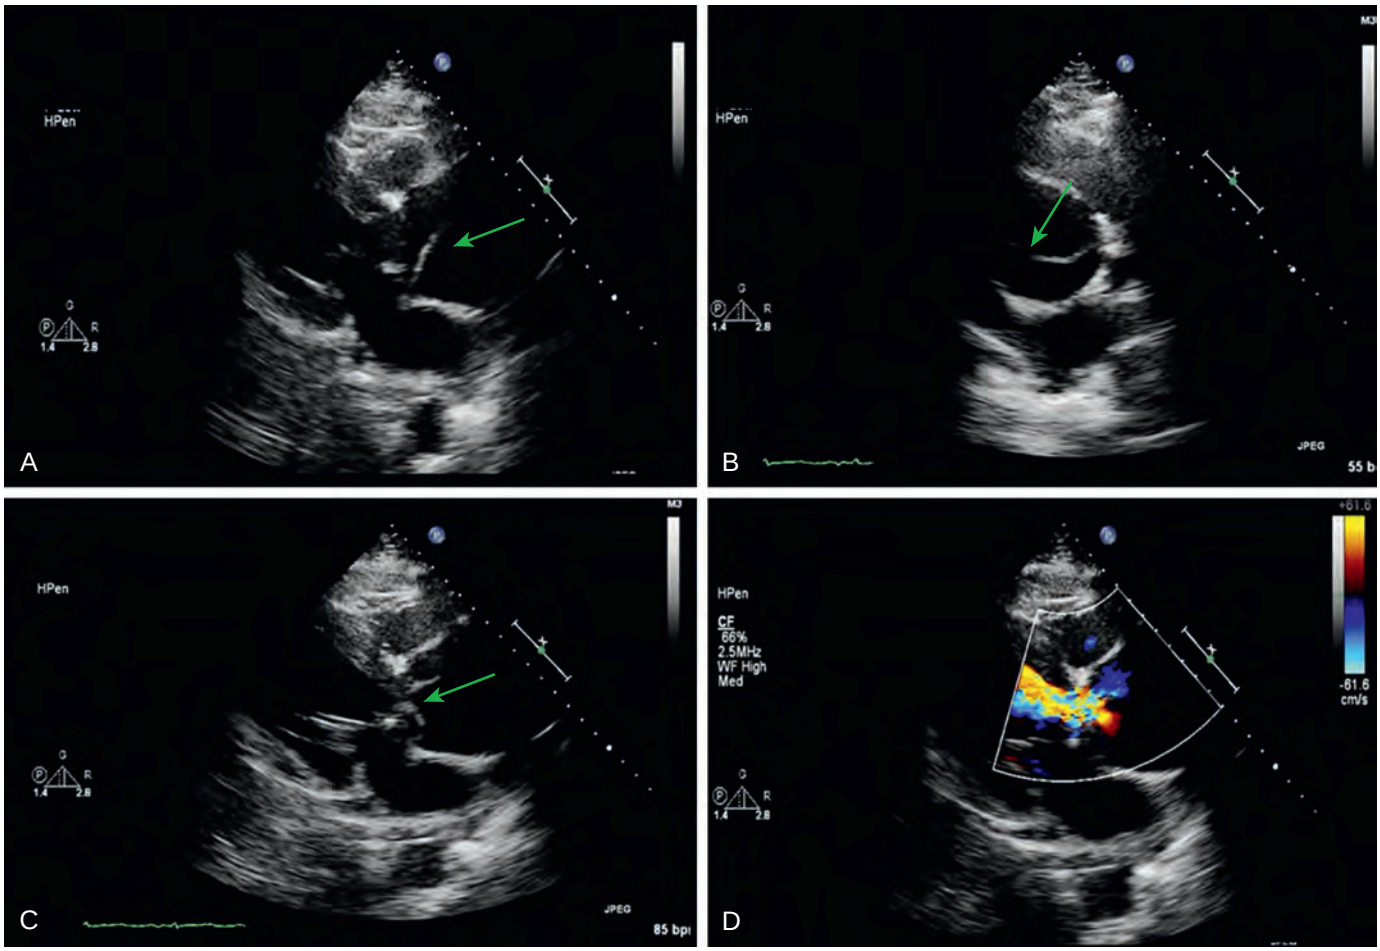

Fig. 2.10 An illustrative example of proximal aortic dissection. Dissection flap *(arrow)* is seen in the ascending aorta in the long-axis view (A) and in the short-axis view (B). The dissection flap is prolapsing though the aortic valve orifice (C, *arrow*), resulting in severe aortic regurgitation (D).

Miscellaneous Disorders

Echocardiography is also useful in providing surgically relevant information about patients undergoing cardiac surgery for various structural lesions such as hypertrophic cardiomyopathy or intracardiac masses. In patients with hypertrophic cardiomyopathy who are undergoing septal myectomy, echocardiography delineates the extent of septal hypertrophy, the site of maximum thickness, the presence of any papillary muscle abnormalities, and the presence, severity, and mechanism of MR, all of which are helpful in planning the surgical procedure.

Stress Echocardiography

Inclusion of a hemodynamic stressor at the time of imaging greatly expands the diagnostic realm of echocardiography. Inducible myocardial ischemia and myocardial viability can be assessed, the patient's symptoms can be corroborated, and the hemodynamic significance of valve lesions can be better assessed if there is ambiguity.

Myocardial Ischemia

Assessment of the presence, extent, and severity of myocardial ischemia is the most common indication for performing stress echocardiography. During stress echocardiography, inducible ischemia is diagnosed by the development of new wall motion abnormalities, which may manifest as delayed thickening, reduced thickening, or no thickening at all.

Patients can be stressed by exercise or by the use of pharmacologic agents.[56] In patients who are physically active, exercise is the preferred modality because it is physiologic, allows symptom correlation, and permits assessment of functional capacity, which itself is a powerful prognostic marker. Exercise is most often done on a treadmill or, less commonly, on a bicycle ergometer.[57] Compared with bicycle ergometry, treadmill exercise typically results in greater workload during the stress test. However, the lower workload achieved during bicycle ergometry is compensated by the ability to image during the exercise itself, so the two modalities have equivalent diagnostic accuracy.[58]

Pharmacologic stress testing is a negative prognosticator in itself because patients who are not able to achieve sufficient physical activity to perform an exercise stress test have a greater incidence of cardiovascular disease and other comorbidities. Pharmacologic stress testing can be performed using either dobutamine, which is a chronotropic/inotropic agent, or a vasodilator such as dipyridamole or adenosine. Atropine is often combined with pharmacologic stress testing to increase the sensitivity of the test.[59–62]

If the patient has an implanted pacemaker and a pacemaker-dependent rhythm, pacing stress echocardiography can be performed using an external programmer to sequentially increase the heart rate. It is usually combined with dobutamine infusion to simultaneously augment contractility.

Regardless of the stress modality, the imaging protocols are almost identical.[56] Representative gray-scale images (typically the parasternal long-axis, midventricular short-axis, apical four-chamber, and apical

two-chamber views) are acquired at baseline and at, or immediately after, peak stress. Bicycle exercise and pharmacologic agents also allow acquisition of low-stress and recovery images. Hemodynamic data (eg, LVFP, TR, MR) are also captured at baseline and at peak stress. The gray-scale images are analyzed for any inducible wall motion abnormalities with the use of a digitized, quad-screen display format to allow side-by-side comparisons.

The accuracy of stress echocardiography for detection of inducible ischemia has been examined in numerous studies. In a large metaanalysis, the average sensitivity and specificity of exercise echocardiography were found to be 83% and 84%, respectively.[63] These values were 80% and 85%, respectively, for dobutamine echocardiography; 71% and 92% for dipyridamole echocardiography; and 68% and 81% for adenosine stress echocardiography.[63] A number of factors that influence the accuracy of stress echocardiography, including the adequacy of stress, delayed imaging after stress, the extent of CAD, the coronary vessel or vessels affected, use of beta-blockers and other antianginal agents, preexisting wall motion abnormalities, previous CABG, the presence of concomitant conduction abnormalities, and the acoustic quality of the gray-scale images. Additionally, the technical expertise of the personnel involved in image acquisition and interpretation greatly influences the diagnostic accuracy of this modality.[56,64,65]

Myocardial Viability

In patients with significant LV systolic dysfunction, the presence of myocardial viability is a good prognostic marker and is associated with greater likelihood of functional recovery after revascularization.[66–70] Accordingly, myocardial viability is often assessed in these patients to determine the need for, and to choose the mode of, revascularization.

Although reduced end-diastolic wall thickness (<6 mm) has been reported to have high negative predictive value for the presence of myocardial viability,[71] the converse is not true. For this reason, dobutamine echocardiography is the primary echocardiographic modality used for the assessment of myocardial viability in clinical practice. The dobutamine infusion is started at a low dose (typically 2.5–5 μg/kg per minute), and the dose is doubled every 3 minutes to a maximum of 40 μg/kg per minute. At low doses (up to 10 μg/kg per minute), dobutamine augments cardiac contractility without any appreciable increase in myocardial oxygen demand. However, when the dose is increased further, there is a progressive increase in heart rate and myocardial oxygen demand. As a result, a dysfunctional but viable segment that is underperfused (ie, a *hibernating* segment) will improve at low doses but worsen again at peak doses. This biphasic response is considered to be the hallmark of myocardial viability and is the most accurate predictor of functional recovery after revascularization.[72] In contrast, when a myocardial segment is dysfunctional but well perfused (i.e., *stunned* myocardium), it will demonstrate a sustained improvement in contractility at both low and peak doses (uniphasic response). Such a segment is likely to improve with time without the need for any revascularization. If there is no improvement in contractility with a low dose, lack of myocardial viability is indicated, and the likelihood of functional recovery is very low. In a metaanalysis comparing various modalities for assessment of myocardial viability, dobutamine echocardiography was reported to have a sensitivity of 84% and a specificity of 81% for predicting functional recovery after revascularization.[73]

An important limitation of stress echocardiography, when used for evaluation of CAD, is the subjectivity of assessment. All interpretation with this modality is based on visual analysis of wall motion. Quantitative techniques such as tissue velocity imaging and strain imaging have been explored to minimize this subjectivity and to improve the diagnostic accuracy of stress echocardiography. The results indicate that the use of tissue velocity and strain as adjuncts to wall motion analysis can indeed enhance the accuracy of stress echocardiography for evaluation of myocardial ischemia and viability.[74–79] Due to several technical limitations, however, the role of these techniques is limited at present.

Valve Lesions

Although valve lesions are typically evaluated at rest only, stress echocardiography may be required in certain situations. For patients who have significant valve disease but are asymptomatic, exercise stress echocardiography can be performed to assess symptoms and to determine overall functional capacity. Development of symptoms at low levels of stress, especially if accompanied by evidence of hemodynamic compromise (eg, fall in blood pressure, significant increase in pulmonary artery systolic pressure), may indicate the need for valve surgery.[33]

A specific indication for stress echocardiography is in the evaluation of low-gradient severe AS in the presence of LV systolic dysfunction.[26] The AS may be truly severe and the gradients spuriously low due to LV systolic dysfunction. Alternatively, the AS may not be severe, with the reduced valve area being a function of inadequate opening force (pseudo-severe AS). Low-dose dobutamine echocardiography (maximum dose, 10–20 μg/kg per minute) can help make this distinction. In the former situation, an increase in LV contractility with dobutamine infusion significantly increases the transaortic gradient without a concomitant increase in valve area. In these cases, LV systolic dysfunction is likely to be secondary to severe AS and can be expected to improve after AV replacement. In contrast, if the AS is not truly severe, dobutamine infusion augments valve opening such that the valve area increases but the gradients do not increase much. In such patients, LV systolic dysfunction is not related to AS, and AV replacement may not be helpful. On occasion, a patient may have fairly advanced LV systolic dysfunction with no contractile reserve, which precludes making the distinction between severe AS and pseudo-severe AS. Patients in this subgroup have high associated surgical mortality rates and poor long-term outcomes, although valve replacement may still improve LV function and outcome in selected individuals.[80]

Stress echocardiography may also have a role in the evaluation of functional MR. An exercise-induced increase in the MR effective regurgitation orifice by greater than 13 mm^2 has been shown to be an independent predictor of mortality and hospital admission for heart failure in patients with chronic ischemic LV systolic dysfunction and functional MR.[81]

Myocardial Nuclear Scintigraphy

Myocardial nuclear scintigraphy is the most widely used modality for assessment of myocardial ischemia and viability, at least in the preoperative setting. There are two main forms of myocardial nuclear imaging, single-photon emission computed tomography (SPECT) and positron emission tomography (PET). Both use the principles of radioactive decay to evaluate the myocardium and its blood supply.

The radionuclides that are used in SPECT are technetium 99m (^{99m}Tc) and thallium 201 (^{201}Tl). ^{99m}Tc is a large radionuclide that emits a single photon or gamma ray per radioactive decay event, with a half-life of 6 hours. The energy of the emitted photon is 140,000 electron volts (140 keV). ^{201}Tl is less commonly used and decays by electron capture. It has a much longer half-life (73 hours), and the energy emitted is between 69 and 83 keV. To obtain images, the gamma rays that are released from the body must be captured and modified by a detector (gamma camera). The standard camera is composed of a collimator, scintillating crystals, and photomultiplier tubes. When a radionuclide emits gamma rays, it does so in all directions. A collimator made of lead that has small, elongated holes is used as a filter to accept only those gamma rays traveling from the target organ toward the camera. Once the selected gamma rays have reached the scintillating crystals, they are converted to visible light and then to electrical signals by the photomultiplier tubes. These signals are processed by a computer to form images. Myocardial regions that are infarcted or ischemic after stress have relatively decreased tracer uptake and therefore decreased signal (counts) in the processed images.

Although PET also uses radioisotopes to produce images, the actual process of image formation is quite distinct from that of SPECT. The most common radioisotopes used for cardiac evaluation by PET

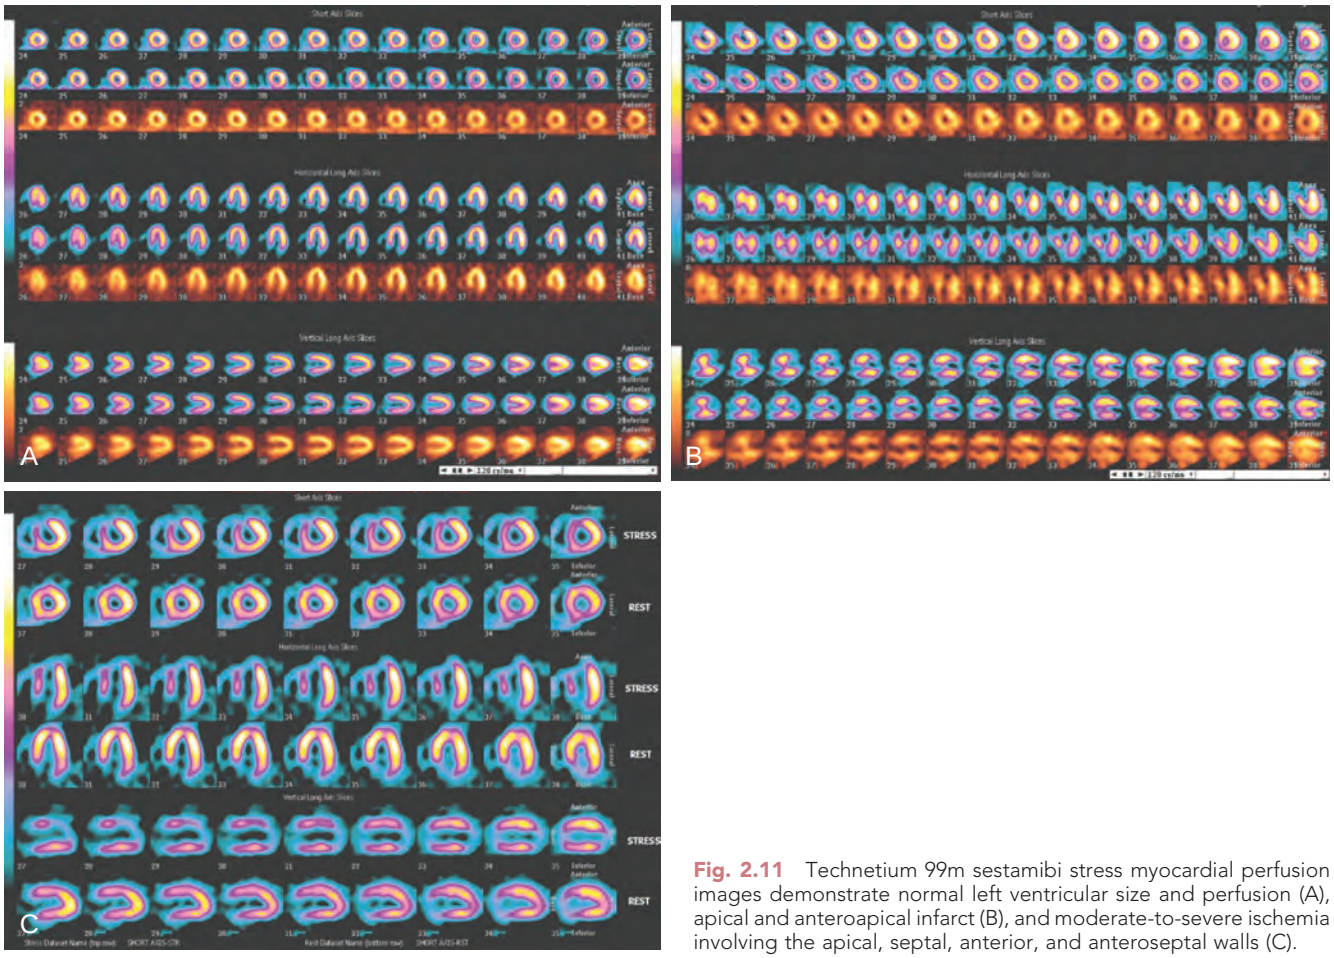

Fig. 2.11 Technetium 99m sestamibi stress myocardial perfusion images demonstrate normal left ventricular size and perfusion (A), apical and anteroapical infarct (B), and moderate-to-severe ischemia involving the apical, septal, anterior, and anteroseptal walls (C).

imaging are rubidium 82, *N*-ammonia 13, and fluorine 18 (^{18}F). ^{18}F is a much smaller radionuclide than ^{99m}Tc. It emits a positron (β^+) antiparticle. This ionized antiparticle travels until it interacts with an electron. The electron and the positron are antiparticles of each other, meaning that they have the same mass but are opposite in charge. When they encounter each other, both particles disintegrate and are converted into energy in the form of two photons, each with the same energy (511 keV), traveling in opposite directions. This phenomenon, known as *pair annihilation*, is used to create the images in PET. PET cameras also differ from SPECT cameras in that they capture only incoming photons that travel in opposite directions and arrive at a circular detector around the body at precisely the same time. PET detectors have much higher sensitivity than SPECT cameras because they do not require a collimator. As in SPECT, PET cameras use scintillating crystals and photomultiplier tubes. PET systems have been combined with CT and magnetic resonance imaging (MRI) systems to simultaneously display PET metabolic images and the corresponding anatomic information.

Detection of myocardial ischemia is the most common indication for performing myocardial perfusion imaging. Either SPECT or PET can be used for this purpose, which is based on assessments of LV myocardial uptake of the radioisotope at rest and after stress. Myocardial uptake is reduced after stress in myocardial regions where significant coronary artery stenosis is present. ^{99m}Tc is the radioisotope most commonly used for this purpose. It must be injected when peak heart rate is reached, and the patient must continue exercising (or the pharmacologic stress must be continued) for at least 1 minute afterward to allow sufficient time for the radioisotope to circulate through the myocardium. The images are displayed in three LV orientations (short-axis, horizontal long-axis, and vertical long-axis) for proper LV wall-segment analysis. The stress images are exhibited directly above the corresponding rest images so that normal myocardium can be differentiated from ischemic myocardium (Fig. 2.11).

PET scanners have inherently less attenuation and higher resolution than those used in SPECT, making PET the more desirable modality.[82] Pharmacologic stressors are usually used in PET myocardial perfusion tests because of the very short half-life of PET radioisotopes. The sensitivity and specificity of SPECT for detection of obstructive CAD are 91% and 72%, respectively; use of PET improves the specificity to 90%.[82] Normal findings on SPECT imply that the probability of experiencing a cardiac event is less than 1% per year, and a normal result on rubidium 82 (^{82}Rb) PET indicates a probability of less than 0.4% per year.

For viability assessment with SPECT imaging, ^{201}Tl is used more frequently, taking advantage of this isotope's long half-life (73 hours). Thallium uptake is dependent on several physiologic factors, including blood flow and sarcolemmal intercellular integrity. The time required for uptake is short in normal myocardium, but 24 hours may be needed in hibernating myocardium that still has metabolic activity. Patients are injected with thallium radioisotope and imaged the same day for baseline studies. After 24 hours, new images are obtained without any further injection. The baseline images and 24-hour images are compared. Defects that are present at baseline but filled in at 24 hours represent viability (Fig. 2.12). Technetium radioisotopes also can be used under different protocols for the evaluation of viable myocardium.

PET imaging is more sensitive than SPECT, and it is considered by many experts to be the gold standard for assessment of viability. PET has the ability to identify the presence of preserved metabolic activity in areas of decreased perfusion when 18-fluorodeoxyglucose (FDG) is used. PET imaging uses both FDG and either rubidium or

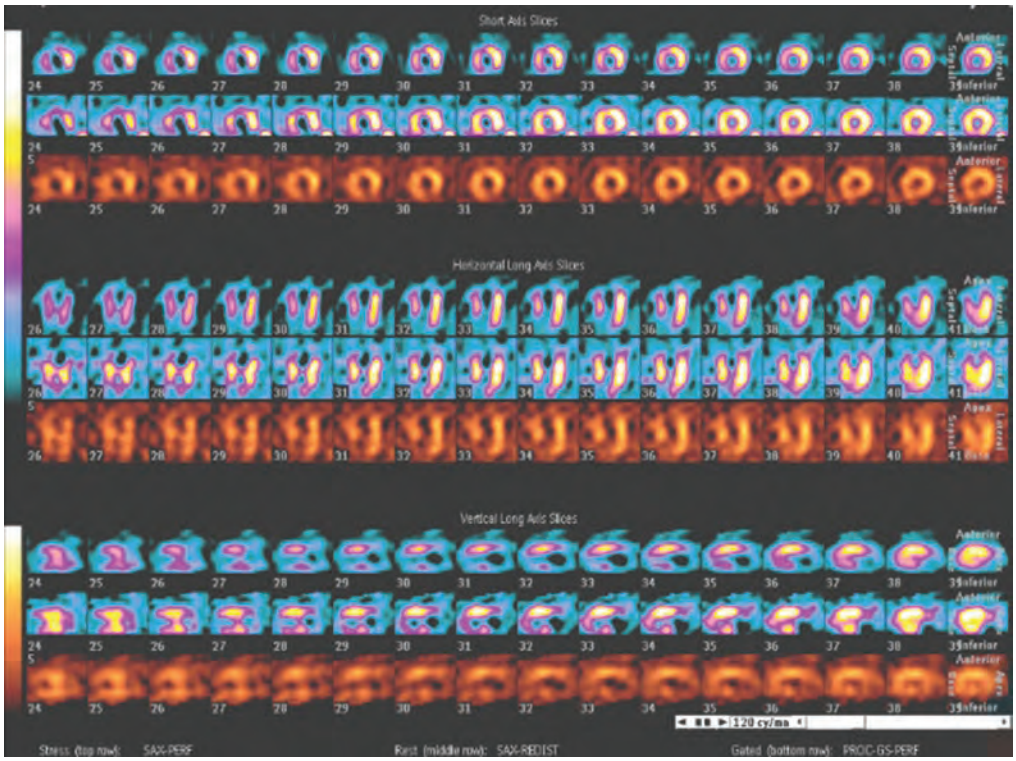

Fig. 2.12 Thallium rest-redistribution scan demonstrates hibernating myocardium involving the apical-basal anteroseptum, midbasal inferior, midbasal inferoseptum, and midbasal inferolateral wall segments. There is infarction of the apex, inferoapical, and apical-lateral wall segments.

ammonia radioisotopes for quantification of energy utilization by the myocardium and for evaluation of patterns of blood flow. Areas with reduced blood flow and reduced FDG uptake are considered to represent scar and infarction. Areas with reduced blood flow and normal FDG uptake are considered viable.[83] A metaanalysis of more than 750 patients demonstrated a sensitivity of 92% and a specificity of 63% for regional functional recovery with this method; the positive and negative predictive values were 74% and 87%, respectively.[84]

Nuclear scintigraphic methods, including both SPECT and PET myocardial perfusion imaging, can also be used to evaluate global and segmental LV systolic function. This is achieved by implementing ECG gating during data acquisition. Most often, eight frames or phases are acquired per cardiac cycle. Gated images can be acquired both at rest and after stress. However, rest images typically involve a lower radiation dose, so the images may be noisy; for this reason, most institutions perform gated imaging on the post-stress images. Accurate LV systolic analysis is limited with this technique in the circumstance of stress-induced ischemia, in which myocardial stunning can transiently reduce the LVEF. Another limitation of ECG-gated SPECT or PET is arrhythmias, specifically frequent premature ventricular contractions or atrial fibrillation. Assessment of LV function also may be inaccurate in patients with extensive myocardial infarction: Because there is absence of isotope in the scar regions, the endocardial border cannot be defined.

An alternative technique is gated blood pool scanning (also known as multiple-gated acquisition, or MUGA). In this technique, the cardiac blood pool is imaged with high resolution during the cardiac cycle. Ventricular function and various temporal parameters can be measured.[85] There is good correlation between echocardiography and MUGA for the evaluation of LVEF, and in fact, MUGA has demonstrated better intraobserver and interobserver reproducibility compared with echocardiography.[86] Nuclear imaging can also be used for assessment of LV diastolic function, but it is much less useful than echocardiography for that purpose. At least 16 phases of the cardiac cycle need to be acquired to evaluate diastolic dysfunction using SPECT. The two main parameters that can be measured by SPECT are LV peak filling rate and time to peak filling rate.

Myocardial infarction causes denervation of the scar, and subsequent interruption of sympathetic nerves induces denervation of adjacent viable myocardium.[87,88] Sympathetic nerves are very sensitive to ischemia and usually become dysfunctional after repeated episodes of ischemia that do not result in irreversible myocyte injury.[89,90] Matsunari and associates[91] demonstrated that the area of denervation is larger than the area of scar and corresponds to the area at risk for ischemia. Additionally, Bulow and coworkers[92] showed that denervation of myocytes can occur in the absence of previous infarction. Myocyte sympathetic innervation can be measured by PET using carbon 11 (^{11}C)-labeled hydroxyephedrine (HED). This is compared with PET resting perfusion images to determine the area of the scar. Areas of normal resting perfusion and reduced HED retention indicate viable myocardium.

SPECT imaging of myocardial uptake of iodine 123 (^{123}I)-labeled metaiodobenzylguanidine (*m*IBG), which is an analog of the sympathetic neurotransmitter norepinephrine, provides an assessment of β-receptor density. Reduced ^{123}I-*m*IBG uptake is associated with adverse outcomes in patients with heart failure and has been proposed as a marker of response to treatment.[93]

Cardiac Computed Tomography

CCT has grown significantly in clinical use since the advent, in the early 2000s, of multidetector CT (MDCT) scanners with submillimeter resolution that allow evaluation of the coronary anatomy. The x-ray tube produces beams that traverse the patient and are received by a detector array on the opposite side of the scanner. The tube and detector arrays are coupled to each other and rotate around the patient at a velocity of 250 to 500 microseconds per rotation. In 1999, the first MDCT scanner used for coronary imaging had four rows of

detectors and a scanning coverage of 2 cm per rotation. Breath-holds on the order of 10 to 20 seconds were required to cover the entire heart. Artifacts produced by the patient's respiration and heart rate variability rendered many studies nondiagnostic for the assessment of coronary stenosis. With today's advanced technology, 256-slice systems are standard, and 320-slice systems with 16 cm of coverage are able to capture the entire heart in one heartbeat and rotation.

CCT uses ionizing radiation for the production of images. Concern about excessive medical radiation exposure has been raised. Although several techniques, such as prospective ECG-gated acquisition, may be implemented to reduce the radiation dose,[94–96] a risk-benefit assessment must be done for the selection of patients who have appropriate indications for CCT.

Coronary angiography is currently one of the most common indications for performing CCT. The patient's heart rate must be lowered to less than 65 beats/minute to achieve adequate results when imaging the coronary arteries. This usually requires the administration of oral or intravenous beta-blockers. After the scan has been completed, images are reconstructed at various points of the cardiac cycle and analyzed on a computer workstation. Cardiac CT angiography (CCTA) has been well studied for the diagnosis of CAD in patients without known ischemic heart disease, demonstrating a sensitivity of 94% and a negative predictive value of 99%.[97] It is being increasingly employed to exclude obstructive CAD before valve surgery in patients with low-to-intermediate pretest probability to avoid invasive testing. In one study of CCTA for this purpose, researchers performed conventional coronary angiography and 64-slice MDCT in 50 patients (mean age, 54 y) who were about to undergo valve replacement for AR. CCTA demonstrated a sensitivity of 100%, a specificity of 95%, and a negative predictive value of 100%. Additionally, it was determined that use of CCTA could have allowed 70% of the patients to avoid invasive catheterization.[98] Two further studies used preoperative 16- and 64-slice CCTA in patients with AS. The mean ages of the patients were 68 and 70 years, respectively. In each study, both the sensitivity and the negative predictive value were 100% for detection of significant stenosis.[99,100] These studies showed that preoperative coronary evaluation with CCTA is safe and accurate. It is important that only patients with no known CAD or those with low-to-intermediate risk be referred for CCTA. In general, patients with degenerative AS are older and have greater risk for CAD. Patients who undergo valve surgery for MR because of MV prolapse are usually younger and are excellent candidates for CCTA.

CT aortography is the imaging modality of choice for evaluation of aortic pathologies such as aortic aneurysms and nonemergency dissections. Imaging protocols used for evaluation of the aorta are similar to those used for CCTA. It is important to have the scan gated to the patient's ECG because the ascending aorta moves significantly during the cardiac cycle. Nongated scans have inherent motion artifacts that can be confused with a dissection. Use of prospective ECG gating also minimizes radiation exposure. Visualization of the aortic root and coronary arteries is crucial because ascending aortic dissections can involve the ostia of the coronary arteries.

Once the images are acquired by specialized CT workstations, the aorta is evaluated and measured. The aorta is lined up in multiple orthogonal views to measure the true short axis throughout the length of the aorta. The excellent spatial and contrast resolution of this modality is useful for the evaluation of dissection. Entry points of dissection, intimal flap location, false lumen, extension into branch arteries, and the abdominal aortic circulation are easily visualized.

Although echocardiography is the gold standard for imaging valvular disease, advanced imaging with CCT or CMR may be required if TTE and TEE are technically difficult or if there are discrepancies in the findings. CMR offers more functional data than CCT, but CCT may be used if further anatomic information about a valve is required. For evaluating prosthetic valves, CCT is usually superior to CMR because of metallic artifact from the valve, which is visualized on CMR (see Chapter 21).

Valvular calcification is common in patients presenting with AS, particularly senile degenerative AS. CCT can accurately quantify AV calcification and can help assess the severity of AS. An AV calcium score of 1100 or greater has 93% sensitivity and an 82% specificity for severe AS.[101] Additionally, contrast-enhanced CCT allows for excellent visualization of the AV morphology and accurately differentiates between bicuspid and tricuspid AVs[102] (Fig. 2.13). Aortic valve planimetry can also be performed. AV areas measured by CCT have been demonstrated to have a strong correlation with valve areas and transvalvular gradients obtained by echocardiography.[103–107]

CCT also can be used for the evaluation of AR. CCT can elucidate the potential mechanism of AR, including inadequate leaflet coaptation during diastole, leaflet prolapse, cusp perforation, and interposition of an intimal flap in cases of type A aortic dissection. Regurgitant orifice areas measured by CCT have an excellent correlation with AR severity parameters, including vena contracta width and the regurgitant jet/LVOT height ratio obtained by TTE.[108,109]

In patients with MS, ECG-gated, contrast-enhanced CCT can permit assessment of MV morphology in a manner analogous to echocardiography.[110,111] Calcium scoring of the MV is also possible but has lower reproducibility than for the AV.[112] The degree of MV calcification correlates significantly with the severity of MS seen on TTE.[113] MV areas obtained by planimetry also correlate significantly with MS data obtained by TTE.[114]

CCT can accurately diagnose MV prolapse by evaluating cine loops of the MV, and the exact scallops that are prolapsing can be identified. Severity of MR can be assessed by planimetry of the regurgitant orifice, which has been shown to correlate with TEE.[115] Additionally, the presence of calcification of the MV annulus and leaflets can help determine whether the valve can be repaired or needs to be replaced.

CCT can also be used to evaluate tricuspid and pulmonary valve (PV) pathologies. For evaluation of the PV, CCT may be superior to echocardiography; adequate visualization of the PV on echocardiography is usually difficult.

CCT is an excellent modality for the evaluation of PHVs. It has the ability to clearly depict the mechanical prosthesis and to detect any abnormality, including valve thrombosis. This is done by using retrospective scanning and acquiring the entire cardiac cycle to play cine loops and visualize the leaflets through systole and diastole. The mechanical valves that are used currently consist of two disks that open symmetrically (Fig. 2.14). In one study, the valve function of the two-disk prosthesis, including opening and closing angles, was evaluated by CCT and compared with findings from fluoroscopy and echocardiography. CCT correlated significantly with both echocardiographic imaging modalities for these valves.[116] The role of CT in the assessment of bioprosthetic valves is similar because the metallic artifacts often preclude adequate assessment by echocardiography.

CCT is excellent for the diagnosis of paravalvular abscesses. The abscesses appear as paravalvular fluid-filled collections on CCT and are imaged by acquiring a delayed scan approximately 1 minute after contrast is administered. The contrast agent is retained within the abscess even after it washes out of the circulation[117] (Fig. 2.15). A study comparing MDCT with intraoperative TEE for the detection of suspected infective endocarditis and abscesses demonstrated excellent correlation. CCT correctly identified 96% of patients with valvular vegetations and 100% of patients with abscess. Additionally, CCT performed better than TEE in the characterization of abscesses.[118]

CCT, with its excellent spatial and temporal resolution, can also facilitate an accurate assessment of LV function.[119–121] CCT uses actual 3D volumes to calculate LV systolic function. Retrospective scanning is used for functional analysis because the entire cardiac cycle (both systole and diastole) must be acquired. The raw data set is then reconstructed in cardiac phase intervals of 10%, from 0% (early systole) to 90% (late diastole), to derive functional information. Advanced computer workstations allow cine images to be reconstructed and displayed in multiple planes. Segmental wall motion analysis can also be performed using the 17-segment model recommended by the American

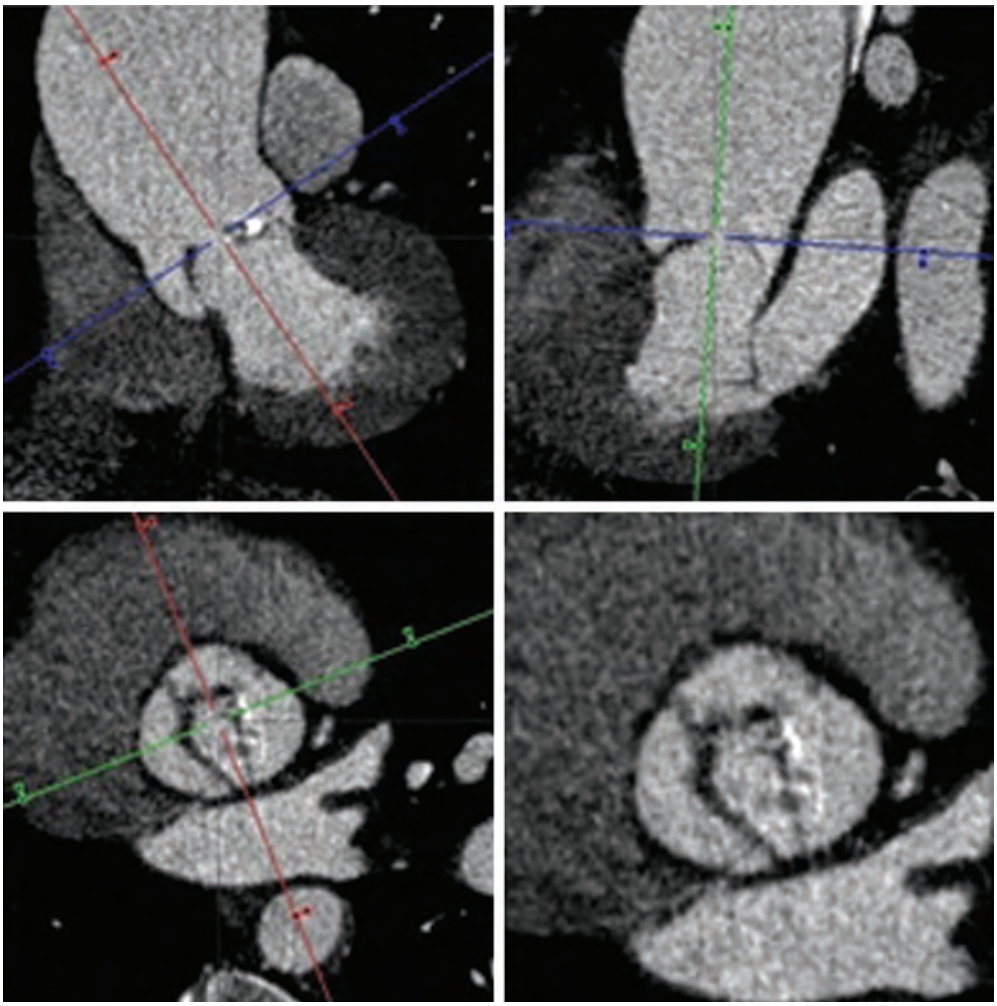

Fig. 2.13 Computed tomographic angiography. (A and B) Orthogonal radiographs display the ascending aortic aneurysm. (C and D) The bicuspid aortic valve (BAV) in short-axis view for evaluation of the valve area by planimetry.

College of Cardiology/American Heart Association.[122] The main limitation to using CCT for LV systolic function assessment is the radiation exposure. Because retrospective ECG gating is required to image the entire cardiac cycle, radiation exposure is relatively high. In comparison, CCT studies performed for other indications require prospective ECG gating and expose the patient to radiation during only 10% to 15% of the cardiac cycle. Therefore, to reduce radiation exposure, LV functional information is not acquired in most clinical scenarios.

Finally, CT is also the test of choice for the diagnosis of pulmonary embolism (Fig. 2.16). MDCT pulmonary angiography has a sensitivity of 83% and a specificity of 96% for the detection of acute pulmonary embolism. Inclusion of a lower-extremity CT venogram has been demonstrated to increase the sensitivity and specificity for pulmonary embolism diagnosis to 90% and 95%, respectively, but at the cost of a much higher level of ionizing radiation exposure.[123] CT pulmonary angiography has largely replaced nuclear ventilation/perfusion imaging (also known as lung scintigraphy or $\dot{V}/\dot{Q}$ scanning) for the diagnosis of pulmonary embolism. The latter has limited use in patients with chronic lung disease, and a high number of $\dot{V}/\dot{Q}$ scans (>72%) are found to have intermediate probability, indicating a 20% to 80% likelihood of pulmonary embolism. However, if CT pulmonary angiography cannot be performed because of increased creatinine level, $\dot{V}/\dot{Q}$ scanning may be used as an alternative (see Chapter 26).

CTA can evaluate signs of pulmonary hypertension by analyzing RV function, RV and RA volumes, RV hypertrophy, enlargement of proximal pulmonary vessels, and pruning of distal ones. ECG-gated CTA is required to assess RV function and volumes.

Cardiovascular Magnetic Resonance Imaging

CMR is a robust and versatile imaging modality. It has the ability to evaluate multiple elements of cardiac status, including function, morphology, flow, tissue characteristics, perfusion, angiography, and metabolism. It can do this because of its unique ability to distinguish morphology without the use of any ionizing radiation by taking advantage of the influence of magnetic fields on the abundance of hydrogen atoms in the human body. Multicontrast CMR uses the intrinsic molecular properties of tissues and three types of contrast: the longitudinal (T1) and transverse (T2) relaxation times in different tissues after an initial radiofrequency pulse, and the concentration of protons in different tissues in the form of water and macromolecules (ie, proton density). These parameters are measured under various pulse sequence protocols to provide information on the structural relationships and processes of interest (eg, tumors, changes in blood flow, metabolism of tissues).

T1-weighted images highlight lipid content; fat depositions appear bright or hyperintense. T2-weighted imaging is used for evaluation of edema[124] and fibrous tissue,[125] both of which appear hyperintense. In dynamic contrast-enhanced CMR, the paramagnetic contrast agent

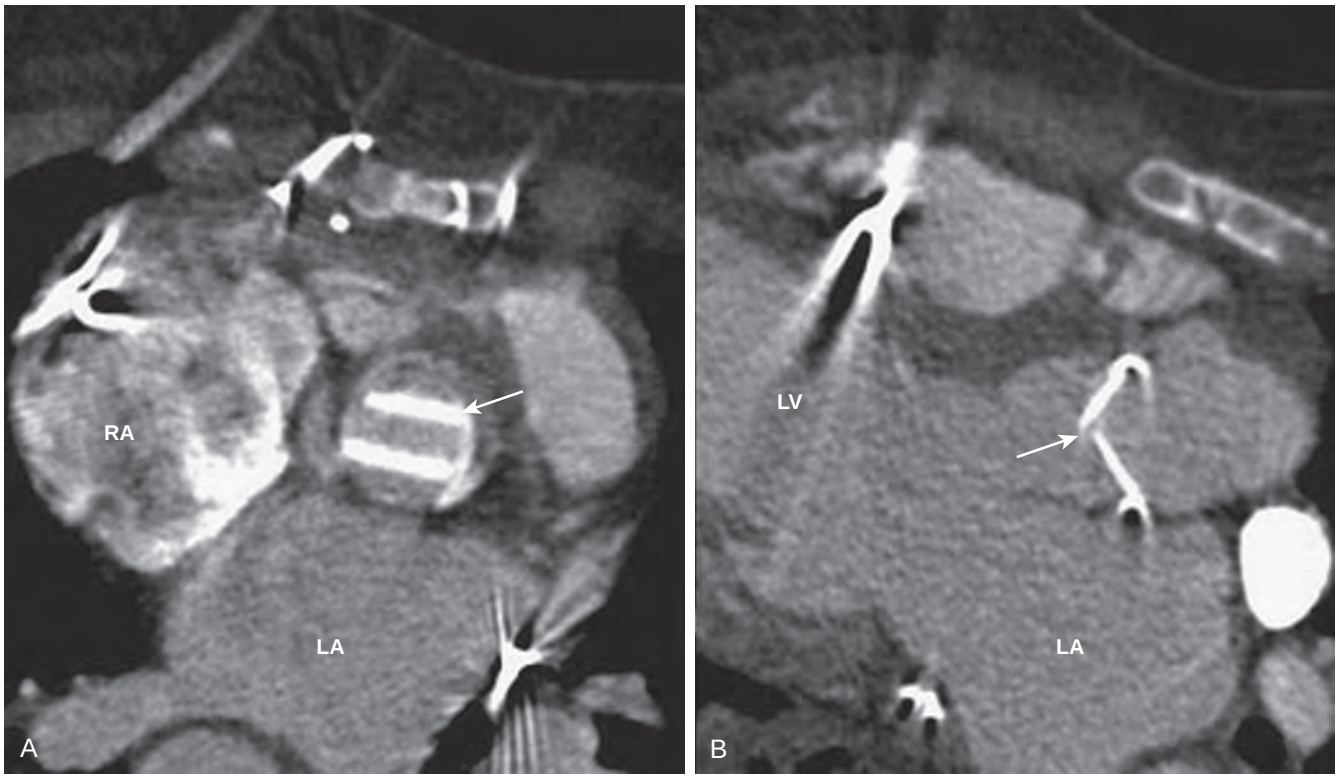

Fig. 2.14 Computed tomography angiography of an aortic mechanical valve *(arrow)* in short-axis view (A) and three-chamber view (B). *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium.

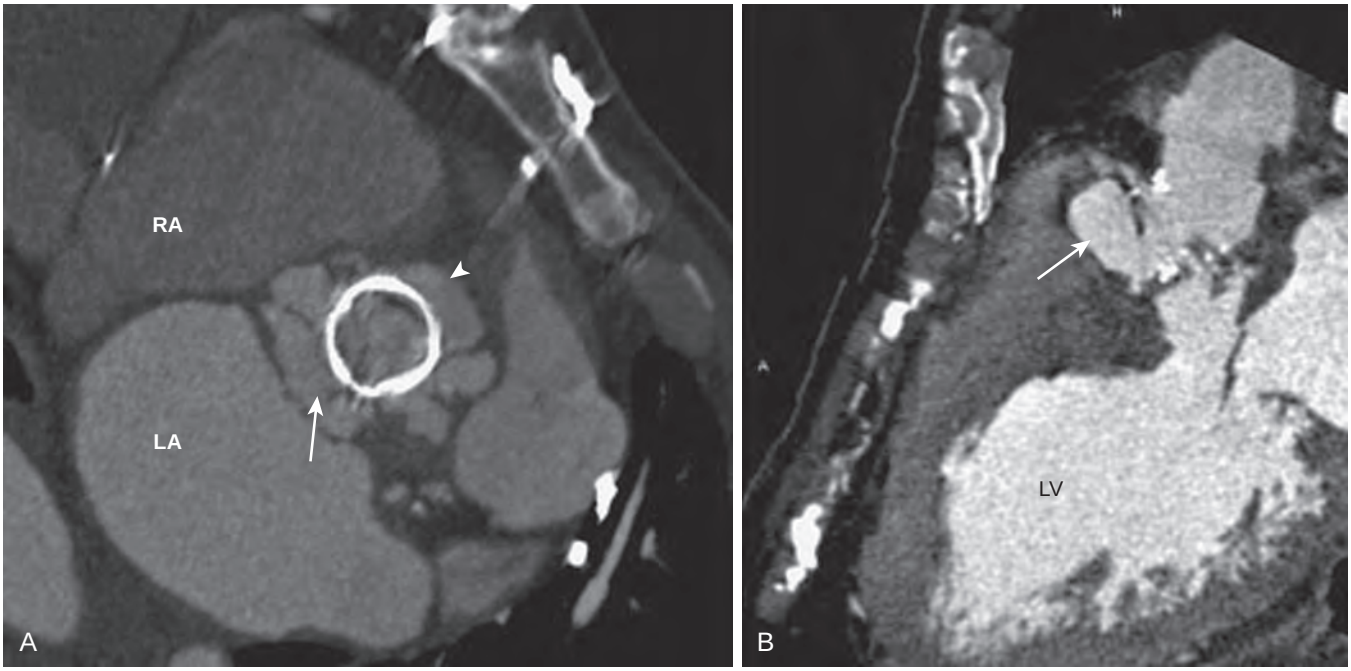

Fig. 2.15 Computed tomography angiography of a bioprosthetic aortic valve *(arrowhead)* with a paravalvular abscess *(arrow)* in the short-axis view (A) and the three-chamber view (B). *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium.

gadolinium is used to enhance the magnetization (T1) of protons in nearby water and create a stronger signal. Additionally, gadolinium contrast permeates through the intercellular space in necrotic or fibrotic myocardium, enabling myocardial scar detection on late gadolinium enhancement.

CMR is considered the gold standard for the quantitative assessment of biventricular volumes, ejection fraction, and mass while also offering excellent reproducibility.[126] CMR has good spatial and temporal resolution, allowing for cine imaging. Typically, a stack of 10 to 14 contiguous 2D slices is acquired and used for LV functional analysis.[127]

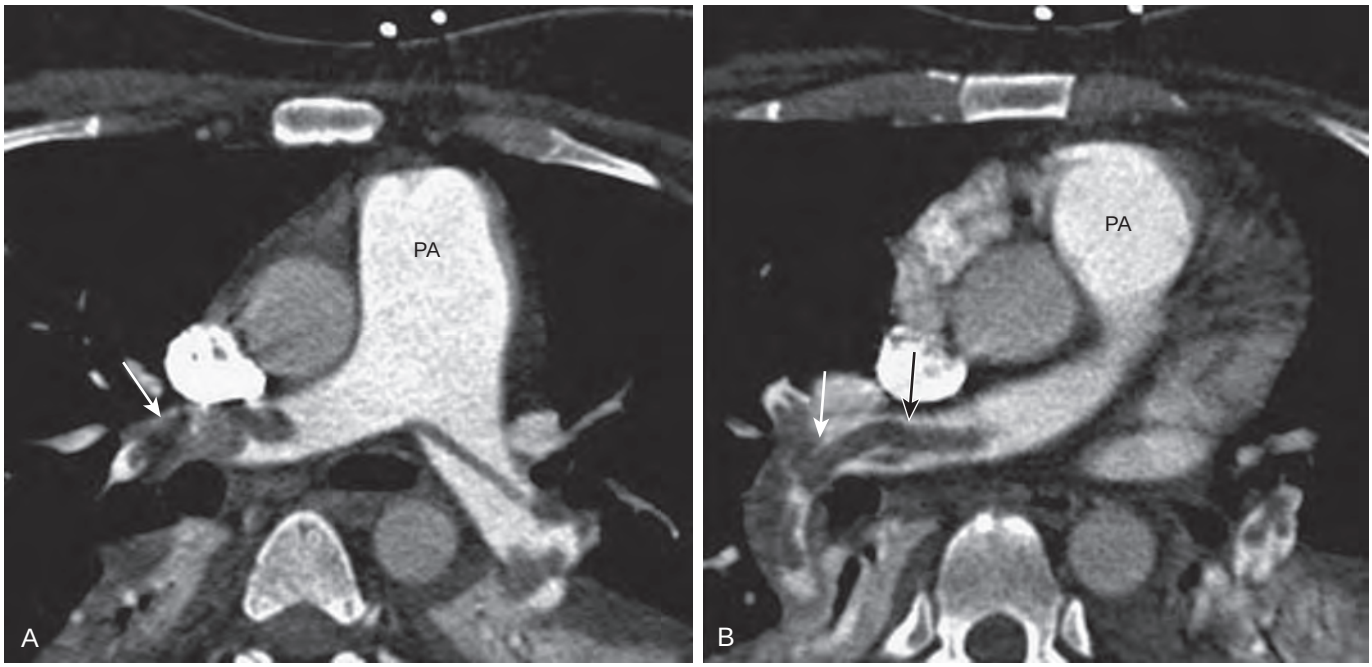

Fig. 2.16 A and B, Computed tomography angiography shows large pulmonary emboli *(arrows)* at two different axial scan levels. *PA,* Pulmonary artery.

The acquisition of each of these images usually requires a breath-hold of at least 10 to 20 seconds. At a computer workstation, the endocardial and epicardial contours of the LV can be traced manually in each short-axis slice at the points of maximal and minimal ventricular dimensions. The software then calculates the volume of the ventricular cavity per slice as the product of the area enclosed within the endocardial contour multiplied by slice thickness. The data are then combined to calculate LV volumes and LVEF. Additionally, cine images may be acquired in the four-, three-, and two-chamber views for LV segmental wall analysis (Fig. 2.17).

Velocity-encoded (phase-contrast) cine-CMR is capable of measuring intraventricular blood flow accurately and can quantify MV and pulmonary vein flows, which are hemodynamic parameters of diastolic function. In patients with amyloidosis, echocardiography and velocity-encoded cine imaging have been shown to correlate significantly in estimations of pulmonary vein systole/diastole ratios, LV filling E/A ratio, and E-wave deceleration time, all of which are diastolic functional indices.[128] In addition to measuring blood flow and velocity through the MV and pulmonary vein, CMR tagging is able to measure myocardial velocities of the walls and the MV, similar to strain rate and tissue Doppler measurements in echocardiography. CMR delayed-enhancement imaging also is used for diagnosis of diastolic dysfunction. The presence and severity of fibrosis on delayed-enhancement imaging correlate significantly with the severity of diastolic dysfunction.[129]

CMR can also be used for perfusion imaging by evaluating the first pass of gadolinium contrast through the myocardium. ECG-gated images are acquired using three LV short-axis slices (base, middle, and apical) and, possibly, a four-chamber image depending on the heart rate. As the contrast agent is injected, it is tracked through the right side of the heart and, subsequently, through the LV cavity and LV myocardium. The assessment of perfusion requires imaging over several consecutive heartbeats, during which time the contrast bolus completes its first pass through the myocardium. Imaging must be completed within a single breath-hold. For stress imaging, first-pass perfusion images are acquired at rest and then again during adenosine or dobutamine infusion. The same three- or four-slice positions are used for both rest and stress images for comparison. Perfusion defects appear as areas of delayed and/or decreased myocardial enhancement and are interpreted visually.

The accuracy of stress MRI perfusion has been validated in several trials. In one trial, which evaluated 147 consecutive women with chest pain or other symptoms suggestive of CAD, MRI perfusion was compared with invasive angiography. The stress perfusion MRI had a sensitivity, specificity, and accuracy of 84%, 88%, and 87%, respectively.[130] Another study comparing stress perfusion MRI with invasive angiography examined 102 subjects. Stress MRI demonstrated a sensitivity of 88% and a specificity of 82% for the diagnosis of significant flow-limiting stenosis.[131] A negative MRI perfusion stress test also confers significant prognostic information: Patients with a normal result have a 3-year event-free survival rate of 99.2%.[132]

CMR has emerged as the gold standard for evaluation of myocardial scarring. Late gadolinium enhancement is used as the marker of myocardial scarring. Gadolinium contrast is injected intravenously, and imaging is performed 5 to 10 minutes later. Gadolinium tends to accumulate extracellularly; however, in normal myocardium, there is insufficient space for gadolinium deposition. In the setting of chronic scar, the volume of gadolinium distribution increases because of an enlarged interstitium in the presence of extensive fibrosis.[133] Hence, normal or viable myocardium appears as nulled or dark, whereas scar appears bright (Fig. 2.18). The advantage of delayed-enhancement imaging is that it allows for assessment of the transmural extent of the scar. The images are analyzed visually, and the thickness of scarring compared with wall thickness is quantified by percentage (ie, none, 1–25%, 26–50%, 51–75%, or 75–100%). A wall segment is considered to be viable and has a high probability of functional recovery if the scar thickness is no more than 50% of the wall thickness.[134] Acquiring LV short-axis images identical to those used for functional assessment allows for side-by-side comparisons of function and delayed-enhancement evaluation.

CMR, like CCT, allows for excellent evaluation of valvular morphology, but it also has advantages over CCT in that blood-flow analysis is feasible and there is no ionizing radiation exposure. CMR allows for differentiation between bicuspid and tricuspid AVs using cine imaging. AS severity can be quantified by using phase-encoded imaging. Similarly to echocardiography, phase-encoded imaging

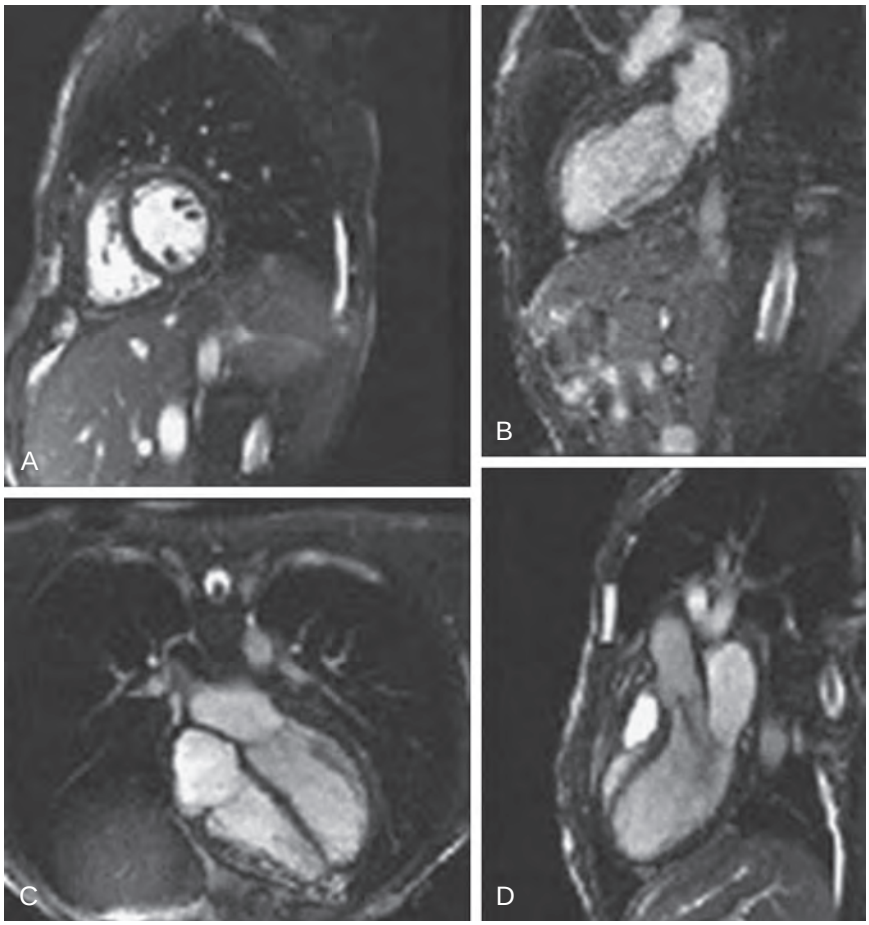

Fig. 2.17 Cardiac magnetic resonance demonstrates short-axis (A), two-chamber (B), four-chamber (C), and three-chamber (D) views.

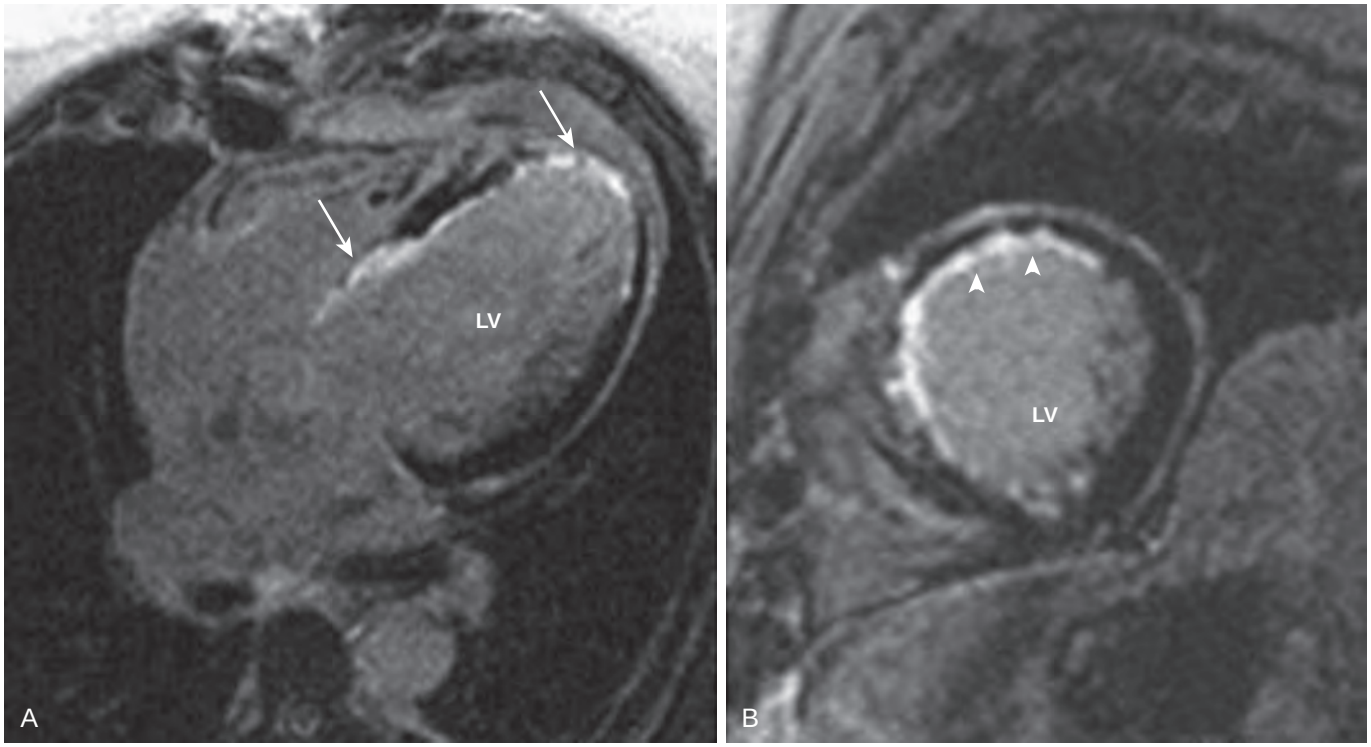

Fig. 2.18 Cardiac magnetic resonance demonstrates delayed-enhancement imaging. A, Four-chamber view with transmural scars *(arrows)* appearing bright in the septum and apex. B, Short-axis view showing partial scar with viability *(arrowheads)* of the anterior wall. *LV*, Left ventricle.

allows for the measurement of velocities through the AV, which can be used to derive mean and peak AV gradients. The effective AV area can also be obtained by measuring the LVOT area and using the continuity equation.[135] Alternatively, AV area can be derived by direct planimetry of the AV using cine images.[136]

CMR phase-encoded imaging can be used additionally for the evaluation of AR. Images are acquired just above the AV, and the velocity and volume of blood per heartbeat are measured in the forward and reverse directions. This allows for measurement of the exact amount of blood exiting the AV, as well as the amount of blood that regurgitates back through the valve. From this, the regurgitant volume and the regurgitant fraction can be determined.

CMR allows for excellent morphologic evaluation of the MV, TV, and PV, and functional assessments can be performed simultaneously with the use of phase-contrast imaging. PHV structure and gradients can also be assessed in the same manner.

CMR is also an excellent tool for the evaluation of aortic aneurysms and dissections. It has no ionizing radiation exposure and is therefore ideal for serial evaluations of the aorta. Similar to CCT, CMR is also ECG gated to compensate for cardiac movement. So-called black-blood imaging provides excellent morphologic information regarding the aortic wall, whereas bright- blood cine sequences provide an alternative anatomic assessment. Delayed-enhancement imaging can also be used to aid in the diagnosis of false lumen thrombosis. 3D images can be acquired and transferred to a workstation for evaluation and measurements, similar to CTA analysis.

CMR is the gold standard for RV functional analysis; however, 64-slice MDCT has been found to have excellent correlation with CMR for RV function and RV volume measurements.[137] Phase-contrast imaging of the pulmonary arteries can be used to evaluate the severity of pulmonary hypertension. This is performed by measuring the velocity of blood in the pulmonary arteries and the elasticity of these vessels.

CMR also can evaluate atherosclerosis[138] in large vessels and is capable of imaging morphology and distinguishing among the various elements of atherosclerotic plaque composition, including fibrous tissue, lipid core, calcification, and hemorrhage.[139]

Invasive Coronary Angiography

Conventional (i.e., invasive) coronary angiography remains the gold standard for evaluation of coronary anatomy and the anatomic extent and severity of CAD. No coronary revascularization procedure can be performed without prior invasive coronary angiography. Additionally, coronary angiography is required to exclude significant CAD in many patients undergoing noncoronary surgery. The indications for coronary angiography before a cardiac surgical procedure include age greater than 40 years for men, postmenopausal status for women, symptoms suggestive of coronary ischemia, LV systolic dysfunction, and the presence of one or more major cardiovascular risk factors.[33] Although CCTA is an alternative in these patients when the pretest probability of CAD is relatively low, conventional coronary angiography is often preferred because of its superior accuracy, its feasibility regardless of heart rate and rhythm, the need for a smaller amount of contrast agent, and noninterference from calcium present in the coronary arteries or the AV.

Vascular Imaging

Atherosclerosis is a generalized disorder and tends to involve multiple vascular beds concurrently. Accordingly, evaluation of noncoronary vascular beds is often required in patients undergoing CABG. Additionally, vascular imaging is required for the evaluation of various nonatherosclerotic disorders, such as deep vein thrombosis, peripheral venous insufficiency, or systemic embolism from an intracardiac mass or thrombus.

Vascular ultrasonography, CTA, and magnetic resonance angiography (MRA) are the primary modalities used for vascular imaging. Typically, ultrasonography is used as the initial screening test, particularly for vessels that are easily accessible to ultrasound imaging. CTA and MRA are used subsequently to further delineate the anatomic extent, severity, and other characteristics of the vascular lesions.

Carotid Artery Stenosis

Stroke is a severely debilitating disease, and extracranial atherosclerotic disease, specifically carotid artery stenosis, is the major cause. Atherosclerotic plaques most often form in the proximal internal carotid artery; however, the common carotid artery is also involved at times. In patients who have had a carotid endarterectomy, the distal common carotid artery is a frequent location for plaque formation. Usually stroke occurs as the first symptom of the disease, and often a carotid bruit is the only sign that can be detected on physical examination. The two main predictors for stroke are previous symptoms (ie, transient ischemic attack or recent stroke) and severity of the stenotic lesions.[140] For this reason, diagnosis is critical for the prevention of stroke. Several imaging modalities can be used for diagnosis. CTA has excellent spatial and contrast resolution for plaque detection and morphology. It is able to detect plaque anywhere in the carotid circulation, and it is used to define the vascular anatomy proximal and distal to a stenotic plaque.

CT, however, is not used as the initial screening test. Vascular ultrasound is easily accessible and can be brought to the patient's bedside. It is inexpensive, risk free, and excellent for the evaluation of carotid anatomy and flow dynamics. B-mode ultrasound is used for the anatomic definition of the arteries; the severity of plaques is evaluated by Doppler ultrasound, which measures the velocity and pressure gradients across lesions. Doppler imaging has limitations, however. It can give false measurements, and anything that decreases the velocity of the blood from the heart to the carotid arteries can interfere with accurate estimation of carotid stenosis. Most commonly, severe LV dysfunction, valvular heart disease, and aortic disease are the problems. Highly calcified plaques also may cause an ultrasound artifact that can interfere with accurate assessment.

MRA is another tool for carotid artery assessment. It is more expensive than the other modalities but is relatively safe and provides detailed information on the anatomy and plaque morphology. Black-blood imaging is a magnetic resonance sequence in which blood appears black and vessel walls are enhanced to highlight and define plaque morphology. Angiography can be performed without gadolinium contrast by using a time-of-flight sequence, which provides high-intensity signals for flowing blood. Additionally, phase contrast imaging can provide information on blood flow velocity pressure across stenotic lesions. In general, CT and MRI are used only in cases in which vascular ultrasonography is limited or the patient requires carotid endarterectomy for carotid artery stenosis.

Renal Artery Stenosis

Renal artery stenosis (RAS) is one of the most common causes of secondary hypertension. It can result from atherosclerosis, fibromuscular dysplasia, or certain systemic disorders. Atherosclerosis is responsible for approximately 90% of all RAS cases.[141,142] Fibromuscular dysplasia is the most common cause in young and middle-aged women, and it is responsible for 10% of all cases. Atherosclerotic RAS is associated with risk factors similar to those for CAD. The clinical presentation can be related to renal or extrarenal complications. Renovascular hypertension induced by RAS can cause renal damage, renal atrophy, and increased creatinine levels. Extrarenal effects range from angina and myocardial infarction to hypertension-induced stroke and flash pulmonary edema.

The initial diagnostic tool is vascular ultrasonography. Renal artery anatomy and flow velocities can be accurately analyzed with the use of B-mode and Doppler ultrasound. Ultrasonography is also a good tool to monitor the renal artery after percutaneous or surgical intervention. Common limitations of ultrasonography for visualization of

renal arteries are patient obesity and gas in the gastrointestinal tract, which affect 15% to 20% of all studies. Additionally, mild stenosis and accessory renal arteries may be completely missed.

CTA of the renal arteries has the same advantages as in coronary evaluation. Data can be reconstructed and visualized on workstations that allow 2D analysis of the renal arteries in any desired plane. One of the main disadvantages is that patients with RAS often have abnormal renal function, in which case iodine contrast is contraindicated.

MRA is an excellent tool for the diagnosis of RAS. With multicontrast and contrast-enhanced magnetic resonance, the sensitivity and specificity for the diagnosis of RAS are 100% and 99%, respectively.[143–150] Anatomic and perfusion evaluations of the kidneys can be performed simultaneously.

Peripheral Arterial Disease

Peripheral arterial disease (PAD) simply means noncoronary atherosclerosis. However, cerebrovascular and renovascular diseases are generally considered separate entities, and the term *PAD* is usually reserved for lower extremity disease.

Because atherosclerosis is a systemic disease, PAD is highly prevalent in patients with CAD, and vice versa. A history of cigarette smoking has a particularly strong association with PAD, conferring a two to three times greater risk for PAD than for CAD.[151] Eighty percent of all patients with PAD are active smokers or have smoked cigarettes in the past.[152,153] In the PARTNERS study, almost 7000 patients were evaluated for the prevalence of PAD using ankle-brachial index as the diagnostic modality. The study included subjects older than 70 years of age and subjects between the ages of 50 and 69 with either a history of tobacco smoking or diabetes. PAD was found in 29% of this population.[154] PAD most often is asymptomatic, with a relatively small percentage of patients experiencing intermittent claudication.[155–157]

Vascular ultrasound is typically the first modality used once PAD has been diagnosed or suspected clinically. It has very high sensitivity and specificity (90% and 95%, respectively) for detection of greater than 50% stenosis from the iliac artery to the popliteal artery.

CTA and MRA are the preferred modalities when percutaneous or surgical intervention is planned. CTA, because of its excellent spatial resolution, has a sensitivity greater than 92.9% and a specificity greater than 96.2% for detection of obstructions greater than 50%.[158,159] MRA also is accurate for the detection of PAD (Fig. 2.19). Its sensitivity and specificity are between 90% and 100% for detection of greater than 50% stenosis when compared with conventional angiography.[160] Compared with CTA, MRA demonstrates greater interobserver agreement.[161,162]

Peripheral Venous Thrombosis and Venous Insufficiency

Venous thromboembolism is a life-threatening complication that commonly occurs in patients undergoing cardiac and major noncardiac surgeries. In the United States, 2.5 million cases of deep vein thrombosis (DVT) occur annually, and it is estimated that approximately 25% of all untreated DVTs embolize and cause pulmonary embolism. Conversely, almost 80% of the cases of pulmonary embolism result from lower extremity DVTs. Vascular ultrasonography is the imaging modality of choice for the diagnosis of DVT. Its sensitivity and specificity for the detection of proximal lower extremity DVTs are 90.6% and 94.6%, respectively.[138,163] MDCT, which is the test of choice for diagnosis of pulmonary embolism, can also be used to perform a lower extremity CT venogram. Although this use enhances the diagnostic accuracy, it is accompanied by a much higher level of exposure to ionizing radiation[123] (see Chapter 26).

Chronic venous insufficiency occurs more often with increasing age and also has a greater incidence in women than in men. Common clinical symptoms include limb pain, swelling, stasis skin changes, itching, restless legs, nocturnal leg cramps, and ulceration. Most cases of deep venous disease have either a nonthrombotic or a postthrombotic cause. Both types can involve reflux, obstruction, or both.

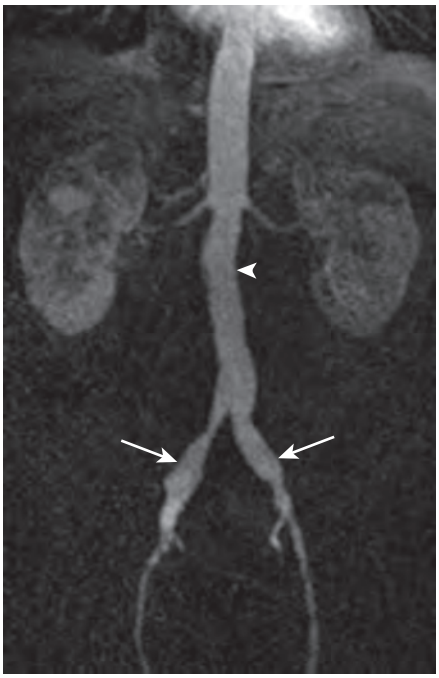

Fig. 2.19 Magnetic resonance angiography demonstrates the abdominal aorta *(arrowhead)* and common iliac arteries *(arrows)* with severe atherosclerosis.

Vascular inflammation, occurring most notably by way of several cytokine mechanisms, causes tissue damage and results in chronic venous insufficiency.[164] Vascular ultrasound is commonly used to diagnose venous insufficiency in the lower limbs, and it can accurately detect the site and severity of venous reflux, incompetent venous perforators, and obstructive changes resulting from previous DVT.

Summary

At least some form of cardiac imaging is essential at almost every step in the management of patients undergoing cardiac surgery. Echocardiography, because of its unmatched attributes, remains the preferred modality for this purpose. Invasive coronary angiography, nuclear scintigraphy, CCT, and CMR are other excellent modalities that are employed for specific clinical indications or when the information obtained from echocardiography is insufficient or equivocal. It is important for anesthesiologists to understand the advantages and limitations of all these imaging modalities and to use them to complement one another. For the overall benefit of the patient, the clinician must take into account the accuracy, cost, and time required for each modality, as well as potential radiation exposures (the long-term effects of which are still not clearly understood).

Cardiac Catheterization Laboratory: Diagnostic and Therapeutic Procedures in the Adult Patient

THERESA A. GELZINIS, MD | MARK KOZAK, MD | CHARLES E. CHAMBERS, MD | JOHN SCHINDLER, MD

KEY POINTS

1. The cardiac catheterization laboratory has evolved from a purely diagnostic facility to a therapeutic one in which many facets of cardiovascular disease can be effectively modified or treated. Despite improvements in equipment, the quality of the procedure depends on well-trained and experienced physicians with proper certification, adequate procedural volume, and personnel committed to the continuous quality improvement process.
2. Guidelines for diagnostic cardiac catheterization have established indications, contraindications, and criteria to identify high-risk patients. Careful evaluation of the patient before the procedure is critical to minimize risks.
3. Interventional cardiology began in the late 1970s as balloon angioplasty, with a success rate of 80% and emergent coronary artery bypass graft surgery (CABG) rates of 3% to 5%. Although current success rates exceed 95%, with CABG rates of less than 1%, failed percutaneous coronary intervention (PCI) presents a challenge for the anesthesiologist because of hemodynamic problems, concomitant medications, and the underlying cardiac disease.
4. Since the introduction of drug-eluting stents (DESs), acute closure due to coronary dissection has diminished significantly, and restenosis rates have fallen precipitously.
5. The first-generation DESs (Cypher, Cordis, Miami Lakes, FL, and Taxus, Boston Scientific, Marlborough, MA) were extremely effective at reducing in-stent restenosis when compared with bare metal stents (BMSs). However, DESs have demonstrated higher rates of late stent thrombosis (LST), especially in the setting of premature discontinuation of dual antiplatelet therapy. Second-generation DESs (Xience, Abbott Vascular, Abbott Park, IL, and Resolute, Medtronic, Minneapolis, MN) have LST rates comparable to those of BMSs and therefore are the preferred stent type.
6. As a treatment strategy for patients with acute myocardial infarction, primary PCI is preferred to the administration of thrombolytic therapy because of its higher rates of infarct artery patency and TIMI grade 3 flow and lower rates of recurrent ischemia, reinfarction, intracranial hemorrhage, and death.
7. In the United States, increasing numbers of diagnostic coronary angiograms and PCIs are performed from a transradial approach because of lower vascular complication rates and patient preference for this approach compared with the more traditional transfemoral approach.
8. In multivessel coronary artery disease, an angiographic SYNTAX score should be calculated to assist with decision making regarding percutaneous versus surgical revascularization. A multidisciplinary heart team meeting (including a cardiologist, a cardiovascular surgeon, and, occasionally, an anesthesiologist) should then convene to discuss and optimize patient care by providing an individualized treatment recommendation.
9. Extensive thrombus, heavy calcification, degenerated saphenous vein graft, and chronic total occlusion present specific challenges in PCI. Various specialty devices have been developed to address these problems and have had varying degrees of success.
10. Acute thrombotic PCI complications can usually be overcome with more aggressive antithrombotic and antiplatelet pharmacotherapy. These medications can complicate the management of an unstable patient who requires transfer for bailout CABG. Appropriate understanding of the pharmacokinetics is essential for the cardiac anesthesiologist.
11. The reach of the interventional cardiologist has extended beyond coronary vessels to include closure of congenital defects and percutaneous treatment of valvular disease. These complex procedures are more likely to require general anesthesia but also can be effectively managed with monitored anesthesia care or regional anesthesia techniques.

The cardiac catheterization laboratory (CCL) began as a diagnostic unit. In the 1980s, percutaneous transluminal coronary angioplasty (PTCA) started the gradual shift to therapeutic procedures. Concomitantly, noninvasive modalities of echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI) improved, and in some cases obviated, the need for diagnostic catheterization studies. Some experts predicted the imminent demise of diagnostic cardiac catheterization studies.[1,2] The promise of PTCA led to various atherectomy and aspiration devices and stents, with or without drug elution. The evolution of the CCL has continued, with many laboratories commonly performing procedures for the diagnosis and treatment of peripheral and cerebral vascular disease.[3] In addition, there has been an expansion of the treatment of noncoronary forms of cardiac disease in the CCL. Closure devices for patent foramen ovale (PFO), atrial septal defect (ASD), and ventricular septal defect (VSD) are emerging as alternatives to cardiac surgery. Many high-risk patients with valvular disease are now being treated with percutaneous valve repair and replacement, decreasing the incidence of balloon valvuloplasty. A variety of devices for circulatory support are available for implantation by percutaneous methods. To accommodate these new procedures, hybrid laboratories have been created to allow a team of cardiologists, cardiac surgeons, and anesthesiologists to safely perform these new percutaneous techniques (see Chapter 27).

The first cardiac catheterization was performed in 1929 by Dr. Werner Forssman, a surgical resident in the Auguste Viktoria Hospital at Eberswald, near Berlin, in an attempt to identify a safer route to administer epinephrine directly into the heart during intraoperative cardiac arrests. Forssmann asked a colleague to place a catheter in his arm. The catheter was successfully passed to his axilla, at which time Forssmann, under radioscopic guidance and using a mirror, advanced the catheter into his own right atrium (RA). Forssmann subsequently practiced in a small town in the Rhine Valley, but eventually he shared the Nobel Prize in 1956 for this procedure.[4]

The world quickly acknowledged Forssmann's accomplishments[5] with right-sided heart catheterization (RHC); in 1930, Klein[5a] employed RHC to measure cardiac output (CO) using the Fick method. In 1941, André Cournand published his work on RHC in the *Proceedings of the Society of Experimental Biology and Medicine*.[5b] Dexter and colleagues first reported cardiac catheterization in the pediatric population in 1947, and they were the first to document correlation between the pulmonary capillary wedge pressure (PCWP) and left atrial pressure (LAP).[5c] Zimmerman[5d] and Limon-Lason and Bouchard[5e] first performed arterial retrograde heart catheterization in 1950, and Seldinger[5f] developed his percutaneous approach in 1953. Ross[6] and Cope developed transseptal catheterization in 1959. The first coronary angiogram was inadvertently performed by Mason Sones in October 1958. While performing angiography of the aorta, the catheter moved during placement of the x-ray equipment, and Dr. Sones injected 50 mL of contrast into the patient's right coronary artery (RCA). Expecting cardiac arrest from this amount of contrast and with no external defibrillator available, Sones jumped to his feet and grabbed a scalpel to perform a thoracotomy. Fortunately, asystole lasted only 5 seconds, the patient awoke perplexed by the commotion, and this incident led to the birth of selective coronary angiography.[7]

Diagnostic catheterization led to interventional therapy in 1977, when Andreas Gruentzig performed the first PTCA.[6a] Refinements in both diagnostic and interventional equipment occurred over the next 15 to 20 years, but the focus remained on coronary artery disease (CAD). More recently, cardiologists have expanded into the diagnosis and treatment of peripheral vascular disease and treatment of structural heart disease. Currently, several transcatheter heart valves have been approved by the US Food and Drug Administration (FDA) and are available for the treatment of aortic stenosis. Transapically inserted heart valves are being developed for the treatment of mitral valve (MV) disease and percutaneously deliverable clips for mitral regurgitation (MR).

Hybrid coronary artery bypass procedures are performed in some institutions, with internal mammary artery grafting to the left anterior descending (LAD) coronary artery via a limited incision, with or without robotic guidance, and with percutaneous treatment of other vessels.[8] Many newer CCLs feature access, ventilation, and lighting designed for these multidisciplinary procedures. Because anesthesiologists will work in these suites, it seems intuitive that they should participate in their design.

This brief historical background serves as an introduction to the discussion of diagnostic and therapeutic procedures in the adult CCL.[9] The reader must realize the dynamic nature of this field. In the past, up to 5% of percutaneous coronary interventions (PCIs) failed, but most centers now report procedural failure rates of less than 1%. Simultaneously, the impact on the anesthesiologist has changed. The high complication rates of years past required holding an operating room (OR) open for all PCIs, but complication rates are now so low that some procedures are performed at hospitals without on-site surgical backup. Despite the lower rate of adverse events, the anesthesiologist is occasionally confronted with a patient who is in need of emergent surgical revascularization. The anesthesiologist may find the information in this chapter useful in planning the preoperative management of these cardiac or noncardiac surgical procedures based on diagnostic information obtained in the CCL. When anesthesia is required for procedures in the hybrid laboratory or the CCL, this chapter will help the anesthesiologist, in collaboration with the cardiology and cardiac surgery team, to provide safe anesthesia care for these challenging patients.

Catheterization Laboratory Facilities: Radiation Safety and Image Acquisition

Room Setup, Design, and Equipment

The setup and design for the hybrid cardiac catheterization OR is covered separately in Chapter 27. This section reviews the importance of radiation safety to prevent the adverse effects of radiation, including dermal necrosis and cellular mutation, that lead to brain, skin, and thyroid cancers; birth defects; and infertility.[10] For the individual laboratory, the monitoring suite is separated from the x-ray imaging equipment by leaded glass and lead-lined walls. Voice communication from the central area is maintained to coordinate tasks performed centrally (eg, monitoring and recording data, determining the activated coagulation time [ACT]), thereby minimizing staff radiation exposure.[11] A representative CCL is shown in Fig. 3.1.

Fig. 3.1 A representative cardiac catheterization laboratory. The x-ray tube is located below the table, and the flat-panel detector is located above the table, both mounted on a C arm. Shielding, image monitors, and emergency equipment can also be seen.

Radiation Safety

Radiation safety must be considered in all aspects of the CCL, from room design to everyday practice.[12] Lead-lined walls, lead-glass partitions, and mobile lead shielding, including aprons and thyroid shields, are useful in limiting the daily exposure of personnel.

A thermoluminescent film badge, also known as a dosimeter, must be worn at all times by any persons exposed to the x-ray equipment, and levels must be monitored regularly. In the past, anesthesiologists responding to emergencies in the CCL were exposed to radiation only briefly and infrequently, if at all. With the requirement for the presence of an anesthesiologist in many of the newer multidisciplinary procedures, the inclusion of anesthesiologists in formal monitoring programs may be appropriate. Radiation levels should not exceed 5 rem (0.05 Sv) per calendar year, 1.25 rem (0.0125 Sv) per calendar quarter, or approximately 100 mrem (0.001 Sv) per week.[13] Operator and staff radiation exposures have been assessed for years, but only recently has the issue of radiation toxicity to the patient gained attention. With long PCI and electrophysiology procedures, radiation injury to the patient and the need to monitor dose delivery to the patient are now appreciated.[14] Contemporary equipment estimates and records patient radiation doses. Lead aprons and thyroid shields are mandatory for all personnel in the procedure suite. Although they are cumbersome, these shields protect the reproductive glands and about 80% of the active bone marrow.[12] Eye shielding also should be considered for those working in close proximity to the x-ray source.[15]

It is not within the scope of this chapter to cover all aspects of radiation safety in cardiovascular imaging. For a more complete review of this topic, the reader is referred to a consensus document published in 2014 by the American College of Cardiology (ACC), American Heart Association (AHA), Heart Rhythm Society, and Society for Cardiovascular Angiography and Interventions (SCAI).[16]

Nevertheless, several features of radiation safety require a brief review. The duration of the procedure increases the exposure. Cine imaging (ie, making a permanent recording) requires about 10 times the radiation exposure of fluoroscopy. Although newer equipment may narrow this ratio and provide a permanent recording of the fluoroscopic images, limiting cine imaging is a way to decrease exposure. Proximity to the x-ray tube, which is usually situated below the patient, is directly related to exposure. The bulk of the radiation exposure to medical personnel is the result of scattered x-rays coming from the patient. When working in an environment where x-rays are in use, clinicians should always remember a simple rule: The amount of radiation exposure is related to the square of the distance from the source. No body part should ever be placed in the imaging field when fluoroscopy or cine imaging is being performed. Finally, the cardiologist can decrease x-ray scatter, and thereby decrease personnel exposure, by placing the imaging equipment as close to the patient as possible.[17]

The anesthesiologist should recognize x-ray use in the CCL and take appropriate precautions. For multidisciplinary procedures, this requires some attention to the location of equipment and the use of portable shields. Most lead aprons have openings in the back and protect best when the wearer is facing the source of the x-rays. Emergent situations, such as when the anesthesiologist is asked to resuscitate a critically ill patient during a procedure, may require the cardiologist to use fluoroscopic imaging while the anesthesiologist is within feet of the x-ray tube or even straddling it. Aprons and thyroid shields are clearly necessary to protect the anesthesiologist while at the head of the patient, and a lead thickness of 0.5 mm will stop 96% of the x-ray beam scatter.[12] The use of x-rays can almost always be interrupted to protect personnel, although needed patient care may require the interruptions to be brief. A collaborative effort between the cardiologist and the anesthesiologist is necessary, and communication is essential. The goal of the anesthesiologist should be to treat the patient while protecting oneself and others from excessive radiation exposure.[16]

Filmless Imaging and Flat-Panel Technology

Essentially all modern laboratories use filmless or digital recording. Radiation is needed to generate an image, and recordings are made at various frequencies (frames per second). The best image quality for film is obtained with frame rates greater than 30 per second. Digital imaging decreases radiation exposure in the CCL by allowing for image acquisition at lower frame rates (ie, 15 frames/second) while still maintaining excellent image quality. Cost savings have been achieved by elimination of the need to purchase, process, and store film. Film imaging was an analog technique, and a single recording was made. Copies rarely were made because of the cost and degradation of image quality. If films were loaned, lost, or misplaced, the study could not be reviewed. With the current digital technologies, images are archived on a central server and can be viewed at remote workstations.[18] An unlimited number of copies can be made at low cost and with no loss of image quality.

The evolution of angiographic recording has extended beyond recording formats. Charged-couple device cameras and flat-panel detectors are now ubiquitous in modern laboratories.[19] X-rays are generated from below the patient by the x-ray tube, pass through the patient, and are captured by the detector. In this system, the x-rays are both acquired and digitally processed by the flat panel.[16] The flat panel is above the patient (analogous to the image intensifier). This current generation of imaging in the CCL delivers improved image quality because the dynamic range of the image (ie, the number of shades of gray) is improved. This type of system has the potential to decrease radiation exposure by providing immediate feedback to the x-ray generator. In laboratories designed for peripheral vascular work, including many of the hybrid ones, the flat panel above the patient can be quite large and may limit access to the patient's face.

Facility Caseload

All catheterization facilities must maintain appropriate patient volume to ensure competence. ACC/AHA guidelines previously recommended that a minimum of 300 adult diagnostic cases be performed to provide adequate care,[13] including a minimum of 200 PCIs.[20–22] However, a 2012 update set no diagnostic minimums and recommended at least 75 PCIs per year. If the individual physician's annual volume is less than 75 cases, a quality assurance committee should perform an annual review of 15% of cases (randomly chosen) to ensure continued quality.[13] Facilities performing PCIs without in-house surgical backup are becoming more prevalent.[23–25] National guidelines now support the performance of both elective and emergent PCI in centers without cardiac surgical capabilities, giving elective PCI a class IIb rating and primary PCI a class IIa rating.[25–27] Although emergent coronary artery bypass graft surgery (CABG) is infrequent in the stent era, a well-established agreement must be in place with an on-site surgical hospital to minimize treatment delays when emergent CABG is required.

Primary PCI for acute myocardial infarction (AMI) is the accepted standard treatment for patients who are in cardiogenic shock, those who have contraindications to thrombolytic therapy, and those who have not responded to thrombolytic therapy. It is the preferred therapy for patients who present late in the course of an infarction, and it is probably the optimal treatment for all myocardial infarctions (MIs), provided that it can be performed in a timely manner.[26–28]

Although minimum volumes are recommended, no regulatory controls currently exist. In a study of volume-outcome relationships published for New York state, a clear inverse relation was identified between CCL caseload and rates of procedural mortality and CABG.[29] In a nationwide study of Medicare patients, low-volume centers had a 30-day mortality rate of 4.2%, whereas in high-volume centers the mortality rate was 2.7%.[30] However, other reports suggest that activity level is an incomplete surrogate for quality. In other words, high-volume operators and hospitals are not necessarily of high quality, and low-volume operators and hospitals are not necessarily of low quality. Centers of excellence, based on physician and facility quality

and the spectrum of overall services provided, may well be the model for cardiovascular care in the future.[31]

Patient Selection for Catheterization

Indications for Cardiac Catheterization in the Adult Patient

Box 3.1 lists indications for cardiac catheterization. The major indication is for the detection of CAD; the remaining indications are focused on hemodynamic assessment to evaluate valvular heart disease, pulmonary hypertension, and cardiomyopathies.[32] With respect to CAD, approximately 20% of the adult population studied will be found to have normal coronary arteries.[13] This reflects limitations in the specificity of the clinical criteria and noninvasive tests used to select patients for catheterization (see Chapters 1 and 2). Despite continued improvements in noninvasive assessment, coronary angiography is currently considered the gold standard for diagnosing and defining the extent of CAD. With advances in MRI and multislice CT scanning, the next decade may well see a further evolution of the CCL to an interventional suite with fewer diagnostic responsibilities.[1]

Patient Evaluation Before Cardiac Catheterization

Diagnostic cardiac catheterization in the 21st century universally is considered an outpatient procedure except for the high-risk patient. Therefore, the precatheterization evaluation is essential for quality patient care. Evaluation before cardiac catheterization includes diagnostic tests that are necessary to identify high-risk patients. An electrocardiogram (ECG) must be obtained for all patients shortly before catheterization. Necessary laboratory studies before catheterization include an appropriate coagulation profile (prothrombin time [PT], partial thromboplastin time [PTT], and platelet count), hemoglobin, and hematocrit. Electrolytes are obtained together with baseline blood urea nitrogen and creatinine (Cr) values to assess renal function. Recent guidelines express a preference for estimation of the glomerular filtration rate (GFR) using accepted formulas, and many clinical laboratories now report this value routinely.[32a] Urinalysis and chest radiography may provide useful information but are no longer routinely obtained by all operators. Prior catheterization reports should be available. If the patient had prior PCI or CABG surgery, anatomic information concerning stent or bypass placement also must be available.

The precatheterization history is important to determine the risk profile for the patient, including previous exposure to contrast dye and the reaction to it, if any. If a true contrast reaction (eg, rash, breathing difficulties, angioedema) occurred with prior contrast exposure, premedication with glucocorticoids and diphenhydramine is required before the patient arrives at the CCL. Nonionic contrast dyes can be administered to patients with a history of anaphylactoid reactions to the ionic contrast dyes. Diabetes mellitus (DM), preexisting chronic kidney disease (CKD), and heart failure are widely accepted risk factors for contrast-induced nephropathy (CIN). A Cr level greater than 1.5 mg/dL, particularly in a patient with DM, or a GFR of less than 60 mL/min should prompt special precautions.[33] If the patient has stage IV CKD with a GFR of less than 30 mL/min, the study may need to be canceled or delayed. Nephrotoxicity is dependent on the amount of dye reaching the renal arteries and can be reduced by hydrating the patient before the procedure, avoiding high-osmolar contrast dyes and nephrotoxic medications (eg, nonsteroidal antiinflammatory drugs), limiting the amount of dye administered, and maintaining an interval of 72 hours between exposures if multiple studies are required.[34] These measures may reduce the risk of transient worsening of renal dysfunction and the need for permanent renal replacement therapy.[12] In patients at risk for nephrotoxicity, validated equations are used to calculate the maximal allowable contrast dose for any given procedure.[35]

A review of the noninvasive cardiac evaluation before cardiac catheterization allows the cardiologist to formulate objectives for the procedure. In patients with hypotension and severely impaired functional capacity on exercise stress testing, left main coronary artery (LM) lesions or high-grade proximal LAD stenoses should be suspected. Knowing the location of perfusion or wall-motion abnormalities in a particular coronary distribution, the cardiologist must specifically identify or exclude coronary lesions in these areas during the procedure. In patients with echocardiographic evidence of a left ventricular

BOX 3.1 INDICATIONS FOR DIAGNOSTIC CATHETERIZATION IN THE ADULT PATIENT

Coronary Artery Disease
Symptoms
Unstable angina
Postinfarction angina
Angina refractory to medications
Typical chest pain with negative diagnostic testing
History of sudden death

Diagnostic Testing
Strongly positive exercise tolerance test
Early positive, ischemia in ≥5 leads, hypotension, ischemia present for ≥6 min of recovery
Positive exercise testing after myocardial infarction
Strongly positive nuclear myocardial perfusion test
Increased lung uptake or ventricular dilation after stress
Large single or multiple areas of ischemic myocardium
Strongly positive stress echocardiographic study
Decrease in overall ejection fraction or ventricular dilation with stress
Large single area or multiple or large areas of new wall motion abnormalities

Valvular Disease
Symptoms
Aortic stenosis with syncope, chest pain, or congestive heart failure
Aortic insufficiency with progressive heart failure
Mitral insufficiency or stenosis with progressive congestive heart failure symptoms
Acute orthopnea/pulmonary edema after infarction with suspected acute mitral insufficiency

Diagnostic Testing
Progressive resting left ventricular dysfunction with regurgitant lesion
Decreasing left ventricular function and/or chamber dilation with exercise

Adult Congenital Heart Disease
Atrial Septal Defect
Age >50 y with evidence of coronary artery disease
Septum primum or sinus venosus defect

Ventricular Septal Defect
Catheterization for definition of coronary anatomy
Coarctation of the aorta
Detection of collaterals
Coronary arteriography if increased age and/or risk factors are present

Other
Acute myocardial infarction therapy—consider primary percutaneous coronary intervention
Mechanical complication after infarction
Malignant cardiac arrhythmias
Cardiac transplantation
Pretransplantation donor evaluation
Posttransplantation annual coronary artery graft rejection evaluation
Unexplained congestive heart failure
Research studies with institutional review board review and patient consent

(LV) thrombus or left-sided endocarditis, left ventriculography may not be performed.

Patient medications may need to be altered in preparation for a heart catheterization. On the morning of the catheterization, antianginal and antihypertensive medications are routinely continued, whereas diuretic therapy is withheld. Diabetic patients are scheduled early, if possible, because the procedure requires NPO status. No short-acting insulin is given, and half of the long-acting insulin dose is usually administered. Patients on oral anticoagulation should stop warfarin (Coumadin) for 48 to 72 hours before catheterization to target an international normalized ratio (INR) of 1.8 or less if femoral artery access is used. Radial artery access is considered an option without discontinuation of warfarin.[36] For patients who are managed with non–vitamin K antagonist novel oral anticoagulant (NOAC) therapy, the dose may need to be withheld for 24 to 48 hours depending on renal function and the bleeding risk of the procedure.[37,38] In patients who are anticoagulated because of mechanical prosthetic valves, the best management may be intravenous (IV) heparin before and after the procedure, when the warfarin effect is not therapeutic.[39] Low-molecular-weight heparins (LMWHs) are used in this setting, but this use is controversial. LMWHs vary in their duration of action, and their effect cannot be monitored through use of the activated PTT. Special dosing is required for certain patient groups including the elderly, those with an elevated body mass index, and those with CKD.[40] The differing pharmacokinetics need to be considered, particularly with regard to hemostasis at the vascular access site. IV heparin is routinely discontinued 1 to 2 hours before catheterization, except in patients with unstable angina. Therapy with aspirin or P2Y12 platelet inhibitors or both is almost always continued for patients with angina for those with prior CABG.[41]

Contraindications, High-Risk Patients, and Postcatheterization Care

Despite advances in facilities, equipment, techniques, and personnel, the precatheterization evaluation must identify those patients who are at increased risk for complications. In a modern facility with an experienced staff, the only absolute contraindication is refusal by a competent patient or an incompetent patient's inability to provide informed consent. Relative contraindications are listed in Box 3.2; the primary operator is responsible for this assessment.[13]

Box 3.3 lists criteria for identifying high-risk patients before catheterization. Procedural alterations may be based on this assessment, such as avoidance of crossing an aortic valve or performing ventriculography.[42] In any case, the determination as to whether a patient is a candidate for catheterization must be based on risk versus benefit for each individual patient.

With the increased emphasis on outpatient procedures in medicine today, outpatient diagnostic catheterization is becoming the standard of care for stable patients. Unstable and postinfarction patients are already hospitalized, and catheterization usually is performed before discharge. Planned PCI usually requires hospital admission; however, same-day discharge in carefully selected patients is gaining momentum because it appears to be safe, especially when radial artery access has been used.[43] Even when outpatient catheterization is planned, assessment of the patient after catheterization is required. Some patients, particularly those with LM CAD, critical aortic stenosis, uncontrolled hypertension, significant LV dysfunction with congestive heart failure, or significant postprocedural complications such as a large femoral access site hematoma, will require hospital admission.[13]

In addition to the high-risk cardiac patient, patients with renal insufficiency may require overnight hydration before and after catheterization. Patients on chronic anticoagulation with warfarin require measurement of their coagulation status and may require heparinization before and/or after the procedure. Day-of-procedure ambulation and discharge are planned for patients undergoing outpatient catheterization.[34] Radial artery catheterization is increasing in popularity and is associated with a reduction of vascular complications.[36,44] For a variety of reasons, the sheaths used for radial access are not suitable for long-term monitoring purposes and should be removed at the conclusion of the procedure. For patients undergoing catheterization via the percutaneous femoral approach, the use of smaller catheters (4 Fr) for the arterial puncture may hasten ambulation.[45] Alternatively, a variety of vascular closure devices are approved for use.[46] Vascular closure devices differ in the material that is used and are classified as active or passive approximators of the arteriotomy. The most commonly used device, Angio-Seal (St. Jude Medical, Plymouth, MN), uses an intraluminal anchor made of bioabsorbable material. However, it is recommended that the treated vessel not be used for repeat arterial access for up to 3 months, to permit absorption of the anchor and limit the risk for embolization. Protocols for early ambulation may permit the patient to be out of bed 2 to 4 hours after hemostasis, or even earlier if a closure device is used.[46]

BOX 3.2 RELATIVE CONTRAINDICATIONS TO DIAGNOSTIC CARDIAC CATHETERIZATION

1. Uncontrolled ventricular irritability: the risk for ventricular tachycardia/fibrillation during catheterization is increased if ventricular irritability is uncontrolled
2. Uncorrected hypokalemia or digitalis toxicity
3. Uncorrected hypertension: predisposes to myocardial ischemia and/or heart failure during angiography
4. Intercurrent febrile illness
5. Decompensated heart failure, especially acute pulmonary edema
6. Anticoagulation state; international normalized ratio (INR) >1.8, femoral approach
7. Severe allergy to radiographic contrast agent
8. Severe renal insufficiency and/or anuria, unless dialysis is planned to remove fluid and radiographic contrast load

Modified from Baim DS, Grossman W. *Cardiac Catheterization, Angiography, and Intervention* (6th ed.). Philadelphia: Lippincott Williams & Wilkins; 2000.

BOX 3.3 IDENTIFICATION OF THE HIGH-RISK PATIENT FOR CATHETERIZATION

Age
- Infant: <1 y old
- Elderly: >70 y old

Functional class
- Mortality ↑ 10-fold for class IV patients compared with I and II

Severity of coronary obstruction
- Mortality ↑ 10-fold for left main disease compared with one- or two-vessel disease

Valvular heart disease as an independent lesion
- Greater risk when associated with coronary artery disease

Left ventricular dysfunction
- Mortality ↑ 10-fold in patients with low ejection fraction (<30%)

Severe noncardiac disease
Renal insufficiency
Insulin-requiring diabetes
Advanced peripheral and cerebral vascular disease
Severe pulmonary insufficiency

Modified from Baim DS, Grossman W. *Cardiac Catheterization, Angiography, and Intervention* (6th ed.). Philadelphia: Lippincott Williams & Wilkins, 2000; from Mahrer PR, Young C, Magnusson PT. Efficacy and safety of outpatient cardiac catheterization. *Cathet Cardiovasc Diagn.* 1987;13:304.

Cardiac Catheterization Procedures

Whether the procedure is elective or emergent, diagnostic or interventional, coronary or peripheral, certain basic components are relatively constant in all circumstances. Variations depend on the specific situation and are discussed later in this chapter.

Patient Preparation

All patients receive a thorough explanation of the procedure, often including pamphlets and videos. A full explanation of the technique and potential risks minimizes patient anxiety and is similar to the preoperative anesthesia visit. It is important for the cardiologist to meet the patient before the study. This relaxes the patient while allowing the physician to become better acquainted with the patient, aiding in the decision-making process. Although some laboratories allow the patient to have a clear liquid breakfast up to 2 to 3 hours before the procedure, outpatients are routinely asked to have no oral intake for 8 hours before the procedure, except for oral medications.

Patients with previous allergic reactions to iodinated contrast agents require adequate prophylaxis.[44] Greenberger and colleagues[47] studied 857 patients who had a prior allergic reaction to contrast media. In this study, 50 mg of prednisone was administered 13 hours, 7 hours, and 1 hour before the procedure. Diphenhydramine (50 mg intramuscularly) also was administered 1 hour before the procedure. No severe anaphylactic reactions occurred, and the overall incidence of urticarial reactions in known high-risk patients was 10%. The use of nonionic contrast agents may further decrease reactions in patients with known contrast allergies.[48] The administration of histamine H_2 blockers (eg, 300 mg cimetidine) is less well studied.[48] For patients undergoing emergent cardiac catheterization who have known contrast allergies, 200 mg of hydrocortisone is administered intravenously immediately and repeated every 4 hours until the procedure is completed. Diphenhydramine (50 mg IV) is recommended 1 hour before the procedure.[48]

CIN is defined as an increase in serum Cr concentration of more than 0.5 mg/dL, or 25% above baseline level, within 48 hours.[34] Although it is infrequent, occurring in fewer than 5% of PCIs, when it does occur its impact on patient morbidity and mortality is significant.[49] Total contrast doses of less than 4 mL/kg are recommended for patients with normal renal function, and lower doses are recommended for those with preexisting renal dysfunction (Cr >1.5), particularly diabetic patients.[34] A study of more than 8000 patients undergoing PCI identified eight risk factors for CIN: hypotension, intraaortic balloon pump (IABP), congestive heart failure, CKD, DM, age older than 75 years, anemia, and contrast volume.[50] It is essential that the patient at high risk be identified and properly treated. In addition, renal function should be monitored for at least 48 hours in patients at high risk for CIN, particularly if surgery or other interventions are planned.

Several methods have been used to decrease renal toxicity from contrast agents. The two most important measures are minimizing contrast dose and providing adequate hydration, either with 0.9% saline at a rate of 1 mL/kg per hour for 12 hours before and after the procedure, if tolerated,[34] or with isotonic sodium bicarbonate. Currently, there are various protocols for the infusion of isotonic sodium bicarbonate, which can be prepared by combining 150 mL of $NaHCO_3$ with 850 mL of sterile H_2O.[51–54] Low-osmolar contrast agents are the standard of care, and despite initial interest in isoosmolar contrast agents, findings in later studies have been mixed.[55,56] *N*-Acetylcysteine (Mucomyst) showed initial promise, but extensive subsequent studies failed to show reductions in CIN, and it is not currently recommended.[56–58] Ultrafiltration dialysis has been beneficial in small studies.[58]

Patient Monitoring and Sedation

Standard limb leads with one chest lead are used for ECG monitoring during cardiac catheterization. One inferior and one anterior ECG lead are monitored during diagnostic catheterization. During an interventional procedure, two ECG leads are monitored in the same coronary artery distribution as the vessel undergoing PCI. Radiolucent ECG leads permit monitoring without interfering with angiographic data.

Sedation in the CCL, from preprocedural administration or from IV administration during the procedure, may lead to hypoventilation and hypoxemia. The administration of midazolam, 1 to 5 mg intravenously, with fentanyl, 25 to 100 μg, is common practice. For older patients, or if there is a risk of respiratory compromise, a dexmedetomidine infusion starting at 0.2 to 1 μg/kg per hour after a loading dose of 0.25 to 0.5 μg/kg per hour over 10 minutes can be helpful because it provides sedation and analgesia without affecting respirations. Institutional guidelines for conscious sedation typically govern these practices. Light to moderate sedation is beneficial to the patient, particularly for angiographic imaging and interventional procedures. Sedation is critical for patients who undergo a radial artery approach; conscious sedation has been shown to reduce the incidence of radial artery spasm, which, when severe, may force the operator to adopt a transfemoral approach to complete the procedure. Deep sedation, in addition to its widely recognized potential to cause respiratory difficulties, poses distinct problems in the CCL. Deep sedation often requires supplemental oxygen, which complicates the interpretation of oximetry data and may alter hemodynamics.

Sparse data exist regarding the effect of sedation on hemodynamic variables and respiratory parameters in the CCL. One study examined the cardiorespiratory effects of diazepam sedation and flumazenil reversal of sedation in patients in the CCL.[59] A sleep-inducing dose of diazepam that was administered intravenously in the CCL produced only slight decreases in mean arterial pressure, PCWP, and LV end-diastolic pressure (LVEDP), with no significant changes in intermittently sampled arterial blood gases. Flumazenil rapidly reversed the sedative effects without significant alterations in hemodynamic or respiratory variables.

More complex interventions have resulted in longer procedures. Although hospitals require conscious sedation policies, individual variation in the type and degree of sedation is common. General anesthesia is rarely required for coronary procedures, but it is frequently used for percutaneous valve procedures (eg, transcatheter aortic valve, MV replacement), ASD closure, and aortic endografts. Advancements in intracardiac echocardiography have decreased the need for intubation and transesophageal echocardiography (TEE) in certain patients and procedures.[60] Pediatric procedures require general anesthesia more commonly than those in adults. As the frequency of noncoronary procedures increases, the presence of an anesthesiologist in the CCL will be required more often.

Left-Sided Heart Catheterization

Catheterization Site and Anticoagulation

Left-sided heart catheterization (LHC) traditionally has been performed by means of a brachial or femoral artery approach. In the 1950s, the brachial approach was first introduced, using a cutdown with brachial arteriotomy. The brachial arteriotomy is often time-consuming, can seldom be performed more than three times in the same patient, and has greater complication rates. This led operators to adopt the femoral approach, which became almost universally accepted. The percutaneous radial artery approach was later developed to improve patient comfort and reduce vascular complications, but its use remained relatively stagnant for more than 10 years. Currently, only a small percentage of procedures are performed via the radial approach in the United States, but that number is increasing rapidly. Over the most recently reported 6-year time period, there was a 13-fold increase in radial artery PCI, with wide geographic variation.[43,61] This approach may be preferred in patients with significant lower extremity peripheral artery disease, recent (<6 months) femoral or abdominal aortic surgery, significant hypertension, coagulopathy, morbid obesity, advanced age, female sex, or an initial cardiac presentation of an acute coronary syndrome (ACS).

The placement of an intraarterial sheath into the radial artery is similar to the placement of devices into any other artery except that the artery has a much smaller caliber and is prone to spasm. Some operators recommend performance of an Allen or a Barbeau test before the procedure to assess for adequate contralateral blood flow into the hand from the ulnar artery.[62] This is an area of controversy because the fundamental question is whether the result of either test is predictive of hand ischemia when radial artery occlusion occurs. Case series of patients with abnormal collateral flow from an absent or diminutive ulnar artery who underwent radial artery harvesting for use as bypass conduits have reported no postoperative hand ischemia.[63] Therefore, because of the lack of outcome data demonstrating the predictive value of testing for dual circulation, some operators have moved away from the routine use of such tests.[64]

Because of the unique characteristics of the radial artery, special dedicated hydrophilic sheaths and access kits are routinely used when gaining access into this arterial bed. Once access has been achieved, to reduce the incidence of radial artery occlusion, intraarterial medications including some combination of nitroglycerin (NTG), a calcium channel blocker (verapamil, diltiazem, or nicardipine), and lidocaine are administered. Most of the time, this combination is physician specific, but at times the patient's hemodynamic status dictates the medical regimen. For example, verapamil and diltiazem should be avoided in the setting of bradycardia, and NTG and nicardipine may be avoided in the setting of hypotension. In addition, the patient who is undergoing a diagnostic heart catheterization from the radial approach requires the use of parenteral anticoagulation with either unfractionated heparin (UFH) or bivalirudin, which have been shown to decrease the rate of radial artery occlusion.[65] The recommended regimen is intraarterial or IV UFH at a dose of at least 500 units/kg or 5000 units. In those patients with heparin-induced thrombocytopenia, the recommendation is to use a bivalirudin bolus dose of 0.75 mg/kg.[66,67]

The development of dedicated catheters for engagement of the coronary arteries when using a radial artery approach has greatly reduced the procedure time. In addition, advances in the management of sheath removal have improved the rates of radial artery occlusion. The current recommendation is to remove the sheath immediately after completion of the procedure and to place a hemostatic compression device, which prevents hematoma formation at the access site but allows for patency of the vessel. Patency of the radial artery can be assessed by evaluating for a radial artery pulse just distal to the compression device.[68] This technique has been called patent hemostasis. When it is used properly, the rates of radial artery occlusion are on the order of 1% to 5%.[64]

There are relatively few contraindications to performing a radial artery procedure: patients who require support devices or other devices that are not compatible with sheaths smaller than 7 Fr, patients with known congenital or noncongenital vascular anomalies of the upper limb, patients who require dialysis fistulas, patients who require use of the radial artery as a conduit for CABG surgery, and patients with known peripheral vaso-occlusive disease, including thromboangiitis obliterans (Buerger disease) and Raynaud disease.

The main advantage of the radial artery approach is that it minimizes vascular complications in patients presenting with ACS, because many of these patients are treated with aggressive anticoagulant and antiplatelet therapy before vascular access is attempted. The RIVAL and RIFLE-STEACS trials both demonstrated lower vascular complication rates and evidence to suggest an overall mortality benefit for the radial approach compared with a transfemoral approach.[69,70] As the adoption of the radial approach continues to increase worldwide, it is important for anesthesiologists to appreciate the unique features of access and hemostasis with this approach compared with the more traditional transfemoral approach.

The percutaneous femoral artery approach is performed using catheters that allow for operator ease and speed of performance. The landmarks for the percutaneous femoral approach are illustrated in Fig. 3.2. The percutaneous approach uses the Seldinger technique or modifications thereof with a Cook needle, which does not have

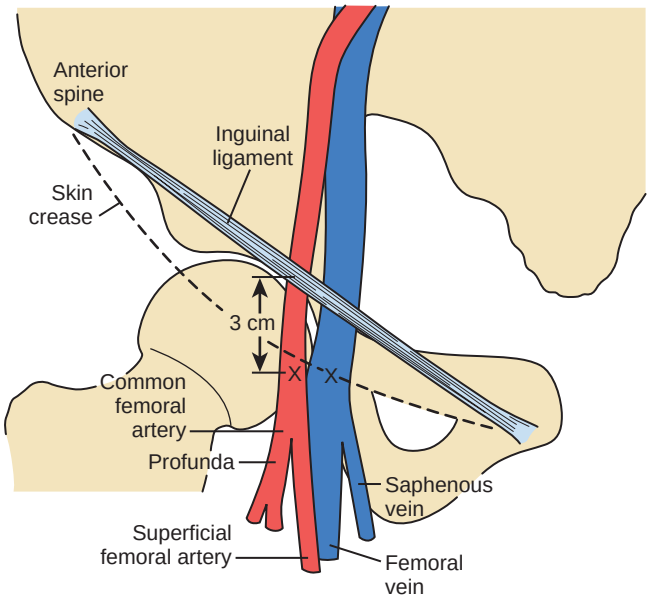

Fig. 3.2 Relevant anatomy for percutaneous catheterization of the femoral artery and vein. The right femoral artery and vein run underneath the inguinal ligament, which connects the anterior-superior iliac spine and the pubic tubercle. The arterial puncture should be made approximately 1.5 to 2 fingerbreadths (3 cm) below the inguinal ligament and directly over the femoral artery pulsation. The venous puncture should be made at the same level but approximately 1 fingerbreadth medial to the arterial position. *X*, Puncture site. *(From Baim DS, Grossman W. Percutaneous approach. In: Grossman W, ed.* Cardiac Catheterization and Angiography *[3rd ed.]. Philadelphia: Lea & Febiger; 1986:60.)*

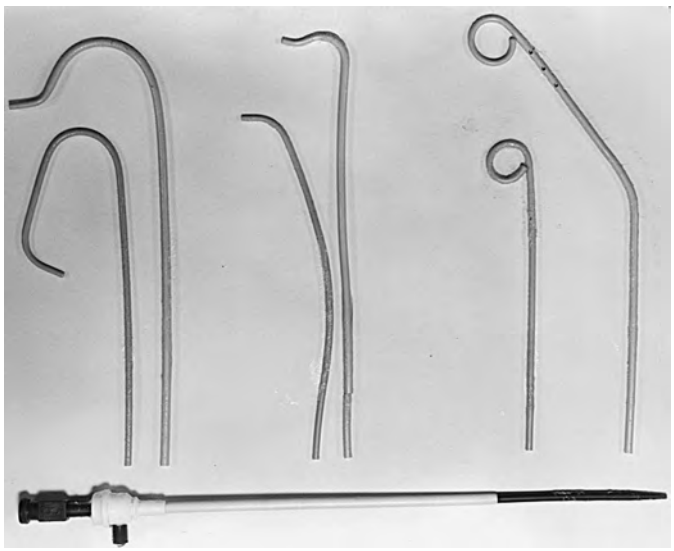

Fig. 3.3 Femoral artery catheters and sheath. *Left,* Standard left coronary artery catheters. *Middle,* Standard right coronary artery catheters. *Right,* Standard ventricular pigtail catheters. *Bottom,* Femoral artery sheath.

an internal obturator. Once the wire is successfully inserted into the vessel, standard sheaths (4 to 8 Fr) are placed in the femoral artery. Through these sheaths, separate coronary artery catheters are inserted to perform left and then right coronary cineangiography, and left ventriculography is performed with the use of a pigtail catheter. These standard catheters and a sheath are illustrated in Fig. 3.3.

In patients with synthetic grafts in the femoral area, arterial access is possible after the grafts are a few months old, and complication rates are similar to those seen in patients with native vessels. An additional

problem may be encountered with aortofemoral grafts. If the native iliac system or distal aorta is occluded, it can be a challenge to advance the catheters through the bypass conduit, and a radial approach should be strongly considered.

At the completion of catheterization via the femoral approach, a closure device may be inserted. If so, femoral arteriography typically is performed via the sheath to assess the adequacy for use of the device. If hemostasis will be obtained with manual compression, the patient is returned to the preprocedure/postprocedure holding area for sheath removal. If an RHC is performed, arterial and venous sheaths should be removed separately to avoid the formation of an atrioventricular (AV) fistula.[71] Pressure is then applied manually or by a compression device. The duration of bed rest depends on the size of the sheath.[72] Closure devices provide for more rapid hemostasis after the procedure, allowing for earlier ambulation and discharge. However, complication rates have not decreased with use of these devices.[73] Closure devices include collagen plugs placed within the artery, which require avoidance of the site for repeat puncture for 3 months, external arterial or subcutaneous plugs that do not hinder repeat access, and suture devices that perform percutaneous arteriotomy closure.[46]

Once hemostasis has been achieved, access site checks and distal pulse assessments should be performed on a regular basis. Sandbag placement is seldom used. In most outpatient diagnostic studies, patients are ambulatory and ready to be discharged 2 to 4 hours after the procedure.[45,72]

In contemporary practice, routine anticoagulation for diagnostic procedures from the femoral approach often is omitted because of the limited arterial access times, unproven need for anticoagulation, and risks for reversing anticoagulation and/or potential delay in sheath removal. If a sheath is to be left in place for longer than 30 to 60 minutes (ie, to confer about management or to transfer a patient), then anticoagulation is recommended. Heparinization is used routinely during brachial or radial catheterization to prevent thrombosis of the smaller arm arteries that may be obstructed by the sheath, as discussed earlier.

Contrast Agents

Adverse reactions have been the major disadvantage of the ionic contrast agents since their introduction for urinary tract visualization in 1923.[48] Contrast agents used for cardiovascular imaging are divided into two groups according to whether they dissociate into ionic particles in solution (ionic media) or do not dissociate (nonionic media). The ionic agents were the first group developed, with sodium diatrizoate and iothalamate anions as the iodine carriers. Commercially available agents using meglumine and sodium salts of diatrizoic acid include Renografin, Hypaque, and Angiovist. In 1975, Shehadi[74] reported on a prospective survey of 30 university hospitals in the United States, Canada, Europe, and Australia, involving 112,003 patients, in which ionic contrast agents were used for cardiovascular diagnosis. The overall rate of adverse reactions was 5.65%, with 0.02% of patients having severe reactions, including death in eight patients.

The next generation of contrast agents began to impact clinical practice in the 1980s. These agents, listed in Table 3.1, are predominantly monomeric, nonionic agents with the exception of the two dimers: ioxaglate (ionic) and iodixanol (nonionic). These agents, particularly the nonionic dimer iodixanol, have lower osmolarity and potentially lower systemic toxicity.[51]

Several areas must be discussed when comparing ionic and nonionic contrast agents. First, the ECG effects (transient heart block, QT and QRS prolongation), depression of LV contractility, and systemic hypotension from peripheral vasodilation are more pronounced with the ionic agents but statistically only marginally different from the effects of the nonionic compounds.[75] The hemodynamic effects of the nonionic dimer, iodixanol, were compared with those of the nonionic monomer, iohexol, in 48 patients; although both agents caused an increase in LVEDP, the increase was significantly less in the iodixanol group.[76] In addition, iodine content may vary among agents, resulting in variations in opacification. In patients who have had previous anaphylactoid reactions to iodinated contrast, nonionic contrast decreases the incidence of an anaphylactoid reaction with repeat contrast exposure.[47,51] Finally, the nonionic agents and dimers are more expensive than the ionic agents. When these agents were first introduced, this difference was large and slowed the adoption of the newer agents. Current price differences are less dramatic, and nonionic agents are used in most laboratories.[51]

TABLE 3.1 Nonionic and Dimeric Contrast Agents

Product[a]	*Type of Contrast Agent*	*Concentration (mg/mL)*	*Osmolality (mOsm/kg water)*
Monomers			
Iohexol (Omnipaque)	Nonionic LOCM	350	844
Iopamidol (Isovue)	Nonionic LOCM	370	796
Ioxilan (Oxilan)	Nonionic LOCM	350	695
Iopromide (Ultravist)	Nonionic LOCM	370	774
Ioversol (Optiray)	Nonionic LOCM	350	792
Dimers			
Iodixanol (Visipaque)	Nonionic IOCM	320	290
Ioxaglate (Hexabrix)	Ionic LOCM	320	600

IOCM, Iso-osmolar contrast media; *LOCM*, low-osmolality contrast media.

Both ionic and nonionic agents have anticoagulant and antiplatelet effects, these being more pronounced with ionic agents. A comparison of the nonionic agents iohexol (monomer) and iodixanol (dimer) with the ionic dimer, ioxaglate, demonstrated a clear distinction, with the in vivo antiplatelet effect of the ionic agent 65% greater than that of the nonionic agents.[77] Regardless of the agent used, these differences are unlikely to be important for diagnostic procedures. Although minute thrombi may form when blood and nonionic contrast remain in a syringe, clinical sequelae have not been reported.[78]

Patients with impaired renal function (Cr >1.5 mg/dL; GFR <60 mL/minute), particularly if they are diabetic, have an increased risk of renal impairment after contrast administration.[34] The effects of contrast agents on the kidneys are more pronounced when larger volumes are delivered near the renal arteries. Therefore, the choice of contrast is most important with arteriography of the renal arteries or the abdominal aorta. Abdominal arteriography can be done with digital subtraction techniques and the intraarterial injection of gaseous carbon dioxide, avoiding the use of any iodinated contrast.

Two large, multicenter trials have compared ionic and nonionic agents in patients undergoing cardiovascular diagnostic imaging.[79,80] One involved 109,546 patients in Australia, and the other involved 337,647 patients in Japan. These studies demonstrated severe adverse reactions in 0.9% and 0.25% those patients exposed to ionic agents, respectively, whereas the rates of severe adverse reactions in patients exposed to nonionic agents were 0.02% and 0.04%, respectively. For intervention procedures, one trial compared the iso-osmolar nonionic dimer, iodixanol, with the ionic dimer, ioxaglate, in 856 PCI patients at high risk and reported a 45% reduction in major adverse cardiac events (MACEs) in the iodixanol group.[81] Iodixanol (Visipaque) has also been compared with low-osmolar contrast agents in attempts to limit nephrotoxicity, with mixed results.[82]

Minimizing the use of contrast is the surest way to limit nephrotoxicity. For patients at greatest risk, this might require that procedures be staged; for instance, a diagnostic study may be performed on one day and an interventional procedure at a later date. An additional concern is that iodinated contrast is administered frequently for other purposes, such as CT. If staging of procedures or repeat contrast administration is required, delaying these additional studies for 72 hours or until renal dysfunction has recovered is recommended.[37]

Right-Sided Heart Catheterization

Indications

The Cournand catheter initially was used to measure right-sided heart pressures but required fluoroscopic guidance for placement. The Cournand catheter permitted the measurement of CO by the Fick method. Clinical applications of right-sided hemodynamic monitoring changed greatly in 1970 with the development of the flow-directed, balloon-tipped, pulmonary artery catheter (PAC) by Swan and Ganz. This balloon flotation catheter allowed the clinician to measure pulmonary artery (PA) and wedge pressures without fluoroscopic guidance. It also incorporated a thermistor, making repeated measurements of CO feasible. With this development, the PAC left the CCL and entered both the OR and the intensive care unit.[83]

In the CCL, RHC is performed for diagnostic purposes. The routine use of RHC during standard LHC was studied by Hill and associates.[84] Two hundred patients referred for LHC for suspected CAD also underwent RHC. This resulted in an additional 6 minutes of procedure time and 90 seconds of fluoroscopy time. Abnormalities were detected in 35% of the patients; however, management was altered in only 1.5% of the patients. With this in mind, routine RHC cannot be recommended. Box 3.4 outlines acceptable indications for RHC during LHC.

CO measurements during RHC using the thermodilution technique allow for a further assessment of ventricular function.[85] This obviously is helpful in the setting of an AMI to identify high-risk groups and to measure the effects of cardiac medications.[86,87] Measurement of CO can differentiate high-output failure states (eg, hyperthyroidism, Paget disease, beriberi, anemia, AV malformations, AV fistula) from those occurring secondary to a low CO. In patients with congenital heart disease, RHC allows for measurement of oxygen saturation in various cardiac chambers and calculation of intracardiac shunting. In patients with ASD, the right-sided heart catheter passes through the defect into the left atrium (LA), allowing for complete saturation and pressure measurements. The thermodilution technique cannot be used to measure CO in the setting of intracardiac shunting; in such cases, the Fick method must be used. With significant tricuspid regurgitation or a very low CO, the Fick method provides a more accurate measurement of CO and is preferred. Pharmacologic therapy for pulmonary hypertension has become more effective, and RHC is used to confirm the diagnosis of pulmonary *arterial* hypertension (PAH) and differentiate it from pulmonary *venous* hypertension. Knowledge of the response of PAH to nitric oxide, adenosine, or a vasodilator is helpful for the cardiologist to determine optimal therapy, so these agents are occasionally administered during an RHC.[88,89]

Procedure

The brachial, femoral, and internal jugular venous approaches are the approaches most commonly used for RHC in the CCL. The brachial approach for RHC may be done percutaneously or by means of a venotomy. One pitfall in the brachial approach is identification of the proper vein for insertion. The basilic and brachial veins are preferable, whereas the cephalic vein on the radial aspect of the arm is tortuous in the axilla and should be avoided for catheter insertion. When the left brachial (or left internal jugular) approach is considered, the operator must be aware of the possibility of an anomalous left-sided superior vena cava (SVC) that empties into the coronary sinus, hindering catheter passage into the right ventricle (RV). Whenever the peripheral arm veins are entered, the catheter or sheath must be moist and inserted quickly to decrease venous spasm.

The femoral approach for PAC insertion is performed under fluoroscopic guidance using one of two approaches. The catheter can be advanced against the lateral wall of the atrium, creating a loop in the RA, after which the balloon is inflated and advanced across the tricuspid and pulmonic valves to the PCWP position. Or, the catheter can be passed from the RA into the RV; with clockwise rotation and balloon inflation, the catheter then enters the pulmonary outflow tract and is advanced into the PA and PCWP positions.

Shunt Calculations

Although it is common to obtain oxygen saturation values from the PA during RHC, a complete oxygen saturation assessment is required in patients with suspected left-to-right shunts. In the adult population, ASDs and postinfarction VSDs are the most common left-to-right shunts requiring identification. In these patients, 0.5 to 1.0 mL of blood is obtained from the following locations: the SVC and the inferior vena cava (IVC); high, middle, and low portions of the RA; the right ventricular apex and outflow tract; and the main PA (rarely, right and left PA). These saturations are obtained on entry with the PAC, and repeat sampling is dune during pullback if the data are ambiguous. The samples must be obtained in close temporal proximity to avoid systemic factors affecting oxygen saturation (eg, hypoventilation). A step-up in saturation identifies the level at which the shunt is occurring. Right-to-left shunts are suspected when the arterial blood is not fully saturated even with maximal oxygen supplementation; this must be differentiated from intrapulmonary shunting.

Pulmonic and systemic flows are calculated as modifications of the Fick equation for CO determination.[90] The Fick equation states that the cardiac output can be calculated as the oxygen consumption divided by the arteriovenous oxygen difference.[90] It is important that measurements be made during steady-state conditions. The $\dot{Q}_p/\dot{Q}_s$ ratio is calculated for patients with left-to-right shunting by the following equation:

$$\dot{Q}_p/\dot{Q}_s = (Sa_{O_2} - S\bar{v}_{O_2})/(Spv_{O_2} - Spa_{O_2})$$

where $\dot{Q}_p$ is pulmonary flow, $\dot{Q}_s$ is systemic flow, Sa_{O_2} is systemic arterial oxygen saturation, $S\bar{v}_{O_2}$ is mixed venous oxygen saturation, Spv_{O_2} is pulmonary venous oxygen saturation, and Spa_{O_2} is PA oxygen saturation. The pulmonary and systemic flows are measured in L/minute and the oxygen saturations in mL/L.

In the presence of an RA step-up, an estimated resting $S\bar{v}_{O_2}$ sample is obtained by the following weighted average:

$$S\bar{v}_{O_2} = [3 \times (\text{SVC saturation}) + 1 \times (\text{IVC saturation})] \div 4$$

Saturation values are measured in high and low regions of the SVC and IVC and are normally the same. If anomalous pulmonary venous drainage is present, regional differences in saturation in either the SVC or the IVC may occur. Calculation of the $\dot{Q}_p/\dot{Q}_s$ ratio does not require measurement of oxygen consumption (mL/minute), and it can be calculated with any stable level of oxygen supplementation. However, calculation of the absolute values of pulmonary and systemic flow does require this measurement, which can be complicated if supplemental oxygen is required.

Correction of the defect is required if the $\dot{Q}_p/\dot{Q}_s$ ratio is greater than 2 but is unnecessary if it is less than 1.5. Ratios between 1.5 and 2.0 require additional confirmatory evidence and clinical assessment before a decision to intervene can be made.

BOX 3.4 INDICATIONS FOR DIAGNOSTIC RIGHT-SIDED HEART CATHETERIZATION DURING LEFT-SIDED HEART CATHETERIZATION

- Significant valvular pathology
- Suspected intracardiac shunting
- Acute infarct—differentiation of free wall versus septal rupture
- Evaluation of right- and/or left-sided heart failure
- Evaluation of pulmonary hypertension
- Severe pulmonary disease
- Evaluation of pericardial disease
- Constrictive pericarditis
- Restrictive cardiomyopathy
- Pericardial effusion
- Pretransplantation assessment of pulmonary vascular resistance and response to vasodilators

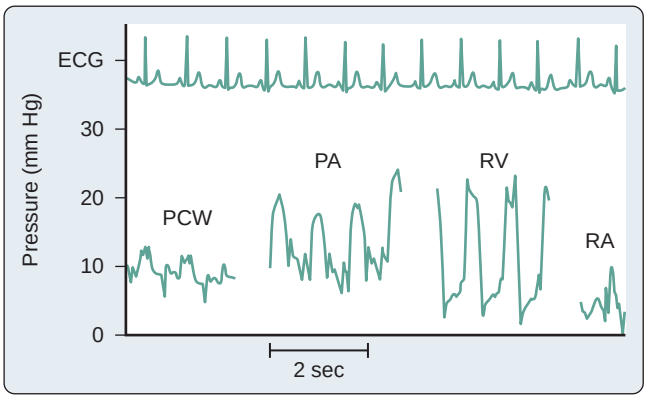

Fig. 3.4 A pullback tracing obtained using a pulmonary artery catheter from the pulmonary capillary wedge *(PCW)* position, to the pulmonary artery *(PA)*, right ventricle *(RV)*, and right atrium *(RA)*. *ECG*, Electrocardiogram.

The following example demonstrates the calculation of left-to-right shunting in a patient with an ASD given the following oxygen saturation values: IVC = 68%; SVC = 60%; mid-RA = 77%; mid-RV = 77%; $SpaO_2$ = 77%; and SaO_2 = 92%.

$$S\bar{v}O_2 = [3(60) + 68] \div 4 = 62$$

$$\dot{Q}_p/\dot{Q}_s = (92 - 62)/(92 - 77) = 30/15 = 2$$

Significant bidirectional or right-to-left shunting is unusual in adult patients. These shunts occur in the setting of congenital heart disease, typically after the development of pulmonary arterial disease. As more children with corrected or partially corrected congenital heart disease reach adulthood, the likelihood of encountering an adult with a complicated shunt will increase. These encounters may be additionally complicated by the development of adult cardiology problems, mainly CAD. However, about 25% of the population has a PFO, and right-to-left shunting through the PFO with systemic oxygen desaturation can occur if the RA pressures become increased. This may occur after pulmonary embolism or after an RV infarction, among other causes.

Calculation of bidirectional shunting involves determination of the effective blood flow ($\dot{Q}_{eff}$). $\dot{Q}_{eff}$ represents the flow if no right-to-left or left-to-right shunting existed.[90] Right-to-left shunting is equal to $\dot{Q}_s - \dot{Q}_{eff}$, and left-to-right shunting is equal to $\dot{Q}_p - \dot{Q}_{eff}$. The following formulas are derived from the Fick equation for CO:

$$\dot{Q}_s = O_2 consumption/SaO_2 - S\bar{v}O_2$$

$$\dot{Q}_p = O_2 consumption/SpvO_2 - SpaO_2$$

$$\dot{Q}_{eff} = O_2 consumption/SpvO_2 - S\bar{v}O_2$$

Right-sided heart pressure may be obtained either on entry or on pullback (Fig. 3.4). Catheter placement via the femoral approach may be time-consuming, with expedited passage necessary to prevent catheter softening. For this reason, pressure measurements often are obtained during catheter pullback to ensure temporal proximity. As with all invasive procedures, complications can occur with RHC, so risks and benefits must be assessed in advance[91] (see Chapter 13). If general anesthesia is required, the fraction of inspired oxygen (FIO_2) is reduced to approximately 25% or lower when checking the saturations in different chambers of the heart. Higher FIO_2 during the procedure may change the pulmonary vascular resistance measurements.

Endomyocardial Biopsy

Endomyocardial biopsy is the only reliable method to detect rejection in the transplanted heart. However, its role in the management of other cardiovascular diseases in adult and pediatric patients remains controversial. In 2007, the ACC/AHA/European Society of Cardiology published recommendations on endomyocardial biopsy.[92] The preferred approach is through the internal jugular vein (in the United States) or the femoral vein (in Europe), with subclavian and even brachial approaches also used. Complications are infrequent and are related to the access site (in 2% of patients), arrhythmia or conduction abnormalities (1–2%), or perforation (0.5%). Death, a rare event, is related to perforation. Histologic evaluation of the tissue is the purpose of the procedure, and it must be done by experienced pathologists to justify the risks.

Indications are controversial, but most groups agree that important information can be obtained in the setting of new-onset heart failure (<2 weeks) and also for those patients who have had heart failure for 2 weeks to 3 months without response to therapy.[92] Other potential indications include unexplained restrictive cardiomyopathy, anthracycline cardiomyopathy, suspected cardiac tumor, unexplained arrhythmias, and heart failure associated with hypertrophic cardiomyopathy (HCM), but these are less clear. A complete review of potential scenarios can be found in the 2007 scientific statement.[92]

Diagnostic Catheterization Complications

Although adult diagnostic catheterization with selective coronary cineangiography has been performed since the late 1950s, complication rates were not monitored until 1979, when the SCAI established the first registry to prospectively follow the performance of participating laboratories. In 1982, the first publication from this registry reported complication rates from a study population of more than 50,000 patients.[93] This was updated in 1989 with a report on 222,553 patients who underwent selective coronary arteriography between 1984 and 1987.[94] Similar complication rates were noted in the two reports. Complications are related to multiple factors, but severity of disease is important. Mortality rates are low. Complications are specific for RHC and LHC (Box 3.5). The registry reported incidences of major complications as follows: death, 0.1%; MI, 0.06%; cerebrovascular accident, 0.07%; arrhythmia, 0.47%; contrast reaction, 0.23%; and vascular complications, 0.46%.[94] Infectious complications are infrequent, although they may be underreported. Guidelines for infection control are based more on extrapolation from OR studies than on randomized control data from the CCL.[95] Although advances in technology have been made, similar complication rates persist, most likely because of the higher risk status of patients undergoing catheterization today.[13] The current registries for identifying complications are focused primarily on percutaneous interventions. In addition to institutional and regional databases such as those of the Cleveland Clinic and Northern New England, the ACC maintains the National Cardiovascular Data Registry (NCDR).

Vascular complications from the percutaneous femoral approach occur in fewer than 1% of diagnostic procedures, with the most common being pseudoaneurysm.[46] This risk is greater for obese patients, in whom compression is more difficult. Therapy for pseudoaneurysm is either ultrasound-directed thrombin injection or surgical repair. In patients with aortic regurgitation (AR), an increased incidence of femoral arteriovenous fistulas is seen because of the widened pulse pressure.[71] Many small arteriovenous fistulas will close spontaneously. If the fistula is large or is associated with high output (rare) or with edema of the affected leg, surgical correction is indicated. Thrombosis of the femoral artery occurs rarely, and underlying atherosclerotic disease usually is severe. Emergent restoration of flow is essential, with a surgical approach used at some hospitals and a percutaneous approach at others.

Arrhythmogenic complications during LHC are more frequent with ionic contrast than with nonionic contrast, and they occur during coronary injection. Surprisingly, the presence of the catheter in the left ventricle rarely causes a sustained arrhythmia. Early contrast media containing potassium produced ventricular fibrillation during coronary arteriography. However, current contrast materials are potassium free and contain added calcium. As a result, the incidence rate of significant ventricular arrhythmias is 0.47%.[94]

BOX 3.5 COMPLICATIONS OF DIAGNOSTIC CATHETERIZATION

Left-Sided Heart Catheterization

Cardiac Complications

Death
Myocardial infarction
Ventricular fibrillation
Ventricular tachycardia
Cardiac perforation

Noncardiac Complications

Stroke
Peripheral embolization
Air
Thrombus
Cholesterol
Vascular surgical repair
Pseudoaneurysm
Arteriovenous fistula
Embolectomy
Repair of brachial arteriotomy
Evacuation of hematomas
Contrast-related complications
Renal insufficiency
Anaphylaxis

Right-Sided Heart Catheterization

Cardiac Complications

Conduction abnormality
RBBB
Complete heart block (RBBB superimposed on LBBB)
Arrhythmias
Valvular damage
Perforation

Noncardiac Complications

Pulmonary artery rupture
Pulmonary infarction
Balloon rupture
Paradoxic (systemic) air embolus

LBBB, Left bundle branch block; *RBBB*, right bundle branch block.

Anaphylactoid reactions has occurred in approximately 5% to 8% of cases when nonionic contrast agents were used. The definition of reaction severity and the differential diagnosis for severe reactions are listed in Table 3.2. Severe hypersensitivity reactions manifest as urticaria and pruritus, bronchospasm, hypotension, laryngeal edema, and cardiovascular collapse. The three most common risk factors for an acute reaction are a history of asthma, a prior reaction to dye, and atopy.

The treatment of the reaction depends on the patient's symptoms. For urticaria without symptoms, the dye injection is stopped and the patient is reassured. If the patient is symptomatic, 25 to 50 mg of diphenhydramine (Benedryl) along with 100 mg of hydrocortisone can be administered; if the reaction is severe, the treatment is 0.1 to 0.3 mg of subcutaneous (SC) or intramuscular (IM) epinephrine. For facial or laryngeal edema, the treatment is oxygen and 0.1 to 0.3 mg of SC or IM epinephrine or, if the patient is hypotensive, 0.1 mg of IV epinephrine up to 1 mg. If respiratory distress is present, the patient should be intubated. For bronchospasm, oxygen and β_2-agonist inhalers should be administered; if the patient is unresponsive, 0.1 to 0.3 mg of epinephrine SC or IM should be given. Consider intubation if the oxygen saturation is low despite treatment.

For anaphylactoid reactions, resuscitation includes airway management and cardiovascular support. Oxygen should be administered, and intubation should be considered if the patient is hypoxic despite oxygen. The circulation should be supported with boluses of isotonic Ringer lactate or normal saline solution. If there is no response, IV epinephrine should be administered 0.1 mg at a time to a maximum of 1 mg. Hydrocortisone, diphenhydramine, and H_2 antagonists may be administered, but these are secondary treatments.[47]

TABLE 3.2 Contrast-Induced Anaphylactoid Reactions

Severity Classification		
Minor	*Moderate*	*Severe*
Urticaria (limited)	Urticaria (diffuse)	Cardiovascular shock
Pruritus	Angioedema	Respiratory arrest
Erythema	Laryngeal edema	Cardiac arrest
	Bronchospasm	

Differential Diagnosis (Severe Reactions)	
Cardiac	*Noncardiac*
Vasovagal reaction	Hypovolemia
Cardiogenic shock	Dehydration
Right ventricular infarction	Blood loss—gastrointestinal, vascular, external
Cardiac tamponade	Drug-related causes
Cardiac rupture	Narcotic, benzodiazepine, protamine
Bezold-Jarisch reflex	Sepsis

Adapted from Goss J, Chambers C, Heupler F, et al. Systemic anaphylactoid reactions to iodinated contrast media during cardiac catheterization procedures. *Cathet Cardiovasc Diagn.* 1995;34:99.

Cholesterol embolization can occur after catheter manipulation, and it has been described after cardiac catheterization.[96] Although the femoral approach can be used in patients with unrepaired abdominal aortic aneurysms, an increased incidence of cholesterol embolization syndrome may occur in this population.[97] Cholesterol embolization produces arterial occlusion of the small vessels by cholesterol crystals and results in a serious clinical presentation including livedo reticularis, acrocyanosis of the lower extremities, renal insufficiency, and accelerated hypertension. The clinical course is variable; the condition does not respond to anticoagulation, and it can potentially lead to an insidious development of progressive renal failure, accelerating hypertension, and a fatal outcome.[98]

Valvular Pathology

The number of patients presenting with valvular heart disease (VHD) in developed countries is growing, primarily because of the increasing age of the population. In 2014, the ACC/AHA published updated practice guidelines for the management of VHD.[99] These guidelines cover the invasive and noninvasive evaluation of valvular problems and the therapeutic approaches. Despite these guidelines, a number of patients are referred for intervention too late in the course of their disease or are not referred at all, either of which results in poor long-term outcomes. On the other hand, intervention in the asymptomatic patient requires expertise in evaluation and noninvasive imaging assessment. The following discussion focuses on valve pathology as a dominant problem. Some patients have mixed valve disease, but there is a paucity of data on the natural history of such coexistent conditions (see Chapter 21).

Stenotic Lesions

The transvalvular gradient and transvalvular flow must be quantified to assess the severity of stenotic lesions. Hydraulic principles state that as valvular stenosis worsens, the valve orifice produces progressively greater resistance to flow, resulting in a pressure drop (pressure gradient) across the valve. At any given stenotic orifice size, greater flow across the orifice yields a greater pressure gradient. Both the CO and the heart rate (HR) determine flow.

Gorlin and Gorlin[100] derived a formula from fluid physics to relate valve area to blood flow and blood velocity:

$$\text{Valve area} \propto \text{Blood flow} \div \text{Blood velocity}$$

In general, as a valve orifice becomes increasingly stenotic, the velocity of flow must progressively increase if total flow across the valve is to be maintained. Flow velocity can be measured by the Doppler principle to estimate valve area; however, in the CCL, this is not as practical as measuring blood *pressures* on either side of the valve.

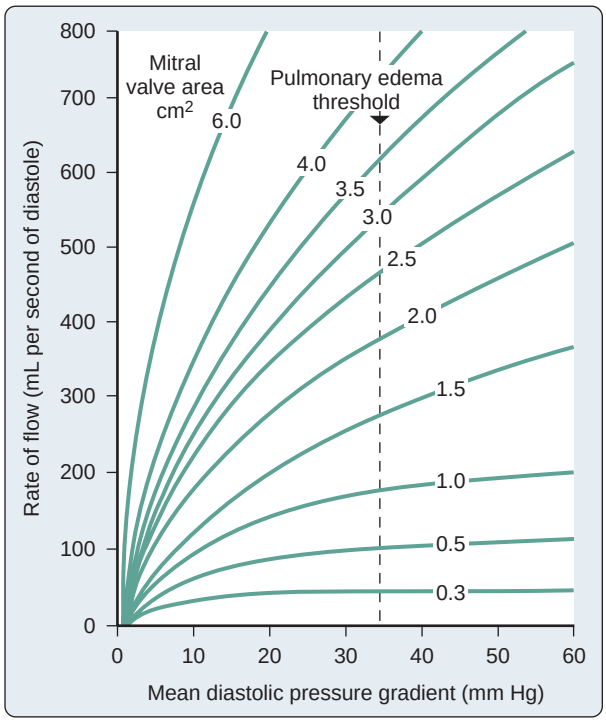

Fig. 3.5 Rate of flow in diastole versus mean pressure gradient for several degrees of mitral stenosis. The pressure gradient is directly proportional to the square of the flow rate. Therefore, as the degree of stenosis progresses, modest increases in flow (eg, with light exercise) will require large increases in the pressure gradient. As an example, a cardiac output of 5.2 L/minute, heart rate of 60 beats/minute, and diastolic filling time of 0.5 second produce a 200 mL/second flow during diastole. With mild mitral stenosis (valve area = 2.0 cm^2), the required pressure gradient remains small (<10 mm Hg), but with severe stenosis (valve area <1.0 cm^2), the resultant gradient is high enough to exceed the threshold for pulmonary edema. *(From Wallace AG. Pathophysiology of cardiovascular disease. In: Smith LH Jr, Thier SO, eds.* Pathophysiology: The Biological Principles of Disease. The International Textbook of Medicine, *Vol. 1. Philadelphia: Saunders; 1981:1192.)*

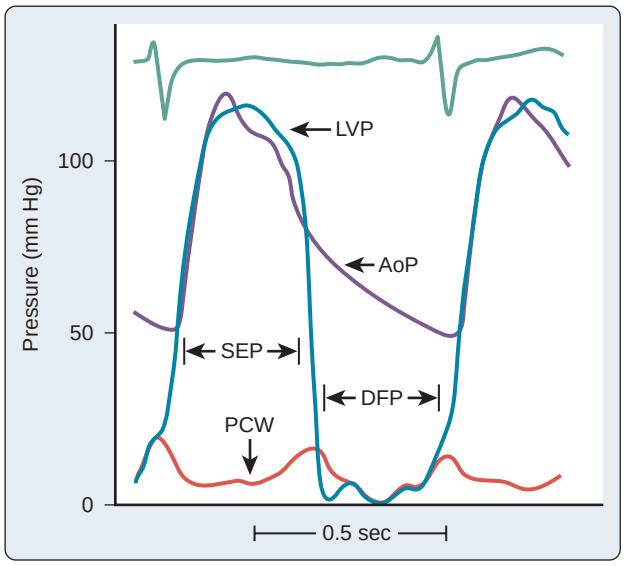

Fig. 3.6 Simultaneous left ventricular pressure *(LVP)*, aortic pressure *(AoP)*, and pulmonary capillary wedge *(PCW)* (ie, left atrial) pressure waveforms. The systolic ejection period *(SEP)* is defined as the period during which the aortic valve is open (extending from the point at which LVP crosses over AoP at the beginning of systole to the point at which AoP crosses over LVP near the end of systole) and forward blood flow is present in the aorta. The diastolic filling period *(DFP)* is the length between the initial PCWP and LV crossover in early diastole to the point of end diastole (peak of R wave). *(Modified from Grossman W, Baim DS, eds.* Cardiac Catheterization, Angiography, and Intervention *[4th ed.]. Philadelphia: Lea & Febiger; 1991:153.)*

As described by Gorlin and Gorlin,[100] the velocity of blood flow is related to the square root of the pressure drop (P) across the valve. Stated another way, for any given orifice size, the transvalvular pressure gradient is a function of the square of the transvalvular flow rate:

$$P_1 - P_2 \propto (\text{Blood velocity})^2$$

For example, with mitral stenosis (MS), as the valve area progressively decreases, modest increases in the rate of flow across the valve cause progressively larger increases in the pressure gradient across the valve (Fig. 3.5).

The actual time of the cardiac cycle during which flow occurs must be known to complete the calculation. For semilunar valves (aortic and pulmonic), flow occurs during the systolic ejection period (SEP)—that is, during ventricular contraction while the aortic valve is open. For AV valves (mitral and tricuspid), flow occurs during the diastolic filling period (DFP), while the MV is open (Fig. 3.6). The HR determines the duration of the SEP or DFP over an entire minute. Also present in the Gorlin formula is a coefficient that quantifies the conversion of potential energy (pressure energy) to kinetic energy (velocity). This term also contains an empirically derived factor that accounts for the difference between calculated and measured valve areas at the time of surgery or postmortem examination.

The final Gorlin formula then becomes

$$\text{Valve area} = \text{CO} \div [(\text{DFP or SEP})(\text{HR})]/44.3 \cdot \text{C} \cdot (P_1 - P_2)^{1/2}$$

where CO is cardiac output (mL/min), DFP or SEP is diastolic filling period or systolic ejection period in seconds per beat, HR is heart rate in beats per minute, C is the orifice constant (aortic, 1.0; mitral, 0.85; tricuspid, 0.7), and $P_1 - P_2$ is the mean pressure difference across the orifice as determined by computer-assisted analysis or area blanketing. The 44.3 coefficient is derived from the energy calculation.

Aortic Stenosis

The normal adult aortic valve area is 2.6 to 3.5 cm^2, which corresponds to a normal aortic valve index of 2.0 cm^2/m^2. As the valve area decreases to a range of 1.5 to 2.0 cm^2 (or a valve index of 1.0 cm^2/m^2), the major hemodynamic finding is a rise in the LV systolic pressure, which is increased to maintain a normal aortic systolic pressure. An elevation in LVEDP also may be observed, which is merely a reflection of the decrease in compliance of the hypertrophied ventricle (see Chapter 21).

As the stenosis becomes moderate and the valve area decreases to 1.0 to 1.5 cm^2 or a valve index of 0.6 to 0.9 cm^2/m^2, symptoms can occur. The left ventricle exhibits a more rounded appearance at its peak systolic pressure, and there is a progressive increase in the LVEDP. As the left ventricle hypertrophies, its filling becomes more dependent on the contraction of the LA; this is reflected as an augmented A wave on the ventricular tracing. At that point, the increased LA pressure makes atrial fibrillation (AF) more likely, and the decreased compliance of the left ventricle makes it poorly tolerated. Widening of the systolic pressure gradient from the left ventricle to the aorta, a decrease in the rate of rise of the upstroke of the aortic pressure tracing, and a delay in the time to peak aortic pressure (*pulsus parvus et tardus*) also are seen (Fig. 3.7).

In the case of severe AS, with a valve area of less than 1.0 cm^2 and a valve area index of less than 0.5 cm^2/m^2, a decrease in systolic function of the left ventricle can occur. Increases in PA pressure, PCWP, and right atrial pressure also are observed. These latter changes often are accompanied by symptoms of congestive heart failure.

In some patients, the mean aortic valve gradient does not correlate with low aortic valve area, and the patient is categorized as having low-flow, low-gradient (LF/LG) AS with either preserved or

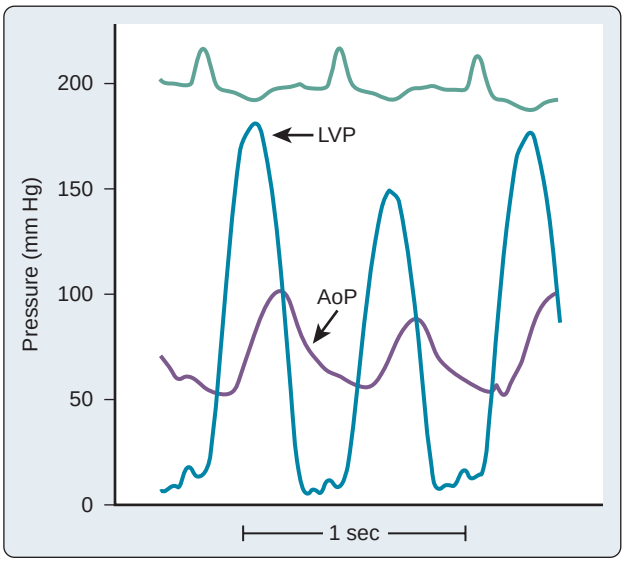

Fig. 3.7 Left ventricular pressure *(LVP)* and aortic pressure *(AoP)* waveforms in a patient with aortic stenosis. Of note are the large pressure gradient from left ventricle to aorta at peak systolic pressure, the delay to onset of the aortic upstroke, and the decrease in the rate of rise of the aortic pressure. End-diastolic pressure is still normal at this stage of the disease.

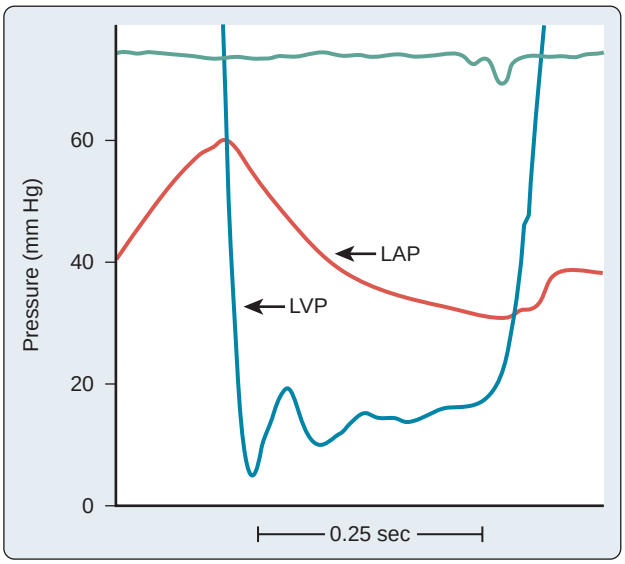

Fig. 3.8 Mitral stenosis, with pressures measured at catheterization. Notice the gradient during diastole between the left atrial *(LAP)* and the left ventricular *(LVP)* pressures and the increase in the LAP.

reduced LV function. Determining optimal therapy and the timing of intervention for patients with LF/LG AS presents unique challenges. Among those patients with classic LF/LG AS with reduced ejection fraction (EF), dobutamine infusions administered in the CCL or in the echocardiography laboratory may help to identify those who will benefit from aortic valve replacement (AVR).[101] For patients who have paradoxical LF/LG AS with preserved LV function, a careful assessment must ensue because the published data are limited and conflicting with respect to the benefit of surgical valve replacement.[102,103] Quite often, these patients need multimodality imaging, including cardiac magnetic resonance (CMR) along with calcium scoring of the aortic valve, to assist with determination of the severity of the disease process.[104,105] Further studies are needed to determine which patients with paradoxical LF/LG AS can benefit from AVR and which type of AVR (surgical vs transcatheter) should be used (see Chapters 21 and 27).

Mitral Stenosis

In normal adults, the MV orifice is 4 to 6 cm^2. Mild MS is considered to be present when the MV orifice is reduced to less than 2.0 cm^2. In this condition, the typical hemodynamic finding is an elevation in either LAP or PCWP. An increase in LAP tends to maintain normal flow across the valve. With an MV orifice of less than 1.0 cm^2, considered to be critical MS, a much larger LA-to-LV gradient is required to maintain reasonable flow across the valve (Fig. 3.8). An increase in LAP during diastole leads to early opening and a slightly delayed closure of the MV (Fig. 3.9). It is easy to understand why a slow HR in the presence of MS is preferred, because a maximal DFP is necessary to maintain reasonable flow and sustain CO across the MV. Another hemodynamic hallmark in patients with MS is the reduced increase in LV pressure during early diastole. Normally, a fairly rapid increase is seen during the DFP, but the slope of this pressure increase is delayed in the presence of severe MS. Elevations in right-sided heart pressures are common in severe MS; with severe long-standing MS, the PA pressure can reach or exceed the systemic arterial pressure. Atrial remodeling in MS is characterized by LA enlargement, loss of myocardium, and scarring, which produces widespread conduction abnormalities and is associated with a higher incidence of AF.

Doppler echocardiography has reduced the importance of performing a catheterization to evaluate valvular disease (see Chapters 14, 15, and 21). However, in stenoses of borderline severity, data from the CCL is still important for clinical decision making. Performance of exercise or administration of inotropic agents increases the CO. In addition to confirmation of inotropic reserve, this increase in output increases the flow across the valves and increases the gradient exponentially. When both the gradient across the valve and the CO are low, augmentation of flow can help to distinguish severe stenosis with reversible ventricular failure from mild stenosis with irreversible ventricular failure.

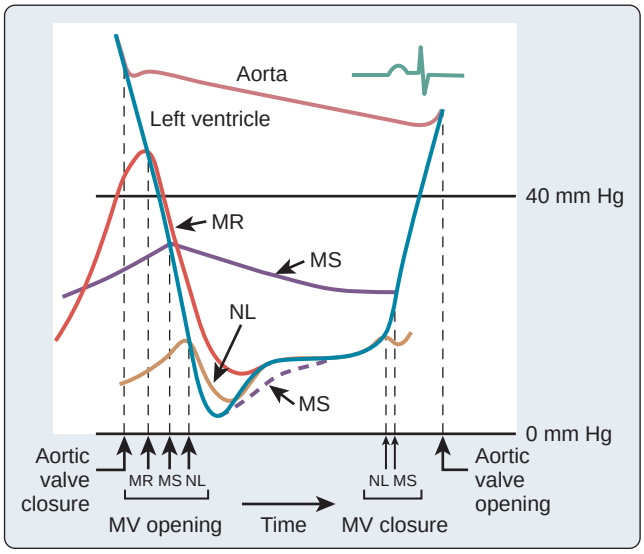

Fig. 3.9 Idealized diagram summarizes mitral valve disorders, concentrating on the diastolic filling period. In mitral stenosis *(MS)*, the increase in left atrial pressure *(solid purple line)* versus normal atrial pressure *(gold line)* causes early mitral valve *(MV)* opening and a slight delay in MV closure. Left ventricular rapid filling is delayed, which delays the increase of ventricular pressure *(dotted purple line)* compared with that seen during normal diastole *(gold line)*. In mitral regurgitation *(MR)*, the left atrial pressure *(red line)* has a large V wave, because the atrium fills with blood from the pulmonary veins and with blood regurgitating through the MV, causing the MV to open early. *NL*, Normal. *(From Braunwald E. Valvular heart disease. In: Braunwald E, ed.* Heart Disease: A Textbook of Cardiovascular Medicine *[3rd ed.]. Philadelphia: Saunders; 1988:1024.)*

Regurgitant Lesions

The severity of valve regurgitation or incompetence is quantified angiographically. However, several hallmark changes occur in the presence of regurgitant lesions. The aortic valve and the MV are discussed as examples here (see Chapters 14, 15, 16, and 21).

Aortic Regurgitation

Acute AR or aortic insufficiency is uncommon unless there is aortic dissection, sudden failure of a valve prosthesis, or native valve destruction in the setting of bacterial endocarditis. In the presence of acute AR, there are sudden increases in end-systolic and end-diastolic volumes and pressures. The normal ventricle is suddenly faced with an increased load and generates greater pressure. During relaxation, because the ventricle is filling with blood from the aorta, there is a delay in the isovolumic pressure decline, accompanied by rapid increases in ventricular diastolic pressures, both because of continued valve regurgitation. The wide pulse pressure, a characteristic sign of chronic AR, may not be seen in the acute setting. In addition, the dicrotic notch, which usually occurs with aortic valve closure, is absent in severe AR. A condition called *pulsus bisferiens,* a common finding in the presence of AR, is caused by the tidal-wave effect as regurgitant blood entering the ventricle during early diastole causes a reflected pressure wave that is seen in the aorta. In the PCWP tracing, an accentuated V wave commonly is seen in the presence of AR, presumably reflecting the decreased compliance of the ventricles.

Chronic AR can be caused by aortic root dilation, bicuspid valves, rheumatic fever, failing prostheses, endocarditis, Marfan syndrome, and other conditions. With chronic AR, the left ventricle dilates and becomes more compliant; this leads to a lower LVEDP than in acute AR. End-diastolic pressure may even be in the normal range until terminal failure is present. The systolic arterial pressure increases, and the diastolic pressure decreases; the former is caused by the greater ventricular pressures generated and the latter by continued runoff from the arterial system into the ventricle (Fig. 3.10). AR imposes both a pressure load and a volume load on the left ventricle. Accordingly, the mass of the left ventricle can increase markedly if the condition is chronic.

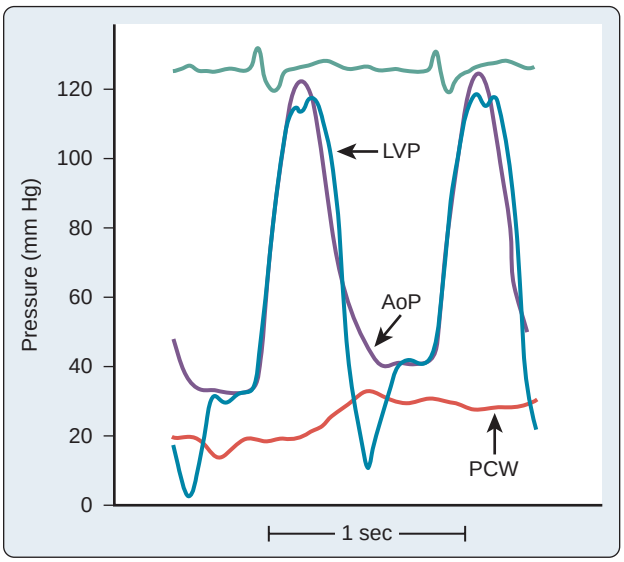

Fig. 3.10 Aortic regurgitation. Simultaneous aortic *(AoP)*, left ventricular *(LVP)*, and pulmonary wedge *(PCW)* pressures demonstrate a wide aortic pulse pressure with absence of the dicrotic notch, a rapid increase in LVP during early diastole caused by regurgitation, and increased PCW, reflective of increased left ventricular end-diastolic pressure. *(Modified from Grossman W, Baim DS. Profiles in valvular heart disease. In: Grossman W, ed.* Cardiac Catheterization, Angiography, and Intervention *[4th ed.]. Philadelphia: Lea & Febiger; 1991:575.)*

Mitral Regurgitation

MR can be either acute or chronic in nature. Acute MR usually occurs secondary to a condition such as acute ischemia that leads to dysfunction of the papillary muscles of the MV or frank rupture of the chordae tendineae or papillary muscles after a significant MI. Rupture of the chordae tendineae can occur in the setting of endocarditis or spontaneously and can cause acute MR (Fig. 3.11). In this instance, it is not uncommon to see an enormously large V wave in the PCWP or LAP tracing as ventricular blood freely flows back into a small, normal, and therefore noncompliant LA. This also is accompanied by acute increases in PA pressure and right atrial pressure, which can lead to significant clinical signs and symptoms of heart failure.

In the setting of chronic MR, the LA can become quite large, nonfunctional, and compliant. Therefore, a significant regurgitant fraction can exist in the presence of a minimal V wave on the pressure tracing.

Prosthetic Valves

The assessment of the function of a bioprosthetic valve is similar to the assessment of a native valve. However, the assessment of a mechanical prosthesis differs in several regards. First, patients with mechanical prostheses require chronic anticoagulation, and this typically needs to be interrupted for the catheterization procedure. Second, mechanical valves should not be crossed with catheters or wires because doing so could cause sudden and severe valvular regurgitation. Finally, the leaflets of a mechanical prosthesis are (slightly) radioopaque, and leaflet motion can be assessed by fluoroscopy. The normal angles of opening and closing are specific to each valve model, size, and location, and these values are available from the manufacturer. Restricted mobility implies that pannus or thrombus has covered one or more leaflets. Similarly, instability of a mechanical prosthesis usually can be detected by fluoroscopy. Echocardiography also is used to evaluate prosthetic valves (see Chapters 14–17). However, transthoracic studies do not reliably view prosthetic mitral leaflets, and fluoroscopy can be repeated serially with little risk or inconvenience to the patient.

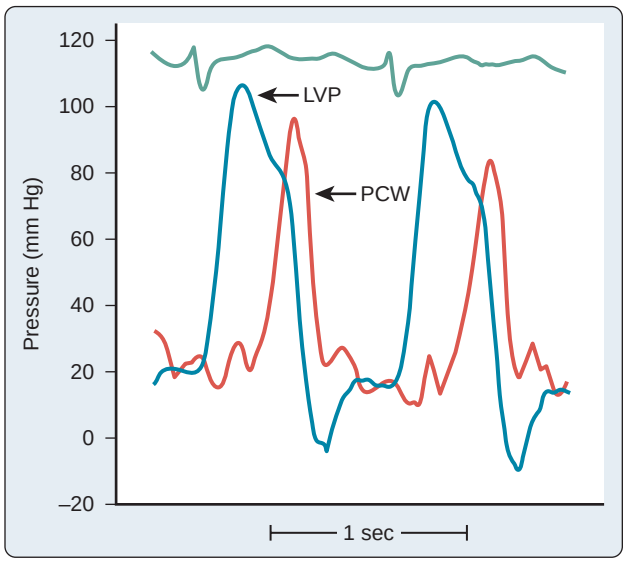

Fig. 3.11 Acute mitral regurgitation caused by chordae tendineae rupture. Simultaneous measurement of left ventricular pressure *(LVP)* and pulmonary wedge *(PCW)* pressure demonstrates a large V wave caused by severe regurgitation into a normal-sized left atrium. Notice that the V wave is delayed temporally. This delay is caused by the time required for the pressure wave to travel through the compliant pulmonary venous and capillary beds to the pulmonary artery catheter. *(Modified from Grossman W, Baim DS. Profiles in valvular heart disease. In: Grossman W, ed.* Cardiac Catheterization, Angiography, and Intervention *[4th ed.]. Philadelphia: Lea & Febiger; 1991:564.)*

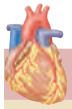

BOX 3.6 ANGIOGRAPHY

Coronary anatomy
- Left anterior descending coronary artery with diagonal and septal branches
- Circumflex artery with marginal branches
- Right coronary artery with conus, sinoatrial nodal, AV nodal, and right ventricular branches
- Dominant circulation (posterior descending): 10% circumflex; 90% right coronary artery

Coronary collaterals
Coronary anomaly
Ventriculography/aortography
EF calculation
Valvular regurgitation

AV, Atrioventricular; *EF*, ejection fraction.

Angiography

Ventriculography

Ejection Fraction Determination

Ventriculography routinely is performed in the single-plane 30-degree right anterior oblique (RAO) or biplane 60-degree left anterior oblique (LAO) and 30-degree RAO projections using 20 to 45 mL of contrast with injection rates of 10 to 15 mL/second (Box 3.6). Complete opacification of the ventricle without inducing ventricular extrasystoles is necessary for accurate assessment during ventriculography. Premature contractions not only alter the interpretation of MR but result in a false increase in the EF.

The EF is a global assessment of ventricular function. It is calculated as follows:

$$EF = [EDV - ESV]/EDV = SV/EDV$$

where EF is ejection fraction, EDV is end-diastolic volume, ESV is end-systolic volume, and SV is stroke volume.

The primary clinical method for calculating ventricular volumes to determine the EF uses the area-length method described by Dodge and coworkers in 1960.[106] Before calculation, visual identification is needed to identify the outer margin of the ventricular silhouette for end-systole and end-diastole in both RAO and LAO projections. The ventricle is approximated as an ellipsoid to facilitate volume calculations (Fig. 3.12). Biplane ventriculography is used to define the major (L) and minor (M and N) axes, following the standard geometric formula for the area (A) of an ellipsoid[107]:

$$A_{rao} = \pi(L_{rao}/2)(M/2)$$
$$A_{lao} = \pi(L_{lao}/2)(N/2)$$

The volume (V) is calculated as follows:

$$V = [8/3\pi][A_{rao}(A_{lao}/L_{min})]$$

where L_{min} is the shorter of L_{rao} and L_{lao}.

Single-plane calculation in the 30-degree RAO projection assumes that M = N and that L is the true long axis. Using the ellipsoid volume calculation, V = π/6 LMN, and substituting 4A/πL for M and N, the following formula is obtained:

$$V = (8A^2/3\pi L)$$

Calculation of EF does not require correction for magnification, but measurement of dimensions or calculation of volumes does. Such correction can be made using a calibrated grid imaged after cineangiography, or the part of the catheter that is in the ventricle can be used for calibration. Catheters with precise calibration markings are available. Contemporary software permits calibration that is based on the heights of the table and the detector. Mathematical equations for ventricular volume overestimate the true volume; regression equations

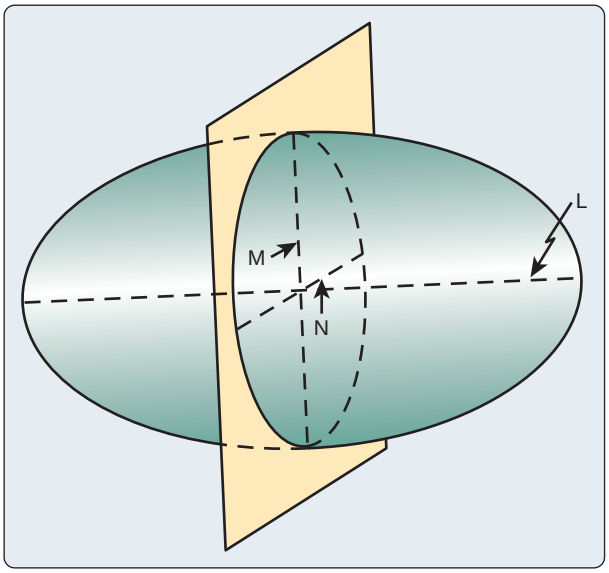

Fig. 3.12 Ellipsoid used as reference diagram for the left ventricle. The long axis *(L)* and the short axes (*M* and *N*) are shown. *(From Fifer MA, Grossman W. Measurement of ventricular volumes, ejection fraction, mass, and wall stress. In: Grossman W, ed.* Cardiac Catheterization and Angiography *[3rd ed.]. Philadelphia: Lea & Febiger; 1986:284.)*

are used to correct for this.[107] This method, or a variation of it, has been incorporated into software on most modern systems.

There are problems with the use of EF as a measure of ventricular function. EFs calculated by various techniques (eg, echocardiography, ventriculography, gated blood pool scanning) may not be identical because of the mathematical modeling involved. When single-plane ventriculography is used to calculate the EF, dysfunction of a nonvisualized segment (eg, the lateral wall in an RAO ventriculogram) and global function may be overestimated. Most importantly, the EF is a load-dependent measure of ventricular function. Changes in preload, afterload, and contractility can significantly alter the EF determination. Therefore, the EF can vary over time without any change in the myocardium if the loading conditions or the inotropic conditions change. Identification of a load-independent measure of LV function has been the quest of many cardiologists over the years. The best approximation requires pressure-volume analysis under various loading conditions to generate a series of curves. Although pressure-volume curve analysis is not used in routine clinical practice, it provides assessment of the systolic and diastolic properties of the ventricle and has been a valuable research tool (see Chapters 6 and 13). In addition to EF calculations, ventriculography allows for estimation of wall stress and LV mass.

Abnormalities in Regional Wall Motion

Segmental wall motion abnormalities are defined in both RAO and LAO projections. A grading scale of 0 to 5 may be used to identify hypokinesis (decreased motion), akinesis (no motion), and dyskinesis (paradoxic or aneurysmal motion). The values are as follows: 0 = normal; 1 = mild hypokinesis; 2 = moderate hypokinesis; 3 = severe hypokinesis; 4 = akinesis; 5 = dyskinesis (aneurysmal). Each wall segment is identified as outlined in Fig. 3.13 for both the LAO and the RAO projection. These segments correspond roughly to vascular territories.

Other details occasionally can be learned from the ventriculogram. Filling defects, particularly in akinetic or dyskinetic segments, can be seen and are suggestive of intracavitary thrombus. VSDs can be detected and localized. Obliteration of the LV cavity or outflow tract during systole suggests intracavitary obstruction, as seen in HCM.

Assessment of Mitral Regurgitation

A qualitative assessment of the degree of MR can be made with LV angiography. This technique depends on proper catheter placement

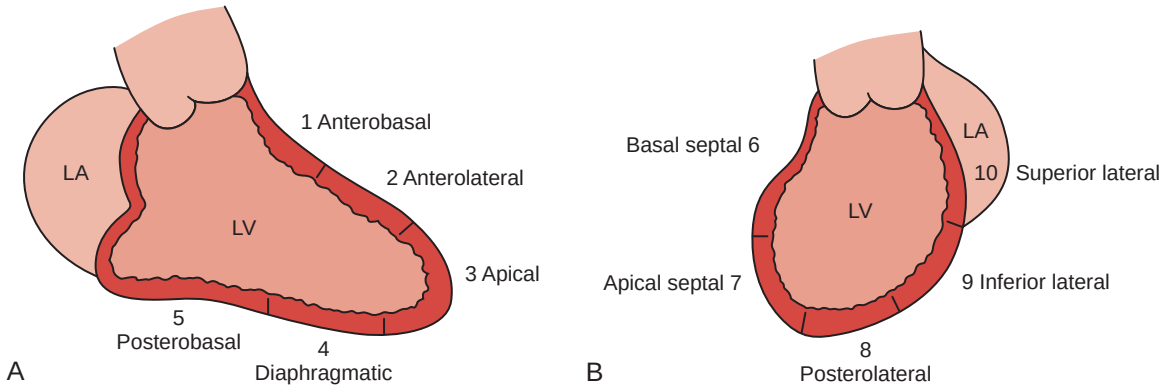

Fig. 3.13 Terminology for left ventricular segments. (A) Terminology for left ventricular segments 1 through 5 analyzed from the right anterior oblique ventriculogram. (B) Terminology for left ventricular segments 6 through 10 analyzed from the left anterior oblique ventriculogram. *LA*, Left atrium; *LV*, left ventricle. *(From Killip T, Principal Investigators of CASS and their Associates. National Heart, Lung, and Blood Institute Coronary Artery Surgery Study.* Circulation. *1981;63[suppl I]:1.)*

outside the mitral apparatus in the setting of no ventricular ectopy. The assessment is, by convention, done on a scale of 1+ to 4+, with 1+ being mild MR and 4+ being severe MR. As defined by ventriculography, 1+ regurgitation is that in which the contrast material clears from the LA with each beat, never causing complete opacification of the LA. Moderate or 2+ MR is present when the opacification does not clear with one beat, leading to complete opacification of the LA after several beats. In 3+ MR (moderately severe), the LA becomes completely opacified and equal in opacification to the left ventricle after several beats. In 4+ MR, the LA densely opacifies with one beat, and the contrast refluxes into the pulmonary veins.

By combining data from left ventriculography and RHC, a more quantitative assessment of MR can be made by calculating the regurgitant fraction. The EDV and ESV are measured, and the difference between them is the total LV stroke volume. The total stroke volume calculated from angiography can be quite high, but in the setting of significant MR, a significant portion of this volume is ejected backward into the LA. The forward stroke volume (FSV) must be calculated from a measurement of forward CO by the Fick or thermodilution method:

$$FSV = CO/HR$$

The regurgitant stroke volume (RSV) then can be calculated by subtracting the FSV from the total stroke volume (TSV):

$$RSV = TSV - FSV$$

The regurgitant fraction (RF) is the RSV divided by the TSV:

$$RF = RSV/TSV$$

An RF of less than 20% is considered mild, 20% to 40% is considered moderate, 40% to 60% is considered moderately severe, and greater than 60% is considered severe MR.

Aortography

The primary indication for aortography performed in the CCL is to delineate the extent of AR. Secondary indications include defining supravalvular lesions and determining the origins of saphenous vein grafts (SVGs). Studies to differentiate proximal and distal dissections may be performed in the CCL. However, TEE, MRI, and CT scanning with contrast are more commonly used to make this diagnosis.[108]

Similar to MR, AR is graded 1+ to 4+ based on the degree of contrast dye present in the LV chamber during aortography. As with MR, assessment of AR is dependent on proper catheter placement free of the valve leaflets but not too high in the ascending aorta. In mild (1+) AR, there is transient filling of the LV cavity by contrast dye that clears after each systolic beat; in moderate (2+) AR, a small amount of contrast dye is regurgitated into the left ventricle and is present throughout the subsequent systolic beat; in moderately severe (3+) AR, a significant amount of contrast dye is present in the left ventricle throughout systole, but not at the intensity of that in the aorta; in severe (4+) AR, contrast dye is present in the left ventricle consistent with the intensity of that in the aorta, with rapid ventricular opacification and delayed clearance after aortic injection.

Coronary Arteriography

Description of Coronary Anatomy

The LM bifurcates into the circumflex (Cx) and LAD arteries and is variable in length (Fig. 3.14). Occasionally, the Cx and LAD arise from separate ostia or the LM trifurcates, creating a middle branch, the ramus intermedius, which supplies the high lateral wall of the left ventricle. Both septal perforators and diagonal branch vessels arise from the LAD, which is described as having proximal, middle, and distal portions based on the location of these branch vessels. The proximal LAD is the portion located before the first septal and first diagonal branch; the middle LAD is between the first and second septal and diagonal branches; and the distal LAD is beyond the major septal and large diagonal vessels. The distal LAD provides the apical blood supply in two-thirds of patients, whereas the distal RCA supplies the apex in the remaining one-third (see Chapters 7 and 20).

The Cx artery is located in the AV groove and is angiographically identified by its location next to the coronary sinus. The latter is seen as a large structure that opacifies during delayed venous filling after left coronary injections. Marginal branches arise from the Cx artery and are the vessels in this coronary artery system usually bypassed. The Cx in the AV groove is often not surgically approachable.

The dominance of a coronary system is defined by the origin of the posterior descending artery (PDA), through which septal perforators supply the inferior one-third of the ventricular septum. The origin of the AV nodal artery often is near the origin of the PDA. In 85% to 90% of patients, the PDA originates from the RCA. In the remaining 10% to 15%, the PDA arises from the Cx artery. Codominance, or a contribution from both the Cx and the RCA, can occur and is defined when septal perforators from both vessels arise and supply the posteroinferior aspect of the left ventricle. Surgical bypass of this region can be difficult when this anatomy exists.

Coronary Anomalies

The coronary anomalies most frequently encountered during coronary angiography are listed in Box 3.7. Anomalous coronary origins are seldom of clinical or surgical significance but potentially make coronary angiography more time-consuming. Rarely, anomalous coronary arteries arising from the opposite cusp and traversing between the PA and the aorta produce vessel compression and ischemia. The Bland–Garland–White syndrome occurs when the LAD arises from the PA. Although most patients present early in life, young adults

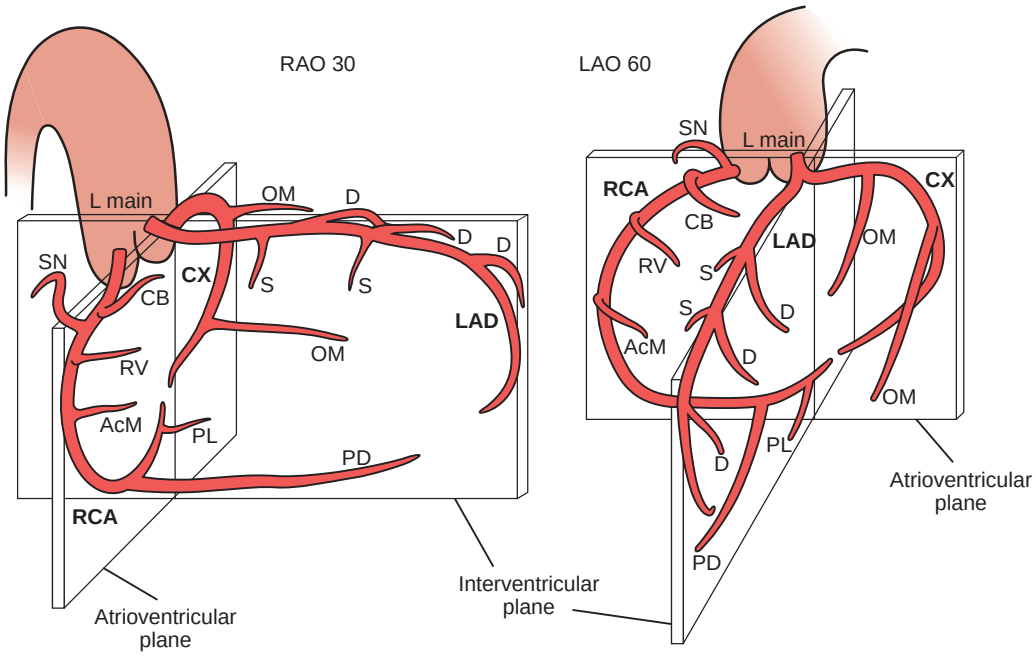

Fig. 3.14 Representation of coronary anatomy relative to the interventricular and atrioventricular valve planes. Coronary branches are indicated as follows: *AcM*, acute marginal; *CB*, conus branch; *CX*, circumflex; *D*, diagonal; *L main*, left main; *LAD*, left anterior descending; *OM*, obtuse marginal; *PD*, posterior descending; *PL*, posterolateral left ventricular; *RCA*, right coronary; *RV*, right ventricular; *S*, septal perforator; and *SN*, sinus node branch. *LAO*, Left anterior oblique; *RAO*, right anterior oblique. *(From Baim DS, Grossman W. Coronary angiography. In: Grossman W, Baim DS, eds.* Cardiac Catheterization, Angiography, and Intervention *[4th ed.]. Philadelphia: Lea & Febiger; 1991:200.)*

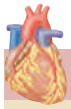

BOX 3.7 CORONARY ANOMALIES

Anomalous Coronary Origin
Left main coronary artery from right sinus of Valsalva separately or with right coronary artery
Circumflex artery as a separate origin off right cusp or with common origin with right coronary artery
Right coronary artery as a separate vessel from left cusp with a separate ostium or having a common ostium with the circumflex branch

Coronary Artery From Pulmonary Artery
Left coronary artery (Bland–Garland–White syndrome)
Right coronary artery

Fistula Formation From Normal Coronary Origin
Coronary branch vessels drain directly into right ventricle, pulmonary artery, coronary sinus, superior vena cava, pulmonary vein

with this syndrome also may present with sudden cardiac death or ischemic cardiomyopathy.[109] Fistulas between a coronary artery and a heart chamber (coronary-cameral fistulas) are not uncommon; most are small and of no clinical significance.[110]

A variety of classification systems have been proposed for coronary anomalies. Some systems try distinguishing significant anomalies from minor ones, whereas others consider all anomalies anatomically, independent of clinical or hemodynamic repercussions.[111] The reported incidence of coronary anomalies varies. The life-threatening anomalies, particularly an anomalous origin of the LM from the right sinus, often are diagnosed at autopsy.[111]

Assessing the Degree of Stenosis

By convention, the severity of a coronary stenosis is quantified as *percentage diameter reduction*. Multiple views of each vessel are recorded, and the worst narrowing is used to make clinical decisions. Diameter reductions can be used to estimate area reductions; for instance, if the narrowing were circumferential, 50% and 70% diameter reductions would result in 75% and 91% cross-sectional area reductions, respectively. Using the reduction in diameter as a measure of lesion severity is difficult if diffuse CAD creates difficulty in defining the "normal" coronary diameter. This is particularly true in patients with insulin-dependent DM and in individuals with severe lipid disorders. In addition, the use of percentage diameter reduction does not account for the length of the stenosis.

Qualitative estimates of percentage of diameter reduction are highly variable among different observers and are not reflective of coronary flow. Using a Doppler velocity probe, White and colleagues[112] demonstrated that lesion severity was underestimated in the overwhelming majority of vessels with more than 60% stenosis. However, when visual interpretation is required for clinical decision making, rather than for research purposes, there may be a systematic bias toward overestimation of lesion severity. Quantitative coronary angiography was developed to overcome the pitfalls of qualitative visual interpretation of lumen reductions. Although the technique was cumbersome in its early iterations, most contemporary imaging systems include a usable quantification program.[113] Even with quantification, however, the limitations of angiography remain.[114] This is especially true in LM disease: Patients with an equivocal stenosis by angiography can often be mistakenly categorized unless a functional assessment of the stenosis is performed.[115] Without this physiologic lesion assessment, mischaracterization of the lesion severity can lead to faulty individual decision making about the need for revascularization.

Accurate interpretation of coronary angiograms and quantitation are possible only when high-quality images are obtained. Contrast

injections must be forceful to fully opacify the artery, and pressure tracings must be closely observed to prevent coronary artery dissection. When smaller catheters are used, smaller syringes or power injection may be required for adequate coronary opacification. Branch vessels must clearly be separated with the use of cranial and caudal angulations. Periodic assessment of image quality is required to ensure that the imaging equipment is functioning properly.[16]

Intravascular ultrasound (IVUS) is an imaging modality that uses a miniature transducer in the lumen of the artery to generate a two-dimensional, cross-sectional image of the vessel. Although electronic (phased-array) transducers exist, most intracoronary systems use mechanical rotation to provide 360-degree imaging. This rotation introduces the potential for artifacts that must be recognized as such. Refinements to these systems permit a transducer diameter of about 1 mm with an imaging frequency of 40 megahertz (MHz) for coronary arteries. However, the transducer is placed into the coronary (or peripheral) artery over a 0.014-inch guidewire. Therefore, it entails greater risk than angiography, and anticoagulation is mandatory. The transducer is placed distally in the vessel, and a mechanical system is used to withdraw the transducer at a controlled rate, typically 0.5 mm/second, while a recording is made. Software permits reconstruction of serial cross-sectional images into longitudinal views, and volumetric analysis is possible. Both the lumen and the vessel wall can be imaged. The apposition of stent struts can be confirmed, and small dissections can be seen. Wall constituents such as calcium and pooled lipids can be identified, allowing a "virtual histology" analysis.

IVUS has been a critical research tool over the years. For instance, early stent implantation was associated with a high risk for subacute thrombosis that seemed refractory to anticoagulants. IVUS identified incomplete expansion of many stents with the existing deployment techniques and incomplete apposition of the struts to the vessel wall. Deployment techniques were modified to include higher pressures and larger balloon diameters, and the incidence of subacute thrombosis subsequently receded. The volumetric measurements made possible by IVUS are sufficiently reproducible to gauge the effects of medication on the progression of atherosclerotic plaque. IVUS is used clinically in selected situations. In a study comparing IVUS findings with quantitative angiography, the plaque burden at maximal obstruction frequently was underestimated by quantitative angiography.[114] IVUS is useful in evaluating equivocal lesions of the LM, ostial stenoses, and vessels overlapping angiographically, and it is superior to angiography in early detection of the diffuse, immune-mediated arteriopathy of cardiac transplantation allografts.[116,117] As an adjunct to PCI, IVUS has been used to assess the adequacy of stent deployment, the extent of vessel calcification, and the presence of edge dissections.[118] IVUS reports contain information on diameter reductions and area reductions, which translate to angiographic values. However, an important value in the IVUS report is the minimal luminal area (MLA). Generally, an MLA of less than 4.0 mm^2 in a proximal coronary vessel correlates with an ischemic response during perfusion imaging, and an MLA of less than 6.0 mm^2 in the LM correlates with ischemia. Finally, IVUS can be used to ensure optimal stent sizing and deployment. Similar equipment exists for peripheral vessels, although the role of IVUS in the periphery remains to be delineated.

A newer imaging modality in the CCL, one that produces images similar to those obtained with IVUS, is optical coherence tomography (OCT). The fundamental difference is the use of light rather than ultrasound for the production of high-resolution intracoronary images. The coronary OCT light source uses a bandwidth in the near-infrared spectrum with central wavelengths ranging from 1250 to 1350 nm. At these wavelengths, tissue penetration is limited to 1 to 3 mm, compared with 4 to 8 mm achieved by IVUS.[119] The image is formed by backscattering of light from the vessel wall. With higher resolution, OCT demonstrates higher sensitivity in the detection of stent malapposition, neointimal hyperplasia, and intrastent tissue protrusion, but it is less valuable for imaging plaque size or determining tissue characteristics (Fig. 3.15).[120] Therefore, the main advantage of OCT is to optimize stent deployment. With continued refinements, this imaging modality will likely become more widely used. At the present time, it remains largely a research tool.

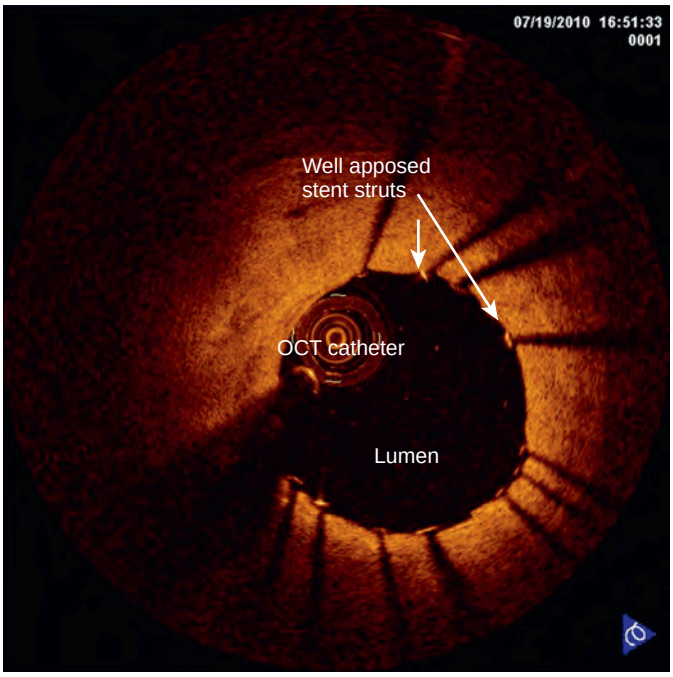

Fig. 3.15 A coronary artery and stent struts after deployment as visualized by optical coherence tomography (OCT).

Anatomic information is usually used to guide management decisions. However, revascularization may offer no advantage over medical therapy when it is guided by anatomic data.[121] This finding has prompted renewed interest in the physiologic assessment of coronary stenoses.[122] One method uses a Doppler probe that is incorporated into a standard, 0.014-inch angioplasty wire (Volcano Therapeutics, San Diego, CA). The Doppler probe is placed distal to the coronary stenosis, and the baseline velocity is recorded. An intracoronary (or IV) agent is administered to produce maximal coronary dilation, and the velocity is recorded again. A normal response is about a fourfold increase in velocity, but for clinical use a value of twofold is used. The stability of velocity recordings varies, and accurate readings require careful placement of the probe into the middle of the vessel. These concerns have limited use of the Doppler wire in clinical practice. An alternative is the Pressure Wire (St. Jude Medical, St. Paul, MN), which incorporates a micromanometer into a standard angioplasty wire. Again, the micromanometer is placed distal to the stenosis, and maximal coronary dilation is induced by administration of an intracoronary or IV vasodilator. The ratio of the distal pressure to the aortic pressure (measured at the tip of the guiding catheter) is calculated at peak vasodilation and is termed the *fractional flow reserve* (FFR). Correlation with nuclear stress testing has been good for both techniques. For instance, an FFR of less than 0.75 after adenosine vasodilation predicts an abnormal nuclear perfusion scan result. This can aid in the assessment of an angiographically borderline stenosis. Clinical outcomes have been good for those patients with a higher ratios.[123,124] Moreover, when PCI is guided by pressure-wire measurements, as opposed to angiography alone, fewer stents are implanted and clinical outcomes are superior.[125–127]

Coronary Collaterals

Common angiographically defined coronary collaterals are described in Box 3.8. Although they are present at birth, these vessels become functional and enlarge only if an area of myocardium becomes hypoperfused by the primary coronary supply.[128] Angiographic identification of collateral circulation requires both knowledge of the potential

BOX 3.8 COLLATERAL VESSELS

Left Anterior Descending Coronary Artery (LAD)
Right-to-Left
Conus to proximal LAD
Right ventricular branch to mid-LAD
Posterior descending septal branches at midvessel and apex

Left-to-Left
Septal to septal within LAD
Circumflex-OM to mid-distal LAD

Circumflex Artery (Cx)
Right-to-Left
Posterior descending artery to septal perforator
Posterior lateral branch to OM

Left-to-Left
Cx to Cx in AV groove (left atrial circumflex)
OM to OM
LAD to OM via septal perforators

Right Coronary (RCA)
Right-to-Right
Kugels—proximal RCA to AV nodal artery
RV branch to RV branch
RV branch to posterior descending
Conus to posterior lateral

Left-to-Right
Proximal middle and distal septal perforators from distal LAD
OM to posterior lateral
OM to AV nodal
AV groove Cx to posterior lateral

BOX 3.9 INTERVENTIONAL CARDIOLOGY TIMELINE

1977 Percutaneous transluminal coronary angioplasty (PTCA)
1991 Directional atherectomy
1993 Rotational atherectomy
1994 Stents with extensive antithrombotic regimen
1995 Abciximab approved
1996 Simplified antiplatelet regimen after stenting
2001 Distal protection
2003 Drug-eluting stents (DES)
2008 Second-generation DES
2010 Percutaneous pulmonary valve approved
2011 Transcatheter aortic valve replacement (TAVR) approved
2012 MitraClip approved
2015 Impella approved

collateral sources and prolonged imaging to allow for coronary collateral opacification.

The increased flow from the collateral vessels may be sufficient to prevent ongoing ischemia. A main coronary or branch vessel must be reduced in luminal diameter by 80% to 90% to recruit collaterals for an ischemic area. Clinical studies suggest that collateral flow can double within 24 hours during an episode of acute ischemia.[129] However, collateral vessels require time to develop, and only well-developed collaterals respond to NTG. The RCA is a better collateralized vessel than the LM. Areas that are supplied by good collaterals are less likely to be dyskinetic or akinetic.

Interventional Cardiology: Percutaneous Coronary Intervention

A timeline of important events in the history of PCI is presented in (Box 3.9). Catheter-based interventions were initially pioneered by Andreas Gruentzig in 1977 as PTCA, and they have expanded dramatically beyond the balloon to include a variety of PCIs.[130] The use of PCI in the United States has grown considerably since the early 1980s; however, the annual volume of PCI procedures peaked in 2006 and has steadily declined since then. Numerous factors have contributed to this reduction in procedural volume, including a reduction in restenosis by drug-eluting stents (DESs), a greater emphasis on medical therapy for the treatment of stable CAD, enhanced primary and secondary prevention efforts, a reduction in the incidence of ST-segment elevation myocardial infarction (STEMI), the increasing use of parameters such as FFR to better evaluate lesion severity, and the development and application of appropriate use criteria.[23]

The discussion of interventional cardiology is divided into two parts. The first part consists of a general discussion of issues that relate to all catheter-based interventions, including indications, operator experience, equipment and procedures, restenosis, and complications. Anticoagulation and controversial issues in interventional cardiology also are reviewed. The second part is a discussion of the various catheter-based systems for PCI, beginning with the first one, PTCA, and including devices in development. With this review, the cardiac anesthesiologist may better understand the current practice and future direction of interventional cardiology.

General Topics for All Interventional Devices

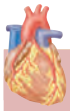
Indications

Throughout the history of PCI, technology and operator expertise have continually advanced. The interventionalist now has the capability to approach places in the coronary tree that were previously inaccessible. This is reflected in the expanded role for PCI. Although PCI was first restricted to patients with single-vessel disease and normal ventricular function who had a discrete, noncalcified lesion in the proximal vessel, it now is performed as preferred therapy in many groups of patients, including selected patients with unprotected LM stenosis (ie, no bypass grafts).[131] The most recently published guidelines state that LM PCI is a reasonable alternative to CABG in patients who have anatomic conditions associated with good procedural and longer-term outcomes and who are at increased risk for surgery.[23]

Box 3.10 provides a summary of current clinical indications for PCI. Primary PCI is the standard of care for patients with STEMI with or without cardiogenic shock.[28,132] Although PCI was initially reserved for patients who were considered suitable candidates for CABG, it is now routinely performed in patients who are not candidates for CABG in both emergent and nonemergent settings.[23] In considering both the indications and the appropriateness of PCI, the physician must review the patient's history, including functional class, treadmill results with or without perfusion data, and wall motion assessment analysis. Noninvasive demonstration of ischemia, either before the procedure or with an intraprocedural physiologic assessment, avoids inappropriate procedures prompted by the significant interobserver variability in visual assessment of percent diameter reduction that occurs even among experienced angiographers.[121,133–135]

Absolute contraindications are few. For unprotected LM stenosis in a patient who is a surgical candidate, has diffusely diseased native vessels, or has a single remaining conduit for myocardial circulation, a PCI approach is used only after the case has been considered by the heart team.[23] Several series of unprotected LM PCI procedures have been published, and this topic is in evolution.[131,136] Although the procedural risk is low, most of these procedures are performed in patients who are not ideal operative candidates (see later discussion). Multivessel PCI frequently is performed and remains a reasonable alternative to CABG in selected patients.[134] However, CABG remains the preferred therapy for many patients, particularly those with DM.[137]

In addition to indications and contraindications, there is the concept of appropriateness. The SCAI, The Society of Thoracic Surgeons (STS), the American Academy of Thoracic Surgeons (AATS), the ACC, and the AHA published a consensus document on coronary revascularization in 2009, followed by an update in 2012.[138,139] These documents attempted to identify the appropriate therapy for various patient scenarios, based on presentation, anatomy, medications, and results of noninvasive and invasive testing. For each scenario, revascularization is considered appropriate, inappropriate, or uncertain. Although this consensus approach is far from all-inclusive and does not replace the physician's judgment in regard to an individual patient, these documents provide an overview of the potential appropriateness of medical therapy, PCI, and CABG.



BOX 3.10 CLINICAL INDICATIONS FOR PERCUTANEOUS TRANSLUMINAL CORONARY INTERVENTIONAL PROCEDURES

Cardiac Symptoms
- Unstable angina pectoris or non–ST-segment elevation myocardial infarction (NSTEMI)
- Angina refractory to antianginal medications
- Angina after myocardial infarction
- Sudden cardiac death

Diagnostic Testing
- Early positive exercise tolerance testing
- Positive exercise tolerance test despite maximal antianginal therapy
- Large areas of ischemic myocardium on perfusion or wall motion studies
- Positive preoperative dipyridamole or adenosine perfusion study
- Electrophysiologic studies suggestive of arrhythmia related to ischemia

Acute Myocardial Infarction
- Cardiogenic shock
- Unsuccessful thrombolytic therapy in unstable patient with large areas of myocardium at risk
- Contraindication to thrombolytic therapy
- Cerebral vascular event
- Intracranial neoplasm
- Uncontrollable hypertension
- Major surgery <14 days previously
- Potential for uncontrolled hemorrhage
- Probably preferred for all cases of ST-segment elevation acute myocardial infarction (STEMI)

Equipment and Procedure

Although the femoral artery is still the most commonly used access site, the radial artery has seen increased adoption, as discussed earlier. Despite numerous advances, all PCIs still involve sequential placement of the following: a guiding catheter in the ostium of the vessel, a guiding wire across the lesion and into the distal vessel, and one or more devices of choice at the lesion site. Routine central venous access is not required and increases access site complications. Its use is reserved for situations in which peripheral venous access is limited, temporary pacing may be required, or hemodynamic monitoring may be helpful.

Guiding catheters are available in multiple shapes and sizes for coronary and graft access, device support, and radial artery entry.[23,130] Guidewires offer flexible tips for placement into tortuous vessels and stiffer shafts to provide support for the newer devices during passage within the vessel. Separate guidewire placement within branch vessels may be required for coronary lesions at vessel bifurcations (Fig. 3.16; see Videos 3-1 and 3-2). In selecting the appropriate device for a particular lesion, IVUS or OCT may be used to determine the size of the vessel and the composition of the lesion.[135,140,141]

While a device is present in a coronary artery, blood flow is impeded to a varying degree. In vessels that supply large amounts of myocardium (eg, proximal LAD), prolonged obstruction of flow is poorly tolerated. However, when only smaller areas of myocardium are jeopardized or the distal vessel is well collateralized, longer occlusion times are possible. Distal protection devices, which involve balloon occlusion, may result in loss of flow down the vessel for up to 5 minutes. However, with current technology, occlusion times seldom exceed 1 minute.

The performance of PCI immediately after a diagnostic procedure is known as an ad hoc intervention. This strategy is obviously preferred in emergent situations and has become the default paradigm in stable CAD as well. It is more convenient for the patient and more cost-effective from a payer standpoint. However, it has been suggested that ad hoc PCI may be performed too frequently in situations in which a procedural pause would be preferable for additional informed consent or for consideration of alternative revascularization strategies.[142] Ad hoc PCI requires careful preparation because the patient and family must understand not only the risks and benefits of the diagnostic procedure but also those of various revascularization strategies. Informed consent is required for all potential procedures before sedation is given. The cardiologist must carefully assess each clinical situation and must have a collegial relationship with his or her surgical colleagues to expedite heart team discussions in cases of complex CAD. In general, ad hoc PCI is appropriate for symptom relief in patients who are receiving optimal antianginal therapy, have symptoms limiting their quality of life, and have evidence of ischemia in the target artery by stress testing or FFR. Among those with stable ischemic heart disease,

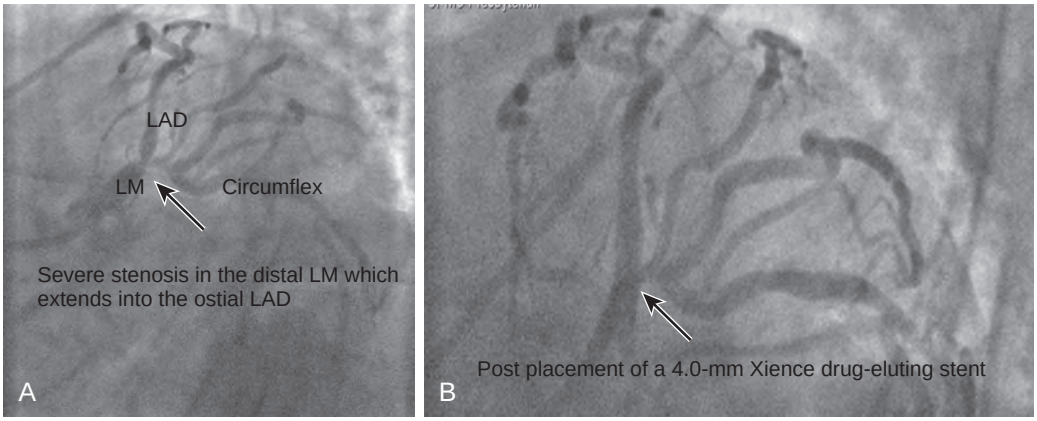


Fig. 3.16 (A) Severe stenosis in the distal left main coronary artery *(LM)* which extends into the ostial left anterior descending coronary artery *(LAD)*. (B) Image obtained after placement of a 4.0-mm Xience drug-eluting stent.

it is most appropriate to proceed with ad hoc PCI when the patient is symptomatic with large areas of myocardium at risk. Ad hoc PCI may be inappropriate if complications have occurred during the diagnostic catheterization, excessive radiation or contrast was used, or a heart team approach is indicated to identify the best strategy for treatment of complex coronary disease.

Antiischemic medications may permit longer periods of vessel occlusion before signs and symptoms of ischemia become limiting.[143] This additional time could permit the completion of a complex case or allow the use of distal protection devices. Most centers use either intracoronary or IV NTG at some point during the procedure to treat or prevent coronary spasm. Intracoronary calcium channel blockers frequently are used to treat vasospasm and the "no-reflow" phenomenon.[144] The latter term describes an absence of flow in a coronary vessel when there is no epicardial obstruction. No-reflow is associated with a variety of adverse outcomes; it is seen when acutely occluded vessels are opened during an MI or when PCI is performed in old SVGs. The cause is believed to be microvascular obstruction from embolic debris or microvascular spasm or both. Intracoronary calcium antagonists may help to restore normal flow, and nicardipine is preferred for its relative lack of hemodynamic and conduction effects.[145] Nitroprusside and adenosine have also been used effectively. Continuous NTG infusions are rarely necessary after PCI unless symptoms or signs of ongoing ischemia are detected.

After the PCI procedure, the patient is transferred to the appropriate unit for the level of care required. The STEMI patient is admitted to the cardiac care unit, the inpatient with ACS often returns to the previous level of care, and the outpatient returns to the equivalent of a preprocedure/postprocedure holding area. As the field of interventional cardiology has changed since the 1970s, so has care of the patient after PCI.[146] Multiple factors enter into the location and duration of post-PCI care. Hospitals must work with physicians and patients to create the appropriate pathways to provide quality patient care.

Restenosis

Once PTCA/PCI became an established therapeutic option for treatment of CAD, two major limitations were realized: acute closure and restenosis. The use of stents and antiplatelet therapy significantly decreased the incidence of acute closure. Before stents were available, restenosis occurred in 30% to 40% of PTCA procedures. With stent use, this figure decreased to about 20%. However, restenosis remained the Achilles heel of intracoronary intervention until the advent of the DES.

Restenosis usually occurs within the first 6 months after an intervention and has three major mechanisms: vessel recoil, negative remodeling, and neointimal hyperplasia.[147] Vessel recoil is caused by the elastic tissue in the vessel and occurs early after balloon dilation. It is no longer a significant contributor to restenosis because metal stents are almost 100% effective in preventing recoil.[148] Negative remodeling refers to late narrowing of the external elastic lamina and adjacent tissue, which accounted for up to 75% of lumen loss in the past.[147] This process also is prevented by metal stents and no longer contributes to restenosis. Neointimal hyperplasia is the major component of in-stent restenosis (ISR) in the current era. Neointimal hyperplasia is more pronounced in the diabetic patient, which explains the increased incidence of restenosis in this population.[149] DESs limit neointimal hyperplasia and have dramatically reduced the frequency of ISR.[150,151]

Establishing the true rate of restenosis requires a uniform definition. Clinical restenosis is defined as recurrence of angina or a positive stress test that results in a repeat procedure. Angiographic restenosis is defined at repeat catheterization and occurs at a greater rate than clinical restenosis. To be classified as a restenotic lesion at follow-up catheterization, there must be a reduction in luminal diameter at least 50% visually, with a decrease of 0.72 mm quantitatively from the post-PTCA result.[152] IVUS can measure the cross-sectional area and may be used in assessing restenosis.[147] Because restenosis usually occurs within 6 to 12 months after intervention, symptoms occurring after the first year more commonly represent progression of atherosclerotic disease.[152]

Several clinical factors have been linked to restenosis. These include cigarette smoking, DM, male sex, absence of prior infarction, and unstable angina. Of these, only DM has consistently shown a statistically significant association with restenosis.[152] Lesion characteristics proven to predict restenosis are lesion location, baseline stenosis diameter and length, post-PTCA stenosis severity, and adjacent artery diameter.[153] In the stent era, the major predictors of restenosis are the presence or absence of DM, lesion length, and stent diameter.

Medical therapy to decrease restenosis has been challenging.[154] Aspirin decreases the risk for acute occlusion but does not significantly decrease the risk for restenosis. The use of cilostazol to prevent ISR has shown promise in the limited clinical trials available.[155] Vascular brachytherapy has been useful to treat ISR, but results for prophylactic treatment have been disappointing.[156,157]

The major gains in combating restenosis have been in the area of stenting.[158] Intracoronary stents maximize the increase in lumen area during the PCI procedure and decrease late lumen loss by preventing recoil and negative remodeling. However, neointimal hyperplasia is enhanced because of a foreign body–like reaction to the stent. Different stent designs and strut thicknesses lead to different restenosis rates.[159,160] Systemic administration of antiproliferative drugs decreases restenosis but causes significant systemic side effects. DESs that use a polymer to attach the antiproliferative drug to the stent have shown the best results to date for decreasing restenosis.[150,151,161]

In the days of balloon angioplasty, the risk for acute vessel closure was 5% to 10%, but these events occurred almost exclusively in the CCL or within the first 24 hours after the procedure. Acute closure was related to dissection, thrombosis, or both. Emergent bypass surgery was frequently necessary to salvage myocardium. Bare metal stents (BMSs) reduced the incidence of acute closure dramatically but introduced a less common phenomenon, stent thrombosis.[162] Stent thrombosis is a rare circumstance, but when it is encountered, it frequently results in a large MI or death. In 2007, the Academic Research Consortium put forth a new standard definition in order to make it possible to compare the true rates of stent thrombosis across different trials and registries. By this definition, early stent thrombosis is defined as an event that occurs within 30 days after the index stent insertion, and late stent thrombosis (LST) is one that occurs between 30 and 360 days after insertion. Very late stent thrombosis is that which occurs after 1 year.[163] In addition to the timing of the event, the definition is also subdivided into definite, probable, and possible stent thrombosis. Adequate stent deployment and thienopyridine therapy reduce the frequently of early stent thrombosis to about 1%.

Important lessons were learned when stent placement was accompanied by brachytherapy. LST was recognized as an important problem and appeared to be caused by delayed coverage of the stent struts. As a result, prolonged use of thienopyridines became imperative because it reduces the likelihood of LST.[164]

In anticipation of a similar situation, namely delayed stent coverage by neointima, the clinical trials of DESs incorporated prolonged thienopyridine therapy. In these trials of predominantly low-risk patients treated with a 3- to 6-month course of thienopyridines, the risk for stent thrombosis was identical to that seen with BMSs, at least out to 1 year.[165] However, case reports and registry reports began to describe LST. Pathologic reports described incomplete tissue coverage of DESs at late time points.[166] In response to this information, the FDA convened a panel to evaluate the problem in December 2006. Several specialty organizations responded by recommending that the course of clopidogrel be extended to 1 year after implantation of a DES if no contraindications exist.[167,168]

Although all DESs have the same general components, they differ with respect to the stent platform, the polymer coating, and the antirestenotic drug type embedded in the polymer. With the advent of second-generation DESs, which use different polymers and different drug elution types, there has been a considerable decline in the rates of LST.[169] This change in technology has reinvigorated the debate about

the optimal duration of dual antiplatelet therapy (DAPT) after DES placement. Randomized published trials have suggested that 6 months of DAPT appears equivalent to longer durations of DAPT.[170] However, another DAPT trial showed improved outcomes in those treated with a combination of aspirin and clopidogrel for 30 months compared with the traditional 12 months.[171] These findings will most likely result in modifications to the current guidelines. Most practicing cardiologists are now attempting to individualize the duration of DAPT by taking into account the type of stent placed, the complexity of the lesion, the patient's bleeding risk, other medical comorbidities, and the need for long-term warfarin or NOAC therapy. Discontinuation of antiplatelet therapy should be approached with caution, and long-term single antiplatelet therapy with aspirin is recommended indefinitely (see Chapters 35 and 44).

Anticoagulation

Thrombosis is a major component of ACS and of acute complications during PCI; its management is continually evolving.[172,173] Proper anticoagulation regimens are essential to limit bleeding complications and thrombotic complications, both of which negatively impact prognosis.[174] This is most important with interventional procedures, in which the guiding catheter, wire, and device in the coronary artery serve as nidi for thrombus. In addition, catheter-based interventions disrupt the vessel wall, exposing thrombogenic substances to the blood. Table 3.3 summarizes current antiplatelet regimens in patients receiving stents (see Chapters 35 and 44).

The primary pathway for clot formation during PCI has proved to be platelet mediated. This has prompted a focus on aggressive antiplatelet therapy. Aspirin was developed in the late 19th century and subsequently was found to block platelet activation by irreversible acetylation of cyclooxygenase. It remains the foundation of antiplatelet therapy for PCI patients. When administered at least 24 hours (and preferably up to 72 hours) before the intervention in doses of 81 to 1500 mg, aspirin decreases thrombotic complications.[172] Aspirin resistance and combination therapy with nonsteroidal antiinflammatory drugs are controversial.[175] Cilostazol, a phosphodiesterase inhibitor with antiplatelet effects, has been used in peripheral vascular disease; data on the use of cilostazol after coronary intervention remain inconclusive.[176]

Clopidogrel, ticlopidine, prasugrel, ticagrelor, and cangrelor block the adenosine diphosphate (ADP) receptor P2Y12 on platelets. Initially, ticlopidine was the thienopyridine used after PCI. However, side effects, including dyspepsia, neutropenia, and a small but clinically significant incidence of thrombotic thrombocytopenic purpura, led to its replacement by clopidogrel, which has a lower incidence of these events.[177,178] Clopidogrel (Plavix) has been shown to be beneficial in patients with ACS for up to 9 months of therapy, both with and without PCI.[179] A 1-month course of clopidogrel is standard therapy after implantation of a BMS for stable disease. An extended course of therapy is used when BMSs are implanted for ACS.[180] At least 1 year of clopidogrel therapy is recommended when a DES is implanted for any indication.[167] Because clopidogrel and prasugrel are prodrugs, their onset of action is slow unless a loading dose is used. A loading dose of 300 or 600 mg is typically administered.[181] The relative efficacy and safety of clopidogrel have been established in men and women, although the variability in individual responsiveness has raised concern.[182,183] Resistance to an antiplatelet drug is a pharmacodynamic phenomenon in which there is no significant reduction from baseline in platelet function after treatment. Despite the variability of platelet reactivity, the most recently updated ACC guidelines do not recommend routine platelet testing in those with stable or unstable coronary syndromes.[23] The 2012 update to the STS guideline on use of antiplatelet drugs in patients undergoing cardiac surgery stated that preoperative point-of-care platelet testing to assess bleeding risk and, ultimately, the timing of surgery may be useful after treatment with usual doses of antiplatelet drugs.[184]

Prasugrel (Effient), like clopidogrel and ticlopidine, is a third-generation thienopyridine prodrug that is converted into an irreversible antagonist of the ADP P2Y12 receptor. However, its onset of action is faster and less variable. When compared with clopidogrel in patients with ACS, prasugrel reduced ischemic complications (ie, nonfatal MI, need for urgent revascularization, and stent thrombosis) but caused more bleeding complications. An unfavorable risk/benefit ratio was identified for three groups: age 75 years or older, body weight less than 60 kg, and a history of stroke or transient ischemic attack. Major bleeding related to CABG was significantly greater with prasugrel (13%, vs 3% with clopidogrel), which is why surgery in patients taking prasugrel should be delayed to permit recovery of platelet function.[185]

Ticagrelor (Brilinta) is a newer, nonthienopyridine inhibitor of the P2Y12 receptor. Unlike the other drugs in its class, binding to the P2Y12 receptor is reversible. It has a much faster onset of action than clopidogrel and has been assigned to a new chemical class of antiplatelet agents, the cyclopentyltriazolopyrimidines. Its safety and effectiveness was documented in the PLATO trial, which involved 18,000 patients presenting with an ACS. There was an overall 2% absolute risk reduction in the composite end point of death, recurrent MI, or cerebrovascular accident with ticagrelor compared with clopidogrel.[186]

TABLE 3.3 Anticoagulation in the Catheterization Laboratory

Medication	*Dose*	*Mechanism of Action*	*Half-Life*	*Monitoring*
Antiplatelet Medications				
Aspirin	75–325 mg	Acetylates cyclooxygenase	3 h	Platelet function assays
Clopidogrel	300–600 mg loading dose 75 mg daily	Irreversibly binds to P2Y12 platelet receptor	6 h	Platelet function assays
Prasugrel	300 mg loading dose 5–10 mg daily	Irreversibly binds to P2Y12 platelet receptor	7 h	Platelet function assays
Ticagrelor	300 mg loading dose 90 mg bid daily	Irreversibly binds to P2Y12 platelet receptor	7 h	Platelet function assays
Glycoprotein IIb/IIIa Inhibitors				
Abciximab	0.25 mg/kg bolus 0.125 μg/kg per min infusion	Monoclonal antibody GPIIb/IIIa platelet receptor inhibition	30 min	Platelet function assays
Eptifibitide	180 μg/kg bolus 2 μg/kg per min infusion	Cyclic heptapeptide GPIIb/IIIa platelet receptor inhibition	2.5 h	Platelet function assays
Tirofiban	25 μ/kg bolus 0.15 μg/kg per min infusion	Nonpeptide GPIIb/IIIa platelet receptor inhibition	2 h	Platelet function assays
Anticoagulants				
Heparin	70–100 U/kg bolus	Indirect inhibitor of thrombin	Dose-dependent, ~1 h	Activated clotting time (ACT), partial thromboplastin time (PTT)
Enoxaprin	0.5–0.75 mg/kg bolus	Inhibitor of factor Xa	4 h	Anti-Xa levels
Bivalirudin	0.75 mg/kg bolus 1.75 mg/kg per h infusion	Direct thrombin inhibitor	25 min	ACT

Another important finding suggested a potential negative interaction between ticagrelor and high-dose aspirin. Therefore, the current recommendations suggest that patients maintain their daily dose of aspirin at 100 mg or less when used in conjunction with ticagrelor for the treatment of ACS, including those patients who undergo stenting.

Cangrelor is another ADP inhibitor that is unique in its delivery form as an IV agent. Advantages of cangrelor, which might improve clinical outcomes over other antiplatelet agents, are its rapid onset of action and rapid return of platelet function after cessation. Cangrelor (Kangrelor) was approved for clinical use by the FDA in late 2015.[187]

Several additional issues should be highlighted regarding antiplatelet therapy. Thienopyridine therapy for ACS patients has been shown to reduce cardiac events, but concerns have been raised about bleeding should CABG be necessary. The consistency and magnitude of this observation have not been sufficient to limit its use in these situations.[188] Management of patients undergoing invasive or noncardiac surgical procedures on DAPT is complicated and requires consideration of all options (see Chapter 44). The risks associated with drug discontinuation (stent thrombosis, MI, death) must be weighed against the risks of continuation of the drugs (bleeding) and the risks of cancellation or deferral of the procedure.[189] All antiplatelet and anticoagulant medications increase the risk for bleeding, and DAPT increases the risk more than single therapy does. The ACC, the American College of Gastroenterology, and the AHA published a Clinical Expert Consensus Document in 2008. This document recommended therapy with a proton pump inhibitor (PPI) for virtually all patients receiving DAPT.[190] More recently, observational data suggested that the combination of clopidogrel and a PPI was associated with a greater rate of ischemic events, and ex vivo studies showed that the combination was associated with less inhibition of platelet function than clopidogrel alone. This led to an FDA warning about the combination in 2009, which was followed by the performance of a randomized trial. The conclusions were that among patients receiving aspirin and clopidogrel, prophylactic use of a PPI reduced the rate of upper gastrointestinal bleeding. In addition, there was no apparent cardiovascular interaction between clopidogrel and omeprazole.[191]

Another clinical conundrum involves combining antiplatelet and anticoagulant therapy in patients with concomitant coronary vascular disease and a high CHA_2DS_2-VASc atrial arrhythmia score,[32a] a combination that has been shown to increase an individual's bleeding risk.[192,193] When confronted with this scenario, many physicians avoid triple therapy with warfarin, aspirin, and a thienopyridine. Published data have shown a reduction in bleeding with double therapy (clopidogrel plus warfarin) compared with triple therapy.[194] Depending on the type of stent used and the time course of treatment, the regimen may also consist of warfarin plus acetylsalicylic acid, which produces an even lower bleeding rate.[192] Overall, the optimal treatment for these patients requires careful consideration of the indications for each therapy as the risks and benefits of combination therapy are weighed.

UFH has been used since the inception of PTCA, with the dose regimen undergoing significant evolution over time. Initially, high doses were used to prevent abrupt closure of the vessel. With experience and the introduction of stents, the dosing has evolved into a weight-based regimen (70–100 U/kg) that is routine and endorsed by the guidelines.[23] The ACT is monitored to guide additional heparin therapy. Protamine is not routinely used, and the femoral sheaths are removed once the ACT is 150 seconds or less. If a transradial approach is used, the sheath is removed immediately after the procedure and a transradial band is placed to apply hemostatic pressure while allowing for adequate perfusion to the affected hand (patent hemostasis). Limitations of UFH include a variable antithrombotic effect requiring frequent ACT measurements, inability to inhibit clot-bound thrombin, and concerns regarding heparin-induced thrombocytopenia syndrome. These limitations have led to the search for a replacement for UFH.[195]

As an alternative to heparin, direct thrombin inhibitors have been investigated in the setting of PCI. The synthetic compound bivalirudin (Angiomax; The Medicines Company, Parsippany, NJ) is the best studied of these agents (see Chapter 35). The advantage of direct thrombin inhibitors is the direct dose response and the shorter half-life, which leads to a lower incidence of bleeding complications. The Bivalirudin Angioplasty Trial randomized 2161 patients and supported the hypothesis that bivalirudin reduces ischemic complications marginally but reduces bleeding dramatically during PCI, compared with UFH.[196] The REPLACE-2 trial randomized 6010 patients undergoing PCI (primarily stenting) to bivalirudin or UFH with glycoprotein IIb/IIIa (GPIIb/IIIa) inhibition.[197] MACEs were similar between the two groups, but major bleeding was significantly less in the bivalirudin group. The ACUITY trial studied 13,819 patients with ACS undergoing PCI, comparing bivalirudin alone with either UFH or enoxaparin and a GPIIb/IIIa inhibitor (GPI). One-year results showed no difference in composite ischemia or mortality among the three groups.[198] The HORIZONS-AMI trial randomized 3602 STEMI patients undergoing PCI to bivalirudin or UFH with a GPI. The bivalirudin group had fewer clinical events, lower mortality rates (cardiac and total), and less major bleeding at 1 year.[199] As a result of these studies, bivalirudin has become the most widely used antithrombin agent for ACS patients. However, newer data have questioned the superiority of bivalirudin over UFH alone with lower dosing and selective use of GPIs. The recently published HEAT-PPCI trial showed no difference in bleeding rates but higher rates of definite stent thrombosis in the bivalirudin arm, and this finding has prompted many operators to reconsider UFH as the first-line antithrombin agent.[200]

Argatroban, another direct thrombin inhibitor, is also approved for use during PCI, although fewer data are available. The direct thrombin inhibitors are easier to use but more expensive than UFH; they are similar in cost to the combination of UFH and a GPI. There currently is no known agent to reverse the effects of these new compounds (see Chapter 35). In patients with normal renal function, coagulation can be expected to return to normal in about 2 hours.

LMWHs are obtained by depolymerization of standard UFH. LMWHs were developed to overcome the limitations of UFH.[201] Enoxaparin (Lovenox) has been studied extensively in patients with ACS. Overall, enoxaparin use leads to a slight reduction in the occurrence of MI when compared with UFH and has a similar side-effect profile.[202] The NICE trials were registries of patients treated with enoxaparin instead of UFH during PCI.[203] In addition, the SYNERGY trial was a randomized comparison of enoxaparin and UFH in patients with an ACS for whom early catheterization was planned; about half of both groups underwent PCI.[204] Based on these and smaller trials, enoxaparin and UFH seem to be associated with similar rates of cardiac events and bleeding complications when used during PCI. Therefore, most interventionalists are comfortable with the use of enoxaparin for ACS and the management of patients receiving enoxaparin in the periprocedural period. However, UFH offers several advantages for the patient who arrives in the CCL without prior antithrombin therapy: a shorter half-life, which facilitates sheath removal; the ability to easily monitor the drug's effect by measuring the ACT; and the ability to reverse the effect of UFH with protamine.

The OASIS 5 trial studied 20,078 patients with ACS who were randomized to enoxaparin or fondaparinux. Fondaparinux is a synthetic pentasaccharide that is thought to bind to the high-affinity binding site of the anticoagulant factor, antithrombin III, increasing the anticoagulant activity of antithrombin III 1000-fold. In patients receiving fondaparinux plus either GPIs or thienopyridines, bleeding was reduced and net clinical outcomes were improved compared with enoxaparin. Although fondaparinux was found to be safe and effective in a few trials, it was associated with an increased risk of guide catheter–related thrombosis in patients who underwent PCI.[205] Because of this potential harmful complication, fondaparinux was given a class III recommendation (harmful therapy) in the updated STEMI guidelines for patients being treated with primary PCI.[29]

Arterial thrombi are rich in platelets. Prevention of these thrombi is complicated by the fact that platelets aggregate in response to many stimuli. Aspirin inhibits only one of these pathways. The final common aggregation pathway is the GPIIb/IIIa receptor on the platelet surface. Fibrinogen can bind to two GPIIb/IIIa receptors on separate platelets to permit aggregation. Several compounds have been developed to target this receptor. The chimeric monoclonal antibody, abciximab (ReoPro) was the first GPI (GPIIb/IIIa inhibitor) approved. Abciximab is given as a bolus followed by a 12-hour infusion. Bleeding times increase to more than 30 minutes, and ex vivo platelet aggregation is almost abolished. The platelet binding of this compound essentially is irreversible, and more than 48 hours is required for normal platelet function to return. During the clinical trials of this agent, patients requiring emergency CABG experienced no significant increase in adverse events with platelet transfusions used to restore normal platelet function. In the EPIC study of high-risk PCI patients, abciximab reduced early ischemic complications by 35% and late events by 26%, with an increase in vascular complications.[206] In the EPILOG study, a similar benefit in lower-risk interventional patients was seen.[207] In addition, fewer vascular complications occurred when adjunctive heparin was used in lower doses, and vascular access site management improved. Abciximab is more expensive than the other GPIs, and its repeated use may lead to thrombocytopenia.[208]

The other GPI compounds, eptifibatide (Integrilin) and tirofiban (Aggrastat), are not antibodies but rather synthetic agents that bind reversibly to the GPIIb/IIIa receptor. Both have half-lives of approximately 1.5 hours in patients with normal renal function; normal hemostasis returns within 6 hours after cessation of the medication.[209] Standard doses lead to very high plasma concentrations of these medicines, so a platelet transfusion is less effective in correcting the hemostatic defect with these agents compared with abciximab. Studies have shown that eptifibatide plus UFH is superior to UFH alone in stable patients undergoing PCI, abciximab plus UFH is superior to UFH alone, and abciximab is superior to tirofiban in more unstable patients undergoing PCI.[210,211] GPIs have not proved beneficial in SVG interventions.[212]

Currently, the choice of GPI for patients undergoing PCI is controversial because the reduction in ischemic complications is almost offset by the increased bleeding complications. Presently, there are four general indications for GPI use: (1) patients with a non–ST-segment elevation myocardial infarction (NSTEMI) undergoing PCI, particularly if they have not been adequately preloaded with a thienopyridine; (2) patients with thrombotic complications or large side-branch closure during any PCI; (3) selected patients with STEMI, particularly those not preloaded with a thienopyridine in the emergency department and those with a large thrombus burden visualized on angiography; and (4) patients undergoing ad hoc PCI for stable or unstable CAD who are not adequately preloaded with a thienopyridine.[213,214] Several oral GPIs have been used in clinical trials, but the results were disappointing for reasons that remain unclear.[215]

Thrombolytic therapy has been used for the treatment of STEMI since the 1980s. Although some of the early studies used intracoronary administration of thrombolytics, the need for a CCL precluded widespread adoption, and IV administration of thrombolytics became standard treatment for STEMI. Several agents have been used, including streptokinase, anistreplase, alteplase, reteplase, and tenecteplase.[216] Alteplase, reteplase, and tenecteplase are recombinant variations of tissue plasminogen activator and are specific for fibrin (as opposed to fibrinogen). They differ primarily in their half-lives, a difference that affects the dosing regimens. Since the early 1990s, emergent or primary PCI has evolved as an alternative, and often this treatment is preferable to use of IV thrombolytics. With both therapies, time to treatment correlates with myocardial salvage and clinical outcome.[217] In the setting of planned primary PCI, use of adjunctive thrombolytic agents (classified as facilitated PCI) has not proved beneficial and may be detrimental.[28,218] In patients with unsuccessful thrombolytic therapy, rescue PCI is beneficial but not without risk, whereas repeat thrombolysis is ineffective.[28,219]

Outcomes: Success and Complications

An important component of an interventional cardiology program is quality assessment. This is not just a score card of complications; it is a process in which risk-adjusted outcomes are compared with national standards and the results are used to identify avenues for improvement.[220,221] Tracking of outcome data has been a feature of interventional cardiology since its beginning and has contributed to the rapid developments in the field. The history of interventional cardiology has been marked by an increase in success rates with a simultaneous decrease in adverse events. This reflects both significant technologic advancement and increased operator skill, both of which were facilitated by the systematic collection of outcomes data. PCI once was considered successful if the luminal narrowing was reduced to less than 50% residual stenosis.[222] In current practice with stent placement, a residual stenosis greater than 20% is seldom accepted, and excellent stent expansion without edge dissection is required before termination of the procedure.[223] The initial National Heart, Lung, and Blood Institute (NHLBI) PTCA registry from 1979 to 1983 reported a success rate of 61% and a major coronary event rate of 13.6%. The 1985 to 1986 NHLBI registry reported a success rate of 78%, with a 4.3% incidence of AMI and a 3.4% incidence of emergency CABG.[218] In the current stent era, success rates are greater than 95% and emergent surgery rates are less than 1% in laboratories performing more than 400 PCIs annually.[224]

The ACC developed the NCDR in the 1990s. Currently, more than 1000 CCLs in the United States participate. Participation in NCDR is voluntary and requires a dedicated employee at each facility for data entry. Outcomes for both diagnostic and interventional procedures are tabulated, adjusted for baseline risk, and provided to the participating facility. Results from an ACC NCDR publication are listed in Table 3.4.

Recent plateaus in the rates of success and complications reflect not only the maturity of the field and changes in demographics but also the scope of practice of PCI. As older patients with more comorbidities undergo PCI, further statistical improvements will be harder to achieve, but risk-adjusted outcomes must be studied. From and colleagues[225] looked at a 19-year experience with PCI in 138 patients 90 years of age or older. There was a high technical success rate and a relatively low morbidity and mortality rate when the patients were properly selected. Patients with chronic total occlusions (>3 months) have also been studied. In an era of increased technical advances, these patients have seen improved procedural success, long-term vessel patency, and survival outcomes.[226] The Occluded Artery Trial (OAT) entered 2201 patients more than 3 days after MI with vessel occlusion, followed them for longer than 3 years, and demonstrated no benefit across various risk categories when PCI was performed.[227] Continued attention to outcomes data will help to identify the limits of PCI.

The incidence of procedure-related MI is controversial and depends on the definition of MI (eg, new Q waves, total creatine kinase [CK] increase, CK-isoform elevation, troponin elevation).[228] Increased CK levels occur in approximately 15% of catheter-based interventional procedures, with significant increases (threefold baseline) present in

TABLE 3.4 Morbidity and Mortality for Percutaneous Coronary Intervention

Complication	*Outcome (%)*
Dissection	5
Abrupt closure	1.9
Successful reopening	41
Angiographic success	94.5
Postintervention myocardial infarction	0.4
Coronary artery bypass graft surgery	1.9
Death	1.4
Clinical success	92.2
No adverse events	96.5

TABLE 3.5 Lesion-Specific Characteristics of Type A, B, and C Coronary Lesions[a]

Type A Lesions (Least Complex)	
Discrete (<10 mm length)	Little or no calcification
Concentric	Less than totally occlusive
Readily accessible	Nonostial in location
Nonangulated segment, <45 degrees	No major branch involvement
Smooth contour	Absence of thrombus
Type B Lesions (Intermediate)	
Tubular (10–20 mm in length)	Moderate to heavy calcification
Eccentric	Total occlusions <3 mo old
Moderate tortuosity of proximal segment	Ostial in location
Moderately angulated, >45 segment degrees, <90 degrees	Bifurcation lesions requiring double guidewires
Irregular contour	Some thrombus present
Type C Lesions (Most Complex)	
Diffuse (>2 cm in length)	Total occlusions >3 mo old
Excessive tortuosity of proximal segment	Inability to protect major side branches
Extremely angulated segments >90 degrees	Degenerated vein grafts with friable lesions

[a]American Heart Association/American College of Cardiology classification of lesion type.

8%.[228] These figures are even greater for interventions in SVGs and with some devices. For years, routine enzymatic assessment of interventional procedural infarctions has been performed at the discretion of the operator. Some studies have suggested that long-term outcome is adversely related to even small periprocedural increases in troponin values ("infarctlets").[229] These increases are reduced by GPIs. Stone and coworkers[230] published data from 7143 PCI patients. In their study, CK-MB isoenzyme increases of more than eight times the upper limit of normal were predictive of death in the subsequent 2-year follow-up. However, smaller enzyme increases, including a threefold increase of enzymes seen in 17.9% of patients, proved to have no impact on survival.[230]

In 1988 (revised in 1993), the ACC/AHA task force developed a lesion morphology classification in an attempt to correlate the complexity of lesions with outcomes. This anatomic characterization of lesion complexity is outlined in Table 3.5. However, as operators have gained experience and equipment has improved, complication rates have decreased across all subsets. A 1998 study of more than 1000 consecutive lesions identified success rates for A, B1, and B2 lesions as approximately equal (95% to 96%), with only C lesions having success rates lower than 90% (88%).[231] B1 lesions are characterized as containing one of the characteristics in Table 3.5, and B2 lesions are characterized as containing two of the characteristics in Table 3.5. The Mayo Clinic devised a risk score for PCI and compared it with the ACC/AHA criteria in 5064 PCIs. They found that the ACC/AHA criteria better predicted success, whereas complications were better predicted with the Mayo classification.[232]

Bleeding complications related to PCI have been studied extensively because they are associated with prolonged hospitalization, increased hospital costs, patient dissatisfaction, morbidity, and 1-year mortality.[233,234] Various anticoagulation regimens to maximize efficacy and minimize bleeding have been studied and were discussed earlier. At present, bleeding avoidance strategies are strongly recommended and encompass procedural (radial artery approach, fluoroscopy-guided femoral approach), pharmacologic (low-dose heparin, shorter GPI infusions, bivalirudin), and technologic (vascular closure devices) strategies.[235]

Iatrogenic pericardial effusion and tamponade are infrequent complications of PCI and may be life-threatening if a large perforation occurs or a small perforation goes unrecognized. Because this is most commonly an acute event, relatively small amounts of blood can result in hemodynamic compromise. The incidence of these events during PCI varies and commonly is reported as occurring in 1% of cases or fewer. However, this complication is dependent on the guidewire and interventional devices, with hydrophilic wires and atherectomy catheters more likely to be involved. Tamponade can also occur in non-PCI procedures such as AF ablation, pacemaker placement, valvuloplasty, use of percutaneous closure devices, and percutaneous valve replacement. Prompt recognition of tamponade is required after PCI or other cardiac procedures and can be facilitated with emergent echocardiography. Pericardiocentesis is life-saving and should be performed without delay.[236]

Intimal dissection was a significant issue in the prestent era, occurring in up to 10% of all PTCAs. Propagation of an intimal dissection is the leading cause of vessel occlusion during an intervention. It is normally initiated by arterial disruption by the PCI device, but it also may be caused by the guiding catheter or wire. Stenting significantly reduces these events by approximating the intimal dissection flap and reestablishing flow down the true lumen.

Bifurcation lesions have become a significant area of interest in the stent era. Side-branch occlusion caused by displacement of plaque from the primary vessel lesion occurs in 1% to 20% of patients, and bifurcation lesions often require attention to both the primary and secondary branch vessels. Various techniques have been used to protect the side branch, ranging from primary vessel stenting with balloon dilation of the branch vessel through the stent strut to various types of branch-vessel stenting. The "crush" technique involves stenting of both the primary and the branch vessel; the initial success rates are excellent, but side-branch restenosis may be a problem.[237] The bifurcation stent technique most widely practiced currently, based on clinical outcomes for non-LM coronary lesions, is treatment of the main branch with provisional stenting of the side branch.[238] In other words, the main vessel is stented, and if adequate flow is maintained in the side branch, no further treatment is rendered (Fig. 3.17).

Recognition of high-risk lesions and patient characteristics allows the cardiologist to better predict which patients are at increased risk for catheter-based interventional therapy.[161] In current interventional practice, when a high-risk patient is identified, the cardiologist should share this information with the surgeon and anesthesiologist so that patient care is not compromised in the event of an emergency.

Operating Room Backup

When PTCA was introduced, all patients were considered candidates for CABG. The physician learning curve in the early 1980s was considered to be 25 to 50 cases; increased complications were seen during these initial cases.[20,21,130] All PCI procedures had immediate OR availability, and often the anesthesiologist was present in the CCL. In the 1990s, OR backup was necessary less often. Perfusion catheter technology had developed to allow for longer inflation times with less ischemia.[239] Over time, the need for emergency surgery declined dramatically as a result of more experienced operators, improved techniques, better stents, and improved antiplatelet and anticoagulation regimens.[240] Because the incidence of emergent CABG has been reduced to 0.2% of PCI procedures, more institutions are beginning to perform PCI despite lack of cardiac surgery facilities on site. The main reasons are to provide timely access for primary PCI in patients with STEMI and to provide care to patients who do not want to travel. In 1911, the AHA, the American College of Cardiology Foundation (ACCF), and the SCAI updated their recommendations for PCI without surgical backup[22] (Table 3.6). Although many coronary lesions can be treated at stand-alone PCI centers, the 2014 SCAI/ACC/AHA guidelines state that intervention should be avoided in patients with specific coronary lesions (Box 3.11) and that transfer for emergency CABG must occur when there is high-grade LM or three-vessel disease with clinical or hemodynamic instability after a successful or unsuccessful PCI attempt in an occluded vessel or if there is a failed or unstable PCI result and ongoing ischemia with IABP support.[241] Transfer agreements with established oversight hospitals with on-site cardiac surgery capability are required; minimal requirements for operators and institutions must be met, and a comprehensive quality assurance program must be in place.[24]

Infrequently, high-risk interventional cases still may require a cardiac OR on immediate standby. This may occur in an emergent

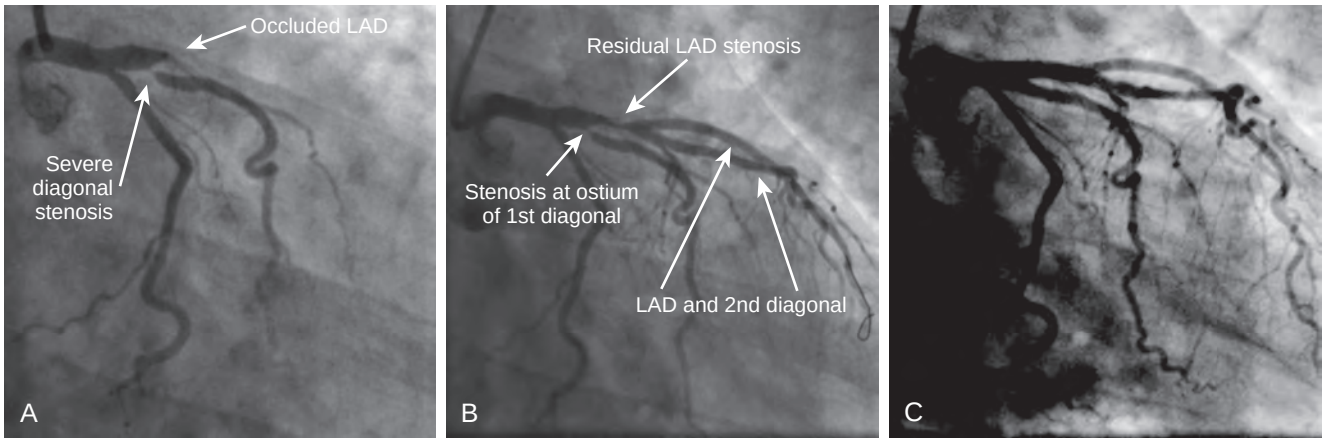

Fig. 3.17 Primary percutaneous coronary intervention for an anterior ST-elevation acute myocardial infarction (STEMI). (A) Complete occlusion of the left anterior descending artery *(LAD)* and high-grade stenosis of the first diagonal. (B) After thrombectomy. Antegrade flow is restored in the LAD and a second diagonal, but severe stenosis persists in the LAD. (C), After stenting of the LAD and first diagonal.

TABLE 3.6 Recommendations for Percutaneous Coronary Intervention (PCI) Without Surgical Backup

Primary PCI is reasonable in hospitals without on-site surgery provided that appropriate planning for program development has been accomplished.	Class IIa Level of Evidence B
Elective PCI might be considered in hospitals without on-site cardiac surgery provided that appropriate planning for program development has been accomplished and rigorous clinical and angiographic criteria are used for proper patient selection.	Class IIb Level of Evidence B
Primary or elective PCI should not be performed in hospitals without on-site cardiac surgery capabilities without a proven plan for rapid transport to a cardiac surgery operating room in a nearby hospital or without appropriate hemodynamic support capability for transfer.	Class III Level of Evidence C

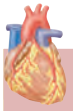
situation in which a patient with STEMI requires assistive support during primary PCI[242] or, more electively, when a patient is identified as being at high risk but is not a candidate for a hybrid laboratory or no such facility is available.[8] A preoperative anesthetic evaluation that allows for assessment of the overall medical condition, past anesthetic history, current drug therapy, and allergic history as well as a physical examination concentrating on airway management considerations is reserved for these high-risk cases.

Regardless of the location of the interventional procedure, when an emergency CABG is necessary, it is essential either to have an OR with a basic cardiac setup ready to go or to have the cardiology and surgery teams provide enough lead time to adequately prepare an OR. A basic cardiac setup includes the essential equipment to perform a CABG and an anesthesia setup with emergency medications such as heparin, epinephrine, vasopressin, and norepinephrine available to support the circulation until the patient is placed on cardiopulmonary bypass (CPB), as well as invasive monitors such as TEE and transducers to measure arterial blood pressure, central venous pressure, and pulmonary artery pressures and resuscitative devices including defibrillators and pacemakers. These patients are often critically ill, with ongoing myocardial injury and circulatory collapse. Time is critical to limit the damage and prevent death. Therefore, the sooner the anesthesiologist, staff, and OR personnel are aware of an arriving patient in this perilous condition, the better for all involved. In addition, because this situation occurs infrequently, cooperation among the interventionalist, the surgeon, and the anesthesiologist is essential for optimal patient care in this critically ill population.



BOX 3.11 CHARACTERISTICS THAT MAKE PERCUTANEOUS CORONARY INTERVENTION INAPPROPRIATE IN STAND-ALONE CENTERS

Avoid Treatment

- >50% Stenosis of the LM proximal to the infarct-related lesion, especially if the area in jeopardy is small and the overall LV function is not severely impaired
- Long, calcified, or severely angulated target lesions at high risk for PCI failure
- Lesions in areas other than the infarct artery unless they appear to be flow limiting in patients with hemodynamic instability or ongoing symptoms
- Lesions with TIMI flow grade 3 in patients with LM or three-vessel disease if CABG is more likely to be a superior revascularization strategy
- Culprit lesions in more distal branches that jeopardize only a modest amount of myocardium if there is more proximal disease that could be worsened by attempted intervention
- Chronic total occlusion

Transfer for Emergency CABG

- High-grade LM or three-vessel disease with clinical or hemodynamic instability after successful or unsuccessful PCI attempt in an occluded vessel, preferably with IABP support
- Failed or unstable PCI result and ongoing ischemia, with IABP support

CABG, Coronary artery bypass graft surgery; *IABP*, intraaortic balloon pump; *LM*, left main coronary artery; *LV*, left ventricular; *PCI*, percutaneous coronary intervention; *TIMI*, Thrombolysis in Myocardial Infarction grading system.

General Management for Failed Percutaneous Coronary Intervention

The main causes of PCI failure are coronary dissection, suboptimal lumen enlargement, no-reflow, and coronary artery perforation.[243] Levi and colleagues[244] reviewed PCIs in STEMI patients from 2001 to 2010 and found that the incidence of primary PCI failure was 5.4%. Independent predictors of primary PCI failure included age greater than 65 years, female sex, unfavorable preprocedural Thrombolysis in Myocardial Infarction (TIMI) grade, presence of vessel calcifications,

and operational factors including nighttime interventions and PCI performed during the first years of the study. Failed reperfusion increased the risks of 30-day, 6-month, and 1-year mortality.

Most PCI failures result from suboptimal lumen enlargement or no-reflow, and most are treated conservatively. Patients undergo repeat PCI, and in most cases flow is restored. If a significant area of myocardium is at risk, these patients can undergo an elective CABG. Of the 5% of patients who present to the OR for emergency CABG, 75% (6.2% of all failures) have coronary artery dissection and the remainder have a mechanical obstruction that produces hemodynamic instability.[243] In such instances, myocardial ischemia or infarction ensues, depending on the degree of collateralization.[245]

In preparation for the OR, a perfusion catheter, pacemaker, and/or PAC may be inserted in the CCL, depending on patient stability, OR availability, and patient assessment by the cardiologist, cardiothoracic surgeon, and anesthesiologist. Although these procedures are intended to better stabilize the patient, this is achieved at the expense of ischemic time. An IABP or one of the newer support devices may be placed. Although these devices can reduce the myocardial oxygen requirements, myocardial necrosis still will occur in the absence of coronary or collateral blood flow. The anesthesiologist should examine the vascular sheaths that are in place and determine which ones are venous and which arterial. He or she should also review any inotropic, vasoactive, and anticoagulant medications that have been administered and determine whether blood products are available (Box 3.12).

In the OR, anesthetic management depends on the hemodynamic instability of the patient. Hemodynamically stable patients can have a controlled induction and intubation with placement of invasive monitors including intraarterial and central venous catheters. If heart failure is anticipated after CPB, placement of a PAC with $S\bar{v}O_2$ and continuous CO measurements will be beneficial, especially if ventricular assist device placement is anticipated. A TEE is also beneficial in these patients. *Because these patients usually have received significant anticoagulation with heparin and occasionally with GPIs, attempts at catheter placement should not be undertaken when direct pressure cannot be applied to a vessel.* The most experienced individual should perform these procedures.

Patients who arrive in cardiogenic shock may require preinduction inotropic support to prevent cardiovascular collapse during induction and intubation. As with all heart failure patients, it is important to remember that these patients have a slower circulatory time and IV inductions will be slower; they also are more susceptible to the hemodynamic effects of the inhalation agents. For induction, medications that provide the most stable hemodynamics should be used.

The worst scenario is the patient who arrives in the OR in profound circulatory shock or in full cardiopulmonary arrest. In these patients, CPB should be established as quickly as possible, and it is important to have IV heparin prepared to anticoagulate the patient before bypass. No attempt to establish access for monitoring should be made if it would delay the start of surgery. The only real requirement to start a case such as this is to have good IV access, a five-lead ECG, airway control, a functioning blood pressure cuff, arterial access from the PCI procedure, and, if available, TEE. Preinduction inotropic support is required for these patients. If large doses of vasoactive medications were administered during the prebypass period, the patient may become severely hypertensive once on CPB, requiring the use of vasodilators.

In many cases of emergency surgery, the cardiologist has placed femoral artery sheaths for access during the PCI. *These should not be removed,* again because of heparin (or bivalirudin) and GPI therapy during the PCI. A femoral artery sheath provides extremely accurate pressure measurements that closely reflect central aortic pressure. Also, a PAC may have been placed in the CCL, and this can be adapted for use in the OR.

Several surgical series have looked for associations with mortality in patients who present for emergency CABG after failed PCI. Complete occlusion, urgent PCI, and multivessel disease have all been associated with an increased mortality.[246] In addition, long delays lead to increased morbidity and mortality. The paradigm shift in cardiovascular medicine toward PCI will be negatively impacted if significant numbers of serious complications occur because of prolonged delays in arranging emergent cardiac surgical care for the infrequent occurrence of failed PCI.[247,248] As the frequency of PCI at institutions with no on-site cardiac surgery facility increases, cooperation among specialties and facilities will be required to ensure that timely transfer can be arranged after a failed PCI. Important time will be lost unless formal arrangements are in place ahead of time.[24]

BOX 3.12 PREPARATION OF THE PATIENT FOR SURGERY AFTER FAILED INTERVENTION

- Perform usual preoperative evaluation for an emergent procedure.
- Inventory vascular access sites (eg, pulmonary artery catheter, intraarterial balloon pump)
- Defer removal of sheaths.
- Review medicines administered.
  - Boluses may linger even if infusion is stopped (eg, abciximab).
  - Check medicines that have been administered before arrival at the catheterization laboratory (eg, enoxaparin, clopidogrel).
- Confirm availability of blood products.

Support Devices for High-Risk Angioplasty

As devices and techniques in the CCL become more sophisticated, interventional cardiologists are expanding their practice to address more complex lesions and more high-risk patients who are deemed unsuitable candidates for surgical repair. Although there is no consensus on the definition of a high-risk PCI, a patient is considered to be at high risk when there is a combination of adverse clinical, anatomic, and hemodynamic factors that, when combined, will significantly increase the risk of periprocedural major adverse cardiac and cerebral events (MACCE) (Box 3.13).[249] These patients are at higher risk for hemodynamic compromise from either LV failure, arrhythmias, ischemia-reperfusion injury, or distal embolization of atherogenic material leading to cardiogenic shock or malignant arrhythmias.[250]

Percutaneous mechanical circulatory devices (MCS) can provide a bridge by maintaining coronary perfusion pressure, supporting the right or left ventricle, and reducing myocardial workload, allowing the cardiologist time to complete the intervention. Another beneficial effect of MCS is to augment mean arterial pressure and CO, allowing vasopressor and inotropic support to be decreased or discontinued. The four mechanical circulatory devices that can be placed percutaneously in the CCL are the IABP, the Impella (Abiomed, Danvers, MA), the TandemHeart (CardiacAssist, Pittsburgh, PA), and extracorporeal membranous oxygenation (ECMO) (see Chapter 28).

The IABP acts as an MCS because it augments diastolic pressure and myocardial perfusion by inflating when the aortic valve is closed, which increases the coronary pressure gradient from the aorta to the coronary circulation, and by deflating at the beginning of isovolumic contraction and immediately before the onset of systole, which creates a dead space in the thoracic aorta, reducing afterload and promoting forward flow[251] (Fig. 3.18). The net result is a reduction in LVEDP and LV volume, wall tension, myocardial work, and oxygen demand with preserved or increased stroke volume, EF, and CO.[252] The effectiveness of the IABP depends on the size of the balloon in proportion to the aorta. The larger the balloon, the more blood is displaced. This is the most commonly used MCS because it is ubiquitous, it is easy to insert, and it is available in a variety of catheter and balloon sizes, allowing for maximum diastolic augmentation while minimizing vascular complications.

The disadvantages of the IABP include the following: (1) it can provide only a limited increase in CO (about 0.3 to 0.5 L/minute)

BOX 3.13 CLINICAL, ANATOMIC, AND HEMODYNAMIC CRITERIA USED TO IDENTIFY HIGH-RISK PERCUTANEOUS CORONARY INTERVENTIONS

1. Clinical
   a. Cardiogenic shock within 12 h or at the start of coronary intervention
   b. Left ventricular systolic dysfunction on presentation with EF <30–40%
   c. Killip class II-IV on presentation or congestive heart failure
   d. Coronary intervention after resuscitated cardiac arrest within 24 h
   e. STEMI
   f. Acute coronary syndrome complicated by unstable hemodynamics, dysrhythmia, or refractory angina
   g. Mechanical complications of acute myocardial infarction
   h. Age >70–80 y
   i. History of cerebrovascular disease, diabetes, renal dysfunction, or chronic lung disease
2. Anatomic
   a. Intervention in an unprotected left main coronary artery or left main equivalent
   b. Multivessel disease
   c. Distal left main bifurcation intervention
   d. Previous CABG including intervention in a graft, particularly a degenerated graft
   e. Last remaining coronary conduit
   f. Duke Myocardial Jeopardy score >8/12
   g. Target vessel providing a collateral supply to an occluded second vessel that supplies >40% of the left ventricular myocardium
   h. SYNTAX score >33
3. Hemodynamic
   a. Cardiac index <2.2 L/min per square meter
   b. PCWP >15 mm Hg
   c. Mean pulmonary artery pressure >50 mm Hg

CABG, Coronary artery bypass graft surgery; *EF*, ejection fraction; *PCWP*, pulmonary capillary wedge pressure; *STEMI*, ST-segment elevation myocardial infarction.

From Myat A, Patel N, Tehrani S, et al. Percutaneous circulatory assist devices for high-risk coronary intervention. *J Am Coll Cardiol Cardiovasc Interv*. 2015;8:229.

and requires some native CO; (2) it relies on synchronization with the cardiac cycle to function and may not be reliable with dysrhythmias; and (3) its function is adversely affected by any increase in aortic compliance, reduction in systemic vascular resistance, or higher HR. Complications include balloon displacement, rupture, leak, or entrapment; thrombus formation in the pressure line or catheter; aortic dissection or rupture; lower limb ischemia; hemolysis; and bleeding at the insertion site. Absolute contraindications for IABP placement include aortic insufficiency, aortic dissection, and aortic stents.

The Impella is an axial flow left ventricular assist device (LVAD) that is positioned across the aortic valve under fluoroscopic or echocardiographic guidance; it is approved by the FDA for use in the CCL. The LVAD aspirates blood from the left ventricle and delivers it to the ascending aorta. It has a pigtail conformation that stabilizes it in the left ventricle while preventing the pump from adhering to the myocardium (Fig. 3.19). This results in LV unloading, reducing end-diastolic wall stress while improving diastolic compliance, aortic and intracoronary pressures, and coronary flow reserve and decreasing coronary

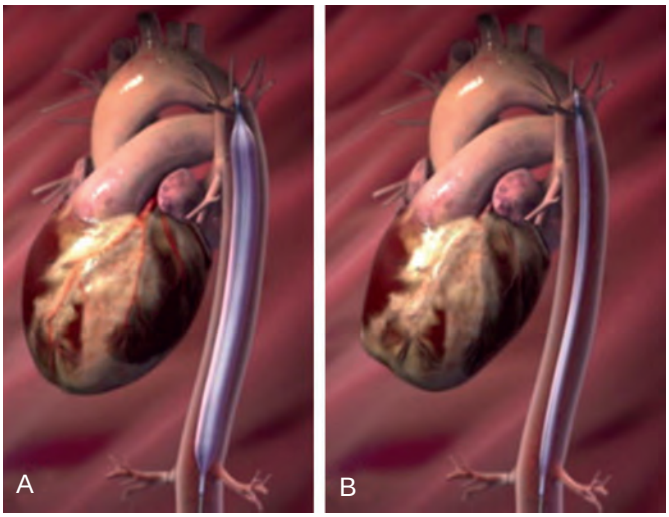

Fig. 3.18 Intraaortic balloon pump. (A) Balloon inflation during diastole increases aortic diastolic pressure and augments coronary perfusion pressure. microvascular resistance. These effects may allow for recovery of hibernating or stunned myocardium. The Impella may also provide a bridge to a surgical procedure (eg, CABG, placement of a more permanent LVAD) or to cardiac transplantation. The Impella pump comes in three sizes: 2.5, 3.8, and 5.0 L/minute. Although the 5.0 L/minute pump can provide total CO, its implantation requires a surgical cutdown of the femoral or axillary artery. The 3.8 L/minute pump was developed to increase the amount of support without requiring a surgical cutdown.

The advantages of the Impella are that it can augment the CO by 2.5 to 3.8 L/minute, it can be used to support the circulation for up to 7 days, and it does not require a stable cardiac rhythm, CO, or blood pressure signal for optimal function, although it does require adequate LV filling.[253] The disadvantages include the following: (1) it has limited availability; (2) it requires large catheters for implantation, increasing the risk of vascular complications; (3) it provides nonpulsatile flow; (4) there is a risk of displacement of the inflow cannula into the aorta; (5) it produces hemolysis and decreased CO; and (6) there is insufficient flow to the periphery in patients weighing more than 100 kg. Compared with the IABP, the Impella has a higher risk of limb ischemia, hemolysis, and bleeding at the insertion site. The Impella is contraindicated in patients with preexisting aortic valve disease or an LV mural thrombus.

The TandemHeart is a centrifugal-flow LVAD in which the inflow cannula is inserted via the femoral vein up the IVC and RA and into the LA through a transseptal puncture; the outflow cannula is inserted into the femoral artery and positioned at the aortic bifurcation, providing flows of up to 5 L/minute (Fig. 3.20). In patients with cardiogenic shock, the TandemHeart can improve the cardiac index and mean arterial pressure and reduce filling pressures including PA pressure, PCWP, and central venous pressure, thus decreasing myocardial workload and demand.[254–257] The advantages of the TandemHeart are that it can augment CO for up to 14 days and, like the Impella, it does not require a stable cardiac rhythm, blood pressure signal, or CO for optimal function. The disadvantages include limited availability, a requirement for expertise in transseptal puncture, the fact that implantation cannot occur during cardiopulmonary resuscitation, hypoxemia due to shunting if the left atrial cannula slips back into the RA, a prolonged implantation time, and the use of large cannulas, which increases the risk of vascular compromise, hemolysis, and limb ischemia. Because the Impella 3.8 L/minute pump can maintain an almost equivalent flow rate with less risk of vascular compromise, the use of the TandemHeart may be limited.

Venoarterial ECMO is a modified CPB circuit that provides a continuous nonpulsatile CO. Venoarterial ECMO can be initiated percutaneously, via cannulation of the femoral artery and vein, or centrally, via the aorta and the SVC/IVC (Fig. 3.21). ECMO removes carbon dioxide from and adds oxygen to venous blood via an artificial membrane, bypassing the pulmonary circulation.[258] It is the only MCS that can oxygenate the blood, and it can support the circulation for several weeks. Unlike the percutaneous LVADs and IABP, ECMO can increase LV afterload and wall stress, increasing myocardial oxygen demand. Initiating ECMO is resource intensive and requires technical skills and

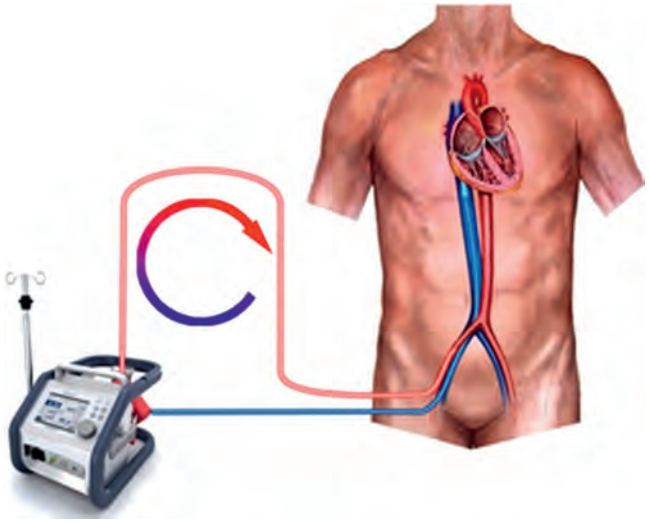

Fig. 3.21 Femoral venoarterial ECMO. *(From Myat A, Patel N, Tehrani S, et al. Percutaneous circulatory assist devices for high-risk coronary intervention.* J Am Coll Cardiol Cardiovasc Interv. *2015;8:229.)*

a team including surgeons, anesthesiologists, and perfusionists. The ECMO system is composed of a venous reservoir, an external centrifugal blood pump, a membrane oxygenator, and a rewarming heparin-coated system. Systemic anticoagulation with heparin is required to achieve an ACT between 150 and 180 seconds.[258] Disadvantages of ECMO that are not seen with the other MCS include relative lung ischemia, overventilation producing tissue alkalosis, poor perfusion to the coronary and cerebral vessels, pulmonary hypertension, and possible requirement for use of an IABP and/or inotropic agents to maintain contractility and thereby avoid LV stasis, distention, and intraventricular thrombus formation. Complications of ECMO include vascular injury, limb ischemia, and increased risk of hemorrhage due to reduced platelet count, hemolysis, consumptive coagulopathy, and systemic heparinization, which may result in intrathoracic, abdominal, or retroperitoneal hemorrhage.

A few studies have been performed to determine where MCS belongs in the care of high-risk patients undergoing PCI. The majority of studies compared the IABP with conventional medical management, and a few compared the LVADs with IABP. The Balloon Pump–Assisted Coronary Intervention Study-1 (BCIS-1) was the first prospective, open, multicenter, randomized controlled trial (RCT) designed to determine whether elective IABP insertion before high-risk PCI reduces MACCE at 28 days.[259] The study found similar rates of MACCE in both treatment arms and no significant difference between them in the secondary end points of 6-month mortality and overall rate of bleeding. This study was flawed because there was crossover in the use of IABP in the medically managed group in patients with higher BCIS-1 Jeopardy scores, suggesting the need for standby MCS in extremely high-risk patients.[259] The 5-year all-cause mortality data from the BCIS-1 study demonstrated a significant mortality advantage with elective IABP insertion, even in the crossover group.[260]

The CRISP-AMI trial was a prospective multicenter RCT with the goal of determining whether prophylactic IABP insertion within 6 hours after the onset of chest pain and planned primary PCI for STEMI in patients without cardiogenic shock could reduce the mean infarct size as measured by cardiac MRI.[261] As in the BCIS-1 trial, the operators had the option of placing an IABP in the primary PCI group for persistent hypotension, cardiogenic shock, malignant arrhythmias, or AMI complications. Although there was no difference in the end points of LV mean EF and ESV, major bleeding, transfusion, or major vascular complications at 30 days and no difference in mortality, recurrent MI, or new or worsening heart failure at 6 months, 8.5% of patients receiving standard care crossed over to the IABP group, supporting the idea that standby MCS is needed for high-risk patients. There was a significant difference between the groups in the time to death, cardiogenic shock, or new or worsening heart failure, which was longer in patients who were randomized in the PCI-IABP group. In the majority of metaanalyses comparing outcomes for prophylactic IABP versus medical management (except for patients in cardiogenic shock), the use of prophylactic IABP in high-risk or STEMI patients is not recommended.[262–264]

The studies comparing percutaneous LVADs for high-risk PCI complicated by cardiogenic shock include the IMPRESS in Severe Shock trial, currently underway, which will compare the Impella 3.8 L/minute LVAD with IABP in patients with AMI complicated by cardiogenic shock who are awaiting primary PCI.[249] In small registries and single-center studies, the Impella improved the cardiac index, but this did not result in a survival advantage. The ISAR-SHOCK trial randomized 25 patients with AMI complicated by cardiogenic shock to IABP or the Impella implanted after revascularization. Although the Impella significantly augmented the cardiac index, it did not improve 30-day mortality, and there was a trend toward greater transfusion requirements.[265] A similar study comparing the TandemHeart and IABP in patients revascularized for AMI complicated by cardiogenic shock[266] and a metaanalysis comparing the Impella and TandemHeart with IABP[267] had similar conclusions. Although the LVADs improved hemodynamic and metabolic variables, they did not confer a survival advantage compared with the IABP and were associated with higher rates of complications, including hemolysis and limb ischemia. Because of selection bias and interhospital differences in the definition of cardiogenic shock, it is difficult to determine which MCS should be used and whether it should be initiated electively, before the procedure, as standby, for rescue, or after the procedure.

No RCTs or metaanalyses are available for ECMO. Current guidelines are derived by expert consensus based on evidence from single-center observational studies and case reports.[249]

Controversies in Interventional Cardiology

Percutaneous Coronary Intervention Versus Optimal Medical Therapy in Stable Coronary Artery Disease

Ischemic heart disease (IHD) remains a major public health problem nationally and internationally. It is estimated that 1 in 3 adults in the United States has some form of cardiovascular disease; more than 17 million have CAD, and almost 10 million have angina pectoris. CAD remains the leading cause of death in men and women worldwide. The costs of caring for patients with IHD are enormous, estimated at $156 billion in the United States for both direct and indirect costs in 2008. More than one-half of direct costs are related to hospitalization. In 2003, the Medicare program alone paid $12.2 billion for hospitalizations due to IHD.

Early revascularization in STEMI patients has been well validated to improve mortality.[268] In addition, early percutaneous revascularization has been shown to improve survival and to reduce the incidence of death or nonfatal MI compared with aggressive medical therapy alone in the management of non–ST-elevation ACS.[269] However, the role of PCI in the management of stable CAD remains controversial. In the most recently published guidelines on stable angina, the goals of care are to minimize the likelihood of death while maximizing the health and function of the patient. How exactly to achieve these well-stated goals remains at the heart of the controversy. The guidelines recommend complementary and overlapping strategies, beginning with education about the etiology, treatment options, and prognosis of IHD and support for active participation of patients in their treatment decisions. It is also necessary to identify and treat conditions that contribute to, worsen, or complicate IHD and to effectively modify risk factors for IHD by both pharmacologic and nonpharmacologic means. Use of an evidenced-based approach to improve patients' health status and survival, with attention to avoiding drug interactions and side effects, is also strongly encouraged. Finally, use of revascularization by PCI or CABG is appropriate when there is clear evidence of the potential to improve patients' health status and survival.[270]

Having clear evidence of overall benefit compared with potential risks is the ideal situation in which to offer revascularization to patients with stable IHD. In a minority of cases, this balance is absent, as evidenced by NCDR data suggesting that approximately 10% to 12% of PCIs could be considered inappropriate because of a lack of perceived benefit.[271] Several beliefs influence patients and physicians to choose revascularization when the likelihood of benefit is less than the potential risks of the procedure. An ingrained preference for action (ie, revascularization) over perceived inaction (ie, medical therapy alone) likely influences the decision making of both patients and physicians in many cases.[272] Moreover, some health care professionals are unduly pessimistic about survival with conservative medical therapy and inaccurately optimistic about the survival benefits of revascularization procedures.[273] Finally, some patients believe mistakenly that PCI has the potential to prevent AMI and prolong survival.

On the other side of the argument, the well-publicized COURAGE trial touting clinical equipoise between optimal medical therapy (OMT) and OMT plus PCI in patients with stable CAD has been criticized.[274] Although this landmark clinical trial appears to have been effective in changing management of low-risk stable CAD to include an initial trial of OMT,[121] some salient points need to be addressed. The study population was a highly selected group of patients; only 6.3% of the more than 36,000 patients screened were randomized. Compliance with OMT was exemplary in this trial, with compliance rates for aspirin, statins, and β-blockers all greater than 90%. In addition, blood pressure was under better control than in the general population and national health data sets; 65% of participants had a systolic blood pressure of less than 130 mm Hg).[275] For these reasons, it is unclear whether similar results can be achieved in everyday medical care outside a clinical trial. From the PCI arm, only 3% of patients received a DES, which explains why more than 20% of PCI-treated patients in this trial underwent an additional revascularization procedure at a median of 10 months of follow-up. Finally, there was a higher than expected crossover rate from the OMT group to the OMT-PCI arm (32%). Many interventionalists now believe that the COURAGE trial confirms earlier data sets suggesting that many highly motivated individuals with low-risk anatomy fare well with OMT as an initial strategy; however, when OMT is combined with PCI, quality of life is improved because of a reduction in the prevalence of angina pectoris.[276–278]

The most recently published PCI guideline recognizes the benefits of PCI in stable CAD as a means to reduce angina pectoris. PCI is given a class IIa indication to improve angina symptoms in patients with unacceptable angina for whom OMT cannot be implemented because of medication contraindications, adverse effects, or patient preferences.[22] The debate over the "best" treatment strategy will undoubtedly continue, but the evidence appears relatively clear. An initial strategy of OMT is reasonable, but in patients with high risk factors or continued symptoms, early angiography is warranted, with revascularization as directed by the angiographic and clinical findings.

Percutaneous Coronary Intervention Versus Surgical Revascularization in Complex Coronary Artery Disease

The choices available for treatment of multivessel CAD are PCI, CABG, and medical therapy. In the 1970s, CABG was compared with medical therapy in several randomized trials. A survival benefit for CABG was seen in only a few subgroups, such as those with LM disease and those with three-vessel disease and impaired LV function. Both CABG and medical therapy have improved since that time, but few recent comparisons have been made.

In the mid-1980s, when PCI consisted only of balloon PTCA, the first comparisons of catheter intervention versus CABG were begun. By the early to mid-1990s, nine RCTs had been published comparing PTCA with CABG in patients with significant CAD. Only the BARI trial was statistically appropriate for assessing mortality.[279] These trials are summarized in Fig. 3.22. These studies concluded that there were similarities between the two approaches with respect to relief of angina and 5-year mortality. Costs were initially lower in the PCI group, but by 5 years costs had converged because of the need for repeat PCI precipitated by restenosis in 20% to 40% of the PCI group.[280] The only clear difference between PCI and CABG for patients with multivessel disease in the BARI trial occurred in the subset of patients with DM.[279] In a subgroup analysis, both insulin-dependent and non–insulin-dependent diabetic patients with multivessel disease had a lower 5-year mortality rate with CABG (19.4%) than with PCI (34.5%).[281]

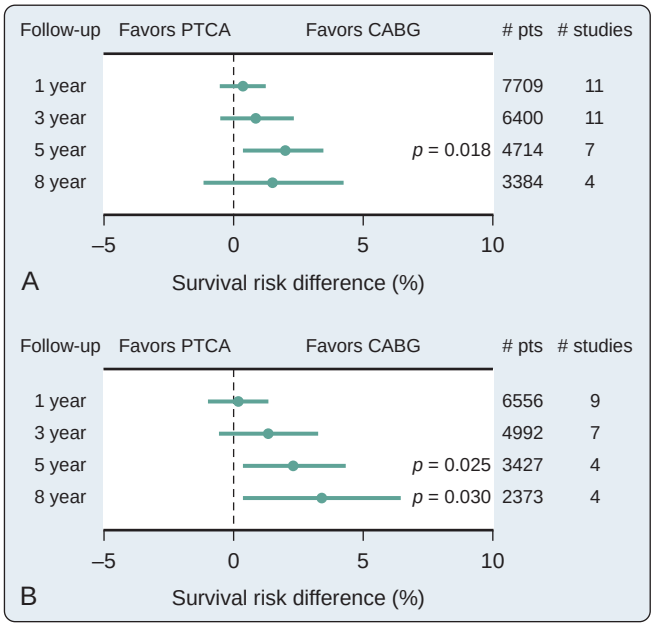

Fig. 3.22 Randomized trials of coronary artery bypass graft surgery *(CABG)* versus percutaneous coronary angioplasty *(PTCA)* in patients with multivessel coronary disease show risk differences for all-cause mortality in years 1, 3, 5, and 8 after initial revascularization. (A) All trials. (B) Multivessel trials. *(Redrawn from Hoffman SN, TenBrook JA, Wolf MP, et al. A meta-analysis of randomized controlled trials comparing coronary artery bypass graft with percutaneous transluminal coronary angioplasty: one- to eight-year outcomes.* J Am Coll Cardiol. *2003;41:1293. Copyright 2003, with permission from The American College of Cardiology Foundation.)*

Regretfully, these trials were outdated by the time of their publication. For patients undergoing PCI, stents had become the norm. Use of stents produced a significant decrease in emergent CABG because of the reduced rate of acute closure and a decrease in repeat procedures because of less restenosis.[152] For patients undergoing CABG, off-pump coronary artery bypass became more common during this time period, with its potential to decrease complications.[282] In addition, the importance of arterial grafting, with its favorable impact on long-term graft patency, was recognized.[283]

To address the changes in PCI and CABG therapy, four more randomized trials were undertaken, and these are included in Fig. 3.22. The results of the newer studies were similar to the results of the earlier ones. In the Arterial Revascularization Therapy Study (ARTS), patients with DM had poorer outcomes with PCI, with rates of MACCE greater than 50% at 5 years. Overall, there was no difference in the rates of mortality, cerebrovascular accident, or MI between the groups at 5 years, but there was a higher MACCE rate in the stenting arm, which was driven by a higher rate of repeat revascularization because BMSs were utilized.[284]

The well-known Synergy Between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX) trial randomized 1800 patients with three-vessel CAD and/or LM stenosis to either CABG or PCI with paclitaxel-eluting stents with the intention of obtaining complete revascularization. Patients were eligible regardless of clinical presentation on the condition that the angiograms were reviewed by both a cardiologist and a cardiac surgeon and complete

revascularization was believed feasible by both techniques. After 1 year, 17.8% of the PCI patients and 12.4% of the CABG patients had experienced a MACCE ($P = .002$). Although this difference was driven primarily by a greater need for repeat revascularization in the PCI group, the rate of death was nonsignificantly greater in the PCI group, at 4.4%, compared with 3.5% in the CABG group. The rate of stroke was significantly greater in the CABG group, 2.2%, versus 0.6% in the PCI group ($P = .003$).[285] The 5-year published data showed that outcomes were stratified based on the calculation of a SYNTAX score, which is an angiographically calculated score that takes into account the burden and location of CAD. For patients with low SYNTAX scores, including those with isolated LM disease, PCI appeared to be an acceptable alternative to CABG. However, in those with intermediate- to high-risk SYNTAX scores, CABG appeared superior mainly because of lower MACCE rates and lower repeat revascularization rates.[286]

A metaanalysis of six major clinical trials that compared PCI with CABG for multivessel CAD revealed an unequivocal reduction in long-term mortality and MI in addition to reductions in repeat revascularizations favoring CABG. These findings were consistent in diabetics and nondiabetics.[287] As with the debate about PCI versus OMT, there will continue to be heated discussions regarding the optimal therapy for patients with multivessel CAD. Perhaps the most important lesson from these trials is the requirement to form and maintain a heart team consisting of cardiovascular surgeons, cardiologists, and anesthesiologists so that complex cases involving difficult anatomy and medical comorbidities can be discussed in an open format. When multidisciplinary care is delivered, outcomes are improved.[288]

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Graft Surgery for Left Main Coronary Artery Disease

Of all patients undergoing coronary angiography, approximately 4% are found to have LM CAD.[289] CABG has long been considered to be the gold standard revascularization method for patients with LM disease because it confers a survival benefit when compared with medical therapy. The data to support this statement comes from RCT subgroup analyses performed 3 decades ago on 91 patients with LM CAD in the Veterans Administration Cooperative Study.[290] A metaanalysis of these trials demonstrated a 66% reduction in relative risk and mortality with CABG, with the benefit extending to 10 years.[291] Since these studies were completed, there have been improvements in medical therapy including the use of acetylsalicylic acid, lipid-lowering therapy (3-hydroxy-3-methyl-glutaryl–coenzyme A [HMG CoA] reductase inhibitors), and angiotensin-converting enzyme inhibitors, along with improvements in surgical technique with the use of left internal mammary artery grafting.[292] For this reason, many have argued for updated comparisons of LM CAD treatments, especially because interventional cardiologists have been steadily expanding the application of coronary stenting to include patients with increasingly complex lesions, such as LM disease.[293]

The majority of studies comparing PCI with CABG for LM stenting have been single-center studies, and in all but one the patient populations were not randomized, so the potential bias in patient selection may confound interpretation of the results.[294–296] In addition, the only published randomized study, the Prospective Randomized Study of Unprotected Left Main Stenting Versus Bypass Surgery (LE MANS study), was small, consisting of approximately 50 patients in each treatment group.[297] Because of the limited strength of published data, LM PCI was previously considered a class III or class IIb recommendation in the US guidelines. More recently, in a significantly larger RCT using DESs, the composite end point of death, MI, or stroke at 2 years occurred in 4.4% of patients treated with PCI and 4.7% of patients treated with CABG. However, ischemia-driven target-vessel revascularization was more often required in those patients treated with PCI (9.0% vs 4.2%).[298] The publication of the results of the SYNTAX LM prespecified subgroup, which included 705 patients, contributed significantly to the data.[299] This landmark study concluded that patients with LM disease who underwent revascularization with PCI had safety and efficacy outcomes comparable to those achieved with CABG at 1 year. The recently published 5-year outcomes from this study suggested that PCI-treated patients had a lower stroke rate but a higher revascularization rate than CABG-treated patients; there was no significant difference in mortality (12.8% vs 14.6% with PCI and CABG, respectively, $P = .53$).[300]

TABLE 3.7 Recommendations for Percutaneous Coronary Intervention in Left Main Coronary Artery Disease

PCI to improve survival is reasonable as an alternative to CABG in selected stable patients with significant (≥50% stenosis) unprotected left main CAD with 1. Anatomic conditions associated with a low risk of PCI procedural complications and a high likelihood of good long-term outcome: a. Low SYNTAX score ≤22 b. Ostial or trunk left main CAD 2. Clinical characteristics that predict a significantly increased risk of adverse surgical outcomes (eg, STS predicted risk of operative mortality ≥5%)	Level of Evidence B
PCI to improve survival is reasonable in patients with UA/NSTEMI when an unprotected left main coronary artery is the culprit lesion and the patient is not a candidate for CABG.	Level of Evidence B
PCI to improve survival is reasonable in patients with acute STEMI when an unprotected unprotected left main coronary artery is the culprit lesion, distal coronary flow is <TIMI grade 3, and PCI can be performed more rapidly and more safely than CABG.	Level of Evidence C

From Levine GN, Piates ER, Blankenship JC, et al. ACCF/AHA/SCAI guideline for percutaneous coronary intervention. *J Am Coll Cardiol.* 2011;58:e44.

The results from these three RCTs suggest (but do not definitively prove) that major clinical outcomes in *selected* patients with LM CAD are similar with CABG and with PCI at 1- to 5-year follow-up, but repeat revascularization rates are higher after PCI than after CABG. The extent of disease should be accounted for when choosing between surgery and PCI. Patients with high SYNTAX scores seemed to benefit more from surgery than those in the lower tertiles. The most recently published PCI guidelines now give PCI a class IIa indication for LM PCI, as outlined in Table 3.7.[22]

In conclusion, the physician must weigh the data, discuss the case within the confines of a dedicated heart team, and then explain the advantages and disadvantages of both techniques to the individual patient. CABG offers a more complete revascularization, with survival advantages in selected groups and a decreased need for repeat procedures.[285,292] The disadvantages of CABG are the higher early mortality risk, longer hospitalization and recovery times, higher initial expense, morbidity associated with leg incisions, increased risk for stroke, and limited durability of venous grafts. The cost of DESs may negate the initial cost advantage of PCI if multiple stents are used. In the future, the balance of acceptance will continue to shift among medical therapy, percutaneous revascularization, and surgical revascularization as more RCTs are completed (see Chapters 1, 2, 20, and 44).

Specific Interventional Devices

Interventional Diagnostic Devices

Percutaneous Transluminal Coronary Angioplasty

PTCA is an important component of the interventional procedure because it provides the opening for stents to be implanted. The mechanism by which balloon inflation leads to vessel patency must be understood to better understand balloon angioplasty. Although four mechanisms have been described to explain the efficacy of this procedure (ie, plaque splitting, stretching of the arterial wall, plaque

compression, and plaque desquamation), the primary mechanism is *discrete* intimal dissection, which results in plaque compression into the media. Desquamation and distal embolization of superficial plaque components have been observed; however, experimental studies demonstrate these to be minor contributors to the procedure's efficacy.[130] Propagation of the intimal dissection is the primary cause of vessel occlusion during angioplasty (see Fig. 3.17).

Although the mechanism of balloon angioplasty has not changed, equipment and operator expertise have improved to the point that procedural success rates now exceed 90%.[224] These advances allow for the treatment of sicker patients and more complex coronary lesions while success rates continue to improve and complication rates decrease.[301]

Atherectomy Devices: Directional and Rotational

Atherectomy devices are designed to remove some amount of plaque or other material from an atherosclerotic vessel. Directional coronary atherectomy was the first nonballoon technology to gain FDA approval, in 1991. In this technique, tissue was removed from the coronary artery, debulking the area of stenosis. Although tissue removal is an attractive concept, application of directional coronary atherectomy was limited. Trials comparing this technique with PTCA did not show improved angiographic restenosis rates, and greater rates of acute complications were seen with directional coronary atherectomy.[302–304]

The FDA approved rotational coronary atherectomy in 1993. The Rotablator catheter (Boston Scientific Corp., Marlborough, MA) is designed to differentially remove nonelastic tissue with the use of a diamond-studded burr rotating at 140,000 to 160,000 rpm. Rotational artherectomy is designed to alter lesion compliance, particularly in heavily calcified vessels, and it is often used before balloon dilation to permit full expansion of the vessel.[305] The ablated material is emulsified into 5-μm particles, which pass through the distal capillary bed. Heavily calcified lesions commonly are chosen for rotational atherectomy (Fig. 3.23). In addition, restenotic (in-stent), bifurcation, ostial, and nondilatable lesions are candidates for the Rotablator.[306] Contraindications to the Rotablator include tortuous anatomy, poor ventricular function, thrombus, poor runoff, and lesions within SVGs.[307]

The main limitation of rotational atherectomy is the no-reflow phenomenon.[144] This effect is thought to be secondary to particle load. It is associated with myocardial ischemia and occasionally with infarction. Hemodynamic problems can occur, particularly in patients with depressed LV function. The frequency of no-reflow has been reduced by shorter, slower ablation passes and the addition of vasodilators to the flush solution.[307] In heavily calcified vessels, rotational atherectomy may be the only procedure that can change the compliance of an artery and permit complete expansion of balloons and stents. However, rotational atherectomy is more cumbersome and time-consuming than balloon dilation. It is rarely used alone, and stent placement usually is necessary to achieve an adequate result. Therefore, although rotational atherectomy is available in most interventional laboratories, it is a niche item primarily relegated to vessels with significant calcification.

Cutting Balloon

Vessel wall damage during interventional procedures is considered to be the initiating factor for neointimal proliferation, which ultimately can lead to restenosis. All interventional technologies damage the

vessel wall to some degree. In an attempt to decrease intimal injury, the cutting balloon (Flextome, Boston Scientific) was introduced, based on the concept of microsurgical dilation. Whereas standard balloon PCI dilates haphazardly and can severely injure the arterial wall, the cutting balloon permits vessel expansion with lower pressure and less wall injury, reducing the stimulus for restenosis.

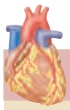
This device is a noncompliant balloon with three or four blades, depending on balloon size. These blades are 10 to 15 mm long and 0.25 mm in diameter and are attached to the balloon by a proprietary bond-to-bond manufacturing process. Once inflated, the balloon introduces the blades into the coronary intima, producing a series of tiny longitudinal incisions before balloon dilation occurs. These microscopic cuts permit less traumatic vessel expansion. The safety and efficacy of this technique have been validated; however, no benefit was found when the cutting balloon was compared with PTCA in a large group of patients. The cutting balloon is currently used to decrease plaque shift in bifurcating lesions, to change artery compliance, and to treat ISR.[308]

A newer cutting balloon technology is the Angiosculpt scoring balloon (Spectranetics, Freemont, CA), which use three 0.005-inch cylindrical nitinol wires as the scoring device. Nonrandomized data suggest improved stent expansion, less geographic miss owing to less slippage of the balloon, and less vessel trauma compared with traditional PTCA or primary stent placement.[309,310] The device is currently FDA approved to treat ISR, complex type C coronary lesions, and bifurcation lesions.

Intracoronary Stents

The introduction of intracoronary stents has had a larger impact on the practice of interventional cardiology than any other development.[311]

The use of intracoronary stents exploded during the mid-1990s[312] (Box 3.14). In April of 1993, the Gianturco-Roubin flex stent (Cook, Bloomington, IN), a coiled balloon-expandable stent, was approved by the FDA for treatment of acute closure after PCI. Use of the Gianturco-Roubin stent was limited by difficulties with its delivery and high rates of restenosis. The first stent to receive widespread clinical application was the Palmaz-Schatz tubular slotted stent (Johnson & Johnson, New Brunswick, NJ), which was approved for treatment of de novo coronary stenosis in 1994.[313] Throughout the 1990s, multiple stents were introduced with improved support, greater flexibility, and thinner struts, resulting in improved delivery and decreased rates of restenosis (Fig. 3.24).[159,160]



BOX 3.14 STENTS

- Antiplatelet therapy after stent placement: indefinite aspirin therapy plus
  - BMS: clopidogrel 4 wk for patients without ACS, 12 mo with ACS
  - DES: clopidogrel 12 mo
- With BMS, thienopyridines reduce subacute thrombosis from 3% to <1%.
- DES have never been tested without clopidogrel.
- A concern with first-generation DES is delay in endothelial coverage of the stent.
- With clopidogrel, subacute and late thrombosis rates for DES and BMS are identical.
- Very late thrombosis rates are greater with first-generation DES.
- Late stent thrombosis rates with second-generation DES are similar to those with BMS.
- Options for elective surgery in patients with stents:
  - Delay surgery until clopidogrel regimen is completed: recommended
  - Perform surgery during clopidogrel therapy: accept bleeding risk

ACS, Acute coronary syndromes; *BMS*, bare metal stents; *DES*, drug-eluting stents.

The major limitations of catheter-based interventions previously had been acute vessel closure and restenosis. Stents offered an option for stabilizing intimal dissections while limiting late lumen loss, major components of acute closure, and restenosis. Clinical trials demonstrated the ability of stents to not only salvage a failed PTCA, thus avoiding emergent CABG (see Fig. 3.17), but also reduce restenosis.[159,314] Multiple studies documented the benefit of stenting compared with PTCA alone in a variety of circumstances, including long lesions, vein grafts, chronic occlusions, and the thrombotic occlusions of AMI. Only in small vessels did stenting not demonstrate a restenosis benefit when compared with balloon angioplasty.[315] Clinical restenosis rates declined from 30% to 40% with PTCA to less than 20% with BMSs.[313]

Stent technology improved in incremental fashion. Modifications in coil geometry, alterations in the articulation sites, and the use of meshlike stents offered minor advantages.[158] Various metals (eg, tantalum, nitinol) were used, and various coatings (eg, heparin, polymers, even human cells) were applied.[159] In addition, the delivery systems used to implant stents were decreased in size.[160] Stent procedures, once requiring 9-Fr guiding catheters, can now be performed through 5- to 6-Fr catheters.

With the realization that restenosis involves poorly regulated cellular proliferation, researchers focused on medicines with antiproliferative effects. Many of these medicines were toxic when given systemically—a tolerable situation in oncology but not for a relatively benign condition such as restenosis. For such medicines, local delivery was attractive, and the stent provided a vehicle.

Rapamycin, a macrolide antibiotic, is a natural fermentation product produced by *Streptomyces hygroscopicus*, which was originally isolated in a soil sample from Rapa Nui (Easter Island).[316] Initially investigated as an antifungal agent, it was soon discovered to have potent immunosuppressant activities, making it unacceptable as an antibiotic but attractive for prevention of transplant rejection. Rapamycin (also called sirolimus) works through inhibition of a protein kinase called the mammalian target of rapamycin (mTOR), a mechanism that is distinct from those of other classes of immunosuppressants. Because mTOR is central to cellular proliferation as well as immune responses, this agent was an inspired choice for a stent coating. A metal stent does not hold drugs well and permits little control over their release. These limitations required that polymers be developed to attach a drug to the stent and to allow the drug to slowly diffuse into the wall of the blood vessel while eliciting no inflammatory response.[317] The development of DESs would not have been possible without these (proprietary) polymers. This led to the true revolution in PCI, which began with the approval in April 2003 of the first DES,[223] the Cypher (Johnson & Johnson/Cordis, Bridgewater, NJ). Use of the Cypher ceased in 2011.

A European trial randomized 238 patients to receive either a sirolimus-eluting stent or a BMS. Remarkably, there was no restenosis in the group that received the DES.[318] A larger American trial randomized 1058 patients to a sirolimus-eluting stent or a BMS. At 9 months, restenosis rates were 8.9% in the DES group and 36.3% in the BMS group, with no difference in adverse events. Clinically driven repeat procedures were required in 3.9% and 16.6% of the two groups,[318] respectively. This benefit was sustained, if not slightly improved, at 12 months.[319] Although these stents were initially approved only for de novo lesions in native vessels of stable patients, similar benefits have been shown in every clinical scenario that has been studied.[320–324]

The next first-generation DES to receive FDA approval, in March 2004, was the Taxus stent (Boston Scientific). The Taxus stent uses a polymer coating to deliver paclitaxel, a drug that also has many uses in oncology. Paclitaxel is a lipophilic molecule derived from the Pacific yew tree, *Taxus brevifolia*. It interferes with microtubular function, affecting mitosis and extracellular secretion and thereby interrupting the restenotic process at multiple levels.[325] The Taxus IV study randomized 1314 patients to the Taxus stent or a BMS. Angiographic restenosis was 26.6% in the BMS group and only 7.9% in the Taxus

Current status of bioabsorbable scaffolds in the treatment of coronary artery disease.* J Am Coll Cardiol. *2014;64:2541.)*

group, with no significant difference in adverse events. Clinically driven repeat procedures were required in 12.0% and 4.7% of the groups, respectively.[151]

Initial concerns regarding LST were validated with the first-generation DESs, as discussed earlier. This rare but rather drastic complication led to the development of second-generation DESs.[169] Two second-generation DESs have been approved in the United States, the zotarolimus-eluting stent (Endeavor; Medtronic, Minneapolis, MN) in 2011 and the everolimus-eluting stent (Xience; Abbott, Abbott Park, IL, and Promus; Boston Scientific) in 2012. The newer stents use different drugs, polymers, and stent platforms. Comparisons of various DESs have shown differences in some angiographic end points but similar clinical outcomes.

The early enthusiasm for first-generation DESs was tempered after widespread concerns about the increased risks of LST and very late stent thrombosis. In addition to the development of second-generation stents, research was also applied to produce a fully biodegradable scaffold. This new technology offers the possibility of transient scaffolding of the vessel to prevent acute vessel closure and recoil during elution of an antiproliferative drug to counteract constrictive remodeling and excessive neointimal hyperplasia. A recent RCT comparing the everolimus-eluting bioresorbable vascular scaffold (Absorb BVS; Abbott Vascular, Santa Clara, CA) with a traditional DES suggested comparable outcomes at 1 year.[326] However, in the largest published registry using the Absorb BVS, the rate of definite stent thrombosis at 6 months was higher than expected (2.1%).[327] This raised concern about the device's initial strut thickness and whether the late potential benefits might be offset by short-term events. Subsequent single-center randomized trial data contradicted this real-world finding,[328] and more patient data will be required to further evaluate the safety and effectiveness of this unique technology.

Currently, stents are placed at the time of most PCI procedures if the size and anatomy of the vessel permit. Multiple studies have been performed comparing BMSs with DESs in various clinical scenarios.[329,330] There are several reasons not to use a DES in every procedure. First, DESs are not manufactured in sizes greater than 4.0 mm, making them useless in large vessels. Second, a longer course of thienopyridine is required, and this may not be desirable if a surgical procedure is urgently needed because it requires an uncomfortable choice between bleeding and increased risk for cardiac events.[331] Stent thromboses, MIs, and deaths have been reported when antiplatelet therapy is interrupted.[332,333] Third, there are cost considerations: DES is two to three times more expensive than a BMS. Finally, a DES may not be the ideal choice in a patient who requires long-term anticoagulation because bleeding rates are increased when triple therapy is used, as discussed previously (see Chapter 44).

Aspiration Thrombectomy Catheters

Primary PCI in the setting of STEMI has been shown to be the optimal treatment strategy because it offers higher rates of infarct artery patency and lower rates of recurrent ischemia, reinfarction, intracranial hemorrhage, and death compared with thrombolytic therapy. Despite the insertion of an intracoronary stent resulting in a patent epicardial vessel, there are a number of patients in whom normal perfusion is not completely achieved, as evidenced by reduced TIMI flow scores, failure of ST-segment resolution, and poor myocardial blush grade.[334] In several studies, primary PCI with stent placement in STEMI patients resulted in a distal embolization rate of approximately 15%.[335,336] Microembolization may lead to occlusion of arterioles in the microcirculation, thus impairing end-myocardial perfusion. To potentially reduce this distal embolization rate, thrombectomy catheters have been developed and tested in clinical trials.

The AngioJet rheolytic thrombectomy system (Possis Medical, Minneapolis, MN) is one such thrombectomy catheter. It creates a Venturi effect by using six high-velocity saline jets distally at a pressure of 2500 psi and a flow rate of 50 mL/minute to generate a low-pressure zone (<600 mm Hg) and cause a powerful vacuum effect. The catheter is a multilumen 4-Fr system and may be passed through a 6-Fr guiding catheter. One lumen delivers the saline, a second is for

guidewire passage, and a third permits thrombus evacuation with the use of a roller pump.[337] This system creates a recirculation pattern at the catheter tip, emulsifying and removing thrombus without embolization. Rheolytic thrombectomy was first approved for SVGs, and a larger, 6-Fr catheter is used. Although it can remove thrombus from native arteries and SVGs, some trials suggest that it may be less effective than alternative therapies for SVGs.[338,339] Initial studies in small patient populations were encouraging for AMI patients,[340] but a larger trial of 480 patients presenting within 12 hours after the onset of MI demonstrated greater mortality in the rheolytic thrombectomy group.[341] Other devices include the Rescue Catheter (Boston Scientific), the X-Sizer system (ev3, Plymouth, MN), and the TransVascular Aspiration Catheter (Nipro, Osaka, Japan). All of these devices have failed to show a clinical benefit in PCI. Nevertheless, this therapy remains an option for the limited number of patients who have large vessels containing a significant thrombus burden.[342]

Simpler manual aspiration devices also have been developed to facilitate thrombus removal, particularly in the setting of AMI.[343] The prototype was the Export catheter (Medtronic); another device was the Pronto extraction catheter (Vascular Solutions, Minneapolis, MN). Both devices employ a simple design using a tube with two lumens. One lumen tracks over a guidewire that has been advanced through the thrombotic area, and the second lumen is connected to a syringe. Negative pressure is generated with a handheld syringe outside the body. The TAPAS trial randomized 1071 patients undergoing primary PCI for AMI to either PCI alone (control) or thrombus aspiration with the Export catheter followed by PCI. Mortality at 1 year was 3.6% in the group that had thrombus aspiration and 6.7% in the control group ($P = .02$).[344] However, results in other multicenter trials have largely been negative, and metaanalyses have been conflicting with respect to infarct size reduction and improved clinical outcomes. A follow-up study to the TAPAS trial suggested no change in mortality at 1 year between aspiration plus PCI and PCI alone (5.3% vs 5.6%, respectively).[345] Therefore, the use of aspiration thrombectomy at present is somewhat controversial and operator dependent (Fig. 3.25).

Distal Occlusion Devices

PCI in degenerative vein grafts is complicated by a significant incidence of MI that is thought to result from embolization of debris. GPIIb/IIIa inhibition has not decreased MI in this situation.[212] Although other factors, such as spasm in the distal arterial bed, may contribute to the complications during PCI in SVGs, most efforts to address this problem have focused on devices that are designed to capture potential embolic debris released as the probable cause of the no-reflow phenomenon during PCI.[144] These distal protection devices come in two types: vessel occlusive and vessel nonocclusive.

Vessel-occlusive devices use a soft, compliant balloon that is incorporated into a wire. The wire is passed distal to the stenosis and inflated during the PCI. A column of blood is trapped that includes the debris liberated during PCI. The blood and debris are aspirated before deflation of the distal balloon and restoration of flow. The GuardWire (Medtronic) is an FDA-approved device of this type. In the SAFER trial, 801 patients undergoing PCI in SVGs were randomized to distal protection with the GuardWire versus no distal protection. The composite end point of death, MI, and repeat target-vessel revascularization was met by 9.6% in the GuardWire group and 16.5% in the standard care group. MI was reduced by 42% in the distal protection group.[346] However, because of the learning curve required to use this device and the development of more user-friendly nonocclusive devices, the GuardWire is now obsolete.

Fig. 3.25 The Export catheter was used to aspirate thrombotic material in the setting of an acute myocardial infarction.

Nonocclusive devices include various forms of filters as well as the thrombolysis or thrombectomy devices discussed earlier.[347,348] The Filter Wire (Boston Scientific) was the first filter approved. It is a 0.014-inch guidewire that incorporates a nonoccluding, polyurethane membrane filter with 80-µm pores. The system includes a retrieval catheter that fits over the device after PCI is completed (Fig. 3.26). Two clinical trials have been reported, the first comparing the Filter Wire EX with PCI alone and the second randomizing patients to either the Filter Wire EX or the GuardWire.[348,349] The Filter Wire was superior to PCI alone and noninferior to the GuardWire system. Other FDA-approved filter devices are used commonly for endovascular interventions performed on the carotid artery.

Therapy for Chronic Total Occlusions

Chronic total occlusions are defined as vessels that have been occluded for longer than 3 months. There has been steady progress in most areas of interventional cardiology, including the development of multilumen catheters that can allow multiple guidewires to treat a lesion,[350a] the creation of a hybrid strategy that bases treatment on the anatomy of the lesion, the use of anterograde and retrograde approaches, and the use of wires and devices.[350b] However, despite this progress therapy for chronic total occlusions has appeared to lag behind.[350] More recent advances, however, have greatly increased success rates and the ability to improve the symptoms and prognosis of patients with stable CAD, resulting in a rise in percutaneous treatment for these lesions.[351,352] Current data suggest that successful PCI for chronic total occlusions is associated with improvements in patient symptoms, quality of life, LV function, and survival compared with unsuccessful attempts.[353] However, all of the scientific evidence supporting this treatment comes from observational studies; no randomized study comparing percutaneous treatment with medical treatment has been published. This field will likely continue to evolve, but for now it remains a time-consuming procedure with high radiation exposure for both the patient and the operator. More clinical data are required to support its widespread use.

Other Catheter-Based Percutaneous Therapies

Percutaneous Valvular Therapy

Balloon Valvuloplasty

Percutaneous mitral valvuloplasty (PMV) was first performed in 1982 as an alternative to surgery for patients with rheumatic MS. The procedure usually is performed via an antegrade approach and requires expertise in transseptal puncture. During the early years of PMV, simultaneous inflation of two balloons in the mitral apparatus was required to obtain an adequate result. The development of the Inoue balloon (Toray, Houston, TX) in the 1990s simplified this procedure. This single balloon has a central waist for placement at the valve and does not require wire placement across the aortic valve.[354]

The key to PMV is patient selection. Absolute contraindications include a known LA thrombus, an embolic event occurring within the preceding 2 months, and a severe cardiothoracic deformity or bleeding abnormality that prevents transseptal catheterization. Relative contraindications include significant MR, pregnancy, concomitant significant aortic valve disease, and significant CAD.[355] All patients must undergo TEE, to exclude LA thrombus, and transthoracic echocardiography, to classify the patient by anatomic group. The most widely used classification, the Wilkins score, addresses leaflet mobility, valve

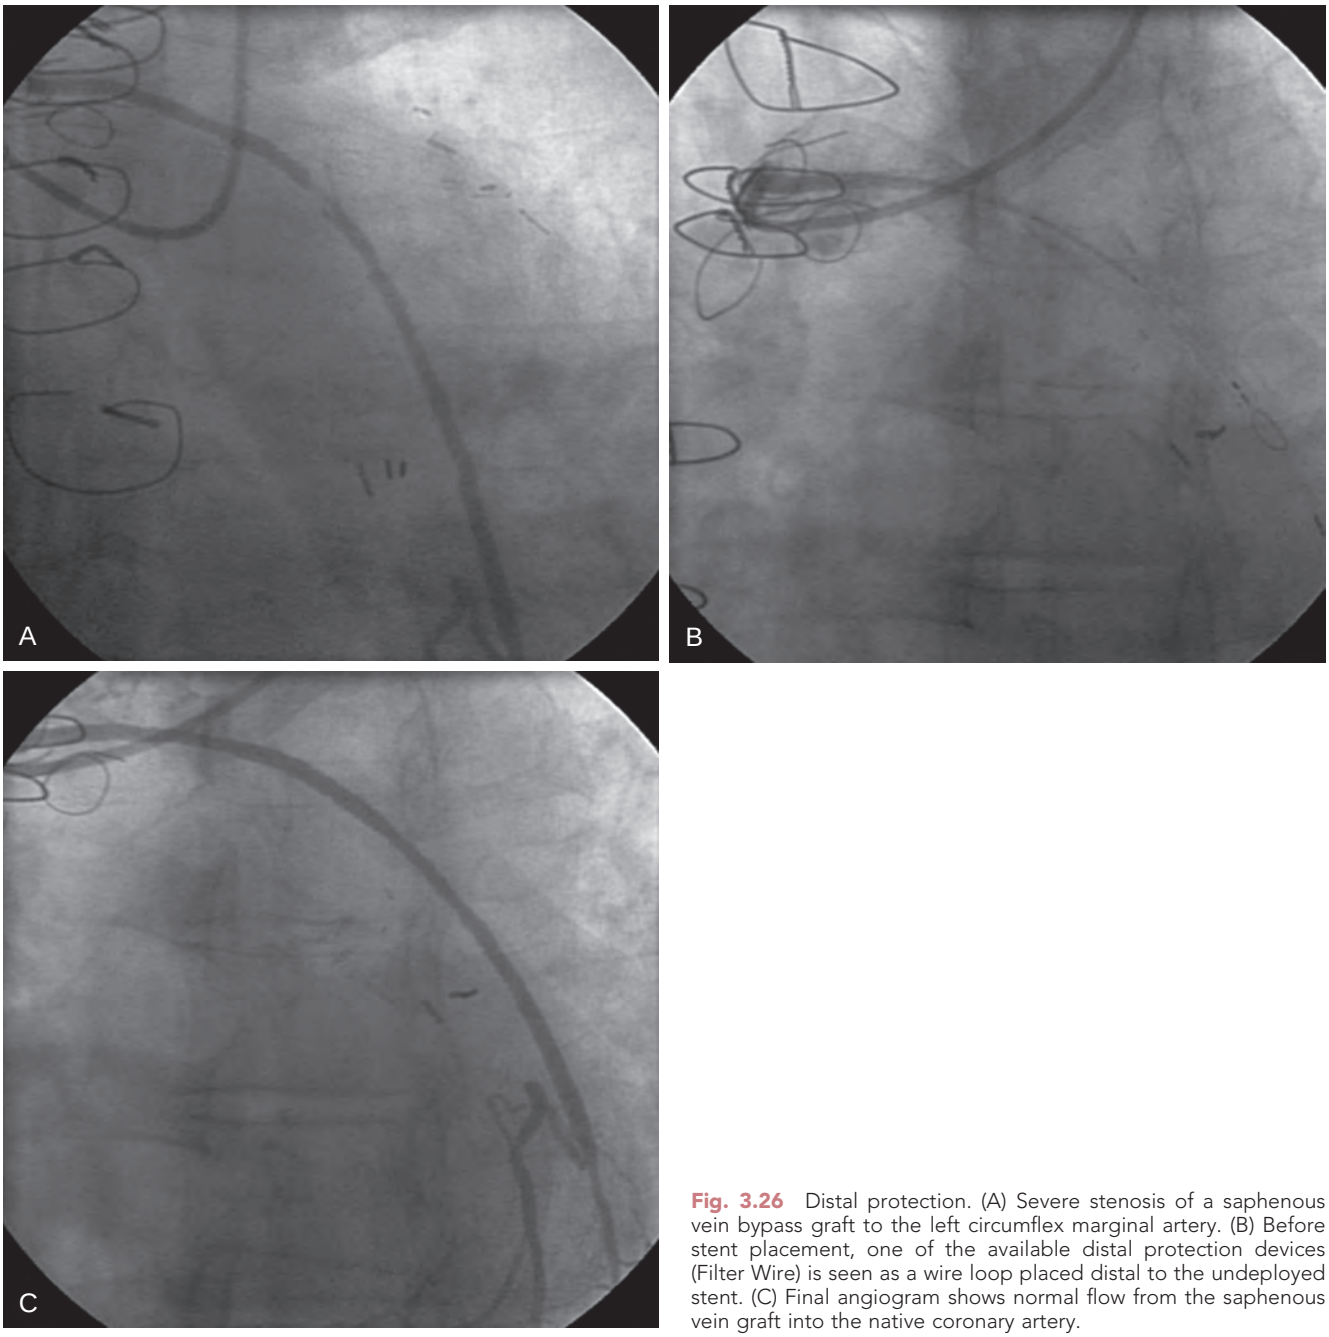


Fig. 3.26 Distal protection. (A) Severe stenosis of a saphenous vein bypass graft to the left circumflex marginal artery. (B) Before stent placement, one of the available distal protection devices (Filter Wire) is seen as a wire loop placed distal to the undeployed stent. (C) Final angiogram shows normal flow from the saphenous vein graft into the native coronary artery.

thickening, subvalvular thickening, and valvular calcification. These scoring systems, along with operator experience, predict outcomes. In experienced hands, the procedure is successful in 85% to 99% of cases.

Risks for PMV include a procedural mortality rate of 0% to 3%, hemopericardium in 0.5% to 12%, and embolism in 0.5% to 5%. Severe MR occurs in 2% to 10% of procedures and often requires emergent surgery.[356] Although peripheral embolization occurs in up to 4% of patients, long-term sequelae are rare. The procedure requires a large puncture in the interatrial septum, which does not close completely in all patients. However, a clinically significant ASD with a $\dot{Q}_p/\dot{Q}_s$ ratio of 1.5 or greater occurs in no more than 10% of cases; surgical repair is seldom necessary. Advances in patient selection, operator experience, and equipment have significantly reduced procedural complications.[356] Restenosis rates are dependent on the degree of commissural calcium.[354] TEE or intracardiac echocardiography is helpful during balloon mitral valvuloplasty.[60] These imaging modalities offer guidance for placement of the transseptal catheter, verification of balloon positioning across the valve, and assessment of procedural success.[356] Long-term results have been good.[357]

Percutaneous balloon aortic valvuloplasty was introduced in the 1980s. This procedure is usually performed via a femoral artery, using large 9- to 11-Fr sheaths and 18- to 25-mm balloons. Initial success rates are acceptable, but restenosis occurs as early as 6 months after the procedure, and almost all patients have restenosis by 2 years. The use of aortic valvuloplasty was largely abandoned after the advent of the transcatheter aortic valve replacement (TAVR) procedure. Currently, percutaneous balloon aortic valvuloplasty is used as a bridge to decision or a bridge to treatment with TAVR in those who are in severe decompensated class IV CHF. Current indications include an inoperable patient willing to accept the restenosis rate for a temporary reduction in symptoms, a patient undergoing noncardiac surgery hoping to decrease the surgical risk, and a patient with poor LV function

attempting to improve ventricular function for further consideration of aortic valve replacement.[358] Symptomatic improvement does occur, with a reduction in gradient of at least 50% in more than 80% of cases. Complications include femoral artery repair in up to 10% of patients, a 1% incidence of stroke, and a less than 1% incidence of cardiac death.[359] Slightly higher complication rates have been described in higher-risk patients.[360] Contraindications to percutaneous balloon aortic valvuloplasty are significant peripheral vascular disease and moderate to severe aortic valve insufficiency. Aortic insufficiency usually increases by at least one grade during valvuloplasty. The development of severe AR acutely leads to pulmonary congestion and possibly death because the hypertrophied ventricle is unable to dilate (see Chapters 21 and 27).

Percutaneous Valve Repair

Catheter-based alternatives to surgical valve replacement have been explored since the 1960s but were not successful until 2000, when percutaneous pulmonic valve replacement was performed.[361] These procedures are performed with the patient under general anesthesia using fluoroscopic and echocardiographic guidance. A bovine jugular valve is sutured onto a platinum-iridium stent and delivered on a balloon. The stent compresses the native valve against the wall of the annulus. Large 22-Fr delivery systems are used. The results in high-risk patients have been promising, and the device is now being tested in a lower-risk group (ie, as a true alternative to surgery). The success of percutaneous pulmonic valve replacement has also prompted interest in percutaneous replacement of the aortic and mitral valves[362,363] (see Chapters 15, 21, and 27).

Percutaneous Mitral Valve Repair

MV repair is preferred over replacement because it is associated with improved survival without the need for anticoagulation. The MV apparatus, including papillary muscle anatomy, is preserved, allowing the ventricle to maintain its shape and function. The two most common mechanisms of valve dysfunction, myxomatous disease and functional regurgitation, are also the most amenable to repair.

Percutaneously, the MV can be repaired with a clip device or with an annuloplasty. The clip devices available are the MitraClip (Evalve, Inc, Menlo Park, CA) and the Mobius II (Edwards Lifesciences, Irvine, CA). There has been more clinical experience with the MitraClip. These devices produce an edge-to-edge repair, opposing the A_2 and P_2 leaflets and simulating the Alfieri repair without requiring a sternotomy or CPB. This decreases the distance between the anterior and posterior leaflets while applying tension to the chordae, the leaflets, and, potentially, the annulus, which stabilizes or even shortens its anteroposterior diameter.[364]

The Alfieri repair[365] was developed by Dr. Alain Alfieri in 1991 for treatment of MR due to anterior leaflet prolapse. He approximated the central segments of the anterior and posterior MV leaflets, creating a double-orifice valve with reduced leaflet excursion and decreased regurgitation. In most patients, the Alfieri stitch was combined with an annuloplasty. Those patients who did not receive an annuloplasty ring still had excellent outcomes, prompting the development of the percutaneous repair.[366]

The clip is delivered though a transseptal puncture followed by deployment of a clip or suture to create a bridge between the anterior and posterior leaflets. The clip can be reopened and repositioned to locate the optimal position, and in some cases two or more clips have to be deployed to ensure an adequate reduction of MR. Within 6 months, the device is incorporated into a tissue bridge, mimicking the result of surgery.

The MitraClip, approved by the FDA in 2012, is a transvenous percutaneous device. It was first used in patients in 2003 and has been implanted in more than 10,000 patients worldwide.[367] This device permanently opposes the A_2 and P_2 segments of the MV leaflets, creating a double orifice (Fig. 3.27). This procedure is performed on a beating heart with the patient under deep sedation or general anesthesia and with fluoroscopic and echocardiographic guidance. Deep sedation is used when intracardiac echocardiography is the imaging modality chosen, and general anesthesia is used when TEE is required.

The MitraClip delivery system includes a steerable guide catheter and the clip delivery system, which comprises a delivery catheter, a steerable sleeve, and the MitraClip device. The MitraClip device is made of a cobalt-chromium metal alloy covered by polypropylene fabric. The clip delivery system, introduced through the femoral vein by the steerable guide catheter, is used to advance and manipulate the MitraClip into proper position and place it on the center segments of the MV leaflets. The MitraClip device, which can be adjusted to fully opened, closed, and inverted positions, grasps and coapts the MV leaflets (Fig. 3.28). The device can also be opened, closed, locked, and unlocked, and the grippers can be raised or lowered. The steerable guide catheter introduces the clip delivery system into the LA via the interatrial septum and then positions it in the approximate location above the MV (Fig. 3.29). Videos 3.3 and 3.4 demonstrate the path of the MitraClip and the MitraClip 1 month after placement.

The steerable catheter is 24 Fr at the femoral vein and 22 Fr after the transseptal puncture. The transseptal puncture is critically important because it determines the path of the clip toward the MV. An inappropriate puncture can decrease device maneuverability. Each arm of the clip is 4 mm long. With the arms extended, and under echocardiographic and fluoroscopic guidance, the clip is aligned perpendicular to the valve with the arms perpendicular to the line of coaptation. The clip is navigated across the mitral orifice and into the left ventricle above the origin of the MR jet.[367] The clip is then slowly retracted, allowing the leaflets to settle between the open arms of the device. The arms are then closed to grasp the leaflet edges, and the valve is interrogated by echocardiography to determine the degree of MR. If the procedure is successful, MR reduction will be immediate. If not, the clip can be readjusted. Once the degree of MR reduction is satisfactory and device stability has been determined, the clip is released. Forty percent of patients require a second clip, and use of as many as three to four clips has been described.[368]

Percutaneous repair of MR is used for patients whose risk is too high for conventional MV surgery; it is not meant to replace surgical techniques in low-risk patients. Specific criteria for MitraClip insertion are a patient with severe symptomatic MR with preserved LV size and function, an asymptomatic patient with LV dysfunction or increased LV size and recent onset of AF or pulmonary hypertension, and a symptomatic patient with severe LV dysfunction characterized by an EF of less than 30% despite maximal medical therapy.[369] Echocardiographic criteria for percutaneous mitral repair are shown in Box 3.15. Initially, clinical and anatomic criteria were based on use of the technique in patients with degenerative MR, but some patients with functional MR can be treated with the MitraClip as long as the jet origin extends beyond the central scallops of the line of coaptation or the jet is panorificial.[367]

Compared with a surgical repair, the quantitative reduction in MR with the MitraClip is reduced but not to the same extent. The advantages of percutaneous MV repair include (1) avoidance of sternotomy and CPB; (2) reduced postoperative mechanical ventilation, length of intensive care unit stay, and transfusion requirements; and (3) improved quality of life and functional capacity. Disadvantages include procedural failure, worsening of MR, and the development of MS. Complications include the creation of a persistent ASD associated with poorer outcomes,[370] torn leaflets and chordae, and rupture of the right or left atrial walls leading to cardiac tamponade. Late surgery in patients with a MitraClip is mainly necessitated by residual MR. Although surgery is more complicated, it is possible for most patients.[371]

Many trials have evaluated the efficacy of the MitraClip. The first set of trials were the EVEREST I, EVEREST II, and EVEREST High-Risk studies. EVEREST I was a phase I study evaluating the safety and efficacy of the clip. The MitraClip was implanted in 24 of 27 patients who had moderate to severe degenerative MV disease without LV dilation and who were candidates for surgical repair. There were four major events (three clip detachments and one limited neurologic event), but

BOX 3.15 SELECTION CRITERIA FOR MITRACLIP PLACEMENT

Noncommisural primary regurgitant jet
- Secondary jets, if present, should be clinically insignificant

Mitral valve area ≥4.0 cm
Coaptation length ≥2 mm and depth <11 mm
Mitral regurgitation jet must arise from central two-thirds of coaptation line
Minimal calcification in the leaflet grasping area
No leaflet cleft in the grasping area
Flail width <15 mm and flail gap <10 mm

18 patients remained free from surgery and with MR no worse than mild after 6 months.[372] In phase II of this trial, the efficacy and long-term effects of the MitraClip were compared with those of standard MV surgery. A total of 279 patients were randomized in a 2:1 ratio to undergo either MitraClip placement or surgical MV repair or replacement.[373] Although the mortality rate and proportion of patients with 3+ to 4+ MR were similar at 1 year, patients in the MitraClip group had a higher frequency of 2+ MR and a higher rate of surgery for MV dysfunction (20%, vs 2.2% in the surgical group). However, the percutaneous group demonstrated superior safety because more bleeding requiring transfusion occurred in the surgery group. There were no reports of clip embolization or MS, and the ability for surgical MV reconstruction was retained.[371]

Beneficial effects of the percutaneous clip measured with echocardiography at baseline and 24 hours after the procedure include significant reductions in MR, regurgitant fraction and volume, and LV end-systolic and end-diastolic dimensions and volume.[374] Other signs of reversal in LV remodeling include decreases in LV mass and wall stress, left atrial volume, and vena contracta area.[375–377]

The 4-year EVEREST II follow-up study demonstrated that the long-term results with the MitraClip were similar to those of surgical repair, including freedom from death, low rates of 3+ and 4+ MR echocardiographic indices, and improvement in functional status. Older patients with functional MR had outcomes that were most similar to those of surgery.[378] The EVEREST High-Risk trial studied patients with severe, predominantly functional MR who were deemed to be at high risk for surgical treatment and had an estimated mortality rate greater than 12%. They were treated with the MitraClip, and the results were compared with those in a nonrandomized concurrent control group treated with standard medical therapy.[379] At 1 year, there was a trend toward increased survival in the MitraClip group and a 45% reduction in hospitalization incidence. Other registries involving high-risk patients have shown similar results.[380,381]

Shillinger and associates[382] studied a selected group of 51 older patients who had lower EF values, functional MR, complex valvular abnormalities, and preexisting comorbidities and were treated with the MitraClip. During the procedure, all patients were hemodynamically stable and had no major periprocedural complications. After treatment, most were discharged with an MR grade of 2+, and significant improvement in New York Heart Association (NYHA) functional class occurred in more than 90%. The MitraClip has been effective in critically ill patients as a bailout procedure and in inoperable patients with ruptured papillary muscles, resulting in rapidly improving hemodynamics, ability to reduce or discontinue inotropic therapy, and discharge to home.[381,383,384] The MitraClip has also been shown to be beneficial in nonresponders to cardiac resynchronization therapy. The European PERMIT-CARE trial was performed in patients with symptomatic MR despite optimal medical therapy and cardiac resynchronization therapy. Those who underwent MitraClip repair had a trend toward improvement of their MR and reversal of LV remodeling, and 75% demonstrated improved NYHA functional class at 1 year.[385]

Two trials, the U.S.-based Clinical Outcomes Assessment of the MitraClip Percutaneous Therapy for Extremely High-Surgical-Risk Patients (COAPT) trial and the European Randomized Study of the MitraClip Device in Heart Failure Patients with Clinically Significant Functional Mitral Regurgitation (RESHAPE-HF), are examining the safety and effectiveness of the MitraClip in high-risk surgical patients with MR and heart failure randomized to percutaneous mitral repair or standard medical therapy. These studies will help to determine the role of MitraClip therapy in patients with MR who are ineligible for surgical repair or replacement.[373] In 2015, Feldman et al[373a] revealed the 5-year follow-up of the EVEREST II study that compared the 1- and 5-year follow-ups in patients undergoing MitraClip versus surgical repair and found that patients who underwent percutaneous repair required surgery more frequently than those who underwent surgical repair after 1 year. However, at 5 years, both groups had low rates for MV surgery due to MV dysfunction, proving the durability of MitraClip as a treatment for MR.

Anesthetic Management of Percutaneous Mitral Valve Repair

In addition to standard monitors, large-bore IV access (usually peripheral) and invasive arterial monitoring are necessary. Central venous catheterization is required if large-bore peripheral access cannot be obtained or if inotropic or vasopressor support is anticipated. If the procedure is not performed in a hybrid CCL, an OR should be available for unexpected emergencies. If TEE is used, the procedure is done under general anesthesia. Deep sedation can be performed if intracardiac echocardiography is used.

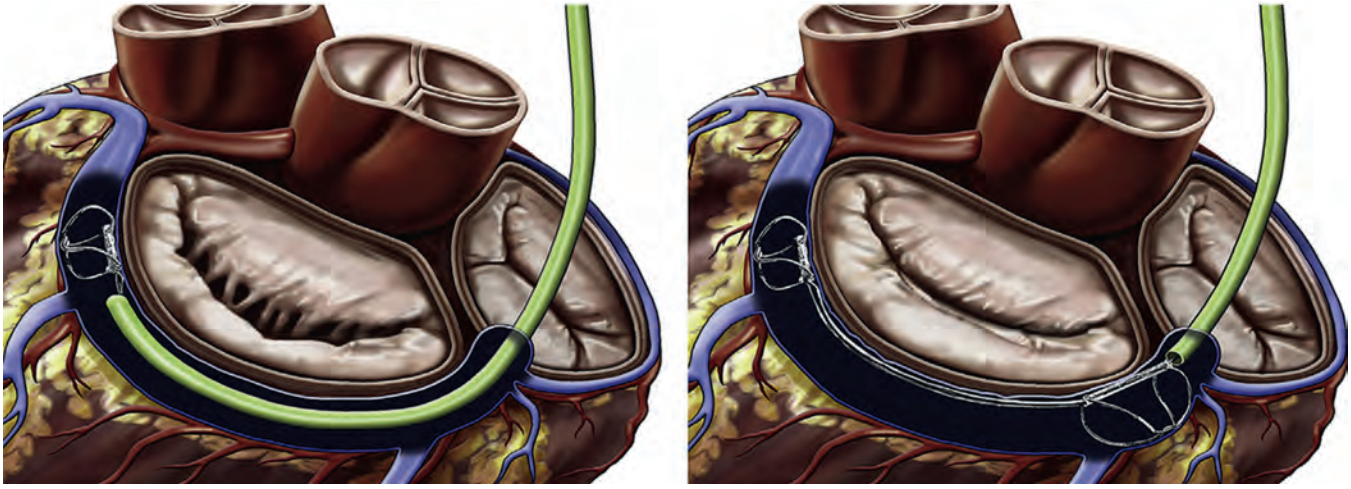

Fig. 3.30 The Cardiac Dimensions Carillon device. The guide catheter is introduced via jugular venous access. The device is inserted into the distal coronary sinus, and the distal anchor is released *(left panel)*; the guide catheter is then pulled back to release the proximal anchor in the coronary sinus ostium. The *right panel* shows the wireform, made of nitinol wire, after release in the coronary sinus. Cinching of the mitral annulus results in compression of the septal lateral dimension and thus the regurgitant orifice. *(From Feldman T, Young A. Percutaneous approaches to valve repair for mitral regurgitation.* J Am Coll Cardiol. *2014;63:2057.)*

The advantages of general anesthesia are that it allows for TEE monitoring and can facilitate the procedure by keeping the patient still and by allowing prolonged breath-holding during critical portions of clip placement. Depending on patient comorbidities, including the degrees of CAD and LV dysfunction, the anesthetic goals of maintaining a normal to slightly increased HR, a normal to slightly decreased systemic vascular resistance, and a normal to slightly increased preload can be accomplished using any of the available anesthetic agents. In patients with decreased ventricular function, smaller doses of anesthetic agents along with the addition of inotropic agents may be required. These patients also have longer circulatory times for IV anesthetics and shorter onset times for inhaled anesthetics.

Heparin is administered when the intraatrial septum is crossed and additional doses are given as necessary to keep the activated coagulation time longer than 250 seconds. The portions of the procedure in which breath-holding needs to occur are during difficult grasping attempts or during advancement of a second clip from the LA into the left ventricle, to avoid damaging the first clip.[386] Hypotension may occur when the clip crosses the MV orifice and may be caused by the clip's impeding LV filling. Vasoactive agents such as phenylephrine, dopamine, norepinephrine, or even epinephrine may be required to support the circulation. At the end of each grasp and before the release of the device, the blood pressure is raised to simulate preinduction physiology or to produce hypertension. This allows the surgeon to evaluate the extent, location, and severity of any residual MR; whether the clip should be deployed; or whether another clip is necessary. Protamine is administered at the end of the procedure. Most patients can be extubated and, depending on their comorbidities, can be monitored in a step-down unit or intensive care unit postoperatively.[386]

Besides leaflet repair, MV annuloplasty techniques are developing. Annuloplasty is a major component of most MV surgery and may be the only repair to treat functional MR. Annuloplasty reduces the anteroposterior diameter of the valve, promoting better leaflet coaptation and reducing regurgitation. Percutaneous annuloplasty can be achieved indirectly through the coronary sinus or directly from retrograde LV access.

Indirect annuloplasty has been developed because of the close relationship of the coronary sinus to the posterior and lateral MV annulus. A device inserted into the coronary sinus is used to shorten or reshape the annulus, mimicking surgical annuloplasty. A catheter is advanced into the coronary sinus via a transjugular approach. An anchoring device is placed in the distal coronary sinus with a tensioning element that attaches the device to the proximal coronary sinus anchor. This creates tension that is transmitted to the annulus, decreasing its circumference and improving leaflet coaptation. This technique has been considered in high-risk patients with degenerative prolapse and ischemic MR. The limitations include variations in normal coronary sinus anatomy, the varying distance between the coronary sinus and the MV, the possibility of Cx artery compromise, and inability to address anterior annulus problems. Although annuloplasty has been described as restoring MV competency and improving hemodynamic indices such as stroke volume and cardiac index, as well as decreasing left-sided and pulmonary arterial pressures and ameliorating symptoms from MR, a long-term survival benefit has not been demonstrated.[387]

The only system that uses the indirect approach is the Carillon Mitral Contour System (Cardiac Dimension, Kirkland, WA). This device is implanted transjugularly with a 9-Fr delivery catheter[388] (Fig. 3.30). The nitrinol device has proximal and distal anchors connected by a ribbon.[389] The distal anchor is released in the coronary sinus near the anterior commissure, and the proximal anchor sits near the coronary sinus ostium. Tension is placed on the delivery system to plicate the tissue around the MV. Then the valve is interrogated to determine whether the MR has been reduced. If not, the device can be repositioned or removed.[373] In the TITAN trial, a prospective, nonrandomized study of patients with functional MR, 36 of 53 patients underwent successful permanent device implantation with significant reductions in functional MR, including regurgitant volume and effective regurgitant orifice area, and favorable LV remodeling that was sustained for 12 months. These patients also had sustained improvements in functional status, including the 6-minute walk test, functional class, and quality of life, that lasted 24 months.[390] However, in the remaining 17 patients, the device could not be permanently implanted because of difficulty in cannulating the coronary sinus, and this led to an ineffective reduction in MR or a compressed coronary artery. The limitations of the Carillion device include ineffective MR reduction resulting from the separation between the coronary sinus and the MV apparatus that occurs with dilated hearts and compression of the Cx artery.[391]

Direct annuloplasty attempts to reproduce a surgical annuloplasty, and three devices are in development. The Mitralign system (Mitralign, Tewksbury, MA) uses the concept of suture annuloplasty via a retrograde transventricular approach to gain access to the mitral annulus. With the use of radiofrequency energy, guidewires penetrate the mitral annulus into the LA. Pairs of pledgets are implanted in the posterior

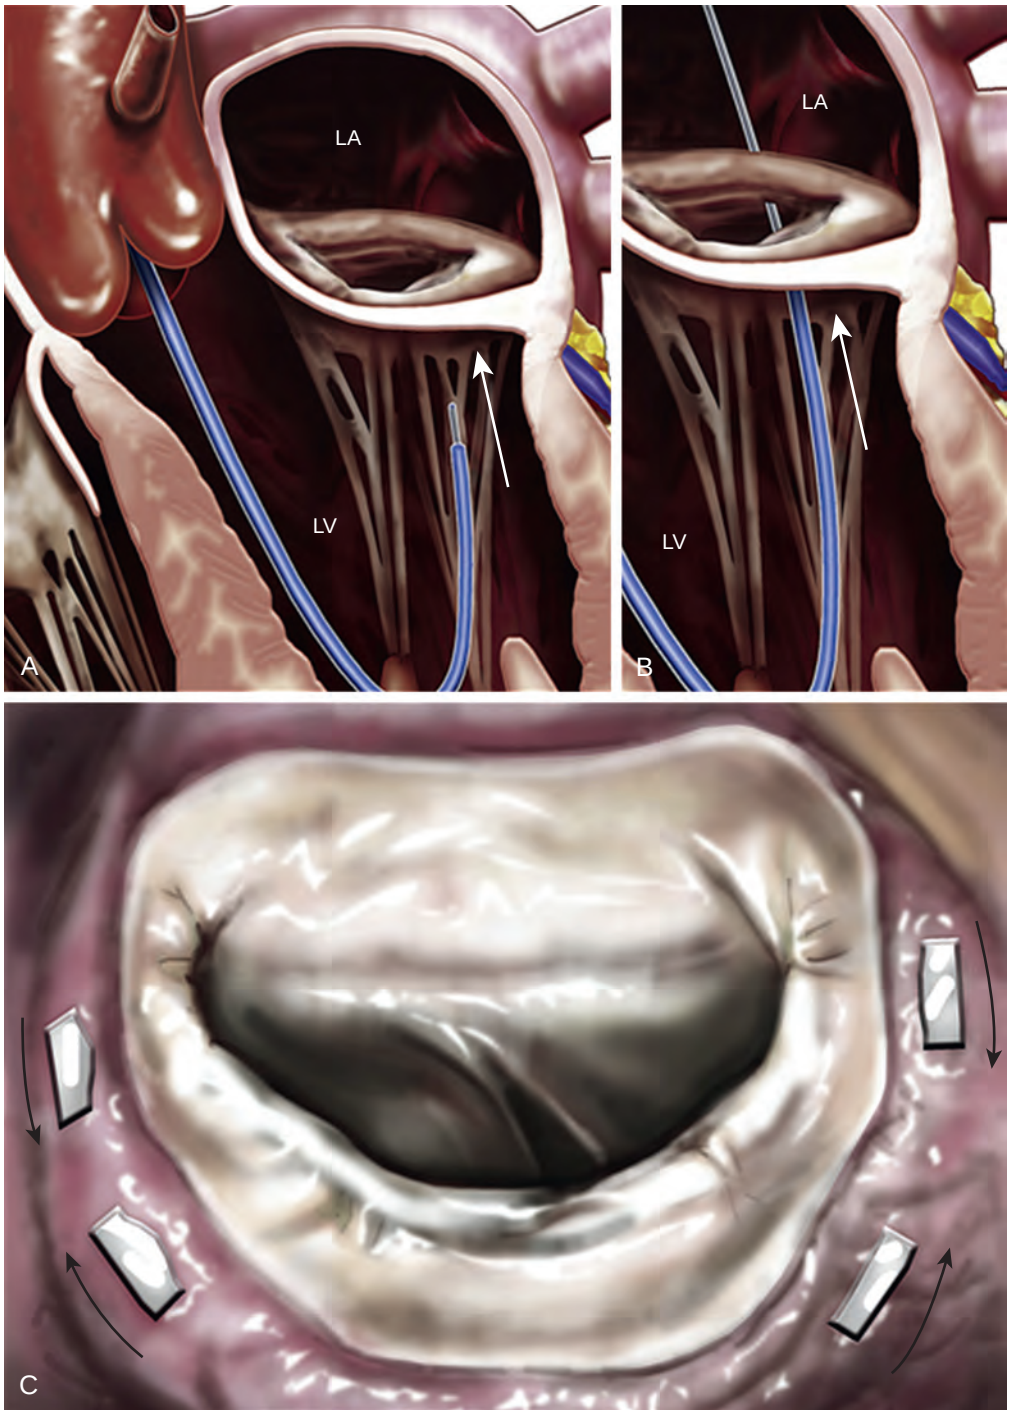

Fig. 3.31 Mitralign annular plication. (A) The retrograde guide catheter has been placed in the left ventricle *(LV)* with the distal catheter tip under the mitral annulus, behind the posterior leaflet. (B) A wire has been passed from the LV through the annulus and into the left atrium *(LA)*. Two pairs of wires are used to place pledgets near both commisures. (C) The pledgets are drawn together to decrease the mitral annular circumference. *(From Feldman T, Young A. Percutaneous approaches to valve repair for mitral regurgitation.* J Am Coll Cardiol. *2014;63:2057.)*

mitral annulus near A_1-P_1 and A_3-P_3 (Fig. 3.31). These pledgets are cinched together by a suture to reduce the mitral annulus and mitral orifice area.

The Accucinch system (Guided Delivery Systems, Santa Clara, CA) also uses the retrograde transventricular approach (Fig. 3.32). With this system, a series of anchors are implanted beneath the MV in the basilar left ventricle. These anchors are connected by a nitinol wire, and tethering of this wire cinches the basal left ventricle and mitral annulus, decreasing MR and producing remodeling of the basal left ventricle.

The Valtech CardioBand system (Valtech Cardio, Or Yehuda, Israel) is a percutaneous ring that resembles a surgical ring. This ring is delivered transseptally and is implanted on the atrial side of the mitral annulus. Screw anchors are deployed from the posteromedial to the anterolateral commissure in a counterclockwise fashion, with the ring extruded from a delivery catheter in small segments (Fig. 3.33).

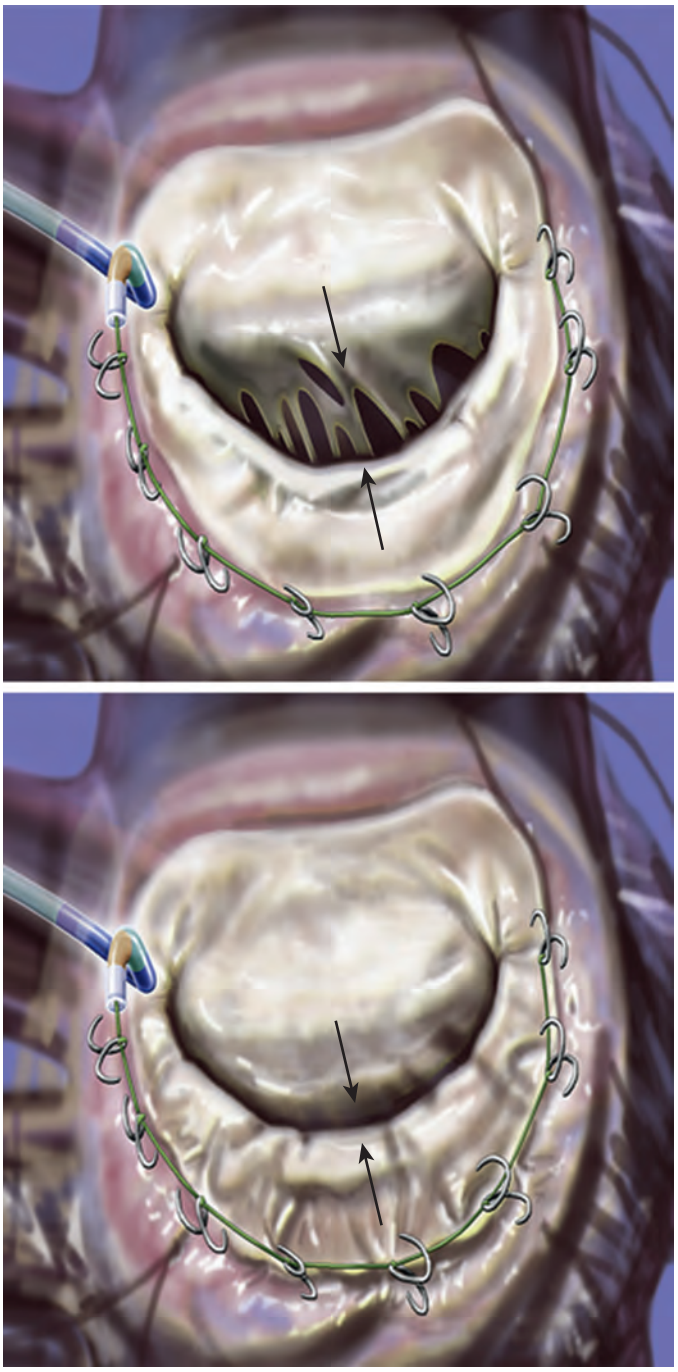

Fig. 3.32 Accucinch device. The Accucinch device is inserted via retrograde catheterization of the ventricle *(top panel)*. The *arrows* highlight the separation of the leaflet edges. Anchors are placed in the posterior mitral valve annulus and connected with a drawstring to cinch the annular circumference. When the cord is tightened, the basilar myocardium and annulus draw the mitral leaflets together *(bottom panel)* to decrease the regurgitant orifice. *(From Feldman T, Young A. Percutaneous approaches to valve repair for mitral regurgitation.* J Am Coll Cardiol. *2014;63:2057.)*

Annular circumference is reduced by controlling tension on the band, which decreases MR.[392] Several patients have undergone successful percutaneous implantations.

For high-risk patients, percutaneous approaches for leaflet repair, annuloplasty, chordal replacement, and LV remodeling are under development.

Other Catheter-Based Intracardiac Procedures

Alcohol Septal Ablation

HCM is a genetic disorder that can manifest with sudden cardiac death or symptoms of heart failure. A minority of patients have asymmetric septal hypertrophy that leads to dynamic outflow tract obstruction and produces severe symptoms. If this condition is refractory to medical therapy, a surgical procedure for septal tissue removal, and often MV repair or replacement, may be required. Since the mid-1990s, percutaneous methods have been studied to induce a controlled infarction and selectively ablate this overgrown septal tissue[393] (see Chapter 24).

Through a standard guiding catheter, a guidewire is placed in the large proximal septal perforator. A balloon catheter is placed over the wire into the septal perforator and inflated to occlude flow. The wire is removed, and 1 to 3 mL of ethanol is injected through the balloon into the septal perforator and left in place for 5 minutes. Temporary pacing is required in all patients, and a permanent pacemaker is required in some. When the procedure is performed by experienced operators, morbidity and mortality are limited, the gradient is reduced, and symptoms are improved.[394,395] Controversy persists regarding the role of alcohol septal ablation compared with surgical septal myectomy, and procedure selection is best based on the individual patient.[396,397]

Left Atrial Appendage Occlusion

Most strokes in patients with nonvalvular AF arise from thrombus formation in the left atrial appendage (LAA). Occlusion or exclusion of the LAA provides at least a theoretical alternative to oral anticoagulation for stroke prevention in such patients. Warfarin therapy is effective for stroke prevention but is associated with morbidity and mortality, and many patients have contraindications to warfarin. The WATCHMAN LAA system (Atritech, Plymouth, MN) is a covered nitinol device that is implanted percutaneously to seal the appendage. The PROTECT AF trial randomized 707 patients with permanent, persistent, or paroxysmal AF who were at high risk for stroke to appendage occlusion with the WATCHMAN device or warfarin therapy in a 2:1 ratio. The annual stroke rate was 2.3% in the device group and 3.2% in the warfarin group. Pericardial drainage was required in 5% of patients undergoing implantation, although no deaths occurred. Periprocedural stroke and device embolization occurred in 1.1% and 0.6% of patients, respectively.[398] The WATCHMAN device was approved by the FDA in March 2015.

An LAA exclusion device with promising human data is the LARIAT suture delivery system (SentreHEART, Redwood City, CA), which received FDA approval in 2009 for surgical suture placement and knot tying. This hybrid system has been used for LAA ligation and involves the epicardial and transseptal placement of magnet-tipped guidewires, forming a single rail for delivery of an endocardial balloon, and an epicardial snare with a pretied suture loop.[399] There are several advantages to this approach, including complete control of the pericardial space in the event of cardiac perforation, lack of any endovascular hardware left behind, and possible elimination of the need for postprocedure anticoagulation. The major disadvantage of the LARIAT system is the need for simultaneous transseptal and pericardial access. In addition, anatomic variables can limit candidacy for the device, including large LAA diameter, posterior LAA, pericardial adhesions from prior cardiac surgery, and pericarditis.[400] In the treatment of AF, individual patient decisions need to be made by weighing the proven long-term benefits and risks of rate control with warfarin against those of invasive therapies such as catheter ablation and LAA occlusion.

Percutaneous Closure of Patent Foramen Ovale and Septal Defects

The Amplatzer device (AGA Medical Corp., Golden Valley, MN) is FDA approved and is preferred to surgical closure for isolated secundum

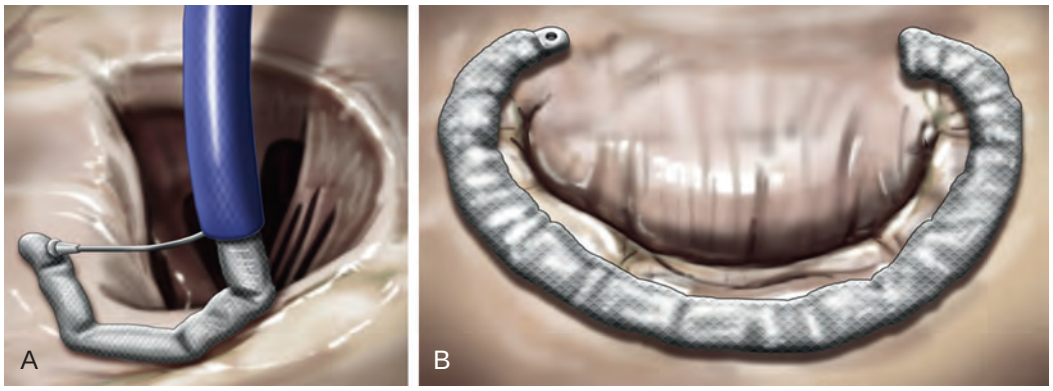

Fig. 3.33 Valtech CardioBand. (A) Transseptal guide catheter delivering angioplasty ring in segments. Each segment is sequentially anchored to the annulus. (B) Final annuloplasty ring encircling the posterior leaflet. *(From Feldman T, Young A. Percutaneous approaches to valve repair for mitral regurgitation.* J Am Coll Cardiol. *2014;63;2057.)*

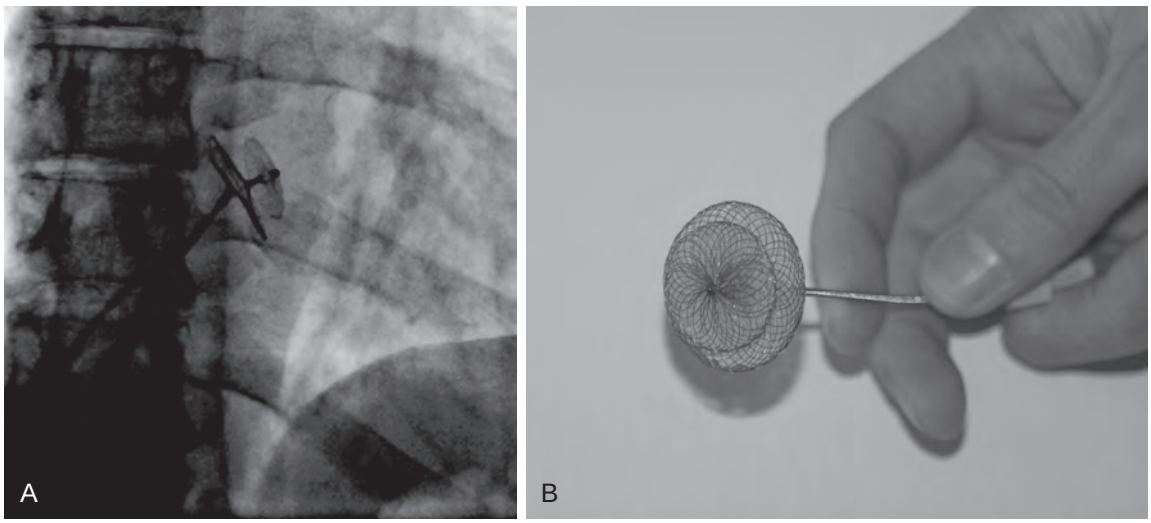

Fig. 3.34 (A) Deployment of a patent foramen ovale (PFO) closure device. (B) PFO closure device.

defects. A newer device, the Helex septal occluder (Gore Medical, Flagstaff, AZ), is an alternative for some smaller defects.[401] Intracardiac or TEE guidance is required.[60] General anesthesia is used frequently, to permit prolonged transesophageal imaging. In appropriately selected patients, success rates are almost 100%, and complications are rare.

Two devices, the Amplatzer PFO Occluder (AGA Medical) and the CardioSEAL (NMT Medical, Boston, MA), were available in the past under the Humanitarian Device Exemption in the United States for use in patients with a PFO who had had a recurrent stroke while receiving warfarin. The devices were withdrawn from the market in 2006 for a variety of reasons, primarily the fact that their use had expanded outside the approved indication without data to support such expanded use. Clinical trials are in progress to determine whether the devices are more effective than anticoagulation in preventing recurrent stroke after the first event (Fig. 3.34). Improvements in migraine headaches after PFO closure have been reported.[402] Surgical closure has been relegated to those few patients whose anatomy precludes percutaneous closure[403] (see Chapters 22 and 24).

These procedures are usually performed with the use of general anesthesia and TEE guidance. The anesthesiologist should know the indication and the hemodynamic effects of the lesion, including the consequences of right-to-left shunting.[404] Use of invasive monitoring depends on the patient's preexisting disease and the presence of right ventricular dysfunction and pulmonary hypertension. Inotropic support, such as the catecholamines, milrinone, or levosimendin, and pulmonary vasodilators, such as nitric oxide or prostacyclin, should be available for patients with severe right ventricular dysfunction and pulmonary hypertension. For patients with severe pulmonary hypertension, ECMO standby should be available. All IV access lines should be de-aired to prevent cerebral emboli. Perioperative complications may include arrhythmias, atrioventricular conduction defects, hypotension, thrombus with pulmonary or systemic embolization, valve dysfunction, Amplatzer device embolization or malposition, worsening of preexisting pulmonary hypertension and right ventricular dysfunction, and cardiac perforation.[404]

Most VSDs have right-to-left flow. The etiology of the lesion can affect management. Postinfarction VSD closure can be more challenging than congenital VSD closure. Patients with postinfarction VSD can be hemodynamically unstable and are more likely to have hypotension and arrhythmias during closure.[405]

The Catheterization Laboratory and the Anesthesiologist

The increasing incidence and complexity of procedures in the CCL or hybrid OR has broadened the scope of anesthesia practice. The CCL is typically in a different location from the main ORs, often in

a remote location or on a different floor. The setup, personnel, and environment are different. The fluoroscope and monitors are large and bulky, and other equipment may also be present in the room, such as leaded screens, defibrillators, code carts, and transesophageal or intracardiac echocardiography machines, limiting the space for the anesthesia machine, monitoring equipment, and cart. Challenges to the anesthesiologist in the CCL include radiation exposure, unfamiliar surroundings, isolation from anesthesia colleagues and resources, limited or ineffectual help from CCL personnel and physicians, and a reduced ability to obtain medications and equipment (eg, a difficult airway cart).[406]

Procedures and interventions in the CCL are more involved and in certain cases are performed on patients who are considered too high-risk for conventional surgery. These procedures take longer to perform and require more attention from the cardiologist. Collaboration and planning between the cardiologist and the anesthesiologist is needed to discuss the patient, the procedure, and the type of anesthetic required for procedural success. A discussion with the CCL nurses and technicians is also beneficial to inform them of the anesthetic plan and how they can assist the anesthesia team, if necessary.

The CCL must be equipped with wall oxygen, air, and suction outlets as well as a scavenging system when use of an inhalation agent is required. Anesthetic and resuscitation medications need to be available at all times, and a mechanism to obtain any additional medications should be discussed. In some CCLs, the automated dispensing cabinets have a draw dedicated for anesthesia-related medications. Although the CCL has monitors to measure HR, noninvasive and invasive blood pressure, central venous pressure, PA pressure, and oxygen saturation, a monitor that measures end-tidal carbon dioxide and inspired and expired concentrations of volatile agents is necessary, especially if a general anesthesia is planned. The anesthesia carts should contain airway equipment, including emergency airway adjuncts such as a laryngeal mask airway and a disposable videolaryngoscope, extra fluids and medications, standard and invasive monitoring supplies, oxygen masks and cannulas that can measure carbon dioxide, and suctioning supplies. Resuscitative medications and devices need to be available at all times. Because the defibrillators in the CCL may be different from those in the OR, the anesthesia staff must comfortable with the equipment. There should also be a means to obtain assistance during an emergency (eg, telephone to call the OR, code button). Patients are frequently far away from the anesthesia team, and with constant movement of the fluoroscopy equipment and table, extensions may be needed to prevent disconnects on the breathing circuit and oxygen tubing, IV and intraarterial lines, and monitors, including end-tidal carbon dioxide tubing.[407] In 2011, the American Society of Anesthesiologists revised its standard for ventilation monitoring in moderate or deep sedation to include end-tidal carbon dioxide monitoring along with qualitative clinical signs.

Depending on the procedure and the patient, a variety of anesthetic techniques are employed in the CCL. Simple catheterization procedures and PCIs are usually performed with minimal sedation and local infiltration under the direction of the cardiologist, according to institutional guidelines.[408] Small doses of midazolam and fentanyl are usually administered for these procedures. Anesthesiologists may be involved if there is a risk of airway, respiratory, or hemodynamic compromise or if the patient is unable to remain still for the procedure.[404]

Regional anesthesia, particularly epidurals, can be beneficial in the management of endovascular abdominal aortic aneurysm repair and in lower extremity stent procedures for vascular patency.[409] General anesthesia is reserved for prolonged interventional procedures and those that require the use of TEE. It is also used for patients who are apneic, pediatric, uncooperative, or critically ill; patients who have difficulty lying still; and patients with pulmonary hypertension, in whom hypoventilation and airway obstruction increases the risk of right ventricular dysfunction.

The preoperative assessment includes the reason for the intervention and the cardiac history, including the type and extent of disease and previous treatments (eg, medications, interventions). Useful information from previous studies includes the type and location of the lesion, left- and right-sided filling pressures, and valvular and ventricular function. Patients may present after a recent MI, in acute heart failure, or with uncontrolled arrhythmias.[404]

In addition to the cardiac history, a complete system-based history should be obtained, focusing on any airway issues, esophageal disease (if the use of TEE is anticipated), renal insufficiency (if dye use is required), use of diuretics (which can cause hypokalemia, increasing the risk of arrhythmias during the procedure), and use of any anticoagulants or antiplatelet agents. Prolonged heparin administration may lead to antithrombin III deficiency, requiring the administration of antithrombin III or fresh-frozen plasma. The patient should also be asked about any dye allergy, and ionic contrast dyes should be avoided in such patients.

Other considerations include urinary catheter placement for prolonged procedures. Blood should be cross-matched and available for procedures associated with bleeding and for those in which the cardiologist administers a variety of medications including anticoagulants (eg, heparin, GPIs) and direct thrombin inhibitors (eg, argatroban, bivalirudin). The cardiologist may also administer bolus medications (eg, nitroglycerin, calcium channel blockers) directly into catheters, and these may produce profound hemodynamic changes. The cardiologist should inform anesthesia personnel in advance of this type of therapy.

TEE is often used as guidance for wire and catheter placement and for determining the location and success of the procedure. If hemodynamic instability occurs during the procedure, TEE can be used to evaluate ventricular and valvular function and fluid status.

The anesthesiologist should be consulted whenever there is a patient issue or the intervention requires regional or general anesthesia. Patient factors include cardiovascular problems (eg, heart failure, hemodynamic instability), need for more extensive monitoring, respiratory conditions (including obstructive sleep apnea), morbid obesity, a known or suspected difficult airway, and severe pulmonary disease. Other considerations are pediatric patients, patients with psychiatric disorders who cannot lie still, patients with claustrophobia, and patients with tolerance to the medications administered by nonanesthesia personnel.[404]

This chapter has provided an overview of the procedures that are performed in the CCL and their anesthetic management. With the increased use of percutaneous therapies, anesthesiologists will play an integral part in the care of these patients.

4 Cardiac Electrophysiology: Diagnosis and Treatment

NADIA HENSLEY, MD | ALAN CHENG, MD | ASHISH SHAH, MD | CHARLES W. HOGUE, MD

KEY POINTS

1. Cardiac arrhythmias are common and result from an ectopic focus or a reentry circuit.
2. Surgical and catheter-based ablative therapies can abolish the origins of arrhythmias by interposition of scar tissue along the reentrant pathway or by isolating an ectopic area.
3. Supraventricular arrhythmias can be hemodynamically unstable, especially in the setting of structural heart disease. In some cases, persistent tachycardia can lead to tachycardia-induced cardiomyopathy.
4. Accessory pathways are typically interrupted using percutaneous, catheter-based techniques, producing high success rates with minimal complications.
5. Atrioventricular nodal reentrant tachycardia results from altered electrophysiologic properties of the anterior fast pathway and posterior slow pathway fibers that provide input to the atrioventricular node. Interruption of the involved pathway is curative.
6. Atrial flutter typically involves a reentrant circuit that circles the tricuspid valve and crosses the myocardial isthmus between the inferior vena cava and tricuspid valve. Catheter ablation of this region can remedy the arrhythmia.
7. Paroxysmal atrial fibrillation often results from ectopic beats originating in the pulmonary veins. Pulmonary vein isolation with catheter-based ablative energy is indicated for patients who have failed antiarrhythmic therapy and are symptomatic or have evidence of structural heart disease due to atrial fibrillation.
8. Catheter ablation for persistent or long-standing atrial fibrillation is less effective than for paroxysmal atrial fibrillation. Although pulmonary vein isolation is recommended, adjuvant ablation strategies are also employed, including abatement of complex fractionated atrial electrograms and targeting areas of ganglionated plexus.
9. Surgical treatment of atrial fibrillation (ie, maze procedure) has been employed with good success and has been modified to avoid the sinus node in an effort to minimize occurrences of chronotropic incompetence.
10. In adults, most episodes of sudden cardiac death are the result of ventricular tachyarrhythmias due to ischemic and nonischemic cardiomyopathy. Other conditions associated with an increased risk of sudden death include infiltrative cardiac diseases (eg, cardiac sarcoidosis, amyloidosis) and genetically based abnormalities such as hypertrophic cardiomyopathy, long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, and arrhythmogenic right ventricular dysplasia.
11. Substantial evidence supports use of an implantable cardioverter-defibrillator for primary and secondary prevention of sudden cardiac death.

Cardiac rhythm disturbances are common and an important source of morbidity and mortality.[1,2] The incidence of supraventricular tachycardias (SVTs) ranges from 35 cases per 100,000 person-years for paroxysmal SVTs to 5 to 587 cases per 100,000 person-years for atrial flutter for 50-year-old individuals and those older than 80 years, respectively.[3,4] Atrial fibrillation is the most common sustained cardiac arrhythmia in the general population, affecting more than 2.3 million Americans.[5] Prevalence is strongly associated with age, occurring in less than 1% of individuals younger than 55 years old but in almost 10% of those older than 80 years.[5] Atrial fibrillation increases health resource consumption, heightens the risk of stroke, and increases associated long-term mortality rates.[6]

The treatment of cardiac arrhythmias has shifted over the past 2 decades to catheter-based and surgical ablation from pharmacologic therapy because of the drugs' limited efficacy and increased risk of death due to their negative inotropic and proarrhythmic effects.[7,8] Data from prospective, randomized trials showing improved survival for patients with implantable cardioverter-defibrillators (ICDs) compared with those given antiarrhythmic drugs bolstered the shift to nonpharmacologic treatments.[9]

Current management options for cardiac arrhythmias include surgical and catheter ablative techniques using various energy sources. The principle in all cases is identification of the electrophysiologic mechanism of the arrhythmia followed by ablation of the involved myocardium using surgical incisions, cryothermy, or radiofrequency (RF) current. As the techniques have become more complex and time intensive, the need for anesthesia support has grown. Anesthesiologists caring for patients undergoing these procedures must be familiar with the anatomy of the normal cardiac conduction system, the electrophysiologic basis of common cardiac rhythm disorders, and the various approaches to ablative treatment. In this chapter, we discuss these basic principles and the anesthesia considerations for particular forms of treatment.

Electrophysiologic Principles

Anatomy and Physiology of the Cardiac Pacemaker and Conduction Systems

Sinoatrial Node

The sinoatrial (SA) node (Fig. 4.1) is a spindle-shaped structure composed of highly specialized cells located in the right atrial sulcus terminalis, which is lateral to the junction of the superior vena cava

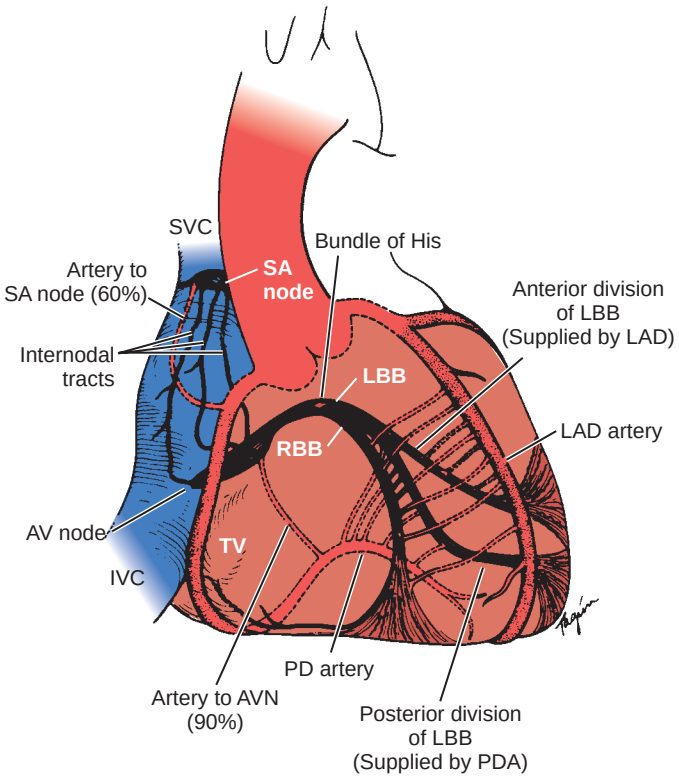

Fig. 4.1 Anatomy of the cardiac conduction system and arterial blood supply. In 60% of patients, the sinoatrial *(SA)* nodal artery is a branch of the right coronary artery, and in the remainder, it arises from the circumflex artery. The atrioventricular *(AV)* node is supplied by a branch from the right coronary artery or posterior descending artery *(PDA)*. *IVC*, Inferior vena cava; *LAD*, left anterior descending coronary artery; *LBB*, left bundle branch; *RBB*, right bundle branch; *SVC*, superior vena cava; *TV*, tricuspid valve. *(From Harthorne JW, Pohost GM. Electrical therapy of cardiac arrhythmias. In Levine HJ, ed.* Clinical Cardiovascular Physiology. *New York: Grune & Stratton; 1976:854.)*

BOX 4.1 ANATOMY OF THE CARDIAC PACEMAKER AND CONDUCTION SYSTEM

Sinus node

Atrioventricular junction
Intraventricular conduction system
- Left bundle branch
  - Anterior fascicle
  - Posterior fascicle

Right bundle branch
Purkinje fibers

(SVC) and the right atrium.[10,11] Box 4.1 summarizes the anatomy of the cardiac pacemaker and conduction system.

The SA node contains three cell types (ie, nodal, transitional, and atrial muscle), but no single cell type is solely responsible for initiating the pacemaker impulse. Instead, multiple cells in the SA node discharge synchronously through complex interactions.[12–14] Studies suggest that the SA node consists of three distinct regions and that each is responsive to a separate group of neural and circulatory stimuli.[15] Interactions among these three regions appear to determine the ultimate rate of output of the SA node.

Although the SA node is the primary site of impulse formation, subsidiary atrial pacemakers located throughout the right and left atria can also initiate cardiac impulses.[16–18] A series of studies in dogs and humans confirmed that there is an extensive system of atrial pacemakers widely distributed in the right and left atria and the atrial septum.[15,19–21] Because the atrial pacemaker system occupies a much larger area than the SA node, it can be severed during arrhythmia surgery, impairing rate responsiveness.[10] However, it is extremely difficult to completely abolish SA node activity through catheter-based ablation techniques.

The blood supply to the SA node (ie, SA node artery) is provided from the right coronary artery (RCA) (60% of the population) or the left circumflex coronary artery (see Fig. 4.1). The SA node is richly innervated with postganglionic adrenergic and cholinergic nerve terminals. By releasing acetylcholine, vagal stimulation slows SA nodal automaticity and prolongs intranodal conduction time, whereas adrenergic stimulation increases the discharge rate of the SA node.[10]

Internodal Conduction

Despite previous controversy about the existence of specialized conduction pathways connecting the SA node to the atrioventricular (AV) node, electrophysiologists agree that preferential conduction unequivocally exists and that spread of activation from the SA node to the AV node follows distinct routes by necessity because of the peculiar geometry of the right atrium.[10] The orifices of the superior and inferior cava, fossa ovalis, and ostium of the coronary sinus divide the right atrium into muscle bands, limiting the number of routes available for internodal conduction (see Fig. 4.1). These routes, however, do not represent discrete bundles of histologically specialized internodal tracts comparable to the ventricular bundle branches.[22] A parallel arrangement of myocardial cells in bundles, such as the crista terminalis and the limbus of the fossa ovalis, may account for preferential internodal conduction. Although electrical impulses travel more rapidly through the thick atrial muscle bundles, surgical transection does not block internodal conduction because alternate pathways of conduction through atrial muscle are available.[23]

Atrioventricular Junction and Intraventricular Conduction System

The AV junction (Fig. 4.2) corresponds anatomically to a group of discrete, specialized cells that are morphologically distinct from working myocardium and divided into a transitional cell zone, compact portion, and penetrating AV bundle (ie, His bundle).[24] Based on animal experiments, the transitional zone appears to connect atrial myocardium with the compact AV node.[25] The compact portion of the AV node is located superficially and anterior to the ostium of the coronary sinus and above the insertion of the septal leaflet of the tricuspid valve. The longitudinal segment of the compact AV node penetrates the central fibrous body and becomes the bundle of His. As the node-bundle axis descends into the ventricular musculature, it gradually becomes completely isolated by collagen and is no longer in contact with atrial fibers.

The AV junction is contained within the triangle of Koch, an anatomically discrete region bounded by the tendon of Todaro, tricuspid valve annulus, and ostium of the coronary sinus (Fig. 4.3). The triangle is avoided in all cardiac operative procedures to prevent damage to AV conduction. Individual variation in the anatomy of the AV nodal area depends on the degree of central fibrous body development.[10]

Branching of the node-bundle axis begins at the superior margin of the muscular interventricular septum. At this level, the bundle of His emits a broad band of fascicles, forming the left bundle branch that extends downward as a continuous sheet into the left side of the septum beneath the noncoronary aortic cusp (see Fig. 4.1). The left bundle divides into smaller anterior and broader posterior fascicles, although this is not a consistent anatomic delineation. The right bundle branch usually originates as the final continuation of the bundle of His, traveling subendocardially on the right side of the interventricular septum toward the apex of the right ventricle. The distal branches of the conduction system connect with an interweaving network of Purkinje fibers expanding broadly on the endocardial surface of both ventricles.

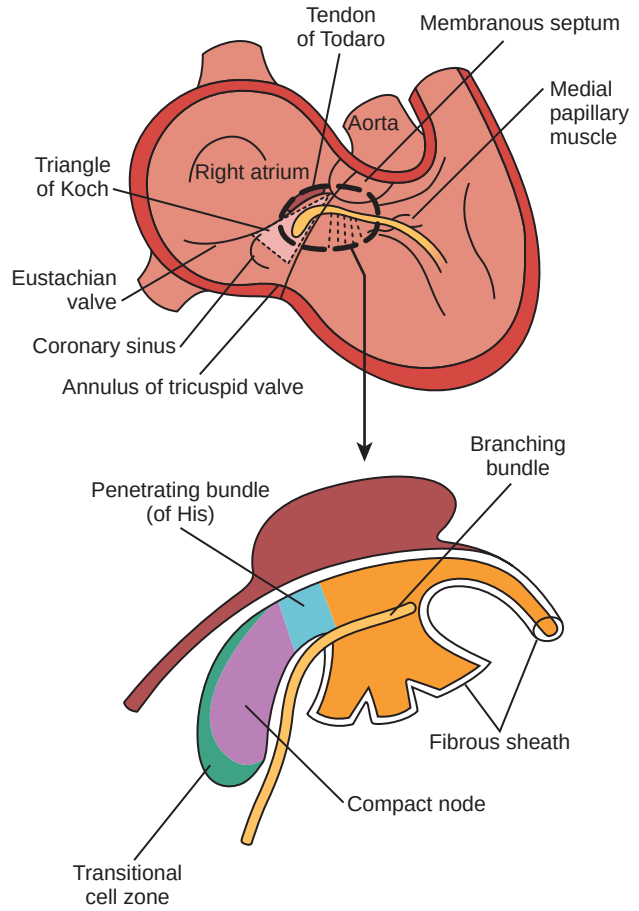

Fig. 4.2 Anatomic relationships of the atrioventricular junction and other cardiac structures. *(From Harrison DC, ed.* Cardiac Arrhythmias: A Decade of Progress. *Boston: GK Hall Medical Publishers; 1981.)*

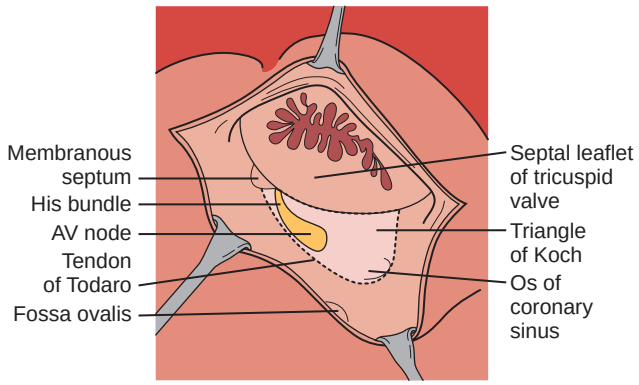

Fig. 4.3 View of right atrial septum through a right atriotomy incision *(superior on the left)*. The triangle of Koch is an important anatomic area that includes the atrioventricular *(AV)* node and proximal portion of the His bundle. This anatomic region is contained in the area between the tendon of Todaro, the tricuspid valve annulus, and a line connecting the two at the level of the os of the coronary sinus. *(From Cox JL, Holman WL, Cain ME. Cryosurgical treatment of atrioventricular node reentry tachycardia.* Circulation. *1987;76:1331.)*

In 85% of the population, most of the blood supply to the AV node is from the RCA, and the left circumflex artery supplies the remainder. The bundle of His is supplied by branches from the anterior and posterior descending coronary arteries.

Innervation of the SA and AV nodes is complex because of substantial overlapping of vagal and sympathetic nerve branches. Stimulation of the right cervical vagus nerve causes sinus bradycardia, whereas stimulation of the left vagus nerve prolongs AV nodal conduction. Stimulation of the right stellate ganglion speeds the SA nodal discharge rate, whereas stimulation of the left ganglion produces a shift in the pacemaker from the SA node to an ectopic site (ie, tissue outside the normal conduction system of the heart that initiates an impulse).[26]

BOX 4.2 ARRHYTHMIA MECHANISMS

Focal mechanisms
- Automatic
- Triggered

Reentrant arrhythmias

Normal automaticity
- Sinoatrial node
- Subsidiary atrial foci
- Atrioventricular node
- His-Purkinje system

Triggered mechanisms occur from repetitive delayed or early afterdepolarizations.

Reentry
- Unidirectional block is necessary.
- Slowed conduction in the alternate pathway exceeds the refractory period of cells at the site of unidirectional block.

Basic Arrhythmia Mechanisms

The mechanisms of cardiac arrhythmias are broadly classified as focal mechanisms that include automatic or triggered arrhythmias or as reentrant arrhythmias (Box 4.2). Cells that display automaticity lack a true resting membrane potential and instead undergo slow depolarization during diastole (Figs. 4.4 and 4.5). Diastolic depolarization results in the transmembrane potential becoming more positive between successive action potentials until the threshold potential is reached, producing cellular excitation. Cells possessing normal automaticity can be found in the SA node, subsidiary atrial foci, AV node, and His-Purkinje system.[10,13,27–29]

The property of slow diastolic depolarization is called *spontaneous diastolic* or *phase 4 depolarization*. Factors that can modify spontaneous diastolic depolarization are shown in Fig. 4.5 and include alterations in the maximal diastolic potential, threshold potential, and rate or slope of diastolic depolarization. The net effect is to influence the rate at which the threshold potential is achieved, resulting in an increase or a decrease in automaticity.

The ionic mechanism of diastolic depolarization involves the funny current (ie, funny channel or pacemaker current), which is expressed in spontaneously active cardiac regions. Diastolic depolarization involves a decrease in net outward potassium ion (K^+) movement or an increase in net inward sodium ion (Na^+) movement, or both.[26,30–33] Pacemaker cells with the fastest rate of phase 4 depolarization become dominant in initiating the cardiac impulse, with other automatic foci subject to overdrive suppression.

Altered automaticity occurs when cells that normally display automaticity (eg, SA node, AV node, Purkinje fibers) change the rate of pacemaker firing. Although the ionic mechanisms resulting in altered automaticity are unchanged, other factors such as those seen in Fig. 4.5 can contribute to an increase in automaticity. Automaticity resulting from abnormal ionic mechanisms, even if occurring in cells that are usually considered automatic (eg, Purkinje fibers), is referred to as *abnormal automaticity*. Abnormal automaticity may also occur in cells in which automaticity is not normally observed (eg, ventricular myocardium).

Arrhythmias caused by a triggered mechanism are initiated from cells that have repetitive afterdepolarizations. Afterdepolarizations are oscillations in the transmembrane potential that occur before (ie, early

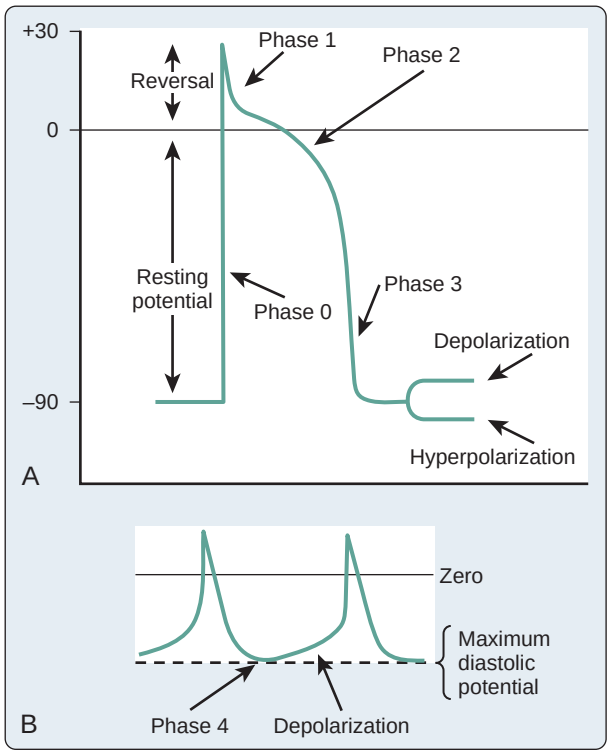

Fig. 4.4 (A) Graph of the cardiac cellular action potential (in millivolts) of the fast-response fiber. (B) Graph of the action potential of slow-response fiber. The slow-response fiber is similar to that found in the sinoatrial node but lacks the rapid upstroke of phase 0. *(From Ferguson TB Jr. Anatomic and electrophysiologic principles in the surgical treatment of cardiac arrhythmias.* Cardiac Surg. *4:19, 1990.)*

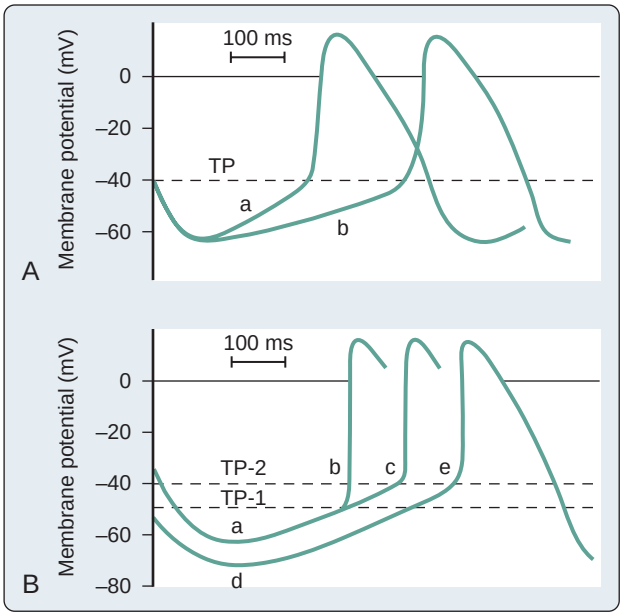

Fig. 4.5 (A) Transmembrane potential of the sinus node. A decrease in the slope of phase 4 or diastolic depolarization *(a to b)* increases the time to reach the threshold potential *(TP)*, slowing the heart rate. *(B)* Heart rate slowing occurs in changing from *TP-1* to *TP-2*, and a longer interval is needed to reach the TP *(b to c)*. Increasing maximal diastolic potential *(a to d)* also slows the heart rate by increasing the time to reach the TP *(b to c)*. *(From Atlee JL III.* Perioperative Cardiac Arrhythmias: Mechanisms, Recognition, Management. *2nd ed. Chicago: Year Book Medical Publishers; 1990:36.)*

afterdepolarizations) or after (ie, delayed afterdepolarizations) membrane repolarization. Different ionic mechanisms are responsible for each form of afterdepolarization, and if the oscillations in membrane potential reach the threshold potential, a triggered cardiac impulse can be generated.[13] Triggered activity is often considered an abnormal form of automaticity. However, because triggered activity requires a prior cardiac impulse (in contrast to automaticity), the abnormal electrophysiologic event cannot be considered a pure form of automaticity.

Reentry is a condition in which a cardiac impulse persists and reexcites myocardium that is no longer refractory.[10] Unidirectional block of impulse conduction is a necessary condition for reentry. The unidirectional block may be in the form of differences in membrane refractoriness (ie, dispersion of refractoriness), and some areas of myocardium are unexcitable, but other areas allow impulse propagation. On repolarization, previously refractory membranes become available for depolarization if the initial impulse has found an alternate route of propagation and returns to the prior site of conduction block. For reentry to occur, slowed conduction in the alternate pathway must exceed the refractory period of cells at the site of unidirectional block.

Partial depolarization of fast-response fibers (ie, depressed fast response) results in reduced Na+ channel availability with a reduced rate of phase 0 of the action potential. The reduced rate of the action potential upstroke of phase 0 can slow conduction and contribute to the previously described conditions conducive to reentry.

Arrhythmias produced by reentrant or triggered mechanisms, but not those due to increased automaticity, can be induced with programmed stimulation in the setting of a diagnostic electrophysiology study (EPS). Pacemaker-induced overdrive suppression is a characteristic of arrhythmias produced by automaticity (see Chapter 5).

Diagnostic Evaluation

The history of symptoms often helps to determine the cause of a patient's palpitations. Abrupt onset and abrupt termination of regular palpitations is consistent with a paroxysmal SVT that most often results from atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT) associated with an accessory AV bypass tract, or atrial tachycardia. Although a history of syncope does not definitively indicate a ventricular or supraventricular cause, it is helpful in determining the how urgently the condition should be evaluated. Whether palpitations are regular or irregular is useful information for differentiating atrial fibrillation as a cause of the symptoms. Precipitating events, number and duration of episodes, and dyspnea, fatigue, or other constitutional symptoms should be sought from the history (Box 4.3).

A 12-lead electrocardiogram (ECG) should be obtained during tachycardia and compared with baseline sinus rhythm ECGs. It is also helpful to run a rhythm strip during periods of intervention such as carotid sinus massage or adenosine administration. Patients with a history of preexcitation manifesting with an arrhythmia should be immediately evaluated because atrial fibrillation in the setting of an accessory pathway can lead to sudden death. For all patients undergoing evaluation of an arrhythmia, an echocardiogram is essential to

BOX 4.3 DIAGNOSTIC EVALUATION OF ARRHYTHMIAS

History of palpitations, syncope, and constitutional symptoms
Physical examination
Twelve-lead electrocardiogram at baseline and during tachycardia if available
Two-dimensional echocardiogram
Twenty-four-hour Holter monitoring of patient-triggered events
Invasive electrophysiologic testing

assess cardiac structural abnormalities and ventricular function. It is particularly warranted for patients with persistent tachycardia, which can lead to tachycardia-associated cardiomyopathy.[34]

Twenty-four-hour Holter monitoring of patient-triggered events may be useful for some patients with frequent but transient symptoms. Other evaluations such as exercise or pharmacologic stress testing have been employed to elicit episodes of tachycardia or determine how robust preexcitation is with increasing heart rates.

Diagnosis of the underlying mechanisms of the arrhythmia may require invasive electrophysiologic testing. Studies involve percutaneous introduction of catheters that provide electrical stimulation and record electrograms from various intracardiac sites. Initial recording sites often include the high right atrium, bundle of His, coronary sinus, and the right ventricle[10,35] (Figs. 4.6 and 4.7). The cardiac activation sequence can be discerned from these recordings along with the surface ECG, as shown in Fig. 4.8 for a patient undergoing evaluation for an accessory AV conduction pathway. The activation sequence is assessed by the depolarization time recorded by the electrodes positioned fluoroscopically at various anatomic sites. A recording obtained during diagnostic evaluation of a patient with a ventricular arrhythmia is shown in Fig. 4.9.

The catheters are most often introduced through the femoral vessels under local anesthesia. Systemic heparinization is required, particularly when catheters are introduced into the left atrium or left ventricle. The most common complications from electrophysiologic testing are those associated with vascular catheterization.[10,36] Other complications include hypotension (1% of patients), hemorrhage, deep venous thrombosis (0.4%), embolic phenomena (0.4%), infection (0.2%), and cardiac perforation (0.1%).[10,37] Proper application of adhesive cardioversion electrodes before the procedure facilitates rapid cardioversion-defibrillation in the event of persistent or hemodynamically unstable tachyarrhythmia resulting from stimulation protocols.

The principles of intraoperative electrophysiologic mapping are similar to those used in the cardiac catheterization suite. Procedures have evolved from early, single-point epicardial mapping systems with a handheld electrode to sophisticated, multichannel, computerized systems. The latter can acquire and store multiple epicardial, intramural, and endocardial electrograms from a single depolarization. Multichannel, computerized mapping allows rapid identification of arrhythmia pathways (eg, accessory pathways) before initiation of cardiopulmonary bypass, reducing the need for excessive cardiac manipulations necessary with a handheld electrode and promoting stable conduction.

Principles of Electrophysiologic Treatment

The paradigm for ablative treatment of cardiac arrhythmias evolved from the surgical treatment of Wolff-Parkinson-White (WPW) syndrome and ventricular tachycardia (VT) developed by Cobb, Sealy, and Boineau and their colleagues.[38–40] The fundamental approach is precise localization of the electrophysiologic substrate for the arrhythmia and ablation of the pathway. In the case of WPW syndrome, the accessory pathway is identified with intraoperative electrophysiologic mapping that initially used handheld electrodes.[10,41] Development of multichannel, computer-based mapping systems allowed identification of the

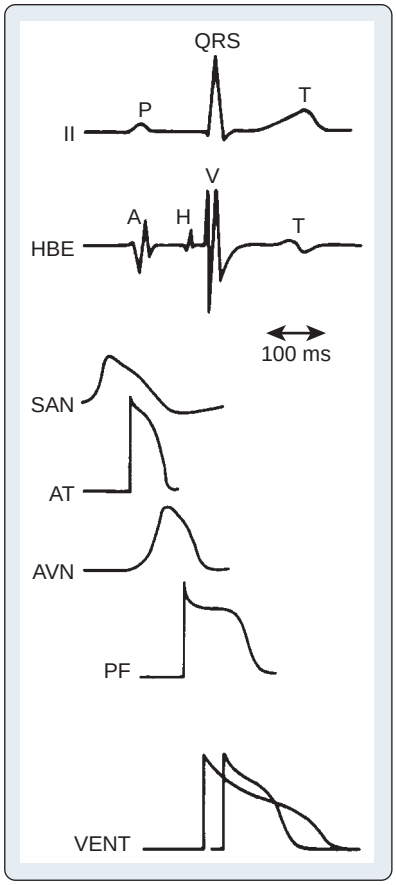

Fig. 4.6 Electrograms from leads placed in various cardiac locations in reference to the surface ECG show the rapid upstroke of the action potential (phase 0) in fast-response fibers compared with the slower upstroke of slow-response fibers. Sequences of action potentials from various cardiac tissues are presented in relation to the surface electrocardiogram and His bundle electrogram. *AT*, Atrium; *AVN*, AV node; *PF*, Purkinje fiber; *SAN*, SA node; *VENT*, ventricle. *(From Atlee JL III.* Perioperative Cardiac Arrhythmias: Mechanisms, Recognition, Management. *2nd ed. Chicago: Year Book Medical Publishers; 1990:27.)*

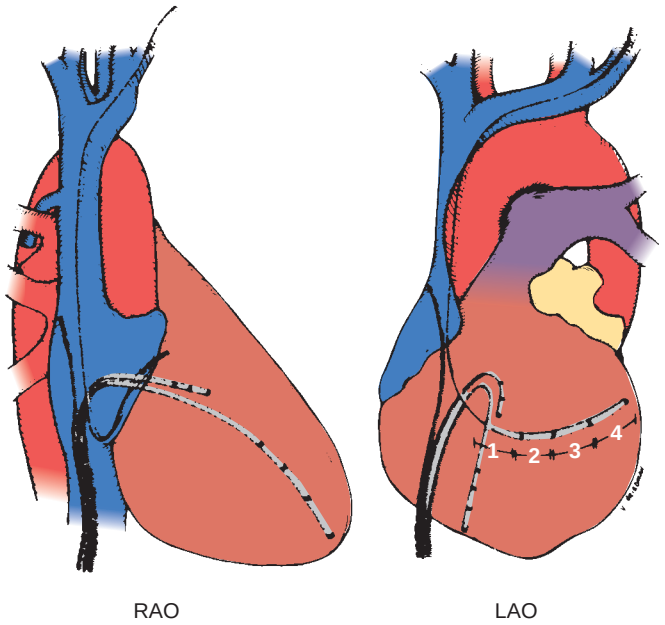

Fig. 4.7 Schematic depiction of an electrophysiologic study of a patient with Wolff-Parkinson-White syndrome. A catheter with multiple recording/pacing electrodes is positioned in the high right atrium, coronary sinus, bundle of His region, and right ventricular apex. Right anterior oblique *(RAO)* projections differentiate anterior from posterior sites. Left anterior oblique *(LAO)* projections differentiate septal from lateral sites. Numbered zones in the LAO projection regionalize electrode positions in the coronary sinus: *1*, posteroseptal; *2*, posterior; *3*, posterior; *4*, posterolateral. *(From Cain ME, Cox JL. Surgical treatment of supraventricular tachyarrhythmias. In: Platia EV, ed.* Management of Cardiac Arrhythmias: The Nonpharmacologic Approach. *Philadelphia: Lippincott; 1987:307.)*

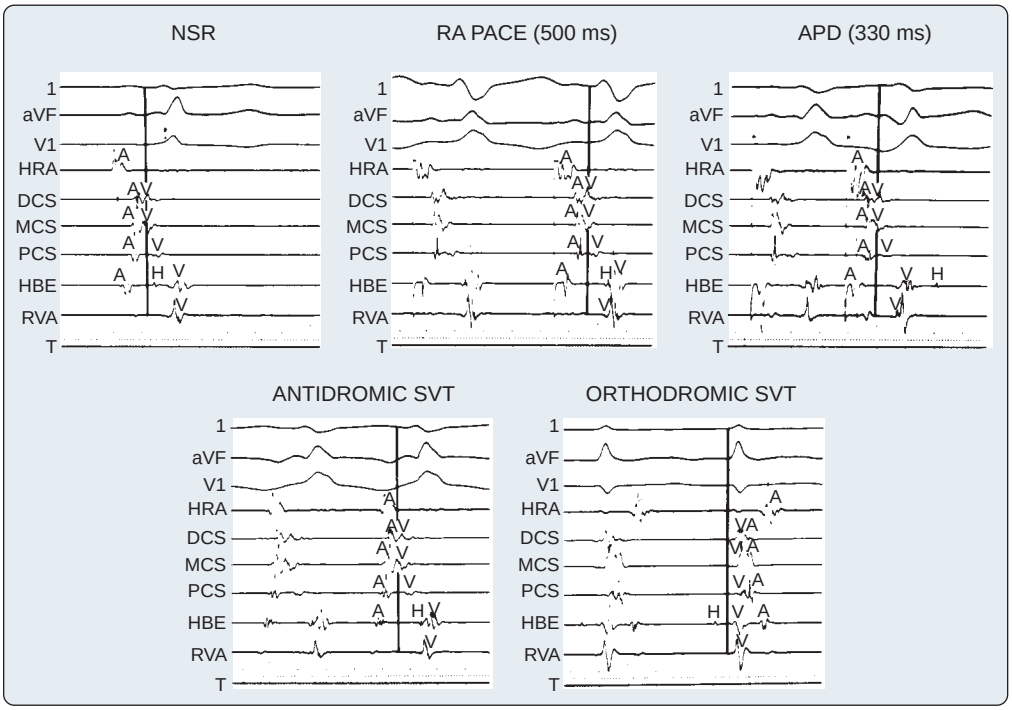

Fig. 4.8 Surface electrocardiogram (ECG) (ie, leads I, aVF, and V_1) and electrograms at various intracardiac sites during normal sinus rhythm *(NSR)*, pacing from the right atrium *(RA PACE)*, after an atrial premature depolarization *(APD)*, and during antidromic and orthodromic supraventricular tachycardia *(SVT)*. The left free wall accessory pathway is identified by the earliest onset of ventricular depolarization at the distal coronary sinus catheter *(DCS)* in relation to the delta wave on the surface ECG *(vertical line)*. This is followed closely by activation in the middle coronary sinus *(MCS)* and proximal coronary sinus *(PCS)* sites. Other catheter locations are the high right atrium *(HRA)*, region on the His bundle electrogram *(HBE)*, and right ventricular apex *(RVA)*. Conduction is followed during SVT by the pattern of cardiac activation from the right atrium *(vertical line)* to the ventricles. *(From Cain ME, Cox JL. Surgical treatment of supraventricular tachyarrhythmias. In: Platia EV, ed.* Management of Cardiac Arrhythmias. *Philadelphia: Lippincott; 1987:308.)*

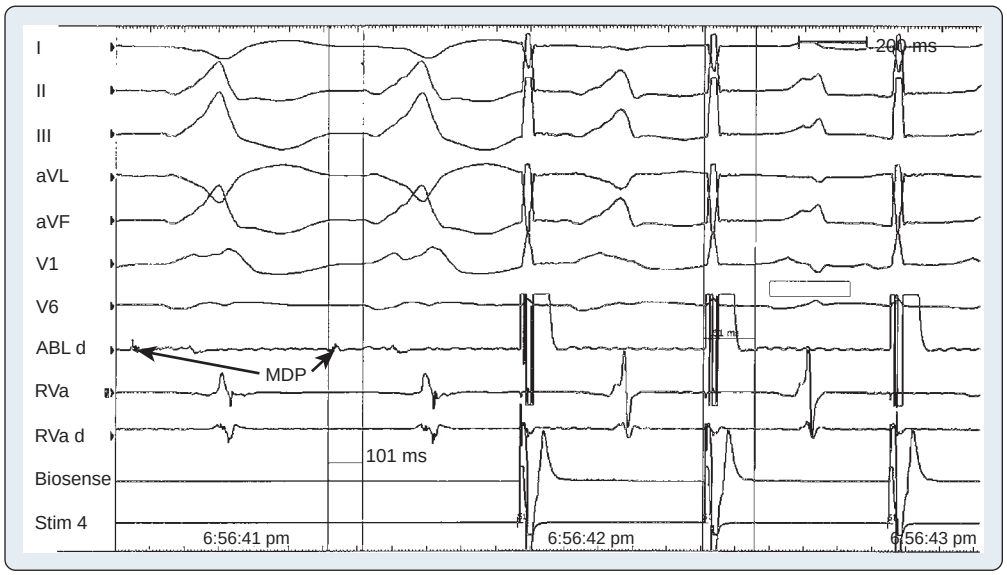

Fig. 4.9 Endocardial mapping of ventricular tachycardia. Surface electrocardiograms and selected endocardial electrograms are shown during sustained ventricular tachycardia in a patient with severe ischemic tachycardia. The mapping catheter distal electrode *(ABL d)* has been positioned at an endocardial site that records a middiastolic potential *(MDP)* that precedes the QRS by 101 ms. Pacing at a cycle length slightly faster than the tachycardia cycle length results in ventricular capture with a QRS morphology that is slightly different from the native tachycardia. The interpretation of this maneuver is that the endocardial pacing site is not at a favorable location for catheter ablation. Pacing at an optimal site for catheter ablation produces a QRS morphology identical to that of the native tachycardia.

BOX 4.4 ELECTROPHYSIOLOGIC ABLATIVE TREATMENT INDICATIONS

Drug-resistant arrhythmias
Drug intolerance
Severe symptoms
Avoiding lifelong treatments

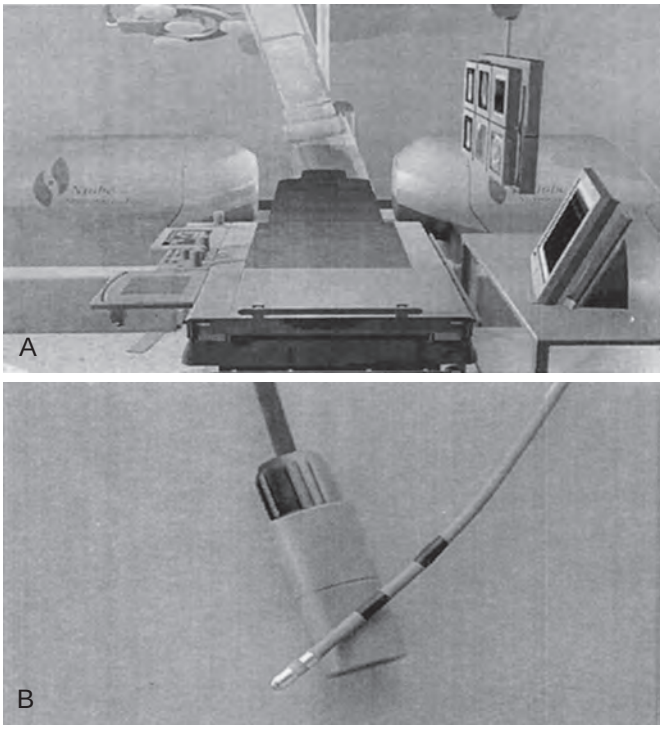

Fig. 4.10 Stereotaxis magnetic catheter navigation system. (A) The Stereotaxis system consists of two permanent magnetic arrays positioned on either side of a standard fluoroscopy table and digital fluoroscopy with a computer control system. The magnetic arrays project a composite magnetic field of 0.08 T in the region of a patient's heart to control the position of a magnetic catheter. (B) The 7-Fr magnetic catheter, which is used with the Stereotaxis system, has two distal electrodes for endocardial pacing, recording, and radiofrequency ablation. An internal permanent magnet allows the catheter to interact with the prevailing magnetic field for motion control.

mechanisms for many arrhythmias (including VT) and their termination by interruption of the underlying substrate.

Experience and insights into arrhythmia mechanisms led to development of the catheter-based methods now routinely used for a variety of supraventricular and ventricular arrhythmias. General indications for ablative treatments include drug-resistant arrhythmias, drug intolerance, severe symptoms, and desire to avoid lifelong drug treatments (Box 4.4).

Manipulation of catheter electrodes in the heart for precise mapping and treatment of arrhythmias can be laborious and time consuming. Robotically and magnetically driven navigational systems and newer catheters have been developed to facilitate the process and improve catheter positioning and stability. With these navigational systems, the catheter tip is localized with three-dimensional fluoroscopy or advanced mapping applications and precisely moved to the myocardial area of interest using a robotic arm or a magnetic field[42] (Fig. 4.10).

Because of the two predominant mechanisms of arrhythmias, surgical and catheter-based treatments often focus on identifying the site

BOX 4.5 ATRIOVENTRICULAR RECIPROCATING TACHYCARDIA ACCESSORY PATHWAY CHARACTERISTICS

- Concealed: accessory pathway displays retrograde conduction.
- Manifest: accessory pathway displays antegrade conduction. Pathways often exhibit retrograde conduction.
- Orthodromic: antegrade conduction from atria to ventricles occurs through the normal atrioventricular (AV) nodal conduction system and retrograde conduction through the accessory pathway.
- Antidromic: antegrade conduction from atria to ventricles occurs through the accessory pathway and retrograde conduction through the AV nodal pathway.
- Abnormal pathways are treated with percutaneous radiofrequency ablation.
- Abnormal pathways are treated surgically from the endocardium to epicardium by transection and/or cryoablation.

of earliest electrical activity (ie, focal automatic or triggered arrhythmias) or identifying the critical isthmus responsible for perpetuating reentrant arrhythmias. Ablation of atrial fibrillation deviates from the traditional paradigm and focuses on isolating the critical anatomic substrate (often the pulmonary veins) responsible for its initiation and perpetuation. The usual aim of electrophysiologic treatments is to interpose scar tissue in the conduction pathway of the arrhythmia. This is accomplished with a properly placed surgical incision or by inducing myocardial injury with the application of energy from a precisely placed catheter.

Various energy sources, including lasers, microwaves, RF current, and extreme cold (ie, cryoablation), have been used for ablation. The most common is RF energy, which destroys myocardium by resistive heating. Success is determined by the volume and depth of tissue injured by RF energy, which is a function of the power delivered, catheter tip size, and amount of convective cooling during energy delivery. Measurement of tissue impedance during application of bipolar RF energy ensures that transmural injury occurs. Depending on the thickness of the tissue, transmural scarring may not occur, and measurement of conduction across the lesion is recommended. Failure to conduct an applied electrical stimulus indicates pathway interruption.

Specific Arrhythmias

Supraventricular Tachyarrhythmias

SVTs are cardiac rhythms with a heart rate greater than 100 beats/minute originating above the division of the common bundle of His. The arrhythmias are often seen as a narrow-complex tachycardia, and in some cases, they can be hemodynamically unstable in the setting of structural heart disease. Tachycardias persisting for weeks to months may lead to tachycardia-associated cardiomyopathy and disabling symptoms.[34]

The differential diagnosis of SVT includes AVRT, AVNRT, atrial tachycardia, inappropriate sinus tachycardia or sinus node reentry, atrial flutter, and atrial fibrillation. Because antiarrhythmic medications have traditionally been used with mixed success, surgical and catheter-based procedures have been developed for their management.

Atrioventricular Reciprocating Tachycardia

Accessory pathways are abnormal strands of myocardium connecting the atria and ventricles across the AV groove, providing alternate routes for conduction that bypass the AV node and bundle of His (Box 4.5). The various classifications used to describe accessory pathways

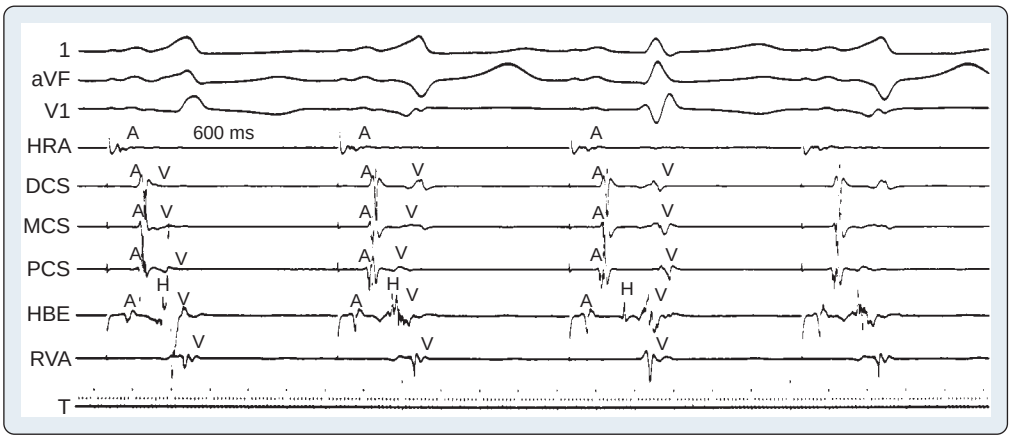

Fig. 4.11 The presence of two accessory pathways is revealed during pacing. The site of earliest ventricular activation is detected with the distal coronary sinus *(DCS)* electrode, indicating a left free wall accessory pathway. The second paced beat shows the site of earliest ventricular activation from the proximal coronary sinus *(PCS)* electrode, indicating a posterior septal accessory pathway. After the third paced beat, neither site is activated due to an anterograde conduction block. In this instance, conduction follows the normal atrioventricular–His bundle and bundle branch pathways. Surface electrocardiographic leads and intracardiac electrograms are organized as in Fig. 4.8. *(From Cain ME, Cox JL. Surgical treatment of supraventricular tachyarrhythmias. In: Platia EV, ed.* Management of Cardiac Arrhythmias. *Philadelphia: Lippincott; 1987:312.)*

are based on their location (eg, tricuspid, mitral), whether they are manifest or concealed on a surface ECG, and the conduction properties exhibited by the pathway (eg, antegrade, retrograde, decremental, nondecremental).[43] *Decremental* conduction along any myocardial tissue describes conduction that is slower as the frequency of impulses reaching it increases. Accessory pathways are more often *nondecremental*; regardless of how quickly impulses reach the pathway, the conduction velocity across the pathway remains the same.

The term *concealed pathway* refers to an accessory pathway that exhibits only retrograde conduction. In this situation, there is no conduction from the atrium to the ventricles through the pathway, which shows no evidence of ventricular preexcitation. In contrast, *manifest pathways* display antegrade conduction from the atrium to the ventricles. Because electrical signals can enter the ventricles from the AV node and the accessory pathway, ventricular preexcitation manifests on the surface ECG as delta waves. Manifest pathways typically conduct in antegrade and retrograde directions. A manifest pathway allows the ventricle to be depolarized (ie, preexcited) before that occurring by the normal route of conduction through the AV node (Figs. 4.11 and 4.12).

During preexcitation, an activation wavefront propagates simultaneously to the ventricles across the bundle of His and the accessory pathway. Because anterograde conduction is delayed at the AV node but not in the accessory pathway, the impulse passing through the accessory pathway initiates ventricular depolarization before the impulse traveling through the normal AV conduction system. The ventricle is preexcited, resulting in a delta wave preceding the QRS complex (see Fig. 4.11).

These electrocardiographic findings (ie, short PR interval and delta wave) were found by Wolff, Parkinson, and White in the 1930s in association with SVT.[44] WPW syndrome is a condition of preexcitation accompanied by tachyarrhythmias due to reentry through the accessory pathway, although only about 30% of individuals with WPW electrocardiographic findings exhibit tachyarrhythmias. Individuals with WPW electrocardiographic findings but without tachyarrhythmias are said to have the WPW signature. AVRT occurs in the absence of the WPW syndrome when the pathway is concealed, and not all tachyarrhythmias in patients with WPW result from the AVRT mechanism.

By identifying the polarity of the delta wave (ie, QRS axis) and precordial R-wave progression, the resting 12-lead ECG can provide clues about the location of the accessory pathway in the left lateral, left posterior, posterior septal, right free wall, or anterior septal regions[45] (Table 4.1). Precise localization depends on the EPS. The investigation can document the AV or other mechanism of the arrhythmia and the conduction properties of the accessory pathways.

TABLE 4.1 Electrocardiographic Patterns for Various Anatomic Locations of Accessory Pathways

Region	*Negative Delta Wave*	*QRS Frontal Axis*	*R>S*[a]
Left lateral free wall	I and/or aVL	Normal	V_1 to V_3
Left posterior free wall	III and aVF	−75 to +75	V_1
Posterior septal	III and aVF	0 to −90	V_2 to V_4
Right free wall	aVR	Normal	V_3 to V_5
Anterior septal	V_1 and V_2	Normal	V_3 to V_5

[a]R>S refers to progression of the R wave in the precordial electrocardiographic leads.
Modified from Lindsay BD, Crossen KL, Cain ME. Concordance of distinguishing electrocardiographic features during sinus rhythm with the location of accessory pathways in the Wolff-Parkinson-White syndrome. *Am J Cardiol.* 1987;59:1093.

The atrial and ventricular insertion sites of the accessory pathway are identified by observing ventricular activation patterns during sinus rhythm and during atrial pacing (see Fig. 4.11). In the setting of an accessory pathway, the interval between the deflection denoting activation of the bundle of His and the earliest ventricular activation (ie, delta wave) is less than the His-ventricular interval. The area with the shortest delta-to-ventricular interval localizes the accessory pathway's ventricular insertion. More than one accessory pathway is suggested by finding different delta-wave morphology with increasing atrial pacing rates or with introduced atrial premature beats (see Fig. 4.12). Atrial activation patterns observed during ventricular pacing, after a ventricular premature beat, or during induced orthodromic SVT can identify the location of the atrial insertion sites.

AVRT can occur as an orthodromic reciprocating tachycardia (ORT) and antidromic reciprocating tachycardia (ART)[46–48] (Fig. 4.13). ORT is by far the most common type and involves antegrade conduction through the normal AV nodal conduction system and retrograde conduction through the accessory pathway. ART involves antegrade conduction down the accessory pathway and retrograde conduction through the AV node. As suggested by their mechanisms, ORT appears as a narrow-complex tachycardia, and ART appears as a wide-complex tachycardia that sometimes can be difficult to distinguish from VT.

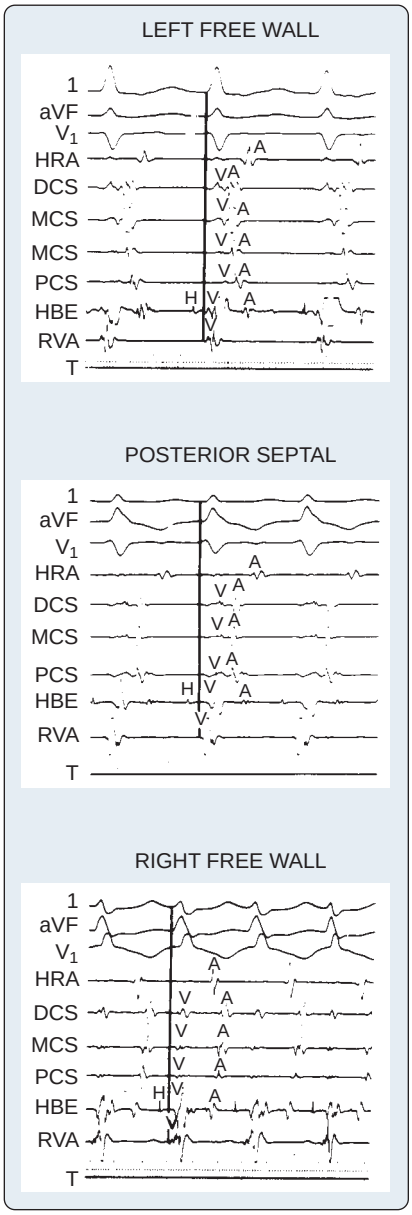

Fig. 4.12 Atrial activation recordings from three patients during orthodromic tachycardia through accessory pathways at distinct locations. Using the *vertical line* as a reference for the QRS complex from the surface electrocardiogram, the first example demonstrates the earliest atrial activation at the distal coronary sinus *(DCS)* site, indicating a left free wall accessory pathway. The posterior septal accessory pathway is indicated by earliest activation of the electrode located in the proximal coronary sinus *(PCS)*. In the last example, atrial activation at the high right atrium *(HRA)* and His bundle *(HBE)* occurs before all the coronary sinus recording sites, indicative of a right free wall accessory pathway. Surface electrocardiographic leads and intracardiac electrograms are organized as in Fig. 4.8. *(From Cain ME, Cox JL. Surgical treatment of supraventricular tachyarrhythmias. In: Platia EV, ed.* Management of Cardiac Arrhythmias. *Philadelphia: Lippincott; 1987:313.)*

Patients with atrial fibrillation and a pathway capable of conducting in an antegrade fashion run the risk of rapid conduction to the ventricles and development of ventricular fibrillation and sudden death. The potential for sudden death due to atrial fibrillation in patients with WPW provides an argument for aggressive ablative treatment when the procedure can be performed in centers with low periprocedural morbidity rates.

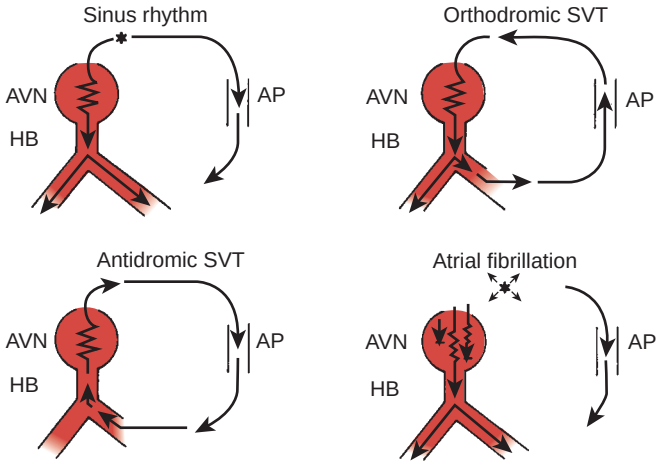

Fig. 4.13 Schematic depiction of conduction through an accessory pathway *(AP)* and the normal conduction system (ie, atrioventricular node *[AVN]* and His bundle *[HB]*) during sinus rhythm, orthodromic supraventricular tachycardia *(SVT)*, antidromic SVT, and atrial fibrillation. *(From Lindsay BD, Branyas NA, Cain ME. The preexcitation syndrome. In: El-Sherif N, Samet P, eds.* Cardiac Pacing and Electrophysiology. *3rd ed. Orlando, FL: Grune & Stratton; 1990.)*

Catheter-Based Therapy for Accessory Pathways

Percutaneous catheter ablation of accessory pathways has largely supplanted surgical treatment. RF ablation is typically performed during EPS after the accessory pathway has been localized. Transseptal or retrograde aortic catheter approaches are used to ablate left-sided accessory pathways, and right-heart catheterization using a venous approach is used to ablate right-sided pathways. Success rates of 95% have been reported using these methods.[43,49–51] Recurrence rates after successful catheter ablation of an accessory pathway usually are less than 5% and are a function of pathway location and stability of the catheter during energy delivery.

Reported complications are low and include those related to vascular access such as hematoma and AV fistula. Other complications are related to catheter manipulations of the left- and right-sided circulation, such as valvular or cardiac damage from the catheter, systemic and cerebral embolization due to catheter manipulation in the aorta, coronary sinus damage, coronary thrombosis and dissection, cardiac perforation, and cardiac tamponade. Complete AV block, cardiac perforation, and coronary spasm due to RF may also occur.

A 1995 survey involving 5427 patients reported serious complications from catheter ablation of accessory pathways in 1.8% of patients and a procedure-related mortality rate of 0.08%.[43,49] Complete AV block is more common with ablation of accessory pathways close to the bundle of His. The procedural success rates for catheter ablation methods are 87% to 99%.[43,50,51] In a randomized study comparing ablation with drug treatment, quality of life, symptom scores, and exercise performance were improved with successful RF ablation.[52]

Atrioventricular Nodal Reentrant Tachycardia

AVNRT results from altered electrophysiologic properties of the anterior fast pathway and posterior slow pathway fibers providing input to the AV node.[10,43,51] In the past, the only treatment for recurrent SVT due to AVNRT was total ablation of the His bundle and permanent pacemaker insertion. Surgical techniques developed in the 1980s provided an alternative that was associated with a high procedural success rate, acceptable morbidity, and preservation of AV conduction.[53–56] Experience with the surgical approach and a better understanding of the physiologic basis for AVNRT led to the development of percutaneous catheter-based treatments.

Interruption of the slow or fast pathway with RF ablation can eliminate AVNRT, with higher success rates reported for ablation of

the slow pathway (68–100%) than for the fast pathway (46–94%).[43,57–60] Complication rates are lower with RF ablation of the slow pathway and include AV block requiring pacemaker insertion (1%)[43] (Box 4.6).

Catheter-Based Therapy for Atrioventricular Nodal Reentrant Tachycardia

Historically, fast-pathway ablation is performed by positioning the catheter adjacent to the AV node–His bundle anterosuperior to the tricuspid valve annulus. The catheter is withdrawn until the atrial electrogram is larger than the ventricular electrogram and the His recording is small or absent. The ECG is closely monitored as RF energy is applied for PR prolongation or heart block. Energy is delivered until there is PR prolongation or the retrograde fast-pathway conduction is eliminated. Noninducibility of AVNRT then is confirmed.

Because of the increased incidence of complete heart block with fast-pathway ablation, most electrophysiologists have adopted ablation of the slow pathway as a safer alternative. Slow-pathway ablation is performed by identifying the pathway along the posteromedial tricuspid annulus near the coronary sinus. Using fluoroscopy, one approach is to divide the level of the coronary sinus os and His bundle recordings into six anatomic regions[61] (Fig. 4.14). Moving anteriorly, lesions are placed beginning with the most posterior region. Rather than using the anatomic approach, the slow pathway can be mapped and then ablated. The end point of slow-pathway ablation is elimination of induced AVNRT.[43,57–60] Development of junctional ectopy during RF ablation of the slow pathway is associated with successful slow-pathway ablation.[10]

BOX 4.6 ATRIOVENTRICULAR NODAL REENTRANT TACHYCARDIA

- Altered electrophysiologic properties of the anterior fast and posterior slow pathways provide input to the atrioventricular node.
- Successful fast pathway ablation occurs when the PR interval is prolonged or fast-pathway conduction is eliminated.
- Successful slow pathway ablation occurs when induced atrioventricular nodal reentrant tachycardia is eliminated.
- Surgical techniques include selective cryoablation.

Focal Atrial Tachycardia

Focal atrial tachycardia accounts for less than 15% of patients undergoing evaluation for SVT.[62] The arrhythmia is caused by atrial activation from a discrete atrial area, resulting in heart rates between 100 and 250 beats/minute.[63] Although a 12-lead ECG may provide clues to the origin of the tachycardia based on the P-wave axis, the site of atrial tachycardia is identified by electrophysiologic investigations, and it tends to reside in certain anatomic zones.[43] Right-sided tachycardias typically originate along the crista terminalis from the SA node to the AV node, and left-sided tachycardias originate from the pulmonary veins, atrial septum, or mitral valve annulus.[63,64]

The mechanisms for atrial tachycardia include abnormal automaticity, triggered activity, and microreentry. Certain characteristics can help to identify the underlying mechanism. Abrupt onset and offset suggest a reentrant mechanism, whereas a pattern of gradual onset (ie, warm up) and offset (ie, cool down) suggests automaticity (Box 4.7).

Catheter-Based Therapy for Focal Atrial Tachycardia

Due to the discrete localized area involved in generating atrial tachycardia, the approach to catheter ablation is the same regardless of the underlying mechanism. The site of tachycardia onset is identified with electrophysiologic mapping and isolated from the remaining atrium by the application of RF current.

The success rate for this approach is 86%, and the recurrence rate is 8%.[43,64–68] Complications occur in 1% to 2% of cases and include

BOX 4.7 FOCAL ATRIAL TACHYCARDIA

- Mechanisms include abnormal automaticity, triggered activity, and microreentry.
- Catheter-based treatment uses radiofrequency ablation.
- Surgical-based treatment uses an incision and cryoablation.

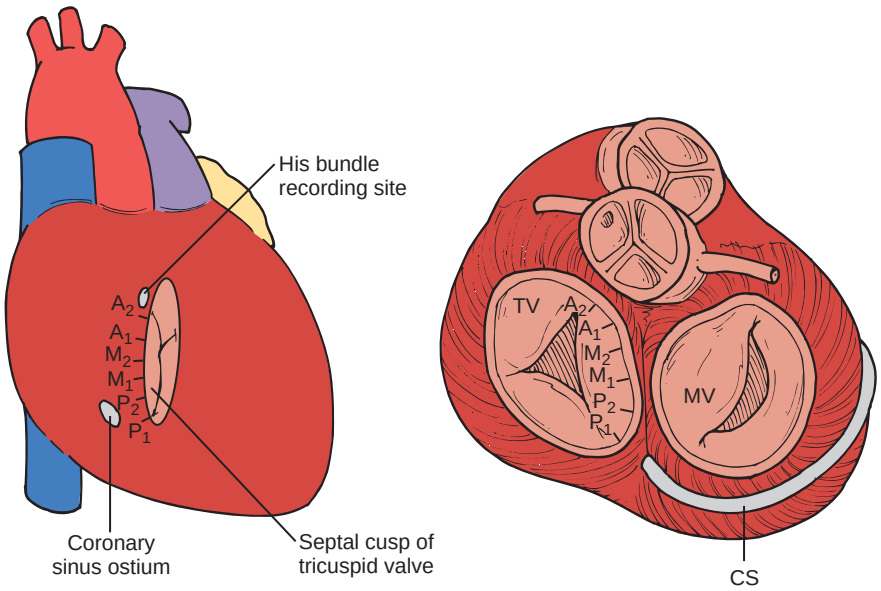

Fig. 4.14 Schematic depiction of sites for atrioventricular nodal modification in relation to other anatomic structures. The posterior location is usually first targeted for ablation of the slow pathway, with subsequent ablative lesions placed more anteriorly depending on the response. *CS*, Coronary sinus; *MV*, mitral valve; *TV*, tricuspid valve. *(From Akhtar M, Jazayeri MR, Sra JS, et al. Atrioventricular nodal reentry: clinical, electrophysiologic, and therapeutic considerations.* Circulation. *1993;88:282.)*

myocardial perforation (rare), phrenic nerve injury, and sinus node dysfunction.[69]

Inappropriate Sinus Tachycardia

Sinus tachycardia is deemed inappropriate when it occurs in the absence of physiologic stressors (eg, increased body temperature, hypovolemia, anemia, hyperthyroidism, anxiety, postural changes, drugs), indicating a failure of normal mechanisms controlling the sinus rate. Proposed mechanisms are enhanced sinus node automaticity or abnormal autonomic regulation, or both. Inappropriate sinus tachycardia is seen most often in women health care providers.

The diagnosis of inappropriate sinus tachycardia is based on nonparoxysmal, persistent resting sinus tachycardia and excessive increases in response to normal physiologic stressors and nocturnal normalization of the rate based on Holter monitoring.[51] The P-wave morphology and endocardial activation are consistent with a sinus origin, and secondary causes have been excluded.

Catheter-based or surgical treatments are considered for a few patients not responding to β-blockers and when symptoms are truly disabling. RF ablative modification of the sinus node promotes dominance of slower depolarizing sinus nodal tissues. The end point of RF application is a change in the P-wave morphology or slowing of the sinus rate.

Reported complications include the need for a permanent pacemaker, SVC syndrome, phrenic nerve injury, and pericarditis.[43,70] Acute and long-term success rates are 76% (ie, catheter) and 66% (ie, surgery).[43,70] Ablation of the sinus node is often reserved for patients who are refractory to medications and highly symptomatic.

Sinus Node Reentrant Tachycardia

Reentrant pathways involving the sinus node may lead to paroxysmal tachycardia rather than nonparoxysmal inappropriate sinus tachycardia.[71] The P-wave morphology is similar to that occurring during sinus rhythm. Like other reentrant tachycardias, the arrhythmia is usually triggered by a premature atrial beat. The endocardial activation sequence during the EPS is in the high right atrium and is similar to sinus rhythm.

The arrhythmia can be initiated with a premature paced beat and is terminated by vagal maneuvers or adenosine administration.[43] The arrhythmia is also responsive to β-blockers, nondihydropyridine calcium channel antagonists, and amiodarone. RF ablation of the identified reentrant pathway can be used for frequently occurring tachycardia episodes not responsive to other treatments.[72]

Atrial Flutter

Atrial flutter usually manifests with acute onset of symptoms (eg, palpitations, shortness of breath, fatigue) accompanied by tachycardia and typical flutter waves on the ECG (Box 4.8). Fixed 2:1 conduction usually occurs with a flutter rate of 300 beats/minute and ventricular rate of 150 beats/minute. When AV conduction is fixed, the heart rate is regular, but varying AV conduction results in an irregular rhythm.

Rapid AV conduction can occur with exercise, in patients with accessory pathways, and paradoxically after administration of class 1C antiarrhythmic drugs.[43] The antiarrhythmic drugs slow the atrial flutter rate, allowing the AV node to support more rapid conduction to the ventricles. This maneuver requires coadministration of drugs with AV conduction-slowing properties (eg, β-blockers).

Atrial flutter is caused by reentry that is referred to as *macroreentry* because the anatomic circuit is large. Typical atrial flutter occupies a circuit that circles the tricuspid valve, crossing the myocardial isthmus between the inferior vena cava (IVC) and the tricuspid valve[43,63] (Fig. 4.15). Counterclockwise rotation through the cava-tricuspid region is usually observed, although other patterns such as clockwise rotation,

BOX 4.8 ATRIAL FLUTTER

Reentry results from a large anatomic circuit.
Macroreentrant pathway is amenable to catheter ablation.

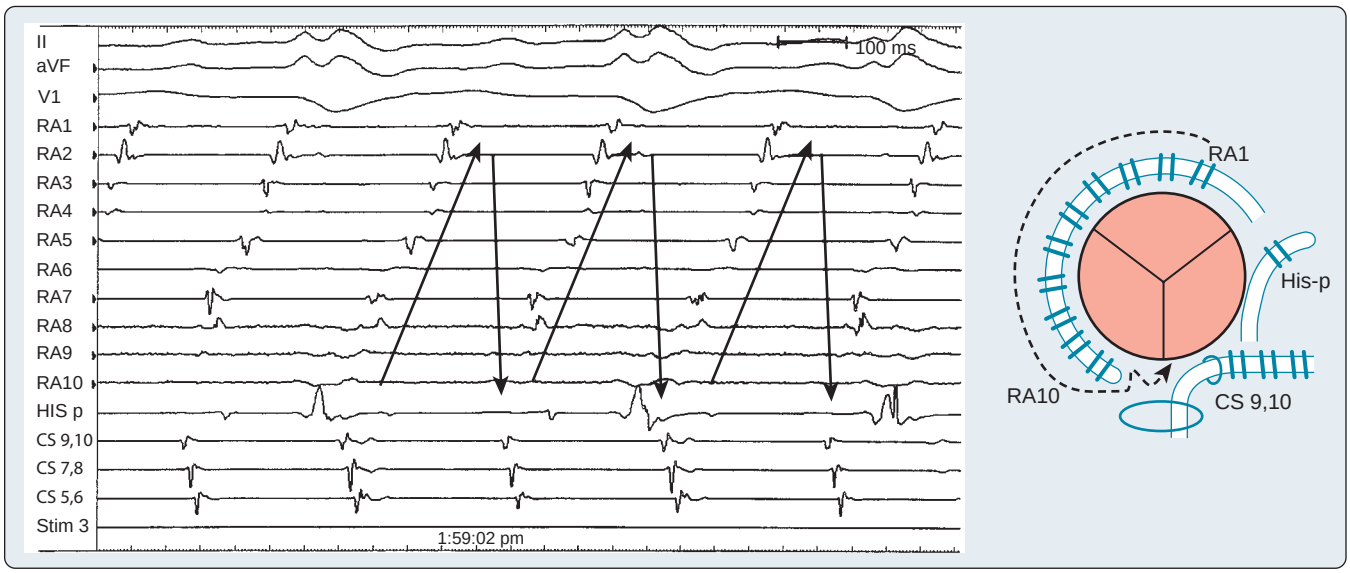

Fig. 4.15 Endocardial mapping of typical atrial flutter. Endocardial signals are recorded from diagnostic catheters. The anatomic basis for this circuit is an electrical wavefront circulating in a counterclockwise direction around the tricuspid valve annulus. A 20-pole catheter has been positioned around the tricuspid valve to record the passage of the activation wavefront by adjacent electrode pairs *RA1* to *RA10*. The wavefront then proceeds across the isthmus connecting the inferior vena cava and the tricuspid valve before passing the ostium of the coronary sinus *(CS)*, recorded by CS electrodes 9 and 10 and the His bundle recording catheter *(HIS p)*. The progress of the activation wavefront is indicated by the *arrows* and by the diagram *(right)*.

double waves, and lower loop reentry (ie, reentry around the IVC) may be seen.[43,73,74] Polarity of the flutter waves on the 12-lead ECG provides insight into the pattern of atrial flutter, especially in patients who have not undergone prior cardiac surgery. Counterclockwise rotation is associated with negative flutter waves in the inferior leads and positive flutter waves in V_1.[43]

The anatomic location of the macroreentrant pathway is amenable to catheter ablation and cure of atrial flutter by creating a linear conduction block across the tricuspid-IVC isthmus. Testing for bidirectional conduction block through the cava-tricuspid region after application of RF energy reduces the likelihood of recurrence.[75,76]

Atrial flutter and atrial fibrillation may coexist, complicating success with catheter ablation methods. Procedural success in treating pure atrial flutter is reported in 80% to 100% of cases, with recurrences reported for less than 5% of patients.[77–81] In a prospective, randomized trial, catheter ablation resulted in sinus rhythm in 80% of patients, compared with 36% of patients treated with antiarrhythmic drugs (mean follow-up of 21 months).[81] Fewer hospitalizations and higher scores on quality-of-life surveys are reported after catheter ablation compared with drug treatment. In the absence of atrial fibrillation, subsequent RF ablation procedures may result in successful elimination of atrial flutter. Even when not present during initial treatment, atrial fibrillation may develop after successful catheter ablation for atrial flutter in 8% to 12% of patients.[43,79]

Atrial scar tissue from prior cardiac surgery (eg, congenital heart surgery, mitral valve surgery, maze procedure) may provide an area for reentry leading to atrial flutter.[64,82–85] Reentrant circuits involving the cava-tricuspid area may coexist, leading to complicated, multiple reentry pathways.[43,85] Characterization of the reentry circuit with electrophysiologic mapping studies may allow successful RF ablation in these circumstances.

Anesthesia Considerations for Supraventricular Arrhythmia Surgery and Ablation Procedures

The approach to the care of patients undergoing percutaneous therapies for supraventricular arrhythmias involves similar principles (Box 4.9). Patients with WPW are usually young and free of other cardiac disease, although the syndrome can be accompanied by the Ebstein anomaly in up to 10% of cases.[41,86] Anesthesiologists must be familiar with preoperative EPS results and the characteristics of associated supraventricular arrhythmias (eg, rate, associated hemodynamic disturbances, syncope), including treatments. Tachyarrhythmias may recur at any time during surgical and percutaneous treatments. Transcutaneous cardioversion-defibrillation adhesive pads are placed before anesthesia induction and connected to a defibrillator-cardioverter. Development of periprocedural tachyarrhythmias is unrelated to any single anesthetic or adjuvant drug.

Treatment of hemodynamically tolerated tachyarrhythmias is aimed at slowing conduction across the accessory pathway rather than the AV node. Therapy directed at slowing conduction across the AV node (eg, β-adrenergic–blocking drugs, verapamil, digoxin) may enhance conduction across accessory pathways and should be used only if proved safe by a prior EPS. Recommended drugs include amiodarone and procainamide. One consideration is that antiarrhythmic drugs may interfere with electrophysiologic mapping. Hemodynamically significant tachyarrhythmias developing before mapping are usually treated with cardioversion.

Accessory pathway ablation is typically performed under conscious sedation, and general anesthesia is reserved for selected patients such as those unable to tolerate the supine position. Considerable experience in anesthetizing patients with WPW for surgical ablation was gained when the treatment approach was prevalent. The effects of anesthetics on accessory pathway conduction have been investigated mostly to evaluate whether the agents interfere with electrophysiologic mapping.

Droperidol depresses accessory pathway conduction, but the clinical significance of small antiemetic doses is likely minimal.[87,88] Opioids and barbiturates have no proven electrophysiologic effect on accessory pathways and are safe in patients with WPW syndrome.[89–92] Normal AV conduction is depressed by halothane, isoflurane, and enflurane, and preliminary evidence suggests that these volatile anesthetics may also depress accessory pathway conduction.[92,93] Although muscle relaxants with anticholinergic effects (eg, pancuronium) have been safely used in patients with WPW, drugs lacking autonomic side effects are most often chosen.[94]

The major goal of managing supraventricular ablative procedures is to avoid sympathetic stimulation and the development of tachyarrhythmias. Clinical studies have evaluated the efficacy of various anesthetic techniques in maintaining intraoperative hemodynamic stability and preventing arrhythmias in patients with WPW syndrome.[10,95,96] An opioid-based anesthetic technique with supplemental volatile anesthetics is typically used.

BOX 4.9 ANESTHESIA CONSIDERATIONS FOR SUPRAVENTRICULAR ARRHYTHMIA SURGERY AND ABLATION PROCEDURES

- Familiarity with electrophysiologic study results and associated treatments
- Transcutaneous cardioversion-defibrillation pads placed before induction
- Hemodynamically tolerated tachyarrhythmias treated by slowing conduction across accessory pathway rather than the atrioventricular node
- Hemodynamically significant tachyarrhythmias treated with cardioversion
- Avoidance of sympathetic stimulation

Atrial Fibrillation

Atrial fibrillation, the most common sustained cardiac arrhythmia in the general population, can lead to palpitations, shortness of breath, chest discomfort, or anxiety due to the irregularly irregular heart rate pattern[5] (Box 4.10). Aims for the treatment of atrial fibrillation include anticoagulation to decrease the risk for stroke and heart rate control to limit symptoms and reduce the risk for tachycardia-associated cardiomyopathy. Restoration of sinus rhythm with cardioversion or antiarrhythmic drugs, or both, is considered in some instances, but data suggest this strategy is no more effective than a strategy of anticoagulation or heart rate control for improving mortality rates for certain populations.[97] Because antiarrhythmic drugs are associated with life-threatening proarrhythmic side effects, the benefits of restoring sinus rhythm may be outweighed by increased mortality due to drug-induced ventricular arrhythmias.[7,8] The rising prevalence of atrial fibrillation and the limitations of pharmacologic treatments have prompted interest in nonpharmacologic treatments.

A growing understanding of the mechanisms of atrial fibrillation led to the introduction of surgical and catheter-based procedures to restore sinus rhythm. Experimental and clinical investigations

BOX 4.10 ATRIAL FIBRILLATION FEATURES

The time of activation from the electrodes is used to generate the isochronous representation of atrial depolarization. *IVC*, Inferior vena cava; *LAA*, left atrial appendage; *M*, mitral valve; *PV*, pulmonary veins; *RAA*, right atrial appendage; *SVC*, superior vena cava; *T*, tricuspid valve. *(From Cox JL, Canavan TE, Schuessler RB, et al. The surgical treatment of atrial fibrillation. II. Intraoperative electrophysiologic mapping and description of the electrophysiologic basis of atrial flutter and atrial fibrillation.* J Thorac Cardiovasc Surg. *1991;101:406.)*

demonstrate that atrial fibrillation is associated with multiple reentrant circuits in the atrium (ie, multiple wavelets) that rapidly and unpredictably change their anatomic location.[98–101] Intraoperative electrophysiologic mapping of a patient in sinus rhythm (Fig. 4.16) and after atrial fibrillation was induced by introducing atrial ectopic beats (Fig. 4.17) demonstrated the random and fleeting nature of the reentrant circuits.[10,101]

The rapidly changing nature of the reentrant circuits precludes a map-directed surgical or ablative strategy for atrial fibrillation. Nonetheless, the realization that certain cardiac structures (eg, pulmonary veins, valve annulus, vena cava) provided the necessary substrate for the fibrillatory reentrant circuits led to the development of an anatomically based operation for atrial fibrillation (ie, Cox maze procedure) with which macroreentrant circuits are interrupted by a series of atrial incisions and cryoablative lesions.[10,101,102]

Investigators have demonstrated that atrial fibrillation in some instances originates from automatic foci in the pulmonary veins or vena cava and that isolating these sites can restore sinus rhythm.[103] Other data have demonstrated focal sources of atrial fibrillation in patients with mitral valve disease.[104,105] These findings are supported by laboratory investigations showing that atrial fibrillation can be maintained by a single atrial source of fibrillatory waves moving away from the originating circuit.[106,107] These and other findings, along with advances in computer-based electrophysiologic mapping systems, opened the possibility of map-guided strategies to eliminate the substrate for atrial fibrillation in some patients.[108–118] The strategy may have the benefit of higher success rates and lower complications than achieved with current procedures.

Catheter-Based Therapy for Atrial Fibrillation

Catheter ablation approaches for atrial fibrillation include AV node ablation with permanent pacemaker placement to control the ventricular rate and catheter ablation procedures that aim to restore sinus rhythm. AV node ablation is used for medically refractory tachycardia due to atrial fibrillation or to eliminate intolerable symptoms due to an irregular heart rate. The procedure requires pacemaker implantation, does not aim to restore sinus rhythm, and does not eliminate the need for anticoagulation.

In an attempt to restore sinus rhythm, ablation strategies involve electrical isolation of the pulmonary veins and not ablating the AV node. It is thought that myocardial sleeves involving the os of the pulmonary veins can initiate atrial fibrillation due to their inherently different electrophysiologic properties. They are electrically isolated to prevent development of atrial fibrillation. Pulmonary vein isolation can be achieved in one of two ways. In the first, complete electrical isolation is achieved by sequential, segmental RF ablation around each pulmonary vein ostium.[103,119] The second strategy is to regionally isolate the posterior left atrium by encircling the pulmonary vein ostia and the surrounding posterior left atrial wall by a circular pattern of adjacent RF ablation lesions (ie, wide area circumferential ablation).[105] A randomized comparison of the two strategies demonstrated a significantly higher success rate with the regional isolation strategy; 88% of patients were free of atrial fibrillation at 6 months compared with 67% free of atrial fibrillation at 6 months using the segmental isolation strategy.[112] The regional isolation procedure also reduces the risk of creating pulmonary venous stenosis that can be associated with the segmental isolation procedure.

Newer technology for catheter-based therapy has improved outcomes for patients. An advancement is the combination of preacquired tomographic reconstructions with electroanatomic mapping (EAM) or three-dimensional image integration (I-EAM). The use of manually controlled, steerable introducers for catheter navigation also has demonstrated a higher clinical success rate compared with nonsteerable sheath technology. Application of ablation catheters that sense the amount of force applied during ablation has also improved therapeutic efficacy.

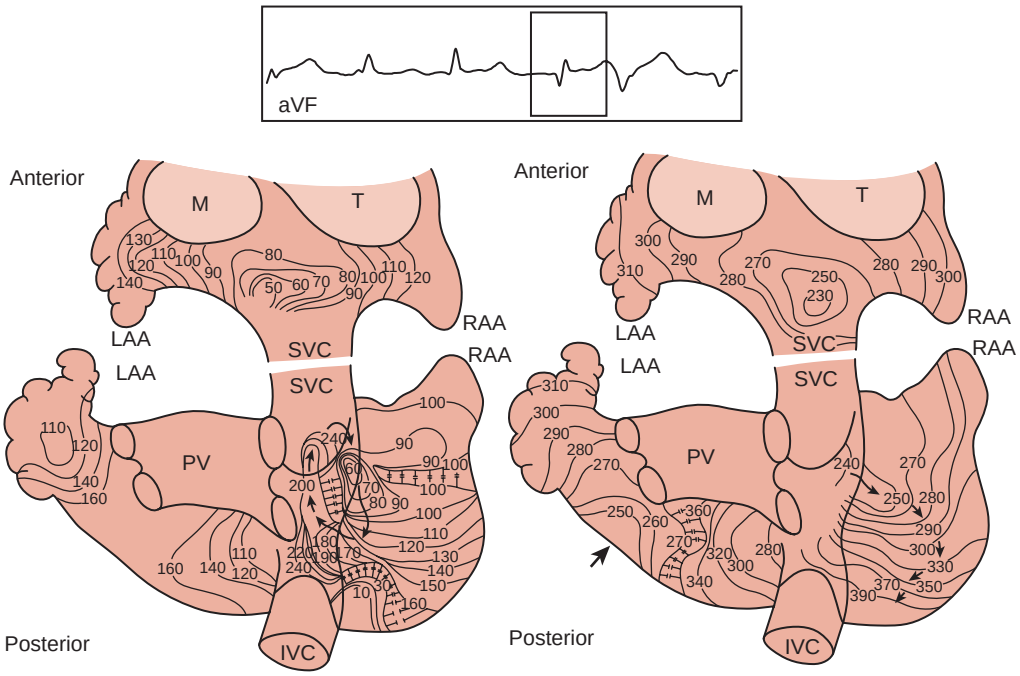

Fig. 4.17 Atrial activation mapping from a human during atrial fibrillation shows a single reentrant circuit. Recordings and isochronous mapping are the same as in Fig. 4.16. The *left* map shows the first 240 ms, with 230 to 400 ms shown in the *right* map. The beat spreads along the anterior and posterior atria *(left)*. Posteriorly, the beat encounters several areas of conduction block, but as it spreads, it encounters myocardium that is repolarized and capable of sustaining conduction. The clockwise, rotating reentrant circuit circulates around natural obstacles such as the orifices of the vena cava. *IVC*, Inferior vena cava; *LAA*, left atrial appendage; *M*, mitral valve; *PV*, pulmonary veins; *RAA*, right atrial appendage; *SVC*, superior vena cava; *T*, tricuspid valve. *(From Cox JL, Canavan TE, Schuessler RB, et al. The surgical treatment of atrial fibrillation. II. Intraoperative electrophysiologic mapping and description of the electrophysiologic basis of atrial flutter and atrial fibrillation.* J Thorac Cardiovasc Surg. *1991;101:406.)*

Randomized trials have found that general anesthesia reduces the prevalence of pulmonary vein reconnection in repeat ablations compared with conscious sedation.[120] During these procedures, patient motion and respiration can affect tissue contact with the catheters, which influences lesion quality. Movement and thoracic excursion can similarly lengthen procedural and fluoroscopy time. The improved results with general anesthesia echoed those of other retrospective studies comparing posterior left atrial isolation using high-frequency jet ventilation (HFJV) with intermittent positive-pressure ventilation (IPPV).[121]

Hutchinson and colleagues examined the 1-year freedom from atrial fibrillation rate for three groups of patients receiving circumferential, antral pulmonary vein isolation (PVI)[122] One treatment group had PVI under general anesthesia with IPPV with no I-EAM, steerable introducers, or HFJV. The second treatment group had the procedure under general anesthesia with IPPV and use of I-EAM and steerable introducers. The third treatment group underwent PVI under general anesthesia with I-EAM, steerable introducers, and HFJV.

There was a significant difference in the 1-year freedom from atrial fibrillation rate for the three treatment groups (52% vs 66% vs 74%; $P = .006$). Patients with nonparoxysmal atrial fibrillation also had an incremental increase in the 1-year freedom from atrial fibrillation rate for the three groups (35% vs 54% vs 67%; $P < .001$). The prolonged tissue contact and minimized ablation catheter mobility due to recent advances in mapping, steerable introducers, and HFJV most likely create an improved pulmonary vein lesion.

Methods emulating the surgical maze procedure continue to evolve but remain investigative (discussed later). Linear ablation techniques involve RF energy application along critical sites for the maintenance of atrial fibrillation.[113–116,118,123] Success has been limited with this approach (28–57%), and the procedures require long durations and are associated with radiation exposure. Complication rates remain high (4–50%).

Surgical Therapy for Atrial Fibrillation

Improved understanding of the mechanisms of atrial fibrillation led to development of a surgical procedure by James Cox and others called the *maze procedure*.[101,102,124–128] The moniker stems from the design of the operation, which creates a mazelike pattern of surgical incisions in the functional myocardium, allowing propagation of atrial depolarization throughout the atrium to the AV node while interposed scar tissue interrupts possible routes of reentry. The principal goals of the maze procedure are to interrupt the electrophysiologic substrate for atrial fibrillation (ie, reentrant circuits), restore sinus rhythm, maintain SA nodal–to–AV nodal conduction, preserve AV synchrony, and preserve atrial mechanical function (ie, atrial kick), thereby improving hemodynamic function.

The current maze operation evolved from the original procedure (ie, maze I) introduced in 1987. The maze I procedure consisted of multiple atrial incisions around the SA node, including an incision anterior to the atrial-SVC junction[102–104,127] (Fig. 4.18). That incision through the sinus tachycardia region of the SA node resulted in the unintended consequence of a blunted heart rate in response to exercise and obtunded atrial mechanical function.[128–130]

The procedure was modified (ie, maze II procedure) to include an incision on the anterior right atrium while allowing the sinus impulse to travel anteriorly across the left atrium but preventing it from reentering the right atrial–SVC junction (Fig. 4.19). Although successfully addressing the limitations of the original procedure, the maze II procedure was technically challenging, particularly the approach to the

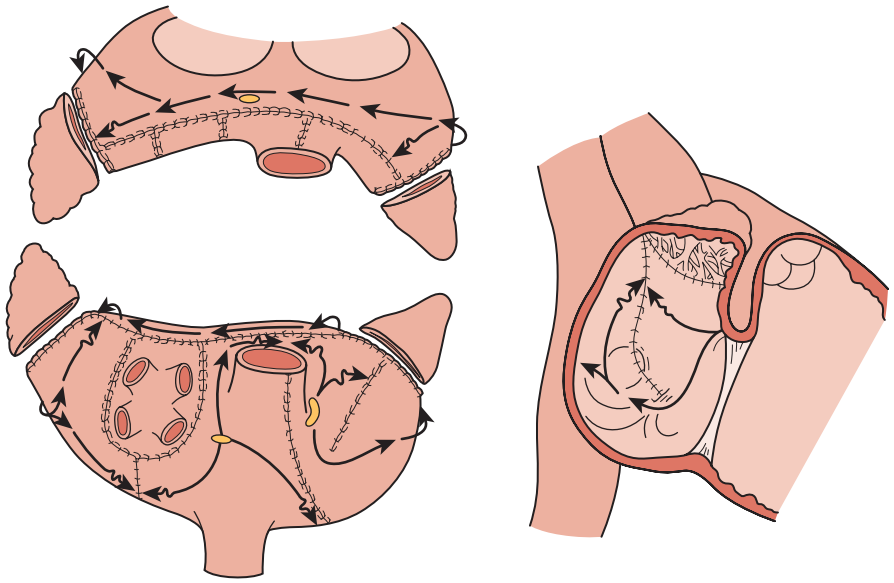

Fig. 4.18 Surgical incisions and resultant conduction pathways of the maze I procedure. The atria *(left)* are splayed open so that the anterior surface is superior and the posterior surface is inferior. The atria are divided in the sagittal plane *(right)*, showing the right atrial septum. Incisions are placed at sites most commonly associated with reentrant circuits *(arrows)* of atrial fibrillation to eliminate the arrhythmia. At the same time, bridges of myocardium are left intact to allow conduction across the atria and to the atrioventricular node, preserving atrial transport function and facilitating sinus rhythm. The pulmonary veins are isolated to eliminate potential conduction of premature beats. *(From Cox JL. Evolving applications of the maze procedure for atrial fibrillation [editorial]. Ann Thorac Surg. 1993'55:578–580.)*

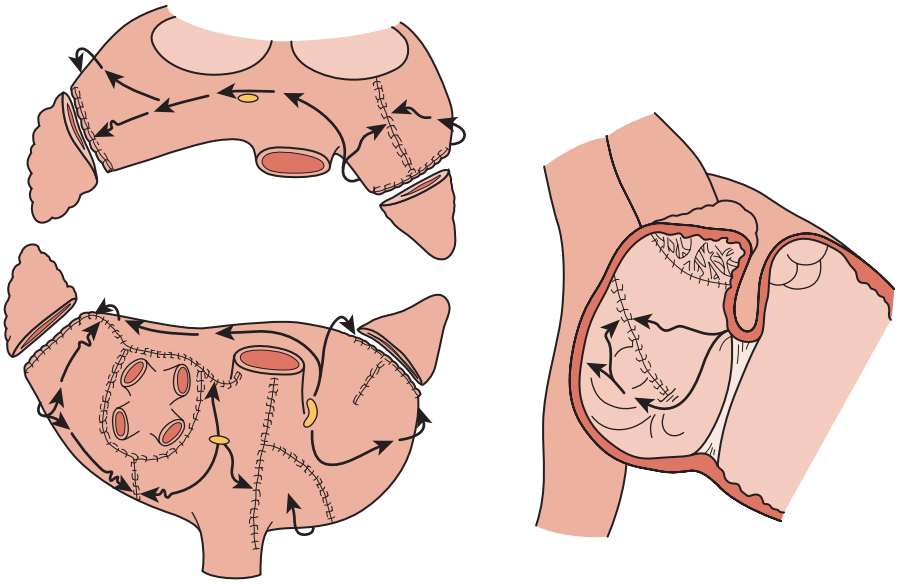

Fig. 4.19 Surgical incisions and conduction pathways of the maze II procedure in views similar to those in Fig. 4.18). The procedure is modified to eliminate incisions through the sinus tachycardia region of the sinus nodal complex performed in the maze I procedure to address chronotropic incompetence. A transverse incision across the dome of the left atrium is moved posteriorly. *(From Cox JL. Evolving applications of the maze procedure for atrial fibrillation [editorial]. Ann Thorac Surg. 1993;55:578–580.)*

left atrium that necessitated division and then reapproximation of the SVC. This problem was addressed by moving the left atrial incision to a more posterior location (Fig. 4.20). These and other modifications led to the introduction of the maze III procedure, which reduced the frequency of chronotropic incompetence, improved atrial transport function, and shortened procedural time.[127]

Surgery for atrial fibrillation continues to advance in two fundamental forms: ablative procedures concomitant with another cardiac operation or as a stand-alone procedure used specifically for terminating atrial fibrillation. Newer energy sources and devices have simplified execution. RF energy consists of alternating electrical current that generates thermal injury and a localized atrial scar. Because unipolar

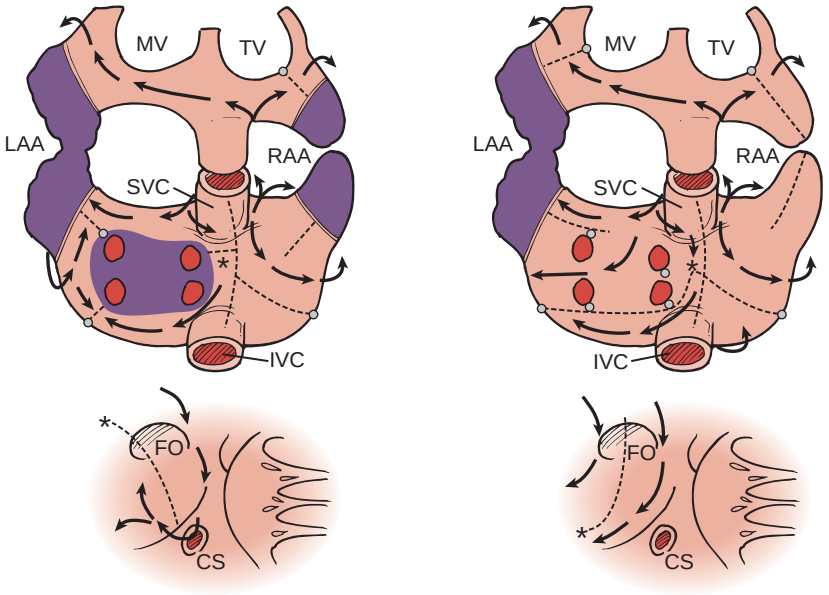

Fig. 4.20 The maze III procedure is shown in views similar to those in Fig. 4.18). The posterior incisions to the vena cava are modified, and the septal incision is placed posterior to the orifice of the superior vena cava. *CS*, Coronary sinus; *FO*, foramen ovale; *IVC*, inferior vena cava; *LAA*, left atrial appendage; *MV*, mitral valve; *RAA*, right atrial appendage; *SAN*, sinoatrial node; *TV*, tricuspid valve *(From Cox JL. Evolving applications of the maze procedure for atrial fibrillation [editorial]. Ann Thorac Surg. 1993;55:578–580.)*

RF energy can cause collateral atrial injury and tissue charring, bipolar probes were developed to minimize the risk. Although bipolar RF energy may be used epicardially for PVI, other ablative lesions require opening the heart, which can be accomplished through a small incision using a purse-string technique.

Because of the generated heat, contiguous structures such as the esophagus have been injured with PVI or posterior atrial lesion generation.[131] When RF energy is employed, the transesophageal echocardiography (TEE) probe should be retracted. However, esophageal injury from RF energy may occur regardless of whether TEE is used during surgery. Monitoring esophageal temperature using a probe fluoroscopically placed behind the left atrium may provide guidance for the operator.

With the availability of these devices, the maze procedure has become a hybrid operation using catheter-delivered RF energy and properly placed surgical incisions. The shortened surgical time allows the maze procedure to be performed with other operations such as mitral valve surgery. Shortened surgical times and lower procedural complexity have also allowed expansion of the eligibility criteria and fostered development of less invasive surgical approaches such as minimally invasive and beating-heart operations. The fundamental requirement for treatment is generation of a transmural lesion that leads to conduction block while minimizing collateral tissue damage. Although the issue of transmurality is somewhat controversial, it remains a basic goal.

The combination of conduction blocks imparted surgically for treating atrial fibrillation is called the *lesion set,* which consists of three components: PVI alone, PVI with lesions connecting to the mitral valve, and lesions involving the right atrium. Cox maze III represents the gold standard of lesion sets in atrial fibrillation surgery. As shown in Fig. 4.20, the pulmonary veins are isolated with lesions connecting to the mitral annulus and left atrial appendage. This constitutes the left-sided lesion set. On the right side, the SVC-IVC line is combined with lesions connecting to the tricuspid annulus and right atrial appendage. Using cryothermy, the coronary sinus is ablated in one spot, and both atrial appendages are removed. The complexity of this procedure and the availability of alternative energy sources motivated surgeons to use other combinations of lesions sets, which are collectively called *modified maze procedures*.

Based on Haissaguerre's seminal paper in 1998,[103] electrical isolation of the pulmonary veins has been used extensively. With modern devices, PVI is very straightforward, and it can be performed epicardially and without cardiopulmonary bypass. Most centers report that up to 80% of patients with paroxysmal atrial fibrillation remain free of the condition 6 months after surgery. For persistent atrial fibrillation, sinus rhythm has been successfully restored in 30% to 40% of patients. The addition of connecting lesions increases the efficacy of the modified maze procedure, especially in patients with persistent or permanent atrial fibrillation.

The right-sided lesion set appears to be important for patients with permanent atrial fibrillation. The lesions also decrease the risk of atrial flutter. Typical atrial flutter arises from the tricuspid isthmus, an area between the coronary sinus, tricuspid annulus, and eustachian valve. Some surgeons omit the right-sided lesion, and if the patient develops atrial flutter postoperatively, ablation is completed using a catheter-based strategy because it is a straightforward procedure in the electrophysiology laboratory.

The left atrial appendage (LAA) is a primary source of intracardiac thrombus in patients with atrial fibrillation, and its exclusion or elimination decreases the thrombotic risk. There are several strategies to manage the LAA. The appendage may be ligated or stapled externally. Because LAA morphology varies, the results can be suboptimal. Left atrial tissue is also very friable, and bleeding from this area can be problematic. The appendage may be completely resected and the base of the appendage oversewn with suture. The LAA may also be excluded from within the atrium. This is easily accomplished with a running suture at the opening of the appendage but requires an atriotomy.

Cryothermy was proposed by Cox and colleagues to simplify the maze III operation.[56] Using a handheld probe, tissue is exposed to a −60 to −90°C temperature, which produces a consistent transmural scar despite being applied only to the heart surface. A variety of flexible and colder probes allow the creation of all lesion sets. The Cox maze IV procedure is the most recent iteration.[132] Bipolar RF and cryoablation are used to create left and right atrial lesion sets. It is still

an extensive intracardiac procedure, but it has outstanding results. The other important practice change is electrical confirmation of PVI.

Conventional, partial sternotomy, and right thoracotomy approaches allow excellent exposure for all lesion sets. The atrium may be opened with a left atriotomy or transseptal approach. As a concomitant procedure, the maze procedure is performed before mitral valve surgery. This allows access to the mitral annulus before placement of a prosthesis. When an atrial fibrillation procedure is combined with coronary artery bypass grafting, the lesions are created before cardioplegic arrest. However, the left-sided pulmonary veins may be difficult to ablate with the beating heart and may be approached after cardioplegic arrest but before bypass graft construction. The left atrium may be reduced in size by resecting atrial tissue between the inferior pulmonary vein and mitral annulus.

Atrial fibrillation procedures may be performed using minimally invasive techniques. A right anterior thoracotomy and femoral cannulation allow access to the left atrium and mitral valve. Alternatively, a bilateral thoracoscopic and off-pump approach has been used.

The choice of atrial fibrillation operation (ie, lesion set and surgical approach) depends on several factors, including the duration and classification of atrial fibrillation, size of the left atrium, and need for concomitant procedures. For example, a patient with paroxysmal atrial fibrillation undergoing coronary artery bypass grafting is well served by a simple epicardial PVI using a bipolar RF ablation device. A patient with heart failure and persistent atrial fibrillation who requires mitral valve intervention is better treated with PVI and connecting lesions. A patient with symptomatic permanent atrial fibrillation and stroke who has failed medical and catheter-based therapy is best treated with a full Cox maze III procedure.

Operative results from many centers show that more than 90% of patients remain free of atrial fibrillation after the classic maze procedure.[130] Episodes of atrial flutter during the immediate perioperative period do not alter the long-term success of sinus rhythm restoration.[130] Procedure-specific complications have included an attenuated heart rate response to exercise resulting in the need for permanent pacemaker implantation.[130] The frequency of these complications is less with newer versions of the procedure. Fluid retention is a common problem after the maze procedure, which is attributed to reduced secretion of atrial natriuretic peptide and elevated levels of antidiuretic hormone and aldosterone.[133,134] The use of furosemide or spironolactone, or both, perioperatively can reduce the likelihood of this complication.[135]

An intended goal of the maze procedure is preservation of atrial transport function. Follow-up of patients early in the experience at Washington University School of Medicine demonstrated that this was achieved for the right atrium in 98% of patients but for the left atrium in only 86% of patients.[136] More detailed analysis revealed that even when left atrial contraction existed, quantitative mechanical function was lower compared with that in control patients.[137,138] In cases of compromised atrial transport function, the incisions used to isolate the pulmonary veins also isolated almost 30% of the left atrial myocardium from excitation.[139]

Preservation of atrial transport function was improved with a maze procedure that used incisions radiating from the SA node (Fig. 4.21) along the path of coronary arteries supplying the atrium rather than across as in the maze III procedure.[140,141] This modification, called the *radial procedure,* was also designed to preserve the right atrial appendage, which is an important source of atrial natriuretic peptide.[142] Compared with the standard maze III procedure, the radial approach results in a more synchronous activation sequence of the left atrium, preserving atrial transport function, and it is equally effective in eliminating the reentrant circuits of atrial fibrillation.

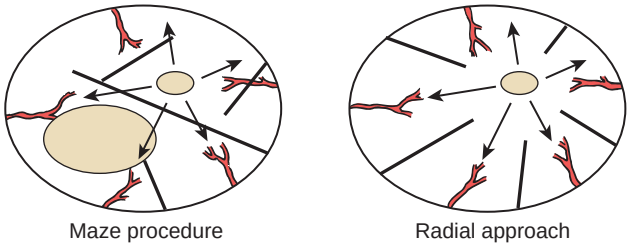

Fig. 4.21 Contrasting concepts of the maze procedure *(left)* and radial approach *(right).* The *small circle* in the middle indicates the sinus node, the *outer circle* indicates the atria, and the *shaded area* indicates atrial myocardium isolated by the incisions. The atrial arterial supply is depicted, and the *arrows* indicate propagation of the depolarizing wavefront. The radial approach preserves atrial arterial blood supply and a more physiologic activation sequence. With the maze procedure, some arteries are divided, and the atrial activation sequence is disrupted. *(From Nitta T, Lee R, Schuessler RB, et al. Radial approach: a new concept in surgical treatment of atrial fibrillation. I. Concept, anatomic and physiologic bases and development of a procedure.* Ann Thorac Surg. *1999;67:27.)*

Anesthesia Considerations

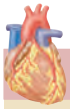
Anesthesiology teams are increasingly asked to care for patients undergoing catheter-based ablative procedures for atrial fibrillation. Monitored anesthesia care may be possible in some situations, but general anesthesia is typically chosen due to the duration of the procedure and the demand for no patient movement during critical lesion placement. Care of the patient undergoing catheter-based therapy or atrial fibrillation surgery is similar. Preparation includes review of preoperative cardiac testing results, assessment of the characteristics of the patient's arrhythmia, and review of the surgical plan and concomitant procedures that may accompany the maze procedure (eg, coronary artery bypass grafting, valve replacement, repair of congenital lesions).

The choice of anesthesia depends on the patient's physical status, including comorbid conditions and ventricular dysfunction. General anesthesia with HFJV can minimize thoracic excursion during respirations, which increases catheter-tissue contact.[121,122] HFJV necessitates the use of intravenous anesthesia, which usually consists of a propofol infusion combined with a short-acting narcotic infusion such as remifentanil. HFJV risks include pneumothorax, barotrauma, inadequate ventilation or oxygenation, respiratory acidosis, pneumomediastinum, gastric distention, and aspiration.[120] These risks are more likely to occur with HFJV than with conventional mechanical ventilation and must be considered as HFJV is increasingly used to improve freedom from atrial fibrillation.

LAA thrombus must be excluded with TEE before proceeding with catheter-based ablation and surgical manipulations. During catheter-based ablation of atrial fibrillation, patients undergo direct arterial pressure and esophageal temperature monitoring. Acute increases in esophageal temperature of only 0.1°C are communicated to the electrophysiologist. Immediately terminating RF energy and cooling the catheter tip with intraprobe saline at room temperature limit the spread of myocardial heating.

Because heparin is administered during the procedure, the activated clotting time is monitored. Constant vigilance is mandated for pericardial tamponade, and immediate transthoracic echocardiography should be performed when abrupt hypotension develops. Percutaneous pericardial drainage is emergently performed, which typically restores blood pressure. Continued collection of pericardial blood after protamine reversal of heparin anticoagulation may necessitate transfer of the patient to the operating room for a sternotomy and repair of the atrial defect.

Patient monitoring modalities for the surgical procedures are similar to those used for other cardiac surgical procedures, including TEE to evaluate ventricular and valvular function, look for new wall motion abnormalities, and assist in evacuation of air from the cardiac chambers at the conclusion of surgery. Ventricular dysfunction (right ventricle more often than the left), at least transiently, and echocardiographic and electrocardiographic ischemic changes (inferiorly more often) are common.[10] Causes include coronary artery air embolization and inadequate myocardial protection. Because the maze procedure



BOX 4.11 VENTRICULAR ARRHYTHMIAS

- Most episodes of ventricular tachycardia or fibrillation result from coronary artery disease and dilated or hypertrophic cardiomyopathy.
- Implantable cardioverter-defibrillator placement is the standard of care with or without medical treatment for life-threatening ventricular arrhythmias and structural heart disease.
- Catheter ablation is adjuvant therapy for medically refractory monomorphic ventricular tachycardia.
- Surgical therapy includes endocardial resection with cryoablation.
- Anesthesia considerations focus on preoperative catheterization, echocardiography, and electrophysiologic testing.
- Monitoring of surgical patients is dictated by the underlying cardiac disease.

entails placement of multiple atrial incisions, initial atrial compliance and performance of the atria appear altered. TEE evaluation of atrial activity is performed after separation from the extracorporeal circulation and decannulation.[10]

Ventricular Arrhythmias

As with supraventricular arrhythmias, the treatment of ventricular fibrillation and VT is aimed at addressing underlying mechanisms (eg, myocardial ischemia; drug-induced, electrolyte, or metabolic abnormalities). In most patients with life-threatening ventricular arrhythmias and structural heart disease, ICD placement is the standard of care with or without concomitant antiarrhythmic drug therapy.[143] In patients with significant structural heart disease, catheter ablation is considered as an adjuvant therapy for medically refractory monomorphic VT.

Rarely, VT occurs in the setting of a structurally normal heart. This syndrome of a primary electrical disorder usually is caused by a focal, triggered mechanism that occurs mostly in younger patients and originates from the right ventricular outflow tract or apical septum [144–146] (Box 4.11). ICDs are not typically indicated in these cases.

Catheter Ablation Therapy for Ventricular Tachycardia

The mechanism for VT can be identified in the electrophysiology laboratory using programmed stimulation.[147,148] Single or multiple extrastimuli are introduced during an excitable gap of cardiac depolarization until a sustained VT develops that is similar in morphology to that of the spontaneous arrhythmia. The diagnostic hallmark of VT due to a reentrant circuit is the ability to entrain the tachycardia by pacing slightly faster than the tachycardia cycle length and demonstrate fusion.[149]

Traditional catheter mapping techniques for guiding catheter ablation of VT position the ablation catheter within a protected isthmus of the reentrant circuit. The pathologic characteristics of this site are thought to be viable myocardium surrounded by scar tissue that is electrically isolated from the bulk of the ventricular myocardium except at the entrance and exit sites. These techniques have important shortcomings because most VTs are not hemodynamically stable enough for mapping and multiple morphologies of inducible VT are commonly identified in a single patient.

Newer strategies that rely on three-dimensional computerized mapping techniques attempt to identify important areas of myocardial scar, such as the perimeter that may participate in reentrant circuits. By strategic placement of areas of conduction block guided by these maps, significant cure rates have been obtained without the necessity of mapping individual reentrant circuits.[150] In rare instances, VT circuits may involve the conduction system, such as in bundle branch reentry or fascicular VT that is easily ablated with RF energy.[151]

There are no data from prospective, randomized trials of VT ablation, but case series report success rates ranging from 37% to 86%.[133,152–158] The latter results mostly represented patients with drug-resistant VT or multiple VT morphologies, and treatment was performed as a last-ditch effort to control the arrhythmia. Reported success rates are higher after RF ablation for primary VT.

Major complications from catheter ablation procedures for VT in the setting of structural heart disease include stroke, myocardial infarction, heart failure exacerbation, vascular injury, and death. The incidence of these complications appears to be low despite the lengthy procedure times that are commonly required.[150]

Anesthesia Considerations

Anesthesia management of patients undergoing catheter-based procedures to ameliorate ventricular arrhythmias is primarily based on the patient's underlying cardiac disease and other comorbidities. Candidates often have coronary artery disease, severely impaired left ventricular function, and dysfunction of other organs (eg, liver, kidney). Because they are receiving multiple medications that may interact with anesthetics (eg, vasodilation from angiotensin-converting enzyme inhibitors), a thorough review of the patient's underlying conditions and treatments is mandated. Special attention is given to cardiac catheterization results and preoperative echocardiogram findings. Information regarding characteristics of the patient's arrhythmia such as ventricular rate, hemodynamic tolerance, and method of arrhythmia termination should be sought.

Prior or current treatment with amiodarone is a particular concern. The long elimination half-life (about 60 days) of amiodarone requires that potential side effects such as hypothyroidism be considered perioperatively.[159] The α-adrenergic and β-adrenergic properties of amiodarone may lead to hypotension during anesthesia, but most anesthesiologists are familiar with the management of this complication. Much attention has been given to bradycardia associated with amiodarone during anesthesia that may be resistant to atropine.[160–164] Methods for temporary cardiac pacing should be readily available to care for patients receiving amiodarone on a long-term basis. Retrospective reports suggest a greater need for inotropic support for patients receiving preoperative amiodarone therapy because low systemic vascular resistance has been observed.[161,162]

Pulmonary complications thought to be related to pulmonary toxicity from amiodarone have been reported.[106,164] In a series of 67 patients receiving preoperative amiodarone, 50% developed acute respiratory distress syndrome that could not be attributed to other factors, including the intraoperative fraction of inspired oxygen (see Chapter 11).[164]

Monitoring includes direct arterial pressure monitoring and central venous access is necessary for administration of vasoactive drugs if needed. Means for rapid cardioversion-defibrillation should be readily available when inserting any central venous catheter. Self-adhesive electrode pads are used most often and connected to a cardioverter-defibrillator before anesthesia induction. Premature ventricular beats induced during these procedures can easily precipitate the patient's underlying ventricular arrhythmia, which may be difficult to convert to sinus rhythm.[162,165] Selection of anesthetics for arrhythmia ablation is dictated mostly by the patient's physical status. General anesthesia with endotracheal intubation is typically chosen due to the duration of the procedures, but deep sedation is also employed.

Because anesthetics can influence cardiac conduction and arrhythmogenesis, there is concern about their ability to alter electrophysiologic mapping results.[166,167] Effects of volatile anesthetics on ventricular arrhythmias vary in different experimental models and according to the mechanism of the arrhythmia. Data showing proarrhythmic, antiarrhythmic, and no effects of volatile anesthetics on experimental

BOX 4.12 IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

- ICDs can pace and provide tiered therapy for tachyarrhythmias (eg, shocks, antitachycardia pacing).
- Insertion of modern devices typically is done with percutaneous techniques.
- ICDs are indicated for the primary or secondary prevention of sudden cardiac death.
- ICDs reduce overall mortality rates compared with standard treatment alone.
- ICDs are indicated for patients surviving sudden death without a reversible cause, those with ischemic cardiomyopathy with an ejection fraction ≤30%, and those with ischemic or nonischemic cardiomyopathy with an ejection fraction of ≤35% and NYHA class II or III heart failure symptoms.

ICD, Implantable cardioverter-defibrillator; *NYHA*, New York Heart Association.

arrhythmias have been reported.[13,166–173] Nonetheless, the small doses administered during ablative procedures may have minimal effects on electrophysiologic mapping. Opioids have had no effects on the inducibility of VT.[170,173,174]

Implantable Cardioverter-Defibrillators

Decreased device size, longer battery life, and improved treatment algorithms have enhanced the reliability of ICDs (Box 4.12). Current ICDs can provide tiered therapy consisting of antitachycardia pacing and shocks to terminate potentially life-threatening ventricular arrhythmias. All ICDs can pace the heart to treat bradycardia as a single-chamber, dual-chamber, or biventricular system.

Advances in lead technology and implementation of a biphasic waveform have considerably reduced defibrillation energy requirements.[175,176] These improvements have simplified lead implantation with the use of transvenous insertion methods instead of the epicardial patch electrodes used in prior generations. Insertion of modern devices uses percutaneous techniques rather than a more invasive median sternotomy, except when body habitus precludes the approach (eg, pediatric population).

The ICD consists of a pulse generator and transvenous leads that continuously monitor the heart rate. When the heart rate exceeds the programmed limit, therapy is initiated that may include a brief burst of rapid pacing (ie, antitachycardia pacing) followed by a biphasic shock if the arrhythmia persists. Electrogram storage capabilities allow review of the appropriateness of delivered treatments and changes in ventricular arrhythmia characteristics. The style of ICD (ie, one, two, or three leads) is chosen based on a patient's requirement for antibradycardia pacing (ie, single- or dual-lead devices) or cardiac resynchronization therapy (ie, biventricular pacing) for medically refractory heart failure and interventricular conduction delay.

Technologic aspects of ICDs have been reviewed (see Chapter 5).[175] Defibrillation voltage is much higher than can be delivered with existing batteries, necessitating the use of storage capacitors and transformers. After the ICD has detected an arrhythmic event, the device begins to charge its capacitor. During charging and immediately after the capacitor has been fully charged, continuation of the arrhythmia is confirmed, and the device delivers therapy. If during the charge or immediately after charging is complete the arrhythmia spontaneously terminates, the energy is dumped to avoid unnecessary energy delivery. If energy is delivered, the device uses a redetection algorithm to assess whether the arrhythmia was successfully terminated. If the arrhythmia persists, the device recharges its capacitor and repeats the process. If the arrhythmia has terminated, the episode is declared complete.

Although much of the ICD's ability to determine whether an arrhythmia needs therapy is based on the rate, all ICDs can apply various algorithms to differentiate ventricular from supraventricular arrhythmias. They include criteria for abruptness of onset, intracardiac signal morphology, and rate stability (ie, stable with VT but irregular with atrial fibrillation).[175] An atrial lead can sometimes enhance the discrimination of atrial fibrillation with a rapid ventricular response from VT.[175]

Guidelines for implantation of ICDs have been issued by the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society[177] (Box 4.13). ICDs are indicated for the primary or secondary prevention of sudden cardiac death. Recommendations are based on data from large, multicenter investigations that have compared ICD therapy with standard care, including antiarrhythmic drugs. For patients with prior cardiac arrest due to VT or ventricular fibrillation (ie, secondary prevention), the data show that ICDs lower the mortality risk by 20% to 30% compared mostly with amiodarone or β-adrenergic receptor blockers.[177–180] Similarly, the relative mortality rate is reduced by 49% to 54% with ICD treatment for patients with nonsustained VT or inducible ventricular arrhythmias with programmed stimulation compared with standard care or serial drug testing in patients with ischemic left ventricular dysfunction.[181,182]

The most persuasive data on primary prevention of sudden death with ICD treatment for patients with ischemic and nonischemic cardiomyopathy come from the MADIT II[181] and SCD-HeFT[183] trials. In contrast to other studies, these two randomized trials did not require a history of inducible or spontaneous ventricular arrhythmias. Enrollment criteria were instead based on the ejection fraction alone (≤30%) in the setting of ischemic cardiomyopathy (ie, MADIT II) or the ejection fraction (≤35%) with New York Heart Association (NYHA) class II or III heart failure symptoms with any type of end-stage cardiomyopathy (ie, SCD-HeFT).[183] Patients were continued on conventional treatments, including β-blockers, angiotensin-converting enzyme inhibitors, and HMG-CoA reductase inhibitors (ie, statins).

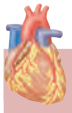
After more than 4 years of follow-up, ICD treatment was associated with a significant reduction in all-cause mortality compared with conventional treatment. Other conditions such as inherited long QT syndrome, hypertrophic cardiomyopathy, Brugada syndrome, arrhythmogenic right ventricular dysplasia, and infiltrative disorders (including cardiac sarcoidosis) may warrant ICD insertion for prevention of sudden cardiac death, although data from large, randomized studies are lacking due to the relative infrequency of the conditions. In the future, genetic screening may provide valuable information about the risk of sudden death for patients with these less common entities.[151,184]

Anesthesia Considerations

Insertion of ICDs is usually performed in the catheterization suite. The procedure typically includes defibrillation testing to ensure an acceptable margin of safety for the device. VT or ventricular fibrillation is induced by the introduction of premature beats timed to the vulnerable repolarization period. External adhesive pads are placed before the procedure and connected to an external cardioverter-defibrillator to provide backup shocks if the device is ineffective.

Monitored anesthesia care is typically chosen, but a short-acting general anesthetic may be given for defibrillation testing. General anesthesia may be chosen for patients with severe concomitant diseases (eg, chronic lung disease, sleep apnea) when control of the airway is desired. Simultaneous insertion of biventricular pacing systems with an ICD is performed for an increasing population of patients with impaired left ventricular dysfunction with or without ventricular conduction delay.

In addition to standard patient monitoring, continuous arterial blood pressure monitoring may be considered during monitored anesthesia care to rapidly assess return of blood pressure after defibrillation testing. Defibrillation testing has been associated with ischemic electroencephalographic (EEG) changes of 7.5 ± 1.8 seconds (mean



BOX 4.13 AMERICAN COLLEGE OF CARDIOLOGY, AMERICAN HEART ASSOCIATION, AND HEART RHYTHM SOCIETY GUIDELINES FOR INSERTION OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Class I Heart Failure

- Survivors of cardiac arrest due to VF or sustained VT after excluding reversible causes
- Patients with structural heart disease and spontaneous, sustained VT, whether hemodynamically stable or unstable
- Patients with syncope of undetermined origin with clinically relevant sustained VT or VF induced at electrophysiology study
- Patients with an LVEF ≤35% due to prior MI occurring at least 40 days earlier and who have NYHA functional class II or III disease
- Patients with nonischemic dilated cardiomyopathy who have an LVEF ≤35% and NYHA functional class II or III disease
- Patients with LV dysfunction due to prior MI occurring at least 40 days earlier with an LVEF ≥30% and who have NYHA class I disease
- Patients with nonsustained VT due to prior MI with an LVEF ≤40% with inducible VF or sustained VT at electrophysiology study

Class IIa Heart Failure

- Patients with unexplained syncope, LV dysfunction, and nonischemic cardiomyopathy
- Patients with sustained VT and normal LV function
- Patients with hypertrophic cardiomyopathy and at least one risk factor for sudden cardiac death
- Patients with arrhythmogenic RV dysplasia with at least one risk factor for sudden cardiac death
- Patients with long QT syndrome with syncope and/or sustained VT while on β-blockers
- Nonhospitalized patients awaiting heart transplantation
- Patients with Brugada syndrome who have syncope or those with documented VT not resulting in cardiac arrest
- Patients with catecholaminergic polymorphic VT who have syncope and/or documented sustained VT while receiving β-blockers
- Patients with cardiac sarcoidosis, giant cell myocarditis or Chagas disease

Class IIb Heart Failure

- Patients with nonischemic heart disease who have an LVEF ≤35% and who have NYHA class I disease
- Patients with long QT syndrome and risk factors for sudden cardiac death
- Patients with syncope and structural heart disease when evaluation has failed to define a cause
- Patients with familial cardiomyopathy associated with sudden cardiac death
- Patients with LV noncompaction

Class III Heart Failure

- ICD implantation not indicated for patients whose reasonable life expectancy at an acceptable functional status is <1 year even if they meet other criteria

Therapeutic Indications by Functional Class

- Class I: There is evidence or general agreement that the treatment is useful and effective.
- Class IIa: Weight of the data or evidence favors benefit of the therapy.
- Class IIb: The conditions for which usefulness or efficacy of the treatment are less well established.
- Class III: Intervention is not indicated.

ICD, Implantable cardioverter-defibrillator; *LV*, left ventricular; *LVEF*, left ventricular ejection fraction; *MI*, myocardial infarction; *NYHA*, New York Heart Association; *RV*, right ventricular; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia.

± SD) after arrest.[185] The changes were transient and not associated with persistent ischemic EEG changes or exacerbation of an existing neurologic deficit, and significant deterioration in neuropsychometric performance was not detected. Repeated defibrillation testing is usually well tolerated without deterioration of cardiac function even in patients with left ventricular ejection fractions less than 35%. Nonetheless, the means of pacing must be available in case bradycardia develops after cardioversion-defibrillation. Restoration of circulatory function after defibrillation testing often is accompanied by tachycardia and hypertension, necessitating treatment with a short-acting β-blocker or vasoactive drugs, or both.

ICD-associated complications may be related to insertion or the device itself. Percutaneous insertion is typically done through the subclavian vein, predisposing the patient to pneumothorax. Cardiac injury (including perforation) is a remote possibility. Cerebrovascular accident and myocardial infarction have been reported, but mostly with the use of older device insertion methods.[10] Device-related complications include multiple shocks that may lead to myocardial injury or refractory hypotension.[186,187] Device infections are particularly difficult to manage, often requiring device and lead explantation.

5 Cardiac Implantable Electrical Devices

MARC A. ROZNER, PhD, MD

KEY POINTS

Preoperative Key Points

1. Identify the type of cardiac implantable electronic device (CIED) (eg, transvenous implantable pacemaker, intracardiac pacemaker, transvenous implantable cardioverter-defibrillator, subcutaneous implantable cardioverter-defibrillator) and the manufacturer of the generator.
2. Establish contact with the patient's CIED physician or clinic to obtain records and perioperative prescription (Heart Rhythm Society [HRS]). Have the CIED interrogated by a competent authority shortly before the procedure (American Society of Anesthesiologists [ASA]).
3. Obtain appropriate records from the CIED clinic (HRS) or preoperative interrogation (ASA). Ensure that the device will appropriately pace the heart.
4. Consider replacing any CIED near its elective replacement period in a patient scheduled to undergo either a major operation or surgery within 25 cm of the generator.
5. Determine the patient's underlying rate, rhythm, and pacing dependency to determine the need for asynchronous or external backup pacing support.
6. If magnet use is planned, then ensure that magnet behavior (pacing mode, rate, atrioventricular delay, shock therapy suspension) is appropriate for the patient.
7. Consider programming minute ventilation and other rate responsiveness features off, if present.
8. Consider programming rate enhancements off, if present.
9. Consider increasing the pacing rate to optimize oxygen delivery to tissues for major operations.
10. If electromagnetic interference is likely or if a central venous catheter guidewire will be placed into the chest, then consider asynchronous pacing for the pacing-dependent patient and suspension of antitachycardia therapy for any implantable cardioverter-defibrillator (ICD) patient. Magnet application might be effective, although magnet use has been associated with inappropriate ICD discharge. Magnet application will never create asynchronous pacing in any type of ICD.

Intraoperative Key Points

1. Monitor cardiac rhythm/peripheral pulse with pulse oximeter (plethysmography) or arterial waveform.
2. Consider disabling the "artifact filter" on the electrocardiographic monitor. If a minute ventilation sensor is active, then ensure that respiratory rate monitoring is disabled.
3. Ask the surgeon to avoid the use of the monopolar electrosurgical unit (ESU) or limit ESU bursts to <4 seconds separated by at least 2 seconds. Use the bipolar ESU if possible; if not possible, then pure cut (monopolar ESU) is better than "blend" or "coag."
4. Place the ESU dispersive electrode in such a way as to prevent electricity from crossing the generator-heart circuit, even if the electrode must be placed on the distal forearm and the wire covered with sterile drape.
5. If the ESU causes ventricular oversensing, resulting in pacing quiescence or atrial oversensing with inappropriate high rate ventricular pacing, then limit the period(s) of asystole, relocate the dispersive electrode, or place a magnet over the pacemaker (not indicated for any ICD).
6. Temporary pacing might be needed, and consideration should be given to the possibility of CIED failure.
7. Consider avoiding sevoflurane, isoflurane, or desflurane in the patient with long QT syndrome.

Postoperative Key Points

1. Have the CIED interrogated by a competent authority postoperatively. Some rate enhancements can be reinitiated, and optimum heart rate and pacing parameters should be determined. The ICD patient must be monitored until the antitachycardia therapy is restored.

Battery operated, implantable pacing devices (collectively, cardiac implantable electronic devices [CIEDs]) were first introduced in 1958, 4 years after the invention of the transistor. Although several generations of physicians have been trained since, these devices remain one of the most poorly understood aspects of medical care throughout the world. Often, these devices are ignored in the overall care of a patient with the erroneous (and possibly life-threatening) belief that mere application of a magnet will prevent any perioperative problem, as well as treat any situation that arises.[1,2] Frequently, implantable cardioverter-defibrillators (ICDs) are labeled as a simple pacemaker, a situation during which the antitachycardia therapy or the inability to deliver magnet-driven asynchronous pacing in a pacing-dependent patient might be overlooked.[3] Nevertheless, the presence of a CIED with therapeutic capability can significantly complicate a patient's life—whether for access to an airport owing to metal and bomb detection equipment, a surgical procedure, a diagnostic procedure such as a computerized axial tomography (CAT) or magnetic resonance imaging (MRI), end-of-life care planning, and funeral or cremation activities. In addition to pacemakers and defibrillators, CIEDs include devices such as implanted loop recorders, with no therapeutic capability, but

whose capability to detect both tachyarrhythmias and bradyarrhythmias remains underutilized in the preoperative evaluation of a patient.

CIED complexity, calculation, data storage abilities, and size minimization allowing direct implantation into the chamber(s) of the heart have grown in a manner similar to that seen within the computer or cell phone industry. The natural progression of pacemaker developments led to the invention of the transvenous implantable cardioverter-defibrillator (TV-ICD) around 1980. As this technology has advanced, the lines between simple pacing generators and defibrillators have become less clear. For example, every TV-ICD currently implanted has robust antibradycardia pacing capability; and patients, the news media, and even physicians often misidentify an implanted defibrillator as a pacemaker. The consequence of mistaking any TV-ICD for a conventional pacemaker can lead to patient harm, mostly attributable to electromagnetic interference (EMI) resulting in inappropriate ICD therapy. In TV-ICDs manufactured before 2009 by Guidant or Cardiac Pacemakers, Inc. (CPI) (now owned by Boston Scientific, Natick, MA), high-energy therapies could have been permanently disabled by magnet placement.[4] However, in October, 2009, Boston Scientific changed their program software to eliminate this feature in nearly every Guidant or CPI TV-ICD that remains implanted. Fig. 5.1 shows a three-lead defibrillation system and identifies the right ventricular (RV) shock coil, which differentiates a TV-ICD system from a conventional pacemaker system.

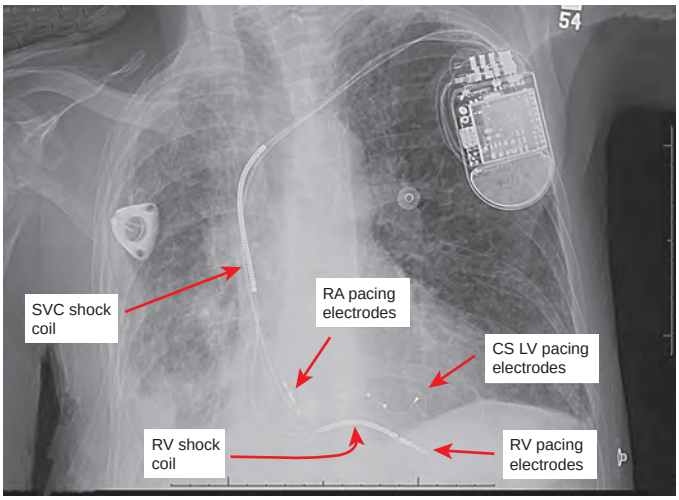

Fig. 5.1 Defibrillator system with biventricular (BiV) antibradycardia pacemaker capability. Note that three leads are placed: a conventional, bipolar lead to the right atrium; a true bipolar right ventricular (*RV*) lead with shock coils in the right ventricle and the superior vena cava (*SVC*), and a quadripolar lead to the coronary sinus (*CS*). This system is designed to provide "resynchronization (antibradycardia) therapy" in the setting of a dilated cardiomyopathy with a prolonged QRS complex (and frequently with a prolonged P-R interval as well). The bipolar lead in the right atrium will perform both sensing and pacing function. The true bipolar (discrete tip and ring) electrodes in the right ventricle provide pacing and sensing function. The presence of a "shock" conductor (termed *shock coil*) on the RV lead in the right ventricle distinguishes a defibrillation system from a conventional pacemaking system. The lead in the CS depolarizes the left ventricle, and this particular catheter has four electrodes in the CS to allow optimization of left ventricular (*LV*) pacing (a close-up of the St. Jude generator is demonstrated in Fig. 5.4I). Because of the typically wide native QRS complex in a left bundle branch pattern, failure to capture the left ventricle can lead to ventricular double-counting (and inappropriate antitachycardia therapy) in a BiV transvenous implantable cardioverter-defibrillator (ICD) system. Many defibrillation systems also have a shock coil in the SVC, which is most often electrically identical to the defibrillator case (called the *can*). When the defibrillation circuit includes the ICD case, it is called *active can configuration*. Incidental findings on this chest radiograph include the presence of a right-sided implanted central venous catheter, right pleural effusion, and scoliosis.

The development of the subcutaneous ICD[5] (S-ICD) (Fig. 5.2), as well as the leadless transcatheter-deployed intracardiac pacemaker[6] (IC-PM) (Fig. 5.3), further complicates this issue. S-ICDs are larger than their transvenous counterparts, cannot provide antitachycardia or sustained antibradycardia pacing, and generally have higher

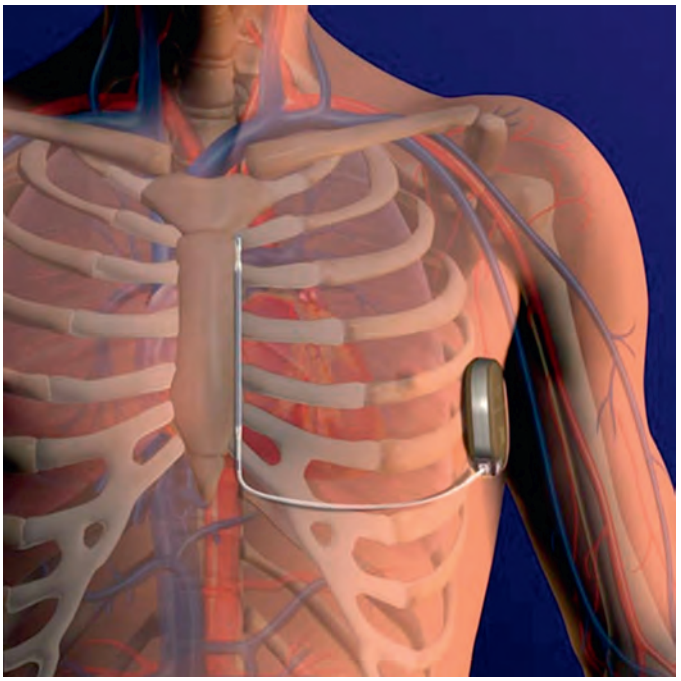

Fig. 5.2 The Boston Scientific subcutaneous implantable cardioverter-defibrillator (S-ICD). Illustration demonstrates an S-ICD (CE mark 2009; US Food and Drug Administration approval 2012), which consists of a generator implanted along the lateral chest wall with a subcutaneous lead tunneled into position over the heart. *(Used with permission. Hauser RG. The subcutaneous implantable cardioverter-defibrillator: should patients want one?* J Am Coll Cardiol. *2013;61:20–22.)*

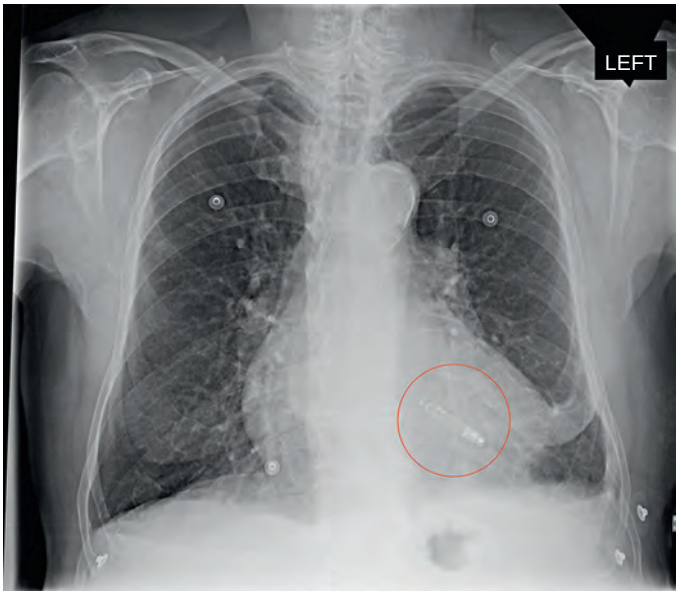

Fig. 5.3 The St. Jude Nanostim leadless intracardiac pacemaker. A leadless pacemaker is shown in the right ventricle *(circle)* on this posteroanterior chest film. Leadless pacemakers are currently approved for implant in several countries outside of the United States. *(X-ray image courtesy of Vivek Reddy, MD, Icahn School of Medicine at Mount Sinai, New York, NY.)*

defibrillation thresholds (DFTs) than TV-ICDs. The IC-PMs likely behave differently from their transvenous-deployed cohorts, especially with respect to overall features and magnet placement. They might be identified only as a generic implant on an x-ray image rather than the actual type of device, owing to information lag on the part of radiologists.

The diversity and complexity of cardiac pulse generators, as well as the multitude of programmable parameters, limits the number of sweeping generalizations that can be made about the perioperative care of the patient with an implanted pulse generator. Population aging, continued enhancements in implantable technology, and new indications for implantation will lead to growing numbers of patients with these devices in the new millennium. Currently, four advisories or guidelines have been published in three countries endorsed by several societies regarding the care of the perioperative patient with a device.[7–10] Table 5.1 compares and contrasts these statements. Work by the Association for the Advancement of Medical Instrumentation to standardize magnet responses has been ongoing since 2000 but without much success (see https://standards.aami.org/kws/public/projects/project/details?project_id=53).

Although incredibly reliable, both transvenous pacemakers (TV-PMs) and TV-ICDs have nonzero failure rates. US Food and Drug Administration (FDA) data for the 13-year period from 1990 to 2002 show 0.5% of TV-PMs and 2.1% of TV-ICDs were explanted annually for reasons other than battery replacement.[11] In a subsequent study, for the period from 2003 to 2007, Laskey and colleagues[12] reported a 0.4% annual failure rate for conventional TV-ICDs and a 2.3% failure rate for TV-ICDs delivering cardiac resynchronozation therapy.[12]

Radiology Imaging Issues

Many patients with a CIED require a computed tomography (CT) scan or an MRI during their lifetime. Both modalities have the ability to interfere with normal CIED function. CT scans directly over the generator can cause oversensing (see Glossary) (which can lead to inappropriate pacing cessation),[13] although Hussein and associates[14] report that this scenario remains clinically rare. However, pacing-dependent patients undergoing high-power axial (vs helical) CAT scans in which the x-ray beam crosses the generator might need special monitoring or reprogramming.

MRI represents another imaging modality requiring special monitoring and CIED reprogramming.[15] This report of 54 patients with modern TV-PMs undergoing 62 scans basically provided a road map for conduction of MRIs in which the benefit of the MRI outweighed the theoretic risk to the patient. Currently, over 3000 patients with both TV-PMs and TV-ICDs appear to have undergone these procedures

TABLE 5.1 Comparison of Perioperative Cardiac Implantable Electronic Device Advisories

	Preoperative Recommendation	*Intraoperative Magnet Use*	*ESU Dispersive Electrode Placement*	*Postoperative Recommendation*	**Emergency Procedures**	
					PM	*ICD*
ASA Periop	"Timely interrogation" before elective surgery	Shuns magnet use in favor of reprogramming.	Prevents presumed current path from crossing the chest and CIED system.	Interrogation is recommended. Footnotes added to 2011 revision suggest that CIED reinterrogation is not needed if no monopolar ESU is used.	(silent)	
HRS/ASA	PM interrogation within 12 months ICD interrogation within 6 months CRT interrogation within 3–6 months CIED physician must provide prescription for perioperative care	Magnet use is suggested for asynchronous pacing (when needed in PM patients) and disabling ICD high-energy therapy, provided that patient position does not interfere with magnet access or observation.	Prevents presumed current path from crossing the chest and CIED system.	For most cases involving EMI (especially those inferior to umbilicus and when no preoperative reprogramming was performed), interrogation can take place within 1 month as an ambulatory procedure. For reprogrammed CIEDs, hemodynamically challenging cases, cardiothoracic surgery, RFA, and external cardioversion, interrogation can take place before transfer from cardiac telemetry.	Use 12-lead ECG to identify pacing need, presume dependence if 100% pacing. Use magnet to mitigate pacing inhibition.	Use magnet to suspend ICD tachyarrhythmia therapy. Maintain cardiac monitoring until postoperative interrogation.
CAS-CCS	De-novo interrogation is not likely needed, but the CIED physician must provide a prescription for perioperative care.	Where reasonable, magnet use is suggested for asynchronous pacing (when needed in PM patients) and disabling ICD high-energy therapy.	No mention	Clear plan for postoperative care is established before elective case.	Use 12-lead ECG to identify pacing need, presume dependence if 100% pacing; maintain careful monitoring to determine magnet action, >5 second pauses if ESU interferes with CIED.	
MHRA[a]	Preoperative contact with the pacemaker ICD follow-up clinic for evaluation and perioperative recommendations	Caution is advised since programming can affect magnet behavior.	"…ensure that the return electrode is anatomically positioned so that the current pathway between the diathermy electrode and return electrode is as far away from the pacemaker/defibrillator (and leads) as possible."	Follow-up clinic prescribes postoperative follow-up.	Attempt to follow routine steps; postoperative interrogation is needed as soon as possible. Magnet might create asynchronous pacing.	Magnet might prevent inappropriate discharge.

No recommendations have been published for the leadless intracardiac pacemaker or the subcutaneous ICD.

[a]Recommendations appear relevant only if EMI will be present.

without significant incident, other than an occasional device electrical reset.[16,17] In the United States, TV-PMs manufactured by Biotronik and Medtronic carry "MR Conditional" labeling. Conditions include magnet strength not exceeding 1.5 tesla (T), patient selection criteria, special monitoring requirements, and magnetic resonance (MR) scan limitations. Several companies outside the United States also have conditional MR labeling for both TV-PMs and TV-ICDs. The FDA believes that unconditional or *MR safe* labeling of CIEDs for MR scanning is unlikely.[18] Devices from Medtronic with "MR Conditional" labeling have a unique x-ray identifier (Fig. 5.4H). Pacing-dependent patients remain at increased risk,[19] and most centers will not perform any MRI on a pacing-dependent patient with an ICD.

Pacemakers

Since 1958, more than 3000 pacemaker models have been marketed in the United States alone. Determining the actual number of implants and prevalence of devices is difficult. A variety of economic and market reports suggest that more than 300,000 adults and children in the United States underwent pacemaker placement (new or revision) in 2014. It is likely that well over 3 million patients in the United States have pacemakers today. Many factors lead to confusion regarding the behavior of a device and the perioperative care of a patient with a device, especially since case reports, textbooks, and literature reviews have not kept pace with technologic developments, and many of these reviews contain incorrect statements.[20,21] In addition, sometimes the preoperative consultation process leads to improper advice as well.[22] Furthermore, a patient might have a very old but possibly still functioning pacing system.

Whether a patient with a pacemaker has significant comorbid disease remains to be investigated. However, the care of these patients requires attention to both their medical and psychologic problems. Additionally, an understanding of pulse generators and their likely idiosyncrasies in the surgical unit or procedure room is needed. Whether the patient with a pacemaker is at increased perioperative risk remains unknown, but two reports suggest that these patients deserve extra perioperative attention. In 1995, Badrinath and colleagues[23] retrospectively reviewed ophthalmic surgery cases in one hospital in Madras, India, from 1979 through 1988 (14,787 cases) and wrote that the presence of a pacemaker significantly increased the probability of a mortal event within 6 weeks postoperatively, regardless of the anesthetic technique. In 2008, Pili-Floury and colleagues[24] reported a prospective study of 65 consecutive patients undergoing any anesthetic for any invasive noncardiac procedure unrelated to their device. They found seven (11%) postoperative myocardial infarctions, two (3%) patients developed left ventricular failure, and two (3%) patients died of cardiac causes during their index hospitalization.

No discussion of pacemakers can take place without an understanding of the generic pacemaker code (North American Society of Pacing and Electrophysiology [NASPE]/British Pacing and Electrophysiology Group [BPEG] generic [NBG] code), last updated in 2002.[25] Shown in Table 5.2, the code describes the basic behavior of the pacing device. Pacemakers also come with a variety of terms generally unfamiliar to the anesthesiologist, many of which are shown in the glossary at the end of this chapter.

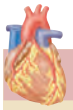
Pacemaker Indications

Common indications for permanent pacing are shown in Box 5.1 and are reviewed in detail elsewhere.[26] Conventional pacing devices have been approved by the FDA for three-chamber pacing (right atrium, both ventricles) to treat dilated cardiomyopathy (DCM),[27,28] (also called biventricular [BiV] pacing or cardiac resynchronization therapy [CRT]). Additionally, specially programmed devices are used to treat hypertrophic obstructive cardiomyopathy (HOCM) in both adults and children.[29,30] BiV pacing and HOCM indications require careful attention to pacemaker programming, since effective pacing in these patients often requires a pacing rate greater than native sinus or junctional escape rate (often accomplished with drugs) and an atrioventricular (AV) delay shorter than the native P-R interval so that the ventricle is paced 100% of the time.[31] Inhibition or loss of pacing (ie, from native conduction, atrial irregularity, ventricular irregularity, development of junctional rhythm, or EMI) can lead to deteriorating hemodynamics in these patients. BiV pacing can lengthen the Q-T interval in some patients, producing torsade de pointes.[32] The newest CRT devices now include a programmable feature that initiates an immediate pace of the other ventricle upon a sensed ventricular event. One significant consequence of this feature is the possibility of inappropriate ventricular pacing in response to EMI.[33] Left atrial or biatrial pacing remains under clinical investigation to prevent atrial fibrillation.[34]

Pacemaker Magnets

Despite often-repeated folklore, most pacemaker manufacturers warn that magnets were never intended to treat pacemaker emergencies or to prevent EMI effects. Rather, magnet-activated switches, both electronic (Hall effect sensor, giant magnetoresistor) and mechanical (reed switch), were incorporated to produce pacing behavior that demonstrates remaining battery life and, sometimes, pacing threshold safety factors. Only rarely will magnet application increase pacing output; consequently, any patient who has an inadequate safety margin for myocardial depolarization might actually be harmed by magnet placement.[1]

Placement of a magnet over a generator might produce no change in pacing since *not all pacemakers switch to a continuous asynchronous mode when a magnet is placed*. The Medtronic "Micra" leadless IC-PM has no magnet sensor. Pacemakers might also be nonresponsive to magnet placement owing to programming (including the default



BOX 5.1 PACEMAKER INDICATIONS

Symptomatic bradycardia from sinus node disease
Symptomatic bradycardia from atrioventricular (AV) node disease
Long QT syndrome
Hypertrophic obstructive cardiomyopathy (HOCM)[a]
Dilated cardiomyopathy (DCM)[a]

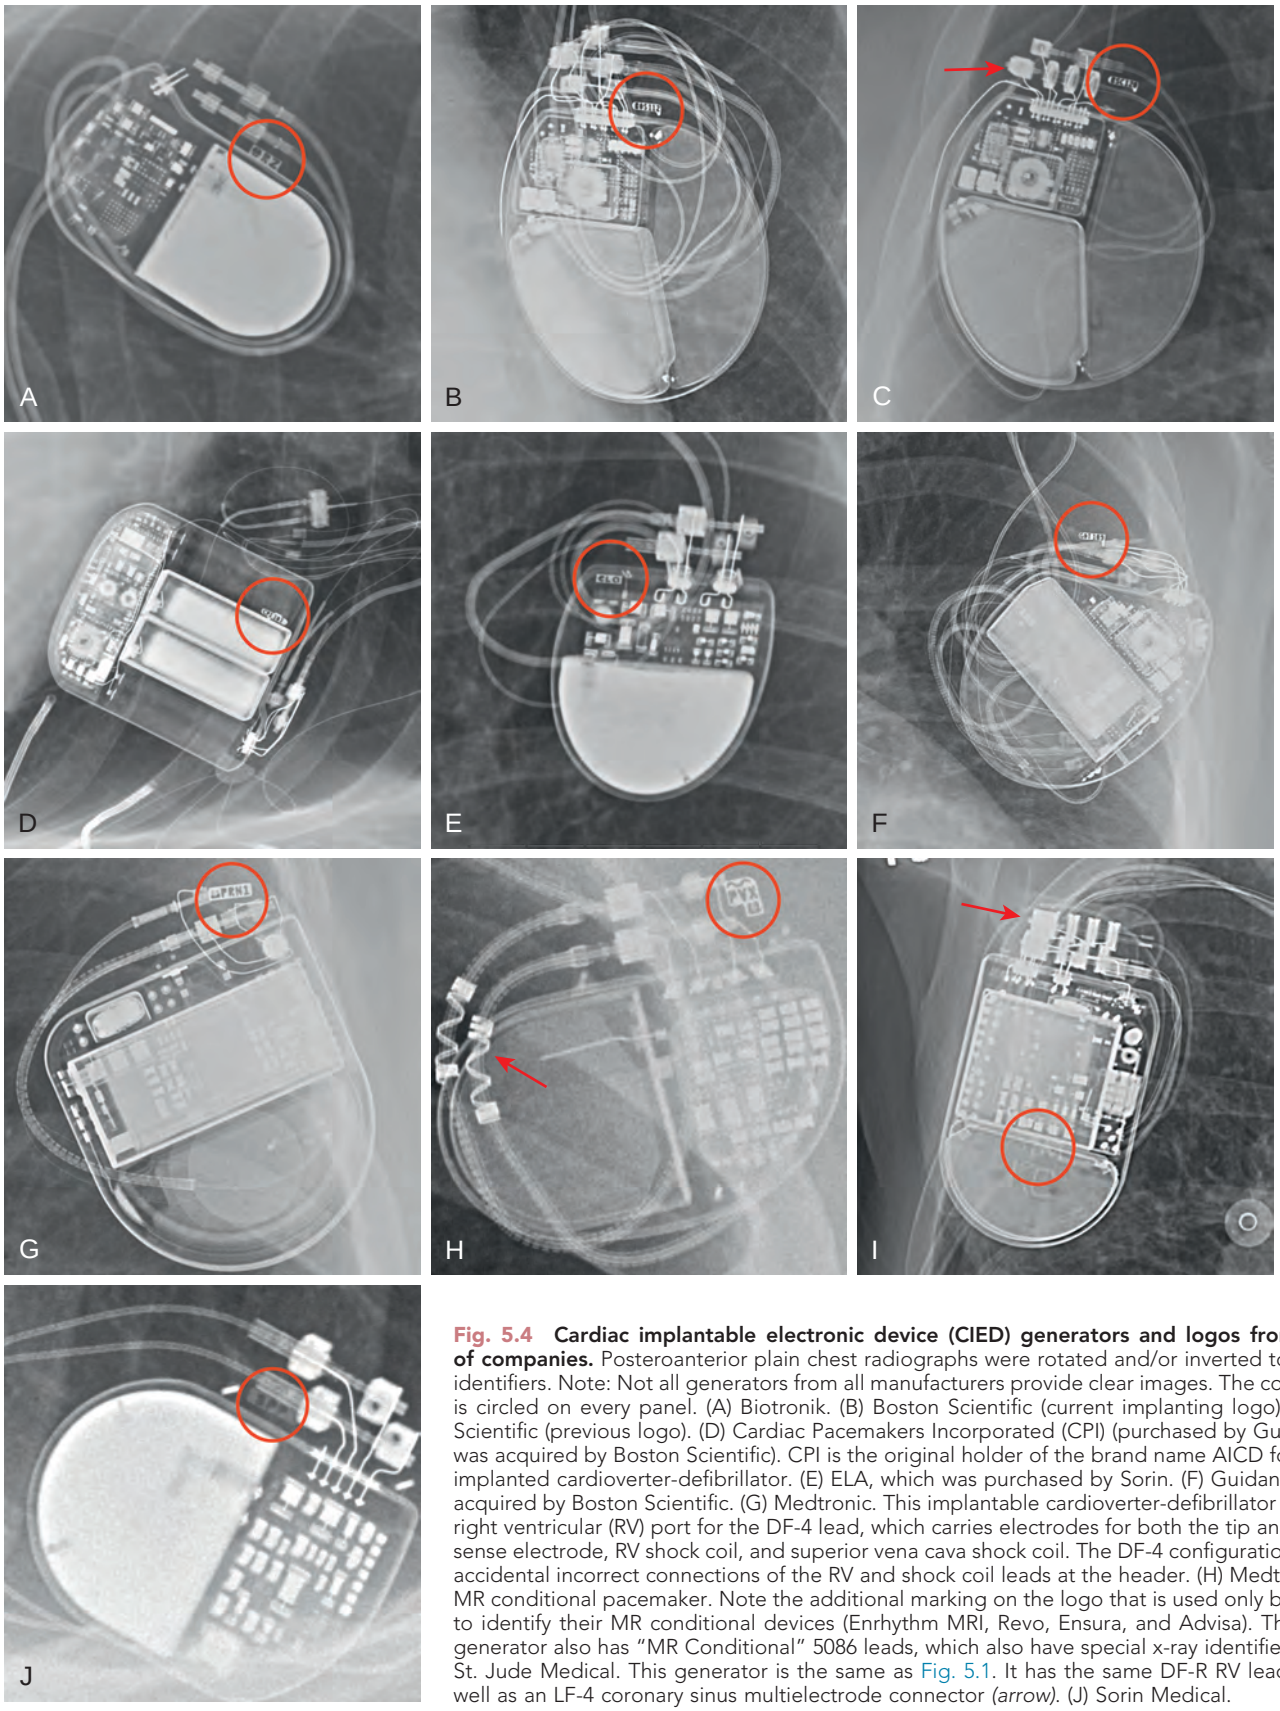

Fig. 5.4 Cardiac implantable electronic device (CIED) generators and logos from a variety of companies. Posteroanterior plain chest radiographs were rotated and/or inverted to show x-ray identifiers. Note: Not all generators from all manufacturers provide clear images. The company logo is circled on every panel. (A) Biotronik. (B) Boston Scientific (current implanting logo). (C) Boston Scientific (previous logo). (D) Cardiac Pacemakers Incorporated (CPI) (purchased by Guidant, which was acquired by Boston Scientific). CPI is the original holder of the brand name AICD for automatic implanted cardioverter-defibrillator. (E) ELA, which was purchased by Sorin. (F) Guidant, which was acquired by Boston Scientific. (G) Medtronic. This implantable cardioverter-defibrillator (ICD) has an right ventricular (RV) port for the DF-4 lead, which carries electrodes for both the tip and ring pace/sense electrode, RV shock coil, and superior vena cava shock coil. The DF-4 configuration eliminates accidental incorrect connections of the RV and shock coil leads at the header. (H) Medtronic Advisa MR conditional pacemaker. Note the additional marking on the logo that is used only by Medtronic to identify their MR conditional devices (Enrhythm MRI, Revo, Ensura, and Advisa). This particular generator also has "MR Conditional" 5086 leads, which also have special x-ray identifiers *(arrow)*. (I) St. Jude Medical. This generator is the same as Fig. 5.1. It has the same DF-R RV lead header, as well as an LF-4 coronary sinus multielectrode connector *(arrow)*. (J) Sorin Medical.

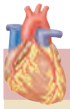

BOX 5.2 PACEMAKER MAGNET BEHAVIOR[a]

- Asynchronous pacing without rate responsiveness using parameters possibly not in the patient's best interest at 85–100 bpm (Asynchronous pacing is the most common behavior except for Biotronik pacemakers. All pacemakers manufactured by Biotronik, Boston Scientific, and St. Jude Medical have programmable magnet behavior.
- Unexpected behavior (eg, VOO pacing in Medtronic or VDD pacing in Biotronik dual-chamber pacemaker), suggesting elective replacement has been reached and the pacemaker should be interrogated promptly
- No apparent rhythm or rate change
- Magnet mode permanently disabled by programming (possible with Biotronik, Boston Scientific, St. Jude Medical) or temporarily suspended (see Medtronic)
- Program rate pacing in the patient who is already paced (many older pacemakers)
- Improper monitor settings with pacing near the current heart rate (pace filter on)
- No magnet sensor (Medtronic Micra leadless pacemaker, some pre-1985 Cordis, Telectronics models)
- Brief (10–100 bpm) asynchronous pacing, then return to program values (most Biotronik and Intermedics pacemakers)
- Continuous or transient loss of pacing
- Inadequate pacing output safety margin with failure to depolarize the myocardium
- Pacemaker enters diagnostic "Threshold Test Mode" (some Intermedics, Medtronic, St. Jude Medical devices, depending on model and programming)
- Discharged battery (some pre-1990 devices)

[a]Also see Appendix 5.1.

mode) or safety mode after an electrical reset from EMI or component failure. Although >90% of pacemakers have high-rate (85 to 100 bpm) asynchronous pacing with magnet application, some respond with only a brief (10 to 100 bpm) asynchronous pacing event, reverting to the original pacing mode and rate thereafter. Box 5.2 provides common magnet behavior for conventional pacemakers, and Appendix 5.1 shows complete magnet results for each manufacturer.

For all generators, calling the manufacturer remains the most reliable method for determining magnet response and using this response to predict remaining battery life. Only rarely can the manufacturer supply the actual custom programming of a device, and manufactures might be unwilling to commit to perioperative care without direct contact with a CIED physician. A list of telephone numbers is provided in Appendix 5.3 at the end of this chapter.

For generators with programmable magnet behavior (Biotronik [Berlin, Germany, US Headquarters Lake Oswego, OR], Boston Scientific, and St. Jude Medical [Syl Mar, CA]), only an interrogation with a programmer can reveal current magnet settings. As Appendix 5.1 shows, pacemaker magnet behavior remains unstandardized and complicated. Nevertheless, one group has published a method to identify the generator manufacturer from the magnet response, assuming completely normal behavior; that is, the device has not undergone elective replacement or a safety reset.[35]

Preanesthetic Evaluation and Pacemaker Reprogramming

Preoperative management of the patient with a pacemaker includes evaluation and optimization of coexisting disease(s). No special laboratory tests or radiographs (chest films are remarkably insensitive for determining most lead problems) are needed for the patient with a pacemaker. Such testing should be dictated by the patient's underlying disease(s), medication(s), and planned intervention. For programmable devices, interrogation with a programmer remains the only reliable method for evaluating lead performance and obtaining current program information. A chest film might be useful to identify the CIED manufacturer (see Fig. 5.4) or to document the position of the coronary sinus (CS) lead in a patient with a BiV pacemaker or defibrillator, especially if central venous catheter placement is planned, since spontaneous CS lead dislodgement was found in more than 11% of patients in early studies[36,37] without much improvement to date.[38] A chest radiograph is certainly indicated for the patient with a device problem discovered during their pacemaker evaluation. Costelloe and associates[39] have published several examples of common defects that can be identified with chest radiography, and Rozner[40] has shown several common presentations of x-ray–identifiable problems.

The prudent anesthesiologist will review the patient's pacemaker history and follow-up schedule. Before its name change to Heart Rhythm Society (HRS), the North American Society of Pacing and Electrophysiology (NASPE) published a consensus statement suggesting that pacemakers should be routinely evaluated with telephone checks for battery condition at least every 3 months. This recommendation also included a comprehensive evaluation (interrogation) at least once a year with additional checks for devices implanted less than 6 or greater than 48 (dual chamber) or 72 (single chamber) months.[41] Updated recommendations continue to include some sort of pacemaker evaluation, whether in person or remote, every 3 to 12 months, depending on the clinical status and needs of the patient.[26,42]Multiple societies recommend against using industry-employed allied professionals without physician review.[43]

The literature contains sparse data about follow-up interval and perioperative patient outcomes. Failure to provide early follow-up after implantation increases the likelihood of death among all CIED patients[44] and TV-ICD patients,[45] whether or not perioperative outcomes are affected by recent versus late or no interrogation can be determined. Nevertheless, two reports suggest that perioperative patients have unmet CIED needs. In a series of 65 patients scheduled for anesthesia, Pili-Floury and colleagues[24] reported the need to reprogram in 12% of patients. In abstract form, Rozner and associates[46] reported a 2-year retrospective review of follow-up intervals in patients with pacemakers who presented for an anesthetic, finding that more than 32% of 172 patients presenting for an anesthetic at their hospital did not meet the HRS/NASPE guideline for comprehensive evaluation. They also reported that 5% of the patients presented for their anesthetic with a pacemaker in need of replacement for battery depletion, and nearly 10% of patients had less-than-optimal pacing settings.

The timing of any preoperative interrogation depends on the local practice and selection of a pacemaker advisory. The American Society of Anesthesiologists (ASA) recommends interrogation within 3 months of the procedure. HRS/ASA, Canadian Anesthesiologists Society (CAS)/Canadian Cardiovascular Society (CCS), and Medicines and Healthcare Products Regulatory Agency (MHRA) recommend review of CIED records and communication with the patient's CIED physician and clinic. For conventional pacemakers, HRS/ASA also recommends interrogation within 12 months of the procedure, shortening that period to 3 to 6 months for CRT devices.[47] Nevertheless, the evaluation of a CIED remains labor intensive, taking approximately 27 minutes in the absence of a problem.[48]

Important features of the preanesthetic device evaluation are shown in Box 5.3. Determining pacing dependency might require temporary reprogramming to a VVI mode with a low rate. In patients from countries where pacemakers might be reused,[49–51] battery performance might not be related to the length of implantation in the current patient. It should also be noted that in a registry of 345 pacemaker generator failures, 7% of failures were not related to battery depletion,[52] and Maisel and colleagues[11] reported a 12-year experience during which pacing systems failed (unrelated to battery depletion) at 0.5% per year.

Appropriate reprogramming (Box 5.4) might be the safest way to avoid intraoperative problems, especially if monopolar Bovie electrosurgery will be used. For lithotripsy, consideration should be given to programming the pacing function out of an atrial-paced mode, as some lithotriptors are designed to fire on the R wave, and the atrial

BOX 5.3 PREANESTHETIC PULSE GENERATOR (PACEMAKER, IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR) EVALUATION

Determining the indication for and the date of initial device placement
Identifying the number and types of leads
Determining the last generator test date and battery status
Obtaining a history of generator events (if any)
Obtaining the current program information (device interrogation)
Ensuring that generator discharges become mechanical systoles with adequate safety margins
Ensuring that magnet detection is enabled
Determining whether the pacing mode should be reprogrammed

BOX 5.4 PACEMAKER REPROGRAMMING PROBABLY NEEDED

Any rate responsive device (Problems are well known,[177,178] problems have been misinterpreted with potential for patient injury,[65,67,179,180] and the FDA has issued an alert regarding devices with minute ventilation [MV] sensors [see Box 5.5 for pacemakers with MV sensors].[73])
Special pacing indication (hypertrophic obstructive cardiomyopathy [HOCM], dilated cardiomyopathy [DCM], pediatric patient)
Pacing-dependent patient
Major procedure in the chest or abdomen
Special Procedures (see Box 5.6)

pacing stimulus could be misinterpreted as the contraction of the ventricle.[53]

Whether CIED manufacturers stand ready to assist with this task or whether this task should be performed by industry-employed affiliated personnel remains controversial (see Appendix 5.3 for company telephone numbers). Reprogramming a pacemaker to asynchronous pacing at a rate greater than the patient's underlying rate usually ensures that EMI will not affect pacing. Reprogramming to asynchronous pacing *will not* protect it from internal damage or reset caused by EMI.

Experts do not agree on the use of asynchronous pacing. Setting a device to asynchronous mode to prevent inappropriate oversensing and ventricular output suppression can cause the CIED to ignore premature atrial or ventricular systoles, which could have the potential to create a malignant rhythm in the patient with significant structural compromise of the myocardium.[54] Reviews by Stone and McPherson,[55] as well as Rozner,[56] and several case reports[57–60] demonstrate inappropriate R-on-T pacing with the development of a malignant ventricular rhythm. Hayes and Strathmore[61] suggest the VVT mode for the pacing-dependent patient, since EMI will generally increase the pacing rate rather than inhibit the pacing output. However, they do not consider the upper pacing rate for this mode. Although some pacemakers (Boston Scientific) limit VVT pacing rates to the maximum tracking rate, others (Medtronic Corporation, Minneapolis, MN) will pace to the lower of the runaway pacing rate (typically around 200 bpm) or the minimum V-V interval defined by the ventricular refractory period, which is typically 200 msec (representing 300 bpm). There are two other caveats for this mode. For the patient with a dual-chamber device and in need of AV synchrony to sustain cardiac output, hemodynamics might be compromised during VVT operation, since ventricular pacing will take place without regard to atrial activity. Additionally, considerable increases and decreases in paced rate could result during EMI if the pacing device does not include rate smoothing. If VVT

BOX 5.5 PACEMAKERS WITH MINUTE VENTILATION (BIOIMPEDANCE) SENSORS

Boston Scientific/Guidant/Cardiac Pacemakers, Inc. (CPI)—All "BSC" labeled (x-ray) pacemakers except CRT-P; Altrua 40 or 60 (S401, S402, S403, S404, S601, S602, S603, S606); Insignia Plus or Ultra (1190, 1194, 1290, 1291, 1297, 1298); Pulsar, Pulsar Max I and II (1170, 1171, 1172, 1180, 1181, 1270, 1272, 1280). Note: Outside the United States "BSC" labeled (x-ray) CRT-P, TV-ICD, and CRT-D have programmable bioimpedance sensor technology.

reprogramming is to be considered, then the manufacturer should be contacted regarding programming for the upper rate.

In general, rate responsiveness and other enhancements (eg, hysteresis, sleep rate, AV search) should be disabled by programming, since many of these can mimic pacing system malfunction (Fig. 5.5).[62–65] Mechanisms to reduce or prevent RV pacing, present in both pacemakers and TV-ICDs, include algorithms that allow dropped QRS events or demonstrate profound second-degree Mobitz I block (RhythmiQ, Boston Scientific; Managed Ventricular Pacing, Medtronic; Ventricular Intrinsic Preference, St. Jude Medical; AAISafeR, Sorin).

Note that for many CPI-logo Boston Scientific devices, the physician's manual recommends increasing the pacing voltage to "5 volts or higher" in cases in which the monopolar ESU unit will be used. In 1986, Levine and associates[66] noted an increase in the amount of energy required to pace the ventricle (ie, a pacing threshold increase) in the setting of intrathoracic surgery and monopolar ESU use. Both Pili-Floury and colleagues[24] and Rozner and associates[46] have reported increases in atrial (Rozner only) and ventricular (both reports) pacing thresholds after surgeries involving pacemaker (but not TV-ICD) cases in which monopolar ESU was used, large volume and blood shifts were observed, or both. Although many of the surgeries were thoracic explorations, no pacing threshold changes were noted for these cases. No cardiopulmonary pump cases were reviewed in these cohorts.

Special attention must be given to any device with a minute ventilation (bioimpedance) sensor (Box 5.5), since inappropriate tachycardia, sometimes with treatment leading to patient injury, has been observed secondary to mechanical ventilation,[67,68] monopolar Bovie ESU,[67,69,70] and connection to an electrocardiographic (ECG) monitor with respiratory rate monitoring.[71–73]

Intraoperative (or Procedure) Management

No special monitoring or anesthetic technique is required for the patient with a pacemaker. However, monitoring of the patient must include the ability to detect mechanical systoles, since EMI, as well as devices such as a nerve stimulator, can interfere with QRS complex and pacemaker spikes on the ECG.[74] To demonstrate pacing pulses, most ECG monitor filtering must be changed to eliminate or reduce high-frequency filtering. However, the Medicines and Healthcare Products Regulatory Agency (MHRA) cautions that ECG monitors can misinterpret these pacing artifacts as QRS complexes and therefore display a

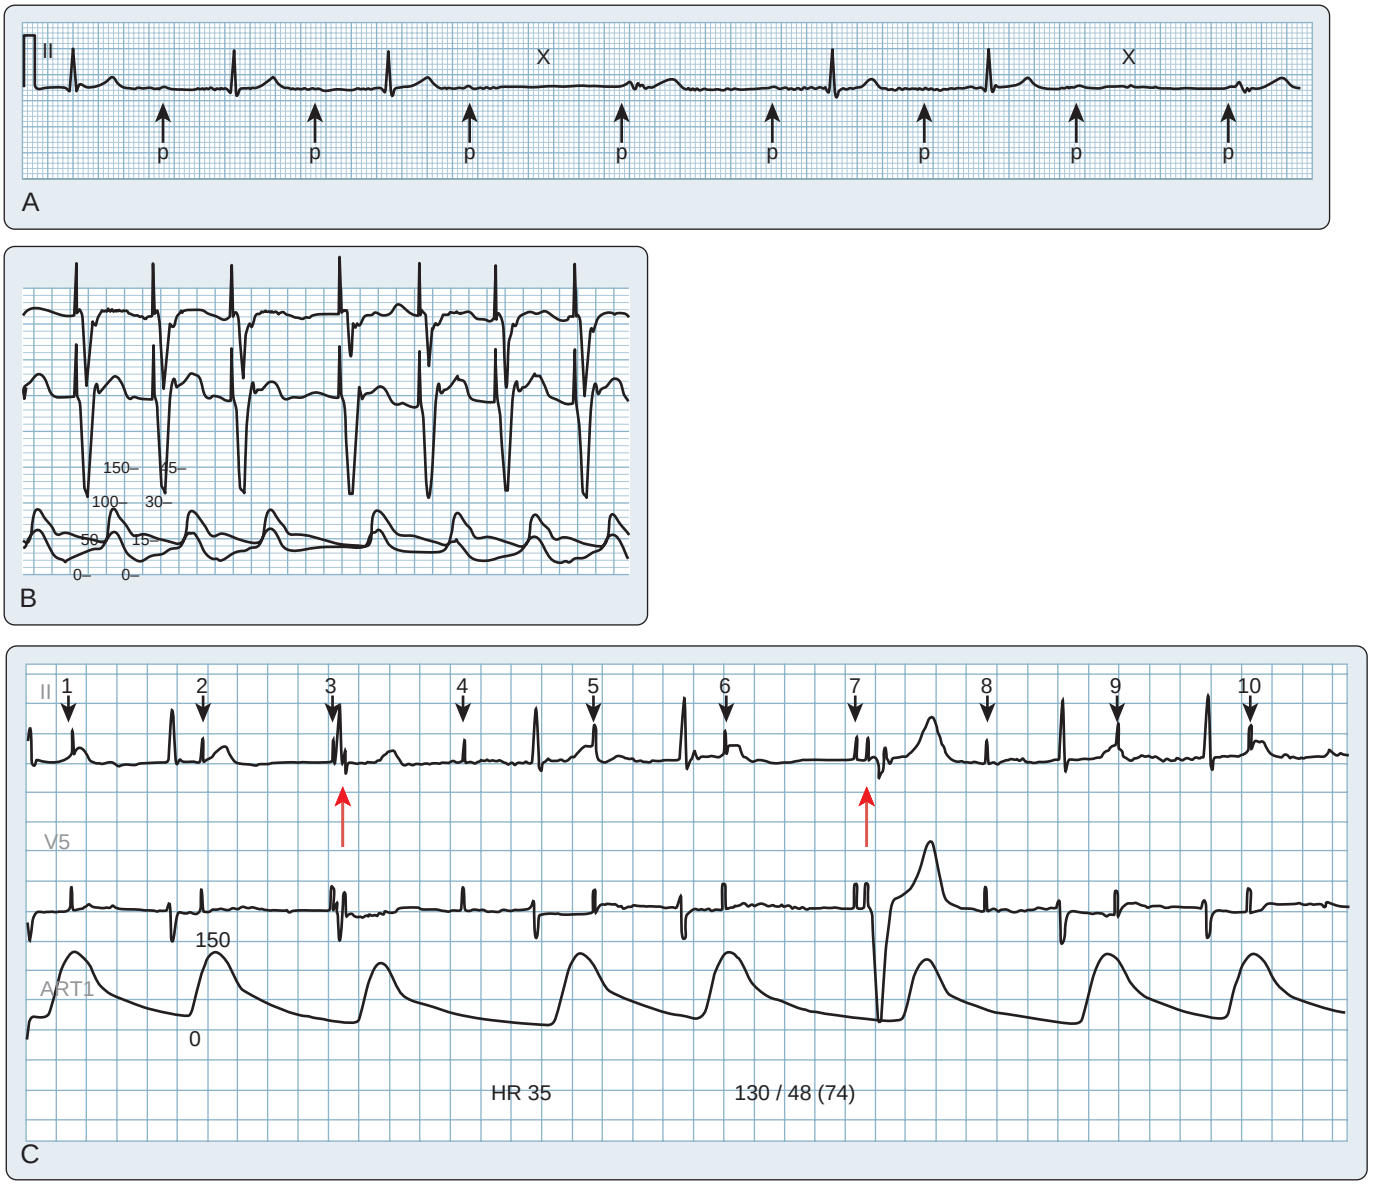

Fig. 5.5 (A) The feature "managed ventricular pacing" mimics pacing system malfunction. This patient has a sinus rate of 50 bpm and a native PR interval of nearly 500 msec. Her Medtronic pacing device was set to AAIR-DDDR (called *managed ventricular pacing* [MVP]), which does not pace the ventricle in response to an atrial event until a native QRS is not conducted (dropped). The next atrial event will be followed by an immediate (60 msec) paced QRS. This figure shows two such events *(X)* after the third and seventh P waves. The subsequent paced QRS morphologic axis is nearly orthogonal to the sensing axis, which is labeled (but might not actually be) lead 2, depending on the placement of the actual leads. MVP does not permit two consecutive dropped QRS events, and if two of any four QRS events are dropped, then the pacing device paces in DDD mode for at least 1 minute before resuming MVP. However, since oversensing from monopolar electrosurgery can convince a pacing device that ventricular systoles are present, a patient with atrioventricular (AV) nodal disease undergoing surgery with monopolar electrosurgery could demonstrate many dropped QRS events. (B) The feature "search hysteresis" mimics pacemaker malfunction. This patient has a single chamber VVI pacemaker set to a lower rate of 70 bpm. It was placed for complete AV block. This programmable feature causes the pacemaker to delay pacing every 256th event for 1400 msec (equal to a rate of 50 bpm). This delay in pacing is shown between the third and fourth QRS complexes. From top to bottom, the tracings are Lead II, Lead V_5, the invasive arterial pressure, and the central venous pressure. Hysteresis (where the pacemaker delays pacing after an intrinsic event) and Search Hysteresis often confuse caregivers regarding pacemaker malfunction (called *pseudomalfunction*). This electrocardiographic tracing could also result from ventricular oversensing, usually related to the T wave. (C) This strip from an implantable cardioverter-defibrillator (ICU) bedside monitor (GE Medical, Hartford, CT) demonstrates typical monitor misreporting of heart rate in the setting of pacing. In this case, the perfused heart rate is approximately 55 bpm, but the monitor has recorded a bradycardia alarm at 35 bpm. This patient also has a profound first-degree AV block, second-degree heart block Mobitz type I (Wenckebach), and pacing system pseudomalfunction owing to managed ventricular pacing (as in A). The third P pace *(numbered down arrows)* occurred without an intervening QRS from the prior P pace, which caused the MVP mechanism to emit a ventricular pace *(up arrows)*. However, the postatrial ventricular blanking caused the pacemaker to functionally undersense the native QRS. To prevent R-on-T pacing, Medtronic MVP issues the backup ventricular pulse 60 msec after the atrial event. No QRS occurred after P pace #6; consequently, another MVP 60 msec sequence was emitted at P pace 7. In this event, the right ventricular pace depolarized the right ventricle. The atrial pace on the QRS at P wave pace #3 is called *pseudo-pseudo fusion pacing*.

nonzero heart rate for an asystolic patient.[7] Mechanical systoles are best evaluated by pulse oximetry, plethysmography, or arterial waveform display; at least one of these monitoring modalities is recommended for these cases by both ASA and HRS/ASA advisories.[10,47] Fig. 5.5C shows underreporting of the ECG heart rate in a paced patient.

Some patients might need an increased pacing rate during the perioperative period to meet an increased oxygen demand. Although many modalities currently exist to evaluate myocardial oxygen delivery, none have been systematically tested in pacing patients.

With respect to anesthetic technique, no studies have championed one technique over another. Nevertheless, a number of reports of prolongation of the QT interval with the use of isoflurane or sevoflurane have been published. Halothane appears to reduce this interval.[75–79] No interactions have been reported for enflurane or desflurane. Drugs such as high-dose opiates and dexmedetomidine suppress underlying rhythms, possibly rendering a patient pacing dependent and reducing any margin of safety for pacing system failure.

Monopolar Bovie ESU use remains the principal intraoperative issue for the patient with a pacemaker. For the 12 years ending in 1997, the FDA was notified of 456 adverse events with pulse generators, 255 from ESU, and a "significant number" of device failures. Although this FDA User Facility Reporting Bulletin is no longer available, EMI from monopolar ESU likely remains the most common form of medically induced EMI in the hospital environment. Monopolar ESU is more likely to cause problems than bipolar ESU, and patients with unipolar electrode configuration are more sensitive to EMI than those with bipolar configurations. Coagulation ESU will likely cause more problems than nonblended "cutting" ESU.[80,81] Additionally, the dispersive electrode should be placed such that the presumed current path from the hand tool to the electrode does not cross the chest.[80] No data have been published regarding the safety of a whole-body dispersive electrode.

Spurious reprogramming of any CIED manufactured after 1995 from EMI should be nearly impossible, but strong EMI can produce an electrical reset or inappropriate detection of battery depletion, which might change the programming mode and/or rate. If monopolar ESU is to be used, then the dispersive electrode should be placed to ensure that the presumed current path does not cross the pacemaker system. For cases such as head and neck surgery, the electrode might be best placed on the shoulder contralateral to the implanted device. For breast and axillary cases, the electrode might need to be placed on the ipsilateral arm with the wire prepped into the field by a sterile plastic cover. Procedures with special pacing ramifications are shown in Box 5.6.

The use of an ultrasonic cutting device, commonly called a *harmonic scalpel*, has been championed to prevent EMI while providing the surgeon with the ability to cut and to coagulate tissue. A number of case reports have demonstrated successful surgery without EMI issues in these patients.[82–85]

MRI deserves special mention. In general, MR examinations have been contraindicated in patients with a pacemaker or TV-ICD.[86,87] However, a landmark paper showing that MRI could be safely conducted in some patients has led to the performance of MRI evaluations in these patients,[88] and several centers throughout the world perform MR scanning as an off-label procedure.[16] Nevertheless, not all MR sequences and energy levels have been studied; therefore judicious monitoring and caution are advised, and the FDA is unlikely to permit unlimited and unmonitored MR examinations.[18,89] Both Medtronic (Enrhythm MRI, Revo, Ensura, Advisa) and Biotronik (Entovis, Eluna) currently manufacture pacemaker systems with MR conditional labeling in the United States. Several manufacturers have "MR Conditional" devices in clinical trial and devices labeled for MR examinations in countries outside the United States.

Pacemaker Failure

Pacemaker failure has three causes: (1) failure of capture, (2) lead failure, or (3) generator failure. Failure of capture attributable to a defect at the level of the myocardium (ie, the generator continues to fire but no myocardial depolarization takes place) remains the most difficult problem to treat. Myocardial changes that result in noncapture include myocardial ischemia or infarction, acid-base disturbances, electrolyte abnormalities, or abnormal levels of antiarrhythmic drug(s). Temporary pacing—transvenous, transcutaneous, transthoracic, or transesophageal—might inhibit pacemaker output at voltages that will not produce myocardial capture.[90] Sympathomimetic drugs generally lower pacing threshold. Outright generator and lead failures are rare.

BOX 5.6 SPECIAL PROCEDURES IN PATIENTS WITH IMPLANTABLE GENERATORS

Lithotripsy. Is acceptable with precautions to protect the generator and, possibly, with programming out of an atrial pacing mode.[53]

Transurethral resection and uterine hysteroscopy. Procedures using monopolar electrosurgery can be easily accomplished after device reprogramming.

Magnetic resonance imaging (MRI). Several companies have MRI conditional labeling for transvenous pacemakers (TV-PMs) (inside and outside of the United States), as well as transvenous implantable cardioverter-defibrillators (TV-ICDs) (outside of the United States only). MRI examinations in any patient with a cardiac implantable electronic device (CIED) requires special personnel capable of rhythm interpretation and immediate CIED reprogramming, as well as monitoring equipment capable of providing electrocardiographic (ECG) and pulse oximeter plethysmographic monitoring from inside the magnetic resonance suite. Patient selection is limited, and most centers currently refuse pacing-dependent patients with implantable cardioverter-defibrillators (ICDs).

Electroconvulsive therapy. This therapy possibly requires asynchronous (nonsensing) pacing mode.[181]

Nerve stimulator testing and therapy. Inappropriate detection of transcutaneous electrical nerve stimulation (TENS), as well as neuromuscular and chiropractic electrical muscle stimulation, as ventricular tachycardia or ventricular fibrillation has been reported.[182,183]

Temporary Pacemakers

Several techniques are available to the anesthesiologist to establish reliable temporary pacing during the perioperative period or in the intensive care unit.[91] Cardiovascular anesthesiologists are more likely than generalists to routinely used temporary transvenous or epicardial pacing in their practices. Temporary cardiac pacing can serve as definitive therapy for transient bradyarrhythmias or as a bridge to permanent generator placement.

The various forms of temporary pacing include many transvenous catheter systems, transcutaneous pads, transthoracic wires, and esophageal pacing techniques. This section reviews the indications for temporary cardiac pacing and discusses the techniques available to the anesthesiologist. Many of the references in this section are old, since temporary pacing is an old technique and not many advances have taken place in the past 10 to 15 years. Table 5.3 summarizes these techniques.

Regardless of temporary modality, most implantable pacemakers or ICDs need to be reprogrammed when placing a transvenous pacing device. Electrical energy entering the body from a temporary pacing device can be sensed by the permanent device on the atrial lead, the ventricular lead, or both. Energy sensed on a ventricular lead can result in an inappropriate shock from any ICD or pacing inhibition from a pacemaker or TV-ICD. Pacing inhibition in a pacing-dependent patient will produce asystole. If energy enters the CIED on the atrial lead in a dual-chamber device, then rapid ventricular pacing might result (intrinsic atrial rate plus temporary atrial rate). The CIED might

TABLE 5.3 Comparison of Temporary Pacing Techniques

Temporary Pacing Method	*Time to Initiate*	*Chambers Paced*	*Advantages*	*Disadvantages*	*Uses*
Transcutaneous	1–2 minutes	Right ventricle	Simple, rapid, safe	Variable capture, chest wall movement, patient discomfort	Arrest, intraoperative, prophylactic
Transesophageal	Minutes	Left atrium	Reliable atrial capture, safe, simple	Requires special generator	Prophylactic atrial pacing, overdrive pacing for supraventricular tachyarrhythmias, monitoring atrial electrogram
Transvenous semirigid	3–20 minutes	Atrium and/or ventricle	Most reliable, well-tolerated	Invasive, time consuming, potential complications	Arrest, prophylactic, maintenance
Transvenous flow-directed	3–20 minutes	Right ventricle	Simple, does not require fluoroscopy	Invasive, stability questions, less readily available	Arrest, intraoperative, prophylactic, maintenance
Pacing pulmonary artery catheter (PAC)	Minutes (if PAC is in place)	Atrium and/or ventricle	Reliable ventricular capture, well-tolerated	Requires specific PAC, which must be placed first	Arrest, intraoperative, prophylactic, maintenance
Epicardial pacing Wires	<1 minute	Atrium and/or ventricle	Reliable short-term	Postoperative only, early lead failure	Arrest, prophylactic, maintenance
Transthoracic	10-60 seconds	Ventricle	Rapid and simple	Many potential complications	Arrest only

detect an atrial arrhythmia condition, resulting in ventricular pacing only, which might produce untoward hemodynamic effects.

Temporary Pacing Generator

Several companies market a variety of single- and dual-chamber temporary external pacing generators. Many dual-chamber generators permit AV programming that might not be in the best interest of the patient, and these inappropriate parameters might be accepted without warning by the generator.[58] For example, a commonly practiced, but clearly off-label use, involves the programming of a dual chamber (ie, DDD) pacing mode in a system with no functional atrial lead. Because the generator cannot detect the lack of an atrial lead, it will issue an atrial pacing stimulus when deemed appropriate. During the period of postatrial ventricular blanking, the generator cannot sense on the ventricular lead while pacing on the atrial lead; consequently, any spontaneous ventricular event taking place within 20 to 60 msec of the atrial pace will not be sensed. As a result, a ventricular stimulus will be delivered approximately 200 msec later, creating an R-on-T pace that can initiate ventricular tachycardia (VT).[57]

Indications for Temporary Pacing

Temporary pacemakers are commonly used after cardiac surgery[92] in the treatment of drug toxicity resulting in arrhythmias, with certain arrhythmias complicating myocardial infarction, and for intraoperative bradycardia attributable to beta blockade. On occasion, the placement of a temporary pacing system can assist in hemodynamic management in the perioperative period. Abnormal electrolytes, preoperative beta-blocker use, and many of the intraoperative drugs have the potential to aggravate bradycardia and bradycardia-dependent arrhythmias.[93] Because drugs used to treat bradyarrhythmias have a number of important disadvantages compared with temporary pacing, hemodynamically unstable perioperative bradyarrhythmias should be considered an indication for temporary pacing (Table 5.4). If the patient already has epicardial wires or a pacing catheter or wires, or transesophageal pacing is feasible, then pacing is preferred to pharmacologic therapy. However, transcutaneous and ventricular-only transvenous pacing, even if feasible, may exacerbate hemodynamic problems in patients with heart disease, because these pacing modalities do not preserve AV synchrony (ie, produces ventricular or global activation).

Nearly every indication for a permanent pacemaker is an indication for temporary pacing in patients without a pacemaker who, because of circumstances (eg, emergency surgery, critical illness) cannot have elective permanent pacemaker implantation. Temporary pacing may also be needed before the implantation of a permanent pacemaker to stabilize patients with hemodynamically significant ventricular bradycardia.

TABLE 5.4 Temporary Pacing Indications

Patient Condition	*Event Requiring Temporary Pacing*
Acute myocardial infarction (AMI)	Symptomatic bradycardia, medically refractory New bundle branch block with transient complete heart block Complete heart block Postoperative complete heart block Symptomatic congenital heart block Mobitz II with AMI New bifascicular block Bilateral bundle branch block and first-degree AV block Symptomatic alternating Wenckebach block Symptomatic alternating bundle branch block
Tachycardia treatment or prevention	Bradycardia-dependent VT Torsade de pointes Long QT syndrome Treatment of recurrent supraventricular tachycardia or VT
Prophylactic	Pulmonary artery catheter placement with left bundle branch block (controversial) New AV block or bundle branch block in acute endocarditis Cardioversion with sick sinus syndrome Postdefibrillation bradycardia Counteract perioperative pharmacologic treatment causing hemodynamically significant bradycardia AF prophylaxis postcardiac surgery Postorthotopic heart transplantation

AF, Atrial fibrillation; AV, atrioventricular; *VT,* ventricular tachycardia.

Temporary pacing is also indicated if a patient with a myocardial infarction complicated by second- or third-degree heart block is scheduled for emergency surgery. Bifascicular block in an asymptomatic patient is not reason enough for temporary pacing preoperatively.[94] Bellocci and colleagues[95] reported no occurrence of complete heart block in 98 patients with preoperative bifascicular block undergoing general anesthesia, despite 14% having prolonged conduction through their His-Purkinje system. The development of new bifascicular block preoperatively, though, suggests perioperative myocardial ischemia or infarction, and temporary pacing might be required. Surgical resection of neck and carotid sinus tumors may give rise to bradyarrhythmias, which require temporary cardiac pacing during surgical manipulation. Neurosurgical procedures involving the brainstem may also be associated with significant bradycardia.

Temporary antitachycardia pacing (ATP) is most commonly used after cardiac surgery.[96] With increased availability of effective noninvasive pacing technology, ATP might be offered to other perioperative patients as well. Even when used properly, these techniques can induce more dangerous arrhythmias, and proper resuscitation equipment should be available.

Atrioventricular junctional tachycardia (AVJT) can occur after cardiopulmonary bypass, during which it could be a manifestation of reperfusion injury or possibly inadequate myocardial protection during the pump run. AVJT does not respond well to most drug therapy, although its rate (≤120 bpm in adults) may be slowed by β-adrenergic blockers or edrophonium. AVJT is best managed by atrial or AV-sequential overdrive pacing, because both of these modalities will preserve AV synchrony. Frequently, sinus rhythm resumes upon withdrawal of temporary pacing.

Most sudden-onset paroxysmal supraventricular tachycardia (PSVT) is initiated by a premature beat, which could be of atrial, AV junctional, or ventricular in origin. PSVT may be terminated by competitive, atrial "underdrive" pacing (paced rate < PSVT rate) if, by chance, an atrial capture beat interferes with the circulating wavefront perpetuating the tachycardia. By contrast, with overdrive pacing, PSVT is paced at a rate 10% to 15% in excess of the tachycardia rate until there is evidence of 1:1 capture with paced beats. Pacing is continued at this rate for 20 to 30 seconds, then gradually slowed to some predetermined rate, and finally terminated. As with all pacing modalities, a gradual reduction in pacing rate is recommended to reduce the risk of prolonged asystole when pacing is terminated in patients known to have sinus node dysfunction. If pacing fails to terminate PSVT, or PSVT produces circulatory collapse, then immediate direct current cardioversion is recommended.

Type I atrial flutter (flutter rate less than 320 to 340 bpm) is pace terminable, but type II flutter (more than 340 bpm) is not. Type I flutter is treated by atrial overdrive pacing at a rate 15 to 20 beats more than the flutter rate, which is increased by 10 to 20 bpm amounts if the first attempt is not successful. Once atrial capture is evident, pacing is continued for 20 to 30 seconds, and then slowed as for PSVT. Usually, overdrive pacing, with prompt restoration of normal sinus rhythm, can terminate type I atrial flutter.

Relative contraindications to transvenous ventricular pacing include digitalis toxicity with VT, tricuspid valve prostheses, or the presence of a coagulopathy. Pacing in the setting of severe hypothermia might induce ventricular fibrillation (VF) or alter the normal compensatory physiologic mechanisms to the hypothermia, although one prospective study in dogs using transcutaneous pacing suggests that pacing decreases rewarming time.[97] Atrial fibrillation, multifocal atrial tachycardia, and significant AV conduction system disease are relative contraindications to transvenous *atrial* pacing.

Transvenous Temporary Pacing

Transvenous cardiac pacing provides the most reliable means of temporary pacing. Temporary transvenous pacing is dependable and well-tolerated by patients. With a device that can provide both atrial and ventricular pacing, transvenous pacing can maintain AV synchrony and improve cardiac output. Disadvantages include the need for practitioner experience, time to place the wire(s) appropriately to provide capture, the potential complications of catheter placement and manipulation, and the need for fluoroscopy in many cases. Three different types of typical transvenous leads are shown in Fig. 5.6.

Rapid catheter position is most easily obtained by using the right internal jugular vein, even without fluoroscopy,[98] although a prudent practitioner might want to document the final position(s) of the catheters clearly. The left subclavian vein is also easily used in emergent situations. Other sites are often impassable without fluoroscopy. In addition, brachial and femoral routes can increase the frequency of lead dislodgments during motion of the extremities, especially during patient transport.

Once central access is obtained, the lead is guided into position using hemodynamic data (not possible with the simple bipolar lead catheter) or by fluoroscopic guidance. ECG guidance is less desirable. The right atrial appendage and RV apex provide the most stable catheter positions. Techniques for placement into these positions are part of cardiology training and are likely foreign to most anesthesiologists. When fluoroscopy is unavailable or in emergency situations, a flow-directed catheter can be attempted using ECG guidance. Once the right ventricle is entered, the balloon is deflated, if used, and the catheter is gently advanced until electrical capture is noted. Flow-directed catheters and a right internal jugular approach afford the shortest insertion times.[99] The reported incidence of successful capture in urgent situations without fluoroscopy ranges from 30% to 90%.[98,100,101]

Once catheters are positioned, pacing is initiated using the distal electrode as the cathode (negative terminal) and the proximal electrode as the anode (negative terminal). Ideally, the capture thresholds should be less than 1 mA and generator output should be maintained at three times threshold as a safety margin. In dual-chamber pacing, AV delays between 100 and 200 msec are used. Many patients are sensitive to this parameter. Cardiac output optimization with echocardiography and/or mixed venous oxygen saturation can be used to maximize hemodynamics when adjusting AV delay.[102] AV sequential pacing is clearly beneficial in many patients,[102–106] but starting emergency pacing with *ventricular* capture alone should be remembered. Interference of external pacemaker generators by walkie-talkies and cellular digital phones is a potential risk.[107,108] Radiofrequency scanning systems used to identify retained surgical material can interfere with pacing,[109,110] and some manufacturers recommend reprogramming to an asynchronous pacing mode. Clinicians should also be aware of all complications related to transvenous lead placement.[111]

Pacing Pulmonary Artery Catheters

The pulmonary artery AV-pacing thermodilution catheter (see Fig. 5.6C) was described by Zaidan[112] in 1983. It allows for AV-sequential pacing via electrodes attached to the outside of the catheter, as well as routine pulmonary artery catheter (PAC) functions. The combination of the two functions into one catheter eliminates the need for separate insertion of temporary transvenous pacing electrodes. However, several potential disadvantages exist with this catheter including: (1) varying success in initiating and maintaining capture,[112] (2) external electrode displacement from the catheter,[113] and (3) relatively high cost as compared with standard PACs. The Paceport PAC (see Fig. 5.6B) provides ventricular pacing with a separate bipolar pacing lead (Chandler probe), which allows for more stable ventricular pacing and hemodynamic measurements.[114] This catheter has been used for successful resuscitation after cardiac arrest during closed chest cardiac massage when attempts to capture with transcutaneous or transvenous flow-directed bipolar pacing catheters have failed. However, this unit does not provide the potential advantages associated with atrial pacing capability. The pulmonary artery AV Paceport adds a sixth lumen to allow the placement of an atrial J-wire, flexible tip bipolar pacing lead. Both of these Paceport catheters are placed by transducing the RV port to ensure correct positioning of the port 1 to 2 cm distal to the tricuspid valve. This position usually guides the ventricular wire (Chandler probe) to the apex where adequate capture should occur with minimal current requirements. Although ventricular capture is easily obtained, atrial capture can be more difficult and less reliable.[102] This catheter has been successfully used after cardiac surgery.[102,115] The atrial wire can be used to diagnose supraventricular tachyarrhythmias (SVTs) by atrial electrograms and to overdrive atrial flutter and reentrant SVTs.[116]

Transcutaneous Pacing

Transcutaneous pacing, first described by Zoll,[117] is readily available and can be rapidly implemented in emergency situations. Capture rate is variable, and the technique may cause pain in awake patients, but it is usually tolerated until temporary transvenous pacing can be instituted. It may be effective even when endocardial pacing fails.[118] Transcutaneous pacing continues to be the method of choice for prophylactic and emergent applications.[119]

Typically, the large patches are placed anteriorly (negative electrode or cathode) over the palpable cardiac apex (or V_3 lead location) and posteriorly (positive electrode or anode) at the inferior aspect of the scapula. The anode has also been placed on the anterior right chest with success in healthy volunteers.[120] The skin should be cleaned with

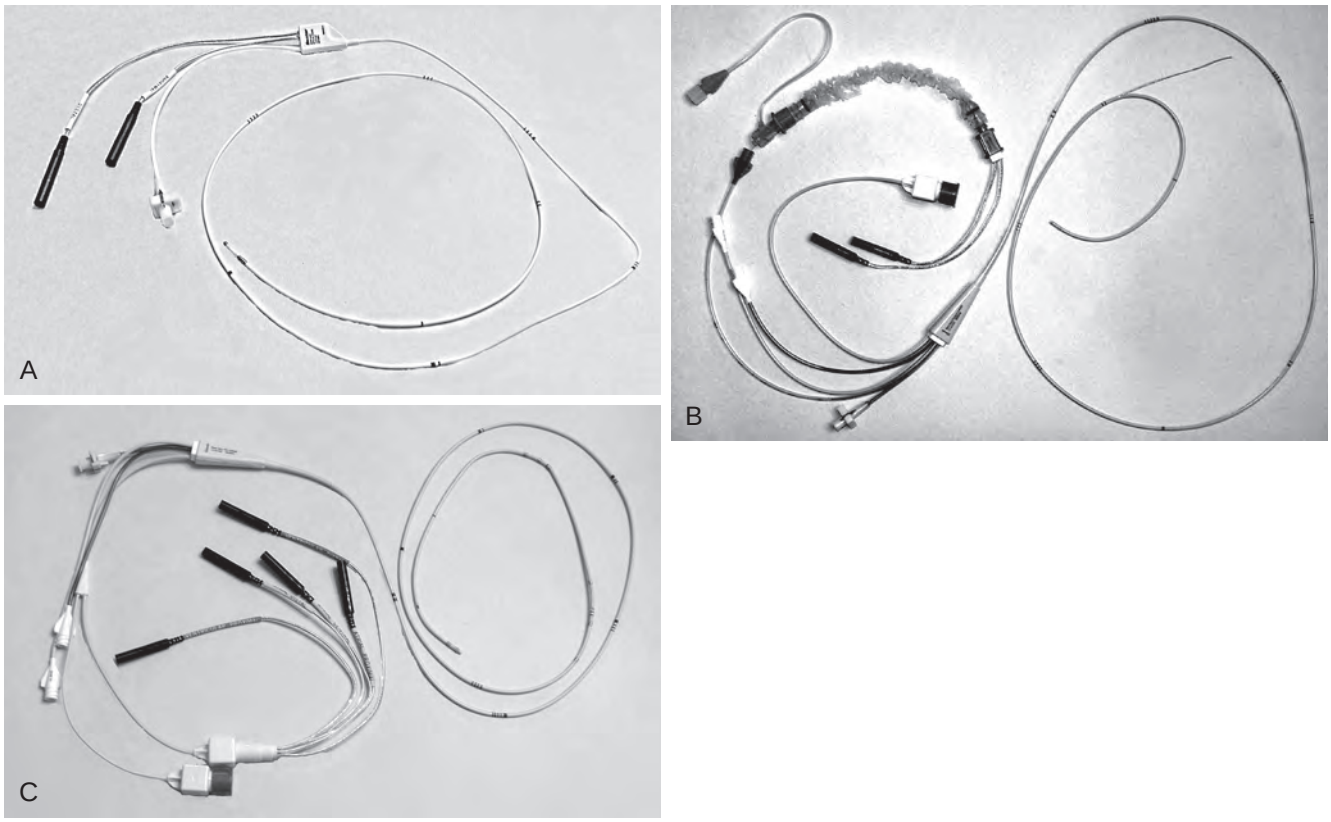

Fig. 5.6 A variety of transvenous pacing leads. (A) A simple, flow-directed, bipolar pacing wire is placed through a 6F introducer sheath and is advanced (usually under fluoroscopy) into the atrium or ventricle until mechanical systoles result from the electrical pacing event (called *pacing capture*). The principle disadvantage of this lead is the lack of hemodynamic measurements to guide placement. (B) A specially adapted pulmonary artery catheter (PAC) is shown with a channel for a bipolar, ventricular pacing wire. The bipolar pacing wire, side-port adapter, and condom are packaged separately from the PAC. Note that the electrode is protruding from its orifice just distal to the 20-cm mark on the PAC. (C) An atrioventricular (AV)–capable, pacing PAC is shown. Five electrodes are present: two for ventricular pacing and three for atrial pacing. This catheter is positioned to provide adequate ventricular capture, after which atrial pacing is attempted using two of the three atrial electrodes. Sometimes, the entire PAC must be repositioned to obtain atrial capture. In the setting of a functioning AV node, the presence of a narrow complex QRS after the atrial pace can determine atrial capture. In the setting of a significant AV block, atrial capture can be difficult to assess.

alcohol (but not abraded) to reduce capture threshold and improve patient comfort. Abraded skin can cause more discomfort. Typical thresholds are 20 to 120 mA, but pacing may require up to 200 mA at long pulse durations of 20 to 40 msec.[121] Transcutaneous pacing appears to capture the right ventricle, followed by near simultaneous activation of the entire left ventricle. The hemodynamic response is similar to that of RV endocardial pacing. Both methods can cause a reduction in left ventricular systolic pressure, a decrease in stroke volume, and an increase in right-sided pressures attributable to AV dyssynchrony. Palpation or display of a peripheral pulse should confirm capture. Maintenance current should be set at least 5 to 10 mA above threshold as tolerated by the patient. Success rates appear to be highest when the system is used prophylactically or early after arrest—upward of 90%.[122,123] When used in emergent situations, successful capture rates are usually lower but range from 10% to 93%.[124–126] This technique has also been used to terminate VT, AV nodal reentrant tachycardia, and AV-reciprocating tachycardia.[126,127]

Coughing and discomfort from cutaneous stimulation are the most frequent problems. The technique poses no electrical threat to medical personnel, and complications are rare. There have been no reports of significant damage to myocardium, skeletal muscle, skin, or lungs in humans, despite continuous pacing up to 108 hours and intermittent pacing up to 17 days.[117,122,128] Several commercially available defibrillators include transcutaneous pacing generators as standard equipment.

Esophageal Pacing

Another technique available to anesthesiologists is esophageal atrial pacing (EAP), and it has been shown to be quite reliable,[128–131] even in children.[132] However, EAP requires a functional, intact atrium and AV node; thus this modality should not be used in the patient with paroxysmal or persistent atrial fibrillation. EAP is relatively noninvasive and well-tolerated, even in the majority of awake patients, and it appears to be devoid of serious complications. This modality is useful for heart rate support of cardiac output, overdrive suppression of reentrant SVT, and for diagnostic atrial electrograms. Ventricular capture must be excluded before attempts at rapid atrial pacing for overdrive suppression to prevent potential VT or VF. Some surgical positions (eg, three-quarter prone) can increase the chance of unintentional ventricular capture.[133]

Problems with esophageal pacing include: (1) the necessity for special generators that must provide 20 to 30 mA of current with wide pulse widths of 10 to 20 msec, and (2) the ability to pace only the left atrium reliably and not the left ventricle, which can be a significant problem in emergency situations.[129] By comparison, typical temporary

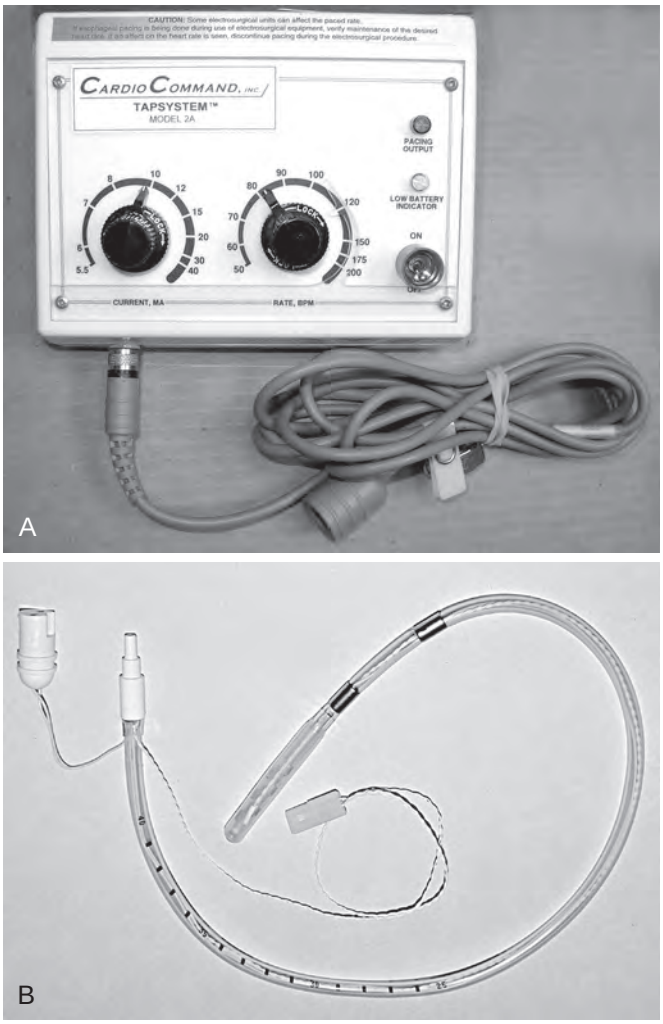

Fig. 5.7 A typical transesophageal pacing generator (A) and esophageal stethoscope with bipolar electrodes (B) are shown. The esophageal stethoscope is placed between 30 and 40 cm from the teeth, and pacing is initiated at a rate greater than the patient's native heart rate using an output setting of at least 20 mA. An increase in peripheral pulse rate determines atrial capture. Detection of capture using only electrocardiographic monitoring can be difficult to discern, as the pacing impulse from these generators produces a large artifact and often distorts the surface electrocardiogram.

generators designed for endocardial pacing have a maximum output of 20 mA with pulse width durations of only 1 to 2 msec.

A typical transesophageal pacing generator and lead are shown in Fig. 5.7. As noted in the figure, the pacing stimulus is delivered in asynchronous atrial-only mode through a modified esophageal stethoscope. AOO pacing is initiated by connecting the system and placing the esophageal stethoscope to a depth of 30 to 40 cm from the teeth. Capture should be confirmed using the peripheral pulse (ie, from the pulse oximeter, plethysmogram, or an invasive hemodynamic monitor) since the pacing stimulus is often large, relative to the QRS, and frequently fools the ECG counting algorithm on the monitor (Fig. 5.8). Atrial capture is obtained in virtually all patients using outputs of 8 to 20 mA, and the output should be set to two to three times the threshold for capture. Thresholds are not influenced by weight, age, atrial size, or previous cardiac surgery.[131]

Transesophageal *ventricular* pacing is generally unreliable, yet the optimal site appears to be 2 to 4 cm distal to the atrial site.[134] The esophageal pacing instrument can also be used (with a special adapter) to record the intraatrial electrogram.

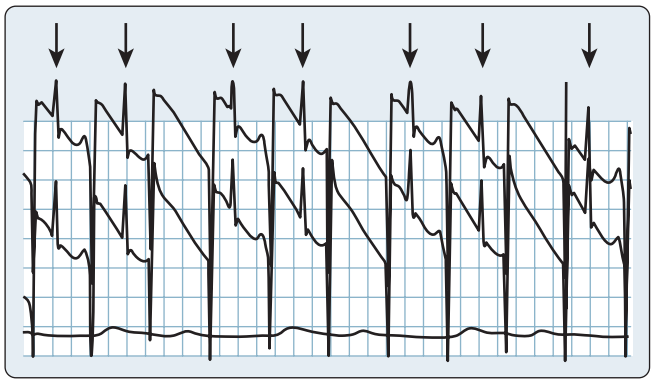

Fig. 5.8 An electrocardiographic strip from a patient with a transesophageal pacemaker demonstrates atrial capture and Wenckebach second-degree atrioventricular nodal block. An 84-year-old man with coronary artery disease and taking atenolol developed a sinus bradycardia (rate 37 bpm) with hypotension during a general anesthetic for transurethral bladder resection. An esophageal pacemaker was placed, and the rate was set to 85 bpm (AOO pacing mode). The top two tracings are electrocardiographic leads II and V5. The downward depolarization artifacts are the pacing stimuli from the esophageal pacemaker (15-mA output). The upward depolarization events are the QRS inscriptions *(downward arrows)*. Atrial P waves can be found shortly after the esophageal pulse. Note the lengthening PR interval with the dropped ventricular depolarizations. Also note how distorted the electrocardiographic signal becomes in the setting of an esophageal pacemaker. The third tracing is the pulse oximeter plethysmographic waveform. The small graticules (representing the 40-msec time points) and the monitor text were digitally removed from this strip to increase the contrast.

No long-term complications with this modality have been described. Induction of ventricular tachyarrhythmias during rapid atrial pacing has been noted. No significant esophageal trauma has been reported, despite long-term therapy of up to 60 hours.[135] Phrenic nerve stimulation has been described.[130]

Transthoracic Pacing

Transthoracic pacing has been used for over 35 years and involves the direct introduction of a pacing wire or needle through the thorax into the ventricular cavity. Several commercial kits are available, and even the use of a spinal needle has been described. The technique is rapid, simple, and does not require venous access or fluoroscopy. In contrast to other temporary pacing modalities, a large potential for misadventure exists and no study demonstrates any benefit in survival. Transcutaneous techniques have supplanted this procedure in essentially all situations.

Postanesthesia Pacemaker Evaluation

Any pacemaker that has been reprogrammed for the perioperative period should be reevaluated and programmed appropriately. For nonreprogrammed devices, most manufacturers recommend interrogation to ensure proper functioning and remaining battery life if any monopolar ESU was used. The ASA advisory recommends interrogation before discharging the patient from monitored care,[10] whereas the HRS/ASA statement suggests that immediate postoperative interrogation is needed only for hemodynamically challenging cases or when significant EMI occurs superior to the umbilicus while operating.[47]

Whether a patient with a pacemaker needs a postoperative evaluation continues to generate controversy. In their retrospective review, Trankina and colleagues[136] reported 6% of 169 patients showed a problem during postoperative checks of pacemakers. Senthuran and associates[137] suggested that failure to perform a postoperative pacemaker check led to an unexpected postoperative death in Great Britain, and both Pili-Floury and colleagues[24] and Rozner and associates[46]

reported perioperative pacing issues that could be found and mitigated at the postoperative check.

Implantable Cardioverter-Defibrillators

The development of an implantable, battery-powered device able to deliver sufficient energy to terminate VT or VF has represented a major medical breakthrough for patients with a history of ventricular tachyarrhythmias. These devices prevent death in the setting of malignant ventricular tachyarrhythmias,[138–140] and they clearly remain superior to antiarrhythmic drug therapy.[141,142] Initially approved by the FDA in 1985, the implantation rate currently exceeds 12,000 TV-ICDs per month in the United States,[143] averaging over 2500 for the 4 years of primary prevention from 2006 through 2010.[144] Industry sources report that more than 300,000 patients have these devices today.

A significant number of technologic advances have been applied since the first TV-ICD was placed, including considerable miniaturization (pectoral pocket placement with transvenous leads) and battery improvements that now permit permanent pacing with these devices. Thus confusing a pectoral ICD with a pacemaker is easy.

Similar to pacemakers, ICDs have a generic code to indicate lead placement and function, which is shown in Table 5.5[145] The most robust form of identification, called the *label form*, expands the fourth character into its component generic pacemaker code (NBG code, see Table 5.2).

All ICDs have many programmable features, but essentially they measure each cardiac R-R interval and categorize the rate as normal, too fast (short R-R interval), or too slow (long R-R interval). When the device detects a sufficient number of short R-R intervals within a period (all programmable), it will begin an antitachycardia event. For appropriately programmed TV-ICDs, the internal computer will decide and choose ATP (less energy use, better tolerated by the patient) or shock, depending on the presentation and device programming. S-ICDs do not perform ATP at this time. If shock is chosen, then an internal capacitor is charged.

Most ICDs are programmed to reconfirm VT or VF after charging to prevent inappropriate shock therapy. Some TV-ICDs will deliver immediate ATP while charging the capacitor in preparation for a shock. Typically, ICDs have six to eight therapies available for each type of event (VT, fast VT, VF), and some of these therapies can be repeated before moving to the next higher energy sequence. Thus ICDs can deliver many shocks per event. In any ICD with ATP, once a shock is delivered, no further ATP will take place.

Inappropriate shock therapy (IST) occurs in 20% to 40% of ICD patients, with shocks for rhythm other than VT or VF,[146–148] Atrial fibrillation with rapid ventricular response and supraventricular tachycardia remain the most common causes of inappropriate shock therapy,[149] although unmitigated hospital-induced EMI appears to play a role in more than 4% of all ISTs.[150] Whether inappropriate shocks injure patients remains a subject of considerable debate, but a significant number of patients who receive IST will demonstrate elevated troponin levels in the absence of an ischemic event,[151] and a death has been reported.[152] Additionally, any TV-ICD therapy (appropriate or inappropriate) has been associated with increased mortality, whether merely ATP[153] or shock.[154–156] Statin therapy might reduce the incidence of IST through a reduction in atrial fibrillation,[157] and dual-chamber ICD technology might reduce IST from atrial fibrillation as well. Programmable features in current ICDs to differentiate VT from a tachycardia of supraventricular origin include[158]:

1. Onset criteria. In general, the onset of VT is abrupt, whereas the onset of SVT has sequentially shortening R-R intervals.
2. Stability criteria. In general, the R-R interval of VT is relatively constant, whereas the R-R interval of atrial fibrillation with rapid ventricular response is quite variable.
3. QRS width criteria. Some ICDs measure the QRS width using the RV lead tip to ICD case-sensing pathway. In general, the QRS width in SVT is narrow (<110 msec), whereas the QRS width in VT is wide (>120 msec).
4. "Intelligence." Dual-chamber devices attempt to associate atrial activity with ventricular activity.
5. Morphology waveform analysis. Analysis of waveform structure is compared with stored historical templates.

Note that once the R-R interval becomes sufficiently short for VF detection, the ICD will begin a shock sequence. As previously noted, once the device delivers any shock therapy, no further ATP will take place.

An ICD with antibradycardia pacing capability will begin pacing when the R-R interval is too long. In July of 1997, the FDA approved devices with sophisticated dual-chamber pacing modes and rate responsive behavior for ICD patients who need permanent pacing (approximately 20% of ICD patients). Currently, S-ICDs provide antibradycardia pacing only after shock therapy.

Implantable Cardioverter-Defibrillator Indications

Initially, ICDs were placed for hemodynamically significant VT or VF. Newer indications associated with sudden death include: long QT syndrome, Brugada syndrome (right bundle branch block, S-T segment elevation in leads V_1–V_3), and arrhythmogenic RV dysplasia.[159] Recent studies suggest that ICDs can be used for primary prevention of sudden death (ie, before the first episode of VT or VF) in young patients with hypertrophic cardiomyopathy,[160] and data from the second Multicenter Automatic Defibrillator Intervention Trial (MADIT II) suggest that any post-MI patient with ejection fraction (EF) less than 30% should undergo prophylactic implantation of an ICD.[161] At the present time, however, the Centers for Medicare and Medicaid requires a prolonged QRS interval (greater than 120 msec) to qualify for ICD placement in this group. A review of 318,000 implants in patients over 65 years of age for the period 2006 to 2010 demonstrated improvements in 6-month all-cause mortality, 6-month rehospitalization rate, and device complications when compared with matched control subjects.[144]

Several trials have included patients with nonischemic cardiomyopathy, as well. Data from the "Sudden Cardiac Death in Heart Failure Trial" (SCD-HeFT)[142] and the "Defibrillators In Non-Ischemic Cardiomyopathy Treatment Evaluation" (DEFINITE)[162] study now suggest that ICD placement will lower mortality in any patient with EF less than 35%, regardless of the cause of the cardiomyopathy. The DEFINITE results are important, as these patients were randomized only after the initiation of beta-blockade and angiotensin-converting enzyme (ACE)–inhibitor therapy, which form the backbone of medical therapy for cardiomyopathy.

Three-chamber (leads placed in the right atrium, right ventricle, and CS) ICDs (see Fig. 5.1) for CRT (also called BiV pacing) have been FDA approved for patients with DCM and prolonged QRS intervals.

BOX 5.7 IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR INDICATIONS

Prophylactic use for patients with:
- Ischemic cardiomyopathy surviving 40 days and longer with EF of 30% or less and NYHA Class I or EF of 35% or less and NYHA Class II/III
- Nonischemic cardiomyopathy with an EF of 35% or less and NYHA Class II/III

Ventricular fibrillation or ventricular tachycardia from nonreversible cause
Ischemic cardiomyopathy, EF 40% or less, NSVT, inducible at electrophysiologic study
Brugada syndrome (right bundle branch block, S-T elevation V_1–V_3)[a]
Arrhythmogenic right ventricular dysplasia[a]
Long QT syndrome
Hypertrophic cardiomyopathy[a]
Infiltrative cardiomyopathy

EF, Ejection fraction; *NSVT*, nonsustained ventricular tachycardia; *NYHA*, New York Heart Association.
[a]Requires one or more risk factors for sudden cardiac arrest.

Two-chamber (leads placed in the right atrium and right ventricle) ICDs are in clinical trial for patients with HOCM who have experienced VT or VF. Box 5.7 reviews ICD indications.

Dilated Cardiomyopathy

With the advent of cardiac resynchronization therapy pacing (CRT-P) for the patient with DCM and prolonged QRS interval,[163] and the approval of ICDs with CRT capability (cardiac resynchronization therapy with defibrillation capability [CRT-D]), the presence of a defibrillator with BiV pacing will become more common. Currently, approximately 550,000 new diagnoses of congestive heart failure (CHF) are made annually in the United States,[164] and the prevalence of this disease includes 5.7 million patients[165] without much change over the past decade.[166] Significant risk factors for the development of CHF include both ischemic heart disease and hypertension.[167] These data, combined with the recent results from SCD-HeFT[142] and MADIT II[161] trials (ICD is indicated in any patient with cardiomyopathy and EF less than 30% to 35%), suggest that the number of patients eligible to receive a defibrillator to include CRT-P will increase dramatically. Whether any country's economy can absorb this economic burden remains to be seen. At present, CRT-P improves functional status and quality of life[168] and reduces heart failure events[169] primarily by decreasing the dyssynchrony between the two ventricles in the dilated heart whether the CRT device includes ICD capability (called CRT-D) or not (called CRT-P). Additionally, CRT-D and has been shown to reduce mortality in some but not all studies.[28] However, approximately 30% of patients who undergo CRT implantation achieve no additional benefit from the multichamber pacing.[170]

Implantable Cardioverter-Defibrillator Magnets

Similar to pacemakers, magnet behavior in some ICDs can be altered by programming. Most devices will suspend tachyarrhythmia detection (and therefore therapy) when a magnet is appropriately placed to activate the magnet sensor. Some devices from Boston Scientific, Pacesetter, and St. Jude Medical can be programmed to ignore magnet placement. If the magnet mode is off, then intraoperative EMI is likely to produce repeated shocks.[1] *Antitachycardia therapy in some Guidant and CPI devices can be permanently disabled by magnet placement for 30 seconds*,[4] although upgrades to the Boston Scientific programmer and ICD attrition through battery depletion or patient death has virtually eliminated this setting. In general, magnet application will not affect antibradycardia pacing rate (except Sorin [Milano, Italy, US Headquarters Arvado, CO]) or pacing mode. Interrogating the device and calling the manufacturer remain the most reliable method for determining magnet response. Magnet effects on ICDs are shown in Appendix 5.2.

Note that reliable confirmation of appropriate magnet placement, and therefore suspension of antitachyarrhythmic therapy, is present only in Boston Scientific ICDs (tone) and Sorin ICDs (pacing rate change to 90 bpm if the battery is good; 80 if the battery is at elective replacement). Medtronic marketed a Smart-Magnet device that houses a magnet and electronics to show appropriate disablement of the ICD functions in their device, but this device is not generally available. When using a Smart-Magnet, the "FOUND" light is often extinguished during EMI from the ESU, even though the magnet remains in place. Despite these features in Medtronic and Boston Scientific ICDs, numerous anecdotal reports exist of inappropriate shock therapy during electrosurgery, most often a result of movement of the magnet during patient repositioning.

Preanesthetic Evaluation and Implantable Cardioverter-Defibrillator Reprogramming

In general, ALL patients with an ICD should be evaluated for the need to disable high-voltage therapy before the commencement of any procedure, although such action might be unnecessary in a setting without EMI or placement of a metal guidewire into the chest.[171] The comments in the pacing section (and in Boxes 5.3 through 5.6) apply here for any ICD with antibradycardia pacing. Guidelines from HRS/NASPE suggest that every patient with an ICD have an in-office comprehensive evaluation every 3 to 6 months.[42] Devices with CRT-P must have a sufficiently short AV delay for sensed events to ensure that all ventricular activity is paced. Failure of ventricular pacing (either right or left) attributable to native AV conduction or threshold issues has been associated with inappropriate antitachycardia therapy (ie, shock).[172]

Intraoperative (or Procedure) Management

At this time, no special monitoring (attributable to the ICD) is required for the patient with any ICD. ECG monitoring and the ability to deliver external cardioversion or defibrillation must be present during the time of ICD disablement. Although many recommendations exist for defibrillator pad placement to protect the ICD, it should be remembered that the patient, not the ICD, is being treated.

No special anesthetic techniques have been championed for the patient with an ICD. Most of these patients will have severely depressed systolic function, dilated ventricular cavities, and significant valvular regurgitation, and the choice of anesthetic technique should be dictated by the underlying physiologic derangements that are present. Conflicting data have been published regarding the choice of anesthetic agent(s) and changes to DFT. In 1993, Gill and colleagues[173] examined DFT in dogs and concluded that neither halothane nor isoflurane changed DFT in open-chest defibrillation, compared with a pentobarbital infusion. However, Weinbroum and associates[174] evaluated DFTs in humans during ICD implantation and found that halothane, isoflurane, and fentanyl increased DFT. Even with these increases, the increased DFTs found were still substantially lower than the maximum energy generally available in ICDs, and these increases would not have been noted under usual ICD testing conditions. As previously noted, both isoflurane and sevoflurane have been reported to lengthen the QT interval, which could increase the risk of torsades de pointes in certain patients.

Caution should be observed when placing a central venous catheter in any patient with an ICD. In the patient with an integrated bipolar ventricular sensing configuration, an inappropriate 30 joule shock was delivered as a result of noise artifact created by the guidewire on the ventricular shock coil (which was serving as the ICD heart rate sensor). The output of the ICD was short-circuited and attributable to the presence of a shock coil in the superior vena cava, and the ICD was unknowingly rendered ineffective. Only after failure to

deliver subsequent therapy was this problem noted, and the patient subsequently expired.[175] It is important to note that some ICDs are configured to the "integrated bipolar sensing configuration" even in the presence of a true bipolar RV lead.

Postanesthesia Implantable Cardioverter-Defibrillator Evaluation

Any ICD that underwent suspension of high-voltage therapy must be reinterrogated and reenabled. All stored events should be reviewed and counters should be cleared, since the next device evaluator might not receive information about the EMI experience of the patient and make erroneous conclusions regarding the patient's arrhythmia events. One patient death that has been reported to the FDA was attributed to the failure to reactivate antitachycardia therapy in a patient with an ICD after a cardiac ablation procedure.[176]

Summary

CIEDs remain a poorly understood therapeutic modality, despite their presence in the medical environment for over 50 years. CIEDs represent the cutting edge of implanted, sophisticated electronics in patients who have need for artificial pacing and/or automated cardioversion-defibrillation of their heart. Both the aging of the population and the ability to care for patients with increasingly complex disease suggest that many more patients with these devices will require subsequent surgery. Safe and efficient clinical management of these patients depends on an understanding of implantable systems, indications for their use, and the perioperative needs that they create.

Glossary

Atrioventricular (AV) Delay Time that a dual chamber system waits after detecting (or initiating) an atrial event before pacing the ventricle. Some generators shorten this time as the heart rate increases (termed *"rate adaptive AV delay"* or *"dynamic AV delay"*). Some generators can be programmed to extend the AV delay to search for intrinsic conduction ("search AV delay"). Some generators will prolong an AV delay after any atrial event during which the last ventricular event was intrinsic ("AV delay hysteresis"). In a patient with a conducting AV node, the sensed AV delay will be slightly longer than the "P-R" interval on the surface electrocardiogram (see "Fusion Beat" and "Pseudofusion Beat"), since the ventricular sensing element is attached to the apex of the right ventricle and detects the depolarization only after RV activation.

Bipolar Lead An electrode with two conductors. Bipolar sensing is more resistant to oversensing from muscle artifact or stray electromagnetic fields. Some pacing generators can be programmed to unipolar mode even in the presence of bipolar electrodes.

Dynamic Atrioventricular Delay See Atrioventricular (AV) Delay.

Electrogram Mode Passive acquisition and internal storage of electrocardiographic data for diagnostic purposes while pacing (or monitoring) with programmed parameters.

Fusion Beat Pacemaker spike delivered shortly before a native depolarization of the ventricle, which alters the morphologic pattern of the QRS, often misdiagnosed as undersensing. Fusion beat is caused by the position of the sensing electrode, relative to the depolarizing wavefront. Confirmation of appropriate sensing behavior can be made by lengthening the sensing interval (ie, lengthening the AV delay). Fusion beats suggest ventricular capture.

Generator Device with a power source and circuitry to produce an electrical impulse designed to be conducted to the heart. Typically, pacing generators are placed in a pectoral pocket, and leads are inserted into the right atrium, right ventricle, or both. Since 1995, though, implantable cardioverter-defibrillators have also been approved for pectoral pocket placement.

Hysteresis If present, the amount the patient's intrinsic rate must fall below the programmed rate before the generator begins pacing. Some pacers periodically decrease the pacing rate to search for resumption of intrinsic activity (called *search hysteresis*). These functions, when present, can mimic pacemaker malfunction.

Implantable Cardioverter-Defibrillator (ICD) Mode Designation of chamber(s) shocked, chamber(s) paced for antitachycardia pacing, method of tachycardia detection, and chambers paced for antitachycardia therapy. Table 5.5 shows the NASPE/BPEG generic ICD code.

Managed Ventricular Pacing Some evidence suggests that right ventricular (RV) pacing increases mortality in patients with intact AV nodal conduction. As a result, several companies have algorithms to reduce the incidence of RV pacing. Pacing modes called *managed ventricular pacing* (Medtronic) or AAI Safe-R (ELA Medical) can permit an occasional dropped QRS (more likely with managed ventricular pacing than with AAI Safe-R). However, no pacing device should allow two consecutive dropped QRS events. After several beats with a dropped QRS, however, these devices begin pacing in a true DDD mode for several cardiac cycles. These dropped QRS events can mimic pacing system malfunction (pseudomalfunction).

Oversensing Detection of undesired signals that are interpreted as cardiac activity. Oversensing can lead to pacemaker-driven tachycardia (pacing device, DDD mode with atrial oversensing and ventricular tracking); ventricular pause (pacing device with electrosurgical-induced ventricular oversensing, leading the pacer to detect ventricular activity), or inappropriate shock (defibrillator, event oversensing).

Pacing Mode Designation of chamber(s) paced, chamber(s) sensed, sensing response, rate responsiveness, and antitachydysrhythmia function for a pacemaker system. Table 5.2 shows the NASPE/BPEG generic pacemaker code.

Postventricular Atrial Blanking Period (PVAB) Present only in a dual-chamber pacemaker, the PVAB is the period immediately after any ventricular event during which atrial events will not be detected by the atrial sensing circuitry. In general, PVAB is used to determine where, in the postventricular period, atrial event counting should resume for mode switch determination. PVAB is the early part of postventricular atrial refractory period (PVARP).

Postventricular Atrial Refractory Period (PVARP) Present only in a dual-chamber pacemaker, the PVARP is the period immediately after any ventricular event during which atrial events are ignored (for the purpose of pacing the ventricle). In some devices, atrial events during PVARP (but after the expiration of the PVAB timer) will be counted for atrial rate determinations, leading to possible mode switch. The duration of PVARP added to the AV delay (called total atrial refractory period [TARP]) determines the 2:1 block rate of pacing. Some devices allow the PVARP to vary, based on the heart rate.

Programmed Rate (also Automatic Rate) Lowest sustained regular rate during which the generator will pace. Typically, the device begins pacing when the patient's intrinsic rate falls below this value.

Pseudofusion Beat (PFB) Pacemaker spike delivered shortly after a native depolarization without alteration of the QRS morphologic pattern. PFBs are often misdiagnosed as undersensing, and they result from the position of the sensing electrode relative to the depolarizing wavefront (see "Fusion Beat"). Confirmation of appropriate sensing behavior can be made by lengthening the sensing interval (ie, decreasing the program rate [atrial fibrillation] or lengthening the AV delay [ventricular PFB]). PFB cannot be used to confirm electronic capture.

Rate Enhancements Features such as rate adaptive AV delay (shortens the AV delay with increasing heart rate); AV search hysteresis (lengthens or shortens the AV delay to produce intrinsic AV conduction); atrial fibrillation suppression, also called *dynamic atrial overdrive*, increases the lower rate upon appearance

of native atrial depolarization so as to create nearly constant atrial pacing but at a rate only slightly higher than the patient's intrinsic rate); rate smoothing (limits changes in ventricular paced rates attributable to changes in atrial rates, rising and falling rate limits can be programmed); sleep rate (see glossary term Sleep Rate); ventricular rate regulation (similar to rate smoothing but is used to prevent atrial fibrillation); and hysteresis (see glossary term Hysteresis). Each of these enhancements can produce pacing or nonpacing that can mimic pacemaker dysfunction, and these enhancements should be programmed *OFF* before any anesthetic is administered.

Rate Modulation Ability of the generator to sense the need to increase the heart rate. Mechanisms include: (1) mechanical sensor in the generator to detect motion or vibration; (2) electronic detection of Q-T interval (shortens during exercise) or transthoracic impedance to measure changes in respiration; or (3) sensor(s) for central venous blood temperature or oxygen saturation. Some generators now incorporate multiple sensors.

Runaway Pacing Rate Highest pacing rate (typically around 200 bpm) that could occur in the setting of multiple internal component failures in a cardiac generator.

Sleep Rate (also Circadian Rate) The rate (lower than the programmed rate) at which the pacing generator will pace during programmed "nighttime" hours.

Total Atrial Refractory Period (TARP) Present only in dual-chamber pacing devices, the TARP refers to the sum of the PVARP and the AV delay, and it determines the point at which the pacing device will pace the ventricle every other atrial event. This 2:1 block rate can be calculated by dividing 60,000 (msec per min) by the TARP (measured in msec). This 2:1 block results from the ignoring of the atrial event during the PVARP, so these 2:1 blocks appear only when ventricular pacing is needed in a patient and the 2:1 block rate is lower than the maximum tracking rate. In some pacing devices, the dynamic AV delay will make the calculation of TARP dependent on the atrial rate, and many of the programmers will report the final 2:1 block rate for any given combination of programmed parameters.

Undersensing Failure to detect a desired event.

Unipolar Lead Electrode with only one conductor. Some devices with bipolar leads are programmed to the unipolar lead mode. Systems with unipolar leads produce larger spikes on the electrocardiogram than bipolar leads. Systems with unipolar leads use the generator case as the second conductor.

Upper Sensor Rate (USR; also Upper Activity Rate [UAR]) Maximum rate to which a rate modulated pacemaker can drive the heart. USR is not affected by UTR, since the pacemaker is pacing the atrium when the USR becomes active.

Upper Tracking Rate (UTR; also called Upper Rate Limit [URL]) Pacemakers programmed to VDDxx or DDDxx mode cause the ventricles to track atrial activity. Should a patient develop an atrial tachyarrhythmia, such as a supraventricular tachycardia, atrial fibrillation or atrial flutter, the generator acts to limit ventricular pacing. When the atrial rate exceeds the UTR, the generator can change mode (ie, switch to DDI) or introduce second-degree AV block. Second-degree blocks can be Mobitz type I (Wenckebach) or Mobitz type II, depending on a variety of programmed settings within the pacemaker.

Ventricular Intrinsic Preference Programmed extension of the AV delay intended to reduce RV pacing by provoking native AV conduction, specific to St. Jude devices. The AV delay can be extended to as much as 450 msec. Periodically at programmed intervals, AV delay is extended across several cardiac cycles by the ventricular intrinsic preference (VIP) setting to test for intrinsic conduction.

Ventricular Refractory Period (VRP) Period immediately after any ventricular event during which the pacing device will not respond to a sensed event on the ventricular channel. Depending on the manufacturer and programming, though, events sensed during VRP might be counted for determining a high-rate ventricular condition.

APPENDIX 5.1 Pacemaker Response to Magnet Placement

Pacemaker Company		*Magnet Mode Designation*	*Explanation*
Biotronik	INOS	ASYNCH (default)	Asynchronous VOO (even if dual-chamber device) pacing at 70 or 90 bpm, depending on programming, if normal conditions. 80 bpm at ERI. There is no way to determine the magnet rate without the programmer or magnet application.
		SYNCH	VVI (even if dual-chamber device) pacing at 70 or 90 bpm, depending on programming, if normal conditions. 80 bpm at ERI. There is no way to determine the magnet rate without the programmer or magnet application. Also, if the patient's intrinsic ventricular rate is greater than 80 bpm, then there will be no way to identify ERI.
	DROMOS	ASYNCH	See AUTO.
		SYNCH	See SYNCH.

APPENDIX 5.1 Pacemaker Response to Magnet Placement—cont'd

Pacemaker Company		*Magnet Mode Designation*	*Explanation*
	All Others	AUTO (default)	If normal conditions, 10 asynchronous events at 90 bpm, then returns to original programmed mode without rate responsiveness. Pacing is at lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, 10 asynchronous events at 80 bpm in VOO mode, then either VDD (dual chamber) or VVI (single chamber) pacing at 11% lower than the lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
		ASYNCH	Asynchronous pacing at 90 bpm if normal conditions. At ERI, 80 bpm (single step change) in VOO mode, regardless of original programming. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
		SYNCH	If normal conditions, pacing in original programmed mode without rate responsiveness. Pacing is at lowest available rate (LRL, sleep rate, or hysteresis rate). If battery at ERI, then either VDD (dual chamber) or VVI (single chamber) pacing at 11% lower than lowest available rate. For any dual-chamber mode (DDD, DDI, or VDD), the AV delay shortens to 100 msec while the magnet is in place.
Boston Scientific includes Guidant Medical CPI	"BSC" x-ray label	ASYNCH (default)	Asynchronous pacing with 100 msec AV delay at 100 bpm if normal conditions, 90 bpm in IFI, and 85 bpm at ERT (single-step changes). All models shorten the pulse width to 50% on the third paced ventricular event (TMT).
		OFF	No change, magnet is ignored. Magnet mode is OFF after a "power on reset" or activation of "Safety Core," which can occur secondarily to EMI.
		PTM mode	No change in pacing. Magnet application initiates data collection.
	All others ("BSC," "GDT," "CPI" x-ray labels)	ASYNCH (default)	If normal conditions, asynchronous pacing with 100 msec AV delay at 100 bpm. If ERI, 85 bpm (single-step change). The Insignia and Altura models have an intermediate step (90 bpm) at ERN. Most models shorten the pulse width to 50% on the third paced ventricular event (TMT). For Triumph and Prelude models, see Medtronic pacemakers.
		OFF	No change, magnet is ignored. OFF is the magnet mode after a "power on reset," which can occur secondarily to EMI.
		Electrogram mode	No change in pacing. Magnet application initiates data collection.
Intermedics (purchased by Guidant, 1998, now Boston Scientific, but special programmer needed)			Five asynchronous events at 90 bpm (regardless of battery voltage), then 60 additional asynchronous events at LRL if normal conditions, 90 bpm if ERI, and 80 bpm if EOL. The fifth paced event is emitted at 50% of the originally programmed pulse width (TMT). After the 65th asynchronous event, the magnet is ignored.
Medtronic (See Cautions in the text following this table.)	Standard transvenous pacemaker		Asynchronous pacing at 85 bpm (programmed mode) if normal conditions, 65 bpm SOO regardless of original programming if ERI (single-step change). Medtronic pacemakers (except Enrhythm P1501 and all "Surescan" models) pace the first three events at 600 msec intervals (rate = 100 bpm) with a short AVd. During the first three to seven asynchronous events, most Medtronic pacemakers emit one or more ventricular pulses at a reduced pulse width or voltage (TMT). Also, Medtronic pacemakers default to single-chamber pacing at 65 bpm, without rate responsiveness, upon reset or detection of ERI when no magnet is present. Important caveat: a Medtronic dual-chamber pacemaker in AAI mode will revert to VVI on ERI or reset, which might result in asystole and death with a dysfunctional ventricular lead but atrial pacing dependence.
	Micra leadless intracardiac pacemaker		No magnet response.
Sorin (was ELA Medical)			Asynchronous pacing at 96 bpm gradually declining to 80 bpm at ERI. ELA pacemakers take eight additional asynchronous pacing cycles (the final two cycles are at LRL with long atrioventricular delay) upon magnet removal.
St. Jude Medical	SJM x-ray logo; standard transvenous pacemaker	Battery Test (default)	Asynchronous pacing at 100 bpm (older models 98.6 bpm) gradually decreasing to 86.3 bpm at ERI.
		OFF	No magnet response.
		Event snapshots	No change in pacing. Magnet application causes pacemaker to collect data. Identity and Entity models lack this feature.
		Event snapshots + Battery Test	For a magnet placed 2 seconds, pacing mode and rate are unchanged and the device stores an electrogram. If the magnet is placed ≥5 seconds, the Battery Test mode (see above) is activated. Identity and Entity models lack this feature.
	Pacesetter x-ray logo(ψ); standard transvenous pacemaker	Battery Test (default)	Asynchronous pacing, and the rate depends on specific model. In general, a pacing rate of less than 90 bpm should prompt further evaluation.
		OFF	No magnet response.
		VARIO mode (present in some models)	VARIO results in a series of 32 asynchronous pacing events. The rate of the first 16 paces reflects battery voltage, gradually declining from 100 bpm to 85 bpm at ERI. The next 15 paces are used to document ventricular pacing capture safety margin. The rate will be 119 bpm with gradually declining pacing voltage. The 16th pace of this group is at no output. The next pace restarts the 32 event sequence. The 32-event sequence repeats while the magnet remains in place.
	Nanostim leadless intracardiac pacemaker	ON (default)	Asynchronous pacing at 100 bpm for eight cycles, then 90 bpm if normal conditions; 65 bpm if ERI.
		OFF	No magnet response.
Telectronics	Meta 1202		Asynchronous pacing at 99 bpm, gradually declining to <93 at ERI.
	Meta 1204 1206 1256		Asynchronous pacing at 100 bpm, gradually declining to < 82.5 bpm at ERI.
	Meta 1230 1250 1254		Asynchronous VOO pacing (regardless of original programming) at >85 bpm, gradually declining to <78 bpm at ERI.

Continued

APPENDIX 5.1 Pacemaker Response to Magnet Placement—cont'd

Pacemaker Company	*Magnet Mode Designation*	*Explanation*
Tempo		Asynchronous pacing at 100 bpm, gradually declining to 80 bpm at ERI.
All Others		Contact St. Jude Medical.

The effect(s) of appropriately placing a magnet over a pacemaker is(are) shown. Column 1 shows the pacemaker manufacturer. If the manufacturer has multiple responses, then Column 1 is subdivided. If the magnet response is programmable, then Column 2 shows the various magnet modes available. The first mode shown is the default. A device reset from EMI might produce some other mode (ie, magnet mode disabled). Column 3 shows the effect on pacing therapy for the magnet mode shown in Column 2. Unless otherwise specified, asynchronous pacing takes place, without rate responsiveness, in the chambers originally programmed. Thus a dual-chamber program would result in DOO pacing, and a single-chamber program would result in VOO (unless an atrial device, which would be AOO) pacing, and a biventricular, dual-chamber device would be DOOOV.

AVd, Atrioventricular delay (For dual-chamber pacing, AVd is a programmed value [see Glossary]. However, the AVd can be shortened during the first 3 to 15 events upon magnet placement. Note that a short AVd can reduce stroke volume and produce untoward hemodynamics in some patients.); *EOL,* end of life; (Device should be replaced immediately.); *ERI,* elective replacement indicator (Device should be promptly replaced. The US Food and Drug Administration requires pacemakers to perform safely for at least 3 months from the onset of the ERI.); *ERN,* elective replacement near (Device should be undergoing monthly checks [IFI].); *ERT,* elective replacement time (Is the same as ERI. For Boston Scientific Pacemakers [Guidant, CPI labels also] at ERT, rate responsive programming is cancelled. At 3 months after ERT, only single-chamber operation continues.); *IC-PM,* intracardiac pacemaker; *IFI,* intensified follow-up interval (Device needs monthly battery checks.); *LRL,* lower rate limit (Programmed lower rate, or set point, of the pacemaker.); *SOO,* single-chamber asynchronous pacing; *SSI,* single-chamber, inhibited mode (If implanted for ventricular pacing, then SSI is in VVI mode. For an atrial pacemaker, SSI is in AAI mode.); *TMT,* threshold margin test (Emission of a single pacing pulse [except VARIO; see St. Jude Medical—Pacesetter logo] at a lower amplitude or pulse width to demonstrate adequacy of pacing output relative to pacing threshold. Typically, this is the third or fifth pacing pulse. Failure to capture (pace) on this event suggests an inadequate safety margin for capture. Properly programmed atrial-only pacemakers are unlikely to demonstrate this feature.); *TV-PM,* transvenous pacemaker.

Cautions

Any dual-chamber pacemakers undergoing a "power on reset" or "Safety Cored Event" (BSC Boston labeled devices) from an electrical fault or exposure to strong EMI could cause a "power on reset," or "Safety Core Event," which causes the pacemaker to switch to VVI pacing only, regardless of prior pacing programming. For a dual-chamber pacemaker with a bad RV lead and programmed to atrial pacing only (AAI, AOO) in a pacing-dependent patient, this event could cause patient injury or death.

All Medtronic transvenous pacemakers except Enrhythm P1501, EMDR series, Revo, Advisa, and Ensura suspend magnet detection for up to 60 minutes following the removal of the programming head after an interrogation session, unless specific programming action (which requires multiple button depressions) is taken before removing the programming head.

APPENDIX 5.2 Implantable Cardioverter-Defibrillator Response to Magnet Placement

ICD Manufacturer		*Magnet Mode Designation*	*Effect on Tachy Therapy*	*Effect on Brady Therapy (regular pacing)*	*Magnet Mode Confirmation*
Biotronik			Disables	No effect	None
Boston Scientific (Guidant Medical, CPI)	Transvenous BSC; all BOS (except 119, 203) x-ray labels	ON (default)	Disables	No effect	Short beep every second or constant tone[a]
		OFF	No effect	No effect	None
	Transvenous GDT, CPI BOS 119, BOS 203 x-ray labels	ON (default)	Disables	No effect	Short beep with each R wave, or constant tone[a]
		OFF	No effect	No effect	None
	Subcutaneous		Disables	No effect. S-ICD has no regular pacing. However, postshock pacing (VVI, 50 bpm, 30 seconds, nonprogrammable) is terminated.	Short beep with each R wave, whether ICD therapy is on or off, for the first 60 seconds of magnet application. Thereafter, no confirmation.
Medtronic	AT-500[b]		Disables	No effect	None
	All others[c]		Disables	No effect	
Pacesetter and St. Jude Medical		Normal (default)	Disables	No effect	
		Ignore	No effect	No effect	None
Sorin (was ELA Medical)			Disables	The pacing rate, but not mode, changes to 96 bpm (new device) declining to 80 bpm, indicating elective replacement time.	Pacing rate changes as noted.

EMI, Electromagnetic interference; *ICD,* implantable cardioverter-defibrillator; *S-ICD,* subcutaneous implantable cardioverter-defibrillator.

The effect(s) of appropriately placing a magnet over an ICD are shown. Column 1 shows the manufacturer. Some manufacturers have multiple responses that can be determined by the x-ray identifier. If the magnet response is programmable, then Column 2 shows the various magnet modes available. The first mode shown is the default mode. A device reset from EMI might produce some other mode (ie, magnet mode disabled). Column 3 shows the effect on antitachycardia therapy (defibrillation, cardioversion, and antitachycardia pacing) for the magnet mode shown in Column 2. Only ICDs from Sorin Medical alter their antibradycardia pacing rate upon magnet placement (Column 4), and this pacing rate can be used to predict remaining battery life provided that the patient's native heart rate is less than the magnet rate. Only ICDs from Boston Scientific/Guidant/CPI produce reliable audio feedback for confirmation of magnet placement (Column 5). For devices from Pacesetter/St. Jude Medical, a device interrogation is required to determine the magnet mode.

[a]Any Boston Scientific/Guidant/CPI ICD that does not emit sound when a magnet is applied should undergo an immediate device interrogation. A stethoscope might be needed; for electronic stethoscopes, only the "Diaphragm" mode should be used since filtering in the "Bell" mode might not permit the sound to be transmitted to the earpiece.

For Boston Scientific/Guidant/CPI ICDs, if magnet mode is programmed to ON, appropriate magnet placement disables tachy detection and therapy, and tachy therapies remain disabled for as long as the magnet remains appropriately applied. When magnet mode is enabled in these devices, the ICD will emit either a constant tone or a beep to identify appropriate magnet placement. If the device emits a constant tone, then tachy therapy is disabled whether or not a magnet is present, and tachy therapy will not be present even after the magnet is removed. If any of these ICDs emit a beep (ICDs with GDT or CPI x-ray codes emit each beep with any paced or sensed R wave; ICDs with BOS or BSC x-ray code emits a beep every second), then a properly working ICD will be enabled for tachy therapy upon magnet removal.

Note that the "Change Tachy Mode with Magnet" feature is present only in very few remaining GDT and CPI x-ray labeled devices. When programmed ON, after 30 seconds of continuous magnet application the tachy mode will toggle (ie, it will switch from enabled when the magnet is removed [beeping with magnet correctly applied] to permanently disabled [constant tone when magnet is correctly applied] or vice versa.) This mode has been phased out for most BOS/GDT/CPI ICD families, and software in programmers since October of 2009 is designed to disable and eliminate this feature.

[b]The Medtronic AT-500 series atrial defibrillators provide antitachycardia pacing in the atrium ONLY, and usually after a delay often exceeding 1 minute from onset of atrial tachyarrhythmia. They do not have any shock coils on any lead and are very difficult to distinguish from a conventional two-chamber pacemaker. They have NO apparent magnet response. The x-ray identifier on these devices includes the Medtronic "M" but the first character is "I." All other Medtronic cardiac generators have the Medtronic "M" with the first letter identifier "P."

[c]Some Medtronic ICDs will emit a tone for 15 to 30 seconds when a magnet is placed on the device. However, this tone is not continuous with magnet placement, and it will not be interrupted with immediate magnet removal. As a result, the tone cannot be used for confirmation of appropriate magnet placement.

6 Cardiac Physiology

PAUL S. PAGEL, MD, PhD | JULIE K. FREED, MD, PhD

KEY POINTS

1. The cartilaginous skeleton, myocardial fiber orientation, valves, blood supply, and conduction system of the heart determine its mechanical capabilities and limitations.
2. The cardiac myocyte is engineered for contraction and relaxation, not protein synthesis.
3. Laplace's law describes the transformation of alterations in muscle tension and length observed during contraction and relaxation in vitro into phasic changes in pressure and volume that occur in the intact heart.
4. The cardiac cycle is a highly coordinated, temporally related series of electrical, mechanical, and valvular events.
5. A time-dependent, two-dimensional projection of continuous pressure and volume during the cardiac cycle creates a phase space diagram that is useful for the analysis of systolic and diastolic function of each cardiac chamber in vivo.
6. Each cardiac chamber is constrained to operate within its end-systolic and end-diastolic pressure-volume relationships when contractile state and compliance are constant.
7. Heart rate, preload, afterload, and myocardial contractility are the main determinants of pump performance.
8. Preload is the quantity of blood that a cardiac chamber contains immediately before contraction begins, and afterload is the external resistance to emptying with which the chamber is confronted after the onset of contraction.
9. Myocardial contractility is quantified using indices derived from pressure-volume relationships, isovolumic contraction, the ejection phase, or power analysis, but these indices have significant limitations because the contractile state and loading conditions are interrelated.
10. Pressure-volume diagrams are useful for describing the mechanical efficiency of energy transfer between elastic chambers, such as the left ventricle and the proximal arterial vasculature.
11. Diastolic function is the ability of a cardiac chamber to effectively collect blood at a normal filling pressure.
12. Left ventricular diastole is a complicated sequence of temporally related, heterogeneous events; no single index of diastolic function completely describes this period of the cardiac cycle.
13. Left ventricular diastolic dysfunction is a primary cause of heart failure in as many as 50% of patients.
14. The left ventricular pressure-volume framework allows the invasive analysis of diastolic function during isovolumic relaxation, early filling, and atrial systole.
15. Transmitral and pulmonary venous blood flow velocities, tissue Doppler imaging, and color M-mode propagation velocity are used to noninvasively quantify the severity of diastolic function.
16. The pericardium exerts important restraining forces on chamber filling and is a major determinant of ventricular interdependence.
17. The atria serve three major mechanical roles, as conduits, reservoirs, and contractile chambers.

The heart is an electrically self-actuated, phasic, variable-speed hydraulic pump composed of two dual-component, elastic, muscular chambers, each consisting of an atrium and a ventricle connected in series that simultaneously provide an equal quantity of blood to the pulmonary and systemic circulations. All four chambers of the heart are responsive to the stimulation rate, muscle stretch immediately before contraction (ie, preload), and the forces resisting further muscle shortening after contraction has begun (ie, afterload). The heart efficiently provides its own energy supply through an extensive coronary circulation.

The heart rapidly adapts to changing physiologic conditions by altering its inherent mechanical properties (ie, Frank-Starling mechanism) and by responding to neurohormonal and reflex-mediated signaling. Overall performance is determined by the contractile characteristics of the atria and ventricles (ie, systolic function) and by the ability of its chambers to effectively collect blood at normal filling pressures before the subsequent ejection (ie, diastolic function). This innate duality implies that heart failure may occur as a consequence of abnormalities in systolic or diastolic function.

A comprehensive understanding of cardiac physiology is essential for the practice of cardiac anesthesia. At an average heart rate of 75 beats/minute, the heart contracts and relaxes more than 3 billion times during the length of a typical human life, supplying oxygen and nutrients required to meet the body's metabolic requirements. The fundamentals of cardiac physiology are discussed in this chapter, with an emphasis on the mechanics that allow the heart to achieve this truly remarkable performance.

Functional Implications of Gross Anatomy

Structure

The heart's anatomy determines many of its major mechanical capabilities and limitations. The annuli of the valves, the aortic and pulmonary

arterial roots, the central fibrous body, and the left and right fibrous trigones form the heart's skeletal foundation. This flexible, strong, cartilaginous structure is located at the superior aspect (ie, base) of the heart. It provides support for the translucent, macroscopically avascular valves, resists the forces of developed pressure and blood flow within the chambers, and provides a site of insertion for superficial subepicardial muscle.[1] Most atrial and ventricular muscle is not directly connected to the central fibrous skeleton. It instead arises from and inserts within adjacent surrounding myocardium. This observation is consistent with the well-known embryologic derivation of the heart from an expanded arterial blood vessel.[2]

An interstitial collagen fiber network composed of thick type I collagen cross-linked with thin type III collagen also provides important structural support to the myocardium. The protein elastin is interwoven in this collagen matrix, providing additional flexibility and elasticity to the heart without compromising its strength. In contrast to William Harvey's original assertion,[3] atrial and ventricular myocardium cannot be separated into distinct bands or layers by the use of an unwinding dissection technique.[4,5] Instead, myocardium is a continuum of interconnecting cardiac muscle fibers. Accordingly, the term "layer" is used metaphorically in this section.

The left atrium (LA) and right atrium (RA) are composed of two relatively thin, orthogonally oriented layers of myocardium. The walls of the right ventricle (RV) and left ventricle (LV) are thicker (approximately 5 and 10 mm, respectively) than those of the atria and consist of three muscle layers: interdigitating deep sinospiral, superficial sinospiral, and superficial bulbospiral. Well-ordered, differential alterations in fiber angle extending from the endocardium to the epicardium are especially apparent in ventricular myocardium and are spatially conserved (Fig. 6.1).[6]

Subendocardial and subepicardial muscle fibers of the LV follow perpendicular, oblique, and helical routes from the base to the apex, but the orientation of these interdigitating sheets of cardiac muscle reverses direction at approximately the LV midpoint. LV fiber architecture resembles a flattened figure eight (Fig. 6.2). Contraction of obliquely arranged subepicardial and subendocardial fibers causes LV chamber shortening along its longitudinal axis, concomitant with a characteristic twisting action that increases the magnitude of force generated by the LV during systole above that produced by basal-apical muscle fiber shortening alone. Transition of this primarily helical geometry into a more spherical configuration may contribute to reduced systolic function during evolving heart failure.[7] Elastic recoil of the systolic wringing motion during LV relaxation is also a crucial determinant of diastolic suction, which facilitates adequate LV filling during hypovolemia and strenuous exercise.[8,9]

In contrast to the subepicardial and subendocardial layers, midmyocardial fibers are circumferentially oriented around the LV cavity's diameter. As expected, their contraction reduces chamber diameter.

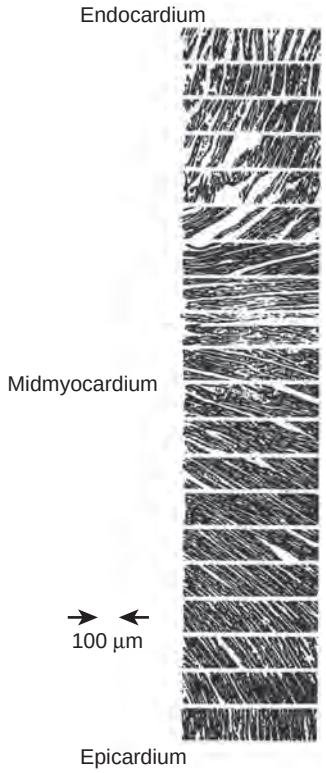

Fig. 6.1 Sequence of photomicrographs depicts myocardial fiber angles at successive sections from the endocardial surface *(top)* to the epicardial surface *(bottom)* through the thickness of the left ventricular anterior wall. Notice the transition in myocardial fiber orientation relative to wall thickness from the subendocardium (ie, perpendicular) to the midmyocardium (ie, parallel). A mirror image transition in fiber orientation is observed from the midmyocardium to the subepicardium. *(From Katz AM.* Physiology of the Heart. *3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2001.)*

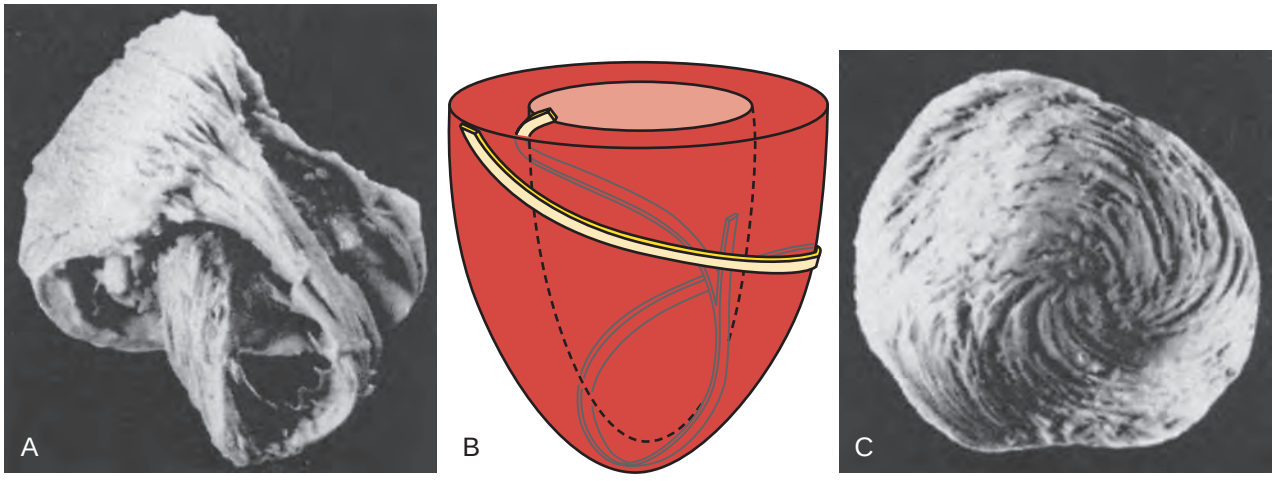

Fig. 6.2 The spiral orientation of fiber continuity in the left ventricle. (A) Photograph demonstrates a dissection of the human left ventricular (LV) anterior and lateral walls and shows spiral cardiac muscle bundles sweeping from the base to the apex. (B) Schematic diagram of the helical orientation. (C) Photograph shows a dissection of endocardial fiber orientation at the LV apex and the spiral fiber structure. *(From Katz AM.* Physiology of the Heart. *3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)*

The LV free walls are thickest near the base and gradually thin toward the apex because of a progressive decline in the relative number of midmyocardial fibers. Subendocardial layers of the LV and RV combine with LV midmyocardium extending from the LV free wall to create the interventricular septum.[1] Structural elements derived primarily from the LV, but not the RV, form the septum. As a result, the septum normally thickens toward the LV chamber during contraction. However, the interventricular septum may move toward the RV chamber during systole under pathologic conditions such as RV distention (eg, from an acute increase in pulmonary arterial pressure) or pressure-overload RV hypertrophy (eg, from a chronic left-to-right shunt).

As in the LV free wall, a gradual decrease in the number of midmyocardial fibers produces a characteristic basal-to-apical reduction in interventricular septum thickness. The LV apical free wall is composed of subendocardial and subepicardial fibers, but the apical interventricular septum contains only LV and RV subendocardium. These regional differences in LV wall thickness and laminar myocardial fiber orientation contribute to load-dependent alterations in LV mechanics.[10] Irregular ridges of subendocardium, called *trabeculae carnae* (Latin for "meaty ridges"), are commonly observed along the apical LV chamber border and within the RV; the precise physiologic implications of these structural features are unknown. Endocardial endothelium lines the subendocardium on the LV chamber surface and may play a minor role in the regulation of myocardial function.[11]

The LV apex and interventricular septum remain relatively fixed in space within the mediastinum, but the lateral and posterior walls move toward the anterior and right during contraction. These actions displace the LV longitudinal axis from a plane oriented toward the mitral valve (ie, favoring LV filling) to a position that is more parallel to the LV outflow tract (ie, facilitating ejection). The anterior-right movement of lateral and posterior LV walls also produces the point of maximal impulse, which is typically palpable on the anterior chest wall in the left fifth or sixth intercostal space in the midclavicular line. Subendocardial and subepicardial fiber shortening, papillary muscle contraction, and mechanical recoil resulting from ejection of blood into the aortic root also cause the LV base to descend toward the apex during systole. Synchronous contraction of LV myocardium shortens the LV long axis, decreases the LV chamber diameter, and rotates the apex in an anterior-right direction toward the chest wall. LV ejection is also associated with an apex-to-base gradient in wall tension, creating the intraventricular pressure gradient required to efficiently transfer stroke volume (SV) from the LV into the aorta.

The RV is located in a more right-sided, anterior position than the LV within the mediastinum. Unlike the thicker-walled, ellipsoidal LV that propels oxygenated blood from the pulmonary venous circulation into the high-pressure systemic arterial vasculature, the thinner-walled, crescentic RV pumps deoxygenated venous blood into a substantially lower pressure, more compliant pulmonary arterial tree.

The activation sequence of the LV is temporally uniform, but the RV contracts in a peristaltic manner, in part because it is composed of embryologically distinct inflow and outflow tracts. The RV moves toward the interventricular septum with a bellows-like action. The interventricular septum and LV provide a splint against which the RV free wall shortens during contraction. LV contraction also makes an important contribution to RV systolic function (ie, systolic ventricular interdependence).[12] These factors give the less muscular RV a mechanical advantage that allows it to eject an SV equivalent to that of the LV. However, the thinner RV is more vulnerable to acute decompensation with modest increases in afterload because the thicker LV can generate pressure-volume work that is fivefold to sevenfold greater than the RV can produce. Conversely, the RV is more compliant and accommodates excess volume more easily than the LV.

The atrioventricular (AV) groove separating the RA and the RV and the adjacent tricuspid valve annular plane (ie, components of the RV base) shorten toward the RV apex during contraction. This motion may be used as an index of RV contractile function by echocardiographic quantification of RV free wall tricuspid annular-plane systolic excursion (TAPSE).[13]

Valves

Two pairs of valves ensure unidirectional blood flow through the right and left sides of the heart. The pulmonic and aortic valves are trileaflet structures located at the RV and LV outlets, respectively, and they operate passively with changes in hydraulic pressure. The pulmonic valve leaflets are identified by their anatomic positions (ie, right, left, and anterior), whereas the name of each aortic valve leaflet is derived from the presence or absence of an adjacent coronary ostium.

The pulmonic and aortic valves open as a consequence of RV and LV ejection, respectively. The effective orifice area of each valve during maximal systolic blood flow is only modestly less than the total cross-sectional area of the valve annulus. The proximal aortic root contains dilated segments (ie, sinuses of Valsalva) located immediately behind each leaflet. The sinuses of Valsalva prevent the aortic valve leaflets from closely approaching or adhering to the aortic wall by facilitating the formation of eddy currents during ejection, preventing the right and left coronary leaflets from occluding their respective coronary ostia. The eddy currents within the sinuses of Valsalva also assist with aortic valve closure when ejection ceases by ensuring that the leaflets remain fully mobile during early diastole.[14] The normal velocity of blood flow through the aortic valve (approximately 1.0 m/s) creates vortices of flow between the aortic valve leaflets and the sinuses of Valsalva that serve to further prevent leaflet-aortic wall contact.[15] In contrast to the aortic root, the proximal pulmonary artery does not contain sinuses.

The thin, flexible, and very strong mitral valve separates the LA from the LV. The mitral valve is an oval, hyperbolic paraboloid[16,17] (ie, saddle-shaped structure) containing two leaflets, identified as anterior and posterior on the basis of their anatomic locations. The valve leaflets coapt in a central curve, with the anterior mitral leaflet forming the convex border. The anterior mitral leaflet is oval and occupies a greater central diameter across the annulus, whereas the posterior mitral leaflet is crescent-shaped and extends further around the annular circumference. As a result, the cross-sectional area of each leaflet is similar. The leaflets are physically joined at anterior-lateral and posteromedial commissures, which are located superior to corresponding papillary muscles. The leaflets thicken slightly along the line of coaptation. The positive pressure gradient between the LA and LV chambers near the end of LV relaxation combined with LV mechanical recoil cause the mitral valve to open, whereas retrograde blood flow toward the valve during LV contraction forces the previously open valve leaflets in a superior direction and ensures their coaptation.

Thin fibrous threads, called *chordae tendineae*, attach to the papillary muscles and prevent inversion of the valve leaflets during contraction. Primary and secondary chordae tendineae insert into the valve edges and the clear and rough zones of the valve bodies (located approximately one-third of the distance between the valve edge and the annulus), respectively, of the leaflets. Tertiary chordae tendineae extend from the posteromedial papillary muscle and insert into the posterior mitral leaflet or the adjacent myocardium near the annulus. Each papillary muscle is an outpouching of subendocardial myocardium that provides chordae tendineae to both mitral valve leaflets and contracts synchronously with the LV itself. Papillary muscle contraction tightens the chordae tendineae, inhibiting excessive leaflet motion beyond the normal coaptation zone and preventing regurgitation of blood.[18] The mitral annular circumference also decreases modestly during LV contraction through a sphincter-like action of the surrounding subepicardial myocardium, reducing the total annular area and assisting in valve closure.[19]

The functional integrity of the mitral valve apparatus is crucial to overall cardiac performance. The apparatus ensures unidirectional blood flow from the LA to the LV by preventing regurgitant flow into the LA and proximal pulmonary venous circulation. It also contributes

to LV systolic function through papillary muscle contributions to LV apical posteromedial and anterior-lateral contraction. It is not surprising that severing chordae tendineae—papillary muscle attachments during mitral valve replacement reduces global LV contractile function. Papillary muscle ischemia or infarction may also contribute to the development of LV systolic dysfunction through a similar mechanism in addition to producing acute mitral regurgitation.

The anterior (ie, anterosuperior), posterior (ie, inferior or mural), and septal (ie, medial) leaflets and their corresponding chordae tendineae and papillary muscles comprise the tricuspid valve that regulates blood flow from the RA to the RV. The anterior and septal leaflets are usually larger than the posterior leaflet. The presence of a septal papillary muscle distinguishes the morphologic RV from the LV in patients with certain forms of congenital heart disease (eg, transposition of the great vessels). A lateral band of myocardium (ie, moderator band) connects the apical anterior and septal papillary muscles and demarcates the RV inflow and outflow tracts.

The RV contains a large quantity of coarse trabeculae carnae throughout the chamber, whereas relatively fine trabeculations characterize the LV subendocardial surface. The reason for the difference in trabeculation is unknown. The tricuspid valve does not have a clearly defined collagenous annulus, unlike the mitral valve. Instead, the RA myocardium is separated from the RV by the AV groove that lies immediately above, may fold into the origin of the tricuspid leaflets, and contains the proximal portion of the right coronary artery.

Blood Supply

Blood flow to the heart is supplied by the left anterior descending coronary artery (LAD), the left circumflex coronary artery (LCCA), and right coronary artery (RCA). Most blood flow to the LV occurs during diastole, when aortic blood pressure exceeds the LV pressure, establishing a positive pressure gradient in the coronary arteries, all three of which contribute to the LV's blood supply. Acute myocardial ischemia resulting from a critical coronary artery stenosis or abrupt occlusion causes a predictable pattern of LV injury based on the known distribution of blood supply. The LAD and its branches (including septal perforators and diagonals) supply the medial one-half of the LV anterior wall, the apex, and the anterior two-thirds of the interventricular septum. The LCCA and its obtuse marginal branches supply the anterior and posterior aspects of the lateral wall, whereas the RCA and its distal branches supply the medial portions of the posterior wall and the posterior one-third of the interventricular septum.

The coronary artery that supplies blood to the posterior descending artery (PDA) defines the right or left dominance of the coronary circulation. Right dominance (ie, PDA supplied by the RCA) is observed in approximately 80% of patients, whereas left dominance (ie, PDA supplied by the LCCA) occurs in the remainder. Direct connections between the distal coronary arteries or collateral blood vessels between the major coronary arteries may also provide alternative routes of blood flow to the myocardium distal to a severe coronary artery stenosis or complete occlusion. However, these connections vary and are often unpredictable in the human coronary circulation.

The RCA (in approximately two-thirds of patients) or the LCCA frequently provides the sole blood supply to the posteromedial papillary muscle, which renders this structure particularly vulnerable to acute ischemia or infarction. Nevertheless, one-third of patients have a dual blood supply (ie, RCA and LCCA) to the posterior papillary muscle[20] and therefore are less susceptible to posteromedial papillary muscle ischemic injury. Because the LAD and LCCA usually provide coronary blood flow to the anterior-lateral papillary muscle, ischemic dysfunction of the muscle is relatively uncommon.

In contrast to the LV, coronary blood flow to the RA, LA, and RV occurs throughout the cardiac cycle because systolic and diastolic aortic blood pressures exceed the pressures within these chambers. The RCA and its branches supply most of the RV, but the RV anterior wall also may receive blood from branches of the LAD. RV dysfunction may occur because of RCA or LAD ischemia.

Coronary blood flow to the LA is derived from branches of the LCCA.[21,22] Augmented LA contractile function resulting from a Frank-Starling mechanism usually occurs in the presence of acute myocardial ischemia or infarction resulting from LAD occlusion,[23] but the compensatory response may not be observed during compromise of LCCA blood flow because of LA ischemia.[24]

Branches of the RCA and LCCA provide coronary blood flow to the RA.[21] For example, a nodal artery from the RCA (55% of patients) or the LCCA (45%) supplies blood to the sinoatrial (SA) node. Similarly, RCA or, less commonly, LCCA branches supply blood flow to the AV node depending on the right or left dominance. A critical stenosis or acute occlusion in either of these two perfusion territories may delay the transmission of electrical signals through the proximal conduction system and cause bradyarrhythmias.

Conduction

The mechanism by which the heart is electrically activated plays a crucial role in its mechanical performance.[25] The SA node is the primary cardiac pacemaker if marked decreases in firing rate, conduction delays or blockade, or accelerated firing of secondary pacemakers (eg, AV node, bundle of His) do not occur. The anterior, middle (Wenckebach), and posterior (Thorel) internodal pathways transmit the initial SA node depolarization rapidly through the RA myocardium to the AV node (Table 6.1). A branch (ie, Bachmann bundle) of the anterior internodal pathway also transmits the SA node depolarization from the RA to the LA across the atrial septum.

Internodal pathways may be clearly demonstrated in the electrophysiology laboratory, but histologic examination most often does not identify anatomically unique bundles of morphologically distinct cardiac cells that are capable of more rapid impulse conduction than the atrial myocardium itself. The cartilaginous skeleton of the heart isolates the atria from the ventricles by acting as an electrical insulator. Atrial depolarization is not indiscriminately transmitted throughout the heart but is instead directed to the ventricles through the AV node and its distal conduction pathway (ie, bundle of His). Electrical isolation of the atrial chambers from the ventricular chambers and the normal transmission delay through the slowly conducting AV node establishes the sequential pattern of atrial followed by ventricular contraction.

Pathologic accessory pathways (eg, bundle of Kent) between the atria and ventricles may bypass the AV node and contribute to the development of reentrant supraventricular tachyarrhythmias (eg, Wolff-Parkinson-White syndrome). The bundle of His pierces the connective tissue insulator of the cartilaginous cardiac skeleton and transmits the AV depolarization signal through the right and left bundle branches to the RV and LV myocardium, respectively, by an extensive Purkinje

TABLE 6.1 Cardiac Electrical Activation Sequence

Structure	*Conduction Velocity (m/s)*	*Pacemaker Rate (beats/min)*
SA node	<0.01	60–100
Atrial myocardium	1.0–1.2	None
AV node	0.02–0.05	40–55
Bundle of His	1.2–2.0	25–40
Bundle branches	2.0–4.0	25–40
Purkinje network	2.0–4.0	25–40
Ventricular myocardium	0.3–1.0	None

AV, Atrioventricular; *SA*, sinoatrial.

network located within the inner one-third of the ventricular walls. The bundle of His, the bundle branches, and the Purkinje network are composed of His-Purkinje fibers that ensure rapid, coordinated distribution of depolarization. This electrical configuration facilitates synchronous ventricular contraction and coordinated ejection.

Artificial cardiac pacing (eg, epicardial RV pacing) bypasses the normal conduction system and produces dyssynchronous LV activation. This dyssynchrony causes uncoordinated contraction that may reduce global LV systolic function, and it is a frequent cause of a new regional wall motion abnormality after cardiopulmonary bypass in cardiac surgical patients. This type of contractile dyssynchrony is also associated with chronic RV apical pacing (eg, for treatment of sick-sinus syndrome or an AV conduction disorder) and is known to cause detrimental effects on LV chamber geometry and function.[26] Recognition of the key relationship between a normal electrical activation sequence and LV contractile synchrony forms the basis for the successful use of cardiac resynchronization therapy in some patients with heart failure.[27]

Cardiac Myocyte Anatomy and Function

Ultrastructure

The ultrastructure of the cardiac myocyte is an elegant example of form following function. The sarcolemma is the external membrane of the cardiac muscle cell. This bilayer lipid membrane contains ion channels (eg, Na^+, K^+, Ca^{2+}, Cl^-), active and passive ion transporters (eg, Na^+/K^+-ATPase, Ca^{2+}-ATPase, Na^+/Ca^{2+} or Na^+/H^+ exchangers), receptors (eg, β_1-adrenergic, muscarinic cholinergic, adenosine, opioid), and transport enzymes (eg, glucose transporter) that modulate intracellular ion concentrations, regulate homeostasis of electrophysiology, mediate signal transduction, and provide substrates for metabolism. Sarcolemmal invaginations (ie, transverse [T] tubules) penetrate deeply within the myoplasm to facilitate rapid, synchronous transmission of cellular depolarization.

The myocyte contains large numbers of mitochondria that are responsible for the generation of high-energy phosphates (eg, adenosine triphosphate [ATP], creatine phosphate) required for contraction and relaxation (Fig. 6.3). The sarcomere is the contractile unit of the cardiac myocyte. Its myofilaments are arranged in parallel, cross-striated bundles of thin fibers that contain actin, tropomyosin, and the troponin complex and thick fibers that are primarily composed of myosin and its supporting proteins. Sarcomeres are connected in series, and the long and short axes of each myocyte simultaneously shorten and thicken, respectively, during contraction.

Light and electron microscopic observations have elucidated sarcomere structure. Thick and thin fibers functionally interact in an area called the *A band*, which becomes wider as the sarcomere shortens, indicating more pronounced overlap. The sarcomere region containing only thin filaments is called the *I band*. The width of this band is reduced during myocyte contraction. One *Z line* (from the German *zuckung*, meaning "to twitch") bisects each I band. The Z line is the border at which two adjacent sarcomeres are joined. An A band and two split I bands (between the Z lines) constitute the length of each sarcomere. The A band also contains a central *M band* composed of thick filaments oriented in a cross-sectional hexagonal arrangement by myosin binding protein C.

Each cardiac myocyte contains a dense sarcoplasmic reticulum (SR) network that surrounds the contractile proteins. The SR is the primary calcium ion (Ca^{2+}) reservoir of the cardiac myocyte, and its extensive distribution ensures an almost homogenous dispersal and reaccumulation of activator Ca^{2+} throughout the myofilaments during contraction and relaxation, respectively. The SR contains specialized structures known as subsarcolemmal cisternae that are located adjacent to the sarcolemma and the T tubules. These cisternae contain ryanodine receptors that are the SR's primary Ca^{2+} release channel and stimulate Ca^{2+}-induced Ca^{2+} release from the SR immediately upon sarcolemmal depolarization.

The contractile apparatus and the mitochondria that supply its energy comprise more than 80% of the myocyte's total volume, whereas the cytosol and nucleus occupy less than 15%. Contraction (not protein synthesis) is the predominant function of the cardiac myocyte. Intercalated disks mechanically join adjacent myocytes by the fascia adherens (which links actin molecules at each Z line) and desmosomes, and they create electrical transparency between myocytes through gap junctions that allow diffusion of ions and small molecules.

Proteins of the Contractile Apparatus

The contractile apparatus has six major components: myosin, actin, tropomyosin, and the three-protein troponin complex. Myosin (500 kDa, 0.17 µm long) contains a pair of intertwined α-helical proteins (ie, tails), each with a globular head that binds the actin molecule, and two adjoining pairs of light chains. Enzymatic digestion of myosin reveals light meromyosin that is composed of the tail sections and heavy meromyosin that contains the globular heads and

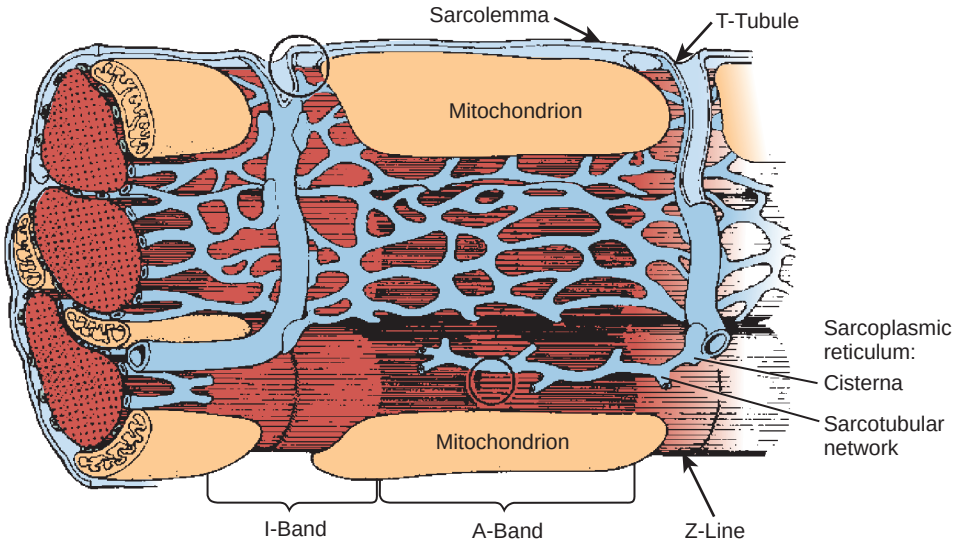

Fig. 6.3 Arnold Katz's schematic depiction of the ultrastructure of the cardiac myocyte. *(From Katz AM. Physiology of the Heart. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)*

the light chains. The primary structural support of the myosin molecule is the light meromyosin. The globular heads of the myosin dimer contain two hinges that are located at the distal light chain tail—double helix junction. The hinges are responsible for myofilament shortening during contraction.

Binding of the myosin head to the actin molecule stimulates a cascade of events initiated by activation of a myosin ATPase that mediates hinge rotation and actin release during contraction and relaxation, respectively. Myosin ATPase activity is a major determinant of the maximal velocity of sarcomere shortening. Several myosin ATPase isoforms have been identified in adult and neonatal atrial and ventricular myocardium that are distinguished by their relative ATPase activity. Myosin molecules are oriented in series along the length of the thick filament, and are joined tail to tail in the filament's center at the M line. This orientation produces equivalent shortening of each one-half of the sarcomere as the actin molecules are pulled toward the center.

The four light chains in the myosin complex are considered regulatory or essential. Regulatory myosin light chains influence myosin-actin interaction by modulating Ca^{2+}-dependent protein kinase phosphorylation. Essential light chains serve important but not precisely defined roles in myosin activity because their removal denatures the myosin molecule. From a pathologic perspective, myosin light chain isoform alterations from ventricular to atrial forms occur in LV hypertrophy that may contribute to contractile dysfunction.[28] Genetic modulation of light chain isoform expression may form the basis of reduced contractile function in some disease states.

Thick filaments are composed of myosin and its binding protein and contain titin, a long, elastic molecule that attaches myosin to the Z lines. Titin is a major contributor to myocardial elasticity, and similar to a bidirectional spring, it acts as a length sensor by establishing greater passive restoring forces as sarcomere length approaches its maximum or minimum.[29] Titin compression and stretching are observed during decreases and increases in load that limit additional shortening and lengthening of the sarcomere, respectively. Titin is another elastic element (in addition to actin and myosin) that mediates the stress-strain behavior of cardiac muscle.[30]

Actin, the major component of the thin filament, is a 42-kDa, oval, globular protein (ie, G-actin) with a diameter of 5.5 nm in greatest dimension. Actin also exists in a polymerized, filamentous configuration (ie, F-actin) wound in double-stranded helical chains of G-actin monomers that resemble two intertwined strands of pearls. Each complete helical revolution of F-actin contains 14 G-actin monomers and is 77 nm long. F-actin does not directly hydrolyze high-energy nucleotides, but the molecule does bind adenosine diphosphate (ADP) and divalent cations such as Ca^{2+} and Mg^{2+}. Actin functions as the activator (hence its name) of myosin ATPase through its reversible binding with myosin. The actin-myosin complex hydrolyzes ATP, supplying the energy required to cause the conformational changes in the myosin heads that mediate the cycle of contraction and relaxation within the sarcomere.

Tropomyosin is a major inhibitor of the interaction between actin and myosin in the myocyte sarcomere. The 40-nm-long molecule consists of a rigid, double-stranded, α-helical, coiled protein linked by a single disulfide bond. Human tropomyosin contains 34-kDa α and 36-kDa β isoforms and may exist as a homodimer (68 or 72 kDa) or heterodimer (70 kDa).[31] A Ca^{2+}-dependent interaction of tropomyosin with the troponin complex initiates excitation-contraction coupling. The association between sarcolemmal membrane depolarization and the resultant binding of actin and myosin is responsible for myocyte contraction. Tropomyosin also stiffens the thin filament because of its position within the longitudinal cleft between the interwoven F-actin helices. Several cytoskeletal proteins, including α-actinin, β-actinin, and nebulette, anchor the thin filaments to the Z lines of the sarcomere.[32]

The troponin complex consists of three proteins that regulate the contractile apparatus. Each serves a distinct role.[33] Troponin complexes are interspersed at 40-nm intervals along the thin filament. A highly conserved, single isoform of troponin C (named for the molecule's Ca^{2+}-binding ability) exists in cardiac muscle. Troponin C consists of a central nine-turn α-helix separating two globular regions that contain four discrete, divalent, cation-binding amino acid sequences, two of which (ie, sites I and II) are Ca^{2+} specific. As a result, the troponin C molecule responds directly to the changes in intracellular Ca^{2+} concentration during depolarization and repolarization of the cardiac myocyte.

The 23-kDa troponin I (ie, inhibitor troponin) exists as a single isoform. Troponin I alone weakly interferes with the actin-myosin interaction, but it becomes the major inhibitor of actin-myosin binding when combined with tropomyosin. This inhibition is responsive to receptor-operated signal transduction because the troponin I molecule contains a serine residue that is susceptible to protein kinase A (PKA)–mediated phosphorylation through the intracellular second messenger cyclic adenosine monophosphate (cAMP). Phosphorylation of this serine residue reduces the ability of troponin C to bind Ca^{2+}, an action that facilitates relaxation during administration of positive inotropic drugs, including β-adrenoceptor agonists (eg, dobutamine) and phosphodiesterase fraction III inhibitors (eg, milrinone).

Troponin T (ie, form that can bind other troponin molecules and tropomyosin) is the largest of the troponin proteins and has four major human isoforms. Troponin T serves as an anchor for the other troponin molecules and may influence the relative Ca^{2+} sensitivity of troponin C.[34]

Calcium-Myofilament Interaction

Binding of Ca^{2+} and troponin C produces a sequence of conformational changes in the troponin-tropomyosin complex that expose the specific myosin-binding site on actin (Fig. 6.4). Small amounts of Ca^{2+} are bound to troponin C when the intracellular Ca^{2+} concentration is low during diastole (10^{-7} M). Under these conditions, the troponin complex confines each tropomyosin molecule to the outer region of the groove between F-actin filaments and prevents the myosin-actin interaction by inhibiting the formation of cross-bridges between these proteins.

The resting inhibitory state is rapidly transformed by the 100-fold increase in intracellular Ca^{2+} concentration (to 10^{-5} M) occurring as a consequence of sarcolemmal depolarization that opens L- and T-type Ca^{2+} channels, allows Ca^{2+} influx from the extracellular space, and stimulates ryanodine receptor–mediated Ca^{2+}-induced Ca^{2+} release from the SR. Ca^{2+} binding to troponin C occurs under these conditions, an action that elongates the troponin C protein and enhances its interactions with troponin T and I. These Ca^{2+}-mediated allosteric alterations in the structure of the troponin complex weaken the interaction between troponin I and actin, promote repositioning of the

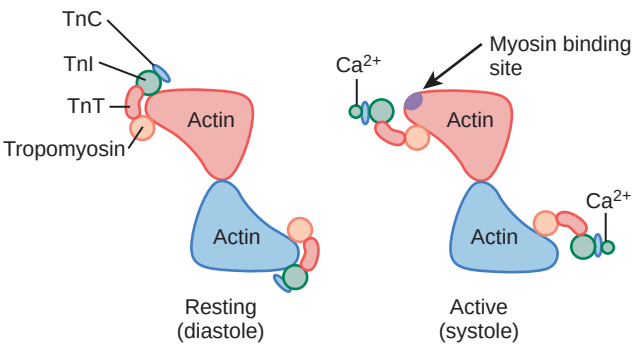

Fig. 6.4 Cross-sectional schematic illustration demonstrates the structural relationship between the troponin-tropomyosin complex and the actin filament under resting conditions (ie, diastole) and after Ca^{2+} binding (ie, systole). Ca^{2+} binding produces a conformational shift in the troponin-tropomyosin complex toward the groove between the actin molecules, exposing the myosin binding site on actin. *TnC,* Troponin C; *TnI,* troponin I; *TnT,* troponin T. *(From Katz AM.* Physiology of the Heart. *3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)*

tropomyosin molecule relative to the F-actin filaments, and minimize the inhibition of actin-myosin binding by tropomyosin that occurs during low intracellular Ca^{2+} concentrations.[35]

Binding of Ca^{2+} to troponin C stimulates several changes in the chemical conformation of the regulatory proteins that result in the exposure of the myosin-binding site on the actin molecule. Opening of the myosin-binding site allows cross-bridge formation and contraction to occur. Subsequent dissociation of Ca^{2+} from troponin C fully reverses the antagonism of inhibition, preventing further myosin-actin interaction and facilitating relaxation by rapidly restoring the original conformation of the troponin-tropomyosin complex on F-actin.

An energy-dependent ion pump located in the SR membrane, the sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA), removes most Ca^{2+} ions from the myofilaments and the myoplasm after the sarcolemmal membrane becomes repolarized. Activator Ca^{2+} is stored in the SR at a concentration of approximately 10^{-3} M and is transiently bound to calsequestrin and calreticulin until the next sarcolemmal depolarization occurs and the ryanodine receptor–activated SR channels open again.

Another Ca^{2+}-ATPase and a Na^{+}/Ca^{2+} exchanger (passively driven by ion concentration gradients) are located in the sarcolemmal membrane and play roles in the removal of Ca^{2+} from the myoplasm after repolarization. Phospholamban is a 6-kDa protein located in the SR membrane that modulates the activity of SERCA by partially inhibiting the dominant form (ie, type 2a) of this Ca^{2+} pump under baseline conditions. However, PKA-induced phosphorylation of phospholamban antagonizes this baseline inhibition and enhances SERCA-mediated Ca^{2+} uptake into the SR.[36] Medications such as dobutamine and milrinone that act by modifying PKA-mediated signal transduction enhance the rate and extent of relaxation by facilitating Ca^{2+} reuptake (ie, positive lusitropic effect) while simultaneously increasing the amount of Ca^{2+} available for the next contractile activation (ie, positive inotropic effect).

Biochemistry of Myosin-Actin Interaction

The biochemistry of cardiac muscle contraction is most often described using a four-component kinetic model (Fig. 6.5).[37] High-affinity binding of ATP to the catalytic domain of myosin initiates a coordinated sequence of events that results in sarcomere shortening. The myosin ATPase enzyme hydrolyzes the ATP molecule into ADP and inorganic phosphate. These products remain bound to myosin, forming an active complex that retains the reaction's chemical energy as potential energy. In the absence of actin, ADP and phosphate eventually dissociate from myosin, and the muscle remains relaxed.

When the myosin-ADP-phosphate complex is bound to actin, myosin ATPase activity is markedly enhanced, and the energy released by ATP hydrolysis is translated into mechanical work. First, myosin binding to actin releases the phosphate anion from the myosin head, producing a tension-inducing molecular conformation within the cross-bridge.[38] Second, release of ADP and potential energy from this activated orientation combine to rotate the cross-bridge (ie, power stroke) at the hinge point separating the helical tail from the globular head of the myosin molecule. Each cross-bridge rotation generates approximately 3.5×10^{-12} newtons of force, and myosin moves 11 nm along the actin molecule.[39] Third, the active-state myosin-actin complex does not immediately dissociate from actin after rotation; it remains in a low-energy bound state (ie, rigor). Fourth, dissociation of the myosin and actin molecules occurs only when a new ATP molecule binds to myosin. This four-step process is then repeated, assuming an adequate supply of ATP and lack of inhibition of the myosin-binding site on actin by the troponin-tropomyosin complex.

Several factors affect cross-bridge biochemistry and the sarcomere shortening that it produces. The maximal velocity of unloaded muscle shortening (V_{max}) is directly related to myosin ATPase activity. The 100-fold increase in intracellular Ca^{2+} concentration associated with sarcolemmal depolarization enhances myosin ATPase activity by a factor of five before it interacts with actin, increasing V_{max}. The extent of sarcomere shortening during contraction also depends on sarcomere length before sarcolemmal depolarization. This length-dependent activation (ie, preload) is known as the Frank-Starling effect in the intact heart, and it may be related to an increase in myofilament Ca^{2+} sensitivity, more optimal spacing between actin and myosin, or titin-induced elastic recoil. Abrupt increases in load during shortening (ie, Anrep effect) or after an extended pause between a series of contractions (ie, Woodworth phenomenon) cause transient increases in

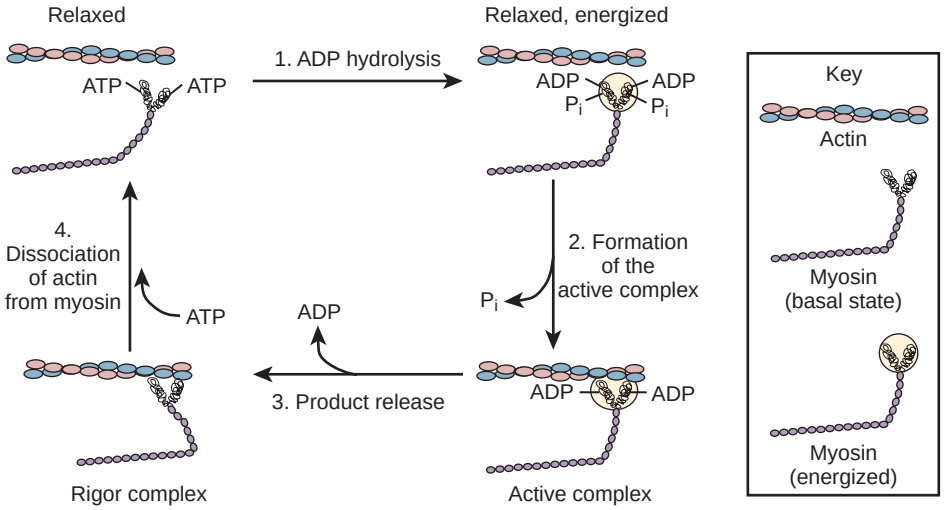

Fig. 6.5 The four-step reaction mechanism for actin-myosin ATPase begins with ATP bound to the myosin heads. Hydrolysis of myosin-bound ATP *(step 1)* energizes the myosin heads, which retain the products of the reaction, ADP and P_i, as potential energy. At the end of this reaction, the muscle remains relaxed because myosin is not attached to actin. Dissociation of phosphate occurs when the activated myosin heads bind to the actin filament *(step 2)*. The dissociation of ADP from the myosin heads releases the chemical energy of the ATP hydrolysis and shifts the position of the myosin cross-bridge, performing mechanical work *(step 3)*. Binding of new ATP molecules to the myosin head dissociates this rigor complex and completes the cycle *(step 4)*. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; P_i, phosphate. *(From Katz AM. Physiology of the Heart. 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001.)*

contractile force through such a length-dependent activation mechanism. An increase in stimulation frequency also augments shortening through enhanced myofilament Ca^{2+} sensitivity and more pronounced release of Ca^{2+} from the SR.

Laplace's Law

The sarcomere generates tension and shortens during contraction. The developed tension is released and the sarcomere lengthens during relaxation. However, the intact heart produces pressure on and forces ejection of a volume of blood. The alterations in muscle tension and length observed in the sarcomere require transformation into the phasic changes in pressure and volume that occur in the intact heart.[40]

Laplace's law facilitates conversion of the contractile behavior of individual sarcomeres or isolated, linear cardiac muscle preparations in vitro into three-dimensional chamber function in vivo, permitting systematic examination of the intact heart's ability to function as a hydraulic pump. The relationship between myocyte length and chamber volume (V) may be modeled as a pressurized, spherical shell (Fig. 6.6),[41] for which volume is proportional to the cube of the radius (r): $V = 4\pi r^3/3$. This model may be pedagogically useful for the following discussion, but the LV and the atria are more precisely described using prolate ellipsoidal geometry, which defines three axes corresponding to the anteroposterior, septal-lateral, and long-axis diameters (D_{AP}, D_{SL}, and D_{LA}, respectively) such that $V = \pi D_{AP} D_{SL} D_{LA}/6$. This technique of measuring LV or atrial volume more closely approximates anatomic reality and has been validated extensively in experimental animals[42,43] and humans.[44,45] However, the method does not apply when attempting to describe RV volume because of the unique bellows-shaped structure of this chamber.[46]

The relationship between wall stress (ie, tension exerted over a cross-sectional area) and pressure within a cardiac chamber is complex. Laplace's law relates wall stress to pressure and chamber geometry, which may be determined based on three assumptions.[40] First, the chamber is spherical with a uniform wall thickness (h) and an internal radius (r). Second, the stress (σ) throughout the thickness of the chamber wall is constant. Third, the chamber remains in static equilibrium (ie, is not actively contracting). Tension development within each sarcomere causes a corresponding increase in wall stress that is translated into the generation of hydraulic pressure within the chamber. In this context, internal pressure (P) is defined as an orthogonal distending force exerted against the chamber walls, and wall stress is a shear force exerted around the circumference of the chamber that resists the distention.[40]

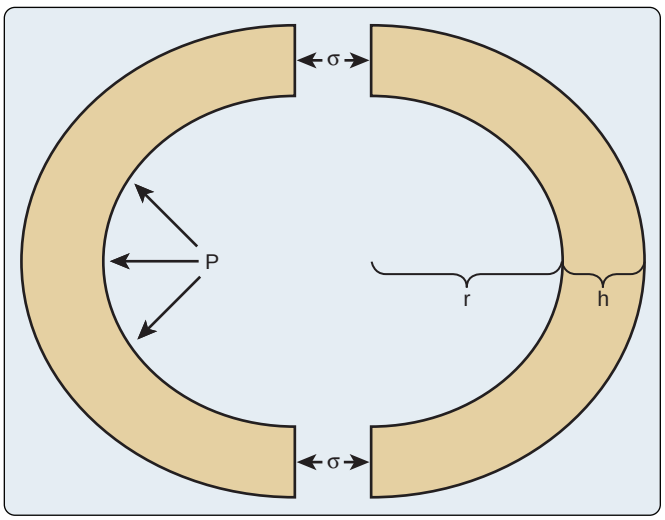

Fig. 6.6 Opposing forces within a theoretical LV sphere that determine Laplace's law. The LV pressure *(P)* tends to push the sphere apart, whereas wall stress *(σ)* holds the sphere together. *h*, Thickness; *LV*, left ventricular; *r*, radius.

Bisecting the chamber into two equal halves exposes the internal forces within it (see Fig. 6.6). The product of internal pressure and wall cross-sectional area (πr^2) represents the total force pushing chamber hemispheres apart. In contrast, the total force within the chamber walls resists this distracting force and is equal to σ times the cross-sectional wall area. The two forces must balance for the chamber to remain in equilibrium such that $P\pi r^2 = \sigma[\pi (r + h)^2 - \pi r^2]$. Removal of redundant terms simplifies this equation to $Pr = \sigma h(2 + h/r)$. The chamber wall is normally thin relative to its internal radius. As a result, the h/r term may be neglected, and the remaining expression may be rearranged to become the familiar $\sigma = Pr/2h$.

Laplace's law for a thin-walled, static sphere indicates that wall stress varies directly with internal pressure and radius and inversely with wall thickness. Despite the observation that the ratio of wall thickness to radius is not entirely negligible (h/r = 0.4) at LV end-diastole in the intact heart,[47] Laplace's law provides a very useful description of the factors that contribute to changes in LV or atrial wall stress. For example, LV dilation (ie, increased r) associated with chronic aortic insufficiency increases global LV wall stress that reflects greater tension on each sarcomere within the chamber wall.[48] Similarly, the persistent elevation of LV pressure (P) observed in the setting of severe aortic stenosis also produces greater stress on the LV wall. The increases in wall stress resulting from chronic volume or pressure overload are directly translated into greater myocardial oxygen consumption because the myofilaments require more energy to develop enhanced tension. In contrast, an increase in wall thickness (h) causes a reduction in global wall stress and tension developed by individual sarcomeres. Laplace's law predicts that hypertrophy is an important compensatory adaptation to chronically altered chamber load that reduces the tension generated by each muscle fiber.

Prolate ellipsoidal models of chamber geometry and those incorporating orthogonal radial, circumferential, and meridional components of wall stress require more complex derivations of Laplace's law[49] that may be corrected with dimensional measurements obtained using echocardiography.[50] Formal derivations of these models are beyond the scope of this chapter, but they are available elsewhere.[51,52] Despite their relative mathematical complexity, the principles linking changes in length and tension in the sarcomere to pressure, volume, and wall thickness in the intact heart are consistently demonstrated in these models.

In contrast to the assumption used in the derivation of Laplace's law described earlier, wall stress is not uniformly distributed across LV thickness in the intact heart.[51] Instead, wall stress is greatest in the subendocardium and progressively declines to a minimum at the epicardial surface. These regional differences in wall stress become especially important in LV pressure-overload hypertrophy, which results from aortic valve stenosis or poorly controlled essential hypertension.[54] Under these conditions, the subendocardium is exposed to more pronounced increases in interventricular pressure concomitant with greater myocardial oxygen consumption that make it more susceptible to acute myocardial ischemia. The combination of elevated subendocardial wall stress and increased myocardial oxygen consumption is particularly deleterious in the setting of a flow-limiting coronary artery stenosis and often contributes to the relatively common occurrence of subendocardial myocardial infarction in the absence of complete coronary occlusion in patients with severe LV hypertrophy.

The Cardiac Cycle

A schematic illustration of the cardiac cycle is useful for demonstrating the highly coordinated, temporally related series of electrical, mechanical, and valvular events that occur with contraction and relaxation of the cardiac chambers (Fig. 6.7).[55] A single cardiac cycle occurs in 0.8 s at a heart rate of 75 beats/minute. Synchronous depolarization of RV and LV myocardium (as indicated by the electrocardiogram QRS complex) initiates contraction of and produces a rapid increase in

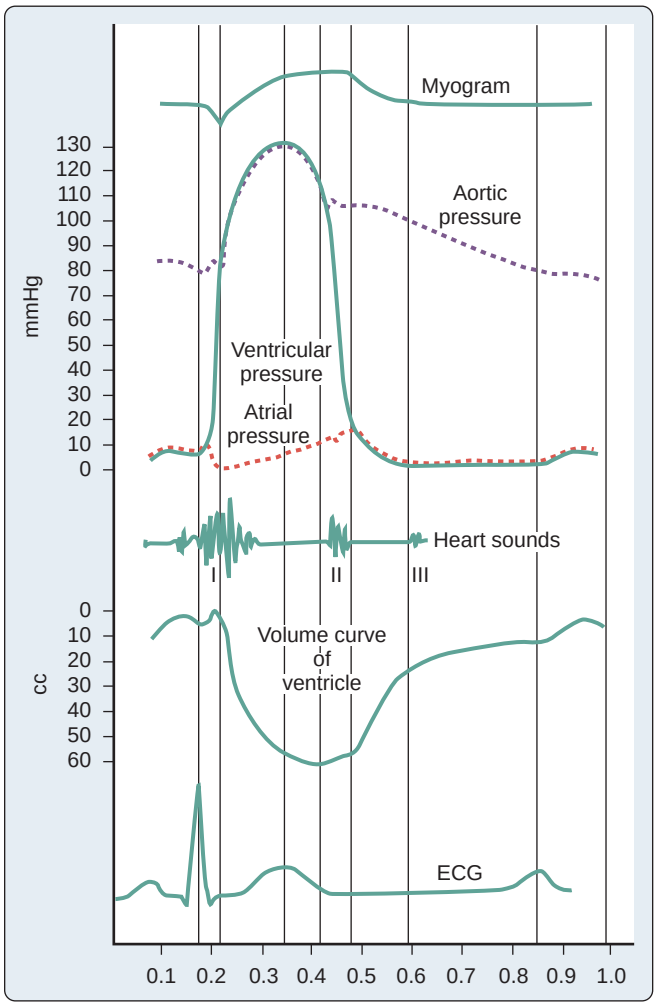

Fig. 6.7 Carl Wiggers' original illustration depicting the electrical, mechanical, and audible events of the cardiac cycle, including the electrocardiogram; aortic, left ventricular, and left atrial pressure waveforms; left ventricular volume waveform; and heart tones associated with mitral and aortic valve closure. *(From Wiggers CJ: The Henry Jackson Memorial Lecture. Dynamics of ventricular contraction under abnormal conditions.* Circulation. *1952;5:321–348.)*

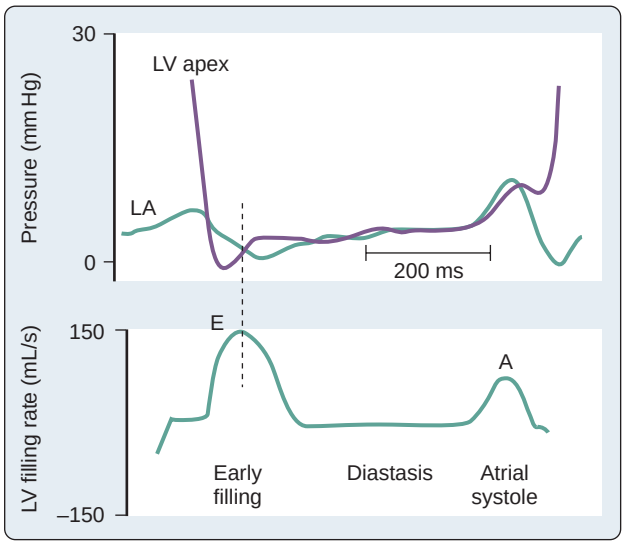

Fig. 6.8 Diagram depicting the relationship between left ventricular *(LV)* and left atrial *(LA)* pressure *(top)* and the corresponding LV filling rate *(bottom)* during early filling *(E)*, diastasis, and atrial systole *(A)*. The LV pressure initially falls below the LA pressure, creating a pressure gradient between the chambers that causes early LV filling. *(From Little WC, Oh JK. Echocardiographic evaluation of diastolic function can be used to guide clinical care.* Circulation. *2009;120:802–809.)*

pressure within these chambers (ie, systole). Closure of the tricuspid and mitral valves occurs when RV and LV pressures exceed the corresponding atrial pressures and causes the first heart sound (S_1).

LV systole is divided into isovolumic contraction, rapid ejection, and slower ejection phases. LV isovolumic contraction describes the time interval between mitral valve closure and aortic valve opening during which LV volume remains constant. This event is somewhat analogous to isometric (ie, constant length) contraction of isolated cardiac muscle in papillary muscle preparations in vitro. Nevertheless, global LV geometry is transformed from an ellipsoidal shape at end-diastole to a more spherical configuration during isovolumic contraction because the length of the longitudinal axis (ie, base to apex) shortens, and LV wall thickness increases.[56] The maximal rate of increase of LV pressure (dP/dt_{max}) occurs during LV isovolumic contraction and may be used to estimate myocardial contractility in vivo. True isovolumic contraction does not occur in the RV because of the sequential nature of contraction of the inflow and outflow tracts.[57] The pressures in the aortic and pulmonic roots fall to their minimal value immediately before the corresponding valves open. Rapid ejection occurs when LV and RV pressures exceed aortic and pulmonary arterial pressures, respectively.

Approximately two-thirds of the end-diastolic volume of each ventricle is ejected during the rapid-ejection phase. Dilation of the elastic aorta and proximal great vessels and the pulmonary artery and its proximal branches occurs concomitant with the rapid increase in volume as the kinetic energy of LV and RV contraction is transferred to the aorta and pulmonary artery, respectively, as potential energy. The pressure gradients cause the aortic and pulmonic valves to close, an action that produces the second heart sound (S_2). This event signifies the end of systole and the beginning of diastole. The aortic valve closes slightly before the pulmonic valve during inspiration because RV ejection is modestly prolonged by augmented venous return. The temporal discrepancy between aortic and pulmonic valve closure causes physiologic splitting of S_2. The normal end-diastolic (V_{ed}) and end-systolic (V_{es}) volumes are approximately 120 and 40 mL, respectively. The difference between V_{ed} and V_{es} (ie, the SV) is 80 mL, and the ratio of SV to V_{ed} (ie, the ejection fraction or EF) is 67%.[58]

Compliance of the proximal systemic and pulmonary arterial vessels determines the amount of potential energy that is stored and subsequently released to their respective distal vascular beds during diastole. Further ejection of additional blood from the LV and RV drops precipitously as the pressures within the aorta and pulmonary artery reach their maximal values. Ejection stops entirely when the LV and RV begin to repolarize and the arterial forces resisting further ejection are greater than the ventricular forces continuing to propel blood forward. As the period of slower ejection comes to an end, aortic and pulmonary artery pressures exceed LV and RV pressures.

LV diastole is divided into isovolumic relaxation, early ventricular filling, diastasis, and atrial systole. LV isovolumic relaxation defines the period between aortic valve closure and mitral valve opening during which LV volume remains constant. LV pressure falls very rapidly as the myofilaments relax. When LV pressure falls below LA pressure, the mitral valve opens, and blood volume stored in the LA enters the LV driven by the initial pressure gradient between the chambers. LV pressure continues to fall after mitral valve opening as sarcomere relaxation is completed and myocardial elastic components recoil (Fig. 6.8).[59–61] These factors contribute to the creation of a pressure gradient between the LA and LV that extends from the base to the apex.[60] The rate and extent of LV pressure decline and the LA pressure when the mitral

valve opens determine the initial magnitude of the pressure gradient between these chambers.[62]

Early LV filling occurs very rapidly, as indicated by the observation that the peak blood flow velocity across the mitral valve during this phase of diastole may exceed the flow rate across the aortic valve during LV ejection.[63] Vortex formation from the primary mitral blood flow jet also facilitates selective filling of the LV outflow tract.[64,65] Delays in LV relaxation may occur as a consequence of age or disease processes (eg, ischemia, hypertrophy) and are a common cause of attenuated early LV filling because the initial LA-LV pressure gradient is reduced.[66] After the mitral valve opens, the pressure gradient between the LA and LV depends on the relative pressure within each chamber. Most of the increase in LV volume observed during early ventricular filling occurs while LV pressure continues to decrease. The LV pressure falls to a subatmospheric level if blood flow across the mitral valve is completely obstructed.[8,67]

The data imply that the LV can continue to fill through the diastolic suction mechanism even if LA pressure is zero.[68,69] The diastolic suction effect is crucial for the preservation of early LV filling during profound hypovolemia and strenuous exercise. The early filling phase of diastole normally provides 70% to 75% of the total SV ejected during the subsequent LV contraction and ends when LA and LV pressures equilibrate or the gradient between these chambers transiently reverses. The mitral valve remains open, and pulmonary venous blood flow directly traverses the LA into the LV after the LA and LV pressures have equalized. The LA acts as a simple conduit during this diastasis phase of diastole, and LV filling markedly slows as a result. The small amount of blood flow from pulmonary veins occurring during diastasis usually adds less that 5% to the total LV SV.[70] Progressive increases in heart rate shorten and may completely eliminate diastasis, but tachycardia has little meaningful effect on overall LV filling because the contribution during diastasis is minor.

Atrial systole is the final phase of diastole. LA contraction increases the pressure in this chamber, creating a second positive pressure gradient for blood flow from the LA and LV during end-diastole. The peristaltic pattern of LA contraction and the unique anatomy of the pulmonary venous–LA junction largely prevent retrograde blood flow into the pulmonary veins during atrial systole at normal LA pressures.[71] Atrial systole usually accounts for 15% to 25% of total LV SV, but this LA component becomes especially important to the maintenance of LV filling in pathologic states characterized by delayed LV relaxation or reduced LV compliance.[72] Similarly, improperly timed LA contraction or the onset of atrial tachyarrhythmias (eg, atrial fibrillation) may cause profound hemodynamic compromise in patients with myocardial ischemia or pressure-overload hypertrophy who depend on atrial systole for LV filling. Descriptions of RV diastole are very similar to those used to characterize LV diastole, with the exception that true isovolumic relaxation most likely does not occur in the RV.

The LA pressure waveform is composed of three major deflections during normal sinus rhythm. The LA contracts immediately after the P wave of atrial depolarization, producing the *a* wave of atrial systole. This *a* wave may be enhanced by an increase in LA preload or contractile state. The rate of decline of the *a* wave is an index of LA relaxation,[73] similar to the rate of LV pressure fall during isovolumic relaxation. LV contraction with the onset of systole causes a pressure wave to be transmitted to the LA in retrograde fashion by closure of the mitral valve, resulting in a small increase in LA pressure. The *c* wave may be more pronounced in the setting of mitral valve prolapse.

During late LV isovolumic contraction, LV ejection, and most of LV isovolumic relaxation, pulmonary venous blood progressively fills the LA and gradually increases LA pressure, resulting in the LA *v* wave. The *v* wave may be enhanced in the setting of mitral regurgitation or reductions in LA compliance.[74]

RA pressure waveform deflections are very similar to those observed in the LA. The RA *a-c-v* waveform morphology is transmitted to the jugular veins and may be clinically observed in the neck during routine physical examination in the supine position. In contrast to the biphasic nature of LA and RA pressure waveforms, the volume waveforms of these chambers are essentially monophasic. For example, minimum LA volume occurs immediately after the completion of LA contraction and corresponds closely to the mitral valve closure, whereas maximal LA volume is observed immediately before the mitral valve opens.

Pressure-Volume Diagrams

A time-dependent, two-dimensional plot of continuous LV pressure and volume throughout a single cardiac cycle creates a phase space diagram, which is useful for analysis of LV systolic and diastolic function in the ejecting heart (Fig. 6.9). Otto Frank initially described the theoretic foundations of this technique at the end of the 19th century.[75,76] In the 1970s, Hiroyuki Suga and Kiichi Sagawa were the first to widely apply pressure-volume analysis after technologic advances enabled the continuous measurement of high-fidelity LV pressure with a miniature micromanometer implanted in the chamber and LV volume with sonomicrometry and a conductance catheter.[77–79] In 1988, the authors provided a detailed description of pressure-volume analysis of cardiac function in *Cardiac Contraction and the Pressure-Volume Relationship* (Oxford University Press, New York).

Alterations in LV pressure with respect to volume occur in a counterclockwise fashion over time. The cardiac cycle begins at end-diastole (see Fig. 6.9, point A). An abrupt increase in LV pressure at constant LV volume occurs during isovolumic contraction. Opening of the aortic valve occurs when LV pressure exceeds aorta pressure (see Fig. 6.9, point B) and ejection begins. LV volume decreases rapidly as blood is ejected from the LV into the aorta and proximal great vessels. When

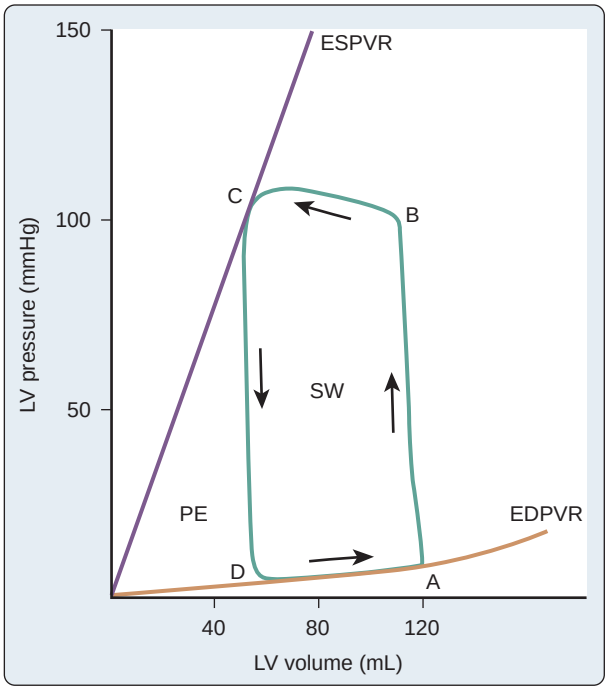

Fig. 6.9 As shown in the steady-state left ventricular *(LV)* pressure-volume diagram, the cardiac cycle proceeds in a time-dependent, counterclockwise direction *(arrows)*. Points A, B, C, and D correspond to LV end-diastole (ie, closure of the mitral valve), opening of the aortic valve, LV end-systole (ie, closure of the aortic valve), and opening of the mitral valve, respectively. Segments AB, BC, CD, and DA represent isovolumic contraction, ejection, isovolumic relaxation, and filling, respectively. The left ventricle is constrained to operate within the boundaries of the end-systolic and end-diastolic pressure-volume relationships (ESPVR and EDPVR, respectively). The area inscribed by the LV pressure-volume diagram represents the stroke work *(SW)* (ie, kinetic energy) performed during the cardiac cycle. The area to the left of the LV pressure-volume diagram between ESPVR and EDPVR is the remaining potential energy *(PE)* of the system. The sum of SW and PE is the pressure-volume area.

LV pressure declines below aortic pressure at the end of ejection, the aortic valve closes (see Fig. 6.9, point C). This event is immediately followed by a rapid decline in LV pressure in the absence of changes in LV volume (ie, isovolumic relaxation). The mitral valve opens when LV pressure falls below LA pressure (see Fig. 6.9, point D), initiating LV filling. The LV pressure-volume diagram is completed as the LV refills its volume for the next contraction concomitant with relatively small increases in pressure during early filling, diastasis, and LA systole.

The steady-state LV pressure-volume diagram provides advantages over temporal plots of individual LV pressure and volume waveforms when identifying major cardiac events without electrocardiographic correlation (eg, aortic or mitral valve opening or closing) or evaluating acute alterations in LV loading conditions. For example, end-diastolic and end-systolic volumes may immediately be recognized as the lower right (point A) and upper left (point C) corners of the diagram, respectively, allowing rapid calculation of SV and EF. Movement of the right side of the pressure-volume diagram to the right is characteristic of an increase in preload concomitant with a larger SV, whereas an increase in afterload causes the pressure-volume diagram to become taller (ie, greater LV pressure) and narrower (ie, decreased SV) (Fig. 6.10). The area of the diagram precisely defines the LV pressure-volume (stroke) work (ie, kinetic energy) for a single cardiac cycle.

As illustrative as a single LV pressure-volume diagram may be for obtaining basic physiologic information, the dynamic changes of a series of these LV pressure-volume diagrams occurring during an acute alteration in LV load over several consecutive cardiac cycles provide unique insights into LV systolic and diastolic function. A series of differentially loaded LV pressure-volume diagrams may be produced using transient changes in preload or afterload with mechanical (ie, vena caval or aortic constriction, respectively) or pharmacologic (ie, sodium nitroprusside or phenylephrine infusions, respectively) interventions.

The nested set of diagrams allows calculation of relatively heart rate– and load-insensitive estimates of myocardial contractility in vivo such as the end-systolic pressure-volume relationship (ESPVR, the slope of which is called *end-systolic elastance* [E_{es}])[79] and the stroke work (SW)–end-diastolic volume relationship, a linear Frank-Starling analog also known as preload recruitable SW.[80] The family of pressure-volume diagrams also describes the end-diastolic pressure-volume relationship (EDPVR) that characterizes LV compliance and is an important determinant of LV filling.[40]

The ESPVR and EDPVR define the operating constraints of the LV (see Figs. 6.9 and 6.10). The ESPVR and EDPVR are determined by the intrinsic properties of the LV during systole and diastole, respectively, but the relative positions of the end-diastolic and end-systolic points that lie along these lines for any given cardiac cycle are established primarily by venous return (ie, preload) and arterial vascular tone (ie, afterload).[81] This model emphasizes that analysis of overall cardiovascular performance in vivo must not consider the LV and the circulation with which it interacts as independent entities.[82] The area to the left of the steady-state LV pressure-volume diagram that lies between the ESPVR and the EDPVR is the remaining potential energy of the system (see Fig. 6.9) and is an important factor in determining the LV energetics and mechanical efficiency.[83] RV systolic and diastolic function also may be quantified using the principles of this pressure-volume theory.[84]

Pressure-volume analysis provides a useful illustration of the pathophysiology of LV systolic or diastolic dysfunction as underlying causes for heart failure.[85] For example, a decrease in the ESPVR slope indicates that a reduction in myocardial contractility has occurred. This observation is consistent with pure LV systolic dysfunction. The event is often accompanied by a compensatory LV dilation (ie, movement of the pressure-volume diagram to the right) along a normal EDPVR (Fig. 6.11). The increase in preload may preserve SV and cardiac output (CO), but occurs at the cost of higher LV filling and pulmonary venous pressures.[81] In contrast, an increase in the EDPVR denotes a reduction in LV compliance such that LV diastolic pressure is higher at each LV volume. Under these circumstances, myocardial contractility may remain relatively normal (ie, ESPVR does not change), but LV filling pressures are elevated, producing pulmonary venous

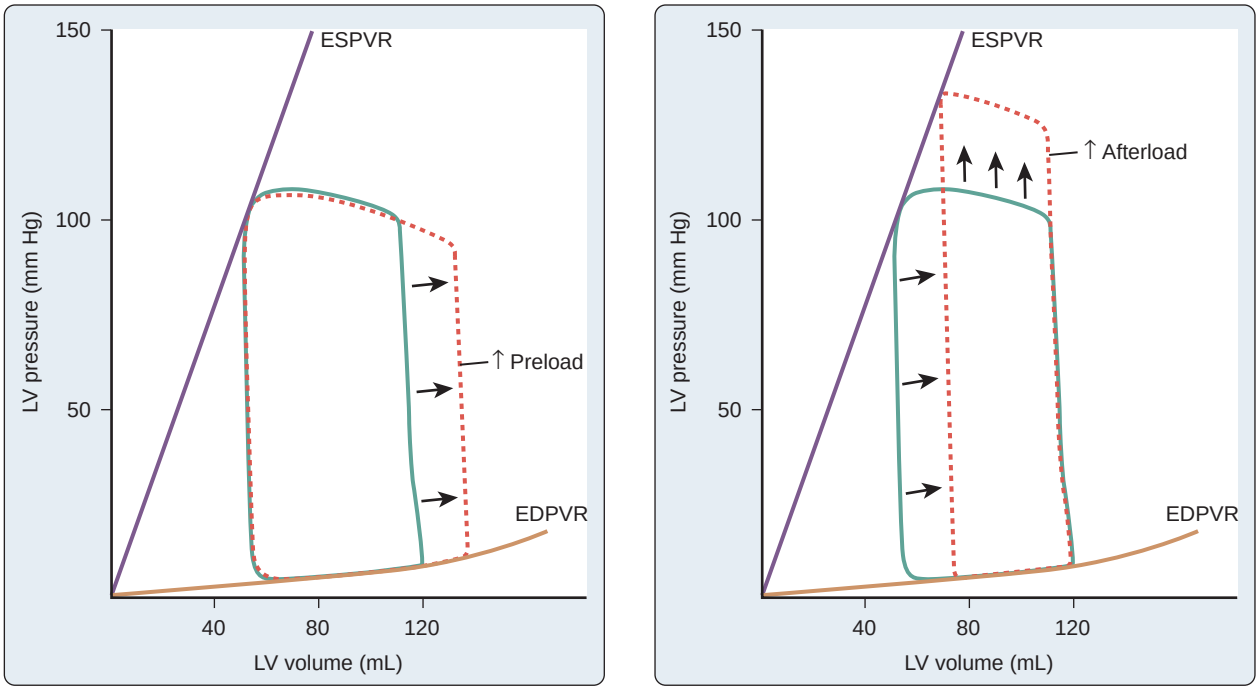

Fig. 6.10 Schematic illustrations of the alterations in the steady-state LV pressure-volume diagram produced by a pure theoretical increase in LV preload *(left)* or afterload *(right)*. Additional preload directly increases stroke volume *(SV)* and LV end-diastolic pressure, whereas an acute increase in afterload produces greater LV pressure but reduces SV. *EDPVR*, End-diastolic pressure-volume relationship; *ESPVR*. end-systolic pressure-volume relationship; *LV*, left ventricular.

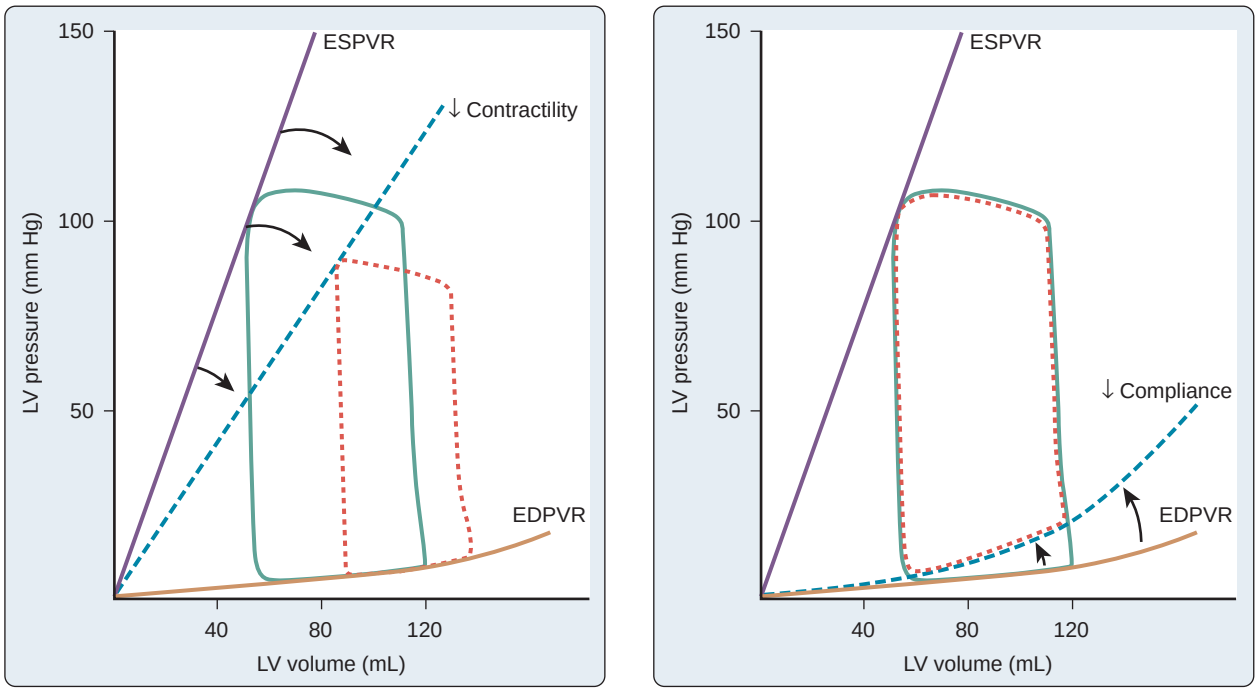

Fig. 6.11 Schematic illustrations of the alterations in the steady-state LV pressure-volume diagram produced by a reduction in myocardial contractility, as indicated by a decrease in the slope of the ESPVR (*left*), and a decrease in LV compliance as indicated by an increase in the position of the EDPVR (*right*). The diagrams emphasize that heart failure may result from LV systolic or diastolic dysfunction independently. *EDPVR*, End-diastolic pressure-volume relationship; *ESPVR*. end-systolic pressure-volume relationship; *LV*, left ventricular.

congestion and clinical symptoms (Fig. 6.11). Simultaneous depression of the ESPVR and elevation of the EDPVR indicate LV systolic and diastolic dysfunction. SV and CO may be severely reduced because available compensatory changes in preload or afterload, depicted by movement of the steady-state LV pressure-volume diagram within the ESPVR and the EDPVR boundaries, are quite limited.

The pressure-volume plane may be extrapolated to a single region or dimension of the LV, and analogous LV pressure-dimension relationships may then be analyzed.[86–88] For example, ultrasonic transducers placed within the LV wall may be used in the laboratory setting to measure changes in segment length[89] or LV diameter[90] during the cardiac cycle. Transducers also may be placed on the LV epicardial and endocardial surfaces to measure continuous changes in wall thickness.[88] The time for ultrasound to be transmitted between a pair of transducers is directly proportional to the length between them (ie, Doppler principle).

Segment length or chamber diameter normally increases during diastole and shortens during systole analogous to changes in continuous LV volume, whereas myocardial wall thickness decreases in diastole and increases during systole.[91] The changes in regional segment length and wall thickness during the cardiac cycle form the basis for speckle-tracking echocardiography.

Acute changes in LV loading conditions may be used to develop a series of diagrams for measurement of LV end-systolic and end-diastolic pressure–segment length, pressure–wall thickness, or pressure-dimension relationships. The use of regional compared with global LV pressure-volume analysis is particularly advantageous when studying the mechanical consequences of myocardial ischemia.[92] For example, acute occlusion of a major coronary artery produces a time-dependent collapse of the steady-state LV pressure-length diagram in the central ischemic zone consistent with a rapidly progressing decline and eventual complete absence of regional SW (Fig. 6.12). In contrast, the LV pressure–segment length diagram tilts to the right in a moderately ischemic area such as a border zone surrounding a central ischemic region. The diagram may be divided into three regions that correspond to systolic lengthening (ie, due to paroxysmal systolic aneurysmal bulging of the ischemic zone), postsystolic shortening (ie, shortening in the ischemic zone that occurs after ejection as a result of tethering to adjacent normal myocardium), and a variable area between the two that makes a contribution to regional LV SW (Fig. 6.13). These parameters may be used to quantify the relative severity of regional myocardial ischemia.[93]

Pressure-volume analysis may be applied to the study of atrial function. In contrast to the almost rectangular shape of the LV pressure-volume diagram, the steady-state LA or RA pressure-volume diagram is composed of two intersecting loops arranged in a horizontal figure-eight pattern that incorporates active (ie, A loop) and passive (ie, V loop) components (Fig. 6.14).[94] The unusual shape of the LA pressure-volume diagram results from the biphasic morphology of the LA pressure waveform (discussed earlier).

Beginning at LA end-diastole (ie, corresponding to the end of LV diastasis), the active component of the diagram traces a counterclockwise outline as the LA ejects its contents into the LV through the open mitral valve. LA end-systole (ie, corresponding to LV end-diastole) marks the end of atrial contraction and is defined at minimal LA volume. Identification of LA end-diastole and end-systole on the diagram facilitates calculation of LA SV and emptying fraction (ie, analogous to LV EF).

After the mitral valve closes, LA filling occurs during LV systole and isovolumic relaxation. LA pressure and volume gradually increase as the chamber is filled with pulmonary venous blood during this reservoir phase, forming the bottom part of the A loop and the upper part of the V loop. The area of the A loop represents active LA SW[95] (ie, analogous to LV SW, the area inscribed by the LV pressure-volume diagram). The passive component (ie, V loop) of the LA pressure-volume diagram proceeds in a clockwise direction (see Fig. 6.14).

Total LA reservoir volume is easily determined from the steady-state LA pressure-volume diagram as the difference between maximal and minimal LA volumes.[73] The V loop area represents the total passive elastic energy stored by the LA during the reservoir phase, and it is an

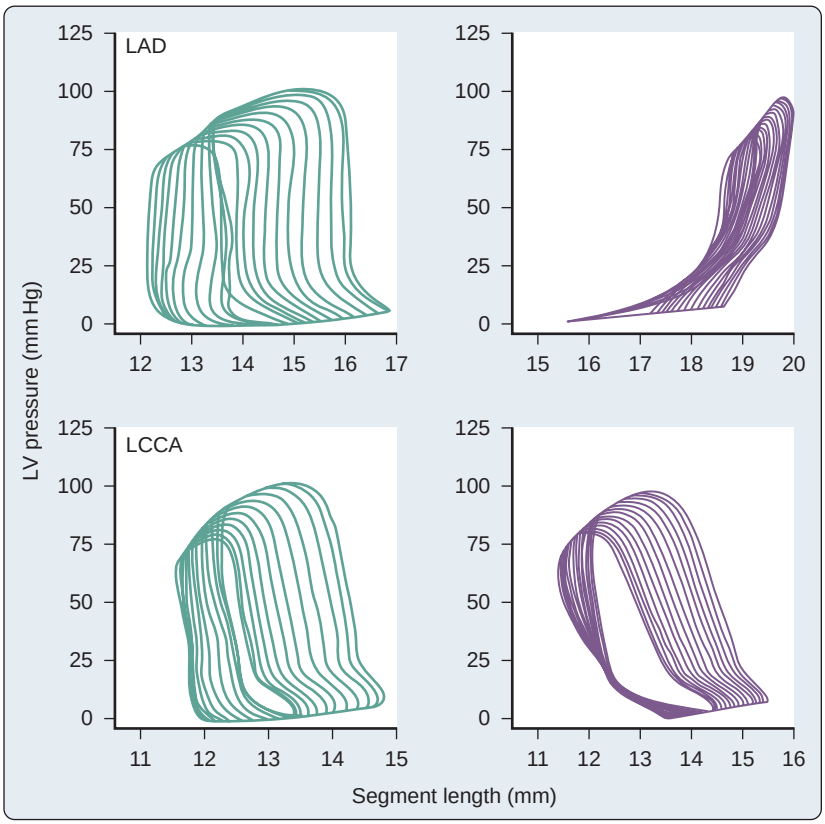

Fig. 6.12 Differentially loaded left ventricular (LV) pressure–segment length diagrams depict an abrupt occlusion of the inferior vena cava in the left anterior descending *(LAD)* and left circumflex coronary artery *(LCCA)* perfusion territories before *(left)* and during *(right)* a 2-minute occlusion of the LAD in a conscious, chronically instrumented dog. Aneurysmal systolic lengthening, postsystolic shortening, loss of effective stroke work, and diastolic creep (ie, segment expansion) occur in the LAD LV pressure–segment length diagram in response to ischemia in this region. Corresponding isovolumic shortening and early diastolic lengthening in the LCCA LV pressure–segment length diagram also occur as the contraction and relaxation of non–ischemic-zone myocardium and partially compensate for the adjacent dyskinetic region. *(Modified from Pagel PS, Hettrick DA, Lowe D, et al. Desflurane and isoflurane exert modest beneficial actions on left ventricular diastolic function during myocardial ischemia in dogs.* Anesthesiology. *1995;83:1021–1035.)*

index of reservoir function.[96] The slope of the line between minimal LA pressure of the A loop and maximum LA pressure in the V loop has been used as an index of static LA compliance. Regional myocardial ischemia[24] or severe LV dysfunction[97] increases the slope of this line, indicating a decrease in compliance. LA emptying after mitral valve opening causes a rapid decline in LA volume that forms the bottom portion of the V loop. Additional pulmonary venous return also enters the LA during LV diastasis, but this blood flow does not alter LA volume because the mitral valve is open.

The LA conduit phase occurs between mitral valve opening and LA end-diastole, and LA conduit volume is calculated as the difference between maximum and end-diastolic volumes (see Fig. 6.14). The relationships among LA loading conditions, LA and LV contractile states, the rate and extent of LA relaxation, LA elastic properties, and pulmonary venous blood flow determine the relative areas of the A and V loops and the point of intersection between them.[94] Analogous to observations of the LV acute alterations in LA loading conditions may be used to assess LA myocardial contractility and dynamic compliance using LA end-systolic and end-reservoir pressure-volume relationships.[43,98,99]

Determinants of Pump Performance

The ability of each cardiac chamber to function as a hydraulic pump depends on how effectively it can collect (ie, diastolic function) and eject (ie, systolic function) blood. For the sake of this discussion, we focus on the LV, but the principles that determine LV pump performance are equally applicable to the other chambers.

From a clinical perspective, LV systolic function is most often quantified using CO (ie, product of heart rate and SV) and EF. These variables depend on the intrinsic contractile properties of the LV myocardium, the quantity of blood the chamber contains immediately before contraction commences (ie, preload), and the external resistance to emptying with which it is confronted (ie, afterload). The interactions among preload, afterload, and myocardial contractility establish the SV generated during each cardiac cycle (Fig. 6.15).

When combined with heart rate and rhythm, preload, afterload, and myocardial contractility determine the volume of blood that the LV can pump per minute (ie, CO), assuming adequate venous return. Mitral or aortic valve malfunction (eg, regurgitation) or an anatomically abnormal route of intracardiac blood flow (eg, ventricular septal defect with left-to-right shunt) reduces effective forward flow, limiting the use of SV, CO, and EF as indices of LV systolic performance.

The LV's structural integrity is an important determinant of its systolic function. Pulmonary venous blood flow, LA function, mitral valve dynamics, pericardial restraint, and the active (ie, relaxation) and passive elastic (ie, compliance) properties of the LV during diastole determine its ability to properly fill. LV diastolic function is considered normal when these factors combine to provide an LV preload that provides sufficient CO to satisfy cellular metabolism without elevations

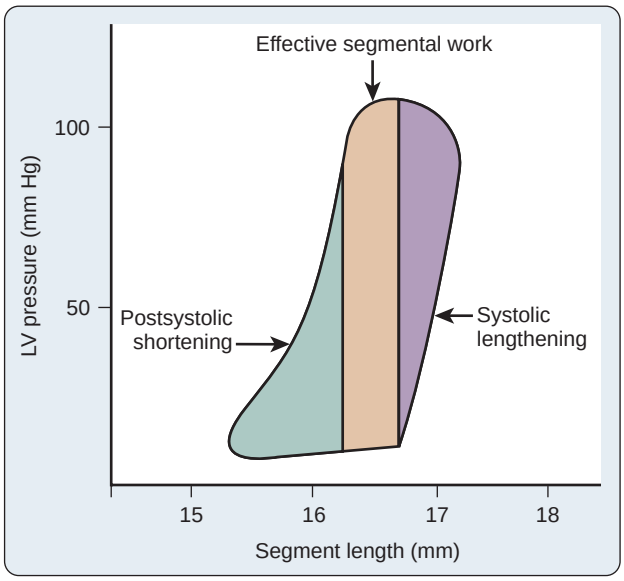

Fig. 6.13 The steady-state left ventricular (LV) pressure–segment length is measured within the border zone of the central ischemic region during acute occlusion of the left anterior descending coronary artery in a dog. Areas of systolic lengthening *(right)* and postsystolic shortening *(left)* produced by partial ischemia and tethering to the central ischemic zone do not contribute to segmental work, but a small area of the diagram *(center)* demonstrates effective segment shortening that contributes to global LV stroke work.

in pulmonary venous and mean LA pressures (ie, normal values of approximately 10 mm Hg for each).[100] In contrast, LA or mitral valve dysfunction, delayed LV relaxation, reduced LV compliance, or increased pericardial pressure may substantially restrict the ability of the LV to properly fill unless pulmonary venous and LA pressures increase. LV diastolic dysfunction is invariably associated with greater pulmonary venous and LA pressures. LV diastolic dysfunction may produce signs and symptoms of congestive heart failure independent of changes in LV systolic function.

Heart Rate

An alteration in the stimulation frequency of isolated cardiac muscle produces a parallel change in LV contractile state. The Bowditch, staircase, or *treppe* (German for "stair") phenomenon is a force-frequency relationship in which a gradual increase in muscular contraction follows rapidly repeated stimulation. The effect has been demonstrated in isolated LV muscle[101] and intact LV.[102] Enhanced Ca^{2+} cycling efficiency and increased myofilament Ca^{2+} sensitivity are responsible for the stimulation-rate dependence of the contractile state.

Maximal contractile force occurs at 150 to 180 stimulations per minute during isometric contraction of isolated cardiac muscle. From a clinical perspective, the treppe-induced increase in LV contractility is especially important during exercise by matching CO to venous return, which occurs at heart rates approaching 175 beats/minute in highly trained athletes. However, contractility deteriorates above this heart rate because the intracellular mechanisms responsible for Ca^{2+} removal from the contractile apparatus are overwhelmed, and LV diastolic filling time is markedly attenuated.[103] These factors directly contribute to the development of hypotension during tachyarrhythmias or very rapid pacing. An increase in heart rate within the normal physiologic range has little effect on overall pump performance despite the modestly associated increase in LV contractile state,[104] but tachycardia and the resultant treppe-induced enhanced contractility are essential compensatory mechanisms that maintain CO during disease states characterized by severely restricted LV filling (eg, pericardial tamponade, constrictive pericarditis).[105]

Myocardial hypertrophy decreases the stimulation rate at which the peak treppe effect occurs, and the phenomenon may be completely abolished in failing myocardium. The force-frequency relationship is also illustrated when a prolonged delay is observed between beats (eg, associated with an AV conduction abnormality) or after an LV extrasystole because the force of the subsequent LV contraction is enhanced. This phenomenon is called the *interval-strength effect*. A time-dependent increase in the amount of Ca^{2+} available for contractile activation and an increase in preload resulting from greater diastolic filling are most likely responsible for this effect.[106,107]

Preload

The definition of preload as sarcomere length immediately before the onset of myocyte contraction is very useful, as is the degree of muscle stretch applied to isolated cardiac muscle before it is stimulated to contract in the laboratory (Fig. 6.16). However, these concepts may have less practical utility in an ejecting heart because of the dynamic, three-dimensional changes in geometry that occur in each chamber throughout the cardiac cycle. As a result, preload is most often defined as the volume of blood contained within each chamber at its end-diastole (although here we refer primarily to the LV). This blood volume effectively establishes the length of each myocyte immediately before isovolumic contraction and is related to LV end-diastolic wall stress.[108] However, precise real-time measurement of continuous LV volume throughout the cardiac cycle (including LV volume at end-diastole) remains a technically challenging problem.[109]

Continuous LV volume may be approximated using ultrasonic sonomicrometers implanted in a three-dimensional orthogonal array in the LV subendocardium,[110] and mathematical models may then be applied to generate remarkably accurate estimates of LV volume in the laboratory. The conductance catheter is another extensively validated method of measuring continuous LV volume in experimental animals[111] and patients in the cardiac catheterization laboratory.[112,113] The technique involves placement of a multiple-electrode catheter within the LV cavity to establish a series of cylindrical electric current fields and measure time-varying voltage potentials from which intraventricular conductance is determined and LV volume is estimated.[114]

Continuous LV volume waveforms derived using sonomicrometry or conductance catheter techniques are beneficial for formal pressure-volume analysis of LV systolic and diastolic function in vivo (discussed later), but the use of invasive methods to determine LV end-diastolic volume is impractical in patients undergoing cardiac surgery. Similarly, LV volume may be accurately measured using noninvasive methods such as radionuclide angiography or dynamic magnetic resonance imaging (MRI), but these techniques cannot be used in the operating room. Instead, cardiac anesthesiologists most often rely on approximations of LV end-diastolic volume using two-dimensional transesophageal echocardiography (TEE), although advances in three-dimensional TEE imaging may facilitate real-time estimates of LV end-diastolic volume during surgery.[115–117] The transgastric LV midpapillary short-axis imaging plane is particularly useful for estimating LV end-diastolic area or diameter. For example, an acute decrease in LV preload may be easily recognized by a corresponding reduction in the end-diastolic area and diameter of the chamber concomitant with physical contact (ie, kiss) between the anterior-lateral and posteromedial papillary muscles.

LV preload may be estimated using a variety of other methods, each of which has inherent limitations (Fig. 6.17). LV end-diastolic pressure may be measured invasively in the cardiac catheterization laboratory or during surgery by advancing a fluid-filled or pressure transducer–tipped catheter from the aorta across the aortic valve or through the LA and across the mitral valve into the LV chamber. LV end-diastolic pressure is related to end-diastolic volume based on the nonlinear EDPVR and may not accurately quantify end-diastolic volume.[118]

Cardiac anesthesiologists commonly use several other estimates of LV end-diastolic volume that depend on measurements obtained upstream from the LV, including mean LA, pulmonary capillary

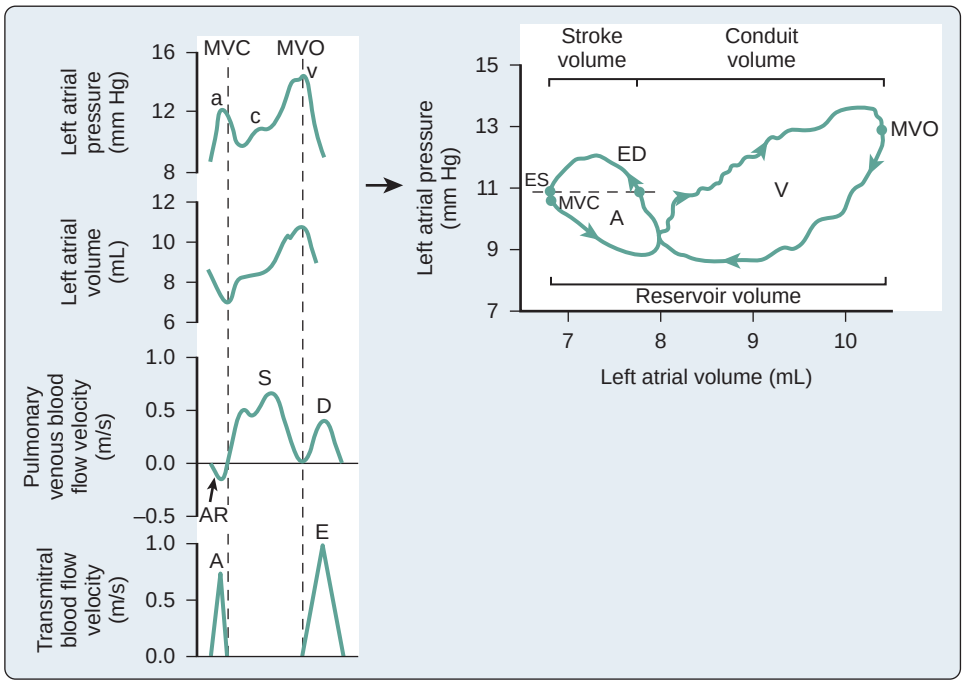

Fig. 6.14 Left atrial (LA) pressure and volume waveforms *(left)* and the corresponding steady-state LA pressure-volume diagram *(right)* inscribed in phase space by these waveforms during a single cardiac cycle. The corresponding schematic pulmonary venous and transmitral blood flow velocity waveforms are also depicted *(left)*. The *a* wave of LA pressure corresponds to atrial systole, the *c* wave represents the small increase in LA pressure that occurs during early left ventricular (LV) isovolumic contraction, and the *v* wave identifies the increase in LA pressure associated with LA filling. In contrast to this biphasic LA pressure waveform, the morphology of the LA volume waveform is monophasic. The resulting LA pressure-volume diagram is shaped in a horizontal figure-eight pattern. *Arrows* indicate the time-dependent direction of movement around the diagram. The A portion of the diagram (ie, left loop) incorporates active LA contraction and temporally proceeds in a counterclockwise fashion. The V portion of the diagram (ie, right loop) represents passive LA reservoir function and proceeds in a clockwise manner over time. The points of mitral valve closure *(MVC)* and opening *(MVO)* are depicted on the individual waveforms and on the LA pressure-volume diagram. LA end-diastole *(ED)* is the point immediately before LA contraction at which LA pressure corresponds to LA end-systolic *(ES)* pressure *(horizontal dashed line)*. LV isovolumic contraction, ejection, and most isovolumic relaxation occur between MVC and MVO, as shown on the LA pressure-volume diagram. The pulmonary venous blood flow velocity waveform consists of an atrial reversal *(AR)* wave, a biphasic *S* wave that occurs during LV systole, and a *D* wave that is observed with opening of the mitral valve. The corresponding atrial systole *(A)* and early LV filling *(E)* waves of transmitral blood flow velocity are shown. The AR and D waves of pulmonary venous blood flow velocity occur in conjunction with the A and E waves of transmitral blood flow velocity, respectively. *(From Pagel PS, Kehl F, Gare M, et al. Mechanical function of the left atrium: new insights based on analysis of pressure-volume relations and Doppler echocardiography,* Anesthesiology. *2003;98:975–994.)*

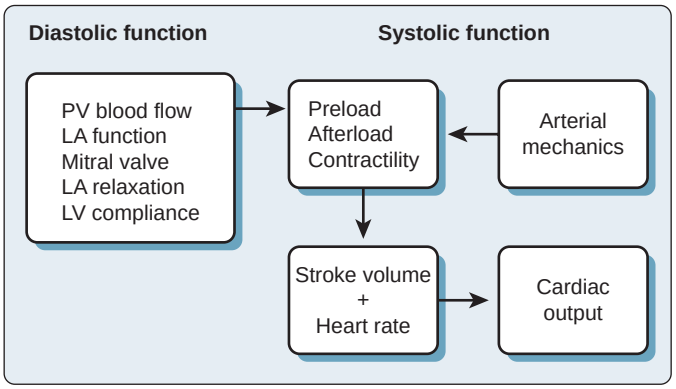

Fig. 6.15 Major factors that determine left ventricular *(LV)* diastolic *(left)* and systolic *(right)* function. Pulmonary venous *(PV)* blood flow, left atrial *(LA)* function, mitral valve integrity, LA relaxation, and LV compliance combine to determine LV preload.

occlusion (wedge), pulmonary arterial diastolic, RV end-diastolic, and RA (central venous) pressures. These estimates of LV end-diastolic volume are affected by functional integrity of the structures that separate each measurement location from the LV. For example, a correlation between RA and LV end-diastolic pressures assumes that the fluid column between the RA and LV has not been adversely influenced by pulmonary disease, airway pressure during respiration, RV or pulmonary vascular pathology, LA dysfunction, mitral valve abnormalities, or LV compliance. The complex relationships among these structures may be fully intact in healthy individuals, but this is often not the case in patients with significant pulmonary or cardiac disease.

Correlation among LV end-diastolic volume, pulmonary artery occlusion pressure, and RA pressure is notoriously poor in patients with compromised LV systolic function,[119] and measurement of pressures upstream from the LV may be of limited clinical utility in the assessment of LV preload under these circumstances. The terms *preload* and *end-diastolic volume* are used as synonyms in the remainder of this chapter.

Afterload

Afterload is the additional load to which cardiac muscle is subjected immediately after the onset of a contraction. This definition of afterload is intuitively clear and easily quantified in an isolated cardiac muscle preparation (see Fig. 6.16), but it is more difficult to envision and measure in the intact cardiovascular system, even under tightly controlled experimental conditions (Box 6.1). Impedance to LV or RV ejection by the mechanical properties of the systemic or pulmonary arterial vasculature provides the basis for the definition of afterload in vivo.

Several methods have been used to quantify afterload. Aortic input impedance, or $Z_{in}(\omega)$, is the ratio of aortic pressure (ie, forces acting on the blood) to blood flow (ie, resultant motion). It is derived from power spectral or Fourier series analysis of high-fidelity measurements of aortic pressure and blood flow. $Z_{in}(\omega)$ incorporates arterial viscoelasticity, frequency dependence, and wave reflection,[120,121] and it is characterized by modulus and phase angle spectra expressed in the frequency domain (Fig. 6.18).[122]

$Z_{in}(\omega)$ is most often interpreted using an electrical three-element Windkessel model[123] of the arterial circulation because the frequency dependence of $Z_{in}(\omega)$ makes this parameter difficult to interpret. The Windkessel model identifies three primary features of $Z_{in}(\omega)$: characteristic aortic impedance (Z_c), total arterial compliance (C), and total arterial resistance (R) (Fig. 6.19).[124] Z_c represents resistance to LV ejection produced by the aorta and great vessels; C is determined primarily by the compliance of the proximal large arterial vasculature (ie, energy storage component); and R equals the combined resistances of the remaining arterial circulation. The three-element Windkessel model closely approximates $Z_{in}(\omega)$ under a variety of physiologic conditions.[123–125] RV afterload has been described using pulmonary input impedance spectra interpreted with a similar Windkessel model.

The mechanical forces to which the LV is subjected during ejection also may be used to define LV afterload. Increases in LV pressure and wall thickness occur during isovolumic contraction and are accompanied by a large reduction in LV volume (ie, radius) after the aortic valve opens. These combined factors cause a dramatic increase in LV systolic wall stress as predicted by Laplace's law. LV systolic wall stress reaches a maximum during early LV ejection and declines thereafter.[49]

The changes in continuous LV systolic wall stress have a number of important consequences. For example, peak LV systolic wall stress is a major stimulus of LV concentric hypertrophy in disease states characterized by chronic pressure-overload (eg, poorly controlled essential hypertension, aortic valve stenosis).[49,126] The integral of LV systolic wall stress with respect to time is an indicator of myocardial oxygen demand.[127] The relationship between LV wall stress at end-systole and the heart rate–corrected maximal velocity of circumferential fiber

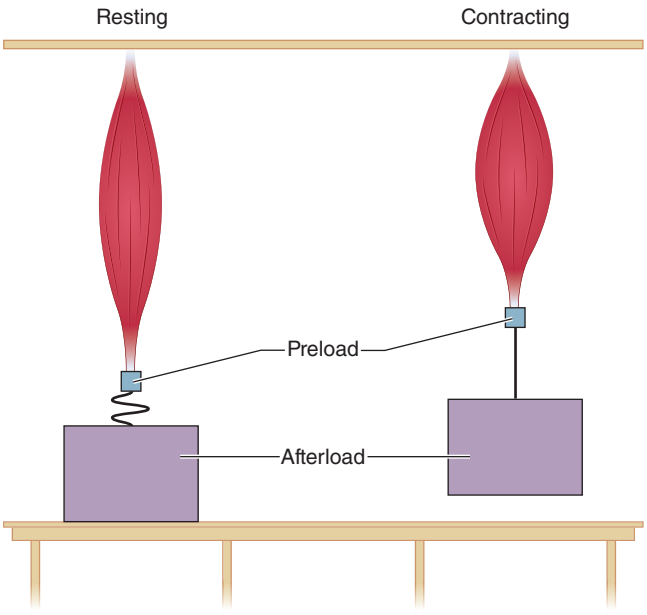

Fig. 6.16 Loading conditions placed on an isolated papillary muscle before and during contraction. The muscle is initially stretched with a small load (ie, preload) *(left)*, but when it contracts, it is almost immediately subjected to an additional, much larger load (ie, afterload) *(right)*. The relative size of preload and afterload in the diagram illustrate the loading conditions to which the intact left ventricle is exposed before and after the aortic valve opens. *(From Katz A. Physiology of the Heart. Philadelphia: Lippincott Williams & Wilkins; 2001.)*

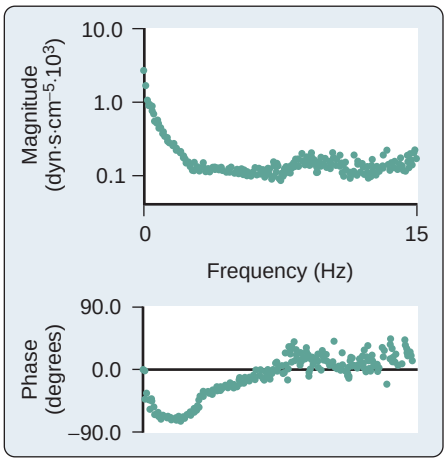

Fig. 6.18 A typical aortic input impedance, $Z_{in}(\omega)$, spectrum obtained from a conscious, chronically instrumented dog. $Z_{in}(\omega)$ has frequency-dependent magnitude *(top)* and phase *(bottom)* components. The $Z_{in}(\omega)$ magnitude at 0 Hz is equal to total arterial resistance. The average of the $Z_{in}(\omega)$ magnitude spectra between 2 and 15 Hz determines characteristic aortic impedance (Z_c). *(Modified from Hettrick DA, Pagel PS, Warltier DC. Differential effects of isoflurane andhalothane on aortic input impedance quantified using a three-element Windkesselmodel.* Anesthesiology. *1995;83(2):361–373.)*

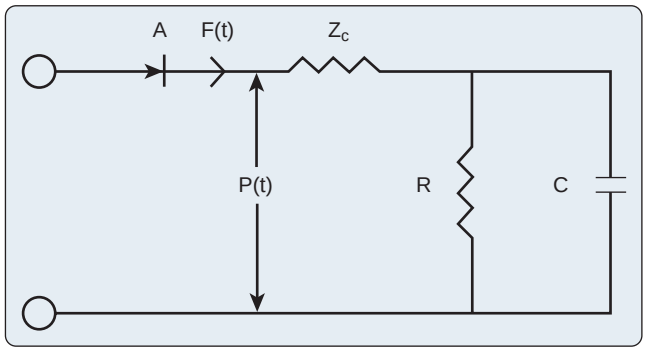

Fig. 6.19 Electrical analog of the three-element Windkessel model of aortic input impedance, $Z_{in}(\omega)$. Diode *A* represents the aortic valve. The time-dependent blood flow, *F(t)*, entering the arterial system from the left ventricle first encounters the resistance of the proximal aorta and great vessels (ie, characteristic aortic impedance [Z_c]). Total arterial resistance *(R)* and total arterial compliance *(C*, the energy storage component of the arterial vasculature) determine further arterial blood flow, which is associated with a time-dependent change in arterial pressure, *P(t)*, from the aortic root to the capillary bed. *(Modified from Hettrick DA, Pagel PS, Warltier DC. Differential effects of isoflurane andhalothane on aortic input impedance quantified using a three-element Windkesselmodel.* Anesthesiology. *1995;83(2):361–373.)*

shortening (V_{cfs}) during contraction has been used as a relatively heart rate– and load-independent index of contractile state in humans (each parameter may be derived noninvasively using echocardiography).[128] LV end-systolic wall stress identifies the magnitude of force that prevents further fiber shortening at the end of ejection, determining the degree of LV emptying that may occur at a fixed inotropic state. LV end-systolic wall stress defines the instantaneous myocardial force at end-ejection for each chamber size, thickness, and pressure and incorporates internal cardiac forces and those external to the heart (ie, arterial system) that oppose it.[129–131]

As discussed with Laplace's law, LV geometric assumptions, the nonlinear force distribution between the subendocardium and subepicardium, and the nonuniformity of wall thickness throughout the LV may complicate the use of LV end-systolic wall stress as a quantitative index of LV afterload.[53] These potentially confounding factors are

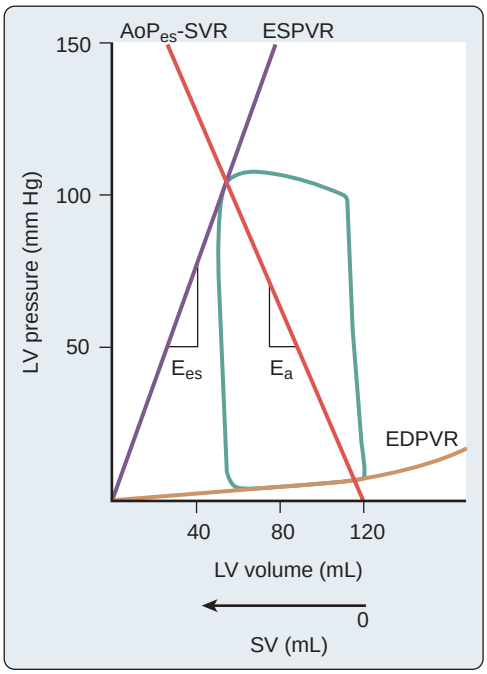

Fig. 6.20 The left ventricular *(LV)* end-systolic pressure-volume relationship *(ESPVR)* and aortic end-systolic pressure–stroke volume *(SV)* relationship *(AoP_{es}-SVR)* are used to determine LV-arterial coupling as the ratio of end-systolic elastance *(E_{es})* (ie, slope of ESPVR) and effective arterial elastance *(E_a)* (ie, slope of AoP_{es}-SVR). *EDPVR*, End-diastolic pressure-volume relationship.

particularly relevant in the setting of acute or chronic regional wall motion abnormalities (eg, critical coronary artery stenosis or occlusion, LV remodeling after infarction).

Optimal transfer of energy from the LV to the arterial circulation during ejection requires that the two elastic chambers are mechanically coupled.[132,133] LV-arterial coupling is another useful model for quantifying LV afterload. LV-arterial coupling is most often described using a series elastic chamber model in which LV E_{es} and effective arterial elastance (E_a) are determined in the pressure-volume plane using the slopes of the LV end-systolic pressure-volume and aortic end-systolic pressure-SV relationships, respectively (Fig. 6.20).[134] The ratio of E_{es} to E_a defines coupling between the LV and arterial circulations,[135,136] identifies the SV that may be transferred between these elastic components, and provides a useful foundation with which to study energetics and myocardial efficiency.[83]

E_a is strictly a composite coupling variable that is affected by total arterial resistance and total arterial compliance, but the parameter also has been suggested as a measure of LV afterload that is somewhat analogous to LV end-systolic wall stress.[132] The product of E_a and heart rate also approximates systemic vascular resistance (SVR). Nevertheless, E_a alone most likely should not be used to quantify LV afterload because the variable does not strictly incorporate alterations in characteristic aortic impedance, an important high-frequency component of arterial mechanics, nor does it consider arterial wave reflection properties.

The magnitude of $Z_{in}(\omega)$primarily depends on total arterial resistance[137] and may be reasonably approximated by SVR, the most commonly used estimate of LV afterload in clinical anesthesiology. SVR is the ratio of pressure to flow (ie, analogous to Ohm's law), which is calculated using the familiar formula (MAP-RAP)80/CO, in which MAP is the mean arterial pressure, RAP is the RA pressure, CO is cardiac output, and 80 is a constant that converts the units of mm Hg/min per liter to dynes·s·cm^{-5}. However, SVR is inherently inadequate as a quantitative description of LV afterload because the parameter ignores the mechanical characteristics of the blood (eg, viscosity, density) and arterial walls (eg, compliance); does not consider the

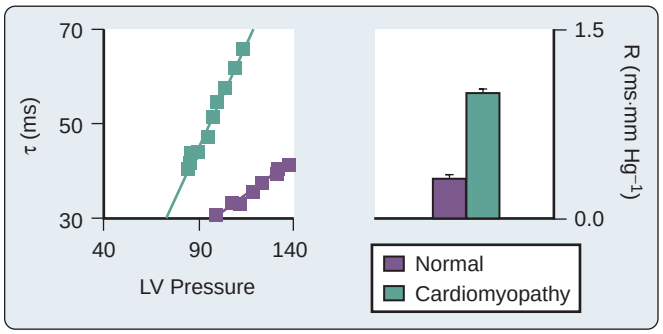

Fig. 6.21 Linear relationship between the time constant of isovolumic relaxation *(τ)* and left ventricular *(LV)* end-systolic pressure during inferior vena caval occlusion *(left)* in a conscious dog before *(purple squares)* and after *(green squares)* the development of rapid LV pacing-induced cardiomyopathy. The histogram illustrates the slope *(R)* of the τ-LV end-systolic pressure relationship before *(purple)* and after *(green)* chronic rapid pacing and indicates that the LV isovolumic relaxation is more sensitive to alterations in LV pressure in this model of heart failure. *(Modified from Pagel PS, Hettrick DA, Kersten JR, et al. Isoflurane and halothane do not alter the enhanced afterload sensitivity of left ventricular relaxation in dogs with pacing-induced cardiomyopathy.* Anesthesiology. *1997;87:952–962.)*

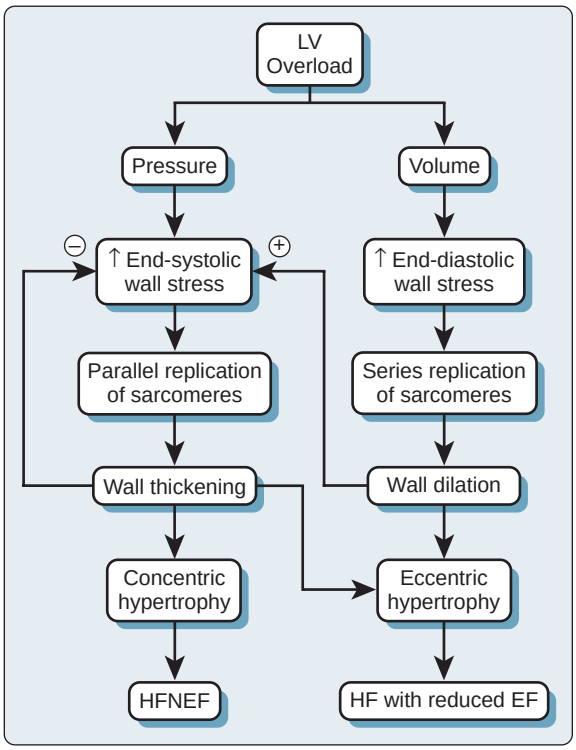

Fig. 6.22 Left ventricular *(LV)* pressure and volume overload produce compensatory responses based on the nature of the inciting stress. Wall thickening reduces (–) and chamber dilation increases (+) end-systolic wall stress, as predicted by Laplace's law. LV pressure-overload hypertrophy has been linked to heart failure with a normal ejection fraction *(HFNEF)*, but LV volume overload most often causes heart failure *(HF)* with a reduced ejection fraction *(EF)*.

frequency-dependent, phasic nature of arterial blood pressure and blood flow (ie, SVR assumes constant blood flow); and fails to incorporate arterial wave reflection. The phasic contributions to arterial load are especially important in the setting of advanced age, peripheral vascular disease, and tachycardia.[138,139] As a result, SVR cannot be reliably used to quantify changes in LV afterload produced by vasoactive drugs or cardiovascular disease and instead should be used as a nonparametric estimate of LV afterload.[140]

Four major components mediate LV afterload in the intact cardiovascular system:

1. Physical properties of arterial blood vessels (eg, diameter, length, elasticity, number of branches)
2. LV wall stress, which is determined by LV pressure development and the geometric changes in the LV chamber required to produce it
3. Total arterial resistance, which is determined primarily by arteriolar smooth muscle tone
4. Volume and physical properties of blood (eg, rheology, viscosity, density)

An acute increase in LV afterload is most often well tolerated in the setting of normal LV systolic function, but the failing LV may be exquisitely sensitive to an acute increase in afterload (Fig. 6.21),[141,142] and the event is likely to precipitate further LV dysfunction. Reflex activation of the sympathetic nervous system occurs in response to LV systolic dysfunction, but this compensatory mechanism also inadvertently increases LV afterload and may further decrease CO, especially when combined with pathologic abnormalities that reduce arterial compliance (eg, atherosclerosis).

LV hypertrophy is an important adaptive response to chronic elevations in LV afterload that reduces LV wall stress by increasing wall thickness. The adaptation may preserve LV systolic function, but the greater mass of LV myocardium associated with hypertrophy also substantially increases the risk of myocardial ischemia and contributes to the development of LV diastolic dysfunction (Figs. 6.22 and 6.23). The primary therapeutic objective in the management of elevated LV afterload is reduction of the inciting stress.

Descriptions of RV afterload are similar to those described for the LV but with two major differences. The pulmonary arterial vasculature is more compliant than its systemic arterial counterpart, and the RV is more sensitive to acute changes in afterload than the LV. The ability of the AV valves to open freely and the compliance of the LV and RV are the primary determinants of LA and RA afterload, respectively. A model of LA afterload analogous to LV-arterial coupling used combined LA and LV pressure-volume analysis to characterize LA compensatory responses to changes in LA afterload.[97,99]

Myocardial Contractility

Rigid control of loading conditions and measurement of the magnitude, velocity, and force of muscle shortening facilitate precise determination of the inotropic state in isolated cardiac muscle preparations, but quantifying myocardial contractility in the intact heart is a challenging problem. Quantification of LV contractility would allow cardiac anesthesiologists to reliably evaluate the effects of pharmacologic interventions or pathologic processes on LV systolic function.

A standard for myocardial contractility in vivo has not been developed, and all contractile indices proposed, including those derived from pressure-volume analysis, have significant limitations because the contractile state and loading conditions are fundamentally related at the level of the sarcomere.[143,144] Interpretation of a change in LV systolic function in vivo must always be considered within the constraints of the loading conditions under which it was measured, regardless of the technique used to estimate contractility. Many indices of myocardial contractility are classified in four broad categories (Box 6.2): pressure-volume relationships, isovolumic contraction, ejection phase, and power analysis.

End-Systolic Pressure-Volume Relationships

Because the LV is an elastic chamber, the relationship between its pressure and volume may be described in terms of time-varying elastance (ie, ratio of pressure to volume) during the cardiac cycle.[77,78] LV elastance increases during systole as LV pressure rises and LV volume declines. Maximal LV elastance (E_{max}) occurs at or very near end-systole, most often corresponding to the left upper corner of the

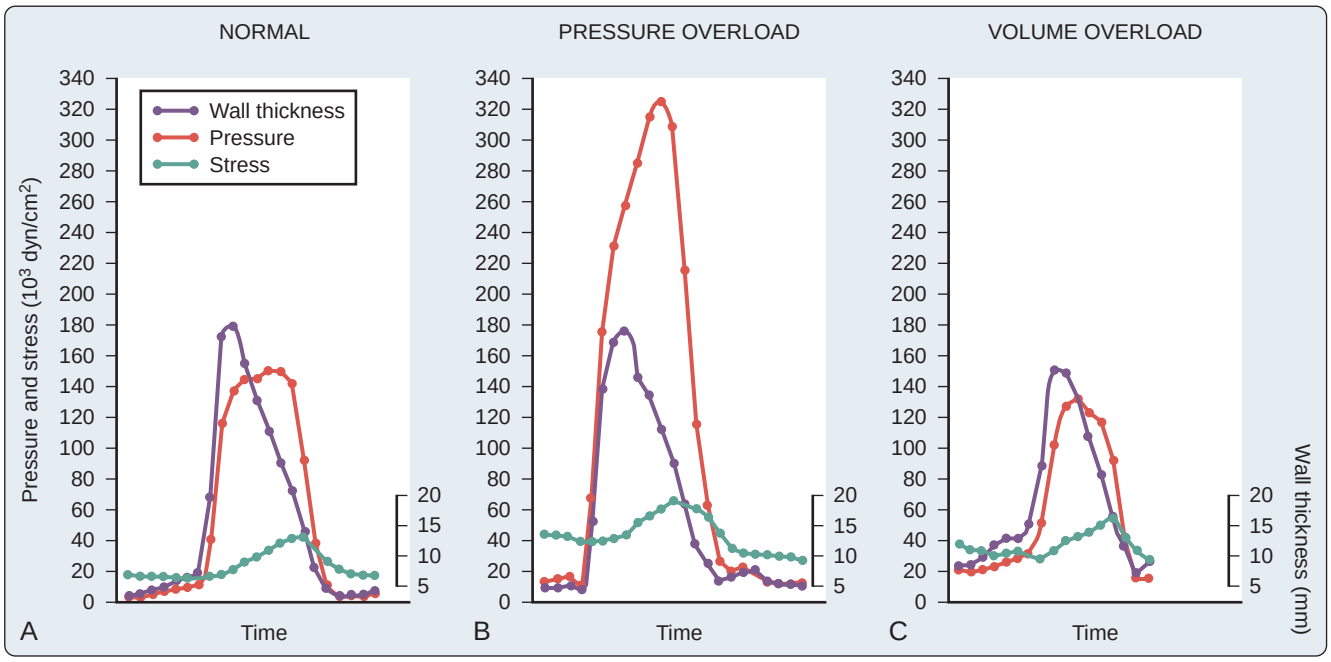

Fig. 6.23 Left ventricular (LV) pressure *(red circles)*, wall thickness *(purple circles)*, and wall stress *(green circles)* during the cardiac cycle. Compared with (A) the normal left ventricle, (B) LV pressure-overload hypertrophy occurs concomitant with dramatic increases in LV pressure, but compensatory increases in wall thickness maintain wall stress in the normal range and configuration. End-diastolic stress is markedly elevated in (C) LV volume-overload hypertrophy. *(From Grossman W, Jones D, McLaurin LP. Wall stress and patterns of hypertrophy in the human left ventricle, J Clin Invest. 1975;56:56–64.)*

steady-state LV pressure-volume diagram. Analogously, minimal LV elastance is observed at end-diastole.

The equation $E(t) = P(t)/[V(t) - V_0]$ describes time-varying elastance, E(t). P(t) and V(t) are the time-dependent changes in LV pressure and volume, respectively, during the cardiac cycle, and V_0 is the LV volume at 0 mm Hg of LV pressure (ie, unstressed volume). The relationship between each E_{max} of a differentially loaded series of LV pressure-volume diagrams establishes the ESPVR and is linear within the normal physiologic range at a constant inotropic state.

The slope (ie, E_{es}) of the ESPVR is a quantitative index of LV contractile state that incorporates afterload because the analysis is conducted at end-systole (Fig. 6.24). As a result, the time-varying elastance equation may be rewritten at end-systole as $P_{es} = E_{es}(V_{es} - V_0)$, in which P_{es} and V_{es} are LV end-systolic pressure and volume, respectively. An increase or decrease in the magnitude of E_{es} produced by a positive or negative inotropic drug (eg, dobutamine or esmolol), respectively, quantifies the corresponding change in LV contractility that has occurred.

Regional LV contractility may also be determined using pressure-dimension relationships based on determinations of continuous segment length, LV midpapillary short-axis diameter, or wall thickness,[77,78,145] and it usually reflects global LV systolic function in the absence of regional wall motion abnormalities.[110] LV end-systolic pressure-volume or dimension relationships have been derived noninvasively using radionuclide angiography[146] or echocardiography[147] with automated border detection[148] to measure continuous LV volume or area. Single-beat estimates of E_{es} (ie, determined as the simple ratio of P_{es} to V_{es} or derived using a modified time-varying elastance method) have been proposed that may provide quantitative information about contractile state assuming that the value V_0 remains small.[149,150] The principle of time-varying elastance also has been successfully applied to the study of RV[84] and atrial contractility[43] (Fig. 6.25) in the intact heart.

The time-varying elastance model of LV contractility is elegant from an engineering perspective, but several potential pitfalls have been identified that may limit its clinical utility as an index of the inotropic state. The position of unstressed volume (V_0) does not consistently remain constant during alterations in contractility.[79,151] For example, administration of dobutamine increases E_{es} and shifts the ESPVR to the left (ie, decrease in V_0), presumably resulting from

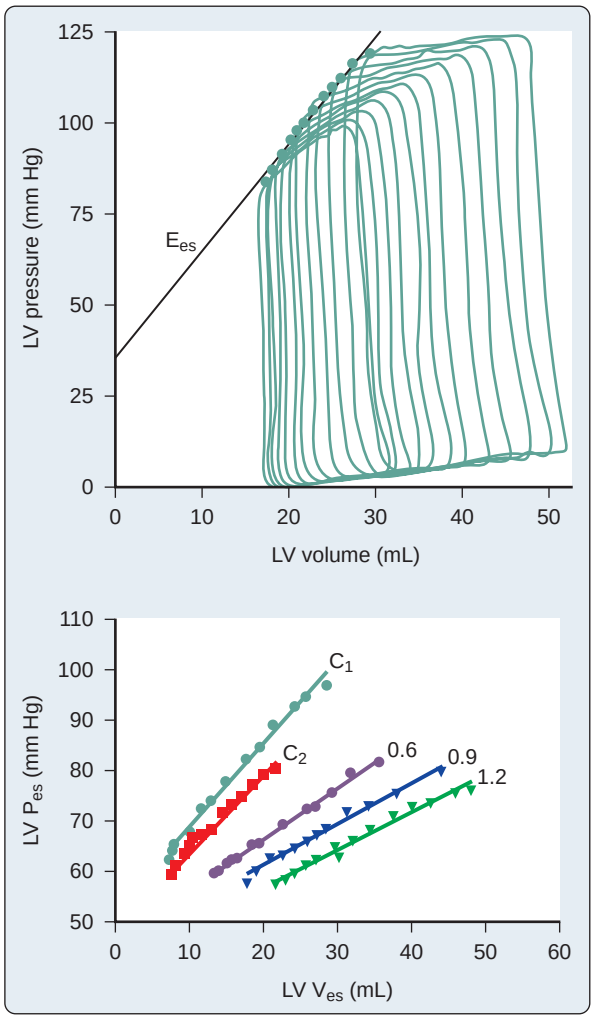

Fig. 6.24 Method used to derive the left ventricular *(LV)* end-systolic pressure-volume relationship (ESPVR) from a series of differentially loaded LV pressure-volume diagrams generated by abrupt occlusion of the inferior vena cava in a canine heart in vivo. *Top panel*: The pressure-volume ratio or maximal elastance (E_{max}) for each pressure-volume diagram is identified *(left upper corner)*, and a linear regression analysis is used to define the slope or end-systolic elastance (E_{es}) and volume intercept of the ESPVR. *Bottom panel:* The effects of isoflurane (0.6, 0.9, and 1.2 minimum alveolar concentrations) on the ESPVR are shown. C_1, Control 1 (before isoflurane); C_2, control 2 (after isoflurane); P_{es}, LV end-systolic pressure; V_{es}, LV end-systolic volume. *(Modified from Hettrick DA, Pagel PS, Warltier DC. Desflurane, sevoflurane, and isoflurane impair canine left ventricular-arterial coupling and mechanical efficiency,* Anesthesiology. *1996;85:403–413.)*

β_2-adrenoceptor–mediated vasodilation,[151] whereas acute coronary artery occlusion–induced regional LV dysfunction has the opposite effect.[152] Because E_{es} and V_0 may reflect alterations in LV contractility, an index of the inotropic state based on the combined effects of the variables was postulated.[153]

Several consecutive LV pressure diagrams must be obtained over a range of LV loading conditions to accurately define E_{es} and V_0, but this necessary intervention may inadvertently produce baroreceptor reflex–mediated increases in heart rate and contractility during generation of the ESPVR by activating the sympathetic nervous system.[154] E_{max} may not occur precisely at end-systole in the setting of markedly elevated or reduced LV afterload and may be delayed or occur earlier, respectively.[155] As a result, E_{max} may deviate from its normal position in the left upper corner of the LV pressure-volume diagram, introducing potential errors in the derivation of ESPVR.

E_{es} inherently depends on chamber size (despite efforts to standardize its measurement) because the units of E_{es} are mm Hg/mL.[156,157] The volume dependence of E_{es} may complicate direct comparison of the contractile state between patients with different LV sizes. Other limitations of the use of E_{es} as an index of contractile state include lack of measurement precision,[158] nonlinearity,[159] load sensitivity,[160] dependence on underlying autonomic nervous system balance[161] or ejection-mediated alterations on LV pressure generation,[162] and interaction with LV diastolic function.[163] Despite these concerns, the ESPVR is a superb conceptual tool with which to define the contractile state and its interactions with loading conditions in vivo.

Stroke Work–End-Diastolic Volume Relationships

Early studies by Frank[75] and Patterson and colleagues[164] defined a fundamental relationship between LV pump performance (eg, CO) and preload determined using indirect indices of LV filling (eg, central venous pressure). Sarnoff and Berglund[165] extended these seminal investigations in his landmark description of ventricular function curves that related estimates of SW to filling pressures. In this familiar framework, movement of an LV function curve upward or to the left indicated that an increase in the contractile state had occurred because the LV was able to generate more SW at an equivalent preload. Unfortunately, Sarnoff's LV function curves were inherently nonlinear and difficult to quantify because the technology available at the time did not allow him to precisely measure LV SW and end-diastolic volume.

Glower and colleagues used a high-fidelity LV micromanometer and three-dimensional orthogonal endocardial sonomicrometers to measure continuous LV pressure and volume, respectively, in a pressure-volume reexamination of Sarnoff's original hypothesis.[80] The investigators demonstrated that the relationship between each LV SW–V_{ed} pair obtained from a series of differentially loaded LV pressure-volume diagrams was linear, and $SW = M_{sw}(V_{ed} - V_{sw})$, in which M_{sw} and V_{sw} were the slope and volume intercept of the relationship (Fig. 6.26). M_{sw} as shown to quantify alterations in the LV inotropic state in a relatively load-independent manner because preload was already incorporated.

Similar linear relationships between regional work and dimensional measurements (eg, segment length, wall thickness) may be used to quantify changes in the regional contractile state. LV SW-V_{ed} relationships may be calculated with the same series of pressure-volume diagrams used to determine the ESPVR. As a result, two independent contractile indices may be derived and compared from the identical experimental data.

The SW-V_{ed} relationship offers several advantages over the ESPVR for the determination of LV or RV contractility. The SW-V_{ed} relationship is highly linear and reproducible over a wide variety of loading conditions, arterial blood pressures, and contractile states because LV pressure and volume data from the entire cardiac cycle are incorporated into its calculation.[80,158] Conversely, the ESPVR displays more pronounced curvilinear behavior and may be more susceptible to instrument noise because it is determined at a single instantaneous time point (ie, end-systole).[160] The ESPVR may also demonstrate some degree of afterload sensitivity,[166] but the SW-V_{ed} relationship is essentially afterload independent over a wide physiologic range.[80] Unlike E_{es}, the unit of M_{sw} is mm Hg. M_{sw} allows direct comparisons of contractility to be made between patients with various LV sizes because M_{sw} is independent of chamber dimensions.

The SW-V_{ed} relationship has two distinct disadvantages compared with the ESPVR. First, integration of data from the entire cardiac cycle implies that the SW-V_{ed} relationship does not strictly separate LV systolic events from those that occur during diastole. For example, a decrease in LV compliance without a simultaneous change in the ESPVR (eg, LV pressure-overload hypertrophy) may introduce errors into the determination of the LV contractile state using the SW-V_{ed} relationship.[144] Second, partial collapse of the LV pressure-volume diagram during regional myocardial ischemia[93] makes calculation of LV contractility more difficult using the SW-V_{ed} relationship compared

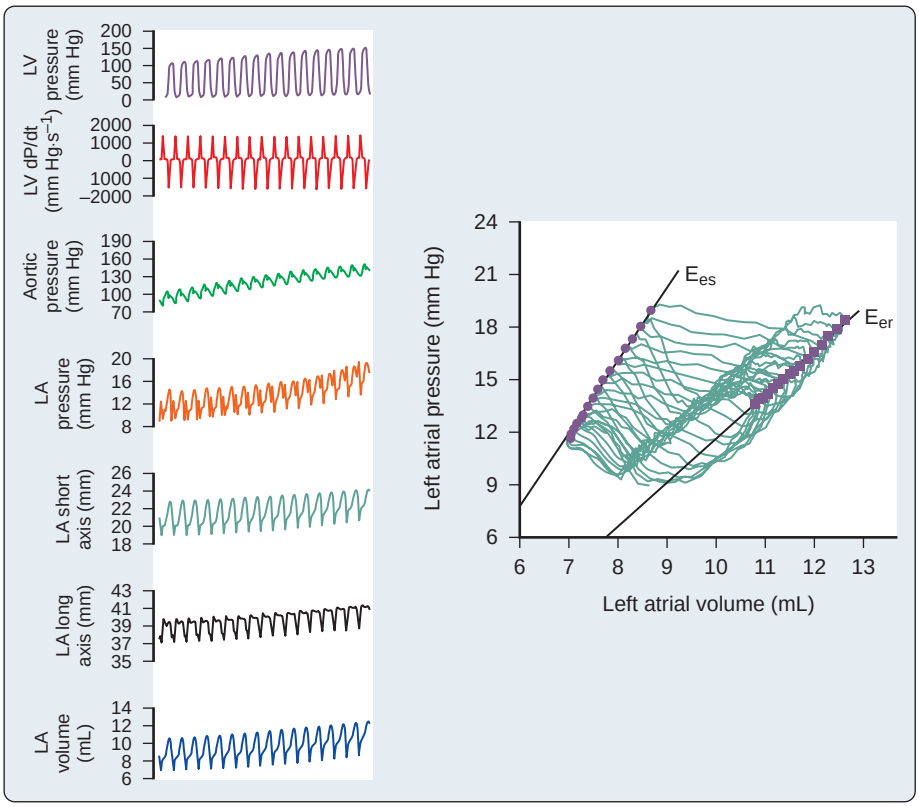

Fig. 6.25 Continuous tracings of left ventricular *(LV)* pressure, rate of increase in LV pressure (dP/dt), aortic pressure, left atrial *(LA)* pressure, LA short- and long-axis dimensions, and LA volume waveforms *(left)* and the corresponding LA pressure-volume diagrams *(right)* resulting from intravenous administration of phenylephrine (200 µg) in a canine heart in vivo. The LA maximal elastance *(circles)* and end-reservoir pressure and volume *(squares)* for each pressure-volume diagram were used to obtain the slopes (E_{es} and E_{er}) and extrapolated volume intercepts of the LA end-systolic and end-reservoir pressure-volume relationships to quantify the LA contractile state and chamber stiffness, respectively. *(From Pagel PS, Kehl F, Gare M, et al: Mechanical function of the left atrium: new insights based on analysis of pressure-volume relations and Doppler echocardiography,* Anesthesiology. *2003;98:975–994.)*

with the ESPVR.[167] Despite these potential shortcomings, the SW-V_{ed} relationship provides a useful index of LV or RV contractile function in the intact heart that has been successfully applied in a variety of experimental settings and in patients with heart disease.

Isovolumic Indices of Contractility

The maximum rate of increase of LV pressure (dP/dt_{max}) is the most commonly derived index of the global LV contractile state during isovolumic contraction. Precise determination of LV dP/dt_{max} requires high-fidelity, invasive measurement of continuous LV pressure and usually is performed in the cardiac catheterization laboratory. LV dP/dt_{max} also may be noninvasively estimated using TEE in patients undergoing cardiac surgery by analysis of the continuous-wave Doppler mitral regurgitation waveform.[168]

LV dP/dt_{max} is sensitive to acute alterations in contractile state,[169] but it is probably most useful when quantifying directional changes in contractility rather than establishing an absolute baseline value.[170] LV dP/dt_{max} is essentially afterload independent because the peak rate of increase of LV pressure occurs before the aortic valve opens unless severe myocardial depression or pronounced arterial vasodilation exists.[171] However, LV preload profoundly affects dP/dt_{max}, and increases in LV dP/dt_{max} produced by greater preload or an enhanced contractile state are virtually indistinguishable. LV mass, chamber size, and mitral or aortic valve disease also affect LV dP/dt_{max}.

The LV dP/dt_{max} may not detect changes in the contractile state produced by regional myocardial ischemia because LV dP/dt_{max} is an index of global LV systolic function. The failure of LV dP/dt_{max} to detect an alteration in regional dysfunction resulting from compromised coronary perfusion may occur because of a compensatory increase in contractility in the remaining normal myocardium through activation of the Frank-Starling mechanism or an increase in sympathetic nervous system activity.

The rate of increase of LV pressure at a fixed developed pressure (eg, dP/dt measured at 50 mm Hg [dP/dt_{50}]) and the ratio of dP/dt to peak developed LV pressure (dP/dt/P) have also been proposed as isovolumic indices of contractility. These measures of the LV contractile state may be somewhat less preload dependent than LV dP/dt_{max}, but neither provides unique additional information compared with LV dP/dt_{max}.

The preload dependence of LV dP/dt_{max} may be used to derive another index of myocardial contractility based on the pressure-volume framework. The relationship between each pair of LV dP/dt_{max} and V_{ed} values obtained from a differentially loaded series of LV pressure-volume diagrams is linear, and $dP/dt_{max} = dE/dt_{max}(V_{ed} - V_0)$, where dE/dt_{max} is the slope and V_0 is the volume intercept of the relationship.[172] Like E_{es} and M_{sw}, the alterations in dE/dt_{max} produced by inotropic drugs or cardiac disease may be used to quantify changes in the LV contractile state. For example, the LV dP/dt_{max}-V_{ed} relationship can precisely determine alterations in contractility in the normal and regionally ischemic LV.[172, 173]

LV dE/dt_{max} and E_{es} are mathematically related,[173] and interventions that shift the ESPVR without altering E_{es} also shift the volume intercept of the LV dP/dt_{max}-V_{ed} relationship without changing dE/dt_{max}.[144]

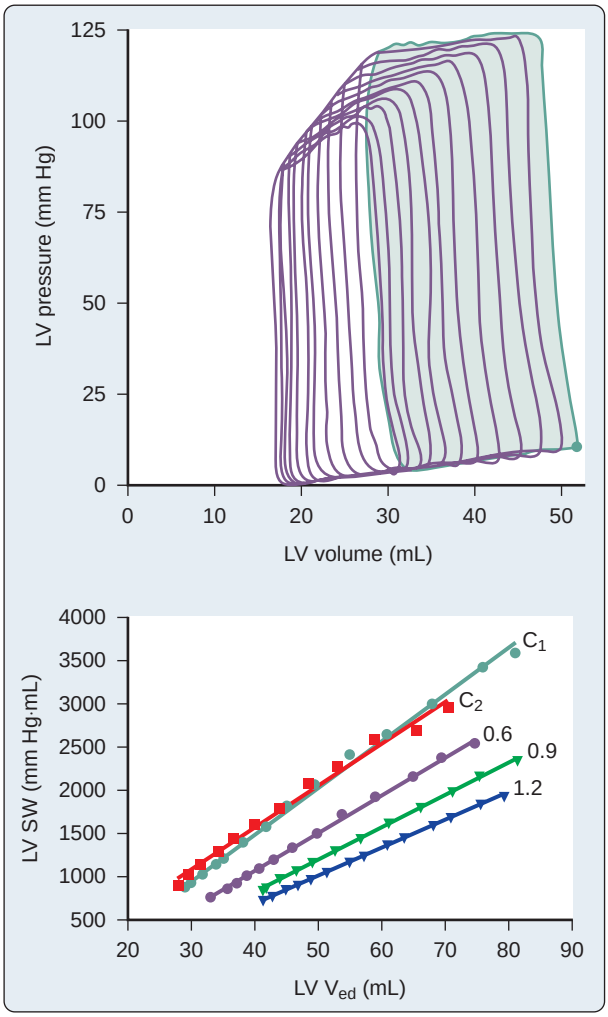

Fig. 6.26 Method used to derive the relationship between left ventricular *(LV)* stroke work *(SW)* and end-diastolic volume *(V_{ed})* from a series of differentially loaded LV pressure-volume diagrams generated by abrupt occlusion of the inferior vena cava in a canine heart in vivo. The area of each LV pressure-volume diagram (ie, *shaded area*), corresponding to SW, is plotted against the corresponding V_{ed} *(top panel)*, and a linear regression analysis is used to define the SW-V_{ed} relationship. The effects of isoflurane (0.6, 0.9, and 1.2 minimum alveolar concentrations) on the SW-V_{ed} relationship are shown in the *bottom panel*. C_1, Control 1 (before isoflurane); C_2, control 2 (after isoflurane). *(Modified from Hettrick DA, Pagel PS, Warltier DC. Desflurane, sevoflurane, and isoflurane impair canine left ventricular-arterial coupling and mechanical efficiency,* Anesthesiology. *1996;85:403–413.)*

Similar to the ESPVR, the LV dP/dt_{max}-V_{ed} relationship becomes more curvilinear at greater LV volumes or contractile states, a finding that is predicted based on isolated cardiac muscle mechanics.[174] Direct comparison among the ESPVR, SW-V_{ed} relationship, and LV-dP/dt_{max} relationship also indicated that dE/dt_{max} might be more variable than E_{es} or M_{sw} during acute changes in contractile state.[158] RV dP/dt_{max}-V_{ed} relationships also have been described.[46]

Ejection-Phase Indices of Contractility

Examination of the degree (eg, EF, SV) or the rate (eg, velocity of shortening) of LV ejection forms the basis of all currently used ejection-phase indices of the LV contractile state, including newer echocardiographic parameters derived from tissue Doppler imaging, myocardial stress-strain relationships, speckle tracking technology, and endocardial color kinesis. From a clinical perspective, the most common ejection-phase index of LV contractility is EF, for which $EF = V_{ed} - V_{es}/V_{ed}$.

LV EF may be calculated using a variety of noninvasive techniques (eg, radionuclide angiography, functional MRI, echocardiography). Cardiac anesthesiologists most often measure LV EF using two-dimensional TEE. Midesophageal four- or two-chamber images are obtained at LV end-systole and end-diastole. They are subsequently analyzed by applying Simpson's rule of disks, which defines the volume as the sum of a finite series of cylinders of various diameters and thicknesses (Fig. 6.27). This method of measuring LV EF is simple, but it is rather time-consuming despite integrated TEE software and may be impractical during rapidly changing hemodynamic conditions.

Two closely related parameters, fractional shortening (FS) and fractional area of change, are often calculated as surrogate measures of LV EF in the midpapillary short-axis plane using images obtained at end-systole and end-diastole. FS is calculated from endocardial measurements of anteroposterior (or septolateral) wall diameter as $FS = D_{ed} - D_{es}/D_{ed}$, in which D_{ed} and D_{es} are the endocardial end-diastolic and end-systolic diameters, respectively (Fig. 6.28).

Fractional area change (FAC) may be determined using the same midpapillary short-axis images by manually tracing the endocardial borders (with the papillary muscles most often excluded) at end-systole and end-diastole. Computer software automatically integrates the end-systolic and end-diastolic areas (ie, A_{es} and A_{ed}, respectively) within each endocardial tracing, and FAC is calculated as $A_{ed} - A_{es}/A_{ed}$. These and all other ejection-phase indices inherently depend on the LV contractile state and loading conditions.[82]

Because preload is incorporated into the denominators of EF, FAC, and FS (ie, V_{ed}, A_{ed}, and D_{ed}, respectively), the indices are relatively unaffected by moderate preload alterations in the setting of normal mitral and aortic valve function.[174] Myocardial stress-strain relationships or speckle tracking techniques also may include modifications (eg, Lagrangian or natural strain) designed to minimize intrinsic preload-dependency. However, EF, FAC, FS, and variables derived from the newer technologies decrease linearly with increases in afterload and vary inversely with heart rate. They are relatively insensitive indices of LV contractile state.

Similar to the observations for LV dP/dt_{max}, EF and FAC are global measures of pump performance that may not reflect the regional contractile dysfunction produced by myocardial ischemia or infarction. Ejection-phase indices also may provide inaccurate information about contractility in the setting of mitral or aortic valvular disease, LV chamber enlargement, or LV hypertrophy.[126,175,176] Similar difficulties with load and heart rate dependency are encountered when ejection-phase indices are used in an attempt to quantify the RV or atrial contractile state.

The velocity of myocardial fiber shortening provides information about the LV contractile state during ejection. Maximal or mean velocity of circumferential fiber shortening may be determined using a variety of invasive and noninvasive techniques. The midpapillary short-axis view on TEE is especially useful for cardiac anesthesiologists measuring these variables in the operating room. Maximal velocity of circumferential fiber shortening (V_{cfs}) is calculated as the ratio of FS to ejection time and may be more sensitive to changes in the contractile state than EF because the velocity (not magnitude) of shortening is evaluated. Nevertheless, V_{cfs} also varies directly with heart rate and inversely with changes in afterload, similar to other ejection-phase indices.[171]

Methods for correcting the inherent heart rate and afterload dependency of V_{cfs} have been suggested based on the force-velocity behavior of isolated cardiac muscle. For example, a linear relationship was shown between LV end-systolic wall stress and heart rate–corrected V_{cfs}. The slope of this relationship provided a relatively heart rate– and afterload-independent index of the LV contractile state in healthy patients[129] and those with hypertension or valvular disease.[126,128] A similar relationship between EF and effective arterial elastance was described.[177] Unfortunately, these and other analogous techniques[178] have not achieved widespread clinical application because extensive, time-consuming analysis is required after data acquisition, making them impractical in an operating room setting.

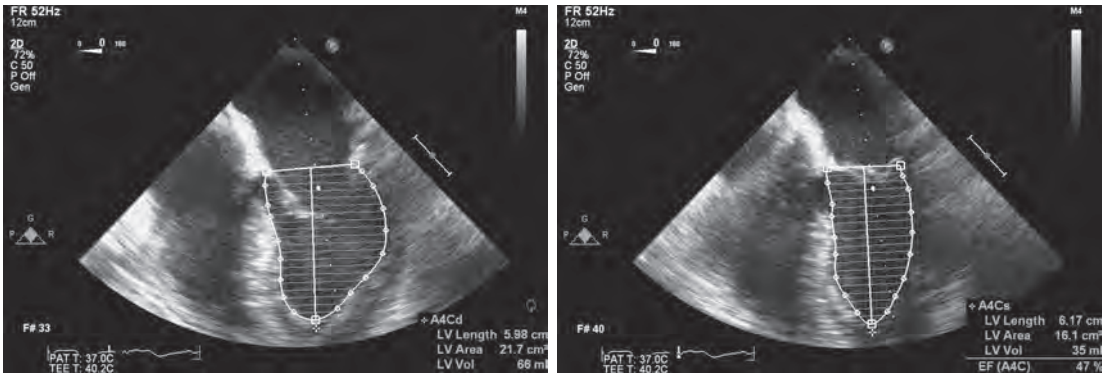

Fig. 6.27 Calculation of ejection fraction from midesophageal four-chamber images obtained at left ventricular (LV) end-diastole *(left)* and end-systole *(right)* using Simpson's rule. After the LV endocardial border is identified in each image, the software generates a series of thin cylindrical disks *(parallel white lines)* and determines the volume based on their sum. LV ejection fraction is then calculated using the standard formula. In this example, the LV ejection fraction is 47%.

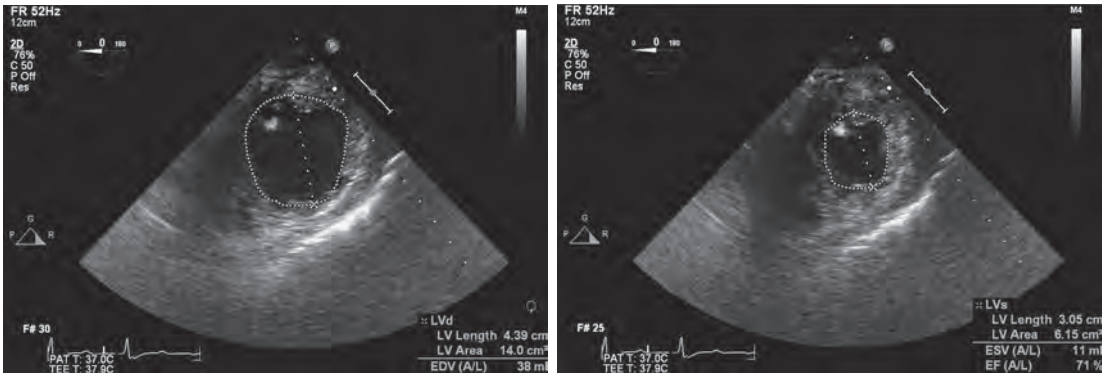

Fig. 6.28 Calculation of fractional area change (FAC) and fractional shortening (FS) from the left ventricular (LV) midpapillary short-axis images obtained at end-diastole *(left)* and end-systole *(right)*. The LV endocardial border is manually traced (excluding the papillary muscles). The software integrates the area inscribed and determines the diameter of the LV chamber. In this example, FAC is 69%, and FS is 59%.

Contractile Indices Based on Ventricular Power

The product of LV pressure and aortic or blood flow defines LV power, which is another index of the inotropic state. Maximal LV power (PWR_{max}) and the rate of increase of LV power during ejection are sensitive to changes in contractile state,[179,180] but these indices are also profoundly affected by LV preload. In contrast, the ratio of LV PWR_{max} to the square of end-diastolic volume is substantially less preload dependent and allows assessment of the LV contractile state from data obtained during a single cardiac cycle.[181]

Alterations in the LV contractile state determined using the preload-adjusted PWR_{max} technique correlate with those calculated with the ESPVR (E_{es}) and the LV dP/dt_{max}-V_{ed} relationship (dE/dt_{max}), and may be measured using noninvasive arterial blood pressure (eg, oscillometry) along with two-dimensional and Doppler echocardiography to define pressure, flow, and dimension variables.[182,183] A regional power quotient using end-diastolic segment length (SL_{ed}) also correlated with the regional SW-SL_{ed} (M_{sw}) and accurately quantified depression of LV contractility produced by volatile anesthetics.[184]

Coupling, Energetics, and Efficiency

The pressure-volume framework is useful to describe the transfer of kinetic energy between two elastic chambers. This mechanical coupling defines the blood volume that may be ejected from one chamber into another. Coupling between the LV and arterial circulation is most often described, but similar relationships between the LA and the LV[99] or analogous structures on the right side of the heart[185] also have been reported.

LV-arterial coupling is defined by the ratio of the slopes of the ESPVR (E_{es}) and the aortic end-systolic pressure-SV relationship (E_a) (see Fig. 6.20) that denote their respective elastances.[133] Ideal coupling between the LV and the arterial circulation indicates optimal transfer of SW between the chambers and occurs when the ratio of their elastances is unity at rest[135] or during exercise.[186,187] LV contractile dysfunction (ie, decrease in E_{es}) or greater resistance to LV ejection (ie, increase in E_a) reduces the E_{es}/E_a ratio to less than 1, indicating that kinetic energy transfer is no longer ideal.[188]

An E_{es}/E_a ratio less than 1 may occur when the global LV contractile state is depressed and compensatory activation of the sympathetic nervous system causes arterial vasoconstriction.[189] The severity of abnormal LV-arterial coupling correlates with serum B-type natriuretic peptide concentration (ie, biochemical marker of LV systolic dysfunction), and an E_{es}/E_a ratio less than 0.68 predicts long-term mortality for patients after myocardial infarction.[190] Tachycardia also increases E_a and worsens LV-arterial coupling in heart failure.[191]

Positive inotropic drugs or vasodilators may improve LV-arterial coupling in heart failure by increasing E_{es} or reducing E_a, respectively.[192] LV-arterial coupling is relatively preserved in the setting of a low end-tidal concentration (0.6 MAC) of desflurane, sevoflurane, or isoflurane (Fig. 6.29), but coupling degenerates when higher concentrations of volatile anesthetics are administered because the magnitude of vasodilation (ie, decrease in E_a) is unable to compensate for greater LV contractile depression (ie, decrease in E_{es}).[134]

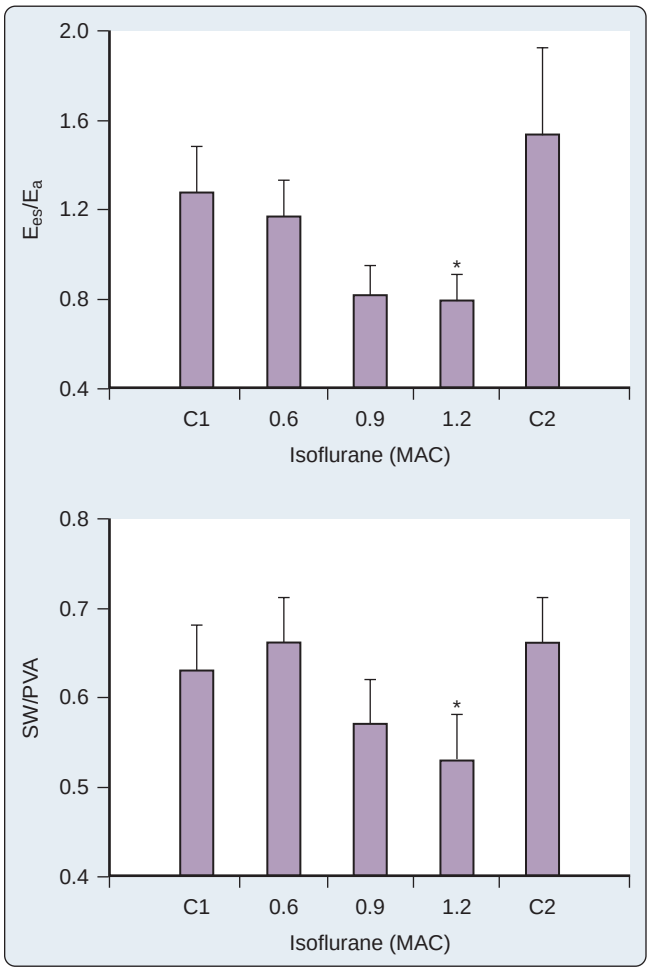

Fig. 6.29 Histograms illustrate the effects of isoflurane (0.6, 0.9, and 1.2 minimum alveolar concentrations [MACs]) on left ventricular (LV)–arterial coupling (ie, LV end-systolic elastance/effective arterial elastance [E_{es}/E_a]) *(top panel)* and energy transfer efficiency (ie, stroke work/pressure-volume area [*SW/PVA*]) *(bottom panel)*. Isoflurane reduces LV-arterial coupling and energy transfer efficiency in a dose-related manner. C_1, control 1 (before isoflurane); C_2, control 2 (after isoflurane). *(From Hettrick DA, Pagel PS, Warltier DC: Desflurane, sevoflurane, and isoflurane impair canine left ventricular-arterial coupling and mechanical efficiency,* Anesthesiology. *1996;85:403–413.)*

EF can be related to the ratio of E_{es} to E_a such that $EF/(1 - EF) = E_{es}/E_a$. It follows from this equation that an EF of 50% produces ideal LV-arterial coupling because $E_{es}/E_a = 1$ under these conditions.[193] The relationship between the EF and coupling ratio also predicts that EF is reduced when E_{es}/E_a is less than 1 because SV is less efficiently transferred from the LV to the arterial vasculature.

LV energetics may be quantified in pressure-volume phase space. Total energy is defined as the sum of the SW generated during a single cardiac cycle (ie, kinetic energy or area within the pressure-volume diagram) and the potential energy that remains in the chamber wall at end-systole as a result of compression of myocardial elastic elements.[83] The triangular area bounded above by the ESPVR, below by the EDPVR, and to the left by the isovolumic relaxation portion of the steady-state pressure-volume diagram defines the remaining potential energy (see Fig. 6.9). This potential energy has the same units as SW (mm Hg • mL = 1.33×10^{-4} joules) and is converted into heat during diastole.[194]

The sum of kinetic and potential energy is called the *pressure-volume area* (PVA)[195] and is linearly related to myocardial oxygen consumption ($M\dot{V}O_2$) such that $M\dot{V}O_2 = \alpha(PVA) + \delta$, in which α is the slope of the relationship and δ denotes basal metabolism in the absence of contraction, or $M\dot{V}O_2$ when PVA is 0.[196–198] The area beneath the $M\dot{V}O_2$-PVA line includes the sum of kinetic and potential energies associated with contraction and relaxation combined with the energy required for the maintenance of cellular function.

Administration of a positive or negative inotropic medication causes the $M\dot{V}O_2$-PVA relationship to shift up or down, respectively, in a parallel manner without a change in the slope of the relationship.[197–199] As a result of the observation, the relationship between $M\dot{V}O_2$ and PVA may be reformulated as $M\dot{V}O_2 = \alpha(PVA) + \beta(E_{es}) + \delta$, in which β is the offset (ie, sensitivity) of the $M\dot{V}O_2$-PVA relationship to E_{es}. This modification indicates that the total energy consumed for excitation-contraction coupling increases or decreases during an enhanced or reduced LV contractile state, respectively, but the energy required for basal metabolism is unaffected.[197]

Another ramification of the pressure-volume energetics framework is that the relative contribution of kinetic and potential energy (ie, PVA) to $M\dot{V}O_2$ is unchanged during alterations in myocardial contractility because the slope (α) of the relationship remains constant. This observation suggests that the biochemical conversion of high-energy phosphates into mechanical activity at the level of the myofilaments is not fundamentally altered by the inotropic state.[197] Alterations in LV compliance (as indicated by the position of the EDPVR) do not substantially influence $M\dot{V}O_2$ despite small changes in PVA because the kinetic and potential energies generated during systole are the predominant determinants of $M\dot{V}O_2$.[194]

LV efficiency also may be described using pressure-volume analysis.[135,200] The SW/PVA ratio indicates the mechanical energy that is converted into external work and is an index of energy transfer efficiency.[136,201] The SW/PVA ratio responds predictably to alterations in the LV contractile state and afterload. For example, an increase in E_{es} produced by a positive inotropic medication enhances the amount of mechanical energy that is converted into work. As a result, the SW/PVA ratio increases.[187] In contrast, greater LV afterload decreases SW and energy transfer efficiency.[201] These observations underscore that LV-arterial coupling is the primary determinant of the SW/PVA ratio.[202]

SW/PVA is mathematically related to E_{es}/E_a, and $SW/PVA = 1/[1 + 0.5(E_a/E_{es})]$.[203] For example, administration of a volatile anesthetic (eg, a vasodilating negative inotropic medication) causes a dose-related decrease in SW/PVA because LV E_{es} is depressed to a greater extent than E_a (see Fig. 6.29).[134] Because E_{es}/E_a is related to EF,[193] the ratio of SW to PVA may be rewritten as $2/[(1/EF) - 1]$. This equation demonstrates that a decrease in EF is associated with less efficient conversion of total mechanical energy into external work.

The ratio of PVA to measured $M\dot{V}O_2$ provides a useful index of the conversion of metabolic to mechanical energy,[204] whereas the product of SW/PVA and $PVA/M\dot{V}O_2$ ($SW/M\dot{V}O_2$) indicates the efficiency with which the LV transfers its metabolic energy into physical work. The ratio of SW to $M\dot{V}O_2$ increases with positive inotropic medications[205] and during exercise,[187] but it is substantially reduced[206] and predicts mortality[207] for patients with heart failure.

Evaluation of Diastolic Function

The ability of each chamber to efficiently fill under normal pressure conditions is essential for the best possible overall cardiac performance. LV diastolic function has been studied most extensively, but the relaxation, filling, and distensibility characteristics of the more compliant RV and the atrial chambers also have been described. This section focuses on LV diastolic function, but many of the techniques used to quantify LV diastolic function also may be applied to the study of RV diastology.

LV diastole encompasses a complicated sequence of temporally related, heterogeneous events (Box 6.3; see Fig. 6.15), and no single index of LV diastolic function can comprehensively describe this period of the cardiac cycle or selectively identify patients at highest risk for developing clinical signs and symptoms of heart failure resulting

BOX 6.3 DETERMINANTS OF LEFT VENTRICULAR DIASTOLIC FUNCTION

Heart rate and rhythm
LV systolic function
Wall thickness
Chamber geometry
Duration, rate, and extent of myocyte relaxation
LV untwisting and elastic recoil
Magnitude of diastolic suction
LA-LV pressure gradient
Passive elastic properties of LV myocardium
Viscoelastic effects (rapid LV filling and atrial systole)
LA structure and function
Mitral valve structure and function
Pulmonary venous blood flow
Pericardial restraint
RV loading conditions and function
Ventricular interdependence
Coronary blood flow and vascular engorgement
Compression by mediastinal masses

LA, Left atrial; *LV*, left ventricular; *RV*, right ventricular.

BOX 6.4 COMMON CAUSES OF LEFT VENTRICULAR DIASTOLIC DYSFUNCTION

Age >60 y
Acute myocardial ischemia (supply or demand)
Myocardial stunning, hibernation, or infarction
Ventricular remodeling after infarction
Pressure-overload hypertrophy (eg, aortic stenosis, hypertension)
Volume-overload hypertrophy (eg, aortic or mitral regurgitation)
Hypertrophic obstructive cardiomyopathy
Dilated cardiomyopathy
Restrictive cardiomyopathy (eg, amyloidosis, hemochromatosis)
Pericardial diseases (eg, tamponade, constrictive pericarditis)

from filling abnormalities.[208] Most indices of LV diastolic function depend on heart rate, loading conditions, and myocardial contractility, and alterations in these variables require careful interpretation within these limitations.

Despite inherent difficulties, the crucial nature of LV diastolic function is emphasized by the striking observation that as many as 50% of patients with heart failure do not have a substantial reduction in LV EF.[209,210] This *heart failure with normal ejection fraction* (HFNEF), previously called *diastolic heart failure*, occurs most frequently in elderly women with poorly controlled essential hypertension, obesity, renal insufficiency, anemia, general deconditioning, or atrial fibrillation.[211] Many of these risk factors contribute to the progressive development of LV hypertrophy and fibrosis that adversely affect LV filling characteristics and increases the risk of heart failure.[211]

The pathophysiology of HFNEF appears to be multifactorial (Table 6.2). It involves delayed LV relaxation, reduced compliance,[212,213] and abnormal ventricular-arterial stiffening.[214,215] Regardless of the underlying cause (Box 6.4), diastolic dysfunction is a ubiquitous feature of HFNEF. Diastolic dysfunction is uniformly identified in all patients with heart failure resulting from LV systolic dysfunction.[216] The severity of LV diastolic dysfunction and its response to medical therapy are important determinants of exercise tolerance[217] and mortality[218] in patients with heart failure independent of concomitant LV systolic dysfunction.

From the perspective of the cardiac anesthesiologist, LV diastolic dysfunction has significant implications in determining the LV response to acute alterations in loading conditions that occur during and after surgery. For example, cardiopulmonary bypass temporally exacerbates preexisting LV diastolic dysfunction in cardiac surgical patients.[219] Volatile and intravenous anesthetics alter LV relaxation and filling properties in the normal and failing heart.[220] Assessing the existence and severity of LV diastolic dysfunction remains an important objective in the management of patients undergoing cardiac surgery.

Invasive Evaluation of Diastolic Function

Isovolumic Relaxation

Based on the previous discussions of intracellular Ca^{2+} homeostasis and myosin-actin interaction, relaxation of the cardiac myocyte is an energy-dependent process requiring active removal of Ca^{2+} from the myoplasm. This event results in rapid dissociation of the contractile proteins and recoil of elastic elements compressed during contraction.

TABLE 6.2 Left Ventricular Structure and Function in Chronic Heart Failure

Parameter	*LV Systolic Heart Failure*	*LV Diastolic Heart Failure*
Remodeling		
End-diastolic volume	Increased	Normal
End-systolic volume	Increased	Normal
LV mass	Increased	Increased
Geometry	Eccentric	Concentric
Cardiac myocyte	Increased length	Increased diameter
Extracellular matrix	Decreased collagen	Increased collagen
LV Systolic Properties		
Stroke volume	Decreased (or normal)	Normal (or decreased)
Stroke work	Decreased	Normal
M_{sw}	Decreased	Normal
E_{es}	Decreased	Normal (or increased)
Ejection fraction	Decreased	Normal
dP/dt_{max}	Decreased	Normal
Preload reserve	Exhausted	Limited
LV Diastolic Properties		
End-diastolic pressure	Increased	Increased
τ	Increased	Increased
β	Normal (or increased)	Increased

β, Myocardial stiffness constant; dP/dt_{max}, maximum rate of increase of LV pressure; E_{es}, slope of the LV end-systolic pressure-volume relationship; *LV*, left ventricular; M_{sw}, slope of the LV stroke work–end-diastolic volume relationship; τ, time constant of LV isovolumic relaxation.

Modified from Aurigemma GP, Zile MR, Gaasch WH. Contractile behavior of the left ventricle in diastolic heart failure: with emphasis on regional systolic function. *Circulation.* 2006;113:296–304.

Delays in relaxation may be viewed as a form of active elasticity because failure of actin-myosin cross-bridges to dissociate occurs when energy supply is inadequate or intracellular Ca^{2+} homeostasis is dysfunctional.[221,222] The delay in relaxation is important because early LV filling may be substantially attenuated, and overall LV filling may become increasingly dependent on LA systole. The subsequent loss of LA contraction occurring, for example, with the onset of atrial fibrillation often precipitates acute signs and symptoms of heart failure in patients with diseases in which delayed LV relaxation is an especially prominent feature (eg, severe pressure-overload hypertrophy, hypertrophic obstructive cardiomyopathy [HCM]). Delayed global LV relaxation produced as a consequence of hypoxemia[223] or regional myocardial ischemia in a relatively large perfusion territory also may translate into reduced LV compliance (ie, upward shift of the EDPVR).[224,225]

LV relaxation delays compromise early diastolic subendocardial coronary blood flow because failure to complete actin-myosin dissociation and facilitate elastic recoil prolong the compression of intramyocardial coronary arterioles.[226] Evaluation of LV isovolumic relaxation

provides essential information about early diastolic mechanical behavior that directly influences subsequent events during chamber filling.

An invasively implanted, high-fidelity pressure transducer is required to precisely determine the rate and extent of LV pressure decline during isovolumic relaxation. Analogous to the use of LV dP/dt_{max} as an index of the inotropic state during isovolumic contraction, the peak rate of LV pressure decrease (dP/dt_{min}) has been used to quantify isovolumic relaxation during the early phase of diastole. LV dP/dt_{min} is regarded as an unreliable index of relaxation because the parameter is highly dependent on the magnitude of LV end-systolic pressure[227] and examines only a single time point near the onset of relaxation. Instead, LV relaxation is most often described based on the observation that LV pressure decline follows an exponential time course between aortic valve closure and mitral valve opening.

LV relaxation may be quantified using a time constant (τ) derived from the equation $P(t) = P_0e^{-t/\tau}$, in which P(t) is time-dependent LV pressure, P_0 is LV pressure at end-systole, e is the natural exponent, and t is time (ms) after LV end-systole. Although conceptually useful, this exponential equation is flawed because it mathematically constrains LV pressure to fall to 0 mm Hg. However, it is known that LV pressure may fall to subatmospheric pressures during marked hypovolemia or intense exercise[67] or remain greater than 0 mmHg when forces outside the LV are acting on it (eg, pericardial tamponade, constrictive pericarditis).[228] As a result, a more physiologically relevant model of isovolumic relaxation allows calculation of the time constant assuming a nonzero asymptote of LV pressure decay such that $P(t) = P_0e^{-t/\tau} + P_a$, in which P_a is the true end point of pressure decline.[229]

Regardless of the method used to derive the time constant, increases in τ quantify delays in LV relaxation that occur during disease processes such as myocardial ischemia,[230] pressure-overload hypertrophy,[231] or HCM[232] or as a consequence of negative inotropic drugs, including volatile anesthetics.[233] Conversely, reductions in τ indicate more rapid LV relaxation that may be observed during tachycardia, sympathetic nervous system activation, or administration of positive inotropic medications.

Interpretation of changes in τ produced by drugs or disease requires qualification because LV loading conditions affect the time constant.[40] For example, LV preload and τ are directly related[229,234] unless arterial pressure remains relatively constant.[235] Similarly, τ is linearly related to afterload because afterload affects the duration, rate, and extent of LV ejection.[40] The afterload dependence of LV relaxation is enhanced in the failing heart (see Fig. 6.21).[142,236] This observation has important clinical ramifications because afterload reduction enhances LV systolic function, facilitates LV relaxation, and indirectly improves early LV filling dynamics in patients with heart failure.[141] Interpretation of changes in the time constant of LV isovolumic relaxation requires consideration of the loading conditions under which τ is measured.[237] Invasive quantification of LA relaxation also has been reported using methods similar to those described in the LV.[73]

Filling

Invasive measurement of continuous LV volume allows indices of LV filling to be easily calculated, but LV volume waveforms also may be obtained noninvasively using echocardiography, angiography, and dynamic MRI. Regardless of the method used to obtain a continuous LV volume signal, its first derivative with respect to time (dV/dt) produces a biphasic waveform characterized by peaks corresponding to early LV filling and LA systole (ie, E and A waves, respectively). The dV/dt waveform is closely related to the transmitral blood flow and annular velocity signals obtained using conventional pulsed-wave echocardiography and tissue Doppler imaging, respectively.

Using the continuity equation, the products of the time-velocity integrals of transmitral blood flow velocity E and A signals (ie, TVI_E and TVI_A) and the mitral valve area can be shown to be identical to the areas inscribed by the E and A waves obtained from differentiation of the LV volume waveform, respectively. A wide variety of filling parameters may be determined using the dV/dt waveform, including the E and A wave peak filling rates, the deceleration rate and half-time

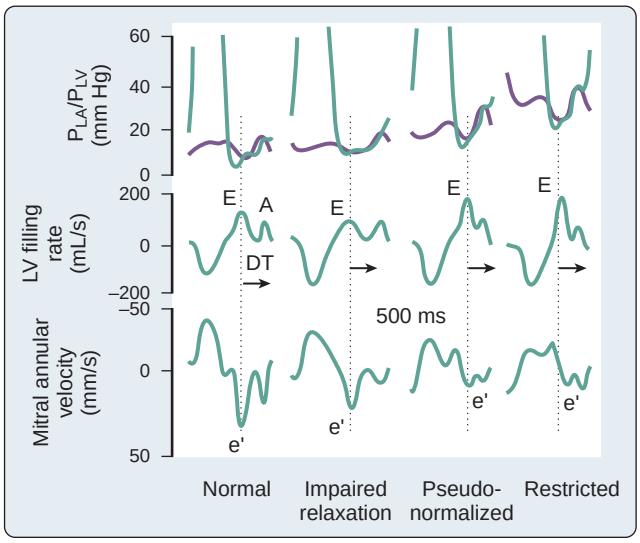

Fig. 6.30 Simultaneous tracings show the relationships between left atrial pressure *(P_{LA})* and left ventricular pressure *(P_{LV})*, the left ventricular *(LV)* filling rate during early filling *(E)* and atrial systole *(A)*, and the early mitral annular velocity *(e')* under normal conditions and during evolving diastolic dysfunction (ie, impaired relaxation, pseudonormal, and restrictive). Notice the initial lengthening of E-wave deceleration time *(DT)* during impaired relaxation and the subsequent shortening of DT as diastolic function worsens. *(From Little WC, Oh JK. Echocardiographic evaluation of diastolic function can be used to guide clinical care.* Circulation. *2009;120:802–809.)*

of the E wave, the E/A ratio, the areas (obtained by integration) of the E and A waves (corresponding to early LV filling and LA systole blood volumes, respectively), the ratio of early LV filling to total LV end-diastolic volumes (ie, percentage of early LV filling), and measurements of time intervals of these events. Progressive development of heart failure produces similar changes in the dV/dt morphology compared with the transmitral blood flow velocity waveform, as indicated by the transition of delayed relaxation through pseudonormal and restrictive filling patterns (Fig. 6.30).[238]

An analogous set of parameters may be derived from continuous measurement of the LV dimension (eg, segment length, wall thickness).[239] However, the relative accuracy with which the variables may be extrapolated to describe global LV filling depend on implicit geometric assumptions, the LV region examined, and the absence of regional wall motion abnormalities.[208]

Passive Mechanical Behavior

Derived from a series of differentially loaded LV pressure-volume diagrams, the EDPVR describes LV passive elastic compliance. The relationship between end-diastolic pressure (P_{ed}) and volume (V_{ed}) is exponential such that $EDP = Ae^{KVed} + B$, in which K is the modulus of chamber stiffness (ie, end-diastolic elastance) and A and B are curve-fitting constants (Fig. 6.31). An increase in K produced by a disease process such as pressure-overload hypertrophy indicates that the LV chamber has become less compliant. This implies that a higher LV pressure will result for a given filling volume.

The modulus of chamber stiffness also may be derived from a single LV pressure-volume diagram by using pairs of diastolic pressure and volume data points obtained after relaxation is complete (ie, during diastasis and LA systole) to avoid viscoelastic effects[240] or estimated noninvasively using the deceleration time of the transmitral blood flow velocity E wave.[241]

The EDPVR provides a simple model of LV compliance that is conceptually useful, but its interpretation is subject to important limitations. LV geometry, mass, and wall thickness influence the modulus of chamber stiffness. Comparison of changes in K between patients

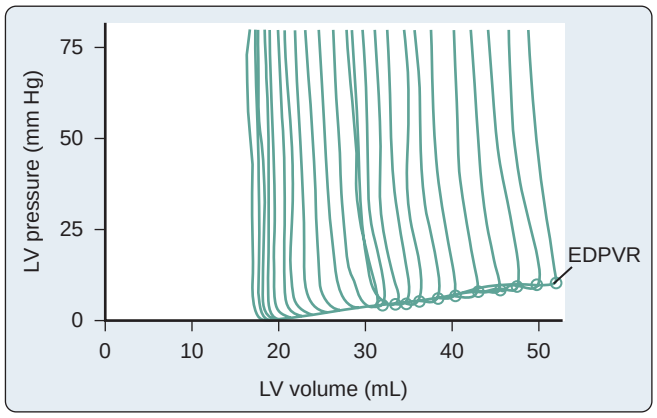

Fig. 6.31 Method used to derive the left ventricular *(LV)* end-diastolic pressure-volume relationship *(EDPVR)* from a series of differentially loaded LV pressure-volume diagrams generated by abrupt occlusion of the inferior vena cava in a canine heart in vivo. The end-diastolic pressure and volume data from each diagram *(right lower corner)* are related by a monoexponential relationship such that $P_{ed} = Ae^{KVed} + B$, where P_{ed} and V_{ed} are the end-diastolic pressure and volume, respectively; e is the natural exponent; K is the modulus of stiffness; and A and B are curve-fitting constants.

requires normalization of these variables.[237] Because the relationship between end-diastolic pressure and end-diastolic volume is exponential, comparisons of the modulus of chamber stiffness between patients or interventions should be made using a similar range of pressure and volume. Measurements of the modulus of chamber stiffness do not consider parallel shifts in the EDPVR.[40] For example, an acute increase in pericardial pressure causes a parallel upward shift of the EDPVR, indicating that LV pressure is greater at each LV volume.[85]

The relative position of the EDPVR, not the magnitude of the modulus of chamber stiffness alone, is equally important in defining overall LV passive mechanical characteristics because a shift in the relationship up or to the left indicates that a higher LV pressure is required to distend the LV to a given volume.[242] Similar descriptions of LA compliance have been reported using differentially loaded end-reservoir pressure-volume diagrams.[99]

The material properties of the myocardium itself (independent of LV size, geometry, and external forces) may be derived from stress-strain relationships. Because myocardium is an elastic material, Hooke's law governs its behavior, indicating that myocardium develops a resisting force (ie, stress [σ]) as its length (ie, strain [ε]) increases. The forces resisting further increases in myocardial length increase as the muscle is stretched, a process that occurs in vivo during LV filling. Strain is the percent change in muscle length (L) from unstressed muscle length (L_0), which is typically estimated at an LV pressure of 0 mm Hg in the intact heart. Lagrangian [$\varepsilon = (L - L_0)/L_0$] or natural ($\varepsilon = L/L_0$) strain is most often used to normalize muscle length. The stress-strain relationship is exponential such that $\sigma = \alpha(e^{\beta\varepsilon} - 1)$, where α is the coefficient of gain and β is the modulus of myocardial stiffness.[240] A shift of the nonlinear stress-strain relationship up and to the left is consistent with an increase in β that occurs in diseases such as HCM, amyloidosis, and hemochromatosis.

Myocardium is an elastic material, but it also demonstrates viscous properties. Viscoelasticity is observed when the forces resisting further alterations in length depend on the magnitude of the change in length and rate with which this change occurs. Viscoelastic effects are most evident in the intact heart during early LV filling, when the rate of change of LV volume is greatest, but they also may be observed during LA systole. Stress-strain relationships incorporating viscoelastic properties may be described using the equation $\sigma = \alpha(e^{\beta\varepsilon} - 1) + \eta(d\varepsilon/dt)$, in which η is the viscoelastic constant and $d\varepsilon/dt$ is the rate of change of strain.[243] An increase in viscous effects may modestly attenuate but is not a major determinant of early LV filling in the normal heart.[244]

Noninvasive Evaluation of Diastolic Function

Isovolumic Relaxation

Isovolumic relaxation time (IVRT) is the period between aortic valve closure and mitral valve opening. IVRT is the most commonly used noninvasive surrogate of invasively derived indices of LV relaxation (eg, dP/dt_{min}, τ). IVRT may be measured with M-mode echocardiography or continuous-wave Doppler echocardiography as the interval between the cessation of aortic blood flow and the onset of transmitral blood flow in the modified midesophageal five-chamber or deep transgastric TEE imaging planes.

The rate of LV relaxation and the difference between LV end-systolic pressure and LA pressure at the mitral valve opening are the major determinants of IVRT in the absence of mitral or aortic valve disease.[245] As a result, IVRT depends on LV relaxation and loading conditions. For example, an increase in LV afterload prolongs IVRT by increasing LV pressure at aortic valve closure, whereas an increase in LA pressure shortens IVRT.

In an attempt to partially circumvent the load-dependence of IVRT, Doppler echocardiographic analysis of mitral or aortic regurgitant jet velocity has been used in combination with the modified Bernoulli equation ($\Delta P = 4v^2$, in which ΔP is the pressure gradient and v is regurgitant blood flow velocity in m/s) to noninvasively estimate the time constant of LV relaxation.[246] However, this technique has not been widely applied in clinical echocardiography because τ is also load dependent.

Transmitral Blood Flow Velocity

Pulsed-wave Doppler echocardiographic evaluation of the pattern of transmitral blood flow velocity forms the basis of noninvasive analysis of LV diastolic function.[247] RV filling properties also may be assessed using pulsed-wave Doppler analysis of transtricuspid blood flow velocity. Cardiac anesthesiologists most often use the midesophageal four-chamber view to record the transmitral blood flow velocity profile by placing a pulsed-wave sample volume between the tips of the mitral leaflets during diastole to obtain a high-quality spectral envelope.

Similar to the invasively derived dV/dt waveform described earlier, the normal pattern of transmitral blood flow velocity contains two peaks associated with early LV filling and LA systole (E and A waves, respectively) (Fig. 6.32).[248] The ratio of peak E-wave to peak A-wave velocities (E/A ratio) is used to characterize the relative contributions of early and late filling to the final LV end-diastolic volume. Time-velocity integrals of the E and A waves (TVI_E and TVI_A, respectively) may be combined with measurements of mitral valve area to quantify the magnitude of blood flow (ie, volume) by application of the continuity equation. The time required for deceleration of the E wave (ie, deceleration time) also is commonly measured as an indicator of the influence of LV relaxation on the pressure gradient between the LA and LV that determines the magnitude and extent of early LV filling.

Normal values of these variables are age dependent and demonstrate a gradual slowing of LV relaxation as age increases (Table 6.3). E-wave velocity and E/A ratio decrease with advancing age, whereas IVRT, deceleration time, and A-wave velocity increase,[249] changes that predispose elderly patients to the development of exercise intolerance and heart failure. Progressive stiffening of the myocardial cartilaginous structure, loss of myocyte elasticity, increased LV muscle mass, and elevated arterial pressure are the major causes of age-related LV filling abnormalities.[250,251]

The alterations in transmitral blood flow velocity related to age are indicative of delayed relaxation, the least severe of three major abnormal LV filling patterns that characterize the continuum of LV diastolic dysfunction (see Fig. 6.30). Clinical symptoms, exercise tolerance, New York Heart Association (NYHA) functional class, and mortality rates are closely correlated with the relative severity of LV diastolic dysfunction.[252] A reduction in early LV filling and a greater contribution of LA systole to overall LV filling are pathognomonic findings in this delayed relaxation pattern. An E/A ratio less than 1

and a deceleration time that is prolonged because of a delay in LV relaxation reduce the initial LV-LA pressure gradient and extend the duration of early LV filling, respectively.[238] The enhanced contribution of LA systole occurs primarily through a Frank-Starling mechanism, increases A-wave size, and compensates for the reduction in early LV filling, preserving relatively normal LV end-diastolic volume. In addition to advanced age, the delayed relaxation pattern is often observed in patients with essential hypertension, pressure-overload LV hypertrophy, and ischemic heart disease.

A pseudonormal pattern of transmitral blood flow velocity appears after the delayed relaxation profile as the underlying disease worsens. The E/A ratio increases to a value greater than 1, and this pseudonormal pattern may be indistinguishable from a normal LV filling pattern when other indices of diastolic dysfunction (eg, pulmonary venous blood flow velocity pattern, tissue Doppler imaging, color M-mode echocardiography) are not examined or when maneuvers to acutely alter loading conditions (eg, Valsalva, nitroglycerin infusion) are not performed.[253] Elevated LA pressure restores the normal LA-LV pressure gradient on mitral valve opening and increases E wave velocity to a normal value despite the continued presence of an LV relaxation abnormality.

The pseudonormal pattern of LV filling may be recognized by a shorter E-wave deceleration time (<200 ms, which is consistent with a reduction in early diastolic LV compliance[221]) or by the reappearance of the delayed relaxation pattern during a decrease in preload.[254] In contrast, the delayed relaxation profile does not appear when preload is reduced in patients with normal LV diastolic function.

The restrictive pattern denotes severe, end-stage LV diastolic dysfunction. LA pressure is profoundly elevated, and the LA-LV pressure gradient is augmented far beyond what is necessary to compensate for the LV relaxation delay. The peak E-wave velocity (>1 m/s) becomes markedly greater than its A-wave counterpart, and the E/A exceeds a value of 2. E-wave deceleration time also becomes very rapid (<150 ms) as LV compliance is further reduced (see Table 6.3).

The restrictive filling pattern frequently is observed in patients with NYHA class IV heart failure resulting from a variety of causes,[255,256] and it is a characteristic finding in those with severe constrictive pericarditis,[257] restrictive cardiomyopathy,[258] or rejection of a transplanted heart[259] independent of changes in LV systolic function. Failure of the restrictive filling pattern to revert to a less severe pseudonormal or delayed relaxation profile in response to a diuretic or a vasodilator is associated with a grim prognosis.[247] Two opposing parabolic curves describing changes in the E/A ratio and deceleration time may be used to illustrate changes in LV diastolic function related to age or progressive deterioration from delayed relaxation to restrictive physiology (Fig. 6.33).

In addition to load dependence, several other factors, including heart rate, abnormal AV conduction, atrial arrhythmias, and mitral valve disease, may adversely influence evaluation of transmitral blood flow velocity patterns. For example, sinus tachycardia and first-degree AV block produce partial or complete fusion of the E and A waves. Fusion complicates assessment of individual peak velocities, time-velocity integrals, and deceleration time. Atrial flutter produces variably loaded LA contractions, depending on the extent of the accompanying AV block, whereas atrial fibrillation completely eliminates the active LA contribution to LV filling.

Severe mitral stenosis limits LV filling, and the transmitral blood flow velocity measurements obtained in cases of stenosis are unreliable for LV diastolic function analysis. Mitral regurgitation increases LA pressure independent of changes in LV diastolic function; this

effect makes isolated recognition of LV diastolic dysfunction difficult or impossible using transmitral blood flow velocity profiles. Normal sinus rhythm and the absence of hemodynamically significant mitral valve disease are required when the morphology of transmitral blood flow velocity is used for the analysis of LV diastolic function (see Chapters 14 and 15).

Pulmonary Venous Blood Flow Velocity

The pulmonary venous blood flow velocity pattern is analyzed to noninvasively determine LV diastolic dysfunction,[260] quantify the degree of mitral regurgitation,[261] or estimate pulmonary capillary occlusion and mean LA pressures.[262] The pattern of hepatic venous blood flow velocity provides important information about the relative severity of RV diastolic dysfunction or tricuspid regurgitation.

Cardiac anesthesiologists most often interrogate pulmonary venous blood flow velocity by placing a pulsed-wave sample volume between 0.5 and 1.0 cm within the right or left superior pulmonary vein in a modified midesophageal bicaval or four-chamber TEE imaging plane, respectively, to obtain a crisp velocity profile.[263] Color-flow Doppler mapping is often used to identify the best location within a pulmonary vein to place the sample volume.

TEE is the preferred method for pulmonary venous blood flow velocity analysis because the anatomic proximity of the right and left upper pulmonary veins to the esophagus provides optimal imaging windows with minimal ultrasound scatter by intervening tissue.[264] The pulmonary venous blood flow velocity profile depends on LV relaxation, filling, and compliance; heart rate; LA and LV loading conditions; and LA contractile function.[265] Conclusions about LV diastolic function derived using this technique require interpretation with these potential limitations in mind. The pulmonary venous blood flow velocity profile is most often combined with the transmitral LV filling pattern and not used as an independent prognostic indicator of disease progression.[266]

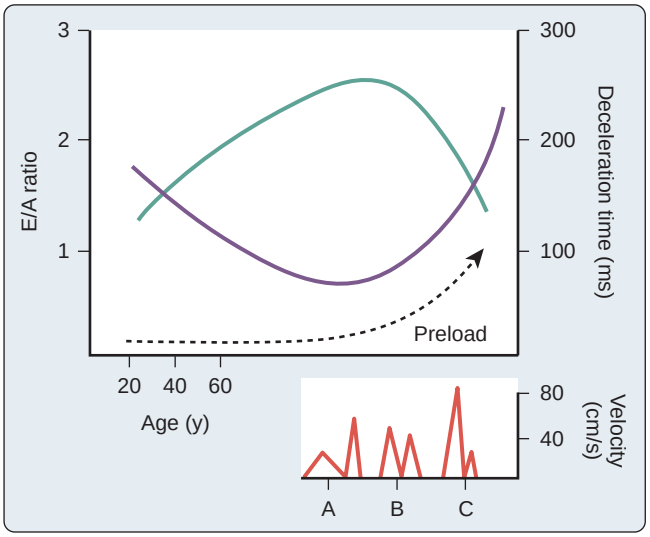

Fig. 6.33 Changes in the ratio of transmitral blood flow velocity during early left ventricular filling and atrial systole *(E/A ratio, purple curve)* and in deceleration time *(green curve)* associated with age and the development of left ventricular diastolic dysfunction. The *dashed line* represents left ventricular preload, which increases as diastolic dysfunction worsens. The lower right diagram demonstrates impaired relaxation *(A)*, pseudonormal *(B)*, and restrictive *(C)* left ventricular filling patterns of diastolic dysfunction measured using pulsed-wave Doppler echocardiography.

The normal pulmonary venous blood flow velocity pattern is composed of a single, small, negative deflection that indicates retrograde flow from the LA chamber into the pulmonary veins (ie, atrial reversal [Ar] wave), and two large, positive deflections that indicate forward flow from the pulmonary veins into the LA.[267] LA preload, LA contractile state, and LV pressure during late diastole affect the magnitude and duration of the Ar wave.[268]

The first positive deflection is known as the S (systolic) wave and occurs during LV systole and isovolumic relaxation when the mitral valve is closed. The S wave displays a biphasic morphology (S_1 and S_2, which are not equivalent to the first and second heart sounds) originating from a series of LA, LV, and RV events.[269] LA relaxation after contraction and the consequent reduction in LA pressure facilitates forward blood flow from the pulmonary veins into the LA during early LV isovolumic contraction.[268] Mitral annular descent toward the apex during LV systole (ie, approximately 1.3 cm in healthy individuals) also causes a piston-like effect that draws blood from the pulmonary veins into the LA.[270] These actions combine to produce S_1. Mitral annular descent may be markedly attenuated in patients with reduced LV systolic function, emphasizing that LV contractility plays an important role in the extent of LA filling.[271]

Transmission of the RV systolic pressure pulse through the pulmonary circulation contributes to additional LA filling later during LV contraction to produce S_2. S_1 and S_2 are most often combined into a single S wave when using pulmonary venous blood flow velocity patterns to assess LV diastolic function.

The second positive deflection (ie, D wave) of the pulmonary venous blood flow velocity pattern occurs immediately after the opening of the mitral valve. The rapid drop in LA pressure that accompanies early LV filling allows subsequent blood flow from the pulmonary veins into the LA (Fig. 6.34). The peak velocity and time-velocity integral of the D wave depend on LV compliance and the magnitude of early LV filling.[272] Factors that attenuate early LV filling (eg, delayed LV relaxation, reduced LV compliance, mitral stenosis) cause decreases in D-wave velocity.[273]

Similar to the pattern of transmitral blood flow velocity, the pulmonary venous blood flow velocity profile is age dependent. The S/D ratio, the peak Ar velocity, and the Ar duration increase with age,[248] consistent with the enhanced importance of LA systole to LV filling during the gradual development of delayed LV relaxation. However, the compensatory increase in LA pressure that restores the E-wave velocity and E/A ratio in pseudonormal physiology attenuates systolic pulmonary venous blood flow and begins to produce pulmonary venous congestion. The S wave becomes progressively blunted, and the S/D ratio falls below 1 while the magnitude and duration of the Ar wave continue to increase, allowing an easily recognizable distinction between otherwise morphologically similar normal and pseudonormal transmitral blood flow velocity patterns.[260]

As restrictive LV diastolic dysfunction develops, the changes are more pronounced concomitant with further elevations in LV diastolic and LA pressures. The S/D ratio declines as systolic LA filling is further

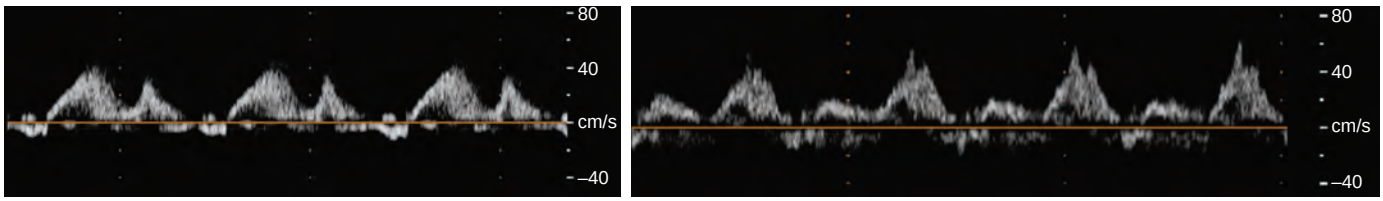

Fig. 6.34 Pulmonary venous blood flow velocity waveforms obtained using pulsed-wave Doppler echocardiography under normal conditions *(left)* and during increased left atrial pressure *(right)*.

attenuated, and the D wave deceleration time becomes more rapid as the LV becomes less compliant (see Fig. 6.34). The Ar blood flow velocity exceeds 35 cm/s, and the duration of the Ar wave becomes greater than that of the corresponding transmitral A wave unless overt LA failure occurs.[274] An Ar-A duration greater than 30 ms is strongly predictive of elevated LV end-diastolic pressure.[275] As observed with transmitral blood flow velocity profiles, atrial arrhythmias, AV conduction abnormalities, and mitral valve disease limit the use of pulmonary venous blood flow patterns for the evaluation of LV diastolic function.

Tissue Doppler Imaging

Interrogation of septal or lateral mitral annular motion using low-velocity (10 to 15 cm/s) pulsed-wave Doppler provides additional information about the relative severity of LV diastolic dysfunction (see Fig. 6.30).[276] Mitral annular motion is an index of the relative LV long-axis lengthening rate during filling. Averaging of septal and lateral tissue Doppler imaging is recommended to account for the effects of regional differences in function.[277]

Cardiac anesthesiologists most often use the midesophageal four-chamber TEE view to acquire tissue Doppler waveforms during LV filling. Similar to the transmitral blood flow velocity profile, the tissue Doppler waveform demonstrates peak velocities associated with early LV filling and LA systole (e′ and a′, respectively), and the e′/a′ ratio demonstrates the relative contributions of these events to the final LV end-diastolic volume. The ratio of transmitral E to tissue Doppler e′ waves (E/e′) is a reliable estimate of elevated LV filling pressure.[278] For example, a septal E/e′ ratio less than 8 strongly suggests that LV filling pressure is normal, but an E/e′ ratio greater than 15 usually indicates that LV end-diastolic pressure is increased.[279] The E/e′ ratio is especially useful for establishing the diagnosis of HFNEF.[280,281]

The determinants of tissue Doppler e′ and a′ velocities are similar to those described for transmitral E and A velocities, respectively. The rate and extent of LV isovolumic relaxation, LV systolic function, and LV preload are the major hemodynamic factors that determine tissue Doppler e′ velocity. Tissue Doppler e′ velocity appears to be less affected by preload than transmitral E velocity, especially when LV relaxation is delayed.[282] As a result, the e′/a′ ratio is less likely to display overt delayed relaxation and subsequent pseudonormal profiles than its transmitral E/A counterpart as LV diastolic dysfunction progresses and LA pressure rises. The relative preload independence of e′ during abnormal LV relaxation also increases the time interval between the onset of the transmitral E and tissue Doppler e′ velocities ($T_{E\text{-}e'}$), which has been shown to be a noninvasive estimate of the time constant (τ) of LV isovolumic relaxation.[283] Unlike transmitral E wave velocity, tissue Doppler e′ velocity is particularly useful in distinguishing between constrictive pericarditis (ie, e′ is normal) and restrictive cardiomyopathy (ie, e′ is reduced).[284]

LA contractile function and LV diastolic pressure are the primary factors that influence the magnitude of tissue Doppler a′ velocity. As observed with transmitral and pulmonary venous blood flow velocities, tissue Doppler velocities are age dependent such that e′ velocity and e′/a′ ratio decrease, whereas a′ velocity and E/e′ increase with age. In addition to age, the use of tissue Doppler imaging to quantify LV diastolic dysfunction may be limited by mitral annular calcification, a prosthetic mitral valve or ring, or mitral valve disease and by technical difficulties in obtaining a reproducible, clean envelope of low-velocity annular motion during diastole.[248]

Color M-Mode Propagation Velocity

The flow propagation velocity (V_p) of the blood column extending from the mitral valve to the apex during early LV filling may be reliably obtained using color M-mode echocardiography, and it is another index of LV diastolic function.[285] V_p is relatively preload insensitive,[286] is particularly useful for evaluating LV relaxation abnormalities,[287] and correlates with invasively derived indices of LV relaxation (eg, τ).[285]

The midesophageal four-chamber imaging plane allows the cardiac anesthesiologist to acquire a color Doppler M-mode envelope by placing the M-mode scan line into the center of LV inflow aligned from base to apex. After adjusting the Nyquist limit to ensure that the highest velocity is blue, V_p is determined as the slope of the first aliasing velocity (Fig. 6.35).[248] A V_p value greater than 50 cm/s is normal and quantifies the rapid movement of blood from the mitral valve to the

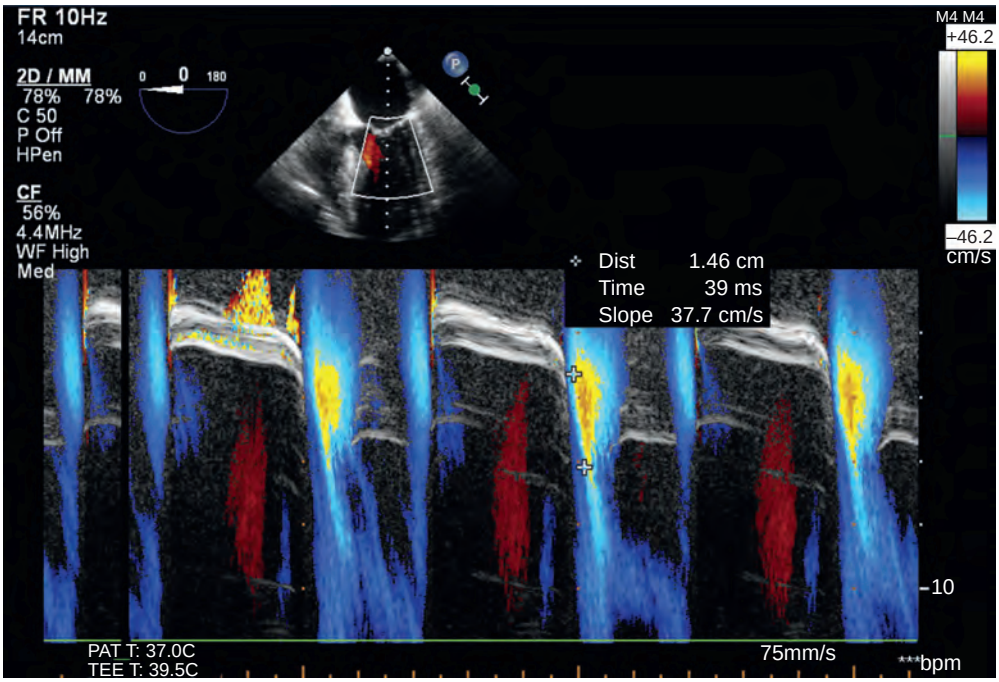

Fig. 6.35 Determination of color M-mode mitral valve blood flow propagation velocity (V_p). A color Doppler M-mode envelope is obtained by placing the M-mode scan line into the center of left ventricular (LV) inflow aligned from base to apex. V_p is determined as the slope of the first aliasing velocity. A value of V_p less than 45 cm/s suggests that early LV filling is attenuated, consistent with LV diastolic dysfunction.

apex, mediated by the pressure gradient between these intraventricular regions (ie, apical suction) during early LV filling.[285,288]

The extent of relaxation and the elastic recoil of the LV are the primary determinants of V_p. Clinical conditions (eg, myocardial ischemia, HCM) in which these factors are attenuated reduce V_p by decreasing the apical suction during early LV filling.[289,290] Nevertheless, the use of V_p as a quantitative index of LV diastolic dysfunction may be limited by other factors, including alterations in chamber geometry, contractile dyssynchrony, and blood flow vortex formation, that become increasingly important in determining the magnitude of apical suction as heart failure evolves.[291] The ratio of transmitral E-wave velocity to V_p (E/V_p) is related to LV filling pressure and has been used as a noninvasive estimate of pulmonary capillary occlusion pressure.[288] For example, an E/V_p ratio greater than 2.5 indicates that wedge pressure is greater than 15 mm Hg, a finding that is common in restrictive physiology.[283]

Pericardial Forces

The pericardium is a sac that encloses the heart, proximal great vessels, distal vena cavae, and pulmonary veins. The smooth surface of the visceral pericardium combined with the lubrication provided by 15 to 35 mL of pericardial fluid (ie, plasma ultrafiltrate, myocardial interstitial fluid, and a small quantity of lymph) and surfactant phospholipids reduce friction and facilitate normal cardiac movement during systole and diastole.

The pericardium also acts as a mechanical barrier that separates the heart from other mediastinal structures and limits abnormal displacement of the heart through its inferior (ie, diaphragmatic) and superior (ie, great vessels) attachments. The fibrous layer of the parietal pericardium determines the J-shaped pericardial pressure-volume relationship (Fig. 6.36), which indicates that the pericardium is substantially less compliant than LV myocardium. As a result of this lack of elasticity, the pericardium has very limited volume reserve and is capable of accommodating only a small increase in volume before a large increase in pressure occurs.[292]

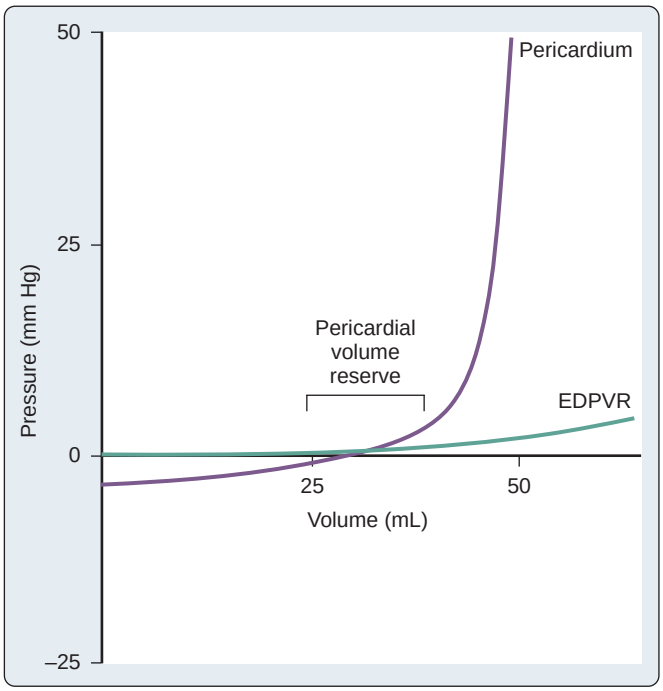

Fig. 6.36 Pressure-volume relationship of the pericardium compared with the left ventricular end-diastolic pressure-volume relationship *(EDPVR)*. Large increases in pericardial pressure occur after the reserve volume is exceeded.

Pericardial pressure is usually subatmospheric (range, –5 to 0 mm Hg), varies with changes in intrathoracic pressure, and produces little or no mechanical effect in a normal heart under euvolemic conditions.[293] Instead, the pericardium exerts a critical restraining force on the filling of all four cardiac chambers,[294] and the effect is exaggerated during pericardial compression (eg, tamponade, constrictive pericarditis) or acute increases in chamber dimension (eg, volume loading).

Pericardial restraint is most apparent in the thinner-walled atria and RV, and it is the primary determinant of the diastolic pressure and volume of these chambers. The pericardium resists further increases in atrial and RV chamber size during volume loading, and pressure within these chambers rises more rapidly than predicted on the basis of myocardial elasticity alone.

The pericardium also plays an important role in LV filling,[295] as an acute increase in pericardial pressure causes a parallel upward shift of the LV EDPVR.[296] Elevation of the EDPVR combined with more pronounced diastolic ventricular interdependence (ie, interaction) is responsible for the severely restricted LV filling observed during pericardial tamponade. Conversely, atrial volume, RV and LV end-diastolic volumes, SV, and CO increase after pericardiectomy because pericardial restraining forces are no longer present and the myocardium is the only remaining determinant of the compliance of each chamber.

In contrast to the effects of an acute increase in pericardial or cardiac chamber volume, chronic pericardial effusion or chamber enlargement progressively stretches the pericardium, increasing its compliance and attenuating or abolishing its restraining effects. This compensatory response to a gradual, chronic increase in pericardial load explains why hemodynamic instability often does not occur in the setting of a very large (>1000 mL) pericardial effusion or profound biventricular dilation that would otherwise precipitate severe hemodynamic instability.

The pericardium plays an essential role in ventricular interdependence (ie, influence of the pressure and volume of one ventricle on the mechanical behavior of the other). The pericardium restrains the LV and RV equally despite the inherent differences in compliance between the chambers. An increase in RV size (eg, ischemia, volume overload) causes pericardial pressure to increase, reducing LV compliance and restricting LV filling.[297] Similarly, acute LV distention (eg, application of an aortic cross-clamp) encroaches on the RV, shifts its EDPVR up and to the left, and limits RV filling.[298] These observations emphasize that the relative position and direction of movement of the interventricular septum are not the only factors that determine ventricular interdependence.

Evidence for diastolic ventricular interaction is readily apparent using pulsed-wave echocardiography to determine changes in RV and LV filling during spontaneous ventilation.[299] Inspiration decreases intrathoracic pressure, enhances venous return, and causes modest RV distention. These effects mildly reduce LV filling by decreasing compliance of the chamber, resulting in small declines in mean arterial pressure and CO. During expiration, RV filling is attenuated, and LV filling is augmented. Compression of the ventricular chambers during pericardial tamponade[300] or constrictive pericarditis[301] markedly exaggerates these respiratory changes in RV and LV filling. Maintenance of spontaneous ventilation is crucial under these circumstances because negative intrathoracic pressure preserves venous return to some degree, whereas institution of positive-pressure ventilation may rapidly cause cardiovascular collapse by profoundly limiting venous return.

Determinants of Atrial Function

The maximum velocity of shortening of LA myocardium is equivalent to or greater than that of LV myocardium under similar loading conditions.[302,303] LA emptying fraction primarily depends on the LA preload and contractile state in vivo unless the LA dilates and its myofilaments are extended beyond optimal operating length.[304] Under these circumstances, the emptying fraction falls precipitously, and LA contraction no longer makes a meaningful contribution to final LV end-diastolic volume.

Alterations in the activity of the autonomic nervous system produce similar changes in the LA compared with the LV contractile state.[305] For example, increases in the LA emptying fraction and the LA contribution to LV filling occur as a result of sympathetic nervous system activation,[306] whereas parasympathetic stimulation causes a direct negative inotropic effect. Volatile anesthetics cause a similar degree of myocardial depression in the LA compared with LV myocardium in vivo.[99,307]

LV compliance and pressure during late diastole determine the afterload to which the LA is subjected during its contraction. LV diastolic dysfunction increases LA afterload and the amount of energy the LA must expend to perform similar pressure-volume work. Analogous to the changes in myofilament composition occurring in response to chronic increases in LV afterload, upregulation of the β-myosin isoform in atrial myocardium is an important compensatory response to elevated LA afterload that preserves the LA emptying fraction.[308] However, the LA, like the RV, has less muscle mass and operates at lower pressures than the LV.

The LA is substantially more susceptible to afterload mismatch than the LV, and increases in LA afterload and energy use produced by impaired LV filling often lead to LA contractile failure.[273] For example, an initial increase in the LA emptying fraction may be observed early in the course of developing LV failure, but LA contractile dysfunction eventually occurs as LV compliance declines and end-diastolic pressure increases.[309] Conversely, drug therapy for chronic hypertension reduces LA and LV afterload and improves the active contribution of the LA to LV filling.[310] Remodeling and reduced compliance of the LA also occur in response to LV diastolic dysfunction. These effects further restrict pulmonary venous blood flow into the LA during the reservoir and conduit phases and may lead to the development of pulmonary edema.

Several factors determine LA reservoir and conduit function. LA relaxation after contraction normally facilitates forward flow from the pulmonary veins during early LV isovolumic contraction,[268] whereas relaxation abnormalities produced by LA ischemia, hypertrophy, or dilation attenuate the ability of the chamber to function effectively as a reservoir. Descent of the LV base toward the apex during LV systole is also an important determinant of LA reservoir function.[270] This action is markedly attenuated in the setting of severe LV contractile dysfunction. As a result, LA reservoir function decreases because pulmonary venous return during the S_1 phase is markedly reduced or entirely absent.[271] Transmission of RV SV through the pulmonary circulation to the LA occurs during the late reservoir phase (S_2).[311] RV systolic dysfunction also adversely affects LA reservoir function.

In addition to the previous factors, LA compliance plays a vital role in the ability of the chamber to act as a reservoir and a conduit. LA diseases in which compliance is reduced are associated with impaired LA filling.[74,312] Pressure-volume analysis has demonstrated that the LA appendage is more compliant than the main body of the chamber[313,314] and plays an essential role in LA filling. Temporary LA appendage exclusion[315] or permanent removal[313] reduces compliance of the remaining LA, attenuating reservoir function and blunting subsequent early LV filling. These effects are particularly important in the setting of LA dilation or hypertension. The pericardium limits LA passive filling, and pericardiectomy was shown to increase LA compliance, enhance early LV filling rate, and augment conduit function and, to a lesser extent, reservoir function.[98]

Exercise and age produce characteristic changes in LA function. LA contractility and reservoir function are enhanced during exercise.[316] The increase in reservoir capacity contributes to the formation of a larger LA-LV pressure gradient during early LV filling and increases LV SV and CO. An increase in conduit function has been observed in endurance athletes compared with normal persons.[317] In contrast to these findings, LA dilation and declines in passive emptying occur in healthy elderly individuals[318] concomitant with a compensatory increase in LA ejection force[319] and augmentation of LA contribution to LV end-diastolic volume.[320] LA dilation also increases storage fraction (ie, ratio of LA reservoir to LV SV),[321] but dilation may contribute to further increases in LA wall stress and eventual LA contractile dysfunction in the elderly.[322]

7 Coronary Physiology and Atherosclerosis

BENJAMIN HIBBERT, MD, PhD | HOWARD J. NATHAN, MD | TREVOR SIMARD, MD | EDWARD R. O'BRIEN, MD

KEY POINTS

1. To care for patients with coronary artery disease in the perioperative period safely, the clinician must understand how the coronary circulation functions in health and disease.
2. Coronary endothelium modulates myocardial blood flow by producing factors that relax or contract the underlying vascular smooth muscle.
3. Vascular endothelial cells help maintain the fluidity of blood by elaborating anticoagulant, fibrinolytic, and antiplatelet substances.
4. One of the earliest changes in coronary artery disease, preceding the appearance of stenoses, is the loss of the vasoregulatory and antithrombotic functions of the endothelium.
5. The mean systemic arterial pressure and not the diastolic pressure may be the most useful and reliable measure of coronary perfusion pressure in the clinical setting.
6. Although sympathetic activation increases myocardial oxygen demand, activation of α-adrenergic receptors causes coronary vasoconstriction.
7. It is unlikely that one substance alone (eg, adenosine) provides the link between myocardial metabolism and myocardial blood flow under a variety of conditions.
8. As coronary perfusion pressure decreases, the inner layers of myocardium nearest the left ventricular cavity are the first to become ischemic and display impaired relaxation and contraction.
9. The progression of an atherosclerotic lesion is similar to the process of wound healing.
10. Lipid-lowering therapy can help restore endothelial function and prevent coronary events.

When caring for patients with coronary artery disease (CAD), the anesthesiologist must prevent or minimize myocardial ischemia by maintaining optimal conditions for perfusion of the heart. This goal can be achieved only with an understanding of the many factors that determine myocardial blood flow in both health and disease. This chapter begins with an overview of the structure and function of coronary arteries. Rapid progress has been made in the past several decades in the understanding of the physiology of blood vessels, particularly the role of the endothelium in maintaining flow. After this overview is an analysis of the major determinants of coronary blood flow. Physiologic or pharmacologic interventions alter myocardial flow by their effects on these factors. The section on coronary pressure-flow relationships explains the important concepts of autoregulation and coronary reserve. Studies of the coronary circulation are sometimes misinterpreted because of inadequate understanding of the complex interrelationships among the heart, the coronary circulation, and the peripheral circulation. The discussion of pathophysiology begins with a description of the process of atherosclerosis and the current understanding of how this disease evolves and causes clinical events. Next, the anatomy and hemodynamic effects of a coronary stenosis are explained. Coronary collateral function and development are reviewed here. These concepts are the basis of predicting how significantly the stenoses seen on angiography will impair myocardial perfusion. The topic of the final section is the pathophysiology of myocardial ischemia. Here, the concepts learned in the preceding sections are applied in an analysis of clinical ischemic syndromes. The final section highlights future directions in the treatment of CAD.

Anatomy and Physiology of Blood Vessels

The coronary vasculature has been traditionally divided into three functional groups: (1) large conductance vessels visible on coronary angiography, which offer little resistance to blood flow; (2) small resistance vessels ranging in size from approximately 250 nm to 10 μm in diameter; and (3) veins. Although it has been taught that arterioles (precapillary vessels <50 μm in size) account for most coronary resistance, studies indicate that under resting conditions, 45% to 50% of total coronary vascular resistance resides in vessels larger than 100 μm in diameter (Fig. 7.1).[1–3] The reason may be, in part, the relatively great length of the small arteries. During intense pharmacologic dilation, the proportion of total coronary vascular resistance contributed by larger arteries and veins is even greater.[1] The regulation of tone in coronary arteries larger than 100 μm in diameter plays an important role in delivering adequate myocardial perfusion.[4] One of the early changes in CAD is a diminished ability of the endothelium of epicardial coronary arteries to dilate in response to increased flow (see "Endothelium-Derived Relaxing Factors," later in the chapter). Advances in technology have enabled measurement, in the beating heart, of diameters of coronary vessels as small as 15 μm. It is becoming evident that, in response to a given intervention, different size classes of coronary vessels can change diameter with different intensity or even in opposite directions.[5,6] This heterogeneity of response according to vessel size would be an important consideration in predicting the effects of vasoactive agents on myocardial perfusion. For example, a drug that dilated large vessels and collaterals but not arterioles would be beneficial to patients with CAD (see the later section "Coronary Steal").

Normal Artery Wall

The arterial lumen is lined by a monolayer of endothelial cells that overlies smooth muscle cells (Fig. 7.2). The inner layer of smooth muscle cells, known as the intima, is circumscribed by the internal elastic lamina. Between the internal elastic lamina and external elastic

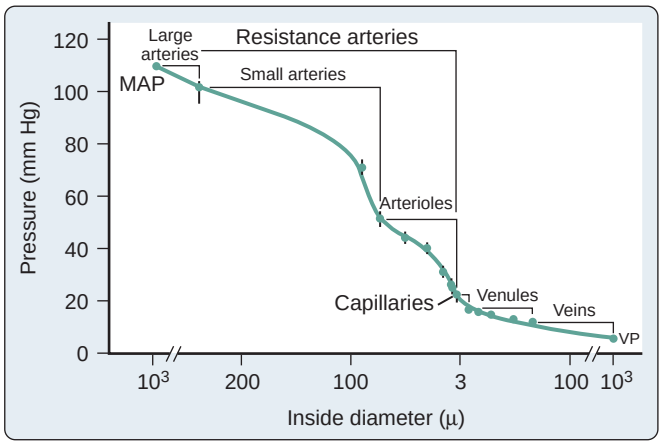

Fig. 7.1 Pressure decline through the hamster cheek pouch circulation illustrates the resistance and nomenclature of various portions of the vascular bed. The important contribution of small arteries to vascular resistance is clearly shown here. Similar observations have been made in the coronary circulation. *MAP,* Mean arterial pressure; *VP,* venous pressure. Error bars indicate SE. *(From Davis MJ, Ferrer PN, Gore RW. Vascular anatomy and hydrostatic pressure profile in the hamster cheek pouch.* Am J Physiol. *1986;250:H291.)*

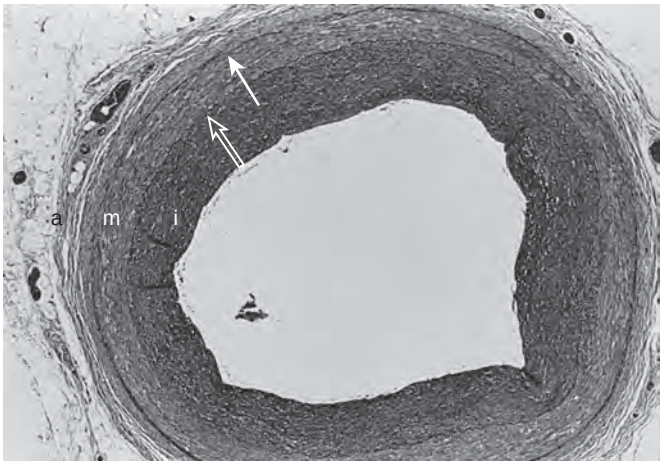

Fig. 7.2 Normal human coronary artery of a 32-year-old woman. The intima *(i)* and media *(m)* are composed of smooth muscle cells. The adventitia *(a)* consists of a loose collection of adipocytes, fibroblasts, vasa vasorum, and nerves. The media is separated from the intima by the internal elastic lamina *(open arrow)* and the adventitia by the external elastic lamina *(closed arrow)* (Movat's pentachrome–stained slide; original magnification ×6.6).

lamina is another layer of smooth muscle cells, the media. Outside the external elastic lamina is an adventitia that is sparsely populated by cells but consists of complex extracellular matrix (primarily collagen and elastin fibers) and the microvessels that comprise the vasa vasorum.

Intima

Traditionally, the intima has been considered the most important layer of the artery wall.[7] The intima can vary from an endothelial monolayer to a more complex structure with an endothelium overlying a patchwork of extracellular matrix and vascular smooth muscle cells. As part of the normal development of many large arteries, smooth muscle cells populate this space and form a neointima. This diffuse form of intimal thickening consists of several layers of smooth muscle cells and connective tissue. For convenience, the intima-to-media ratio is often measured, and the normal range is 0.1 to 1.0. The intima represents a physiologic adaptation to changes in arterial flow and wall tension, and the mechanisms that underlie its development remain poorly understood. The intima is made up of two distinct layers.[8] As seen on electron microscopy, the inner layer subjacent to the luminal endothelium contains an abundance of proteoglycan ground substance.[9] Smooth muscle cells found in this layer are usually distributed as isolated cells in a sea of matrix, rather than as contiguous layers. A few macrophages may also be found in this layer, under the endothelial monolayer. The outer, musculoelastic layer of the intima is adjacent to the internal elastic lamina and contains smooth muscle cells and elastic fibers.

Media

In normal adult arteries, several smooth muscle cell subpopulations with distinct lineages exist within the media.[9] These diverse cell populations likely fulfill different functions to maintain homeostasis in the artery wall. For example, in response to pressure elevations, increases in smooth muscle cell mass and extracellular matrix may be required. Alternatively, for arteries to be able to stretch both longitudinally and circumferentially, smooth muscle cells with variable orientations of cytoskeletal fibers must be present. These distinct cell types may be important in both health and disease. The biologic determinants of medial smooth muscle cell diversity are unknown.[10]

Adventitia

The adventitia, the outermost layer of the artery wall, normally consists of a sparse collection of fibroblasts, microvessels (vasa vasorum), nerves, and few inflammatory cells. Most of the vasa vasorum that nourish the inner layers of the artery wall originate in the adventitia. Traditionally, the adventitia was ignored and was not thought to play a role in vascular lesion formation. However, more recent studies elucidated the role of the adventitia as not only a source of inflammatory cells in the development of atherosclerosis, but also a hub for paracrine signaling in maintaining vascular homeostasis in a variety of vascular diseases.[11]

Transmembrane and Transcellular Communication

Blood vessels respond to a multitude of neural, humoral, and mechanical stimuli in fulfilling their role in homeostasis. When norepinephrine, released from adrenergic nerve terminals in the adventitia, binds to receptors on the vascular smooth muscle cell membrane, a series of events takes place, culminating in a change in vessel diameter. Much progress has been made in understanding this transmembrane signaling since the discovery of cyclic adenosine monophosphate (cAMP) in the late 1950s. Hormones circulating in the blood must interact with receptors on endothelial cells before the message reaches the vascular smooth muscle cells. The mechanism of communication between cells has been one of the central themes of biologic research in the last decades. Future understanding of cardiovascular disease will likely be based on identification of abnormalities of the molecules involved in transmembrane and transcellular communication. A brief introduction to these topics is provided here.

Fig. 7.3 illustrates examples of pathways of transmembrane signaling. Up to five components can be involved: (1) receptor, (2) G protein, (3) effector producing a second messenger, (4) phosphorylation of regulator protein, and (5) the consequent change in cell behavior. G proteins (guanine nucleotide binding regulatory proteins) are made up of three subunits (α, β, γ) and float in the cell membrane. On contact with a ligand-receptor complex, guanosine diphosphate on the α subunit is replaced by guanosine triphosphate. The activated α subunit then dissociates from the β-γ complex and can interact with several membrane targets (see Fig. 7.3B). For example, β-receptor activation results in the activation of G_s (s = stimulate), which stimulates the synthesis of cAMP by adenylyl cyclase. Muscarinic receptor activation activates a G_i (i = inhibit) protein that inhibits adenylyl cyclase. A single G protein can

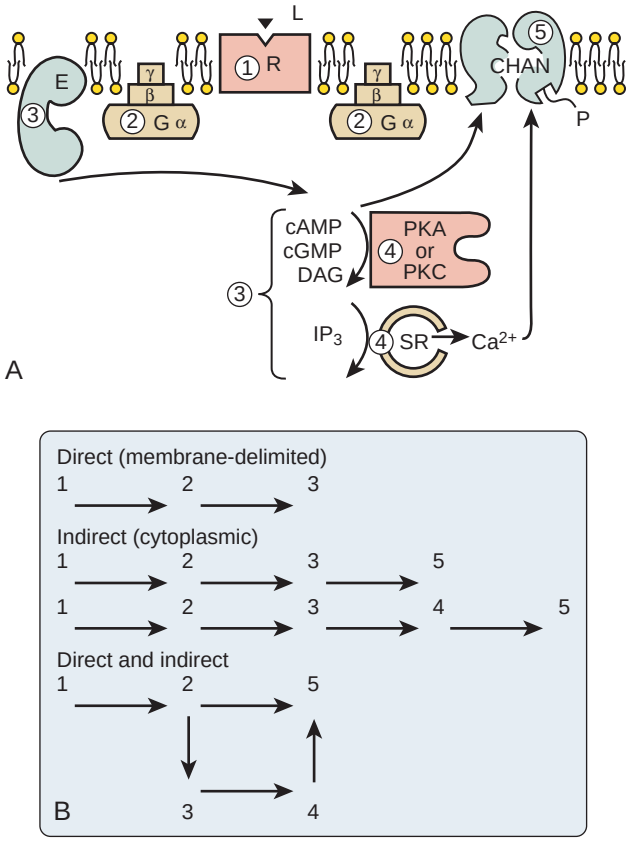

Fig. 7.3 Steps in the process whereby hormone-receptor binding results in a change in cell behavior. In this example, the final result is the opening of an ion channel. (A) A hormone or ligand *(L)* binds to a receptor *(R)* embedded in the cell membrane. The receptor-ligand complex interacts with G protein *(G)* floating in the membrane, with resulting activation of the α subunit *(Gα)*. The activated α subunit can then follow different pathways (B). Effector enzymes in the membrane *(E)*, such as adenylyl cyclase, cyclic guanosine monophosphate *(cGMP)*, phospholipase C, or phospholipase A_2, change the cytoplasmic concentration of their "messengers": cyclic adenosine monophosphate *(cAMP)*, cGMP, diacylglycerol *(DAG)*, and inositol-1,4,5-triphosphate *(IP_3)*. These soluble molecules activate protein kinase A or C *(PKA, PKC)*, or release calcium *(Ca^{2+})* from sarcoplasmic reticulum *(SR)*. Subsequently, cell behavior is changed by phosphorylation of an ionic channel on the cell membrane *(CHAN)* or by release of Ca^{2+} from SR. (B) Several pathways coupling receptor activation to final effect are illustrated. It is likely that multiple pathways are activated concomitantly, both facilitatory and inhibitory. In this way, the final response can be determined by the sum of the effects of several stimuli. *(From Brown AM, Birnbaumer L. Ionic channels and their regulation by G-protein subunits.* Annu Rev Physiol. *1990;52:197.)*

interact with more than one effector. In this way the G protein can be a branch point for the regulation of multiple effectors in response to a single signal. These proteins have already been implicated in human disease; cholera toxin covalently modifies G_s so that it becomes persistently active in stimulating adenylyl cyclase in intestinal epithelial cells, thus likely causing the severe diarrhea of cholera.

Several second-messenger systems have been characterized. G_s can directly enhance conductance through calcium channels, with the increased intracellular calcium acting as a second messenger. The cyclic nucleotides, cAMP and cyclic guanosine monophosphate (cGMP), act as second messengers. Their intracellular action is terminated when they are cleaved by phosphodiesterase enzymes, which, in turn, are also regulated by stimuli and second messengers. The breakdown products of membrane phosphoinositide constitute another, more recently recognized, set of second messengers.[12] In response to agonists such as vasopressin, G protein is activated, leading to activation

of the membrane-associated enzyme phospholipase C. This enzyme cleaves phosphatidylinositol-4,5-biphosphate on the inner leaflet of the plasma membrane, to produce inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). Both are second messengers. IP_3 diffuses through the cytoplasm and mobilizes calcium from intracellular stores. DAG remains within the plasma membrane and activates protein kinase C, which modulates cellular activity by phosphorylating intracellular proteins. In many cell types, activation of the same receptors that control phosphoinositide breakdown also results in the liberation of arachidonate or eicosanoids (prostaglandins, leukotrienes, and thromboxanes). The resultant change in cell behavior can be opening of an ion channel, contraction or relaxation of smooth muscle, secretory activity, or initiation of cell division (see Chapter 8).

Endothelium

Although the vascular endothelium was once thought of as an inert lining for blood vessels, it is more accurately characterized as a very active, distributed organ with many biologic functions. It has synthetic (Table 7.1) and metabolic (Table 7.2) capabilities and contains receptors for a variety of vasoactive substances (Box 7.1). Functions of the endothelium that may play an important role in the pathophysiology of ischemic heart disease are discussed here.

Endothelium-Derived Relaxing Factors

The first vasoactive endothelial substance to be discovered was prostacyclin (PGI_2), a product of the cyclooxygenase pathway of arachidonic acid metabolism (Fig. 7.4 and Box 7.2).[13] The production of PGI_2 is activated by shear stress, pulsatility of flow, hypoxia, and a variety of vasoactive mediators. On production it leaves the endothelial cell and acts in the local environment to cause relaxation of the underlying smooth muscle or to inhibit platelet aggregation. Both actions are mediated by the stimulation of adenylyl cyclase in the target cell to produce cAMP.

In 1980, Furchgott and Zawadzki[14] observed that the presence of an intact endothelium was necessary for acetylcholine-induced vasodilation. Investigators have since shown that many physiologic stimuli cause vasodilation by stimulating the release of a labile, diffusible, nonprostanoid molecule termed *endothelium-derived relaxing factor* (EDRF) (see Fig. 7.4), now known to be nitric oxide (NO). NO is the basis of a widespread paracrine signal transduction mechanism

BOX 7.1 STIMULATORS OF ENDOTHELIUM-MEDIATED VASODILATION

Transmitters
Acetylcholine
Norepinephrine

Peptides
Angiotensin
Bradykinin
Calcitonin gene–related peptide
Oxytocin
Substance P
Vasoactive intestinal peptide
Vasopressin

BOX 7.2 ENDOTHELIUM-DERIVED RELAXING AND CONTRACTING FACTORS

Healthy endothelial cells have an important role in modulating coronary tone by producing:
- vascular muscle relaxing factors
  - prostacyclin
  - nitric oxide
  - hyperpolarizing factor
- vascular muscle contracting factors
  - prostaglandin H_2
  - thromboxane A_2
  - endothelin

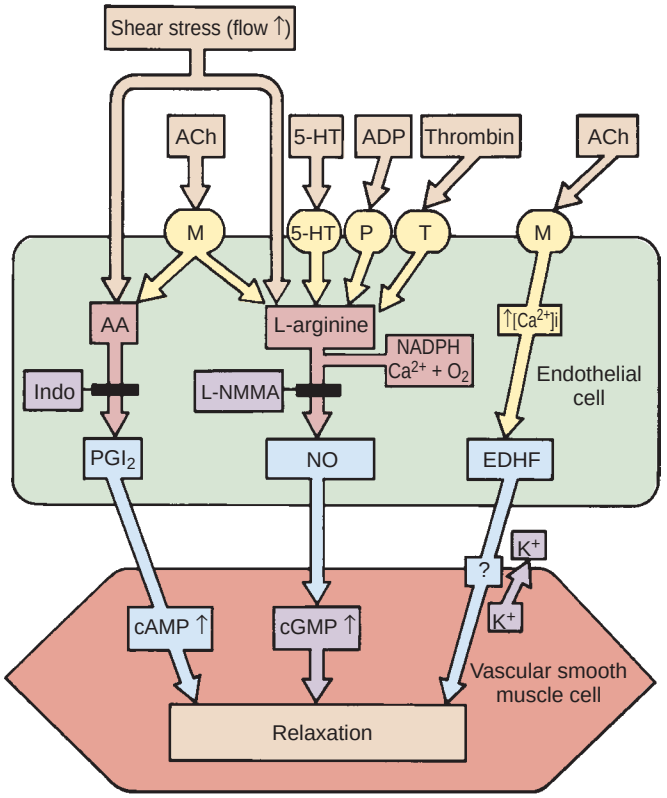

Fig. 7.4 The production of endothelium-derived vasodilator substances. Prostacyclin *(PGI_2)* is produced by the cyclooxygenase pathway of arachidonic acid *(AA)* metabolism, which can be blocked by indomethacin *(Indo)* and aspirin. PGI_2 stimulates smooth muscle adenylyl cyclase and increases cyclic adenosine monophosphate *(cAMP)* production, actions that cause relaxation. Endothelium-derived relaxing factor *(EDRF)*, now known to be nitric oxide *(NO)*, is produced by the action of NO synthase on L-arginine in the presence of reduced nicotinamide adenine dinucleotide phosphate *(NADPH)*, oxygen *(O_2)*, and calcium *(Ca^{2+})* and calmodulin. This process can be blocked by arginine analogues such as N^G-monomethyl-L-arginine *(LNMMA)*. NO combines with guanylate cyclase in the smooth muscle cell to stimulate production of cyclic guanosine monophosphate *(cGMP)*, which results in relaxation. Less well characterized is an endothelium-derived hyperpolarizing factor *(EDHF)*, which hyperpolarizes the smooth muscle membrane and probably acts by activation of potassium *(K^+)* channels. *ACh*, Acetylcholine; *ADP*, adenosine diphosphate; *$[Ca^{2+}]_i$*, intracellular calcium; *5-HT*, serotonin; *M*, muscarinic receptor; *P*, purinergic receptor; *T*, thrombin receptor. *(From Rubanyi GM. Endothelium, platelets, and coronary vasospasm.* Coron Artery Dis. *1990;1:645.)*

whereby one cell type can modulate the behavior of adjacent cells of a different type.[15,16] NO is a very small lipophilic molecule that can readily diffuse across biologic membranes and into the cytosol of nearby cells. The half-life of the molecule is less than 5 seconds so that only the local environment can be affected. NO is synthesized from the amino acid L-arginine by NO synthase (NOS). In vascular endothelium, the enzyme (eNOS or NOS_3) is always present (constitutive) and resides in the cytoplasm. Its function depends on the presence of calcium (Ca^{2+}) and calmodulin as well as tetrahydrobiopterin. The enzyme is activated in response to receptor occupancy or physical stimulation (see Box 7.1). When NO diffuses into the cytosol of the target cell, it binds with the heme group of soluble guanylate cyclase; the result is a 50- to 200-fold increase in production of cGMP, its secondary messenger. If the target cells are vascular smooth muscle cells, vasodilation occurs; if the target cells are platelets, adhesion and aggregation are inhibited. In vascular smooth muscle, cGMP leads to activation of protein kinase G, which phosphorylates various intracellular target proteins, including the myosin light-chain regulatory subunit and proteins that control intracellular calcium.[17]

NO is probably the final common effector molecule of nitrovasodilators (including sodium nitroprusside and organic nitrates such as nitroglycerin). The cardiovascular system is in a constant state of active vasodilation that depends on the generation of NO. The molecule is more important in controlling vascular tone in veins and arteries compared with arterioles. When the microcirculation dilates in response to metabolic myocardial demand (eg, exercise), increased flow through epicardial coronary arteries augments shear stress at the endothelium. This change leads to release of NO, which causes vascular smooth muscle relaxation and dilation of the conductance vessels, thereby facilitating the increase in flow. The importance of the loss of this mechanism in atherosclerosis is underlined by the finding that in this situation more than 50% of the resistance to flow in the coronary circulation resides in vessels larger than 100 μm in diameter (see Fig. 7.1). Abnormalities in the ability of the endothelium to produce NO

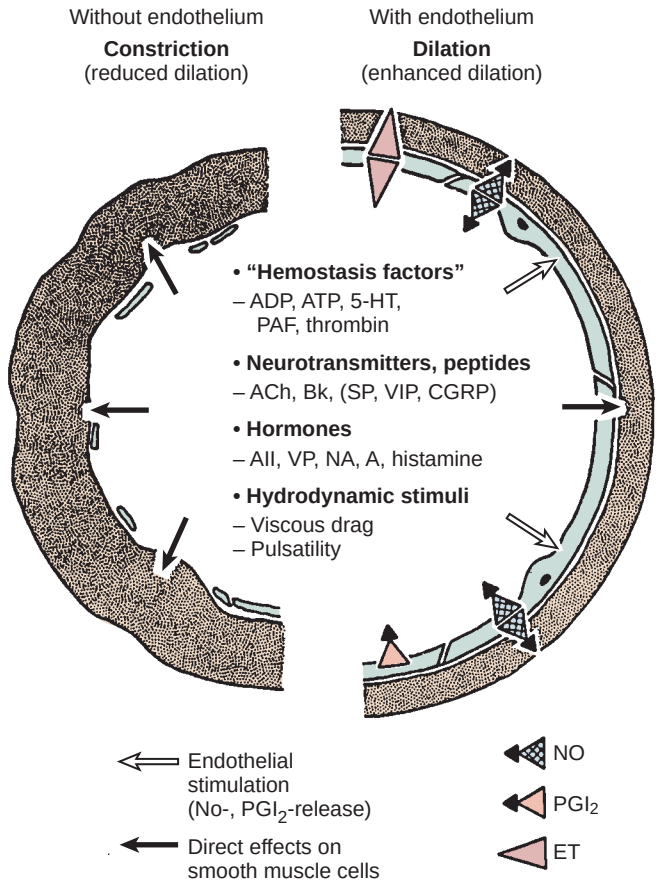

Fig. 7.5 The role of endothelium in the control of coronary tone. Intact endothelium has an important modulatory role in the effect of numerous factors on vascular smooth muscle. In the absence of a functional endothelium (mechanical trauma, atherosclerosis), many factors act directly on smooth muscle to cause constriction *(left side).* Under normal conditions *(right side),* the release of nitric oxide (*NO;* endothelium-derived relaxing factor *[EDRF]*) and prostacyclin *(PGI_2)* stimulated by these same factors can attenuate constriction or cause dilation. PGI_2 release is predominantly into the lumen, whereas EDRF release is similar on both the luminal and abluminal sides. Substances in parentheses elicit only vasodilation. *A,* Adenosine; *ACh,* acetylcholine; *ADP,* adenosine monophosphate; *AII,* angiotensin II; *ATP,* adenosine triphosphate; *Bk,* bradykinin; *CGRP,* calcitonin gene–related peptide; *ET,* endothelin; *5-HT,* serotonin; *NA,* norepinephrine; *PAF,* platelet-activating factor; *SP,* substance P; *VIP,* vasoactive intestinal polypeptide; *VP,* vasopressin. *(From Bassenge E, Heusch G: Endothelial and neurohumoral control of coronary blood flow in health and disease.* Rev Physiol Biochem Pharmacol. *1990;116:77.)*

Do we need endothelin antagonists?* Cardiovasc Res. *1997;29:2089. Reproduced with permission of Elsevier Science-NL, Sara Burgerhartstraat 25, 1055 KV Amsterdam, the Netherlands.)*

likely plays a role in diseases such as diabetes, atherosclerosis, and hypertension.[18,19] The venous circulation of humans seems to have a lower basal release of NO and an increased sensitivity to nitrovasodilators compared with the arterial side of the circulation.[20]

Many agents, such as acetylcholine and norepinephrine, can cause contraction when they are applied directly to the vascular smooth muscle membrane; conversely, relaxation occurs when they are applied to the intact endothelium (Fig. 7.5). The net effect of neural or humoral stimuli depends on a combination of direct effects mediated by binding to vascular smooth muscle receptors and indirect effects related to the ligand binding to endothelial receptors causing NO release from the endothelium. In the presence of healthy endothelium, vasodilation usually predominates. When the endothelium is absent (eg, injured vessel) or diseased (eg, atherosclerosis), vasoconstriction may be the net effect. NO has important roles in neurohumoral regulation of vascular tone, in prevention of intravascular platelet aggregation, and in the structural adaptation of blood vessels to the demands of blood flow and pressure.

Endothelium-Derived Contracting Factors

Contracting factors produced by the endothelium include prostaglandin H_2, thromboxane A_2 (generated by cyclooxygenase), and the peptide endothelin. Endothelin is a potent vasoconstrictor peptide (100-fold more potent than norepinephrine) with remarkable similarities to the toxin of the burrowing asp.[21] Both have potent coronary constrictor activity to which the strong cardiac toxicity and lethality of the toxin are attributed.[22] Three closely related 21–amino acid peptides have been identified: endothelin-1 (ET-1), ET-2, and ET-3. The primary product of vascular endothelium is ET-1, which is synthesized from prepro-ET-1 within vascular endothelial cells by the action of endothelin-converting enzymes. ET-1 is not stored but is rather rapidly synthesized in response to stimuli such as ischemia, hypoxia, and shear stress and is released predominantly abluminally (toward the underlying smooth muscle).[23] In vascular smooth muscle cells, ET-1 binds to specific membrane receptors (ET_A) and, through phospholipase C, induces an increase in intracellular calcium resulting in long-lasting contractions.[24] It is also linked by a G_i protein to voltage-operated calcium channels. This peptide has greater vasoconstricting potency than any other cardiovascular hormone, and in pharmacologic doses it can abolish coronary flow, thereby leading to ventricular fibrillation and death.[25] Another receptor subtype, ET_B, is expressed by both smooth muscle and endothelium and binds ET-1 and ET-3 equally well (Fig. 7.6). When isolated vessels are perfused with ET-1, initial NO-mediated vasodilation results from binding with ET_B receptors on the endothelial cells, followed by contraction secondary to binding of ET-1 to ET_A receptors on the vascular smooth muscle membrane. Studies with bosentan, a combined oral ET_A and ET_B receptor antagonist, demonstrated that endothelin exerts a basal coronary vasoconstrictor tone in humans.[26] Evidence indicates that endothelin may play a role in the pathophysiology of pulmonary and arterial hypertension, atherosclerosis, myocardial ischemic syndromes, and heart failure.[23] Clinical trials of bosentan in patients with congestive heart failure[27] and hypertension have shown promise, but hepatic side effects have

BOX 7.3 ENDOTHELIAL INHIBITION OF PLATELETS

Healthy endothelial cells have a role in maintaining the fluidity of blood by producing:
- anticoagulant factors: protein c and thrombomodulin
- fibrinolytic factor: tissue-type plasminogen activator
- platelet inhibitory substances: prostacyclin and nitric oxide

BOX 7.4 DETERMINANTS OF CORONARY BLOOD FLOW

The primary determinants of coronary blood flow are:
- perfusion pressure
- myocardial extravascular compression
- myocardial metabolism
- neurohumoral control

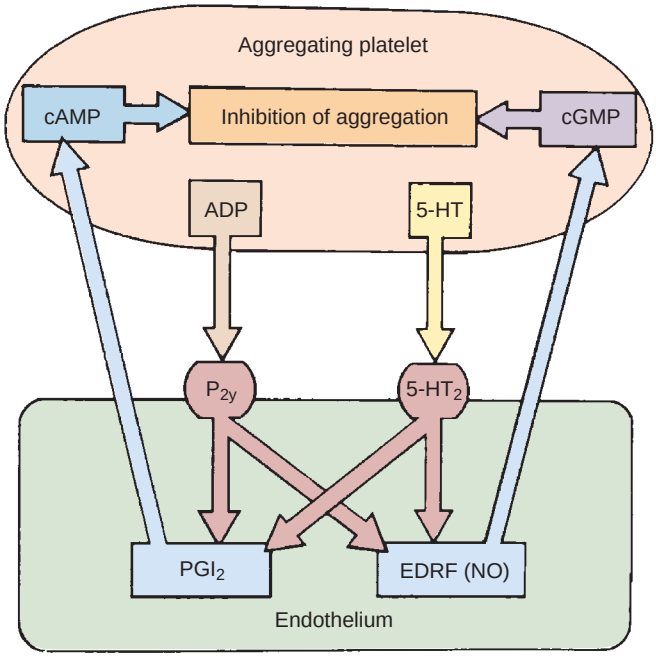

Fig. 7.7 Inhibition of platelet adhesion and aggregation by intact endothelium. Aggregating platelets release adenosine diphosphate *(ADP)* and serotonin *(5-HT)*, which stimulate the synthesis and release of prostacyclin (PGI_2) and endothelium-derived relaxing factor (*EDRF;* nitric oxide *[NO]*), which diffuse back to the platelets and inhibit further adhesion and aggregation and can cause disaggregation. PGI_2 and EDRF act synergistically by increasing platelet cyclic adenosine monophosphate *(cAMP)* and cyclic guanosine monophosphate *(cGMP)*, respectively. By inhibiting platelets and also increasing blood flow by causing vasodilation, PGI_2 and EDRF can flush away microthrombi and prevent thrombosis of intact vessels. P_{2y}, purinergic receptor. *(From Rubanyi GM. Endothelium, platelets, and coronary vasospasm.* Coron Artery Dis. *1990;1:645.)*

limited the dose to less than 500 mg daily; the primary indication for bosentan therapy is severe pulmonary hypertension.[28]

Endothelial Inhibition of Platelets

A primary function of endothelium is to maintain the fluidity of blood. This is achieved by the synthesis and release of anticoagulant (eg, thrombomodulin, protein C), fibrinolytic (eg, tissue-type plasminogen activator), and platelet inhibitory (eg, PGI_2, NO) substances (Box 7.3).[29] Mediators released from aggregating platelets stimulate the release from intact endothelium of NO and PGI_2, which act together to increase blood flow and decrease platelet adhesion and aggregation (Fig. 7.7).

With vital roles in modulating the tone of vascular smooth muscle, inhibiting platelets, and processing circulating chemicals, it seems clear that endothelial cell dysfunction would cause or contribute to ischemic syndromes. Evidence indicates endothelial dysfunction in atherosclerosis, hyperlipidemia, diabetes, and hypertension.[30] Procedures such as coronary artery surgical procedures and angioplasty disrupt the endothelium and may in part contribute to vascular dysfunction and accelerate atherosclerotic disease. The role of endothelium in the pathophysiology of myocardial ischemia is discussed later (see "Dynamic Stenosis").

Determinants of Coronary Blood Flow

Under normal conditions, coronary blood flow has four major determinants: (1) perfusion pressure, (2) myocardial extravascular compression, (3) myocardial metabolism, and (4) neurohumoral control. Changes in myocardial perfusion caused by different interventions can be explained by analyzing the effects of those interventions on these four factors.

Perfusion Pressure and Myocardial Compression

Coronary blood flow is proportional to the pressure gradient across the coronary circulation (Box 7.4). This gradient is calculated by subtracting downstream coronary pressure from the pressure in the root of the aorta. The determination of downstream pressure is complicated because the intramural coronary vessels are compressed with each heartbeat.

During systole, the heart throttles its own blood supply. The force of systolic myocardial compression is greatest in the subendocardial layers, where it approximates intraventricular pressure. Resistance resulting from extravascular compression increases with blood pressure, heart rate, contractility, and preload. Because it is difficult to measure intramyocardial pressure, the relative importance of these factors is controversial.[31,32] Flow is impeded both by direct compression and by shear caused by twisting of vessels as the heart contracts. Myocardial extravascular compression is less in the right ventricle, where pressures are lower and coronary perfusion persists during systole (Fig. 7.8). In pathologic conditions associated with pulmonary hypertension, right coronary blood flow assumes a phasic pattern similar to left coronary flow. Under normal conditions, extravascular compression contributes only a small component (10% to 25%) to total coronary vascular resistance. When the coronary vessels are dilated by pharmacologic agents such as dipyridamole or during ischemia, the effects of extravascular compression on myocardial perfusion become more important (see "Transmural Blood Flow," later).

With each contraction the intramural vessels are squeezed, and blood is expelled forward into the coronary sinus and in retrograde fashion into the epicardial arteries. The large coronary arteries on the epicardial surface act as capacitors, charging with blood during systole and expelling blood into the coronary circulation during diastole.[33] Coronary capacitance likely explains the findings of Bellamy,[34] who reported that flow in the proximal left anterior descending coronary artery of dogs ceased when arterial pressure decreased to less than 45 mm Hg. It was suggested that flow throughout the coronary circulation stopped at pressures far in excess of the pressure at the coronary sinus. This pressure at which flow stopped was termed *critical closing pressure* or *zero-flow pressure* (P_{zf}). This suggestion had important implications in the calculation of coronary resistance because the

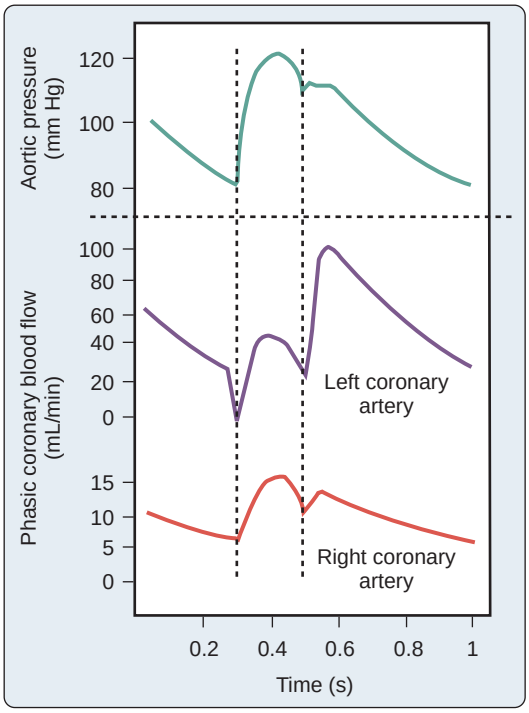

Fig. 7.8 Blood flow in the left and right coronary arteries. The right ventricle is perfused throughout the cardiac cycle. Flow to the left ventricle is largely confined to diastole. *(From Berne RM, Levy MN. Special circulations. In: Berne RM, Levy MN, eds.* Physiology. *St. Louis: Mosby; 1988:540–560.)*

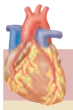
effective downstream pressure would be P_{zf} and not the much lower coronary venous pressure. This is analogous to a stream with a waterfall, in which flow rate over the waterfall depends on the drop from the source to the waterfall edge and is unaffected by the distance to the bottom of the falls. Investigators later suggested that flow through the intramural coronary vessels continues after coronary inflow near the ostia (measured by Bellamy[34]) has ceased.[35,36] Evidence indicates that antegrade movement of red blood cells in 20-µm arterioles continues until coronary pressure is a few millimeters of mercury higher than coronary sinus pressure.[37] Thus the concept of a critical closing pressure greatly in excess of coronary sinus pressure is probably not valid in the coronary circulation.

Although the true downstream pressure of the coronary circulation is likely close to the coronary sinus pressure, other choices may be more appropriate in clinical circumstances. In patients with CAD, the subendocardial layers of the left ventricle are at greatest risk of ischemia and necrosis (see "Transmural Blood Flow," later). Because these layers are perfused mostly when the aortic valve is closed, the most appropriate measure of the driving pressure for flow here is the average pressure in the aortic root during diastole. This value can be approximated by aortic diastolic or mean pressure. Pressures monitored in peripheral arteries by routine methods in clinical settings can differ from central aortic readings. The reasons for this difference are distortion of the pressure waveform as it is propagated through the arterial tree and inaccuracies associated with the hydraulic and electronic components of the monitoring system. Under these conditions, the mean arterial pressure may be the most reliable measure of coronary driving pressure. The true downstream pressure of the left ventricular subendocardium is the left ventricular end-diastolic pressure, which can be estimated by pulmonary artery occlusion pressure. When the right ventricle is at risk of ischemia (eg, severe pulmonary hypertension), right ventricular diastolic pressure or central venous pressure may be a more appropriate choice for measuring downstream pressure.



BOX 7.5 MYOCARDIAL METABOLISM

Several molecules have been proposed as the link between myocardial metabolism and myocardial blood flow, including:

- oxygen
- reactive oxygen species
- carbon dioxide
- adenosine

Current evidence suggests that a combination of local factors, each with differing importance during rest, exercise, and ischemia, acts together to match myocardial oxygen delivery to demand.

Myocardial Metabolism

Myocardial blood flow, like flow in the brain and skeletal muscle, is primarily under metabolic control. Even when the heart is cut off from external control mechanisms (neural and humoral factors), its ability to match blood flow to its metabolic requirements is almost unaffected.[30] Because coronary venous oxygen tension is normally 15 to 20 mm Hg, only a small amount of oxygen is available through increased extraction. A major increase in myocardial oxygen consumption ($M\dot{V}O_2$), beyond the normal resting value of 80 to 100 mL O_2/100 g of myocardium, can occur only if oxygen delivery is increased by augmentation of coronary blood flow. Normally, flow and metabolism are closely matched, so that over a wide range of oxygen consumption coronary sinus oxygen saturation changes little.[38] Flow and metabolism could be coupled either through feedback or feedforward control or a combination of both. Feedback control requires myocardial oxygen tension to fall and provide a signal that can then increase flow. That would require vascular tone to be linked either to a substrate that is depleted, such as oxygen or adenosine triphosphate (ATP), or to the accumulation of a metabolite such as carbon dioxide or hydrogen ion. The lack of a decrease in myocardial oxygenation with large increases in $M\dot{V}O_2$ under physiologic conditions suggests the presence of feedforward as well as feedback control. Feedforward control would couple blood flow to oxidative metabolism and could therefore match oxygen delivery and consumption without accumulating a signal. Reactive oxygen species have been proposed as mediators of feedforward control.[39]

Despite intensive research over the past several decades, the mediator or mediators linking myocardial metabolism so effectively to myocardial blood flow are still unknown (Box 7.5). Feigl[38] proposed six criteria for a chemical transmitter between the cardiac myocyte and the coronary vascular smooth muscle cell:

1. The transmitter is released under appropriate conditions and can be recovered from the tissue under those conditions.
2. Transmitter substance infused into the target tissue should faithfully mimic physiologic activation.
3. The biochemical apparatus for production of the proposed transmitter is present in the tissue in an appropriate location.
4. A mechanism for inactivation or uptake, or both, of the transmitter is present at an appropriate location in the tissue.
5. The action of various inhibitors and blocking agents on synthesis, release, target-organ receptor function, or transmitter inactivation should have effects consistent with the hypothesis. Blocking agents should give the same effect whether the transmitter is released physiologically or is artificially applied.
6. Quantitative studies should indicate that the amount and time course of transmitter release under physiologic conditions are appropriate to give the indicated effect.

Many potential mediators of metabolic regulation have been proposed.[40] Although NO has a role in many coronary vasoregulatory pathways, it does not fulfill the role of metabolic regulator because blockade of NOS does not alter the increase in myocardial blood flow associated with an increase in myocardial oxygen demand.[41] The arguments for oxygen, carbon dioxide, and adenosine are briefly examined.

Oxygen

For oxygen to regulate coronary flow through a direct vascular action, the coronary smooth muscle would have to be more sensitive to lack of oxygen than the working cardiocytes. Coronary microvessels in vitro do not relax until the partial pressure of oxygen (P_{O_2}) is less than 5 mm Hg, a level much lower than the average P_{O_2} of 20 mm Hg in cardiac muscle cytosol.[42,43] With $M\dot{V}O_2$ held constant, increases in arterial oxygen content cause coronary flow to decrease, whereas decreases in arterial oxygen content cause flow to increase. These changes could explain only 40% of the increase in flow observed with tachycardia.[44] It is undecided whether the constancy of myocardial oxygen tension is the cause or the consequence of the excellent match between myocardial metabolism and myocardial blood flow.[45]

Reactive Oxygen Species

Increased production of hydrogen peroxide (H_2O_2) has been proposed as a feedforward response to increased $M\dot{V}O_2$.[39] As myocardial oxidative metabolism increases, leak of electrons from mitochondria is heightened and results in the production of superoxide, which is rapidly converted by superoxide dismutase into H_2O_2, known to be a coronary vasodilator.[46,47] In vitro and in vivo data have supported the role of H_2O_2 in coupling flow and metabolism.

Carbon Dioxide

The end product of substrate oxidation is carbon dioxide, the formation of which is directly related to the level of cardiac work. Carbon dioxide is highly diffusible and can easily reach coronary smooth muscle cells. Unfortunately, it is very difficult to separate the effects on coronary tone of increasing carbon dioxide from concomitant increases in other metabolites. Broten and colleagues[44] pump perfused the left main coronary artery of dogs and used an oxygenator in the perfusion circuit to alter coronary arterial partial pressure of carbon dioxide (PCO2) and P_{O_2} at a constant level of myocardial metabolism. Increases in arterial and coronary sinus P_{CO_2} augmented coronary blood flow in the absence of changes in $M\dot{V}O_2$. A synergistic action of P_{CO_2} and P_{O_2} was observed; the increase in flow with elevation of P_{CO_2} was much greater at low P_{O_2} and vice versa. The effect of increasing carbon dioxide, however, could not completely account for flow changes associated with an increase in $M\dot{V}O_2$.

Adenosine

Adenosine is a powerful coronary vasodilator through its activation of receptors on vascular endothelium and smooth muscle. In 1963, both Berne[48] and Gerlach and associates[49] independently demonstrated the production of adenosine in ischemic heart muscle. These investigators hypothesized that the release of adenosine may serve as a feedback signal inducing coronary vasodilation and augmenting coronary blood flow in proportion to myocardial metabolic needs. Initially, it was suggested that adenosine formation was coupled to myocardial oxygen tension.[48] To explain metabolic regulation by adenosine under both normoxic and ischemic conditions, a substrate theory was proposed whereby adenosine production is linked to the cardiac energy state by the regulation of cytosolic AMP concentration.[50] According to this theory, increases in cardiac work lead to a fall in ATP potential that results in a quantitatively appropriate change in cytosolic AMP concentration, thereby leading to increased adenosine release. In this way the rate of adenosine production is determined by the myocardial oxygen supply-to-demand ratio. It is likely that adenosine causes coronary arteriolar dilation through stimulation of A_1-receptors directly coupled to ATP-sensitive K^+ (K^+_{ATP}) channels and A_2-receptor–mediated elevation of cAMP/protein kinase A that leads to vasodilation in part by opening of K^+_{ATP} channels.[51,52]

Evidence against the adenosine hypothesis is accumulating. Adenosine deaminase is an enzyme that, when introduced in sufficient quantity into the myocardium, can significantly reduce the interstitial concentration of adenosine. Aminophylline and theophylline interfere with the coronary dilating effects of adenosine by acting on the receptor on vascular smooth muscle. Experiments using these agents to inhibit adenosine effect showed that resting coronary blood flow, exercise-induced coronary dilation, autoregulation, and reactive hyperemia are largely unrelated to adenosine.[53–56] Measuring coronary microvessel diameters in beating hearts in situ, Kanatsuka and colleagues[6] found that when $M\dot{V}O_2$ was doubled by pacing, vessels between 40 and 380 μm dilated, whereas when a similar increase in flow was induced by the infusion of adenosine or dipyridamole at constant $M\dot{V}O_2$, only vessels smaller than 150 μm dilated. Although adenosine does not seem to have an important role in metabolic regulation in the normal heart, adenosine blockade has been shown to cause a lowering in blood flow to hypoperfused myocardium sufficient to decrease systolic segment shortening.[57]Adenosine may have other important roles in ischemia, in which evidence indicates a cardioprotective action.[58,59]

Current evidence suggests that a combination of local factors acts together, perhaps with differing importance in different situations, to match myocardial oxygen delivery to demand. The extreme difficulty of designing an experiment that can distinguish the effects of individual factors on coronary blood flow suggests that the exact mechanism of metabolic coronary regulation will not soon be elucidated.

Neural and Humoral Control

Neural Control

The role of neural control in the regulation of myocardial blood flow is difficult to study because sympathetic or parasympathetic activation can cause profound changes in heart rate, blood pressure, and contractility. The resulting changes in coronary tone, mediated by metabolic regulation, can mask the concomitant direct effects of autonomic nerves on coronary smooth muscle. Studies of isolated vessels have given results that contradict in vivo studies in part because of damage to the endothelium during preparation. Despite these difficulties, exploring the role of autonomic control has elicited much interest because it is implicated in the pathogenesis of myocardial ischemia.

Coronary Innervation

The heart is supplied with branches of the sympathetic and parasympathetic divisions of the autonomic nervous system. Thicker vagal fibers end in the adventitia of coronary vessels, whereas fine nonmedullated sympathetic fibers end on vascular smooth muscle cells.[60] Large and small coronary arteries and veins are richly innervated. The sympathetic nerves to the heart and coronary vessels arise from the superior, middle, and inferior cervical sympathetic ganglia and the first four thoracic ganglia. The stellate ganglion (formed when the inferior cervical and first thoracic ganglia merge) is a major source of cardiac sympathetic innervation. The vagus nerve supplies the heart with efferent cholinergic nerves.

Parasympathetic Control

Vagal stimulation causes bradycardia, decreased contractility, and lower blood pressure. The resultant fall in $M\dot{V}O_2$ causes metabolically mediated coronary vasoconstriction. When myocardial metabolism is held constant, however, cholinergic coronary dilation is consistently observed in response to exogenous acetylcholine, electrical vagal stimulation, and reflex activation through baroreceptors, chemoreceptors, and ventricular receptors.[30,38,61] These effects can be abolished by atropine.

In patients with angiographically normal coronary arteries the response to intracoronary acetylcholine injection is predominantly dilation, whereas in atherosclerotic segments of epicardial arteries constriction is observed.[62–64] Acetylcholine injected intraluminally binds to muscarinic receptors on the endothelium and stimulates the release of NO, which causes smooth muscle dilation. Acetylcholine is not normally found circulating in the blood but is released from

BOX 7.6 α-ADRENERGIC CORONARY CONSTRICTION

Sympathetic activation causes increased heart rate, contractility, and blood pressure that lead to a marked metabolically mediated increase in coronary blood flow. Surprisingly, the direct effect of sympathetic stimulation on the coronary vessels is vasoconstriction, sufficient to restrict the increase in blood flow and increase oxygen extraction.

vagal fibers and reaches the coronary smooth muscle from the adventitial side. Surprisingly, activation of muscarinic receptors on vascular smooth muscle cells causes constriction. Parasympathetic stimulation normally causes coronary vasodilation. This response depends on the ability of the coronary endothelium to elaborate NO and perhaps also endothelium-derived hyperpolarizing factor (see earlier).[65,66] Parasympathetic control has not been shown to be important in the initiation of myocardial ischemia.

β-Adrenergic Coronary Dilation

β-Receptor activation causes dilation of both large and small coronary vessels even in the absence of changes in blood flow.[30,38] Studies in animals indicate that both β_1- and β_2-receptors are present throughout the coronary circulation but that α_1-receptors predominate in the conductance vessels, whereas β_2-receptors predominate in the resistance vessels. Mature canine coronary collaterals respond similarly to the conductance vessels.[67,68] β-Adrenergic coronary artery dilation may improve the speed and accuracy of coronary blood flow regulation during exercise.[69]

α-Adrenergic Coronary Constriction

Activation of the sympathetic nerves to the heart results in increases in heart rate, contractility, and blood pressure that lead to a marked, metabolically mediated increase in coronary blood flow (Box 7.6). This finding suggested to early investigators that the effect of sympathetic coronary innervation is vasodilation. More recent investigation revealed that the direct effect of sympathetic stimulation is coronary vasoconstriction, which is in competition with the metabolically mediated dilation of exercise or excitement. Whether adrenergic coronary constriction is powerful enough to diminish blood flow in ischemic myocardium further or whether it can have some beneficial effect in the distribution of myocardial blood flow is controversial.

Classification

α-Adrenergic receptors can be classified anatomically as presynaptic or postsynaptic and according to their pharmacologic properties as α_1 and α_2 (Table 7.3). The receptors can be further divided into subtypes according to their signal transduction mechanism (G-protein subtype) and second messenger (eg, adenylyl cyclase, phospholipase C).[70]

Presynaptic α-Receptors

α-Receptors on cardiac sympathetic nerve terminals mediate feedback inhibition of neuronal norepinephrine release. Both α_1- and α_2-receptors seem to be involved because exercise-induced increases in heart rate and contractility can be potentiated by either idazoxan (α_2-blockade) or prazocin (α_1-blockade).[71]

Cardiac Muscle Cells

Activation of myocardial α_1-receptors results in a positive inotropic effect that, in contrast to β-receptor activation, is associated with prolongation of contraction. Although normally of minor functional importance, this effect may serve as an inotropic reserve mechanism when β-receptor–mediated inotropy is impaired (eg, hypothyroidism, cardiac failure, long-term propranolol treatment).[72] The importance of this mechanism in humans is uncertain. An increase in inotropy secondary to stimulation of myocardial α-receptors would result in increased $M\dot{V}O_2$ and metabolically mediated coronary dilation.

TABLE 7.3 Classification of α-Adrenergic Receptor Subtypes in the Heart

Selective Agonists	*Selective Antagonists*	*Effects of Activation*
α_1-Receptor		
Phenylephrine	Prazosin	*Presynaptic:* feedback inhibition of norepinephrine release
Methoxamine		*Postsynaptic:* coronary vasoconstriction, increase in myocardial inotropism, arrhythmias
α_2-Receptor		
Clonidine	Yohimbine	*Presynaptic:* feedback inhibition of norepinephrine release
Azepexole	Rauwolscine	*Postsynaptic:* coronary vasoconstriction, arrhythmias (?)

[a]Norepinephrine is a nonselective agonist. Phentolamine and phenoxybenzamine are nonselective antagonists. Phenylephrine also causes β-receptor activation.
Modified from Heusch G. Alpha-adrenergic mechanisms in myocardial ischemia. *Circulation.* 1990;81:1, by permission of the American Heart Association.

Coronary Endothelium

Binding of norepinephrine to α_2-receptors on vascular endothelium stimulates the release of NO, which acts to relax vascular smooth muscle. The endothelium can also limit the effect of norepinephrine by metabolizing it. In these ways the endothelium modulates the direct constrictive effects of α-adrenergic activation. Abnormal endothelial function in atherosclerosis may predispose to excessive α-adrenergic constriction and is implicated in the pathogenesis of myocardial ischemia (see "Dynamic Stenosis," later).

Coronary Resistance

The magnitude of α-adrenergic vasoconstriction that occurs in the coronary bed is small compared with that in the skin and skeletal muscle. In the presence of β-blockade, intense sympathetic stimulation results in only a 20% to 30% increase in coronary resistance.[73] Mohrman and Feigl[74] examined the effect of sympathetic activation on coronary flow in the absence of β-blockade. The net effect of α-receptor vasoconstriction was to restrict the metabolically related flow increase by 30%, thereby increasing oxygen extraction and decreasing coronary sinus oxygen content.

Epicardial coronary diameter changes little during sympathetic stimulation.[75] α_1-Adrenergic and α_2-adrenergic receptors are found throughout the coronary circulation; however, α_1-receptors seem to be more important in the large epicardial vessels, whereas α_2 predominates in small coronary vessels less than 100 μm in diameter.[76] Studies of mature coronary collateral vessels in dogs generally failed to provide evidence of α-receptor–mediated vasoconstriction.[77] After heart transplantation, patients demonstrated a lesser increase in myocardial blood flow after a cold pressor test in denervated regions of the heart.[78] The authors argue that this was not the result of increased myocardial metabolism secondary to myocardial β-receptor activation. They suggest that sympathetic innervation has an important role in coronary vessel dilation during stress.

Exercise

α-Adrenergic coronary constrictor tone during exercise is exerted predominantly by circulating catecholamines.[79] Numerous studies indicate that myocardial blood flow during exercise is limited by α vasoconstriction.[30] In a study of exercising dogs, Huang and Feigl[80] found that despite an increase in total coronary flow in an α-blocked region of myocardium, flow to the inner, subendocardial layer was diminished. These results suggest a beneficial effect of α-adrenergic

coronary constriction on the distribution of blood flow within the myocardium.

Myocardial Ischemia

Buffington and Feigl[81] demonstrated the persistence of α-adrenergic coronary vasoconstriction distal to a moderate coronary stenosis during norepinephrine infusion. Investigations in dogs demonstrated that as coronary reserve is depleted by increasing stenosis severity, the response to sympathetic stimulation shifts from metabolically induced coronary dilation to coronary constriction.[82,83] These observations suggest that sympathetic coronary vasoconstriction limits coronary blood flow even during myocardial ischemia, when autoregulatory reserve is exhausted (see "Coronary Reserve," later). No consensus has been reached on the importance of α_1- versus α_2-receptors in ischemic myocardium.[30] Using constant flow coronary perfusion in anesthetized dogs, Nathan and Feigl[84] compared the transmural distribution of myocardial blood flow in α-blocked and intact regions of myocardium during hypoperfusion. Surprisingly, α-blockade diverted blood flow from the subendocardium to the subepicardium. This finding suggests that α vasoconstriction had limited flow more in the subepicardium, thereby producing an anti-steal effect and improved perfusion of the more vulnerable inner layers of the left ventricle. Chilian and Ackell[85] found similar results in exercising dogs with artificial coronary stenosis. Conversely, work by Baumgart and Heusch[86] and by Seitelberger and colleagues[87] demonstrated improved subendocardial perfusion distal to a severe coronary stenosis with α_2-receptor blockade. This controversy is unresolved.[88,89] α-Receptor blockers have not been shown to have a role in the treatment of myocardial ischemia in patients with CAD.

Studies in Humans

Studies indicate that little α-adrenoceptor–mediated tone is present in resting humans.[90] Clinical studies have failed to provide convincing evidence that α-adrenergic coronary constriction plays an important role in Prinzmetal variant angina (angina with ST-segment elevation at rest).[91] During sympathetic activation, however, evidence indicates that α vasoconstriction can precipitate myocardial ischemia by further narrowing diseased coronary arteries. This effect has been shown during isometric exercise, during dynamic exercise, and with the cold pressor test (see "Dynamic Stenosis," later).[92–97]

Humoral Control

A complete understanding of the effects of circulating substances on the coronary vessels would require determining their effects on large versus small coronary vessels while separating direct effects on coronary vessels from changes in tone mediated by changes in myocardial metabolism. This issue is further complicated by the critical role of an intact vascular endothelium in modulating these responses (see "Endothelium," earlier). Some of the better-studied agents are discussed briefly.

The peptide hormones include vasopressin (also known as arginine vasopressin), atrial natriuretic peptide, vasoactive intestinal peptide, neuropeptide Y, and calcitonin gene–related peptide.[40] Of these hormones, vasopressin and atrial natriuretic peptide have been the most closely studied. Investigators have demonstrated in dogs that vasopressin, in concentrations 3 to 30 times those found in stressed patients, can cause vasoconstriction sufficient to produce myocardial ischemia.[98] In large coronary arteries, the dilator response (through NO) likely exceeded the constrictor response.[30] In physiologic concentrations, vasopressin acts primarily as an antidiuretic hormone with little effect on the coronary circulation. Atrial natriuretic peptide can cause endothelium-dependent coronary dilation but is not known to have significant vascular effects in physiologic concentrations.[99]

Angiotensin-converting enzyme (ACE) is present on vascular endothelium and converts angiotensin I to angiotensin II, which causes coronary vasoconstriction. Angiotensin II also facilitates the release of norepinephrine from presynaptic adrenergic nerve terminals. ACE inactivates bradykinin, which can attenuate vasoconstriction by NO stimulation. Thus angiotensin-converting enzyme inhibition can reduce coronary tone by suppressing angiotensin II formation and degrading bradykinin and perhaps also by decreasing norepinephrine release. Despite these theoretical considerations, ACE inhibition has not been shown to be of benefit in human myocardial ischemia other than through control of afterload.[100]

PGI_2 and thromboxane A_2 are synthesized from arachidonic acid in a reaction catalyzed by cyclooxygenase. PGI_2 is synthesized in the vascular endothelium and, in addition to inhibiting platelet aggregation, induces vasodilation (see "Endothelium-Derived Relaxing Factors," earlier). Thromboxane A_2 is mainly synthesized in platelets and causes platelet aggregation and vasoconstriction in the presence of damaged vascular endothelium. In response to thromboxane A_2 the intact endothelium releases NO, thereby causing both vasodilation and platelet disaggregation, mechanisms to maintain patency of normal vessels (see "Endothelial Inhibition of Platelets"). Unlike platelets, the vascular endothelium can synthesize proteins de novo, and thus cyclooxygenase acetylation through aspirin administration has a lesser effect in reducing vascular PGI_2 than platelet thromboxane A_2. Other than in platelet-vessel interactions and inflammation, prostaglandins are not known to have an important role in the regulation of coronary blood flow.[30] Serotonin (5-HT) is another platelet product that can cause endothelium-dependent dilation of coronary arterial vessels smaller than 100 μm but causes constriction of larger epicardial coronary arteries.[101]

Histamine receptors are present in the coronary vessels. Histamine-1 (H_1) receptors are located on vascular smooth muscle cells of large and small coronary arteries and mediate vasoconstriction. H_2 receptors are located on smooth muscle cells of arterioles and mediate vasodilation. H_1 receptors are also located on vascular endothelium and can mediate vasodilation by stimulation of NO release. In patients with vasospastic angina and endothelial dysfunction, administration of exogenous histamine can cause vasospasm.[51,102]

Coronary Pressure-Flow Relations

Autoregulation

Autoregulation is the tendency for organ blood flow to remain constant despite changes in arterial perfusion pressure.[103] Autoregulation can maintain flow to myocardium served by stenotic coronary arteries despite low perfusion pressure distal to the obstruction. This is a local mechanism of control and can be observed in isolated, denervated hearts. If $M\dot{V}O_2$ is fixed, coronary blood flow remains relatively constant between mean arterial pressures of 60 and 140 mm Hg. At a given cardiac workload, the level of flow (determined by metabolic regulation) is maintained constant over a broad range of pressure by autoregulation (Fig. 7.9).

To study autoregulation, coronary perfusion pressure must be varied while holding $M\dot{V}O_2$ constant. This is difficult in the heart because changing aortic pressure alters both the perfusion pressure for the coronary arteries and the afterload of the left ventricle. Thus changes in aortic pressure inevitably change $M\dot{V}O_2$. This problem is overcome by cannulating the coronary arteries and perfusing them with a pump. However, even when heart rate and aortic pressure are held constant, $M\dot{V}O_2$ alters with changing coronary pressure. This is because myocardial contractility and metabolism increase when coronary pressure is raised to a level greater than the normal autoperfused level. This phenomenon is known as the Gregg effect and may be explained by the "garden hose" hypothesis of Lochner whereby engorgement of the coronary vasculature elongates the myocardial sarcomere length during diastole and contractile strength is increased as a result of the Frank-Starling mechanism (for a detailed review see Feigl[38] and Gregg[104]).

In addition to the Gregg effect, two other issues complicate studies of autoregulation: collateral flow and myocardial oxygen extraction. If pressure is lowered in the left coronary artery and not in the right, a

pressure gradient for flow will exist from the right to the left coronary artery through collateral vessels. Flow measured proximally in the left coronary artery then underestimates flow reaching the myocardium. Normal coronary sinus oxygen tension (CSO_2) is less than 20 mm Hg. Dole and Nuno[105] observed that autoregulation was effective when CSO_2 was less than 25 mm Hg but was completely lost when CSO_2 exceeded 32 mm Hg. Autoregulation can be intensified by vasoconstriction (increased oxygen extraction) and attenuated by vasodilation (decreased oxygen extraction).[105,106] The degradation of autoregulation with α-receptor blockade suggests a benefit of adrenergic coronary vasoconstriction.[107]

Early reports indicated that autoregulation is less effective in the right ventricle than in the left. Investigators currently suggest that increases in right coronary artery pressures may produce large changes in $M\dot{V}O_2$, perhaps in response to an exaggerated Gregg effect. When changes in myocardial metabolism are taken into account, autoregulation in the right and left ventricles is similar.[108,109]

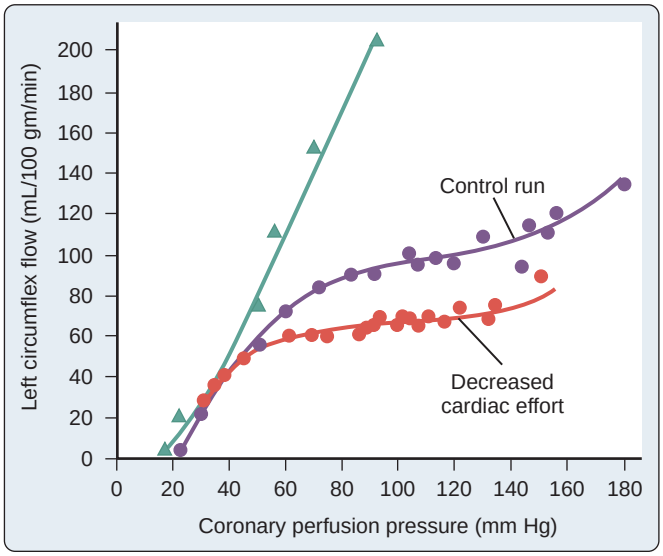

Fig. 7.9 Autoregulation at two levels of myocardial oxygen consumption. Pressure in the cannulated left circumflex artery was varied independently of aortic pressure. When pressures were suddenly raised or lowered from 40 mm Hg, flow instantaneously increased with pressure *(steep line, triangles)*. With time, flow decreased to the steady-state level determined by oxygen consumption *(circles)*. The vertical distance from the steady-state (autoregulating) line to the instantaneous pressure-flow line is the autoregulatory flow reserve (see text). *(From Mosher P, Ross J Jr, McFate PA, Shaw RF. Control of coronary blood flow by an autoregulatory mechanism.* Circ Res. *1964;14:250.)*

Quantitation of the degree of autoregulation must involve a comparison of the observed change in vascular resistance with the change in resistance that would have occurred in the absence of flow autoregulation. Some degree of autoregulation exists when the relative change in flow (ΔF/F) is less than the relative change in pressure (ΔP/P). From these definitions, Dole[106] derived an autoregulation index that can be used to quantify the effects of different agents on coronary autoregulation.[110]

Three theories have been proposed to explain coronary autoregulation: (1) the tissue pressure theory, (2) the myogenic theory, and (3) the metabolic theory.[111] The tissue pressure hypothesis proposes that changes in perfusion pressure result in directionally similar changes in capillary filtration and therefore tissue pressure. In this way extravascular resistance would oppose changes in flow with changes in perfusion pressure. Experimental evidence has shown, however, that no relationship exists between the degree of autoregulation and the magnitude of change in tissue pressure. Arterial smooth muscle contracts in response to augmented intraluminal pressure; this is known as the myogenic response. This response has been demonstrated in coronary arterioles in the presence and absence of functioning endothelium.[112]

The argument for myogenic regulation of coronary flow is that myocardial metabolic changes are not rapid enough to explain large decreases in resistance after coronary occlusions for one or two heartbeats. However, myocardial metabolic events have been shown to occur during the course of a single cardiac contraction.[113]

The metabolic theory of autoregulation proposes that coronary arteriolar tone is determined by the balance of myocardial oxygen supply and demand. An increase in flow greater than the requirements of metabolism would wash out metabolites or cause accumulation of substrates, and this would be the signal for an appropriate change in coronary tone. Although metabolic regulation and autoregulation are separate phenomena, they may have a common underlying mechanism. Metabolic regulation is discussed earlier (see "Myocardial Metabolism"). For an instructive, three-dimensional, graphic analysis of the interrelations among coronary artery pressure, myocardial metabolism, and coronary blood flow, see Feigl and colleagues.[114]

Coronary Reserve

Myocardial ischemia causes intense coronary vasodilation. After a 10- to 30-second coronary occlusion, restoration of perfusion pressure is accompanied by a marked increase in coronary flow. This large increase in flow, which can be five or six times resting flow in dogs, is termed *reactive hyperemia*. The repayment volume is greater than the debt volume (Fig. 7.10). However, no overpayment of the oxygen debt occurs because oxygen extraction falls during the hyperemia.[115] The presence of high coronary flows when coronary venous oxygen content is high suggests that mediators other than oxygen are responsible for this metabolically induced vasodilation.[38] The difference between resting coronary blood flow and peak flow during reactive

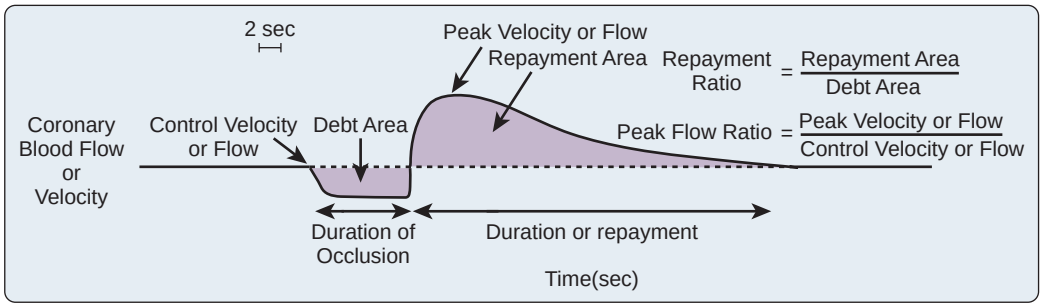

Fig. 7.10 Schematic diagram of the reactive hyperemic response to a 10-second coronary occlusion. *(Redrawn from Marcus M, Wright C, Doty D, et al: Measurements of coronary velocity and reactive hyperemia in the coronary circulation of humans.* Circ Res. *1981;49:877–891.)*

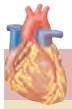

BOX 7.7 TRANSMURAL BLOOD FLOW

- When coronary perfusion pressure is inadequate, the inner one-third of the left ventricular wall is the first region to become ischemic or necrotic.
- During systole, intramyocardial pressure is highest in the inner layers of the ventricle, and this restricts perfusion to that region.
- In eccentric hypertrophy, this effect is exaggerated, and the subendocardium is at increased risk of ischemia.

hyperemia represents the autoregulatory coronary flow reserve: the further capacity of the arteriolar bed to dilate in response to ischemia. Fig. 7.9 shows that the flow reserve is the vertical distance from the autoregulating pressure-flow curve (circles) to the nonautoregulating curve (triangles). The reserve is greater at higher perfusing pressure and lower $M\dot{V}O_2$. Unlike cannula-perfused preparations in which these data are obtained, in the clinical setting increases in pressure elevate both perfusing pressure and $M\dot{V}O_2$. Reactive hyperemia responses have been used in animals and humans to estimate coronary reserve in conditions such as obstructive coronary disease, aortic stenosis, and left ventricular hypertrophy (see "Hemodynamics," later).[116–118] The myocardial fractional flow reserve (FFR) is calculated by dividing the pressure in a coronary vessel distal to a stenosis during maximal pharmacologic dilation by the aortic root pressure. This ratio can be easily measured in the angiography suite and has been recommended as a useful index of the functional severity of coronary stenoses of intermediate morphologic severity on angiography, as well as a measure of residual obstruction after interventions[119,120] (see "Intracoronary Evaluation of Atherosclerosis," later).

That the coronary resistance vessels are maximally dilated when coronary perfusion pressure is reduced sufficiently to cause myocardial ischemia is generally accepted. In fact, agents such as adenosine, carbochromen, and dipyridamole can cause further increases in coronary flow in the presence of intense ischemia, when autoregulatory reserve is believed to be exhausted. This pharmacologic vasodilator reserve is greater than the autoregulatory vasodilator reserve. If flow to ischemic myocardium can be increased by pharmacologic dilation of resistance vessels, the use of these agents should reverse ischemic dysfunction and metabolism. Arteriolar dilators have, in general, not been found to be beneficial during myocardial ischemia. Coronary blood flow in the different layers of the ventricle must be reviewed to understand the reason (Box 7.7).

Transmural Blood Flow

It is well known that when coronary perfusion pressure is inadequate, the inner one-third to one-fourth of the left ventricular wall is the first region to become ischemic or necrotic.[121] This increased vulnerability of the subendocardium may reflect an increased demand for perfusion or a decreased supply, compared with the outer layers. Transmural distribution of oxygen consumption, use of oxidizable substrates, activity of glycolytic and mitochondrial enzymes, tissue contents of endogenous substrates, high-energy phosphates, lactate, isoforms of contractile proteins, and fiber stress and fiber shortening have been studied extensively. In general, these studies indicate that if such differences exist between the layers of the left ventricle, they are unlikely to exceed 10% to 20%.[38,122] Preferential underperfusion of the subendocardium probably is the primary determinant of its increased vulnerability.

Regional blood flow in the myocardium is usually determined using radioactive microspheres. These plastic beads, labeled with a radioisotope, are injected into the bloodstream. The assumption is that they mix uniformly with blood and are distributed in proportion to blood flow, as if they were red blood cells.[123] Because they are rigid and larger than red blood cells (9- or 15-μm diameters are usually chosen), these beads are trapped in the microcirculation. At the end of an experiment, the heart can be divided into small blocks and the amount of radioactivity in each piece measured in a gamma counter. The blood flow to each block of tissue is proportional to the number of microspheres in each piece, which can be determined from its radioactivity. By using different radioisotopes as labels, several sets of microspheres can be injected during an experiment, thus giving "snapshots" of flow at the time of each injection. It is difficult to reduce the variability of the technique to less than 10%.[38,124] By using this technique, subendocardial blood flow is found to be approximately 10% greater than subepicardial blood flow under normal circumstances. This gives a normal subendocardial-to-subepicardial or inner-to-outer (I/O) blood flow ratio of 1:10. This ratio is maintained at normal perfusing pressures even at heart rates higher than 200 beats/minute.

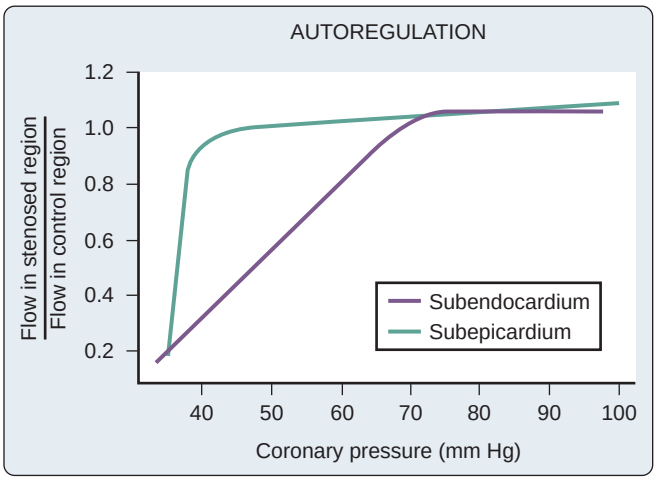

Fig. 7.11 Pressure-flow relationships of the subepicardial and subendocardial thirds of the left ventricle in anesthetized dogs. In the subendocardium, autoregulation is exhausted and flow becomes pressure dependent when pressure distal to a stenosis falls to less than 70 mm Hg. In the subepicardium, autoregulation persists until perfusion pressure falls to less than 40 mm Hg. Autoregulatory coronary reserve is less in the subendocardium. *(Redrawn from Guyton RA, McClenathan JH, Newman GE, Michaelis LL. Significance of subendocardial ST segment elevation caused by coronary stenosis in the dog.* Am J Cardiol. *1977;40:373.)*

If coronary artery pressure is gradually reduced, autoregulation is exhausted, and flow decreases in the inner layers of the left ventricle before it begins to decrease in the outer layers (Fig. 7.11). This finding indicates less flow reserve in the subendocardium than in the subepicardium. The limits of autoregulation depend on the level of cardiac work (see "Autoregulation," earlier) and on the experimental conditions. In conscious dogs, the mean coronary artery pressure at which evidence of subendocardial ischemia appeared was 38 mm Hg at a heart rate of 100 beats/minute, and it increased to 61 mm Hg at 200 beats/minute. Subepicardial flow during tachycardia did not fall even at pressures as low as 33 mm Hg.[125] Because subepicardial flow is rarely inadequate, a subendocardial-to-subepicardial blood flow ratio close to 1.0 indicates adequate subendocardial flow and an appropriate matching of myocardial oxygen supply to oxygen demand. For this reason, the I/O blood flow ratio is often used as a measure of the adequacy of myocardial blood flow.

Three mechanisms have been proposed to explain the decreased coronary reserve in the subendocardium: (1) differential systolic intramyocardial pressure, (2) differential diastolic intramyocardial pressure, and (3) interactions between systole and diastole. Because the force of systolic myocardial compression is greatest in the inner layers of the ventricle and is low at the subepicardium, investigators believed that the outer layers of the heart were perfused throughout the cardiac

cycle, whereas the subendocardium was perfused only during diastole. The subendocardium would have to obtain its entire flow during only a portion of the cycle and therefore would have to have a lower resistance. Studies suggesting very little systolic flow, even to the outer layers, argued against this explanation.[121] The second mechanism is based on the high coronary artery pressures observed when coronary flow has ceased during a long diastole, P_{zf} (see "Perfusion Pressure and Myocardial Compression," earlier).[34] The shape of the pressure-flow relation during a long diastole suggests that P_{zf} is higher in the subendocardium. This means that perfusion pressure for the subendocardium is lower in diastole compared with the outer layers of myocardium. Available evidence suggests that P_{zf} is not high in any layer and is unlikely to be more than 2 to 3 mm Hg higher in the subendocardium than in the subepicardium.[121] Hoffman[121] and Hoffman and Spaan[108] proposed an interaction between systole and diastole as the explanation for the increased vulnerability of the subendocardium to ischemia. During systole, intramyocardial pressure is high enough throughout most of the ventricular wall to squeeze blood out of the intramural vessels and into the extramural coronary veins and arteries. Because the compressive force is greatest in the subendocardium, vessels here are the narrowest at the end of systole. At the beginning of diastole, blood is directed first to vessels with the lowest resistance, then to the larger vessels in the subepicardium, and last to the most severely narrowed vessels in the subendocardium. In this way, should the duration of diastole or the diastolic perfusion pressure be reduced, the subendocardial muscle would receive the least flow. Spaan[31] presented an interesting analysis of the interaction between arterial pressure and force of contraction as an intramyocardial pump. Although this theory is compatible with existing evidence, support for it remains indirect until it becomes possible to measure phasic pressures and flows in separate layers of myocardium.

When the left ventricle hypertrophies in response to a pressure load (aortic stenosis, hypertension), myofibrillar growth outstrips the capillary network, with resulting decreased capillary density and increased diffusion distances. The net effect is to reduce coronary autoregulatory reserve.[126] The transmural gradient of reserve is also exaggerated, so that the subendocardium is at increased risk of ischemia in the hypertrophied heart compared with normal.[127]

In addition to the transmural gradient of coronary reserve from outer to inner layer of the left ventricle, marked variation of reserve occurs between small regions of myocardium within a layer.[128] This heterogeneity of flow reserve may explain why pharmacologic reserve exceeds autoregulatory reserve (see "Coronary Reserve," earlier). During hypoperfusion regional myocardial blood flow is decreased, but in all layers some small pieces of muscle have no flow reserve left, whereas adjacent pieces can have substantial reserve. Fewer pieces retain reserve in the subendocardium than in the subepicardium. The increase in flow in response to an infusion of adenosine results from increased flow in the small regions with reserve, with no change in the adjacent fully dilated regions.[129–131] These findings suggest that ischemia causes maximal coronary vasodilation and that increases in flow with adenosine or dipyridamole are caused by dilation of vessels in nonischemic regions. Contrasting evidence was provided by Duncker and Bache,[51] who used a balloon occluder to simulate coronary stenosis in exercising dogs. The occluder was adjusted to maintain distal coronary pressure constant at 43 mm Hg. During exercise, an intracoronary infusion of adenosine increased blood flow to all myocardial layers and improved regional systolic segment shortening. Although this is evidence of vasodilator reserve in ischemic myocardium, the constant distal pressure preparation does not faithfully mimic coronary stenosis because it makes transmural steal impossible (see "Coronary Steal," later). In general, pharmacologic dilation of resistance vessels has the potential to worsen ischemia by producing coronary steal. Dilation of larger penetrating vessels (50 to 500 µm in diameter) with nitrovasodilators could preferentially decrease resistance to blood flow to the subendocardium, and this may, in addition to favorable effects on the systemic circulation, explain the usefulness of nitrates in the treatment of angina.[51]

Atherosclerosis

The atherosclerotic lesion consists of an excessive accumulation of smooth muscle cells in the intima, with quantitative and qualitative changes in the noncellular connective tissue components of the artery wall and intracellular and extracellular deposition of lipoproteins and mineral components (eg, calcium) (Box 7.8). By definition, *atherosclerosis* is a combination of "atherosis" and "sclerosis." The term *sclerosis* refers to the hard collagenous material that accumulates in lesions and is usually more voluminous than the pultaceous "gruel" of the atheroma (Fig. 7.12).

Stary[132] noted that the earliest detectable change in the evolution of coronary atherosclerosis in young people was the accumulation of intracellular lipid in the subendothelial region that gave rise to lipid-filled macrophages or "foam cells." Grossly, a collection of foam cells may give the artery wall the appearance of a "fatty streak." In general, fatty streaks are covered by a layer of intact endothelium and are not characterized by excessive smooth muscle cell accumulation. At later stages of atherogenesis, extracellular lipoproteins accumulate in the musculoelastic layer of the intima and eventually form an avascular core of lipid-rich debris that is separated from the central arterial lumen by a fibrous cap of collagenous material. Foam cells are not usually seen deep within the atheromatous core but are frequently found at the periphery of the lipid core.

BOX 7.8 ATHEROSCLEROSIS

- The atherosclerotic process begins in childhood and adolescence.
- The progression of an atherosclerotic lesion resembles the process of wound healing.
- Inflammation, lipid infiltration, and smooth muscle proliferation have important roles in atherogenesis.
- Impairment of endothelial function is an early consequence of atherosclerosis.
- Statin therapy has been shown to improve endothelial function, impede development of atherosclerosis, and in some cases reverse established disease.

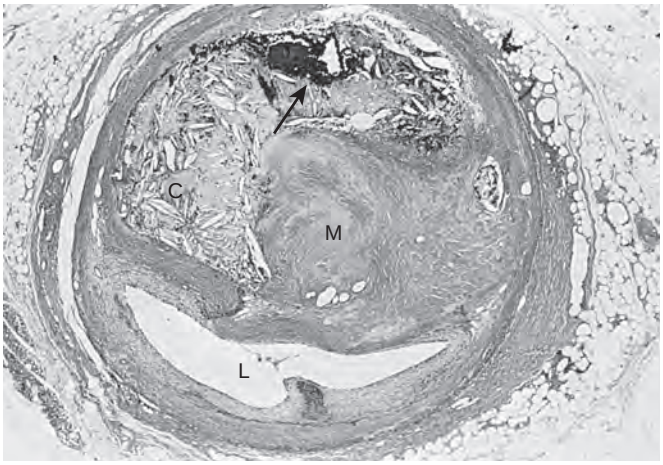

Fig. 7.12 Atherosclerotic human coronary artery of an 80-year-old man. He has severe narrowing of the central arterial lumen *(L)*. The intima consists of a complex collection of cells, extracellular matrix *(M)*, and a necrotic core with cholesterol *(C)* deposits. Rupture of plaque microvessels has resulted in intraplaque hemorrhage *(arrow)* at the base of the necrotic core (Movat's pentachrome–stained slide; original magnification ×40).

Atherogenesis

Certain human arteries are more prone to develop atherosclerosis than others. For example, the coronary, renal, and internal carotid arteries, as well as some areas of the aorta, are known to be common sites of lesion formation.[132] In the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study, the aorta and right coronary arteries of 1378 young people 15 to 34 years old who died as a result of trauma were studied.[133] Two-dimensional maps of lipid-laden fatty streaks and fibrous plaques were made for each vessel. Although atherosclerosis is usually clinically silent until middle age or later, these investigators found that the disease process begins in adolescence or childhood. Moreover, fatty streaks and fibrous plaques do not occur randomly in the circulation, but rather they follow a well-defined distribution pattern. For example, in the right coronary artery fatty streaks were found with the highest probability in the proximal 2 cm of this vessel, a location that closely parallels the distribution of raised fibrous lesions. In the abdominal aorta, however, where aortic lesions are commonly found, the high prevalence of fatty streaks did not always correlate with the prevalence of raised fibrous lesions. Therefore, at least in the aorta, the role of childhood fatty streaks in the development of adult fibrous lesions is uncertain.

The atherogenic stimuli that promote the progression of early lesions to clinically relevant stenoses are not known. The development of CAD is associated with various risk factors. Dyslipidemias, hypertension, diabetes mellitus, cigarette smoking, and a family history of premature CAD are known to correlate with premature vascular disease. The association between lipid disorders and atherogenesis is best understood and is discussed later. More recently, genetic factors that predispose to development of atherosclerosis have been identified, and early work suggests that changes in response to inflammation may in part explain the hereditary nature of the disease.[134,135] Unfortunately, with the exception of dyslipidemia and hypertension, targeted pharmacotherapy for the remaining risk factors is lacking.

Historically, two classic theories of atherogenesis were proposed. According to von Rokitansky's thrombogenic (or encrustation) theory,[136] fibrin is the initiating factor in lesion development. Later, Duguid[137] expanded on this theory by suggesting that atherosclerosis is the result of altered fibrinolysis, whereas more recent studies documented the overexpression of prothrombotic factors, such as plasminogen activator inhibitor-1, in atherosclerotic plaques.[138] Alternatively, Virchow's inhibition (or insudation) theory[139] proposed in 1856 that atherosclerotic lesions were the result of altered vessel wall permeability.

Variations of this theory have been suggested by others, and all support the concept that the accumulation of various plasma components, including lipoproteins, may be important during lesion formation. For example, Ross and Glomset[140] blended the concepts of these original hypotheses into the "response-to-injury" hypothesis in which both lipid infiltration and thrombus formation play important roles in atherogenesis. Similarly, Schwartz and colleagues[141] compared arterial narrowing in atherosclerotic arteries with the process of wound healing. This perspective has advantages because it allows a multifactorial process such as atherosclerosis to be broken down into components of a more completely understood process such as the biology of a skin wound. For example, wound healing of any form begins with the formation of a clot (fibrin- and fibronectin-containing gel) that fills the wound and provides a provisional matrix for inflammatory cells, fibroblasts, and newly formed microvessels.[142,143] This phase is followed by the proliferation and migration of fibroblasts into the wound.[144] By day 7 after injury, microvessels grow into the base of the wound and form granulation tissue. As the wound matures and undergoes contracture, these blood vessels regress and fibroblasts disappear. After resorption of microvessels, tissue hypoxia develops and likely plays a role in the completion of the final scarring process.[145]

As discussed later, ample evidence suggests that many similar events take place during arterial wound healing; however, because atherosclerosis is a chronic process, vascular lesion formation probably involves indolent levels of inflammation with ongoing cycles of injury and repair over many years.[142,146,147]

Arterial Wall Inflammation

Studies have demonstrated the presence of monocytes or macrophages and T lymphocytes in arteries not only with advanced lesions but also in arteries with early atherosclerotic lesions in young adults.[148,149] Moreover, in experimental atherosclerosis, leukocyte infiltration into the vascular wall is known to precede smooth muscle cell hyperplasia.[150] Once inside the artery wall, mononuclear cells may play several important roles in lesion development. For example, monocytes may transform into macrophages and become involved in the local oxidation of low-density lipoproteins (LDLs) and accumulation of oxidized LDLs. Alternatively, macrophages in the artery wall may act as a rich source of factors that, for example, promote cell proliferation, migration, or the breakdown of local tissue barriers. The process of local tissue degradation may be important for the initiation of acute coronary artery syndromes because loss of arterial wall integrity may lead to plaque fissuring or rupture.[151]

Normally, the endothelium exhibits a low affinity for circulating leukocytes. The transmigration of leukocytes into the artery wall must occur as a facilitated process. The release of proinflammatory cytokines such as interleukin-1 may promote the expression of leukocyte adhesive molecules.[152] For simplicity, the interaction between leukocytes and the endothelium can be considered to involve three steps.[153] First, leukocytes in the bloodstream must loosely associate and roll along the endothelium, a process mediated by selectins expressed on endothelial cells.[152] Second, firm adhesion of these leukocytes to endothelial cells occurs by the interaction between integrins, such as $\alpha_4\beta_1$ (also known as very late antigen-4), expressed on leukocytes, and counterreceptors, such as vascular cell adhesion molecule-1, on endothelial cells.[154] Finally, the transmigration of leukocytes into the subendothelial space is mediated by various migration-inducing factors, such as monocyte chemoattractant protein-1.[155]

Dysfunction, discontinuity, or injury of the endothelial cell monolayer has been postulated to play a significant role in facilitating the transmigration of leukocytes into the intima and the development of intimal hyperplasia. However, the premise that regrowth of healthy endothelium limits neointimal accumulation is inconsistent with the results of several independent lines of investigation. For example, in experimental models, smooth muscle cell proliferation is not increased in arterial regions devoid of an endothelium.[156] Moreover, restoration of the endothelium, as could be achieved by seeding endothelial cells back into a denuded artery, does not decrease neointimal accumulation after vascular interventions.[157] The presence of endothelium in the central lumen of an artery and resistance to intimal growth do not appear to be inextricably linked. Finally, the endothelium is not restricted to the central lumen because the artery wall also has a rich supply of microvessels (ie, vasa vasorum).[158–161] The vasa vasorum likely comprise another portal of entry for inflammatory cells into the artery wall, particularly because the expression of certain adhesion molecules is more abundant in the endothelium lining these microvessels than in the central arterial lumen.[162]

Role of Lipoproteins in Lesion Formation

The clinical and experimental evidence linking dyslipidemias with atherogenesis is well established and need not be reviewed here. However, the exact mechanisms by which lipid moieties contribute to the pathogenesis of atherosclerosis remain elusive. Although the simple concept of cholesterol accumulating in artery walls until flow is obstructed may be correct in certain animal models, this theory is not correct for human arteries.

Much of the pioneering work in understanding cholesterol metabolism is based on seminal observations by Brown and Goldstein.[163] The work of these two investigators focused on LDL, the so-called bad form of cholesterol, and the absence (or deficient forms) of the

LDL receptor that are seen in familial hypercholesterolemia. Patients with familial hypercholesterolemia have high levels of LDL cholesterol and have accelerated forms of atherosclerosis as cholesterol moieties enter the cell by an alternate route. In the absence of a functional LDL receptor, LDL cholesterol is oxidized and taken up by scavenger receptors of monocytes and macrophages resident within the artery wall. Steinberg[164] integrated these data into a theory of atherogenesis that highlights the central role of LDL oxidation and the formation of lipid-laden monocytes in fatty streaks.

One of the major consequences of cholesterol accumulation in the artery wall is thought to be impairment of endothelial function. The endothelium is more than a physical barrier between the bloodstream and the artery wall. Under normal conditions, the endothelium is capable of modulating vascular tone (eg, through NO), thrombogenicity, fibrinolysis, platelet function, and inflammation. In the presence of traditional risk factors, particularly dyslipidemias, these protective endothelial functions are reduced or lost. The loss of these endothelium-derived functions may occur in the presence or absence of an underlying atherosclerotic plaque and may simply imply that atherogenesis has begun. Aggressive attempts to normalize atherosclerotic risk factors (eg, diet and lipid-lowering therapies) may markedly attenuate endothelial dysfunction, even in the presence of extensive atherosclerosis. Some clinical studies demonstrated dramatic improvements in endothelial function, as well as in cardiovascular morbidity and mortality, with the use of inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, or "statins."[165–167] Future studies may help clarify the exact mechanisms by which dyslipidemias (and other risk factors) alter endothelial function.

Smooth Muscle Cell Proliferation, Migration, and Arterial Remodeling

The dominant cell type in atherosclerotic lesions is the smooth muscle cell, and as lesions progress the number of smooth muscle cells in the artery wall tends to increase. Therefore smooth muscle replication must occur at some time during atherogenesis. Perhaps the first line of evidence that cell replication occurs in human arteries is from the observation that atherosclerotic plaques contain monoclonal cell populations. Elegant studies by Benditt and Benditt[168] demonstrated that groups (or clones) of cells that arose from a single progenitor cell were present in tissue from atherosclerotic coronary arteries of women who were deficient in glucose-6-phosphate dehydrogenase (G6PD). Because G6PD is an X-chromosome–linked enzyme that has two isoforms, cells would express only one isoform, with the other isoform suppressed on the inactivated X chromosome. Groups of cells in an atherosclerotic plaque that contain only one isoform of G6PD are likely the result of proliferation of a single progenitor cell. Murry and colleagues[169] studied the monoclonality of atherosclerotic plaques by using X chromosome inactivation patterns. Using the polymerase chain reaction, these investigators examined the monoclonality of plaques according to the methylation pattern of the human androgen receptor gene, a highly polymorphic locus on the X chromosome for which 90% of women are heterozygous. These investigators noted that diseased and normal arteries contain monoclonal populations (or patches) of cells. They speculated that the monoclonality of plaques could result from expansion of a preexisting monoclonal patch of cells, rather than mutation or selection of individual cells in the artery wall.

Little is known about when and why cells proliferate in the artery wall. However, it is known that rapid expansion in neointimal smooth muscle cell mass occurs early in life. Sims and associates[170,171] described the accumulation of intimal smooth muscle cells in the left anterior descending coronary artery of neonates. Using electron microscopy, these investigators demonstrated interruptions in the internal elastic lamina in coronary arteries where a neointima had formed. These interruptions in the internal elastic lamina are not present in all human arteries. Indeed, the internal mammary artery, which typically is devoid of atherosclerosis, has an intact internal elastic lamina. Investigators have suggested that medial smooth muscle cells migrate inward through breaks in the internal elastic lamina to expand and form a neointima. The frequency and degree of smooth muscle cell replication in adult coronary arteries were examined by various investigators. Most of these studies demonstrated very low replication rates in tissue from both normal and diseased arteries.[172–175] Whether these low cell replication rates are sufficient to result in gradually advanced lesions or whether sporadic bursts of replication occur in response to injury is unknown. Finally, it is recognized that programmed cell death, or apoptosis, occurs in the artery wall.[176] The accumulation of cells in the artery wall is a function of not only cell proliferation but also apoptosis.

The role of smooth muscle cell migration in adult CAD is poorly understood. Investigators have suggested, however, that like fibroblasts that migrate into the base of a wound, arterial wall smooth muscle cells migrate inward to expand plaque mass. Smooth muscle cell migration into the intima was studied in various animal models of neointimal formation (eg, rat carotid artery model).[10] Most of these models demonstrated the inward migration of medial smooth muscle cells after normal arteries were subjected to balloon injury. Certain growth factors (eg, platelet-derived growth factor) were shown to play an important role in facilitating smooth muscle cell migration in these models.[177–179] Unfortunately, the clinical relevance of these experimental observations remains to be clarified because the milieu for cell migration in complex human lesions appears to be very different from that of normal animal arteries that are subjected to injury. More information is required on the factors that regulate smooth muscle cell migration, as well as why smooth muscle cells differ in their propensity to migrate after injury.

Finally, the buildup of atherosclerotic plaque does not always translate into the formation of arterial obstructions.[142] For example, Glagov and colleagues[180] noted that human vessels can accumulate massive amounts of atherosclerotic plaque without encroaching on the central arterial lumen. Instead, abluminal expansion of the artery wall may occur until 40% of the area encompassed by the internal elastic lamina is occupied by plaque; no further enlargement may occur thereafter, and luminal narrowing may ensue. Although this form of compensatory enlargement is referred to as "remodeling," the term is confusing because it has different meanings in different contexts (Figs. 7.13 and 7.14).[181–182] For example, remodeling has also been used to describe the arterial response to changes in blood flow (eg, during pregnancy or in the neonatal period) or pressure (eg, hypertension).[183] In addition, remodeling has been invoked as a key component of the response to arterial injury, although with quite a different meaning.[184] In animal models of arterial injury as well as in studies of human coronary arteries that have undergone angioplasty (or percutaneous transluminal coronary angioplasty), "shrinkage" or constrictive remodeling of the artery wall is a major determinant of luminal narrowing, whereas neointimal formation plays a minor role in this process.[185–192]

How arterial wall constriction is accomplished or why some but not all arteries undergo compensatory dilatation to preserve lumen area is incompletely understood.[141,193,194] Blood flow and shear stress are known to play critical roles in remodeling. The response of arteries to chronic alterations in blood flow is endothelium dependent.[182,195] For example, Langille and O'Donnell[195] demonstrated in rabbit carotid arteries that decreased blood flow resulted in narrowing of the vessel diameter that was unchanged with papaverine and was likely caused by structural changes in the artery wall. However, when the endothelium was removed from these vessels, the response to reduced blood flow was abolished. In atherosclerotic arteries that contain a rich network of endothelial cell-lined microvessels or vasa vasorum, the role of the endothelium in regulating remodeling may be important.[180,196,197]

Pathophysiology of Coronary Blood Flow

Coronary Artery Stenoses and Plaque Rupture

Coronary atherosclerosis is a chronic disease that develops over decades and remains clinically silent for prolonged periods (Box 7.9).

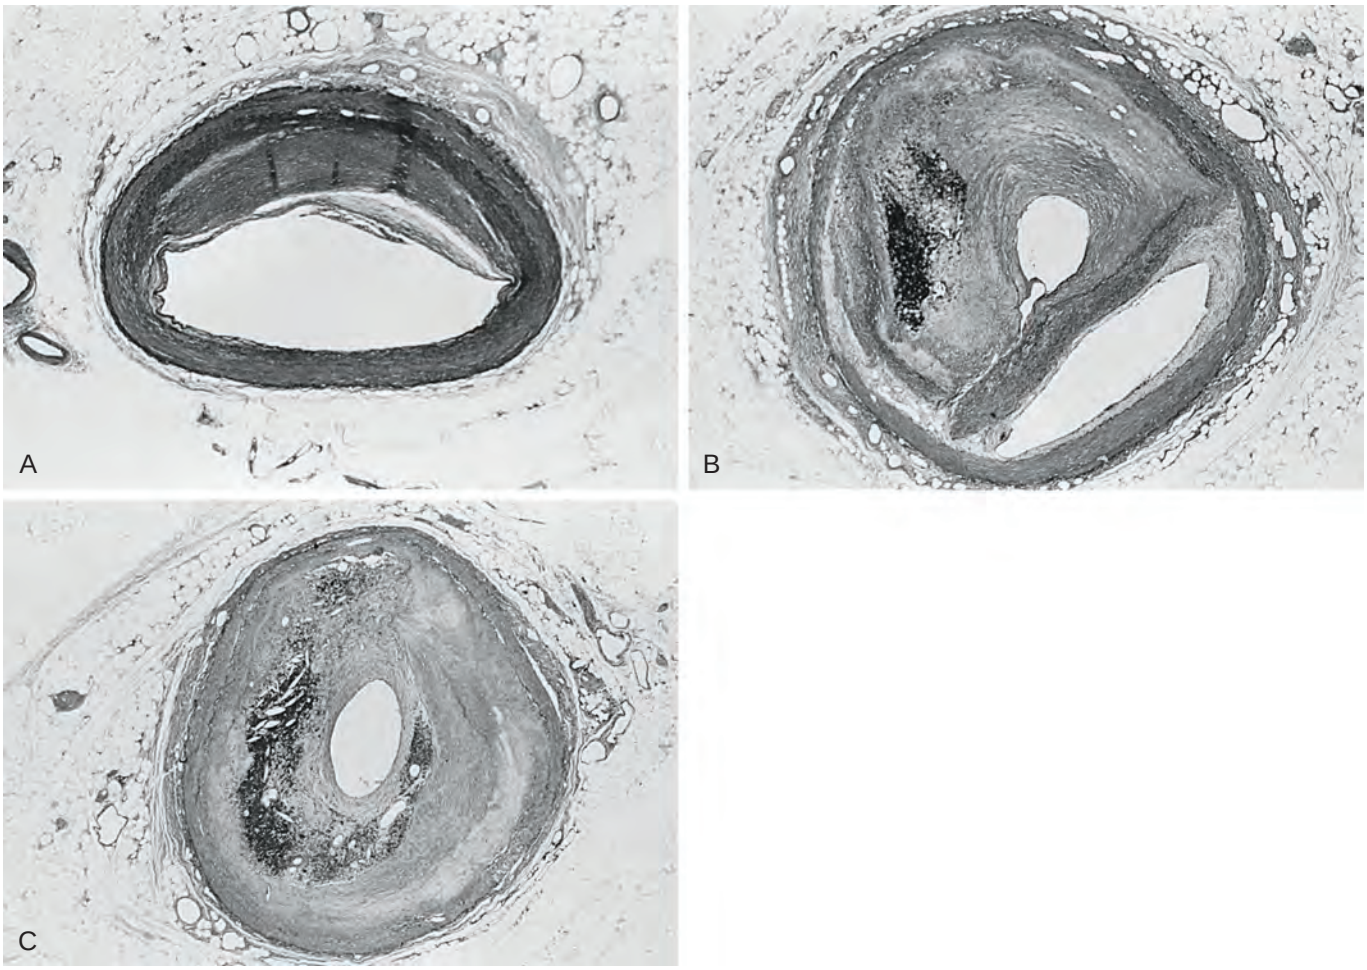

Fig. 7.13 Arterial remodeling. Serial sections of an atherosclerotic human left circumflex coronary artery (Movat's pentachrome–stained slide; original magnification ×40). (A) Proximal. (B) Middle. (C) Distal. Narrowing of the central arterial lumen is visible in the middle and distal sections; however, the total arterial area of these sections is also larger than that of the proximal section. The ability of arteries to undergo compensatory enlargement is referred to as *arterial remodeling*.

BOX 7.9 PATHOPHYSIOLOGY OF CORONARY BLOOD FLOW

- In most patients experiencing a myocardial infarction, the coronary occlusion occurs at the site of less than 50% stenosis.
- Plaque rupture leads to incremental growth of coronary stenoses and can cause coronary events.
- Plaque rupture occurs at the shoulder of the plaque where inflammatory cells are found.

Clinical manifestations of CAD occur when the atherosclerotic plaque mass encroaches on the vessel lumen and obstructs coronary blood flow to cause angina. Alternatively, cracks or fissures may develop in the atherosclerotic lesions and result in acute thromboses that cause unstable angina or myocardial infarction.

Patients with stable angina typically have lesions with smooth borders on angiography. Only a few coronary lesions are concentric; most have complex geometry varying in shape over their length. Eccentric stenoses, with a remaining pliable, musculoelastic arc of normal wall, can vary in diameter and resistance in response to changes in vasomotor tone or intraluminal pressure. Most human coronary artery stenoses are compliant.[198] The intima of the normal portion of the vessel wall is often thickened, thus making endothelial dysfunction probable (see "Dynamic Stenosis," later). In contrast, patients with unstable angina usually have lesions characterized by overhanging edges, scalloped or irregular borders, or multiple irregularities. These complicated stenoses likely represent ruptured plaque or partially occlusive thrombus, or both.[199] On angiography these lesions may appear segmental, confined to a short segment of an otherwise normal proximal coronary artery. At autopsy, however, the most common pathologic finding is *diffuse* vessel involvement with superimposed segmental obstruction of greater severity.[200] In a diffusely narrowed vessel, even modest progression of luminal narrowing can be significant. In such an artery, rating the significance of the obstruction by the percentage of diameter reduction relative to adjacent vessel segments underestimates its physiologic importance.[201,202] Therefore understanding the characteristics of atherosclerotic plaques is of central importance to the management of acute coronary artery syndromes.

The intuitive notion that the severity of coronary artery stenoses should correlate with the risk of complications from CAD was disproved by several key investigations. Ambrose and associates[203] reviewed the coronary angiograms of 38 patients who had had Q-wave myocardial infarction in the interval between serial studies. On the preinfarct angiograms, the mean percentage of stenosis at the coronary segment that was later responsible for infarction was only 34%.

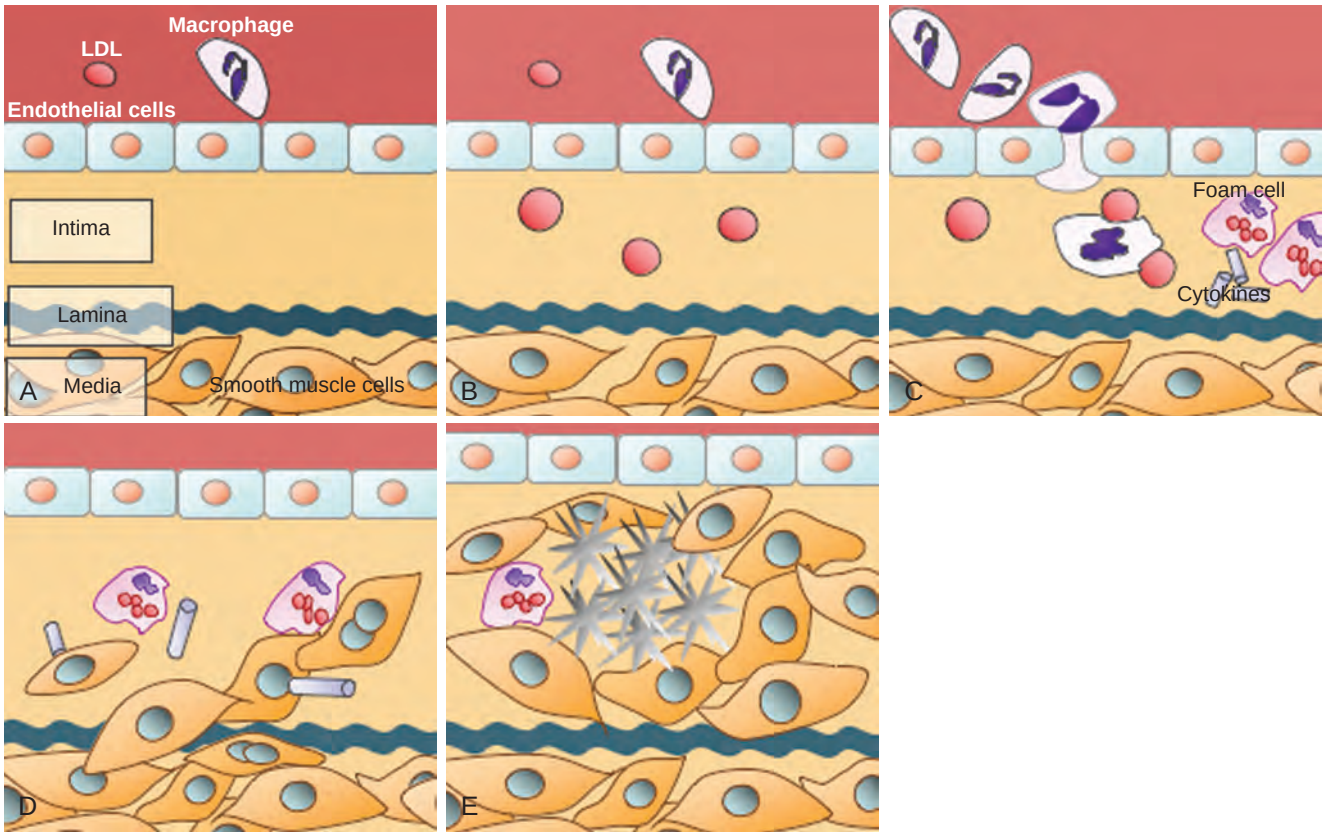

Fig. 7.14 A model of atherogenesis in human coronary arteries. (A) Infiltration of the intima by low-density lipoproteins *(LDL)* stimulates expression of adhesion molecules on the luminal surface of the endothelium and facilitates macrophage translocation into the intima. (B) Uptake of LDL by scavenger receptors on macrophages gives rise to foam cells. Infiltration of mononuclear cells and uptake of LDL stimulate secretion of proinflammatory cytokines, such as interleukin-1, that further promote accumulation of macrophages in the intima and stimulate division and migration of medial smooth muscle cells. (C) Ongoing inflammation stimulates accumulation of smooth muscle cells, foam cells, and extracellular matrix in the intima. (D) Ongoing inflammation can lead to regional apoptosis and development of a necrotic core with accumulation of cholesterol deposits. (E) Arterial remodeling is demonstrated by marked intimal thickening with minimal encroachment on the arterial lumen.

Similarly, Little and colleagues[204] reviewed the coronary angiograms of 42 patients who also had this procedure performed at an interval before and after myocardial infarction. Total occlusion of a previously patent artery was observed in 29 patients; yet for 19 of these occluded arteries, the degree of stenosis was less than 50% on the initial angiogram. Therefore, although the revascularization of arteries with critical stenoses in target lesions is appropriately indicated to reduce symptoms and myocardial ischemia, a risk of further cardiac events remains because atherosclerosis is a diffuse process, and mild or modest angiographic stenoses are more likely to result in subsequent myocardial infarction than are severe stenoses.

With this background comes the problem of predicting which arterial segments with minimal angiographic disease will later develop new critical stenoses. Clues to the solution emerged from careful pathologic studies of lesions by Davies and Thomas.[205] Superficial intimal injury (plaque erosions) and intimal tears of variable depth (plaque fissures) with overlying microscopic mural thrombosis are commonly found in atherosclerotic plaques. In the absence of obstructive luminal thrombosis, these intimal injuries do not cause clinical events. However, disruption of the fibrous cap, or plaque rupture, is a more serious event that typically results in the formation of clinically significant arterial thromboses. From autopsy studies it is known that rupture-prone plaques tend to have a thin, friable fibrous cap.[206] The site of plaque rupture is thought to be the shoulder of the plaque, in which substantial numbers of mononuclear inflammatory cells are commonly found.[207] The mechanisms responsible for the local accumulation of these cells at this location in the plaque are unknown; presumably, monocyte chemotactic factors, the expression of leukocyte cell adhesion molecules, and specific cytokines are involved.[162,208] Moreover, macrophages in plaques have been shown to express factors such as stromelysin, which promote the breakdown of the extracellular matrix and thereby weaken the structural integrity of the plaque.[151] Currently, no effective strategies have been designed to limit the possibility of plaque rupture; however, as discussed later, aggressive lipid-lowering therapy may be a helpful preventive measure.

Hemodynamics

If accurate angiographic assessment of the geometry of a coronary stenosis is made, hydrodynamic principles can be used to estimate the physiologic significance of the obstruction.[209] Energy is lost when blood flows through a stenosis because of entrance effects, frictional losses in the stenotic segment, and separation losses secondary to turbulence as blood exits the stenosis (Fig. 7.15). The Eq. relating stenosis geometry to hemodynamic severity is:

$$\Delta P = fQ + sQ^2$$

where ΔP is the pressure drop across the stenosis, Q is the volume flow of blood, f is a factor accounting for frictional effects, and s accounts for separation effects.

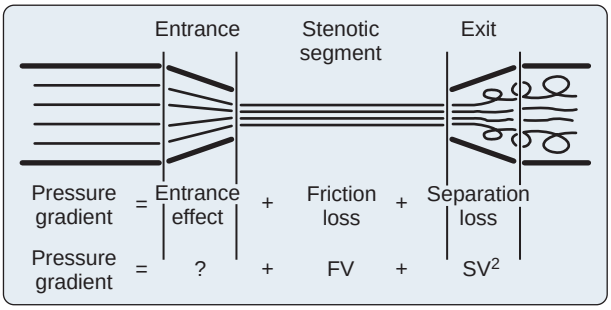

Fig. 7.15 Sources of energy loss across a stenosis. Equations that (accurately) predict the pressure gradient across a stenosis usually ignore entrance effects. Frictional losses are proportional to blood velocity but are usually not important except in very long stenoses. Separation losses, resulting from turbulence as blood exits the stenosis, increase with the square of blood velocity (V^2) and account for more than 75% of energy loss. *F,* Friction coefficient (Poiseuille); *S,* separation coefficient (see text). *(From Marcus ML: The physiologic effects of a coronary stenosis. In: Marcus ML, ed.* The Coronary Circulation in Health and Disease. *New York: McGraw-Hill; 1983:242–269. Reproduced with permission of The McGraw-Hill Companies.)*

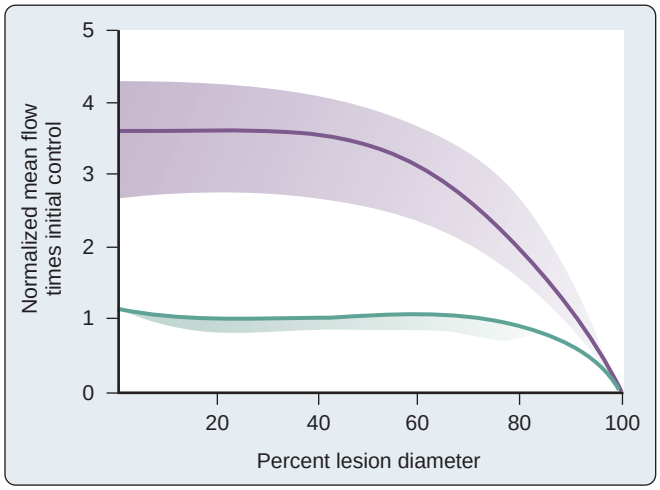

Fig. 7.16 Effect of increasing stenosis severity at resting *(bottom line)* and maximal *(top line)* coronary flows. At rest, lumen diameter must be reduced by more than 80% before flow decreases. Because pressure drop across a stenosis increases exponentially with blood velocity, maximal coronary flow is restricted by a 50% diameter reduction. *(From Gould KL, Lipscomb K. Effect of coronary stenoses on coronary flow reserve and resistance.* Am J Cardiol. *1974;34:48.)*

Based on the Poiseuille law for laminar flow:

$$f = \frac{8\pi\eta L A_n}{A_s^2}$$

where η is the blood viscosity, L is stenosis length, An is the cross-sectional area of the normal vessel, and As is the cross-sectional area of the stenosis. The separation or turbulence factor is:

$$s = \frac{\rho k}{2}\left(\frac{A_n}{A_s} - 1\right)^2$$

where ρ is blood density, and k is an experimentally determined coefficient.

Thus frictional losses are directly proportional to the first power of stenosis length but are inversely proportional to the square of the area (or fourth power of diameter). Separation losses are particularly prominent because they increase with the square of flow. Even at resting flows, more than 75% of energy loss results from this turbulence when blood exits the stenosis. Except for very long stenoses, the frictional term can be neglected.[198] The amount of energy loss or pressure drop across the obstruction therefore increases exponentially as flow rate increases. For this reason, exercise, anemia, and arteriolar vasodilator drugs (eg, dipyridamole) are poorly tolerated in the presence of severe stenosis. Fig. 7.16 illustrates that although resting flow is unaffected until coronary diameter is reduced by more than 80%, maximal flow begins to fall when diameter is reduced by 50%.

Resting flow in Fig. 7.16 remains constant as lumen diameter decreases because the coronary arterioles progressively dilate, thereby reducing the resistance of the distal coronary bed sufficiently to compensate for the resistance of the stenosis. As the severity of the stenosis increases further, the arteriolar bed can no longer compensate, and flow begins to fall. As stenosis severity increases, distal perfusion pressure falls, arterioles dilate to maintain flow until autoregulation is exhausted (in the subendocardium first), and flow becomes pressure dependent. As illustrated in Fig. 7.9, the distal pressure (or stenosis diameter) at which flow becomes pressure dependent is lower at low levels of myocardial metabolism ($M\dot{V}O$). The interpretation of normal resting flow can be difficult in the presence of CAD. A coronary artery supplying blood through collaterals to a large mass of myocardium requires high resting flow rates, and even mild stenosis may be flow limiting.

The frequently used term *critical stenosis* is usually defined as coronary constriction sufficient to prevent an increase in flow over resting values in response to increased myocardial oxygen demands.[210] This is a greater degree of obstruction than angiographically significant stenosis, which is usually defined as a reduction in cross-sectional area of 75%, equivalent to a 50% decrease in the diameter of a concentric stenosis.[202] A critical stenosis is demonstrated experimentally by blunting or abolishing reactive hyperemia (see "Autoregulation," earlier). This is evidence that autoregulation has been exhausted in at least the inner layer of myocardium (see "Transmural Blood Flow," earlier). The critical nature of the stenosis is relative to the resting $M\dot{V}O_2$. If oxygen demand decreases, some coronary autoregulatory reserve is recovered and the stenosis is no longer critical. The failure to recognize this situation has led to misinterpretation of studies designed to demonstrate coronary steal (see later).

Coronary Collaterals

Coronary collaterals are anastomotic connections, without an intervening capillary bed, between different coronary arteries or between branches of the same artery. In the normal human heart, these vessels are small and have little or no functional role. In patients with CAD, well-developed coronary collateral vessels may play a critical role in preventing death and myocardial infarction. Individual differences in the capability of developing a sufficient collateral circulation are determinants of the vulnerability of the myocardium to coronary occlusive disease.[211] Great interspecies variation is observed in the ability of the collateral circulation to support myocardial perfusion after acute coronary occlusion; pigs and rats have very little collateral circulation and have infarcts in almost all the area at risk, whereas dogs and cats with better collateralization have infarcts in less than 75% of the area at risk.[212] In the guinea pig, collaterals are so well developed that coronary occlusion does not even decrease myocardial blood flow. Differences also occur in the location of collateral vessels. In dogs collaterals develop in a narrow subepicardial zone, at the border of the potentially ischemic region, whereas in pigs a dense subendocardial plexus develops in response to coronary occlusion. In the presence of coronary disease, humans exhibit a small number of large epicardial collateral vessels and numerous small subendocardial vessels.

In response to coronary occlusion, native coronary collateral vessels (present from birth) do not passively stretch but undergo an active growth process that within 8 weeks in dogs can restore perfusion sufficient to support normal myocardial function even during exercise.

Human collaterals have a tortuous corkscrew-like pattern visible on angiography. The reason may be an embryonal pattern of vascular development in which longitudinal growth of smooth muscle cells occurs at the same time as radial growth. In the nongrowing adult heart, this increase in length results in tortuosity.[213] Much interest has been shown in discovering the factors that control collateral vessel growth in the hope of providing therapy for patients who cannot undergo revascularization otherwise.

Arteriogenesis refers to the transformation of preexisting collateral arterioles into functional arteries with a thick muscular coat and the acquisition of viscoelastic and vasomotor properties.[214] Fujita and Tambara[215] provided an overview of the process: a high-grade coronary stenosis decreases distal intraarterial pressure and results in an increased pressure gradient across the preexisting collateral network. Increased collateral blood flow results in increased shear stress at the endothelium, which upregulates cell adhesion molecules. Upregulation leads to adherence of monocytes, which transform into macrophages, and the production and release of growth factors such as granulocyte-macrophage colony-stimulating factor, monocyte chemoattractant protein-1, and basic fibroblast growth factor. Angiogenesis is not directly related to collateral vessel development but rather refers to the proliferation, migration, and tube formation of capillaries in the central area of ischemic regions.[216] The development of a treatment to promote collateral growth in patients with intractable CAD is currently a subject of intense investigation. Experimental approaches include mechanical strategies to increase shear stress as well as cell therapies.[217] Ischemic preconditioning, sometimes used in off-pump coronary artery surgical procedures, may in part be mediated by collateral recruitment.[218]

Evidence in dogs suggests that mature coronary collaterals respond differently to neurohumoral stimulation than do normal coronary arteries. Collaterals do not constrict in response to α-receptor activation but do dilate in response to β_1- or β_2-agonists. They constrict in response to prostaglandin $F_{2\alpha}$ and angiotensin II, but less so than do normal vessels. Remarkably, collateral vessels constrict in response to vasopressin to a much greater extent than normal vessels. In vivo studies in dogs indicated that levels of vasopressin present during stress (hemorrhage, cardiopulmonary bypass) diminished flow to collateral-dependent myocardium. This finding likely reflects both constriction of collateral vessels and enhanced vasoconstriction of the resistance vessels in the collateral-dependent myocardium.[77] It is possible that the endothelial cells of both types of vessels are dysfunctional.[219] Relaxation in response to nitroglycerin is enhanced. This is a further mechanism for the beneficial effects of nitroglycerin in CAD. The deleterious effects of coronary arteriolar dilators such as adenosine and dipyridamole are discussed later (see "Coronary Steal").

Investigators have estimated that, in humans, perfusion through collaterals can equal perfusion through a vessel with a 90% diameter obstruction.[220] Although coronary collateral flow can be sufficient to preserve structure and resting myocardial function, muscle dependent on collateral flow usually becomes ischemic when oxygen demand rises to more than resting levels.[221] A metaanalysis carried out in 2012[222] estimated that, among patients with stable CAD, the presence of "high collateralization" is associated with a reduction in mortality rates of greater than 30% compared with patients with low collateralization. It is possible that evidence from patients with angina underestimates collateral function of the population of all patients with CAD. Perhaps persons with coronary obstructions but excellent collateralization remain asymptomatic and are not studied.

Pathogenesis of Myocardial Ischemia

Ischemia is the condition of oxygen deprivation accompanied by inadequate removal of metabolites consequent to reduced perfusion.[223] Clinically, myocardial ischemia is a decrease in the blood flow supply-to-demand ratio that results in impaired function. No universally accepted gold standard exists for the presence of myocardial ischemia. In practice, symptoms, anatomic findings, and evidence of myocardial dysfunction must be combined before concluding that myocardial ischemia is present.[224] Conclusive evidence of anaerobic metabolism in the setting of reduced coronary blood flow (relative to demand) would be convincing. Such evidence is extremely difficult to obtain, even in experimental preparations.

Determinants of Ratio of Myocardial Oxygen Supply to Demand

An increase in myocardial oxygen requirement beyond the capacity of the coronary circulation to deliver oxygen results in myocardial ischemia (Box 7.10). This is the most common mechanism leading to ischemic episodes in chronic stable angina and during exercise testing. Intraoperatively, the anesthesiologist must measure and control the determinants of $M\dot{V}O_2$ and protect the patient from "demand" ischemia. The major determinants of $M\dot{V}O_2$ are heart rate, myocardial contractility, and wall stress (chamber pressure × radius/wall thickness). Shortening, activation, and basal metabolic requirements are minor determinants of $M\dot{V}O_2$ (Fig. 7.17).

An increase in heart rate can reduce subendocardial perfusion by shortening diastole. Coronary perfusion pressure may fall in response to reduced systemic pressure or increased left ventricular end-diastolic

BOX 7.10 DETERMINANTS OF MYOCARDIAL OXYGEN SUPPLY-TO-DEMAND RATIO

The major determinants of myocardial oxygen consumption are:

- heart rate
- myocardial contractility
- wall stress (chamber pressure × radius / wall thickness)

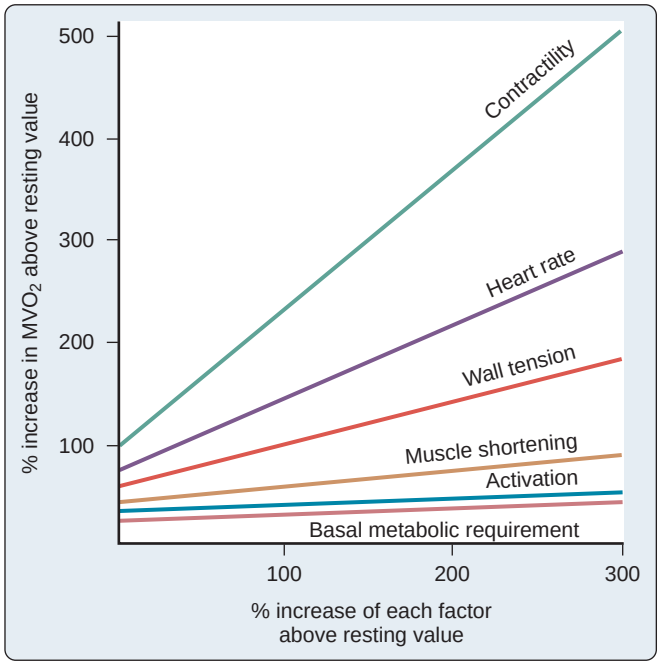

Fig. 7.17 Relative importance of variables that determine myocardial oxygen consumption ($M\dot{V}O_2$). Each line roughly approximates the effect of manipulating one variable without changing the others. Most interventions cause changes in several of the variables at the same time. The importance of contractility, which is difficult to monitor in practice, is apparent. *(From Marcus ML. Metabolic regulation of coronary blood flow. In: Marcus ML, ed.* The Coronary Circulation in Health and Disease. *New York: McGraw-Hill; 1983:65–92. Reproduced with permission of The McGraw-Hill Companies.)*

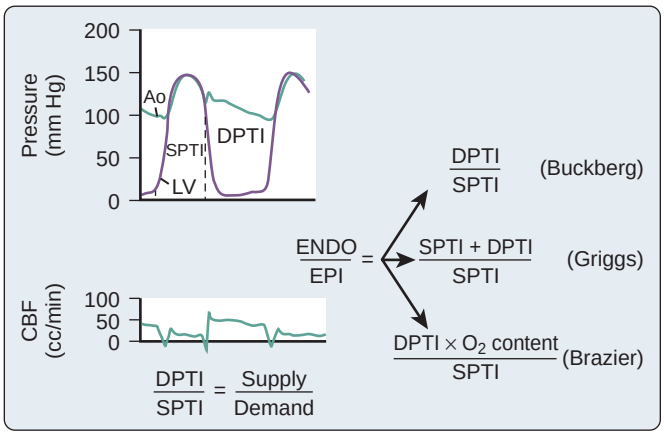

Fig. 7.18 Three indices, proposed to predict the adequacy of subendocardial perfusion in normal dogs, illustrate the variables determining myocardial oxygen supply and demand. The systolic pressure-time index *(SPTI)* relates to oxygen demand. The diastolic pressure-time index *(DPTI)* relates to the supply of coronary blood flow *(CBF)* to the inner layers of the left ventricle. Arterial oxygen content *(O_2 content)* is important when there are large changes in hematocrit. *Ao,* Aortic pressure; *ENDO,* subendocardial layer of left ventricle; *EPI,* subepicardial layer of the left ventricle; *LV,* left ventricular pressure. *(From Hoffman JIE, Buckberg GD. Transmural variations in myocardial perfusion. In: Yu PN, Goodwin JF, eds.* Progress in Cardiology. *Philadelphia: Lea & Febiger; 1976:37.)*

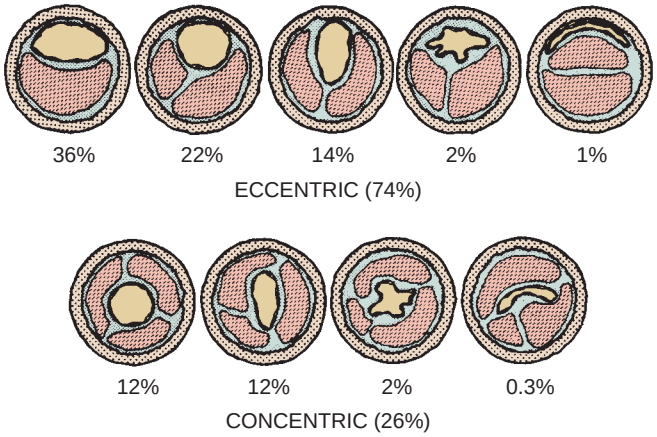

Fig. 7.19 Drawings and incidence of the various types of structure of stenoses observed in human coronary artery specimens. In almost three-fourths of vessels with greater than 50% narrowing, the residual arterial lumen was eccentric and partially circumscribed by an arc of normal arterial wall. In such lesions, a fall in intraluminal pressure or an increase in vasomotor tone can cause lumen diameter to decrease sufficiently to precipitate myocardial ischemia. *(From Brown BG, Bolson EL, Dodge HT. Dynamic mechanisms in human coronary stenosis. Circulation. 1984;70:917; redrawn from Freudenberg H, Lichtlen PR. The normal wall segment in coronary stenoses—a postmortem study.* Z Kardiol. *1981;70:863.)*

pressure. With the onset of ischemia, perfusion may be further compromised by delayed ventricular relaxation (decreased subendocardial perfusion time) and decreased diastolic compliance (increased left ventricular end-diastolic pressure). Anemia and hypoxia can also compromise delivery of oxygen to the myocardium. Several indices of myocardial oxygen supply-to-demand ratio have been proposed to guide therapy. The rate-pressure product (heart rate × systolic blood pressure) gives a good estimate of $M\dot{V}O_2$ but does not correlate well with ischemia. A patient with a systolic pressure of 160 mm Hg and a heart rate of 70 beats/minute has a much lower likelihood of ischemia than does a patient with a systolic pressure of 70 mm Hg and a heart rate of 160 beats/minute, although both patients have a rate-pressure product of 11,200. The ratio of the diastolic pressure-time index (DPTI) to the systolic pressure-time index (SPTI) was devised to estimate subendocardial perfusion and takes into account determinants of oxygen delivery (Fig. 7.18).[225–227] When blood oxygen content was included, the index became a good predictor of endocardial flow in animals with normal coronary arteries. The ratio of mean arterial pressure to heart rate has been proposed as a correlate of myocardial ischemia.[228] In dogs with moderate to severe coronary stenoses, systolic shortening was best with high pressures and low heart rate and worst with low pressure and high heart rate. None of these indices has proved reliable in the clinical setting. The major value of these indices is to bring attention to the important variables determining the supply-to-demand ratio, These variables should be measured (or estimated) and controlled individually.

Dynamic Stenosis

Patients with CAD can have variable exercise tolerance during the day and between days. Ambulatory monitoring of the electrocardiogram has demonstrated that ST-segment changes indicative of myocardial ischemia, in the absence of changes in oxygen demand, are common.[229] These findings are explained by variations over time in the severity of the obstruction to blood flow imposed by coronary stenoses.

Although the term *hardening of the arteries* suggests rigid, narrowed vessels, in fact most stenoses are eccentric and have a remaining arc of compliant tissue (Fig. 7.19). A modest amount (10%) of shortening of the muscle in the compliant region of the vessel can cause dramatic changes in lumen caliber.[198] This was part of Prinzmetal's original proposal to explain coronary spasm. Maseri and associates[230] suggest that the term *spasm* be reserved for "situations where coronary constriction is both focal, sufficiently profound to cause transient coronary occlusion, and is responsible for reversible attacks of angina at rest" (ie, variant angina). Although this syndrome is rare, lesser degrees of obstruction in response to vasoconstrictor stimuli are common among patients with CAD.

Sympathetic tone can be increased by the cold pressor test (immersing the arm in ice water) or by isometric handgrip testing. In response to this maneuver, coronary resistance decreased in normal subjects but increased in patients with coronary disease, some of whom experienced angina.[231] This increase in resistance appears to be mediated by α-receptors because it can be prevented by phentolamine. Studies using quantitative coronary angiography have documented reductions in caliber in diseased vessels in contrast to dilation of vessels in normal subjects.[97,232] Zeiher and colleagues[232] showed that the same vessel segments that constricted with the cold pressor test also constricted in response to an infusion of acetylcholine. Because the normal, dilatory response to acetylcholine depends on intact endothelium, these findings suggest that the abnormal response of stenotic coronary arteries is the result of endothelial dysfunction.

Animal models of coronary vasospasm demonstrated that enhanced vascular smooth muscle reactivity may also underlie vasospasm.[233] Rho, a guanosine triphosphate–binding protein, sensitizes vascular smooth muscle cells to calcium by inhibiting myosin phosphatase activity through an effector protein called Rho-kinase. Upregulation of this pathway may be a mechanism of coronary vasospasm. Rho-kinase inhibitors have been shown to block agonist-induced vasoconstriction of internal thoracic artery segments from patients undergoing coronary artery surgical procedures.[234]

In addition, in patients with coronary disease, some of the angiographically normal appearing segments also respond abnormally.[64,235] It seems likely that endothelial dysfunction precedes the appearance of visible stenoses during the development of coronary atherosclerosis. In patients with angiographically smooth coronary arteries, Vita and associates[236] found that an abnormal response to acetylcholine was correlated with serum cholesterol, male sex, age, and family history of coronary disease. The normal dilation of epicardial coronary arteries

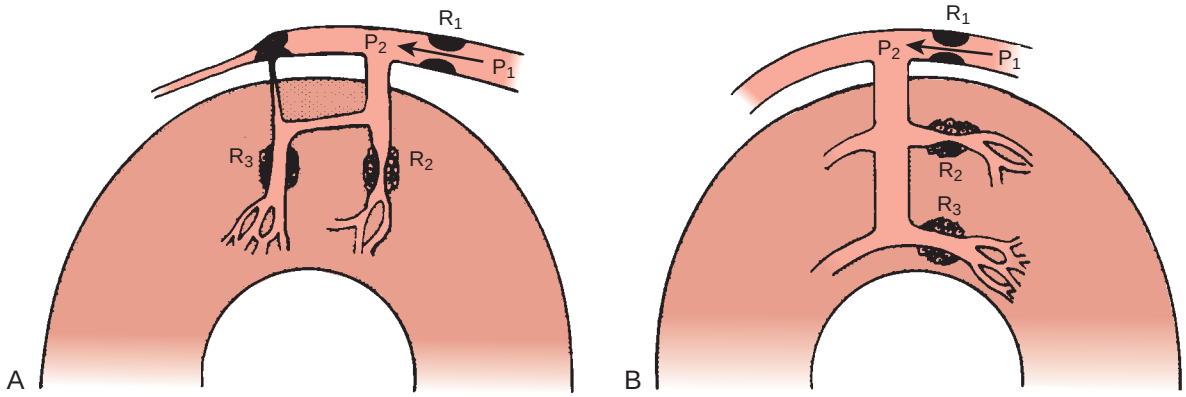

Fig. 7.20 Conditions for coronary steal in different areas of the heart and between the subendocardial and subepicardial layers of the left ventricle. (A) Collateral steal. (B) Transmural steal. See text for details. P_1, Aortic pressure; P_2, pressure distal to the stenosis; R_1, stenosis resistance; R_2 and R_3, resistance of autoregulating and pressure-dependent vascular beds, respectively. *(From Epstein SE, Cannon RO, Talbot TL. Hemodynamic principles in the control of coronary blood flow.* Am J Cardiol. *1985;56:4E.)*

in response to increased blood flow (shear stress) was shown to be absent in atherosclerotic vessels.[237] In addition, investigators demonstrated that patients with coronary disease respond to serotonin with coronary vasoconstriction instead of the normal vasodilatory response.[238,239] The concentrations of serotonin used were within the range found in coronary sinus blood of patients with coronary disease. Extremely high concentrations of serotonin may be found on the endothelium at the site of aggregating platelets.[238] All these findings point to the central role of endothelial dysfunction in the abnormal coronary vasomotion of patients with atherosclerosis (see "Endothelium," earlier).[240]

Coronary Steal

Steal occurs when the perfusion pressure for a vasodilated vascular bed (in which flow is pressure dependent) is lowered by vasodilation in a parallel vascular bed, with both beds usually distal to a stenosis. Two kinds of coronary steal are illustrated: collateral and transmural (Fig. 7.20).

Fig. 7.20A shows collateral steal in which one vascular bed (R_3), distal to an occluded vessel, is dependent on collateral flow from a vascular bed (R_2) supplied by a stenotic artery. Because collateral resistance is high, the R_3 arterioles are dilated to maintain flow in the resting condition (autoregulation). Dilation of the R_2 arterioles increases flow across the stenosis R_1 and decreases pressure P_2. If R_3 resistance cannot further decrease sufficiently, flow there decreases, thus producing or worsening ischemia in the collateral-dependent bed. The values of all the resistances, including collaterals, and the baseline myocardial metabolic state determine how powerful the vasodilator stimulus must be to produce ischemia in the collateral bed. Failure to recognize this has confounded studies of vasodilator drugs. If collateral vessels are extremely well developed or if $M\dot{V}O_2$ is low, sufficient autoregulatory reserve may remain in the collateral-dependent bed to maintain adequate myocardial blood flow even with the administration of a moderately powerful vasodilator.

Transmural steal is illustrated in Fig. 7.20B. Normally, vasodilator reserve is less in the subendocardium (see "Transmural Blood Flow," earlier). In the presence of stenosis, flow may become pressure dependent in the subendocardium, whereas autoregulation is maintained in the subepicardium. This situation is illustrated in Fig. 7.11, in which at a perfusion pressure of 50 mm Hg, flow has fallen in the subendocardium while at the same time the subepicardium retains autoregulatory reserve. Dilation of the subepicardial arterioles, R_2, then increases flow across the stenosis (R_1), thereby causing P_2 to fall and resulting in decreased flow to the subendocardium as subepicardial flow increases.

The term *steal* is most appropriate when the vasodilation is caused by a pharmacologic agent (adenosine, dipyridamole) producing "luxury" flow (beyond metabolic requirements) in the vascular bed with coronary reserve (R_2). The same redistribution of blood flow also occurs during exercise in response to metabolically mediated vasodilation. The study of coronary steal clearly demonstrates the complex interrelationships among the determinants of myocardial blood flow.

Intracoronary Evaluation of Atherosclerosis

A detailed description of diagnostic and therapeutic procedures performed in the cardiac catheterization laboratory is provided in Chapter 3. However, given that an integral understanding of the anatomy and physiologic impact of the coronary artery and the atherosclerotic lesion is necessary for the appropriate interpretation and use of these technologies, a brief review of new developments in invasive assessment is provided here.

Standard coronary arteriography gives operators a two-dimensional representation of the lumen. By examining arteries in multiple views, the operator estimates coronary stenoses by comparison of the lumen diameter at the point of maximal narrowing with adjacent disease-free segments. However, as discussed earlier, development of the atherosclerotic plaque results not only in luminal encroachment but also in arterial remodeling,[180] meaning that significant disease may be overlooked on traditional angiography. Thus newer technologies such as intravascular ultrasonography (IVUS) and optical coherence tomography (OCT) rapidly became the gold standard for defining the coronary anatomy and determining the severity of a stenosis.

Intravascular Ultrasound

IVUS of coronary arteries was first popularized in the 1990s,[241] and subsequent refinement of catheter delivery systems and commercialization made it a common component of the modern catheterization laboratory. Compatible with most guiding catheters, IVUS probes are delivered to the coronary arteries by standard angiographic techniques, and both manual and mechanical pullback of the IVUS probe allows operators to assess real-time cross-sectional images through use of a miniaturized ultrasound probe. Complementary software can then allow users to generate either longitudinal or three-dimensional reconstructions of the interrogated vessel.

IVUS images demonstrate remarkable fidelity to cross-sectional histologic specimens and permit accurate visualization and measurement of the intima, the media, and in some instances the adventitia (Fig. 7.21). Arterial remodeling with significant intimal hyperplasia but relatively intact lumen diameter can thus identify occult disease not

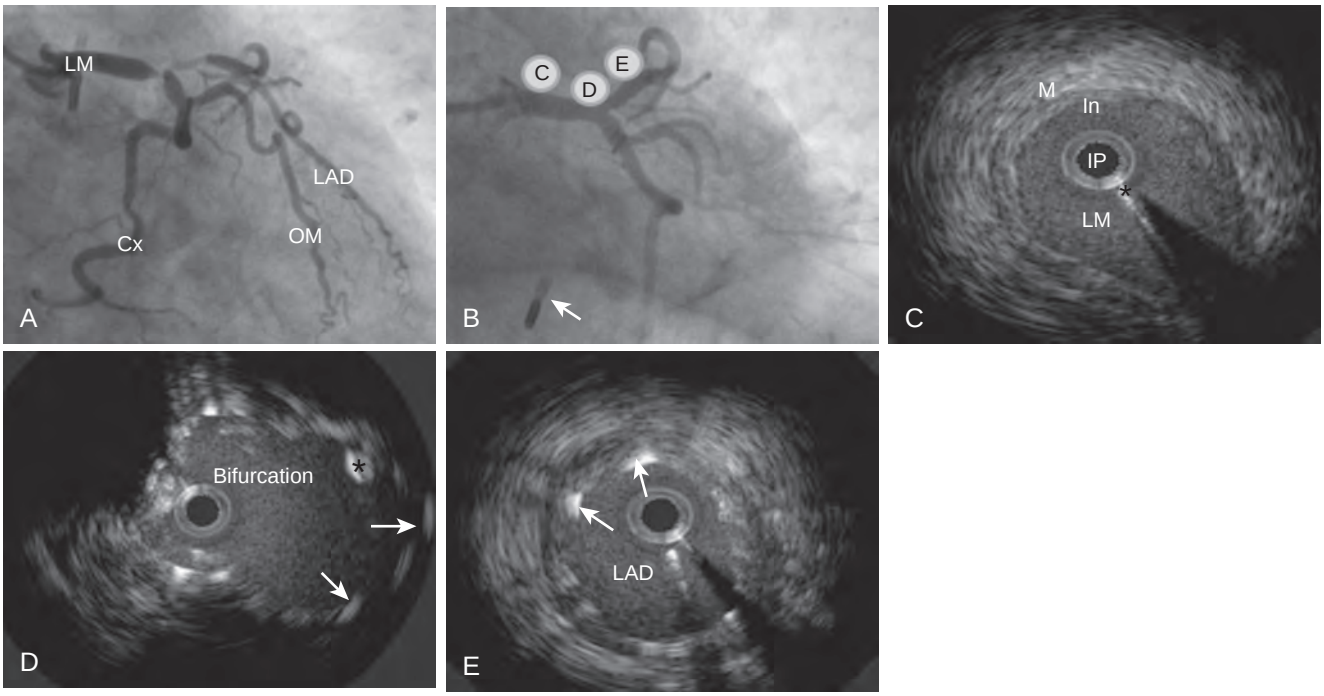

Fig. 7.21 Intravascular ultrasonography *(IVUS)* for assessment of human coronary arteries. (A) Right anterior oblique projection of the left coronary circulation. The left main coronary artery *(LM),* left anterior descending coronary artery *(LAD),* circumflex artery *(Cx),* and obtuse marginal artery *(OM)* are seen. Severe distal LM stenosis is seen bifurcating into the LAD and Cx. (B) Postpercutaneous intervention angiogram demonstrates no residual stenosis. Drug-eluting stents were placed in the LM, LAD, and Cx. The tip of an aortic balloon pump can be seen *(arrow).* Letters indicate the location of IVUS images for correlating panels. (C–E) IVUS images of the LM, LM bifurcation, and LAD, respectively. *Arrows,* Stent struts; *asterisk,* guidewire; *In,* intima; *IP,* IVUS probe; *M,* media.

otherwise appreciated on standard angiography. One landmark article noted that even if only minor luminal irregularities exist, atherosclerotic disease can be demonstrated throughout most other vessels in the coronary circulation, a finding suggesting that luminograms may be simply the tip of the atherosclerotic iceberg.[242] Indeed, IVUS is now commonly used to quantify intermediate-severity lesions more accurately,[243] appropriately assess the size of vessels, or delineate regions that are otherwise difficult to assess on standard angiography such as left main CAD. Especially given that undersized or malapposed stents are known to cause subsequent stent thrombosis, this ability is of significant importance from a clinical perspective. Moreover, IVUS allows operators to assess arteries after percutaneous intervention for adequate stent deployment and for complications, such as arterial dissection, that can be missed on standard angiography.[244] However, IVUS is not limited simply to documenting and quantifying atherosclerotic burden. Plaque composition can also be assessed qualitatively and classified based on acoustic impedance by allowing differentiation among fibromuscular "soft" lesions, dense "fibrous" lesions, and "calcified" hyperechoic lesions.[245] Although accurate prognostication remains limited, ongoing studies are aimed at identifying which plaques are "vulnerable" or susceptible to rupture, thus causing acute vessel closure and myocardial infarction.[246,247] The widespread adoption of IVUS has been limited largely by cost and increased procedural time; however, metaanalysis of both randomized and observational studies suggested an impact on clinical outcomes after percutaneous coronary intervention (PCI).

Optical Coherence Tomography

OCT provides a complimentary tool to IVUS for assessing coronary anatomy. OCT is a real-time catheter-based technology that uses near-infrared light in place of ultrasound to generate cross-sectional images. In this way OCT is able to generate a 10-fold increase in axial resolution compared with IVUS and can image structures as small as 10 to 15 μm.[247] Consequently, OCT has permitted even greater insight into coronary stenting and the intricacies of vascular biology.[248,249] Specifically, OCT enables classification and quantification of plaque morphology including identification of thin fibrous caps, lipid, and calcium without equivocation (Fig. 7.22). Most importantly, however, OCT affords unparalleled assessment of coronary stents after implantation including re-endothelization profiles, dissection flaps, stent apposition, and thrombus, thereby providing a wealth of information both for planning PCI and for stent optimization after deployment.[247,250] This technology has been particularly helpful with the development of bioresorbable vascular scaffolds, which resorb over a period of 2 years.[251,252] The greater resolution of this technology not only better visualizes stent struts but also greatly improves the detection of stent malapposition and prolapsed tissue.[253] However, convincing studies that OCT-guided PCI reduces events are lacking, and studies are needed to determine the impact of this imaging technology on patients' outcomes.

Fractional Flow Reserve

Although IVUS and OCT provide anatomic information on coronary artery structure, atherosclerotic plaque morphology, and luminal dimensions, neither technology is able to assess the physiologic significance of a coronary stenosis or detect myocardial ischemia. Indeed, the goal of revascularization is the relief of ischemia to improve symptoms and to reduce the risk of adverse outcomes. Numerous studies have highlighted the limitations of angiography alone in identifying responsible atherosclerotic plaques.

FFR is the ratio of the pressure distal (P_{distal}) to the pressure proximal ($P_{proximal}$) to a coronary stenosis when in a state of maximal coronary flow (assuming resistance is constant under hyperemia and the mean venous pressure is negligible). Practically, this ratio is assessed in the cardiac catheterization laboratory using wires equipped with pressure sensors that are placed distal to a coronary

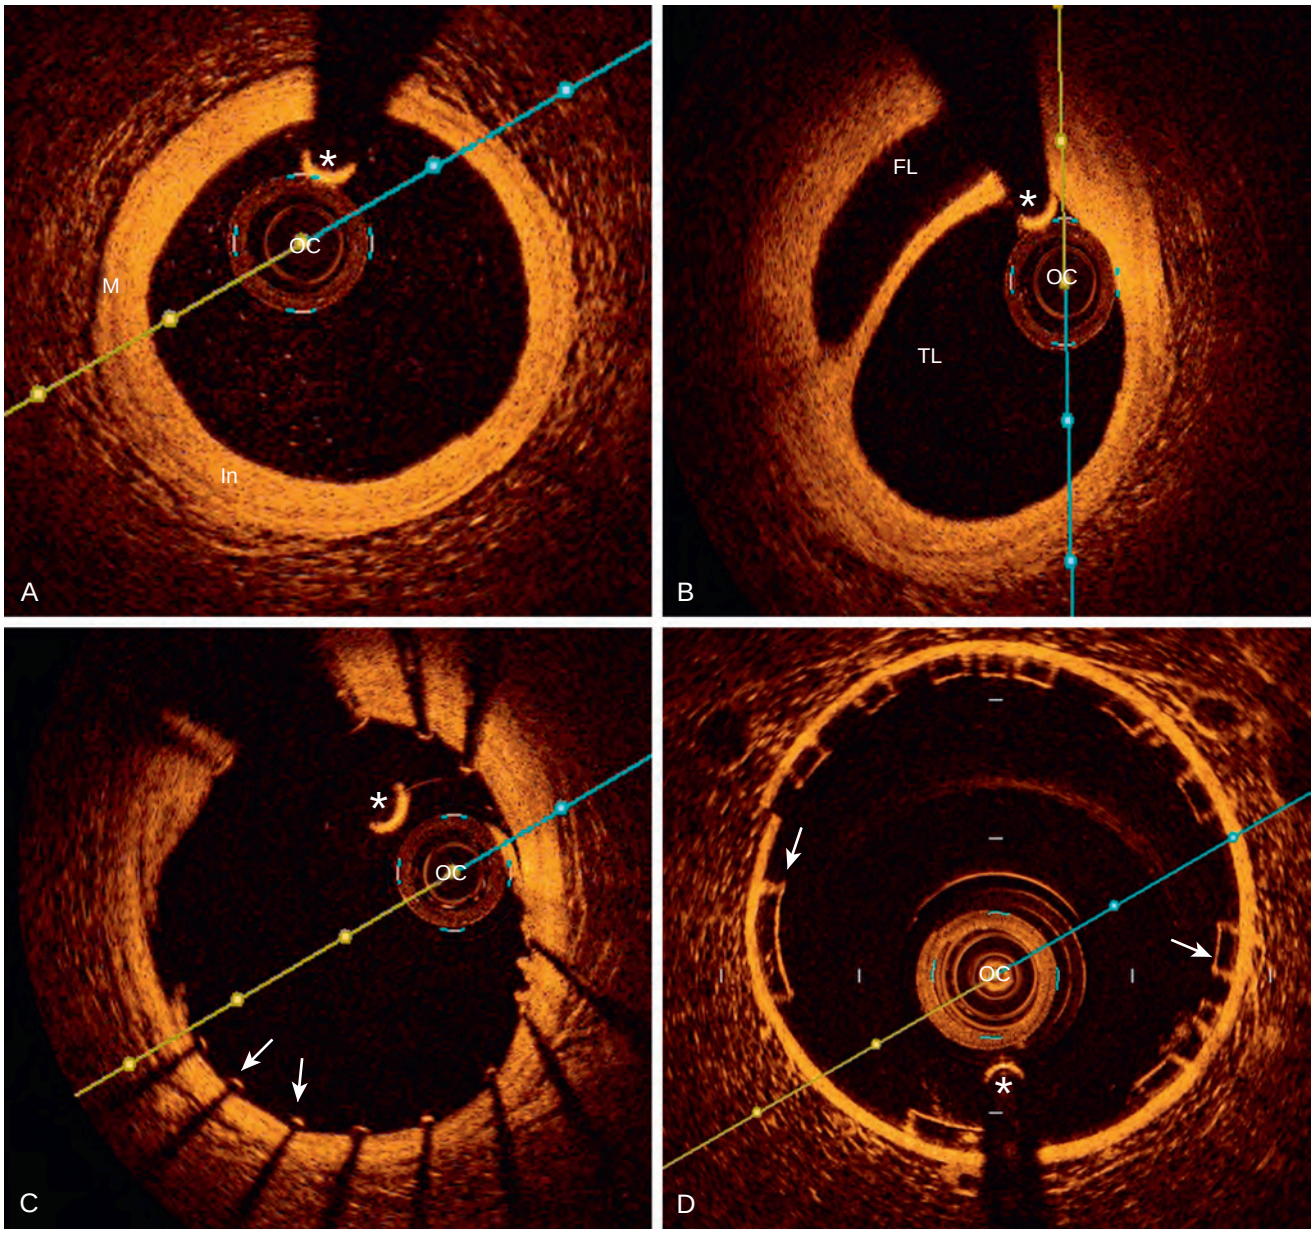

Fig. 7.22 Optical coherence tomography images. (A) Right coronary artery demonstrating mild intimal *(In)* thickening. The media *(M)* is represented by the thin dark band. (B) Resolution of a dissection flap with the wire in the true lumen *(TL)* and a clear false lumen *(FL)* present. (C) Stenotic atherosclerotic plaque after percutaneous coronary intervention with a drug-eluting metallic stent. *Arrows* represent stent struts. stenosis. Hyperemia is subsequently induced using adenosine (or less frequently nitroprusside), and the FFR ratio is calculated using the following formula:

$$FFR = P_{distal} / P_{proximal}$$

Typically, one would expect the flow to be equal throughout an artery (ie, a pre-to-post ratio of 1) without any stenosis. Studies have demonstrated that a reduced FFR value (ie, an FFR <0.75–0.8) is predictive of myocardial ischemia on noninvasive testing.[254] Although a correlation exists between angiographic and physiologic severity, this assumption does not always hold true because the drop in flow is a function not only of the degree of stenosis but also of the size of the vascular bed the coronary serves. Thus when assessing multiple intermediate lesions on angiography, FFR enables interventional cardiologists to identify functionally significant lesions and to target revascularization to those lesions for which revascularization will confer benefit.[255] Indeed, the FAME-I (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial randomized patients with multivessel CAD to undergo angiography-guided or FFR-guided PCI and demonstrated reduced rates of stent implantation, death, myocardial infarction, and repeat revascularization at 1 year.[120] This trial was followed by the FAME-II trial, which studied patients with multivessel CAD and similarly showed improved outcomes in patients who underwent physiologically guided PCI.[256]

Overall, coronary angiography remains the cornerstone of the assessment and management of obstructive CAD. However, novel intravascular assessment tools shed new light on the assessment of CAD at both an anatomic (IVUS, OCT) and a physiologic (FFR) level,

thus further refining both our approach to coronary intervention and our appreciation of underlying vascular biology.

Future Directions

A major need exists not only to identify but also to treat the vulnerable nonstenotic plaque that is prone to rupture. Although angiography is ideal for imaging the lumen of arteries, it provides little information about the atherosclerotic process within the vessel wall. Unfortunately, newer imaging techniques such as IVUS and OCT have yet to evolve as practical modalities that can be used to predict which patients are at risk for acute coronary syndromes secondary to plaque rupture. It is unlikely that either of these imaging modalities alone will be successful in identifying the at-risk patient or lesion; rather, biomarkers of risk will probably help identify patients in need of invasive assessment or medical intensification.[257,258]

Most recently, a focus on the adventitia of the coronary artery and its' role in initiation of inflammation in the vessel wall and subsequent development of atherosclerosis has been renewed.[11,259] Although much effort has been devoted to studying the intima and media in development of vascular lesions, the adventitia is just now garnering the focus it may deserve. The adventitia is unique in that it houses the vasa vasorum that provide nutrients and vasoactive factors and act as portals of entry for inflammatory cells into the media and intima of epicardial coronary arteries. Moreover, the adventitia alone supplies all neural input to the vessel wall, input that has been implicated in plaque progression and destabilization.[260] Supporting this notion of an "outside-in" hypothesis to the development of atherosclerosis is that changes in the adventitial vasa vasorum often precede intimal changes.[261] In addition to atherosclerosis, the adventitia has also been implicated as a source of cells in neointimal development after vascular injury such as balloon angioplasty.[262,263] Given the dynamic nature of the adventitia in disease and the unique role it serves in vessel homeostasis, an understanding of adventitial biology is lacking.

Finally, the need remains to identify genuine targets for lessening atherosclerotic burden outside of LDL reduction. To date, the most compelling clinical data support the ubiquitous use of statins in patients to prevent future clinical events. However, statin-associated muscle symptoms such as muscle pain, stiffness, or tenderness affect as many as one-third of treated patients and influence their quality of life and the ability to titrate therapy to target doses.[264] Data from the IMPROVE-IT (Improved Reduction of Outcomes: Vytorin Efficacy International Trial) trial suggested added benefit with the addition of ezetimibe in patients who have had acute coronary syndromes; this benefit was still derived by lowering LDL cholesterol levels. A novel class of agents, called PCSK9 inhibitors, is also under early clinical investigation and may offer a third class of agents, although these studies remain preliminary. Nonetheless, despite the ever increasing understanding of the molecular processes that underlie lesion development, investigators have failed to develop truly novel therapies that affect disease progress. The goal remains expanding an understanding of how anatomy, physiology, and biology influence disease development and progression to prevent rather than treat myocardial infarctions.

Molecular and Genetic Cardiovascular Medicine

AMANDA A. FOX, MD, MPH | SONAL SHARMA, MD |
J. PAUL MOUNSEY, BM BCh, PhD, FRCP, FACC | MARCEL E. DURIEUX, MD, PhD

KEY POINTS

1. The rapid development of molecular biologic and genetic techniques has greatly expanded the understanding of cardiac functioning, and these techniques are beginning to be applied clinically.
2. Cardiac ion channels form the machinery behind the cardiac rhythm; cardiac membrane receptors regulate cardiac function.
3. Sodium, potassium, and calcium channels are the main ion channel types involved in the cardiac action potential. Many subtypes exist, and their molecular structure is known in some detail, thus allowing a molecular explanation for phenomena such as voltage sensing, ion selectivity, and inactivation.
4. Muscarinic and adrenergic receptors, both of the G-protein–coupled receptor class, are the main regulators of cardiac function.
5. Adenosine plays important roles in myocardial preconditioning through an action on adenosine triphosphate–regulated potassium channels and is an effective antiarrhythmic drug by its action on G-protein–coupled adenosine receptors.
6. Volatile anesthetic agents significantly affect calcium channels and muscarinic receptors.
7. Powerful genetic analysis techniques are being used to better understand adverse cardiovascular events through molecular approaches. Research using these techniques has begun to explore links between genomics and perioperative adverse cardiovascular events.
8. Treatment through gene therapy is evolving in cardiovascular medicine, although it currently does not have a prominent role in the perioperative setting.

The past decades have witnessed what may be termed a revolution in the biomedical sciences, as molecular and genetic methodologies suddenly jumped onto the clinical scene. The birth of molecular biology is commonly identified with the description of the structure of deoxyribonucleic acid (DNA) by Watson and Crick in the 1950s.[1] For many years afterward, molecular biology was explored in research laboratories but was not translated into the clinical realm. During this time much molecular biology research focused on the laborious process of sequencing the human genome and identifying genes that encode specific proteins. Although at the time most workers in the field realized that these advances would one day be of immense importance to clinical medicine, the exact place that these advances would take was unclear.

Now, long since the discovery of the structure of DNA, the human genome has been sequenced completely. The development of the polymerase chain reaction, a technique of remarkable simplicity and flexibility, has dramatically increased the speed with which many molecular biology procedures can be performed, and it has allowed the invention of many new techniques. More recent years have seen the development of approaches allowing screening of large amounts of genetic material for changes associated with disease states. As a result of these and other developments, molecular biology has become a practical tool for studying the expression and functioning of proteins in health and disease.

Cardiovascular medicine has benefited from these advances. Not only have the electrophysiologic and pumping functions of the heart been placed on a firm molecular footing, but also the underlying molecular mechanisms have been determined for numerous pathologic cardiac states, thereby allowing progress in therapeutic development. Nothing indicates that the pace of progress in molecular biology is slowing down. If anything, the opposite is the case, and more dramatic advances may be expected in the years to come. Thus techniques such as gene therapy may become effective therapeutic options in cardiac disease.

This chapter reviews key aspects of molecular and genetic cardiovascular medicine, with specific emphasis on medical issues relevant to the anesthesiologist. The myocyte membrane signaling proteins are of prime importance in this respect, and the two major classes—membrane channels and membrane receptors—are discussed. Simply stated, membrane channels form the machinery behind cardiac rhythms, and the receptors are involved in regulation of cardiac function. This statement is, of course, an overgeneralization because close interactions among the various systems exist. In fact, the interactions between cardiac channels and receptors have stimulated some of the more exciting areas of investigation in molecular cardiovascular medicine. In describing each of these proteins, a brief overview of the general properties of the class is provided, and then several examples specific to the cardiovascular system are discussed. Each section ends with a discussion of some clinical correlates flowing from the material discussed.

The actions of anesthetic agents on the molecular mechanisms of cardiac function and dysfunction comprise an area of active investigation. Much detail remains to be filled in, but it is clear that anesthetic agents, at clinically relevant concentrations, interact with numerous cardiac signaling systems. Although it is too early to explain completely the cardiac effects of the various anesthetic agents through these mechanisms, no doubt exists that such interactions can be of significant clinical relevance. Considering the rapid pace of research in this area, rather than attempting to be all inclusive, this chapter discusses two investigational areas for which clinical relevance seems high: (1) function of cardiac calcium (Ca^{2+}) channels, and (2) the actions of the muscarinic acetylcholine (ACh) receptors.

The final section of this chapter looks at the role of genetics in cardiovascular medicine, again with emphasis on developments of relevance to adverse cardiovascular events after cardiac operations and procedures. Techniques for genetic diagnostic screening and their applications in the clinical setting are discussed. In addition, the potential of genetic therapy is described briefly, although at this time these advances do not yet influence the care of the cardiac surgical patient.

In addition to providing an overview of the current state of knowledge, this chapter demonstrates a few of the many methodologies that have been used to obtain these results, to enable the reader to access the current literature with more ease. In quoting the literature, the authors have therefore chosen to provide references to many of the original articles describing techniques and findings, complemented by references to more recent review articles to provide a current viewpoint.

Machinery Behind the Cardiac Rhythm: Ion Channels

The cardiac action potential results from the flow of ions through *ion channels,* which are the membrane-bound proteins that form the structural machinery behind cardiac electrical excitability. In response to changes in electrical potential across the cell membrane, ion channels open and allow the passive flux of ions into or out of the cell along their electrochemical gradients. This flow of charged ions results in a current, which alters the cell membrane potential toward the *equilibrium potential* (E) for the ion, which is the potential at which the electrochemical gradient for the ion is zero. Depolarization of the cell could, in principle, result from an inward cation current or an outward anion current; for repolarization, the reverse is true. In excitable cells, action potentials are mainly caused by the flow of cation currents. Membrane depolarization results principally from the flow of sodium (Na^+) down its electrochemical gradient (E_{Na} is approximately +50 mV), whereas repolarization results from the outward flux of potassium (K^+) down its electrochemical gradient (E_K is approximately −90 mV). Opening and closing of ion channels selective for a single ion result in an individual ionic current. The integrated activity of many different ionic currents, each activated over precisely regulated potential ranges and at different times in the cardiac cycle, results in the cardiac action potential. Ion channels are usually highly (but not uniquely) *selective* for a single ion, hence the terms *K^+ channels, Na^+ channels,* and so forth. Channels may *rectify,* that is, pass current in one direction across the membrane more easily than the other. Electrical and chemical stimuli, which lead to opening and closing of the channel, cause a conformational change in the channel molecule *(gating).* The rate of change of channel conformation *(gating kinetics)* may be rapid, in which case the channel opens *(activates)* almost immediately (eg, Na^+ channels), or relatively slowly, resulting in a delay in channel activation (eg, delayed rectifier K^+ channels). After activation, ion channels may stay open until closed by another stimulus (eg, repolarization of the membrane), or they may close *(inactivate)* in the presence of a continued stimulus. Inactivated channels do not usually reopen on repeat stimulation until they have recovered from inactivation (Box 8.1).

Patch Clamping

Much of the understanding of the molecular mechanisms behind the action potential derives from the development and implementation of three techniques: (1) *patch clamping,* which allows recording of ion flow through individual channel molecules; (2) *voltage clamping* of isolated cardiac cells; and (3) *cloning and heterologous expression* of ion channel genes. Comparison of ionic currents recorded in isolated myocytes with currents recorded from cells expressing ion channel genes resulted in the identification of many of the ion channel molecules that underlie the cardiac action potential.

The development of the voltage clamp technique in the early 1950s and its application to multicellular preparations of cardiac muscle allowed identification of the major ionic currents that underlie the cardiac action potential. The whole-cell currents recorded by the technique were smooth waveforms derived from summation of the activity of thousands of ion channels, and many different patterns of events at the single-channel level, arising from more than one molecular species, can summate to produce identical whole-cell current waveforms. Patch clamping allows resolution of events at the single-channel level. In this technique, small patches of cell membrane (<1 μm^2) are isolated electrically and physically in the tip of a glass micropipette.[2] Single-channel events can then be resolved because only a few ion channel molecules are present in the patch. Current flowing across the patch typically jumps between well-defined values corresponding to sudden opening and closing of the ion-conducting pore (Fig. 8.1A). The whole-cell current is the sum of the currents through all the individual channels in the cell membrane; summation of the current flowing through a single channel during repeated stimuli reproduces the macroscopic whole-cell current (see Fig. 8.1). As channel opening and closing in response to a stimulus are stochastic phenomena, the regulation of ion flow, whether resulting from a change in membrane potential or from

Currents are listed on the *left*, and the ion channel genes encoding the currents are listed on the *right*. *4-AP*, 4-Aminopyridine; *Ca^{2+}*, calcium; *CFTR*, cystic fibrosis transmembrane regulator; I_{Cl}, chloride current; I_{K1}, I_{Kr}, I_{Ks}, I_{KUR}, potassium currents; I_{TO}, transient outward current; *Na^+*, sodium. *(From Roden DM, Lazzarra R, Rosen R, et al. Multiple mechanisms in the long QT syndrome: current knowledge, gaps and future directions.* Circulation. *1996;94:1996.)*

interaction with regulator molecules, is usually achieved by altering the *probability* that the channel will be open. Thus in Fig. 8.1, which shows records from human cardiac muscle Na^+ channels, the channels open *(activate)* a few milliseconds after depolarization because the probability that the channel will be open increases. Similarly, as the channels spontaneously close *(inactivate)*, the open probability decreases.

An ion current with distinct electrical and pharmacologic properties indicates the presence of a population of identical ion channel molecules. Application of molecular techniques has allowed the identification of many ion channel molecules and hence a better understanding of the currents that underlie the cardiac action potential. Tailoring of pharmacologic agents that interact with specific channel types to shape the action potential is an unrealized dream.

BOX 8.2 CARDIAC ACTION POTENTIAL

Phase 0 (rapid upstroke): primarily Na^+ channel opening
Phase 1 (early rapid repolarization): inactivation of Na^+ current, opening of K^+ channels
Phase 2 (plateau phase): balance between K^+ and Ca^{2+} currents
Phase 3 (final rapid repolarizations): activation of Ca^{2+} channels
Phase 4 (diastolic depolarization): balance between Na^+ and K^+ currents

Ca^{2+}, Calcium; *K^+*, potassium; *Na^+*, sodium.

Electrical Events Underlying the Cardiac Action Potential

Fig. 8.2 shows a diagram of a cardiac action potential with a summary of the ionic currents flowing during each phase. The probable molecular identity of the ion channels that underlie these currents is also given. This section examines the biophysical properties of these currents; subsequent sections focus on possible molecular mechanisms underlying the biophysical phenomena.

Resting Membrane Potential and the Role of the Inwardly Rectifying Potassium Current

The resting cardiac membrane potential is maintained close to the equilibrium potential for K^+ (E_K) by a background, inwardly rectifying, highly selective K^+ current (I_{K1}). Under physiologic conditions, the E_K is approximately −90 mV, and displacement of the membrane potential from this value should result in an inward or outward current through I_{K1}, thus returning the membrane potential toward E_K. However, although I_{K1} passes significant *inward* current at potentials negative to E_K, at positive potentials, the channels display inward rectification (ie, they pass inward current more easily than outward current), which limits outward current flow and reduces the tendency for I_{K1} to hyperpolarize the membrane. This process has obvious significance for an excitable cell; inward rectification[3] allows the initiation of action potentials and limits cellular K^+ loss during the action potential. I_{K1} is large in ventricular cells, smaller in atrial cells, and almost absent in nodal tissue.[4] For this reason, ventricular cells rest near E_K and have a high threshold for excitation, atrial cells have a more positive resting potential, and nodal cells have no defined resting potential.

Phase 0: Rapid Upstroke of the Cardiac Action Potential

The rapid upstroke of the cardiac action potential (phase 0) is caused by the flow of a large inward Na^+ current (I_{Na}) (Box 8.2).[5] I_{Na} is activated by depolarization of the sarcolemma to a threshold potential of −65 to −70 mV. I_{Na} activation, and hence the action potential, is an all-or-nothing response. Subthreshold depolarizations have only local effects on the membrane. After the threshold for activation of fast Na^+ channels is exceeded, Na^+ channels open (ie, I_{Na} activates), and Na^+ ions enter the cell down their electrochemical gradient. This action results in displacement of the membrane potential toward the equilibrium

potential for Na^+ ions, approximately +50 mV. I_{Na} activation is transient, lasting at most 1 to 2 ms because, simultaneous with activation, a second, slightly slower conformational change in the channel molecule occurs: inactivation, which closes the ion pore in the face of continued membrane depolarization (see Figs. 8.1A and B). The channel cannot open again until it has recovered from inactivation (ie, regained its resting conformation), a process that requires repolarization to the resting potential for a defined period. Thus the channels cycle through three states: (1) *resting* (and available for activation), (2) *open,* and (3) *inactivated*. While the channel is inactivated, it is absolutely refractory to repeated stimulation. Stimuli that occur during recovery from inactivation result in opening of fewer Na^+ channels (because not all have recovered), and the subsequent action potential has a reduced maximal rate of depolarization and slower conduction velocity. Na^+ channels do not need to open to become inactivated. If the resting membrane potential depolarizes for some time, inactivation will occur in some channels, and subsequent stimulation will result in an action potential of reduced amplitude and conduction velocity.

Phase 1: Early Rapid Repolarization

The early rapid repolarization phase of the action potential, which follows immediately after phase 0, results both from rapid inactivation of the majority of the Na^+ current and from activation of a transient outward current (I_{TO}), carried mainly by K^+ ions. On depolarization of the membrane, I_{TO} activates rapidly, over approximately 20 ms, before spontaneously inactivating. I_{TO} comprises two separate currents: the rapidly inactivating I_{TO1}, which is activated by depolarization and blocked by 4-aminopyridine; and the slowly inactivating I_{TO2}, which is activated by elevated intracellular Ca^{2+} (possibly explaining the observation that action potential duration tends to decrease with rapid heart rates and hypercalcemia)[6,7] (Fig. 8.3).

In addition to its effect on phase 1, I_{TO}, in combination with the delayed rectifier K^+ currents (I_{Kr} and I_{Ks}) and I_{K1}, also contributes to membrane repolarization. Arrhythmogenic prolongation of the action potential in myocardial cells recovered from patients with myocardial hypertrophy[8] and congestive cardiomyopathy,[6] as well as from the border zone of myocardial infarction (MI) in animals,[9] appears to result from depression of I_{TO}.

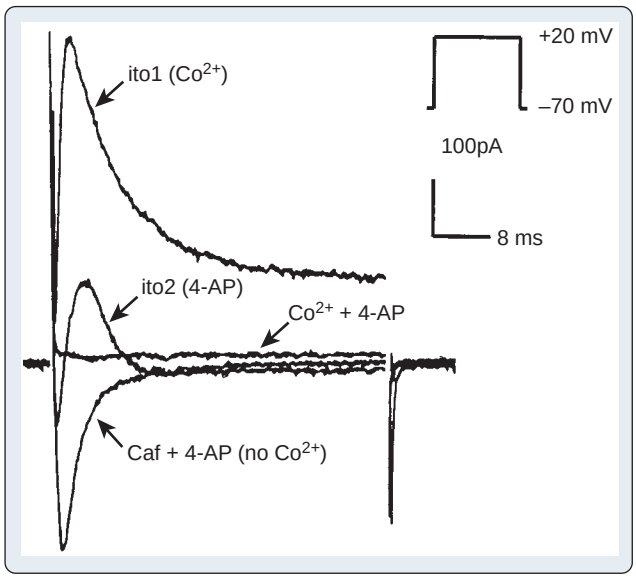

Fig. 8.3 Voltage clamp recordings from an atrial myocyte showing pharmacologic separation of transient outward current 1 ($I_{TO1;}$ *ito1*) and I_{TO2} *(ito2).* In the presence of cobalt ions *(Co^{2+}),* only I_{TO1} is seen. When Co^{2+} is omitted and 4-aminopyridine *(4-AP)* is added, I_{TO2} is revealed. Caffeine *(Caf)* eliminates I_{TO2}, thus leaving the underlying inward calcium current. In the presence of both 4-AP and Co^{2+}, all outward currents are inhibited. *(From Wang Z, Fermini B, Nattel S. Delayed rectifier outward current and repolarization in human atrial myocytes.* Circ Res. *1993;73:276.)*

Phases 2 and 3: Plateau Phase and Final Rapid Repolarization

The action potential plateau and final rapid repolarization are mediated by a balance between the slow inward current and outward, predominantly K^+ current. During the plateau phase, membrane conductance to all ions falls, and very little current flows. K^+ conductance is low because of inward rectification of I_{K1} (ie, inward current passes more easily than outward current), so little outward current flows despite the large outward electrochemical gradient for K^+ ions and the delayed onset of the outwardly rectifying K^+ currents (I_{Ks}, I_{Kr}, and I_{Kur}). The resulting small outward current is balanced by inward current, predominantly through L-type Ca^{2+} channels ($I_{Ca\text{-}L}$), but also through a slowly inactivating population of Na^+ channels and a small inward flux of chloride (Cl^-) ions, possibly carried by the cardiac variant of the adenosine triphosphate (ATP)–dependent channel (abnormalities of which underlie cystic fibrosis).[10,11] Phase 3, regenerative rapid repolarization, results from time-dependent inactivation of L-type Ca^{2+} current and increasing outward current through delayed rectifier K^+ channels. The net membrane current becomes outward, and the cell repolarizes.

Slow Inward Calcium Current

The slow inward current ($I_{Ca\text{-}L}$) is activated by depolarization of the cell to potentials less negative than −40 to −50 mV. In ventricular and atrial myocytes and in Purkinje fibers, $I_{Ca\text{-}L}$ is activated by the regenerative depolarization caused by I_{Na} during phase 0 of the action potential. $I_{Ca\text{-}L}$ does not contribute significantly to phase 0 because, in comparison with I_{Na}, it activates much more slowly (over approximately 10 ms) and is smaller in amplitude. $I_{Ca\text{-}L}$ also inactivates slowly and therefore contributes the major inward current during the plateau of the action potential. $I_{Ca\text{-}L}$ flows through L-type (long-lasting) Ca^{2+} channels, which are sensitive to block by dihydropyridines (eg, nifedipine), and activation of contraction is related to the magnitude of the resulting Ca^{2+} influx.[12] Gating of $I_{Ca\text{-}L}$ is generally similar to I_{Na} in that channel opening and closing depend on membrane potential and time. Ca^{2+} channels are also dynamically regulated by the autonomic nervous system.[13] β-Agonists activate $I_{Ca\text{-}L}$ (and hence increase myocardial contractility) indirectly by activating adenylyl cyclase through a guanosine triphosphate (GTP)–binding protein, G_s (Fig. 8.4). The resulting increase in intracellular cyclic adenosine monophosphate (cAMP) activates protein kinase A (PKA), which phosphorylates the Ca^{2+} channel. Phosphorylated channels open in response to membrane depolarization; nonphosphorylated channels do not, so the effect of β-adrenergic stimulation is to increase the number of functional channels. The electrophysiologic result is illustrated in Fig. 8.5, which shows enhancement of the slow inward current by increase of AMP level in single-channel Ca^{2+} channels and intact cells. β-Adrenergic effects on $I_{Ca\text{-}L}$ are antagonized by ACh, which, in myocardial cells, activates M_2 muscarinic receptors and inhibits adenylyl cyclase through activation of the GTP-binding protein G_i.

In the relatively depolarized pacemaker cells, which lack I_{K1}, I_{Na} is inactivated, and the slow inward current is solely responsible for the upstroke of the action potential. $I_{Ca\text{-}L}$ also can generate slowly propagated action potentials in diseased or damaged myocardial cells in which I_{Na} has been inactivated by depolarization. These *slow responses,* which may occur in the border zone of MIs, are important because they may cause the slow conduction that can lead to reentrant arrhythmias.

Delayed Rectifier Potassium Currents

Delayed rectifier K^+ channels are present in all cardiac myocytes. They open slowly (over 200 to 300 ms) after depolarization of the membrane to the plateau level (−10 mV and greater), and produce a K^+-selective outward current, I_K. I_K does not inactivate on prolonged depolarization (unlike I_{Na} and $I_{Ca\text{-}L}$), and the channels close on repolarization of the membrane. Unlike I_{K1}, I_K displays outward rectification (ie, it passes

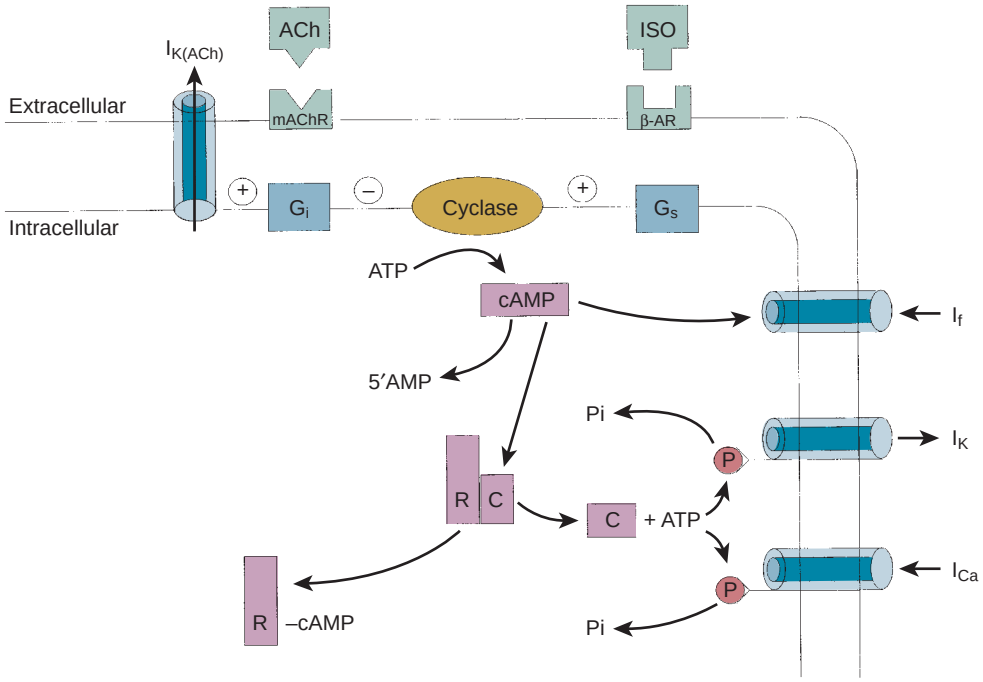

Fig. 8.4 Autonomic regulation of ion currents. *ACh,* Acetylcholine; *5′AMP,* adenosine 5′- monophosphate; *β-AR,* β-adrenergic receptor; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *Cyclase,* adenylyl cyclase; G_i and G_s, guanosine triphosphate–binding proteins; I_{Ca}, calcium current; I_f, pacemaker current; I_K and $I_{K(ACh)}$, potassium currents; *ISO,* isoproterenol; *mAChR,* M_2 muscarinic receptor; *P,* phosphate; *Pi,* pyrophosphate; *R* and *C,* regulatory and catalytic subunits, respectively, of protein kinase A.

outward current more easily than inward current). This is expected behavior for a K^+-selective channel because both the concentration and electrical gradients for K^+ are outward. Thus for any depolarizing displacement of membrane potential from E_K, the driving force is larger in an outward direction. Similar to $I_{Ca\text{-}L}$, I_K is under autonomic control (see Fig. 8.4). β-Adrenergic stimulation enhances I_K by a mechanism similar to that of the enhancement of $I_{Ca\text{-}L}$, thus ensuring repolarization of the cell in the presence of increased inward Ca^{2+} current.[14]

Three components of I_K, carried by different channel molecules, can be distinguished. A rapidly activating component, I_{Kr}, is blocked by the compound E4031 (a class III antiarrhythmic agent), which leaves a slower activating component, I_{Ks}, unaffected.[15] This process is illustrated in Fig. 8.6, which also emphasizes the importance of I_K in the regulation of repolarization and hence of action potential duration. A third component, the ultrarapidly activated delayed rectifier, I_{Kur}, can be distinguished in atrial (but not ventricular) myocytes.[16] This additional repolarizing current partly explains the enhancement of repolarization in atrial myocardium when compared with ventricle and Purkinje fibers.

Repolarization in Different Cardiac Tissue Types

Phase 3 repolarization in atrium and pacemaker tissues, but not in ventricular myocardium, is also enhanced by the presence of a large outward repolarizing K^+ current ($I_{K[ACh]}$).[17,18] This potential independent current is activated indirectly by stimulation of muscarinic (M_2-type) receptors by ACh or purinergic (A-type) receptors by adenosine.[19] This channel is potential independent and is activated by binding of an activated, membrane-bound GTP-binding protein (G_i), as discussed later.[20]

Action potential duration varies among cells in normal ventricle.[21] A gradient in action potential duration exists across the myocardium (from epicardium to endocardium), and specialized midmyocardial cells (M cells) have been identified that exhibit prolongation of action potential duration at slow stimulation rates, possibly as a result of a decrease in I_{Ks}.

Phase 4: Diastolic Depolarization and Pacemaker Current

Phase 4 diastolic depolarization, or normal automaticity, is a normal feature of cardiac cells in the sinus and atrioventricular nodes, but subsidiary pacemaker activity is also observed in the His-Purkinje system and in some specialized atrial and ventricular myocardial cells (see Chapter 4). Pacemaker discharge from the sinus node normally predominates because the rate of diastolic depolarization in the sinoatrial node is faster than in other pacemaker tissues. Pacemaker activity results from a slow net gain of positive charge, which depolarizes the cell from its maximal diastolic potential to threshold.

Pacemaker cells in the sinus node are relatively depolarized, with a maximal diastolic potential of −60 to −70 mV and a threshold potential of −40 mV. Rapid regenerative depolarization (phase 0) depends on opening of T-type and then L-type Ca^{2+} channels. Repolarization is dependent on activation of delayed rectifier K^+ channels, and the maximum diastolic potential is approximately −80 mV. Pacemaker channels are activated by hyperpolarization to this potential and produce a slow inward Na^+ current, I_f. This current flows against slowly inactivating delayed rectifier K^+ currents and results in diastolic depolarization.[22] Because the current is nonselective among cations, its reversal potential lies between E_K and E_{Na}, at approximately −10 mV, and activation of I_f tends to depolarize the cell toward this value. Similar to $I_{Ca\text{-}L}$, I_f is under autonomic control (see Fig. 8.4) through GTP-dependent binding proteins G_s and G_i, which regulate cAMP production by adenylyl cyclase.[23,24] β-Adrenergic stimulation shifts the voltage dependence of activation of I_f to more depolarized potentials, so for any hyperpolarizing stimulus, more I_f is activated and diastolic depolarization is enhanced. ACh has the opposite effect (Fig. 8.7).

Molecular Biology of Ion Channels

The preceding sections focus on the electrical events that underlie cardiac electrical excitability and on the identification of cardiac ionic currents on the basis of their biophysical properties. This section

reviews the molecular structures behind these electrical phenomena. The first step in understanding the molecular physiology of cardiac electrical excitability is to identify the ion channel proteins responsible for the ionic currents. Fig. 8.2 gives the current classification of the ion channel responsible for each of the cardiac ionic currents. Voltage-gated Na^+ and L-type Ca^{2+} channels have firm molecular candidates. Similarly, channel molecules with properties similar to delayed rectifier K^+ channels, the 4-aminopyridine–sensitive component of I_{TO}, the inward rectifier I_{K1}, the ligand-gated K^+ channel $I_{K(ACh)}$, and the pacemaker current I_f have been cloned. Fig. 8.8 shows diagrams of

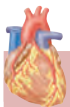
the predicted membrane topology of some of these channels. Voltage-gated Na^+, Ca^{2+}, and K^+ channels exist as conglomerates of molecules, consisting of a large α subunit and several accessory subunits (labeled β, γ, and δ in Fig. 8.8). The α subunit alone is usually sufficient to induce channel activity in biologic membranes, but its activity is modulated by the presence of the accessory subunits. The diagrams in Fig. 8.8 were deduced from hydrophobicity analysis of the primary structure of the major channel polypeptides. Regions of the polypeptides predicted to span the membrane are those that contain a high concentration of hydrophobic amino acids, whereas peptides linking these transmembrane sections are hydrophilic. Similarities among the various channels strongly suggest a common evolutionary ancestry. Na^+ and Ca^{2+} channel α subunits (see Figs. 8.8A and B) are strikingly similar, each consisting of four homologous transmembrane domains (labeled I to IV), linked by cytoplasmic peptides. Each homologous domain contains six linked membrane-spanning segments (labeled S1 to S6). These large polypeptides, containing more than 2000 amino acids, form a tetrameric structure and generate Na^+ or Ca^{2+} channel activity in biologic membranes. Voltage-gated K^+ channel α subunits, in contrast, are much smaller (see Fig. 8.8C) and consist of a single transmembrane domain with six membrane-spanning segments, an arrangement similar to one of the individual domains of Na^+ and Ca^{2+} channels. Four molecules are noncovalently linked in the membrane to produce a tetrameric structure, similar to an Na^+ or Ca^{2+} channel, to produce K^+ channel activity. The structure of the inwardly rectifying K^+ channel molecules, I_{K1} and $I_{K(ACh)}$, is dissimilar to that of other K^+ channels (see Fig. 8.8C). The molecules are much less complex, having only two membrane-spanning segments, although these segments share considerable homology with the S5 and S6 segments of the classic voltage-gated K^+ channel.

Voltage-gated ion channel activity requires that the channel molecule should sense and respond to changes in membrane potential, form an ion-selective membrane pore, and (in some cases) inactivate despite continuing depolarization. The molecular mechanisms for these phenomena are examined in separate sections later.

Molecular Mechanisms

Voltage Sensor

Channel proteins respond to changes in electrical potential across the cell membrane by conformational changes *(gating)* that result from electrostatic interactions between charged portions of the molecule and the membrane electric field (Box 8.3). Gating of the channel is associated with a measurable flow of electrical charge through the membrane lipid bilayer (called *gating current*), as a zone of the molecule rich in electrical charge moves within the membrane.[25] This charge movement is linked to opening of the channel pore. The voltage sensor of voltage-dependent ion channels resides in the mobile S4 membrane-spanning segments, α-helical structures unusually rich in positively charged amino acids.[26] At rest, each of the positive charges in the S4 segment is balanced by fixed negative charges in other segments of the molecule. The resting membrane potential (negative inside) forces the (mobile) positive charges inward and the fixed negative charges outward. This dynamic equilibrium holds the channel pore closed. On depolarization, the force pulling the positive charge inward is relieved; positive charges (the S4 segments) are repelled outward and assume new partners with the fixed negative membrane charges. This charge movement comprises the *gating current*. If the depolarizing stimulus is short, repolarization of the membrane is followed by a gating current of equal and opposite magnitude as the S4 segment relaxes to its original position. If the depolarizing stimulus is prolonged, however, the movement of the S4 segments induces a conformational change in the channel molecule, which prohibits easy return to baseline. This conformational change in the channel molecule is manifested as activation (or channel opening), which is closely coupled to channel closing (or inactivation in channels that inactivate; see later). Thus small changes in the membrane electric field cause conformational changes in the channel molecule that result in opening (and closing) of the channel pore. An S4 segment rich in positive charge is a remarkably consistent feature of voltage-gated ion channels from numerous different species and with various ion selectivities. The dependence of channel activation on membrane potential is proportional to the density of positive charge in the S4 segment.



BOX 8.3 MOLECULAR MECHANISMS OF ION CHANNELS

Selectivity filter

Ion Channel Pore and Selectivity Filter

The presence of four homologous domains in voltage-gated Na^+ and Ca^{2+} channels suggests that basic ion channel architecture consists of a transmembrane pore surrounded by the four homologous domains arranged symmetrically (see Fig. 8.8). The membrane-spanning segments each form an α helix, so the walls of the pore are derived from α-helical segments from each of the four domains. A pore formed from four such α helices would have limiting dimensions of 3 by 5 Angstrom units, similar to the size inferred for the Na^+ channel pore by measurement of the permeability of cations of different sizes.[27,28]

The selectivity filter is formed by the S5 and S6 membrane-spanning segments of each domain together with their peptide linker.[29] As emphasized in Fig. 8.8, unlike the hydrophilic extracellular linkers between other membrane-spanning segments, the S5/S6 linker is sufficiently hydrophobic to place it (at least partially) within the membrane lipid bilayer. The channel pore is lined both by the S5/S6 linker and the S5 and S6 membrane-spanning segments. Point mutations in the S5/S6 linker have dramatic effects on channel ion selectivity and reduce channel conductance to its primary ion. Extensive site-directed mutagenesis experiments of the S5/S6 linkers from various channels suggest that these linkers form a funnel that allows the passage of a specific ion into the pore. In Na^+ channels, selectivity is imposed by two rings of negatively charged amino acids at the outer mouth of the funnel, which collect Na^+ ions for transmission into the cell.[27]

Channel Inactivation

Inactivation gating is the process by which ion channels close in the presence of continuing depolarization. Inactivation is characteristic of voltage-gated Na^+ and Ca^{2+} channels, as well as the K^+ channels underlying I_{TO}. Inactivation begins after activation gating as a second, slower conformational change in the molecule that halts the ion flux through the channel. Inactivation gating is thus closely coupled to activation gating, and ionic current flows only while both the activation and inactivation gates are open simultaneously. In Na^+ channels, the inactivation gate is formed by the intracellular peptide linker between homologous domains III and IV (Fig. 8.9A).[30] This peptide is postulated to act as a hinged lid, which moves upward to plug the ion pore (and thus halt current flow) shortly after membrane depolarization.[26] For the channel to recover from inactivation (ie, to be ready to open in response to a new depolarizing stimulus), the III/IV linker peptide must resume its resting position, a process that requires hyperpolarization of the membrane to the resting potential for a finite period. Site-directed mutagenesis of the III/IV linker peptide has revealed a trio of hydrophobic amino acid residues (isoleucine [I], phenylalanine [F], and methionine [M]), near the domain III end of the peptide, that are crucial for normal channel inactivation. Replacement of just one of these residues (the phenylalanine) almost completely removes inactivation. These residues are postulated to latch onto a receptor in the channel pore to close the channel.

The molecular basis of inactivation in K^+ channels is different from that in Na^+ channels. Because the four domains of K^+ channels are

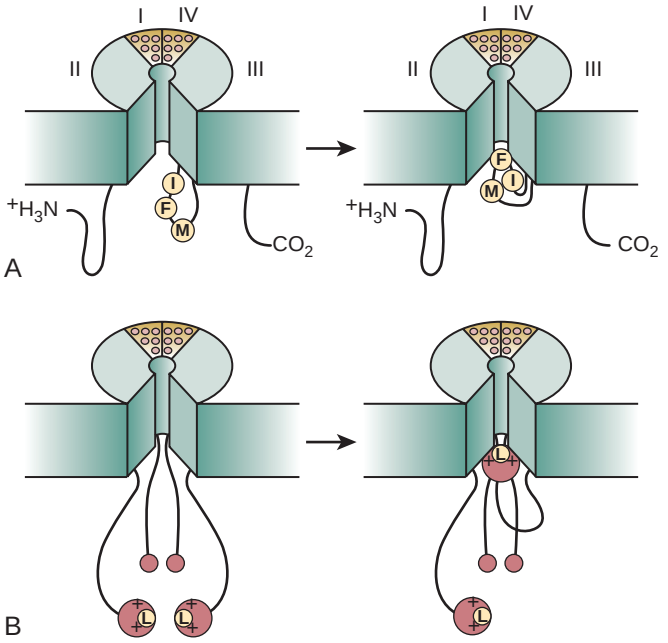

Fig. 8.9 Mechanism of inactivation of sodium *(Na^+)* and potassium *(K^+)* channels. (A) Hinged-lid mechanism of Na^+ channel inactivation. formed by noncovalently linked molecules, no interdomain linkers exist to plug the channel pore. In K^+ channels, a picture of an N-terminal ball-and-chain mechanism has emerged (see Fig. 8.9B).[31] The terminal 20 or so amino acids are very hydrophobic and are postulated to swing up and attach to the open pore. The next few amino acids contain several positively charged residues that draw the whole N-terminal end up to the membrane. These two domains act as a ball. The remaining amino acids, up to the beginning of the transmembrane S1 segment, act as a chain. If the chain is made longer, inactivation is slower, and vice versa.

Clinical Correlates

Ion Channels and Antiarrhythmic Drugs

Drug therapy of cardiac arrhythmias would ideally be targeted at an individual ionic current, thereby tailoring the cardiac action potential in such a way that abnormal excitability is reduced but normal rhythmicity is unaffected. This goal remains unrealized. The prototype antiarrhythmic agents (eg, disopyramide and quinidine) have diverse effects on cardiac excitability and, similar to agents introduced more recently, frequently exhibit significant proarrhythmic activity with potentially fatal consequences. In the Cardiac Arrhythmia Suppression Trial (CAST), the mortality rate among asymptomatic patients after MI was approximately doubled by treatment with the potent Na^+ channel-blocking agents encainide and flecainide, an effect likely attributable to slowing of conduction velocity with a consequent increase in fatal reentrant arrhythmias.[32] The results of CAST prompted efforts to approach antiarrhythmic drug therapy by prolonging action potential duration (eg, dofetilide), a strategy with some support from animal studies, but one that also may cause proarrhythmia through induction of polymorphic ventricular tachycardia (the acquired long QT syndrome [LQTS]).[33] Drugs that prolong action potential duration all block I_{Kr}, and it is not clear that this therapeutic goal will result in arrhythmia control without induction of clinically significant proarrhythmia. The only drugs currently available that definitely prolong life by reducing fatal arrhythmias are β-blockers (eg, the First International Study of Infarct Survival [ISIS-1], 1997), and these agents have no channel-blocking effects.

TABLE 8.1 Major Long QT Syndromes and Genes

Type	*Gene*	*Current*	*Chromosome*	*Comment*

I_{Kr}, Inward rapidly activating potassium current; *I_{Ks}*, inward slowly activating potassium current; *I_{Na}*, inward sodium current; LQT1 to 3, long QT syndrome 1 to 3.

Ion Channels in Disease

Elucidation of the molecular mechanisms of the cardiac action potential is beginning to have a direct impact on patient management. This is most obvious in patients with inherited genetic abnormalities of ion channels that lead to cardiac sudden death. Two groups of diseases illustrate this point: LQTS and Brugada syndrome. An understanding of the molecular mechanism of cardiac electrical excitability is also starting to lead to the emergence of gene therapies and stem cell therapies that may in the future allow manipulation of cardiac rhythm and function.

Long QT Syndromes

LQTSs are estimated to occur in as many as 1 in 2000 people.[34] These syndromes are caused by inherited abnormalities that prolong the cardiac action potential and can result in early afterdepolarizations (ie, oscillations in the action potential during the plateau phase) that can trigger extrasystoles and death from polymorphic ventricular tachycardia (torsades de pointes).[35] To date, 15 LQTS subtypes have been identified and classified on the basis of the affected gene.[34,35] Three genes account for approximately 75% of diagnosed cases of LQTS (Table 8.1).[34,35] LQTS results from abnormally prolonged cardiac repolarization caused by either enhancement of inward depolarizing current or reduction of outward current. LQT3 is mediated by a gain-of-function mutation of the cardiac Na^+ channel that results in slow or incomplete channel inactivation, most commonly from a deletion of three amino acids from the inactivation gate.[35] LQT1 and LQT2 result from loss-of-function mutations of the slowly activating and rapidly activating delayed rectifier K channels, I_{Ks} and I_{Kr}, respectively. LQT5 and LQT6 result in reductions of I_{Kr} and I_{Ks} function through mutations in channel accessory subunits. Loss of repolarizing current prolongs the QT interval, and this leads to the syndrome. LQT4 is unique in that it results from a mutation in ankyrin B, an adapter protein that binds to the Na^+ pump and Na^+/Ca^{2+} exchanger. The resulting effects on cellular Ca^{2+} homeostasis cause ventricular arrhythmias.[36] Identification of the molecular substrate for LQTS allows detection of the disease in asymptomatic carriers and helps determine treatment. β-Blockers (preferably those with longer half-life such as propranolol or nadolol) are considered first-line therapeutic agents for LQT1 and LQT2, whereas Na^+ channel blockers are considered for LQT3.[35] Stem cell and gene therapy research is being performed, and investigators are reporting inroads into potential translation to clinical treatment of patients with inherited LQTS.[37–40]

Brugada Syndrome

The Brugada syndrome comprises a group of ion channel abnormalities that affect cardiac repolarization and can result in cardiac sudden death from polymorphic ventricular tachycardia and ventricular fibrillation. Brugada syndrome is characterized by incomplete right bundle branch block and persistent ST-segment elevation in the anterior precordial leads of the electrocardiogram (ECG).[41] Although two-thirds of patients with Brugada syndrome have no known genetic cause of

the disorder, variants within 19 different genetic loci have been associated with the findings in Brugada syndrome on the ECG. These genes involve cardiac Na^+, Ca^{2+} and K^+ channels.[35,42] The genetic variant most frequently identified in patients with Brugada syndrome is within the *SCN5A* gene on chromosome 3. This channel mutation reduces depolarizing Na^+ current. This results in loss of the action potential dome, an effect that is most marked in the right ventricular epicardium where the transient outward current I_{TO1} is strongly expressed (hence the ST-segment elevation in the anterior chest leads on the ECG). Early repolarization of the epicardial action potential results in a transmural repolarization gradient, and this can lead to reentry and sudden cardiac death.[43] Work remains to be done to elucidate the full spectrum of molecular mechanisms contributing to this condition.

Controlling Cardiac Functioning: Receptors

Receptors are membrane proteins that transduce signals from the outside to the inside of the cell. When a *ligand*—a hormone carried in blood, a neurotransmitter released from a nerve ending, or a local messenger released from neighboring cells—binds to the receptor, it induces a conformational change in the receptor molecule. This process changes the configuration of the intracellular segment of the receptor and results in activation of intracellular systems, with various potential effects ranging from enhanced phosphorylation and changes in intracellular (second) messenger concentrations to activation of ion channels.

Receptor Classes

Receptors are grouped in several broad classes, and the most important are the *protein tyrosine kinase receptors* and the *G-protein–coupled receptors* (GPCRs). The protein tyrosine kinase receptors are large molecular complexes that incorporate phosphorylating enzyme activity in the intracellular segment. Ligand binding induces activation of this enzyme activity. Because phosphorylation is one of the major mechanisms of cellular regulation (see, for example, the phosphorylation of the Ca^{2+} channel described earlier), such receptors can have numerous cellular effects (Box 8.4). GPCRs are much smaller than protein tyrosine kinase receptors. Ligand binding results in activation of an associated protein *(G protein)* that subsequently influences cellular processes. The receptors discussed in this section all belong to the GPCR superfamily, and the properties of this class are discussed in some detail.

The number of GPCRs is large. For more than 100 receptors, function has been defined. In addition, the olfactory epithelium expresses hundreds of GPCRs, which are thought to mediate the sense of smell, and another large group, with unknown function, is expressed on sperm cells. Taken together, the superfamily has more than 1000 members.

All these receptors have similar molecular characteristics. They are generally several hundred to 1000 amino acids in length and contain 7 stretches of 20 to 25 hydrophobic amino acids. These hydrophobic domains are thought to form α helices and traverse the membrane, thus anchoring the receptor to the cell (Fig. 8.10). For this reason, the family is often referred to as the seven transmembrane family. Although crystallographic data are not yet available for the clinically relevant GPCRs, the seven-transmembrane domains are believed to be arranged in a funnel-like structure, the inside of which forms the ligand-binding domain. The intracellular domains, particularly the third intracellular loop and the C terminus, bind to the G protein.

The heart and blood vessels express various GPCRs. The β-adrenergic and muscarinic ACh receptors are those most important for regulation of cardiac functioning, but several others play relevant modulatory roles. These include the α-adrenergic, adenosine A_1, ATP, histamine H_2, vasoactive intestinal peptide (VIP), and angiotensin II receptors.

G Proteins

G proteins (GTP-binding proteins) have two families: the small (cytoplasmic) G proteins and the heterotrimeric (membrane) G proteins. Common to both groups is their mechanism of function. In their resting state, they bind a molecule of guanosine diphosphate (GDP). When activated by a GPCR (in the case of heterotrimeric G proteins) or by an intracellular messenger (in the case of cytoplasmic G proteins), this GDP is exchanged for a GTP molecule. The activated G protein can now perform functions within the cell, as discussed later, until it is inactivated when an intrinsic enzyme activity hydrolyzes the GTP to a GDP. The critical point about this hydrolytic activity is that it is (molecularly speaking) very slow, on the order of seconds. As a result, brief activation of a receptor (on the order of milliseconds) can lead to more prolonged activation of the intracellular signaling machinery.

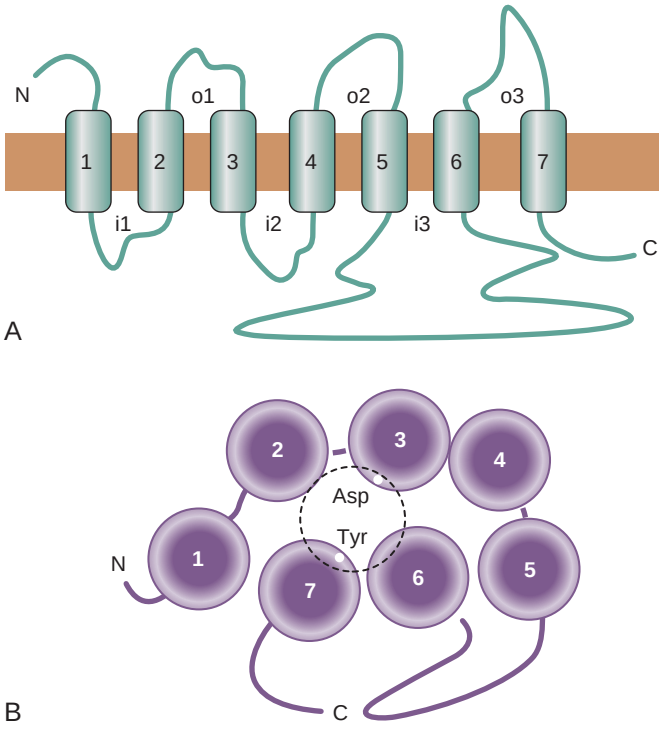

Fig. 8.10 Model of G-protein–coupled receptor. (A) Linear model. Seven hydrophobic stretches of approximately 20 amino acids are present, presumably forming α-helices that pass through the cell membrane, thus forming seven transmembrane domains (*t1* to *t7*). Extracellularly, the amino terminus *(N)* and three outside loops (*o1* through *o3*) are found; intracellularly there are similarly three loops (*i1* through *i3*) and the carboxy terminus *(C)*. (B) *Top-down view.* Although in (A), the molecule is pictured as a linear complex, the transmembrane domains are thought to be in close proximity, forming an ellipse with a central ligand-binding cavity *(dashed circle)*. Asp and Tyr refer to two amino acids important for ligand interaction. G-protein binding takes place at the i3 loop and the carboxy terminus.

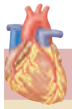
BOX 8.4 G-PROTEIN–COUPLED RECEPTORS

β-Adrenergic receptors
α-Adrenergic receptors
Muscarinic acetylcholine receptors
Adenosine A_1 receptors
Adenosine triphosphate receptors
Histamine H_2 receptors
Vasoactive intestinal peptide receptors
Angiotensin II receptors



BOX 8.5 G-PROTEIN CLASSES

G_s: activates adenylate cyclase
G_i: inhibits adenylate cyclase
G_q: activates phospholipase C
G_o: subtype of G_i, found mostly in brain; activates phospholipase C
G_k: subtype of G_i, linked to K^+ channels

GPCRs bind to *heterotrimeric* G proteins, so called because they consist of three subunits: α, β, and γ. Of these, the β and γ subunits are so tightly associated that, for practical purposes, they can be viewed as a single unit, often termed the βγ unit. The α subunit contains both the GDP-GTP binding domain and the hydrolytic activity, and it was classically thought to be the "business end" of the molecule, with the βγ unit roaming freely and inactively, serving as an anchor and a sink of free α units. This turns out not to be the case; the βγ subunit has activating functions as well, as discussed later in relation to the muscarinic K^+ channel.

Several classes of heterotrimeric G proteins exist, indicated by subscripts (Box 8.5). The classic types are G_s and G_i, which stimulate and inhibit, respectively, the enzyme adenylate cyclase, thereby leading to changes in cytoplasmic cAMP concentrations. G_q proteins (and G_o in brain) activate phospholipase C (PLC) and thereby induce the generation of inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG) from phosphatidylinositol bisphosphate (PIP_2). IP_3 acts on its own receptor-channel complex on intracellular Ca^{2+} storage sites and induces release of Ca^{2+} from these sites, thus increasing intracellular Ca^{2+} concentrations. DAG activates protein kinase C (PKC), an action leading to phosphorylation of various targets (including the receptors that initiated the cascade). Cloning efforts have shown each of these classes of G proteins to consist of several members, but their functional differences are incompletely defined.

Adrenergic Receptors and Signaling Pathways

Adrenergic Receptors

Main control over cardiac contractility is provided by the β-adrenergic signaling pathways, which can be activated by circulating catecholamines (derived from the adrenal glands) or those released locally from adrenergic nerve endings on the myocardium.

The two main subtypes of β-adrenergic receptors are the β_1 and β_2 subclasses. A β_3 subtype also exists, but its role in the cardiovascular system is unclear[44]; its most important role is in fat cells. Both β_1- and β_2-receptors are present in the heart, and both contribute to the increased contractility induced by catecholamine stimulation (this is different from the situation in vascular muscle, where β_2-adrenergic stimulation induces relaxation). Under normal conditions, the relative ratio of β_1- to β_2-receptors in heart is approximately 70:30, but as discussed later, this ratio can be changed dramatically by cardiac disease.

The β-adrenergic receptors are closely related structurally as well as functionally. Both the β_1- and β_2-adrenergic receptors couple to G_s proteins and, as described earlier, thereby activate adenylate cyclase, thus leading to increased intracellular levels of cAMP. Some differences in their intracellular signaling are likely, however. For example, investigators have suggested that β_2-receptors couple more effectively than β_1-receptors and induce greater changes in cAMP levels.[45] In addition to their effect on cAMP signaling, β-receptors may couple to myocardial Ca^{2+} channels.[46] However, these additional actions are species specific, and care should be taken in extrapolating animal data to humans.

The inotropic and electrophysiologic effects of β-adrenergic signaling are indirect results of increases in intracellular cAMP levels. cAMP activates a specific protein kinase (PKA) that, in turn, is able to phosphorylate several important cardiac ion channels (including L-type Ca^{2+} channels, Na^+ channels, voltage-dependent K^+ channels, and Cl^- channels). Phosphorylation alters channel functioning, and the resulting changes in membrane electrophysiology modify myocardial behavior.

The α-adrenergic receptors, like their β-receptor counterparts, can be divided into two groups: α_1- and α_2-receptors. Both groups consist of several closely related subtypes, with different tissue distributions and functions that are as yet not fully differentiated. In general, α_1-receptors couple to G_q proteins and thereby activate PLC, a process that results in increases in intracellular Ca^{2+} concentrations. α_2-Receptors couple to G_i proteins, which inhibit adenylate cyclase and consequently reduce intracellular cAMP concentrations.

The primary role of α-receptors is in the vasculature, where α_1-receptors on vascular smooth muscle are the main mediators of neuronally mediated vasoconstriction. α_2-Receptors on the neurons themselves function in a negative feedback loop to control α-adrenergic vasoconstriction.

In the heart, the primary subtype present is α_1. Activation of these receptors leads to a modest increase in cardiac contractility.[47]

Regulation of β-Receptor Functioning

β-Receptor stimulation allows the dramatic increases in cardiac output of which the human heart is capable, but this β-receptor effect is clearly intended to be a temporary measure. Prolonged adrenergic stimulation has significant detrimental effects on the myocardium, with pronounced increases in cAMP levels resulting in increased intracellular Ca^{2+} concentrations, reduced RNA and protein synthesis, and finally cell death. Thus β-receptor modulation is best viewed as part of the "fight-or-flight" response: beneficial in the short term, but detrimental if depended on for too long. Cardiac failure, in particular, has been shown to be associated with prolonged increases in adrenergic stimulation, even to the extent that norepinephrine "spillover" from cardiac nerve endings can be detected in the blood of patients in heart failure.[48]

For this reason, the regulation of β-receptor functioning has received significant attention, and investigators now know that several mechanisms are capable of modifying adrenergic responsiveness of the myocyte. Unfortunately, it appears that the reduction of adrenergic responsiveness necessary to prevent cell death in the presence of adrenergic overstimulation may be in large part responsible for the decreased myocardial performance that is the hallmark of cardiac failure.

One mechanism for decreasing β-receptor functioning is the *downregulation* (ie, decrease in density) of receptors. In cardiac failure, receptor levels are reduced up to 50%. β_1-Receptors downregulate more than β_2-receptors do, thus resulting in a change in the β_1/β_2 ratio; in the failing heart, this ratio is approximately 3:2.[49] Various molecular mechanisms exist for this downregulation. In the long term, β_1-receptors are degraded and permanently removed from the myocyte cell surface. In the short term, receptors can be temporarily removed from the cell membrane and "stored" in intracellular vesicles, where they are not accessible by an agonist. These receptors are, however, fully functional and can be recycled to the membrane when adrenergic overstimulation has ceased.[50]

An additional method by which β-adrenergic receptor functioning can be modified is through phosphorylation of the agonist-occupied receptor by a specific β-adrenergic receptor kinase (β-ARK, which can itself be activated by βγ subunits).[51] Phosphorylation by this kinase allows a protein, β-arrestin, to bind to the receptor where it inhibits receptor functioning.[52] In addition, the β-receptor can be phosphorylated by PKA, which itself can be activated by several other receptors. The detrimental actions of adrenergic overstimulation can also be modified by activation of muscarinic receptors, as discussed in the next section.

Despite the existence of these various regulatory mechanisms and the known detrimental effects of adrenergic overstimulation, paradoxic increases in β-receptor functioning occur in clinical disease states. For example, under ischemic conditions, β-receptors are upregulated, so after periods of ischemia as brief as 15 minutes, significant increases in expressed and functional receptor levels are found. Reperfusion rapidly decreases the number of receptors back to their normal levels.

Muscarinic Receptors and Signaling Pathways

Muscarinic Acetylcholine Receptors

The second major receptor type in cardiac regulation is the muscarinic receptor. Although five subtypes of muscarinic receptors exist, only one of these (M_2) is present in cardiac tissue. Most of these muscarinic receptors are present on the atria. Indeed, it was formerly thought that the ventricles had no vagal innervation, but this view turns out to be incorrect. The ventricles are innervated by the vagus nerve, and muscarinic receptors are in fact present in the ventricles, albeit at lower concentrations than in the atria. The amount of muscarinic receptor protein in atrium is approximately twofold greater than in ventricle (200 to 250 vs 70 to 100 fmol/mg protein).[53] Thus, although the primary function of cardiac muscarinic signaling is heart rate control through actions at the atrial level, vagal stimulation can directly influence ventricular functioning.

M_2-muscarinic receptors couple to G_i proteins, thereby inhibiting adenylate cyclase and decreasing intracellular levels of cAMP. The M_2 receptors have been used as an elegant model to determine the site of G-protein binding to the receptor. Exchanging approximately 20 amino acids of the third intracellular loop (i3) (see Fig. 8.10) between M_2 and M_3 receptors resulted in altered coupling; M_2 receptors mutated in this manner were now able to release Ca^{2+} from intracellular IP_3-sensitive stores by coupling to G_q.[54]

In the impulse-generating system of the heart, a more important signaling mechanism than changes in cAMP is opening of an inwardly rectifying K^+ channel (K_{ACh}) in the plasma membrane. The coupling between M_2 receptor and K_{ACh} is performed by G_K, a member of the G_i class of G proteins. It is not the α subunit of G_K that activates K_{ACh}, but rather the $\beta\gamma$ subunit.[55] As discussed later, cardiac adenosine receptors also couple to this channel.

Whereas the adenylate cyclase system is ubiquitous, differential expression of K_{ACh} determines the actions of muscarinic signaling on the heart. K_{ACh} is largely absent from ventricular tissue. Therefore in the ventricle, muscarinic signaling primarily involves decreases in cAMP levels, and because these levels are low under resting conditions, little effect is seen unless the heart has been stimulated previously by adrenergic agents. In other words, in the absence of adrenergic stimulation, ACh has little effect on the ventricle; in conditions of high adrenergic tone, however, muscarinic stimulation can modify the adrenergic effects, as discussed in the next section.

Regulation of Muscarinic Acetylcholine Receptors

Whereas the role of atrial muscarinic receptors in impulse generation and the conduction system is straightforward, the role of ventricular muscarinic receptors is not as clear. It appears that under nonstressed conditions, muscarinic signaling has little influence on cardiac contractility. In contrast, the system may act as a brake on overstimulation by adrenergic receptors (see earlier discussion). The effects of muscarinic signaling, which almost universally oppose those induced by adrenergic signaling (because muscarinic receptors couple to G_i and adrenergic receptors couple to G_s), may counteract adrenergic effects and thereby preserve cardiac functioning during prolonged stress responses.

Unfortunately, these compensatory mechanisms may not be available in the aging heart. Increased age is accompanied by changes in cardiac muscarinic receptor expression that may make it more difficult for the heart to respond to adrenergic stress. In senescent rats, muscarinic receptor density was decreased by approximately 50%.[56] Adrenergic receptor levels also were decreased, but to a lesser extent. As a result, the adrenergic-to-muscarinic receptor ratio is increased, from 0.29 in young adults to 0.42 in senescent animals. Although the physiologic implications of these changes are not well known, the data at least suggest that the muscarinic systems in the aged heart may not be as well prepared to react to prolonged adrenergic stimulation, such as observed in hypertension and cardiac failure.

With the exception of age, muscarinic receptors are minimally affected in settings that profoundly modify β-receptor expression. For example, no consistent data support changes in muscarinic receptor expression in hypertension, cardiac failure, or ischemic heart disease.[57,58] Therefore imbalances between adrenergic and muscarinic stimulation may occur in each of these situations.

Regulation of G-Protein Functioning

In view of the profound changes in GPCR expression that occur in various disease states, the expression and function of G proteins in cardiovascular disease have been studied with interest. G_s proteins appear unchanged in cardiac failure, both in expression level and in function. With G_i proteins, the situation is more interesting because $G_{i\alpha}$ is considered to have a secondary role in addition to its inhibition of adenylate cyclase. Under normal conditions, G_i is present in greater amounts than G_s. Activation of receptors coupled to G_i would therefore lead to the release of a large number of free $\beta\gamma$ subunits. These subunits could combine with any free $G_{s\alpha}$, thereby making it unavailable for activation of adenylate cyclase.[59] In addition, these $\beta\gamma$ units can enhance the phosphorylation of β-receptors by β-ARK.[60] In failing human cardiac tissue, the amount of G_i (as assessed by ADP ribosylation by pertussis toxin) is increased.[61] Although this would be expected to make muscarinic signaling more efficacious (thereby helping counteract the adrenergic overstimulation), it has been difficult to correlate these changes with alterations in adenylate cyclase functioning. It is similarly unclear whether the reported increases in G_i levels are a result of increased messenger RNA (mRNA) expression or increased stability of the G protein itself.

The catalytic subunit of adenylate cyclase appears little influenced by cardiac disease. Pressure overload is the only situation in which a consistent decrease in its activity has been observed.[62]

Other Receptors

As stated earlier, the heart and vasculature express many GPCRs apart from the adrenergic and muscarinic receptors. A few examples are mentioned here. Angiotensin receptors mediate hormonal vasoconstriction in the vascular tree and are also present in the heart, although their function there is not fully defined. Receptors for several purinergic compounds are also expressed in the heart and are the subject of intense investigation, as discussed in the next section. In addition, histamine H_2 and VIP receptors are present, and H_2 receptors mediate the inotropic action of histamine.

Although less is understood about the role and regulation of these receptors than about their adrenergic and cholinergic counterparts, it is clear that some receptors are affected by cardiovascular disease. For example, VIP receptors are downregulated by 70% in idiopathic dilated cardiomyopathy (DCM), whereas histamine receptors are unaffected.[63] In general, receptors coupled to G_i show little alteration in expression and function during disease states, whereas G_s-coupled receptors are affected more profoundly.

Clinical Correlates

Understanding of the role of adenosine in cardiac regulation has expanded significantly over the past decades. Its established use as an antiarrhythmic compound and its probable role in cardiac preconditioning are two examples of clinical advances resulting from this increase in understanding. Adenosine acts through a GPCR, by activating several intracellular signaling systems. This section discusses the molecular aspects of adenosine signaling, as well as their clinical implications. More detailed reviews on the topic are available.[64,65]

Adenosine Signaling

Although adenosine can be generated by several pathways, in the heart, it is usually found as a dephosphorylation product of AMP.[66] Because AMP accumulation is a sign of a low cellular energy charge, an increased adenosine concentration is a marker of unbalanced energy demand and supply; thus ischemia, hypoxemia, and increased

catecholamine concentrations are all associated with increased adenosine release.[67] Adenosine is rapidly degraded by various pathways, both intracellularly and extracellularly. As a result, its half-life is extremely short, on the order of 1 second.[68] Therefore, not only is it a marker of a cardiac "energy crisis," but also its concentrations fluctuate virtually instantly with the energy balance of the heart; it provides a real-time indication of the cellular energy situation.

Adenosine signals through GPCR of the purinergic receptor family. Two subclasses of purinoceptors exist: P_1 (high affinity for adenosine and AMP) and P_2 (high affinity for ATP and ADP). The P_1 receptor class can be divided into two main receptor subtypes: A_1 and A_2. A_1 receptors are present mostly in the heart and when activated inhibit adenylate cyclase; A_2 receptors are present in the vasculature and when activated stimulate adenylate cyclase. The A_2 receptors mediate the vasodilatory actions of adenosine. The A_1 receptors mediate its complex cardiac effects, and they are the topic of the remainder of this section.

The A_1 adenosine receptor couples to (at least) two intracellular signaling systems. Both actions are mediated by G proteins of the G_i class. The first intracellular system is one already encountered: the K_{ACh} channel. Presumably, through the same G_K protein, adenosine activates this channel in the same way as does M_2 muscarinic stimulation, and the cardiac electrophysiologic effects of ACh and adenosine are therefore similar. The specific effect of adenosine depends on the cardiac tissue studied because K_{ACh} expression varies with location. As discussed earlier, whereas the channel is present in large amounts in the atrial conduction system and atrial myocardium, it is virtually absent in the ventricle. Therefore in the unstimulated heart, adenosine shortens the atrial action potential, decreases atrial refractoriness, and decreases atrial contractile force, but it is almost without effect on the ventricle.[69]

The second intracellular signaling system activated is a G_i protein that inhibits adenylate cyclase. Given that cAMP levels are quite low under resting conditions, this mechanism plays a minor role until cAMP concentrations are increased by adrenergic stimulation of the heart. Therefore cAMP-mediated cardiac actions of adenosine are observed only under conditions of adrenergic drive. Because the adenylate cyclase system is present throughout the heart, its effects are widespread; L-type Ca^{2+} channel functioning is diminished (by inhibiting cAMP-induced phosphorylation of the channel) in atrium as well as ventricle, thus resulting in decreased inotropy and shortening of the action potential.[70]

Antiarrhythmic Actions of Adenosine

From these molecular actions of adenosine, its clinical effects can be deduced easily. The antiarrhythmic actions are largely a result of its activation of K_{ACh}. Recalling the tissue distribution of K_{ACh}, it could be anticipated that adenosine would be much more effective in the treatment of supraventricular arrhythmias than ventricular arrhythmias, and such is indeed the case. Because of its negative chronotropic effects on the atrial conduction system, the compound is most effective in treating supraventricular tachycardias that contain a reentrant pathway involving the atrioventricular node. The efficacy of adenosine in terminating such tachycardias has been reported as greater than 90%.[71] In contrast, it is consistently ineffective in tachycardias not involving the atrioventricular node.[72]

Most ventricular tachycardias are insensitive to adenosine. The only exception is again easily deduced from the compound's molecular mechanism of action; a rare form of exercise- or catecholamine-induced ventricular tachycardia responds promptly to adenosine.[73] Presumably, in this setting, adenosine-mediated inhibition of adenylate cyclase counteracts the stimulatory effects of catecholamines.

Occasionally, adenosine may be useful because of its ability to differentiate between true ventricular tachycardia and supraventricular tachycardia with aberrant conduction. In view of concerns that the often already precarious cardiovascular status of patients in ventricular tachycardia could be temporarily worsened by vasodilatation, many clinicians have been hesitant to use adenosine for this purpose. In contrast, adenosine has been found very useful as a diagnostic agent for supraventricular tachycardias. Care should be taken, however, in the patient with Wolff-Parkinson-White syndrome, who may respond with increases in ventricular rate and hemodynamic deterioration.

The side effects of adenosine would be significant if the half-life of the compound were not as short as it is. Many of the adverse effects result from activation of A_2 receptors in the vascular system: flushing, headache, and lightheadedness. Chest pain, anxiety, nausea, vomiting, and occasional bronchospasm are also seen. However, these effects are usually short-lived, and if the patient has been adequately warned about their occurrence, they are rarely of significance. Profound but brief electrophysiologic responses are observed on the ECG, ranging from premature atrial and ventricular beats to short periods of asystole. Again, these findings are rarely significant.

Adenosine and Myocardial Preconditioning

Myocardial preconditioning is the phenomenon in which brief exposure of the myocardium to ischemic conditions allows it to withstand subsequent, more prolonged exposure. The phenomenon has received much attention because its application in the clinical setting may allow the heart to better withstand, for instance, the insults of cardiac surgical procedures. Thus the mechanisms of this effect were investigated in the hope that they could be activated directly, without the need for ischemia. Various mechanisms may account for preconditioning and have been reviewed in the literature.[65,74,75]

Mitochondria play an important role in modulating cell function and survival during myocardial ischemia and reperfusion through multiple channels including mitochondrial Ca^{+2} and K_{ATP} channels and the mitochondrial permeability transition pore.[76] The mitochondrial K_{ATP} channel (mitoK_{ATP}) is a G-protein–linked K^+ channel located on the mitochondrial membrane that is a key mediator in myocardial preconditioning. Opening of this channel by using compounds that selectively open mitoK_{ATP} without affecting other cellular K_{ATP} channels[77] was shown to have a protective effect, whereas inhibition of the channel (with the channel blocker glibenclamide) increases ischemic damage to the myocardium. For example, abolition by glibenclamide of preconditioning was shown in a study measuring ST-segment changes and cardiac pain in patients undergoing balloon angioplasty.[78] Similar findings were observed in various animal studies. K_{ATP}, like K_{ACh}, belongs to the class of G-protein–coupled inward rectifier-type channels; its structure is indicated in Fig. 8.10. In contrast to K_{ACh}, however, it appears to be modulated primarily by changes in intracellular ATP derivatives. For example, intracellular increases in ATP levels have a direct inhibitory effect on the channel. In addition, K_{ATP} can be modulated by PKC, which phosphorylates the channel. PKC can be activated directly by ischemic conditions or by activation of α-adrenergic and adenosine receptors. In addition, adenosine also may be able to influence behavior of K_{ATP} in the same manner that it regulates K_{ACh}: through a G_i protein.[79]

The mechanisms by which mitoK_{ATP} opening is protective are still a focus of investigation. Potential beneficial effects involve inhibition of mitochondrial Ca^{2+} uptake, regulation of mitochondrial volume, and modulation of the generation of reactive oxygen species. Of interest from the anesthesiologist's point of view are observations that volatile anesthetic agents induce preconditioning by similar mechanisms. For example, sevoflurane preconditions human myocardium against hypoxia through activation of K_{ATP} channels and activation of A_1-adenosine receptors.[80] Similarly, lidocaine was shown to induce protection against inflammatory stimulation of endothelial and vascular smooth muscle cells by affecting mitoK_{ATP}.[81]

Anesthetic Actions

Although the functioning and physiologic roles of the receptors and channels described are of obvious importance to the anesthesiologist, from a practical perspective, the interactions between anesthetic drugs and these signaling molecules are at least as relevant. As mentioned previously, the effects of anesthetic agents on such proteins may be

beneficial to the cardiovascular system. However, detrimental interactions may also exist.

Volatile anesthetic agents are administered in extremely high concentrations as compared with most other pharmacologic agents. For example, most cardiovascular drugs are administered in doses that result in micromolar blood concentrations. Such doses are effective because a half-maximal effect on the site of action can be attained with these concentrations. Anesthetic agents, in contrast, require low millimolar concentrations in blood to be effective, almost a thousand times as much. Although they commonly are referred to as "potent agents," they are certainly not very potent as compared with many other pharmacologic compounds. As a result, it is not surprising that these compounds have a wide range of actions in addition to their primary effect site (which, of course, is still not defined completely). In addition, volatile anesthetic agents are lipophilic compounds, and if under laboratory conditions concentrations are increased even further, they can be found to interact with almost any preparation exhibiting a certain degree of lipophilicity. As a result, data demonstrate interactions between volatile anesthetic agents and virtually every component of the cardiovascular system. The problem then is not in ascertaining which channels and receptors interact with the anesthetic agents, but rather in identifying which of all these interactions are clinically important, and this has been difficult to determine. A first test that should be applied, of course, is that of reasonable concentrations; if effects are not observed at 1 to 2 minimal alveolar concentration (MAC) equivalents, it is unlikely that an interaction has clinical relevance. Because many experiments are performed at temperatures lower than 37°C, temperature correction of anesthetic solubility is an important issue. It is also important that actions are shown in several models. Effects observed in an isolated system may not necessarily be reproduced in an organ or whole-animal model; in that case, the relevance of the finding is in doubt. This issue has been reviewed in some detail.[82]

Injected anesthetic agents are less troublesome in this regard. Most of these drugs act at defined sites (the γ-aminobutyric acid [$GABA_A$] receptor-channel complex for most of them; the primary action of ketamine on the *N*-methyl-D-aspartate [NMDA] receptor-channel complex is an exception), they are more potent, and they are therefore active at significantly lower concentrations. However, this does not necessarily mean that they are without other interactions, as their various side effect profiles show.

This section focuses on some of the interactions between anesthetic agents and the molecular systems described earlier: those interactions with the most support in the literature and that also help explain some of the specific side effects of anesthetic drugs. Thus rather than providing a detailed overview of all interactions reported, several well-described examples with probable clinical relevance are presented. Unfortunately, many of these interactions have not yet been described in the molecular and submolecular detail desired. Although it may be known that an anesthetic agent inhibits functioning of a receptor or channel type, the location in the molecule where this interaction takes place is not usually identified. Usually, it cannot even be ascertained that the interaction occurs with the protein itself, rather than with the lipid membrane environment surrounding the protein. More detailed site-directed mutagenesis and the study of chimeric molecules are likely to shed light on these issues.

Interactions With Channels: Calcium Channels

Of the various ion channels present in the heart, those most likely to be significantly affected by anesthetic agents in the clinical setting are the voltage-gated Ca^{2+} channels. However, interactions with other cardiac channel types may also be relevant (particularly with K^+ channels, such as the K_{ATP} channel, described earlier).

Anesthetic actions on cardiac Ca^{2+} channels have been studied in a variety of models. The original observations that halothane blocked Ca^{2+} flux into heart cells date back to 1975,[83] and much specific information has been gained since. In particular, voltage-clamp and patch-clamp studies have contributed significantly to an understanding of the interactions between anesthetic agents and Ca^{2+} channels and have elegantly described the effects of anesthetic agents on electrophysiologic behavior. However, it is not straightforward to assign the observed electrophysiologic effects to a molecular substrate. This issue is only beginning to be addressed with the use of recombinant technology.

Almost all volatile anesthetic agents inhibit L-type Ca^{2+} channels.[84,85] Inhibition is modest, approximately 25% to 30% at 1 MAC anesthetic, but certainly sufficient to account for the physiologic changes induced by the anesthetic agents. Volatile anesthetic agents decrease peak current and also tend to increase the rate of inactivation.[86] Maximal Ca^{2+} current is therefore depressed, and duration of Ca^{2+} current is shortened. Together, these actions significantly limit the Ca^{2+} influx into the cardiac myocyte. However, some specific actions may depend on the particular anesthetic agent studied. In the presence of β-adrenergic stimulation, halothane, but not sevoflurane, is associated with long-lasting enhancement of Ca^{2+} channel function that may contribute to its proarrhythmic effects.[87] Xenon is without effect on cardiac Ca^{2+} channels, a finding that partly explains its lack of effect on myocardial contractility. Other types of Ca^{2+} channels have different sensitivities. Neuronal (N-type) channels have been shown to be resistant to volatile anesthetic agents. T-type channels in general tend to be much more sensitive than L-type channels; at clinical concentrations of most volatile anesthetic agents, T currents are inhibited 50% or more.

The effects of volatile anesthetic agents on cardiac Ca^{2+} channels can be modulated greatly by concurrent interactions of the compounds with other cardiac signaling systems. As discussed later, volatile anesthetic agents inhibit function of several types of muscarinic ACh receptor systems. Because Ca^{2+} channel function can be inhibited by muscarinic signaling, as discussed earlier, clinicians would anticipate additional interactions when this system is exposed to volatile anesthetic agents, and such is the case. Halothane and isoflurane further inhibited currents through Ca^{2+} channels when either volatile anesthetic was applied after inhibition produced by previous muscarinic stimulation. However, when muscarinic receptors were stimulated after administration of volatile anesthetic, its effect was reduced. Thus, whereas volatile anesthetic agents directly inhibit L-type channels, they also interfere with channel modulation by GPCR.[88]

Both volatile and injected anesthetic agents have been reported to inhibit cardiac L-type Ca^{2+} channels in some models. However, the concentrations used generally exceed those used in clinical practice. Thiopental and methohexital block L-type Ca^{2+} currents.[85,89] Similarly, propofol has been reported to inhibit these channels, but at concentrations well beyond the clinical range.

Interactions With Receptors: Muscarinic Receptors

As with cardiac channels, anesthetic interactions with a variety of GPCRs may be of potential relevance to cardiovascular side effects of anesthetic compounds. However, most of these potential interactions have not been described in significant detail. The two main control systems of myocardial functioning, the muscarinic and adrenergic systems, have been studied to some extent, and a generalizing conclusion can be that muscarinic receptors are and adrenergic receptors are not sensitive to many anesthetic agents. Thus the focus is on muscarinic receptors in this section.

Determination of anesthetic effects on GPCR is in some ways more complex than determination of the effects on channels. Although the receptors are smaller and consist of a single subunit, they are only one component of very complex signaling pathways. Therefore it is not sufficient to determine the effects on the receptor itself; actions on intracellular signaling should also be investigated.

No doubt exists that at least some volatile anesthetic agents interfere with muscarinic signaling. Unfortunately, most of these investigations have not studied the heart or even looked specifically at the M_2 receptor, the only subtype expressed in cardiac tissue.

Aronstam and colleagues published a series of articles reporting the effect of various anesthetic agents on muscarinic receptor binding; a summary of their findings has also appeared in print.[90] Several studies investigated the effect of halothane on agonist and antagonist binding.[91,92] The conclusions drawn from this work were as follows: (1) the anesthetic agent enhanced antagonist binding by slowing the rate of ligand dissociation, and (2) the anesthetic agent inhibited agonist binding (by 48%, using 10% halothane).

The site of action of these effects was studied in more detail by investigating the interactions of anesthetic agents with G-protein functioning.[93] As discussed earlier, G proteins are activated by GDP-GTP exchange. Intrinsic but remarkably slow enzyme activity hydrolyzes GTP back to GDP, thereby inactivating the G protein after several seconds. While active, the G protein is no longer able to couple to the receptor, and uncoupled receptors exhibit a decreased affinity for their agonist. This decrease in activity can be induced in the experimental setting by including a nonhydrolyzable analogue of GTP, such as Gpp(NH)p, in the reaction mixture, thereby resulting in irreversibly activated G proteins. This effect is known as the GTP shift in receptor affinity. Halothane shifts the Gpp(NH)p concentration-response relationship to the right. In other words, a greater concentration of the GTP analogue was necessary to induce a similar decrease in agonist binding. In the absence and presence of 5% halothane, the half-maximal inhibitory concentration (IC_{50}) values for the inhibitory effect on agonist binding of Gpp(NH)p were 0.7 and 83 μM, respectively—a 100-fold difference. These findings were interpreted as an ability of halothane to stabilize high-affinity G-protein–receptor complexes.

Therefore halothane appears to affect receptor binding, as well as receptor–G-protein interaction. In a subsequent study, the effect of the anesthetic agent on G-protein functioning—its ability to hydrolyze bound GTP—was investigated. Halothane was found not to inhibit binding of radiolabeled GTP analogue to G proteins.[91] However, the anesthetic agent completely blocked the stimulation of G-protein GTPase activity induced by ACh, with a half-maximal effect at the clinically relevant halothane concentration of 0.3 mM. The site of this effect was not determined. Similar findings were obtained with other anesthetic agents. Halothane also has been shown to interfere with G-protein–mediated Ca^{2+} sensitization in airway smooth muscle by inhibiting G proteins.[94] More recently, however, the interaction between halothane and purified recombinant G_i was investigated. In contrast to the findings described earlier, no effect of the anesthetic on G_i protein function was found.[95] The earlier results may therefore have been contaminated by interactions with other G-protein subtypes that are less relevant to muscarinic M_2-receptor signaling. The conclusion to be drawn from these studies is that anesthetic agents may interfere with several components of the muscarinic signaling pathway. However, the following should be kept in mind: (1) a mixture of muscarinic receptor subtypes was most commonly studied; (2) the anesthetic agents were administered in relatively high, and clinically unequal, concentrations; and (3) anesthetic effects on functional properties of the receptor–G-protein unit were not specifically addressed.

Magyar and Szabo,[96] using the patch-clamp technique, investigated the effects of halothane (0.9 mM) and isoflurane (0.8 mM) on ACh (10 μM)–induced activation of the muscarinic K^+ channel in frog atrial myocytes. These investigators found that if anesthetic and agonist agents were administered at the same time, a reduction in the peak K^+ current was observed, which was greater with halothane than with isoflurane. However, pretreatment with the anesthetic agent was found to have a significant, time-dependent, additional effect: 25-minute exposure to halothane restored the peak and significantly increased the steady-state current, whereas exposure to isoflurane decreased both. Because equilibration of the anesthetic agent with the direct signaling pathway should be complete within milliseconds to seconds, the prolonged time course of these effects appears to indicate that additional intracellular pathways (eg, PKC-mediated phosphorylation) are involved. Exposure of the membrane patches to the nonhydrolyzable GTP analogue GTPγS, thereby irreversibly activating G_K, prolonged the current. When single-channel measurements were performed, halothane was found to enhance the frequency of channel opening without significantly affecting the single-channel conductance. Isoflurane was without effect. Therefore halothane affects the signaling pathway downstream of the muscarinic receptor in this model. Whether this action is on the G protein or on the channel itself cannot be conclusively determined from these studies.

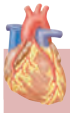
When time considerations are taken into account, it appears likely that the initial action of halothane on the system is inhibiting, whereas that of isoflurane is less so. After prolonged exposure, halothane is found to enhance signaling, whereas isoflurane inhibits it. These results probably reflect various effects of the anesthetic agents on intracellular systems that modify the signaling properties of the muscarinic pathway. In addition, halothane, but not isoflurane, has a direct activating effect downstream of the muscarinic receptor. This is consistent with findings of the effect of halothane on Ca^{2+} channels mentioned earlier.

Remote Ischemic Conditioning

Remote ischemic conditioning is the phenomenon by which brief periods of ischemia and reperfusion to one tissue bed or organ of the body (often induced by repeatedly inflating a blood pressure cuff on the arm) confer protection against ischemic injury in a remote organ such as the heart. This phenomenon appears to be a consequence of both neuronal and neurohumoral transfer of signals from the remote organ to the heart, the mechanisms of which are complex and still under investigation.[97] Multiple studies have explored the efficacy of remote ischemic preconditioning for mitigating adverse cardiac outcomes after cardiac surgical procedures. Most of these studies focused on patients undergoing coronary artery bypass graft operations, with the primary study end point being association with a reduction in myocardial injury biomarkers (ie, troponin I, troponin T, creatine kinase MB isoenzyme) 24 to 72 hours postoperatively.[97] Most of these studies were small, but slightly more than one-half of these studies demonstrated a significant reduction in levels of myocardial injury biomarkers in patients who underwent remote ischemic preconditioning induced by applied cycles of intermittent occlusion of blood flow to an upper or lower extremity.[97] The largest of these studies included more than 320 patients undergoing coronary artery bypass graft operations. This study identified a significant reduction in troponin I at 72 hours after the surgical procedure in the remote ischemic preconditioning intervention group as well as reduced all-cause mortality rates.[98] In addition to the need to understand the potential protective mechanisms of remote ischemic conditioning more clearly, additional large studies are needed to determine what timing and methods of invoking remote ischemic conditioning may incur the most myocardial protection during cardiac operations. Further studies are also needed to determine which concurrent anesthetic agents may potentiate or inhibit effects of remote ischemic conditioning.[97] One trial showed renal protection from remote preconditioning during cardiac surgical procedures, a finding suggesting that multiorgan protection conferred during cardiac operations should be evaluated for potential impact and translation into clinical practice.[99]

Genetic Cardiovascular Medicine

Considerable progress has been made in the identification and understanding of the genetic basis of cardiovascular disease. These disorders, spanning all aspects of cardiovascular disease and affecting all parts of the heart, can be divided into two groups (Box 8.6). *Monogenic disorders* are mendelian disorders for which changes in a single gene are implicated in the disease process and that usually exhibit characteristic inheritance patterns (ie, additive, dominant, or recessive genetic models). More than 40 cardiovascular disorders are known to be caused directly by single gene defects. Examples include familial hypercholesterolemia, hypertrophic cardiomyopathies (HCMs), DCMs, and the LQTSs.[100,101]



BOX 8.6 EXAMPLES OF IMPORTANT CARDIOVASCULAR DISORDERS WITH A GENETIC BASIS

Monogenic disorders
- Familial hypercholesterolemia
- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy
- Long QT syndrome

Multigenic disorders
- Coronary artery disease
- Hypertension
- Atherosclerosis

More commonly, however, multiple genes influence the disease process by enhancing disease susceptibility or by augmenting the impact of environmental risk factors. The genetic component in those *multigenic disorders* comprises a collection of gene variants such as single nucleotide mutations, referred to as *single nucleotide polymorphisms* (SNPs). Each individual SNP may have a modest effect on the quantity or function of a translated protein product. However, when individual SNPs aggregate and interact with environmental risk factors, they may have a major impact on disease biology. Common complex diseases that appear to follow this paradigm include coronary artery disease (CAD), atherosclerosis, hypertension, and atrial fibrillation.[102–104]

This section discusses the current status of genetic diagnosis of monogenic and complex cardiovascular disorders, as well as the main techniques used to perform such diagnostic testing.

Monogenic Cardiovascular Disorders

Great progress has been made in the identification and characterization of the disease genes specific to mendelian cardiovascular diseases,[100,101,105] but several factors complicate these investigative efforts. *Locus heterogeneity* (many genes causing the same disease) is one of those factors.[106] The channelopathies, encompassing the LQTS, Brugada syndrome, and other genetic arrhythmogenic disorders, are accounted for by at least 30 genes.[35] Whereas HCM genes *MYH7, MYBPC3,* and *TNNT2* (encoding the β-myosin heavy chain, cardiac myosin-binding protein C, and cardiac troponin T genes, respectively) account for 70% to 80% of cases of HCM as diagnosed by molecular genetic approaches,[107] an additional 21 genes have been implicated to cause the HCM phenotype.[108] In addition, more than 40 genes have been implicated in DCM.[108] A second, related factor complicating genetic diagnosis of "monogenetic" disorders is *allelic heterogeneity* or the concept that multiple different mutations typically occur within a single culprit gene and may result in a certain cardiovascular phenotype such as HCM (ie, within the list of genes known to cause HCM, hundreds of pathogenic mutations have been identified, but many of them are rare variants). Furthermore, although the list of known disease-causing genetic variants is expanding rapidly, not all disease loci have been identified, and this information gap diminishes the sensitivity of molecular testing to screen for genetic susceptibility to disorders. Whereas investigators have estimated that a mutation causing LQTS can be identified in up to three-fourths of index patients, this is not true for other cardiovascular single-gene disorders. For example, only 30% to 60% of the genetic causes of HCM[109] and only 20% to 30% of the genetic causes of DCM have been identified.[105,106] As an example, *MYH7* consists of 40 exons encoding the β-myosin heavy chain protein, and 194 mutations in this structure have been reported to be associated with HCM. For diagnostic purposes, this necessitates sequencing the entire coding sequence and intron/exon boundaries of each gene. The advent and refinement of next-generation sequencing have made this an increasingly clinical viable approach (discussed further later).

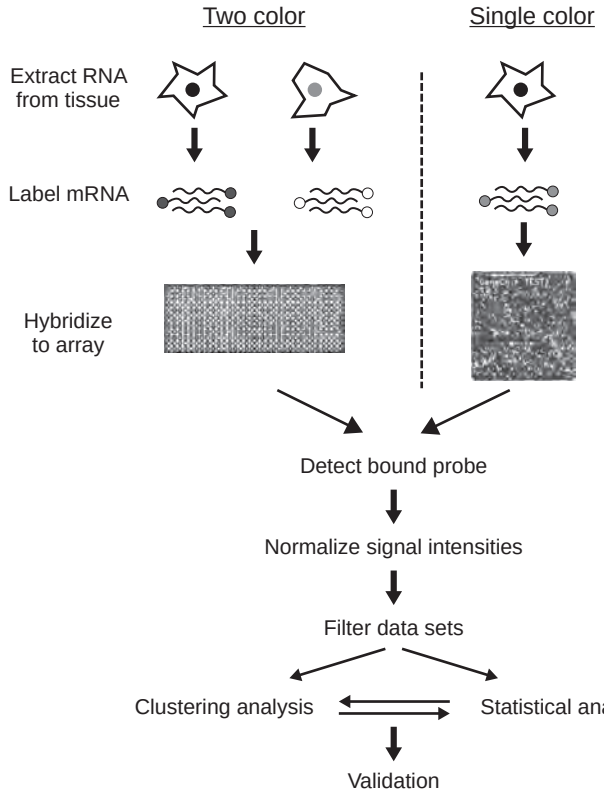


Fig. 8.11 Schematic representation of a microarray experiment. RNA is extracted from the tissues of interest, labeled, and then hybridized (competitively, two color arrays; noncompetitively, one color array) to the DNA microarray, where it binds complementary sequences. Bound sequences are identified by their position on the array. Signal intensities are normalized, allowing interarray comparisons. Normalized data sets are filtered and subjected to computational analysis. Finally, differentially regulated transcripts should be prospectively validated or confirmed using independent methods. *(From Cook SA, Rosenzweig A. DNA microarrays: implications for cardiovascular medicine.* Circ Res. *2002;91:559–564.)*

Methodologies for Identifying Mutations: Linkage Analysis, Sequencing, and Microarrays

Linkage analysis is a nonbiased and powerful approach for identifying causative genes underlying familial monogenetic and complex diseases.[110] The analysis is conducted after a priori identification of potential candidate genes or their chromosomal locations. It then looks for DNA markers that cosegregate with the disease phenotype between affected family members at a rate that is statistically greater than random chance. The chromosomal region containing the DNA markers can then be examined in further detail to look for potential candidate genes. Several successful studies have been performed using CAD as a model.[111–113]

Techniques for identifying gene sequences have evolved from the classic Southern blotting procedure into highly automated systems that can rapidly screen hundreds of thousands of gene sequences. Southern blotting, invented in the mid-1970s, is based on the transfer to nitrocellulose of DNA molecules separated on gels and their subsequent identification with DNA probes. It allows detection of small mutations, as well as large deletions, duplications, and gene rearrangements. The principle was expanded and automated in the development of DNA microarrays (Fig. 8.11), which consist of series of thousands of microscopic spots of DNA oligonucleotides, each containing tiny amounts of a specific DNA sequence. The arrays are

printed on a platform, usually a glass slide. A DNA probe, encoding a specific sequence, is then used to bind to and identify homologous nucleic acids, as detected by fluorophore-labeled targets whose signal is proportional to the relative abundance of nucleic acid sequences in the target. This technique makes it possible to examine for genetic variants with high density across large numbers of disease genes at the same time in large numbers of patients.

Sanger "first-generation" sequencing was the method of choice for several decades for determining a person's exact base-pair by base-pair genetic DNA sequence. Although Sanger sequencing is accurate, it is also slow (one patient at a time and one gene at a time) and expensive. Next-generation high-throughput sequencing platforms allow base-pair by base-pair simultaneous sequencing of multiple specific genes (ie, targeted sequencing), the whole exome, or the whole genome in a rapid and cost-effective fashion.[114] Multiple patients can undergo sequencing in a parallelized fashion by using next-generation sequencing techniques. The steps involved in next-generation sequencing platforms are shown in Fig. 8.12.[115] Next-generation sequencing has been useful for the discovery of novel (often rare) variants that cause monogenetic disorders. Next-generation sequencing also has enhanced genetic screening for monogenetic cardiovascular disorders, although some sequence variants of uncertain clinical significance that have been discovered create challenges for physicians who counsel and manage families susceptible to inherited cardiovascular disease.[115]

Clinical Applications

The ability of these techniques to identify diseases before they become clinically manifest allows preventive treatment (Table 8.2). For example, implantable cardioverter-defibrillators (ICDs) can prevent sudden cardiac death in patients with certain genetic cardiomyopathies and arrhythmias (Fig. 8.13).[116–118] Medical therapy may ameliorate the progression of genetic DCM. Prospective identification of those patients who are asymptomatic but at greater risk for development of the disease enables closer surveillance and early intervention. Knowledge of the LQTS genotype may be used to tailor the treatment plan (Fig. 8.14). For instance, patients with LQT3 benefit less from β-blockers,

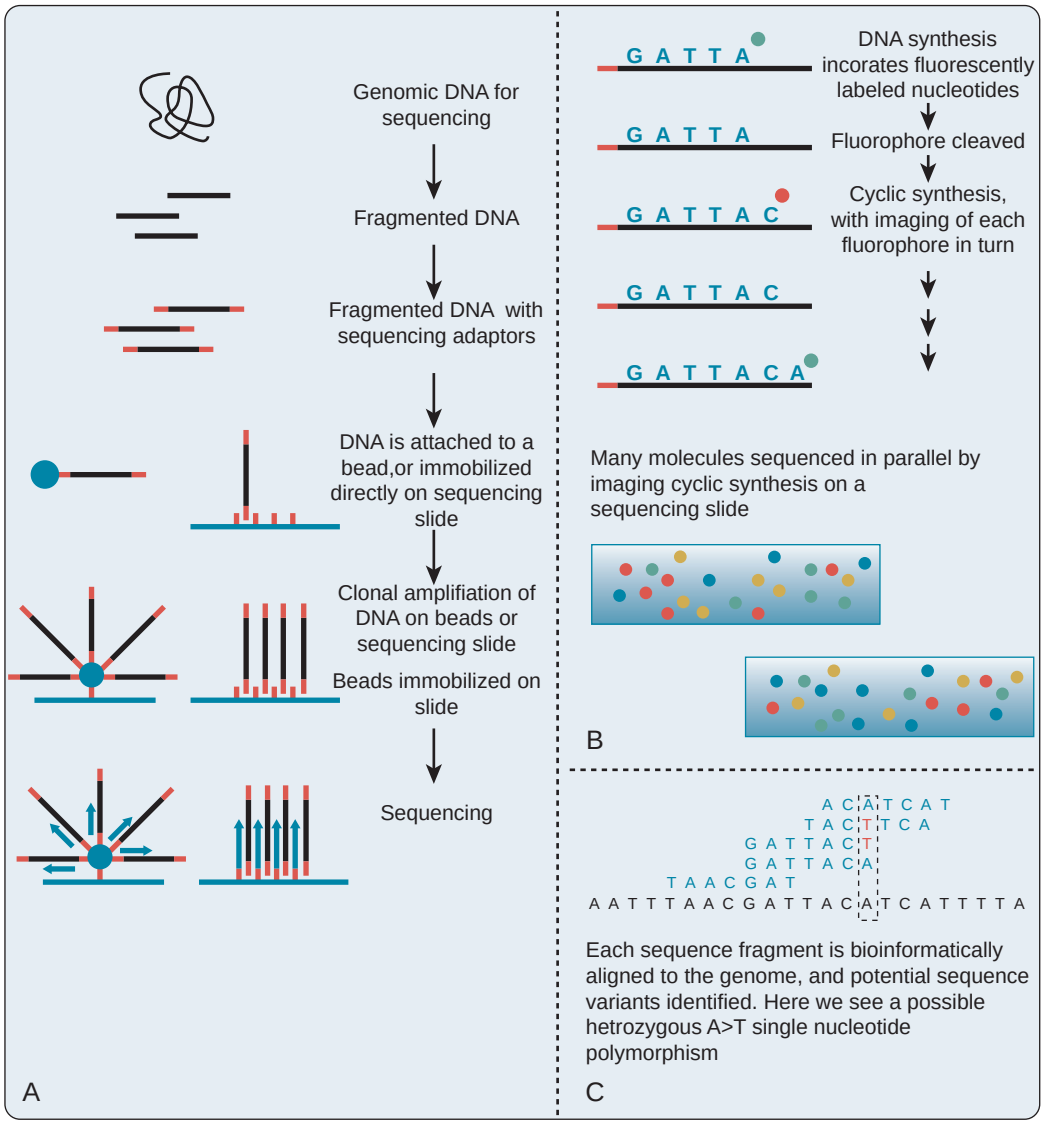

Fig. 8.12 A to C, Next-generation high-throughput sequencing is parallel sequencing process that is faster and less expensive than Sanger sequencing. *(From Mogensen J, van Tintelen JP, Fokstuen S, et al. The current role of next-generation DNA sequencing in routine care of patients with hereditary cardiovascular conditions: a viewpoint paper of the European Society of Cardiology working group on myocardial and pericardial diseases and members of the European Society of Human Genetics.* Eur Heart J. *2015;36:1367–1370.)*

so a lower threshold for ICD placement is advised in these patients.[119] In addition, the triggers for malignant arrhythmias have been found to differ based on the affected gene; for example, patients with LQT1 can be asked to avoid vigorous activities such as exercise and competitive sports.[120]

TABLE 8.2 Clinical Applicability of Genetic Testing in Monogenic Cardiac Diseases[a]

Disease	*Success Rate (%)*	*Identification of Silent Carriers/ Diagnosis*	*Reproductive Risk Assessment*	*Prognosis*	*Therapy*
HCM	60–65	+	+	±	–
DCM	NA	+	+	–	–
ARVC	<10	+	+	–	–
MFS	80–90	+	+	–	–
LQTS	60–65	+	+	+	+
BrS	20	+	+	–	–
CPVT	50	+	+	+	–
NS	40	+	+	–	–

Common Complex Multigenic Cardiovascular Disorders

Identifying the gene variants associated with the development and progression of multigenic common complex cardiovascular diseases provides the potential for these variants to be used to better predict who will develop certain cardiovascular disorders, as well as to target preventive and treatment strategies more accurately and to develop novel treatments. The obvious challenges are to identify the genes and gene variants that collectively contribute to a cardiovascular disease such as CAD and to understand how these genetic variants interface with environmental insults to perpetuate cardiovascular disease. Several genomic technologies allow researchers to study the genetic components of multigenic disorders such as CAD.

State-of-the Art Methodologies for Multigenic Genetic Screening: Whole-Genome Association and Gene Expression Profiling

Genetic association studies are performed to determine whether a genetic variant is associated with a disease or trait; if association is present, a particular allele, genotype, or haplotype of a polymorphism or polymorphisms will be seen more often than expected by chance in a subject carrying the trait. Thus a person carrying one or two copies of a high-risk variant is at increased risk for development of the associated disease or having the associated trait. Using modern genomic technologies, researchers can now assay more than a million SNPs simultaneously in a single subject by using "SNP chips." The

The linear topologies for the three principal cardiac channels that account for two-thirds of LQTSs are superimposed on the cardiac action potential of a ventricular myocyte. The *inset* next to each channel summarizes some of the signature phenotypes associated with the three most common LQTS-causing genotypes. *AV,* Atrioventricular. *(From Ackerman MJ. Genetic testing for risk stratification in hypertrophic cardiomyopathy and long QT syndrome: fact or fiction?* Curr Opin Cardiol. *2005;20:175–181.)*

principle is the same as previously described for gene arrays. Studies have performed whole-genome association to identify SNPs associated with the development and progression of MIs.[121,122] Next-generation high-throughput sequencing technologies are also now being used to explore for genetic variants contributing to common complex diseases, particularly when using targeted and whole exome sequencing. Targeted next-generation sequencing may be used to explore for rare variants (SNPs and copy number variations) within genes where more frequent SNPs have been associated already with a certain cardiovascular phenotype (ie, this allows assessment of both common and rare genetic variants because SNP chips contain fewer low-frequency SNPs; <2% of the population).

Gene expression profiling (functional genomics) is another approach to identify genes and pathways that contribute to the development and progression of complex cardiovascular diseases such as coronary atherosclerosis. This approach analyzes disease in relevant tissues to look for changes in the abundance of transcribed genes mRNA that correlate with a disease state, clinical outcome, or therapeutic response.[123,124] Next-generation RNA sequencing techniques are now being used in research to provide an unbiased assessment of the transcriptome and its role in the biology of cardiovascular responses such as to myocardial ischemia. For example, next-generation RNA sequencing was used to examine changes in left ventricular myocardial gene expression before and after cold-blood cardioplegia–induced myocardial arrest and ischemia in 45 patients undergoing aortic valve replacement.[125]

Clinical Application

Knowledge of the multiple genetic variants associated with complex cardiovascular disease phenotypes such CAD could potentially be used to better define individual risk for developing these disorders beyond what can be assessed from currently available clinical knowledge and nongenetic tests. Discovery of novel genetic loci associated with common complex diseases such as CAD could also lead to understanding of new dimensions of the biology underlying CAD and consequently could lead to development of new medical treatments for CAD. Finally, knowledge of individual genetic profiles could allow enhanced selection of the most effective therapies to prevent or treat disorders such as CAD.

However, barriers remain to using genetics to enhance risk assessment for, prophylaxis of, and treatment of common complex diseases such as CAD. Unlike with monogenetic disorders, for multigenic disorders, each genetic variant identified is likely to contribute only very small percentages to increased risk.[104] The advent of whole-genome association studies conducted and assessed across multiple very large CAD cohorts has resulted in identification of 50 genetic variants that have been associated with development of sporadic CAD in communities.[104] A person who carries many of these risk variants is potentially at higher risk for developing CAD than a patient who is a carrier of fewer of these risk variants. If a validated genetic risk score could be established using an unweighted or weighted assessment of known genetic variants that are associated with CAD, then patients at identified higher genetic risk could receive more intensive preventive medical treatments to delay or prevent CAD development. However, just because a patient carries multiple genetic risk variants for a common complex disease such as CAD does not provide certainty that the patient will indeed develop CAD. Environmental risk factors in and of themselves, or the combination of certain environmental factors with specific genetic variants, may carry equal or more weight in determining CAD development.

Another study evaluated 45 genetic variations that have been associated in genome-wide association studies with CAD, ischemic heart disease, or MI. This study assessed more than 6000 Danish subjects to evaluate a risk score that added the number of risk alleles of the 45 SNPs that each subject carried and assessed for association with development of MI or CAD over a mean 11.6-year follow-up. The genetic risk score when assessed by allele was significantly associated with occurrence of MI but not with development of CAD, and the hazard ratio for Cox proportional hazards regression assessment for association MI revealed a statistically significant but small effect size (hazard ratio, 1.06; 95% confidence interval, 1.02 to1.11).[126] No association was found between genetic risk score and development of CAD. Furthermore, when the association between genetic risk score and MI was adjusted for EuroSCORE (European System for Cardiac Operative Risk Evaluation), the association was no longer significant.[126] This finding suggests that if a meaningful genetic risk score for predicting CAD is possibly to be developed in the future, the basis will need to be a strong understanding of the biology behind each of these whole-genome association study discovered SNP associations. Understanding of the biology of the variations that would include determining the interface between genetic variant and environment will be necessary to determine how the existence of these variants can be used to determine meaningful risk. Furthermore, a negative test result for genetic risk factors does not guarantee that the patient will not ultimately develop CAD secondary to environmental risk factors or even genetic risk variants that have yet to be identified. Approaches such as blood pressure reduction, augmented antiplatelet therapy, and aggressive cholesterol lowering have all been shown to reduce the risk for CAD substantially and are considered safe, but universal administration of these therapies is financially unfeasible and would lead to unavoidable side effects. Theoretically, with the use of more precise genomic information, it may be possible to identify disease-susceptible patients for whom intensive prevention is cost effective. However, this remains to be proven. Finally, even if future studies determine useful genetic risk panel assessments for multigenic diseases such as CAD, potentially problematic legal and ethical issues could complicate clinical genetic testing for complex diseases because these tests they may have potentially significant effects on health insurance premiums or employment. Another application of identifying the biology underlying genetic associations with multigenic disorders lies in the development of new therapeutic approaches. Most genetic variants discovered to be associated with CAD in whole-genome association studies act through biologic pathways that are not yet fully understood.[104] However, the discovery of significant associations between genetic variants in the gene encoding PCSK9 (proprotein convertase subtilisin/kexin type 9)

at chromosomal location 1p32 and increased incidence of CAD has helped lead to the development of a therapeutic monoclonal antibody (evolocumab) to inhibit PCSK9 for purposes of lowering low-density lipoprotein cholesterol.[104,127] Use of evolocumab has been assessed in multiple phase II and phase III trials and in a randomized trial was shown over 1-year follow-up to be associated with significant decreases in low-density lipoprotein cholesterol as well as decreased adverse cardiovascular events (hazard ratio in the evolocumab group, 0.47; 95% confidence interval, 0.28 to 0.78).[127] However, the evolocumab-treated group was noted to have significantly increased incidence of neurocognitive events, although these events occurred in fewer than 1% of patients.[127]

Finally, another way to translate genetic information into practice of clinical cardiovascular medicine is through better understanding of genetic responsiveness of patients to medications prescribed to address cardiovascular diseases and their sequelae. This concept that drug selection can be personalized to a person's genetic susceptibility is a straightforward idea. However, several hurdles must be overcome for this to become common practice in cardiovascular medicine. The primary problem is to provide convincing evidence that a gene contributes to disease development and progression. In gene association studies, an SNP associated with an outcome phenotype is not necessarily functionally relevant and may simply be tightly linked with the real (but unidentified) causal genetic variant. In some cases, the SNP identified in an SNP association study may not even lie within a known or putative gene. Additionally, for candidate genes identified by functional genomic studies, the difficulty is in determining whether gene expression levels are altered because the genes are contributing to disease biology or whether the genes are altered as a consequence of the disease process.

In some areas, however, knowledge of genetic variation has led to pharmacogenomic personalization of treatment in cardiovascular medications.[128] The pharmacogenomics of warfarin is an example. Warfarin is an anticoagulant administered to patients with prothrombotic risks such as chronic atrial fibrillation or the presence of a mechanical heart valve to prevent thrombosis and associated thromboembolic events. Warfarin also has a narrow therapeutic window, is metabolized by cytochrome P450, and shows large variations in dose requirements between patients. Patients with CYP2C9*2 and CYP2C9*3 allele variants (cytochrome P450 2C9 enzyme) and patients with the A haplotype of the *VKORC1* gene (vitamin K epoxide reductase complex subunit 1) seem to require lower doses of warfarin to achieve an optimal state of anticoagulation.[128–130] In 2005, the US Food and Drug Administration changed the label of warfarin to point out the potential relevance of genetic information to prescribing decisions.[131] However, randomized trials of pharmacogenetic algorithms that have used *CYP2C9* and *VKORC1* genotyping to guide warfarin dosing have had mixed results, and further studies are needed to determine how these genotypes may effectively guide initial dosing of warfarin as well as long-term monitoring of international normalized ratio.[132,133]

Perioperative Genomics in Cardiac Surgery

Despite advances in surgical, anesthetic, and cardioprotective strategies, the incidence of perioperative adverse events in cardiac surgical procedures continues to be significant and is associated with reduced short- and long-term survival.[134] Because all surgical patients are exposed to perturbations that potentially activate inflammation, coagulation, and other stress-related pathways, but only a subset of patients experience adverse perioperative events (even after controlling for coexistent disease), a genetic component is likely (Fig. 8.15).[135–137] The field of perioperative genomics uses gene association study approaches to identify novel genetic loci associated with adverse short- and long-term postoperative events, but it is also beginning to use functional genomic approaches to discover underlying biologic mechanisms that explain why similar patients have dramatically different postoperative outcomes.[138]

Gene association studies of cardiac surgical patients have identified genetic loci associated with adverse postoperative events such as myocardial ischemia or myocardial injury,[139,140] postoperative ventricular dysfunction,[141] postoperative atrial fibrillation,[142–144] vein graft restenosis,[139] renal compromise,[145] neurocognitive dysfunction,[146] stroke,[147] and death,[139] as well as other, in some cases more systemic, outcomes such as bleeding,[148] thrombosis,[149] inflammatory responses, and severe

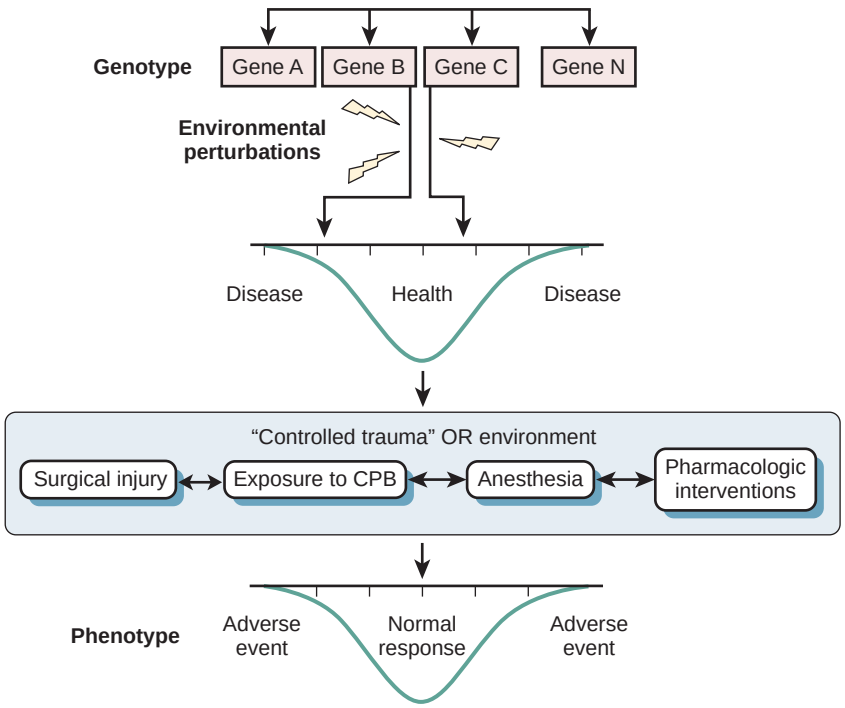

Fig. 8.15 The possible role of genetic factors combined with perioperative insults in adverse postoperative outcomes. *CPB*, Cardiopulmonary bypass; *OR*, operating room.

sepsis.[150–153] Just a few examples of perioperative genomics research resources within the United States are listed here:

- The Duke Perioperative Genomics investigative team initiated a single institution prospective study in 2001 (the Perioperative Genomics and Safety Study, US [PEGASUS]).
- Also in 2001, investigators at Texas Heart Institute, Houston, and Brigham and Women's Hospital, Boston, initiated a multiinstitution perioperative genomics research group now known as PeriGRen (Perioperative Genomics Research Network), which since added a third study site enrolling at the University of Texas Southwestern Medical Center in Dallas, Texas.
- Vanderbilt University Medical Center in Nashville, Tennessee created a DNA and data repository across their hospital system that allows for fruitful exploration of perioperative genomics research questions.

The overriding goals of the these large perioperative genomics research database and biobank projects is to identify genetic loci associated with adverse postoperative cardiovascular and renal events during the months and years following surgical procedures, to investigate the biology that underlies genetic contributions to adverse cardiovascular events, to determine how to alter clinical management of surgical patients based on knowledge of patent genetics, and finally to explore overlap between genetic contributions to adverse cardiovascular events in the postoperative setting and similar phenotypes that occur in nonsurgical patients (ie, ambulatory heart failure, atrial fibrillation).

Will genetic or genomic studies result in practical information capable of facilitating therapeutic interventions designed to improve outcome after cardiovascular operations? This has yet to be determined because perioperative genomics is still in its early phases. Cardiac surgical study cohorts with data and biobanks are just becoming large enough to allow for powerful multiinstitution collaborations. Such collaboration is vital to being able to replicate genetic associations. These collaborations will also be essential for pooling data in large enough numbers to be able to leverage fully the large amount of potential information provided by whole-genome genotyping but allow adequate statistical power to detect modest but biologically relevant effect sizes. The 4q25 locus, which has been identified by whole-genome association studies of ambulatory patients as containing SNPs associated with atrial fibrillation,[154] is also associated with increased incidence of atrial fibrillation after cardiac operations.[143] The 9p21 locus, which has been associated in whole-genome association studies with CAD[122] and MI[121] in ambulatory cohorts, contains a variant also associated with postoperative myocardial injury after coronary artery bypass graft operations.[140] The key will be to understand the biology that underlies these associations to best design perioperative interventions to prevent these postoperative outcomes in all patients, but particularly those patients identified at highest genetic risk. Advances in gene expression techniques and analyses as well as proteomics should expand meaningful assessment of functional genomics for applicability to cardiac surgical patients.

Gene Therapy

Although molecular diagnostic techniques have advanced rapidly, gene therapy is still just tantalizingly out of the scope of routine clinical practice for treating cardiovascular disorders. One overriding concept of gene therapy is to correct a faulty genetic sequence by using an affected cell's molecular workings. Another gene therapy objective is the targeting of drug delivery to specific organs by using molecular techniques. The focus of this discussion is on studies of gene therapy designed to address heart failure in human patients.

Gene therapies are designed to modify expression of genetic material. Although myriad approaches have been suggested, these all fall into three basic strategies: (1) gene transfer to restore or increase gene expression, (2) gene silencing to inhibit gene expression selectively, and (3) gene editing to "correct" DNA.[37] Each gene therapy strategy requires a vector (usually a modified virus) to carry a therapeutic genetic component such as complementary DNA, small interfering RNA, microRNA (miRNA), or small hairpin RNA into a target cell for the purpose of generating altered protein synthesis.[37] Cardiac gene transfer is now a routine technique in laboratory cell cultures and can be performed with reasonable ease in animal models such as transgenic animals. However, application in the clinical setting has been slow, to ensure gene therapy techniques that appropriately target cardiac myocytes while minimizing expression of the delivered gene in nontarget organs

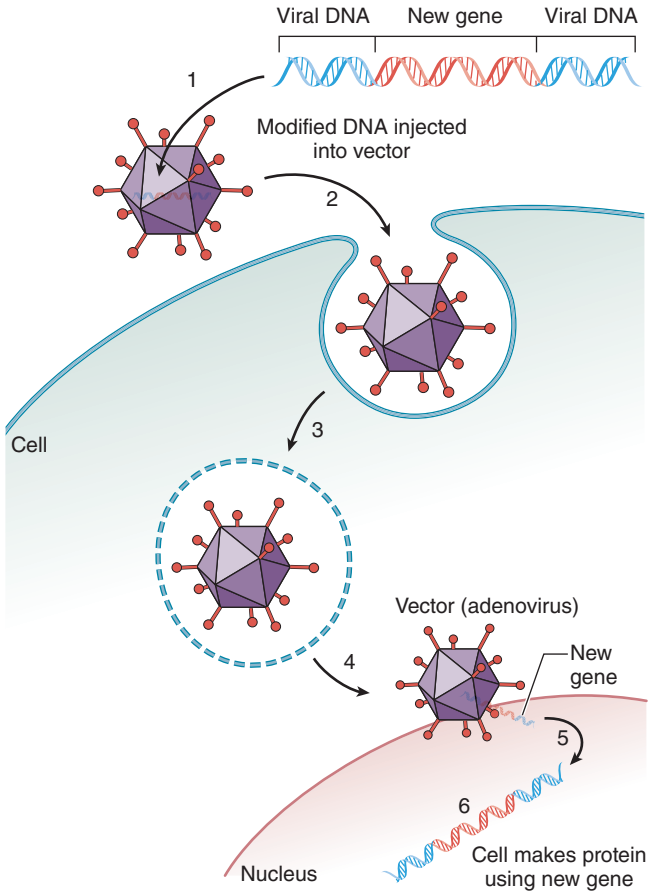

Fig. 8.16 Gene transfer in gene therapy. *Top left* in *1*, the new gene attaches to the viral DNA. In *2*, the vector binds to the cardiomyocyte's membrane and enters the cell. In *3* and *4*, it traverses the cytoplasm. In *5*, it docks on the nuclear membrane, and in *6*, the gene is incorporated into the host cell's DNA. *(From National Library of Medicine. In: Braunwald E. The war against heart failure: the Lancet lecture.* Lancet. *2015;385:814.)*

Fig. 8.16 is a schematic of gene transfer using a viral vector. Recombinant adenoassociated viruses (AAVs) are cardiotropic and thus are potentially good vectors in gene transfer therapies designed to treat heart failure.[155] Sarcoplasmic-endoplasmic reticulum ATPase (SERCA2a) plays an important role in intracellular Ca^{2+} handling and cardiomyocyte relaxation. Impaired SERCA2a activity has been reported in patients with heart failure.[155] After a large series of preclinical studies, SERCA2 cDNA was the first cardiac gene transfer to be tested in humans. The Calcium Upregulation by Percutaneous Administration of Gene Therapy in Cardiac Disease (CUPID) trial was a phase I/II trial that provided a single intracoronary gene therapy infusion of AAV1/SERCA2a in nine patients who had systolic heart failure (left ventricular ejection fraction ≤30%; New York Heart Association functional class III to IV).[156] Two of these patients had anti-AAV1 antibodies and did not respond to therapy.[37,156] This possibility is a disadvantage of using viral vectors for gene transfer therapy.[155] Six patients showed some improvement in heart failure assessments during the 6 months after gene therapy.[156]

This study was followed by the CUPID 2 trial, which was a double-blind, placebo-controlled phase II trial that enrolled 39 patients with systolic heart failure. Patients in the intervention group received intracoronary gene therapy infusion of AAV1/SERCA2a cDNA (some received lower dose, some medium dose, some high dose). At 6 months after infusion, subjects in the intervention group had significantly better simultaneous assessments of heart failure symptoms, functional status, N-terminal prohormone of brain natriuretic peptide (NT-proBNP) heart failure biomarker, and left ventricular ejection fraction.[157] At 12 months and 3 years after infusion, patients in the intervention group had experienced significantly decreased frequency of cardiovascular events, and no adverse effects of the intervention were noted.[157,158] Evidence of long-term transgene presence was observed in the patients who received high-dose AAV1/SERCA2a cDNA therapy.[158] A 200-patient multicenter, multinational, double-blind randomized placebo-controlled phase IIb trial is currently being undertaken, and the results of this trial may move this gene transfer therapy to clinical practice.[159]

Inhibition of gene expression by antisense treatment is similarly full of promise.[160–162] The basis of this technique is that mRNA can no longer be translated efficiently into protein when it is bound to a complementary strand of nucleic acid, a so-called antisense strand. Thus by introducing specific antisense DNA into cells, expression of a selected gene product can be inhibited. The problem here again is efficient targeting of the tissue of interest. Remarkably, cells are able to take up antisense material from the extracellular environment without degrading it, but the material still must be brought in contact with the tissue of interest. A second technical problem involves the stability of the antisense DNA. Because most diseases for which this technique seems suitable require constant inhibition of gene expression over long periods, the antisense construct must be highly stable, and this degree of stability has not yet been consistently achieved.

MicroRNAs and Antagomir Therapy

Micro-RNAs (miRNAs) are short, noncoding RNA gene products that silence mRNA by pairing with mRNA messenger sites and preventing protein translation. Preclinical research on miRNA identified that these molecules play an integral role in development of heart failure and other diseases. Thus the potential exists to manipulate miRNAs to treat cardiovascular diseases. The potential also exists to use circulating miRNAs for biomarker assessment of severity of clinical phenotypes such as heart failure.[155] Antagomirs are single-stranded mRNA analogues designed to be complementary to and thus silence specific miRNAs. Antagomir therapy (miravirsen; a locked nucleic acid modified DNA phosphorothioate antisense oligonucleotide that sequesters mature miRNA122) was shown in a phase IIa trial to treat hepatitis C successfully in human patients.[155,163] Although antagomir therapy has not yet been tested in human subjects to address cardiovascular phenotypes such as heart failure, some antagomirs have been administered in animal studies with corresponding improvement in cardiac function.[155]

Thus molecular therapy for cardiovascular disease seems feasible but is not yet quite ready for the clinic. Nonetheless, the concepts appear sound, and they have been proved in animal models. It appears to be only a matter of time before patients will be treated with these methods.

Cell Therapy

Cell therapy is primarily being investigated in cardiovascular medicine for the purpose of regenerating damaged myocardium.[155] Stem cells are undifferentiated precursor cells that can differentiate into specialized cells including cardiomyocytes. Embryonic stem cells derived from cryogenically preserved human embryos have been differentiated into cardiomyocytes that have been used to regenerate myocardium in infarcted primate hearts. However, certain disadvantages hinder moving the use of allogeneic embryonic stem cells into clinical practice for myocardial regeneration. These include ethical concerns about use of cells from human embryos, the need for immunosuppression to avoid rejection of allogenic cells, and the risk for teratoma formation.

As an alternative to embryonic stem cell therapy, research has focused on induced pluripotent stem cells that can be derived from autologous adult somatic cells and then differentiated into cardiomyocytes. Although the use of induced pluripotent stem cells avoids the need for immunosuppression, concerns remain regarding teratoma formation, and no clinical trials conducted thus far have used induced pluripotent stem cells in human subjects.[155]

Other types of adult stem cells are more limited in their ability to differentiate into different tissue cell types (multipotent stem cells), but they have shown promise in treatment of myocardial injury and heart failure.[40,155,164] Bone marrow contains a variety of stem cells, and unfractionated autologous bone marrow–derived mononuclear cells (BMMNCs) have been studied in multiple clinical trials to treat heart failure and post-MI injury.[155] BMMNCs do not differentiate into cardiomyocytes, but they may potentiate myocardial function and recovery through paracrine effects that involve secretion of cytokines and chemokines and induction of angiogenesis.[155,164] A metaanalysis of 50 clinical trials of adult bone marrow cell therapy administered by intracoronary or intramyocardial routes to treat ischemic heart disease (n = 2625 patients) found that patients treated with bone marrow cells (BMCs) or BMMNCs had significantly increased left ventricular ejection fractions (3.96%; 95% confidence interval, 2.90% to 5.02%), smaller infarct size, and lower end-diastolic left ventricular volume ($P < 0.0001$). Mortality rates were also significantly lower in the BMC/BMMNC-treated patients.[165] Although these results appear promising, the efficacy of BMC/BMMC treatment remains controversial in that that several studies within the metaanalysis group did not show a clinically significant impact.[155] The BAMI Trial (Effect of Intracoronary Reinfusion of BMMNC on All-Cause Mortality in Acute Myocardial Infarction Trial; NCT01569178) is an ongoing multinational, multicenter randomized trial that is scheduled to enroll 3000 patients with systolic left ventricular dysfunction through May 2017; it should provide greater clarity regarding the efficacy of this mode of cell therapy.[155]

Studies of mesenchymal stem cells in swine suggest that these cells also can differentiate into cardiomyocytes and have paracrine effects that may reduce myocardial fibrosis.[155,166] Mesenchymal stem cells may be hypoimmunogenic, so the potential exists not only for effective autologous treatment but also for possible allogeneic treatment without the need for immunosuppressive therapy.[155] Adipose tissue–derived stem cells have also been studied for efficacy in cardiac regeneration and appear to be able to differentiate into cardiomyocytes; these cells had promising results in the PRECISE trial (n = 36; NCT00426868) of subjects with ischemic heart failure.[155,167] A multisite, phase II international placebo-controlled, blinded trial of the efficacy of intracoronary injection of adipose derived regenerative cells in the setting of acute ST-segment elevation MI is under way (ADVANCE Trial; NCT01216995).[155]

The final two categories of cell therapy currently being investigated for treatment of ischemic cardiomyopathy are transplantation of autologous cardiac stem cells and intracoronary infusion of cardiospheres. The Autologous Human Cardiac-Derived Stem Cell to Treat Ischemic Cardiopathy (ALCADIA; NCT00981006) trial is investigating the effectiveness of administering autologous multipotent cardiac stem cells in addition to fibroblastic growth factor in patients with heart failure and ischemic cardiomyopathy.[155] Cardiospheres are a mixture of cardiac stem cells, mesenchymal cells, and endothelial cells that are adherent to one another and can be harvested from the human heart by percutaneous endomyocardial biopsy.[155] The Cardiosphere-Derived Autologous Stem Cells to Reverse Ventricular Dysfunction (CADUCEUS; NCT 00893360) trial was a phase I trial that assessed the efficacy of intracoronary infusion of autologous cardiospheres and found a reduction of myocardial scar and an increase in myocardial viability and regional myocardial function in the treatment versus control group in patients who had reduced left ventricular ejection fraction 1.5 to 3 months after acute MI.[168] Like mesenchymal stem cells, cardiospheres may also be hypoimmunogenic and may not require immunosuppression to be used for allogeneic treatment.[155]

This concept is important because some research suggests that autologous stem cell therapy in older patients is less effective than autologous treatment in younger patients. This suggests the question whether allogeneic treatment with certain types of adult stem cells from younger patients to older patients could be more effective than autologous treatment if it could be accomplished without immunosuppression.[164] Efficacy of allogeneic cardiosphere treatment of patients after MI who have reduced left ventricular ejection fraction is being studied in the phase II and then phase II multicenter trial Allogeneic Heart Stem Cells to Achieve Myocardial Regeneration (ALLSTAR; NCT01458405). Although clinical trials are bringing cell therapy closer to reality for routine treatment of clinical heart failure, future research will need to identify which forms of cell therapy are most effective in which patients and with what timing of therapy and by what route of administration.

9 Systemic Inflammation

RICHARD WHITLOCK, MD, PhD | ELLIOTT BENNETT-GUERRERO, MD

KEY POINTS

1. Mortality and morbidity are relatively common after major surgical procedures.
2. Postoperative morbidity often involves multiple organ systems, and this implies a systemic process.
3. Excessive systemic inflammation is proposed to be a cause of postoperative organ dysfunction.
4. No interventions that attenuate systemic inflammation have been proved in large, randomized clinical trials to protect patients from morbidity and mortality.

Numerous advances in perioperative care have allowed increasingly high-risk patients to undergo cardiac surgical procedures safely. Although mortality rates of 1% are quoted for "low-risk" cardiac operations, results from large series of patients older than 65 years of age suggest that mortality rates are actually more substantial.[1] For example, Birkmeyer and colleagues[1] reviewed a large number (N = 474,108) of "all-comers" undergoing coronary artery bypass graft (CABG) procedures or aortic valve surgical procedures who were in the Medicare Claims Database. Notably, the 30-day all-cause mortality rate was in the range of 4.0% to 5.4% after CABG and 6.5% to 9.1% after aortic valve replacement. The patient population studied, although older (age >65 years), would not be considered to be particularly high risk by today's standards. These data do not point to the cause of death. Nevertheless, they indicate that the outcome after routine cardiac surgical procedures is poor for many patients. The outcome after these procedures is even worse if the extent of postoperative complications is considered. Postoperative morbidity is common,[2] and complications include atrial fibrillation, poor ventricular function requiring inotropic agents, and non–cardiac-related causes such as infection, gastrointestinal dysfunction, acute lung injury, stroke, and renal dysfunction. For example, in the report by Rady and associates[3] of large series of patients who were 75 years of age or older and who underwent cardiac surgical procedures (N = 1157), the mortality rate was 8%. The rate of serious complications, however, exceeded 50%.

An exaggerated systemic proinflammatory response to surgical trauma is a proposed cause of many postoperative complications ranging from organ dysfunction to death.[4–6] However, the cause and clinical relevance of systemic inflammation after cardiac operations are poorly understood. Systemic inflammation is a multifactorial process and has profound secondary effects on both injured and normal tissues. Proinflammatory mediators can have beneficial as well as deleterious effects on multiple organ systems. According to most theories, tissue injury, endotoxemia, and contact of blood with the foreign surface of the cardiopulmonary bypass (CPB) circuit are some of the major factors postulated to initiate a systemic inflammatory response. Nevertheless, controversy surrounds the cause and pathogenesis of inflammation in the perioperative period.

Terminology

The terminology of inflammation is confusing and has hampered effective communication among scientists and clinicians. Despite attempts to standardize this terminology, variation in usage still exists in the scientific literature, as well as the clinical setting.[7] Much of the confusion relates to the term *inflammation*, defined as "a fundamental pathologic process consisting of a dynamic complex of cytologic and chemical reactions that occur in the affected blood vessels and adjacent tissues in response to an injury or abnormal stimulation caused by a physical, chemical, or biologic agent, including (1) the local reactions and resulting morphologic changes, (2) the destruction or removal of the injurious material, and (3) the responses that lead to repair and healing."[8] This definition acknowledges the potential role of noninfectious causative factors (ie, infection is not a prerequisite for the development of inflammation). The American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference developed definitions for terms related to inflammation (Box 9.1). Fig. 9.1 demonstrates the possible interrelationships among many of these terms.

In particular, the *systemic inflammatory response syndrome* (SIRS) refers to an inflammatory process that can arise from infection or in its absence. A viewpoint consistent with the recommended terminology is that systemic inflammation is a spectrum from mild systemic inflammation without organ dysfunction to a more severe form characterized by multisystem organ failure and death. Many clinicians do not routinely think of systemic inflammation as a clinical entity, for three reasons: (1) no universally accepted tests (eg, physical diagnosis or laboratory assays) are available to measure the degree of systemic inflammation reliably and accurately; (2) even if such a test existed and it was known that a patient had "severe" SIRS, the clinician still would not be able to predict (a) whether organs would fail, (b) which organs would fail, and (c) when organs would fail; and (3) even if SIRS could be diagnosed accurately, currently no therapies in widespread clinical use improve clinical outcomes through the prevention or treatment of systemic inflammation.

In surgical patients, the use of the phrase SIRS and the definition of SIRS have generated some controversy.[9] The reason is that almost all patients after major surgical procedures fulfill the criteria for SIRS. Most patients, however, clearly do not develop clinically significant organ dysfunction from systemic inflammation. Critics may argue that the use of the term *SIRS* in cardiac surgical patients is therefore meaningless because it does not differentiate patients who will have a benign course from those with a complicated postoperative course. For these reasons, *SIRS* is used more commonly by investigators than by practicing physicians. Nevertheless, the use of this term has the benefit of increasing awareness regarding the many noninfectious causes of inflammation.

The distinction between systemic and local inflammation is important. Local inflammation has several beneficial purposes. Invasion of the injured or infected tissue by inflammatory cells (ie, neutrophils and macrophages) results in high concentrations of cells involved in host defense. Local mediator-induced edema and clotting of lymphatics by fibrinogen result in the effective "walling off" of the injured area. In contrast, systemic inflammation is not limited to the initial

BOX 9.1 DEFINITIONS RELATED TO INFLAMMATION

Infection: microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms

Bacteremia: presence of viable bacteria in the blood

Systemic inflammatory response syndrome (SIRS): systemic inflammatory response to a variety of severe clinical insults that is manifested by two or more of the following conditions: (1) temperature >38°C or <36°C; (2) heart rate >90 beats/min; (3) respiratory rate >20 breaths/min or $PaCO_2$<32 mm Hg; and (4) white blood cell count >12,000/mm^3, <4000/mm^3, or >10% immature (band) forms

Sepsis: systemic response to infection, manifested by two or more of the following conditions as a result of infection: (1) temperature >38°C or <36°C; (2) heart rate >90 beats/min; (3) respiratory rate >20 breaths/min or $PaCO_2$<32 mm Hg; and white blood cell count >12,000/mm^3, <4000/mm^3, or >10% immune (band) forms

Severe sepsis: sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.

Septic shock: sepsis-induced with hypotension despite adequate fluid resuscitation together with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are receiving inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured.

Sepsis-induced hypotension: systolic blood pressure <90 mm Hg or reduction of ≥40 mm Hg from baseline in the absence of other causes of hypotension

Multiple organ dysfunction syndrome (MODS): presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention

$PaCO_2$, Arterial partial pressure of carbon dioxide.

area of infection or injury. The systemic elaboration of inflammatory mediators may be beneficial by heightening the host's general defenses. However, it may also lead to "autodestruction" of the host through secondary damage to tissues and organs not originally affected by the primary injury or infection.

The *acute-phase response* to tissue injury and infection is characterized by leukocytosis, fever, increased vascular permeability, a negative nitrogen balance, changes in plasma steroid and metal concentrations, and increased synthesis of hepatic acute-phase proteins. Examples of these proteins include haptoglobin, fibrinogen, C-reactive protein (CRP), complement factors (C3, factor B), serum amyloid A, α_1-acid glycoprotein, and α_1-antichymotrypsin.[10] The terms *acute-phase response* and *systemic inflammation* often are used interchangeably.

A common misconception relates to the terms *bacteremia* and *endotoxemia*. Whereas *bacteremia* refers to the presence of viable bacteria in the blood, *endotoxemia* refers to the presence of endotoxin in the blood. Endotoxin, also known as lipopolysaccharide (LPS), is a component of the cell membranes of gram-negative bacteria, and hence its presence does not require the existence of viable organisms. In fact, investigators have clearly established that cardiac surgical patients have a high incidence of intraoperative endotoxemia despite simultaneously exhibiting a low incidence of culture-proven bacteremia. This observation is consistent with the finding that "sterile" instruments and solutions, including intravenous fluids and the CPB circuit, may be contaminated with endotoxin.[11]

Systemic Inflammation and Cardiac Surgical Procedures

The systemic inflammatory response after cardiac operations is multifactorial. As described earlier, the term *SIRS* is not particularly helpful in clarifying the pathophysiology of inflammation in cardiac surgical procedures.[9] A schematic of the inflammatory process is depicted in Fig. 9.2. Clinicians generally agree that all these processes may happen and may be associated with complications in cardiac surgical patients.

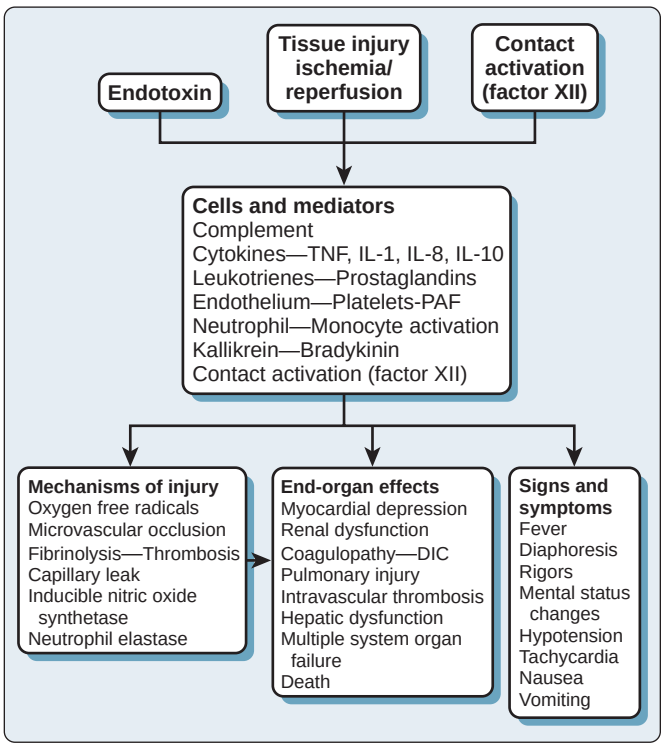

Fig. 9.2 Overview of inflammation. *DIC,* Disseminated intravascular coagulation; *IL,* interleukin; *PAF,* platelet-activating factor; *TNF,* tumor necrosis factor.

Tissue injury, endotoxemia, and contact of blood with the foreign surface of the CPB circuit are thought to initiate a systemic inflammatory response after cardiac surgical procedures. What is least understood and most controversial is the issue of which of these many processes is the most clinically relevant. It appears as if major surgical procedures comprise an important cause of systemic inflammation, and CPB further exacerbates the elaboration of proinflammatory mediators. Various causes and mediators of inflammation are reviewed in the subsequent sections.

Mechanisms of Inflammation-Mediated Injury

It is not entirely clear how inflammation ultimately damages cells and organ systems. Activation of neutrophils and other leukocytes is central to most theories of inflammation-induced injury.[6,12–15] Neutrophil activation leads to the release of oxygen radicals, intracellular proteases, and fatty acid (ie, arachidonic acid) metabolites. These products, as well as those from activated macrophages and platelets, can cause or exacerbate tissue injury.

In localized areas of infection, oxygen free radicals liberated by activated neutrophils aid in the destruction of pathogens.[16] Complement, in particular, C5a, results in activation of leukocytes and oxygen free radical formation.[17] These activated neutrophils liberate toxic amounts of oxygen free radicals such as hydrogen peroxide, hydroxyl radicals, and superoxide anion. Oxygen free radicals are thought to cause cellular injury, ultimately through damage to the lipid membrane.[18–20] Increased levels of lipid peroxidation products (ie, products of oxidation of membrane lipids such as malondialdehyde) are thought to reflect the severity of free radical cellular damage.[21] Consistent with this model of injury, Royston and colleagues[22] demonstrated increased levels of peroxidation products in cardiac surgical patients. In another study, oxygen free radicals were found to be increased in 21 patients undergoing cardiac operations; however, the clinical relevance of these changes was not studied.[21]

A related mechanism of injury results from the degranulation of neutrophils. Activated neutrophils release granules that contain myeloperoxidase, as well as other toxic digestive enzymes such as neutrophil elastase, lactoferrin, β-glucuronidase, and *N*-acetyl-β-glucosaminidase.[23–26] Release of these intracellular enzymes not only causes tissue damage but also reduces the number of cells that can participate in bacterial destruction. In one study, cardiac surgical patients who developed splanchnic hypoperfusion, a possible cause of inflammation, had increased neutrophil degranulation and increased plasma neutrophil elastase concentrations.[26]

Another mechanism of inflammation-mediated injury involves microvascular occlusion. Activation of neutrophils leads to adhesion of leukocytes to endothelium and formation of clumps of inflammatory cells (ie, microaggregates).[14,27] Activated leukocytes have less deformable cell membranes, and this affects their ability to pass through capillaries.[28] Microaggregates can cause organ dysfunction through microvascular occlusion and reductions in blood flow and oxygen at the local level.[22,28,29] After the disappearance of these microaggregates and restoration of microvascular flow, reperfusion injury may occur.

Finally, activated leukocytes release leukotrienes such as leukotriene B_4. Leukotrienes are arachidonic acid metabolites generated by the lipoxygenase pathway. They markedly increase vascular permeability and are potent arteriolar vasoconstrictors. These leukotriene-mediated effects account for some of the clinical signs of systemic inflammation, in particular, generalized edema, as well as "third-space losses." Prostaglandins, generated from arachidonic acid through the cyclooxygenase pathway, also act as mediators of the inflammatory process.

Physiologic Mediators of Inflammation

Cytokines

Cytokines are believed to play a pivotal role in the pathophysiology of acute inflammation associated with cardiac surgical procedures.[30,31] Cytokines are proteins released from activated macrophages, monocytes, fibroblasts, and endothelial cells that have far-reaching regulatory effects on cells.[32] They are small proteins that exert their effects by binding to specific cell-surface receptors. Many of these proteins are called *interleukins* because they aid in the communication between white blood cells (leukocytes).

Cytokines are important components of the acute-phase response to injury or infection. The acute-phase response is the host's physiologic response to tissue injury or infection and is intended to fight infection, as well as contain areas of diseased or injured tissue. Cytokines mediate this attraction of immune system cells to local areas of injury or infection. They also help the host through activation of the immune system, thus providing for an improved defense against pathogens. For example, cytokines enhance the function of both B and T lymphocytes, therefore improving both humoral and cell-mediated immunity. Most cytokines are proinflammatory, whereas others appear to exert an antiinflammatory effect, suggesting a complex feedback system designed to limit the amount of inflammation. Excessive levels of cytokines, however, may result in an exaggerated degree of systemic inflammation that may lead to greater secondary injury. Numerous cytokines (tumor necrosis factor [TNF], interleukin-1 [IL-1] to IL-16), as well as other protein mediators (eg, transforming growth factors, macrophage inflammatory proteins), have been described and may play an important role in the pathogenesis of postoperative systemic inflammation. The cytokines that have received the most attention related to cardiac surgical procedures include TNF, IL-1, IL-1 receptor antagonist (IL-1ra), IL-6, IL-8, and IL-10.

Tumor Necrosis Factor

TNF is one of the earliest cytokines detected in the blood after the activation of macrophages and other proinflammatory cells. One factor complicating studies of TNF is that TNF has two similar forms, TNF-α and TNF-β, as well as two distinct receptors, TNFR-I and TNFR-II. TNF appears to be pivotal in initiating the complex inflammatory cascade. Endotoxin is a potent stimulus for TNF production.

Endotoxemia unequivocally results in initiation of proinflammatory pathways, most likely through stimulation of TNF.[33–36] Michie and associates[33] administered endotoxin intravenously to human volunteers and detected peak levels of TNF 90 to 180 minutes later. Peak concentrations of TNF correlated with increased temperature and heart rate (HR), as well as circulating levels of adrenocorticotropic hormone and epinephrine. In this and other studies, TNF levels soon appeared after a proinflammatory stimulus and disappeared quickly, thus helping explain a common finding from clinical studies. TNF levels are often not increased when they are measured in patients with systemic inflammation, probably because test samples are obtained long after exposure to the primary inflammatory stimulus. This issue of sampling time may partially account for the finding that some cardiac surgical studies have detected increased TNF levels, whereas others have not.[37–53]

Interleukins

After the appearance of TNF, levels of IL-1 increase in cardiac surgical patients.[47,50,52,54] Measured levels are low and may peak within several hours after CPB.[54] Other studies have demonstrated maximum levels 1 day after cardiac surgical procedures, and this may explain the inability of some investigators to detect IL-1 during the intraoperative period.[50] IL-1 may decrease systemic vascular resistance after CPB through induction of nitric oxide synthesis in vascular endothelial cells.[55] Although IL-1 appears to be important in the initiation and propagation of the inflammatory cascade, it is not clear whether IL-1 levels cause deleterious effects or even serve as a marker for patients who will develop organ dysfunction after cardiac operations. Some of the reported effects of IL-1 may instead be caused by other cytokines, in particular, TNF, which are detected at the same time.

IL-8 is also believed to be an important component of the proinflammatory cascade. It is a potent chemoattractant of neutrophils to the site of injury or infection. IL-8 also is responsible for the activation, priming, and degranulation of neutrophils.[56,57] The relevance of

increases in IL-8 levels to outcome after cardiac surgical procedures has not been established.[42–44,46,47,51,53,58,59] Rothenburger and colleagues[60,61] observed a significant association between prolonged mechanical ventilation and postoperative IL-8 levels but not IL-6 levels.

IL-6 levels have been shown to increase in the setting of cardiac surgical procedures, although this finding is not universal.[10,42,43,45–48,51–54,58,62–65] Peak levels of this cytokine appear after maximum values for TNF and IL-1. For example, Steinberg and associates[54] measured plasma cytokine levels in 29 patients undergoing CPB. IL-6 levels peaked at 3 hours after separation from CPB and remained increased 24 hours postoperatively. No association was found between IL-6 levels and hemodynamic parameters or postoperative pulmonary function.

Antiinflammatory Cytokines

The regulation of inflammation is complex and involves a balance between proinflammatory and antiinflammatory cytokines. IL-10 is a potent inhibitor of the synthesis of TNF, IL-1, IL-6, and IL-8, and it increases in the perioperative period.[44,66–68] McBride and colleagues[68] obtained blood samples perioperatively from 20 patients undergoing cardiac surgical procedures. Before and during CPB, increases were observed in the proinflammatory cytokines TNF, IL-1, and IL-8. At the same time that proinflammatory cytokine levels began to decrease, increases in the antiinflammatory cytokines IL-10 and IL-1ra were observed. These investigators suggested that the balancing effects of these two types of cytokines may determine whether a patient suffers from the effects of excessive systemic inflammation (ie, postoperative organ dysfunction) or the effects of inadequate immune system enhancement (ie, postoperative infection and poor wound healing). Using this theory to improve outcome has not been translated yet into a clinical trial involving surgical patients. One concern related to potentially deleterious effects of inhibiting proinflammatory mediators has been borne out in sepsis trials in which mortality rates were increased in the group given an antiinflammatory agent.[69] An understanding of the interaction between proinflammatory and antiinflammatory mediators may result in the development of an effective and safe approach to reducing complications related to excessive systemic inflammation.

Complement System

The complement system describes at least 20 plasma proteins and is involved in the chemoattraction, activation, opsonization, and lysis of cells. Complement also is involved in blood clotting, fibrinolysis, and kinin formation. These proteins are found in the plasma, as well as in the interstitial spaces, mostly in the form of enzymatic precursors.

The complement cascade, illustrated in Fig. 9.3, can be triggered by either the *classic pathway* or the *alternate pathway*. In the alternate pathway, C3 is activated by contact of complement factors B and D with complex polysaccharides, endotoxin, or exposure of blood to foreign substances such as the CPB circuit. *Contact activation* describes contact of blood with a foreign surface with resulting adherence of platelets and activation of factor XII (Hageman factor) (Fig. 9.4). Activated factor XII has numerous effects, including initiation of the coagulation cascade through factor XI and conversion of prekallikrein to kallikrein. Kallikrein leads to generation of plasmin, which is known to activate the complement and the fibrinolytic systems. Kallikrein generation also activates the kinin-bradykinin system.

The classic pathway involves the activation of C1 by antibody-antigen complexes. In the case of cardiac surgery, two mechanisms for the activation of the classic pathway are likely. Endotoxin can be detected in the serum of almost all patients undergoing cardiac surgical procedures. Endotoxin forms an antigen-antibody complex with anti-endotoxin antibodies normally found in serum that can then activate C1. The administration of protamine after separation from CPB has been reported to result in heparin-protamine complexes, which also can activate the classic pathway[70,71] (see Chapters 31 through 36). Other investigators, however, have not observed this effect.[72] Contact activation leads to activation of factor XII, which results in the generation of

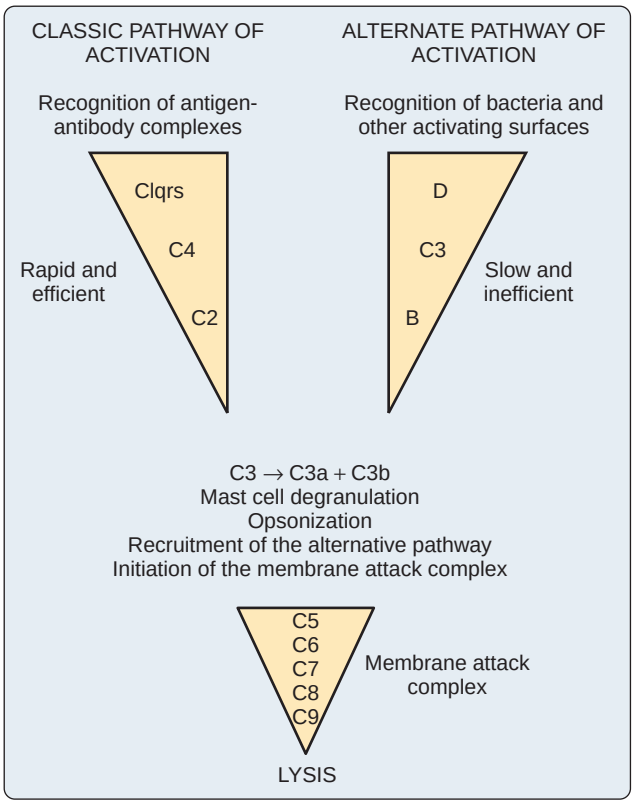

Fig. 9.3 Simplified components of the complement system. *(From Haynes BF, Fauci AS. Introduction to clinical immunology. In: Braunwald E, Isselbacher KJ, Petersdorf RG, et al., eds.* Harrison's Principles of Internal Medicine. *11th ed. New York: McGraw-Hill; 1987:328–337.)*

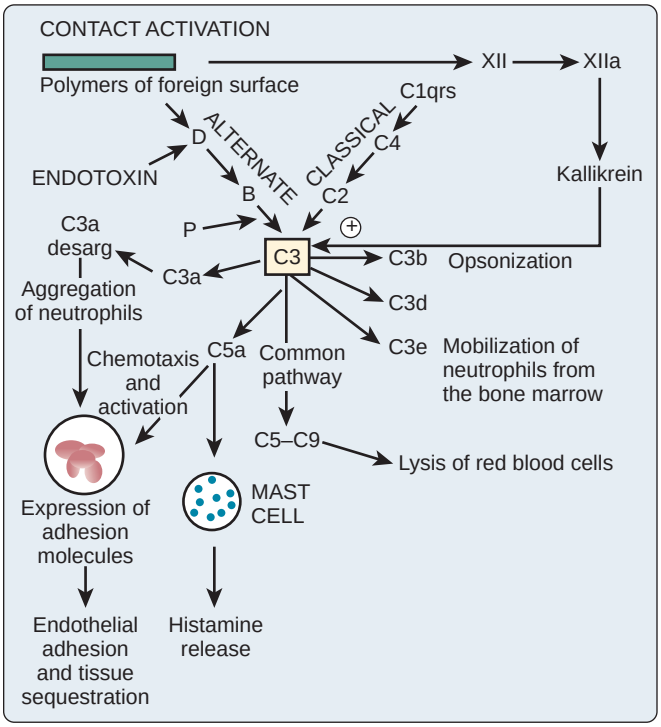

Fig. 9.4 Contact activation of the complement cascade during cardiopulmonary bypass. Activation of complement occurs primarily through the alternate pathway. *(From Ohri SK. The effects of cardiopulmonary bypass on the immune system.* Perfusion. *1993;8:121.)*

plasmin. Plasmin is capable of activating complement factors C1 and C3. Table 9.1 is a summary of the physiologic effects of the complement system.

Activated C3 and other complement factors downstream in the cascade have several actions. The effects of activated complement fragments on mast cells and their circulating counterparts, the basophil cells, may be relevant to the development of postoperative complications potentially attributable to complement activation. Fragments C3a and C5a (also called *anaphylatoxins*) lead to the release of numerous mediators including histamine, leukotriene B_4, platelet-activating factor, prostaglandins, thromboxanes, and TNF. These mediators, when released from mast cells, result in endothelial leak, interstitial edema, and increased tissue blood flow. Complement factors such as C5a and C3b complexed to microbes stimulate macrophages to secrete inflammatory mediators such as TNF. C3b activates neutrophils and macrophages and enhances their ability to phagocytose bacteria. The lytic complex, composed of complement factors C5b, C6, C7, C8, and C9, is capable of directly lysing cells. Activated complement factors make invading cells "sticky," such that they bind to one another (ie, agglutinate). The complement-mediated process of capillary dilation, leakage of plasma proteins and fluid, and accumulation and activation of neutrophils makes up part of the acute inflammatory response.

Although some elements of complement activation have been elucidated, clinicians are continuing to learn about the clinical relevance of this process to patients undergoing cardiac operations.

TABLE 9.1 Biologically Significant Effects of the Various Complement-Split Products

Biologic Effect	*Complement-Split Products*
Mast cell degranulation, contraction of smooth muscle, increased vascular permeability	C3a, C5a
Chemotaxis of neutrophils	C5a, C5a des Arg
Neutrophil aggregation	C5a, C5a des Arg
Lysosomal enzyme release	C5a, C3b
Leukocytosis	C3e
Immune adherence/opsonization	C3b, C4b
Membrane lysis	C5b-9 (membrane attack complex)

From Knudsen F, Andersen LW. Immunological aspects of cardiopulmonary bypass. *J Cardiothorac Anesth.* 1990;4:245.

Several studies reported increased complement levels during cardiac surgery.[38,58,73–78] Chenoweth and associates[73] measured plasma C3a and C5a levels at different time points in 15 adults undergoing cardiac surgical procedures with CPB. Although C3a levels were not affected by surgical stimulation, complement activation increased significantly during CPB. This and other studies did not test the association between increased complement levels and adverse postoperative outcome. Thus the studies do not provide any evidence that complement activation causes clinically significant systemic inflammation. Kirklin and colleagues[75] measured plasma C3a levels in 116 patients undergoing cardiac operations with CPB and in 12 patients undergoing operations without CPB. In this study, an increase of complement activation during CPB was associated with postoperative morbidity, although this study has significant limitations. Patients undergoing procedures without CPB did not demonstrate increases in complement. This result suggests that a factor unique to CPB causes activation of complement.

In several large, randomized clinical trials, complement activation was selectively blocked.[79–81] These studies indicated that attenuation of complement activation results in less myocardial injury; however, it did not appear to have an impact on complications such as pulmonary and renal dysfunction and severe vasodilation. These results suggest that complement activation may not play as large a role in the development of systemic inflammation-mediated morbidity as previously thought. These trials are discussed in more detail later in this chapter.

Endotoxin

Endotoxin, also called *LPS,* is a component of the cell membrane of gram-negative bacteria. It is a potent activator of complement and cytokines, and it appears to be one of the initial triggers of systemic inflammation, as summarized in Fig. 9.2.[12,82–84] Although the LPS constituent varies from one bacterial species to another, it generally may be described with reference to Fig. 9.5 as consisting of three structural regions: lipid A, core, and O-polysaccharide outer region. The lipid region of lipid A is embedded in the outer leaflet of the outer membrane. The oligosaccharide core region is positioned between lipid A and the O-polysaccharide outer region. Lipid A has the same basic structure in practically all gram-negative bacteria and is the toxic component of endotoxin. The LPS core region shows a high degree of similarity among various bacteria. It usually consists of a limited number of sugars. For example, the inner core region consists of heptose and 3-deoxy-D-*manno*-2-octulosonate (KDO) residues, whereas the outer core region comprises galactose, glucose, or *N*-acetyl-D-glucosamine residues displayed in various manners depending on the strain.

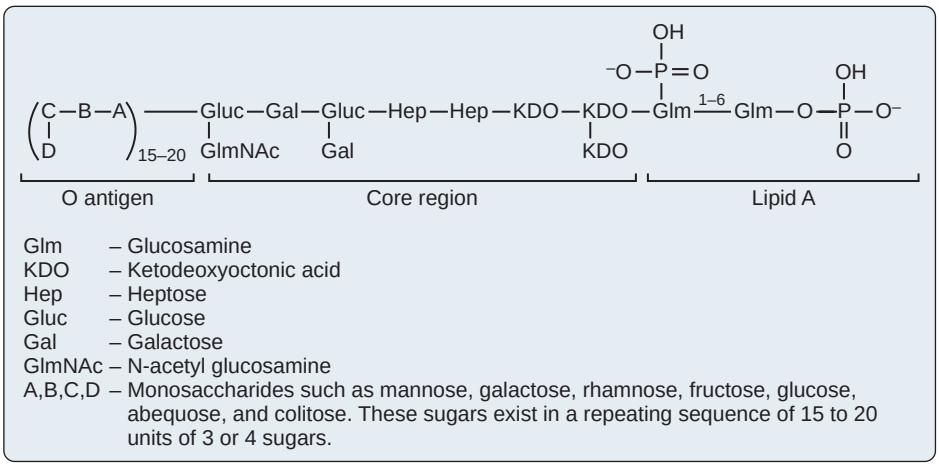

Fig. 9.5 Schematic structure of one unit of *Salmonella* cell wall lipopolysaccharide (*LPS;* endotoxin). The structure of the cell wall LPS may vary slightly from one genus of gram-negative organism to another, but as far as is known, all contain three general regions, as shown. Although not shown here, all free hydroxyl groups of the glucosamines in lipid A are esterified with fatty acids. The serologic differences among different strains within a genus lie in the kinds of sugars and their linkages that exist in the O-antigen region. *(From Volk WA, Benjamin DC, Kadner RJ, Parsons JT, eds.* Essentials of Medical Microbiology. *3rd ed. Philadelphia: Lippincott; 1986:399.)*

The O-polysaccharide outer region (also called *O-specific antigen* or *O-specific side chain*) is highly variable and is composed of one or more oligosaccharide repeating units characteristic of the serotype.

Endotoxemia

Endotoxemia refers to the presence of endotoxin in the blood. This disorder is common in cardiac surgical patients.[10,11,38,41,60,64,65,85–95] It is not surprising that some investigators have failed to detect endotoxemia during cardiac surgical procedures given its transient and intermittent nature, although differences in endotoxin-assaying techniques used also may contribute to this discrepancy.[51,52,96,97] Andersen and associates[11] measured circulating endotoxin levels in 10 patients undergoing cardiac operations. All preoperative blood samples were free of endotoxin; however, substantial levels of endotoxin were detected intraoperatively. Blood endotoxin levels from eight typical patients undergoing cardiac operations are presented in Fig. 9.6.[85] Although endotoxin can be found in sterile fluids administered to patients, it is believed that the majority of endotoxin arises through a patient's impaired gut barrier.[11] Rothenburger and colleagues[60] studied the association of endotoxin levels with prolonged mechanical ventilation in 78 cardiac surgical patients. Endotoxin levels were three times greater in patients with a postoperative mechanical ventilation time longer than 24 hours (n = 13) compared with patients with ventilator time less than 24 hours.

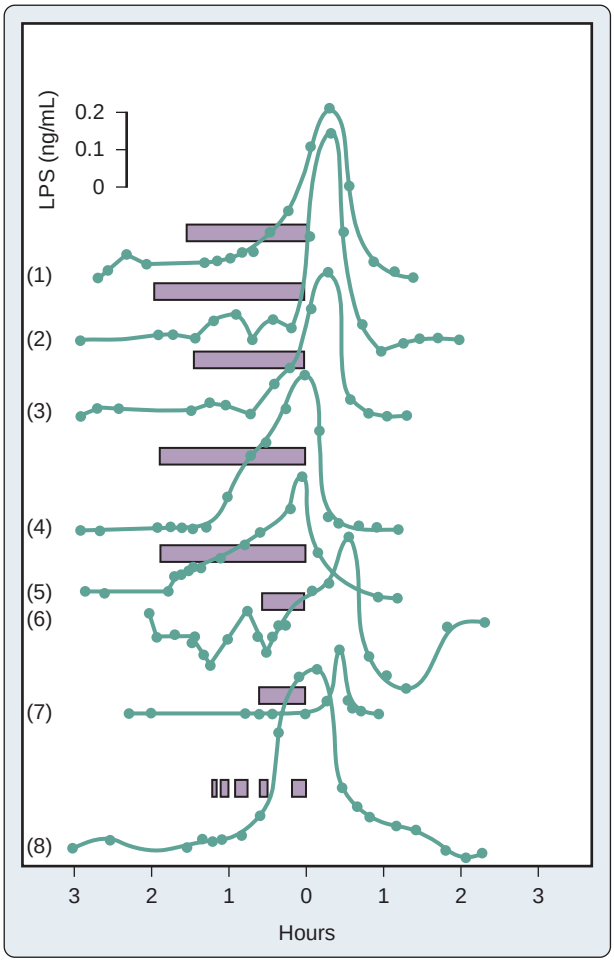

Fig. 9.6 Time course of plasma lipopolysaccharide *(LPS)* concentrations during cardiopulmonary bypass procedures for patients 1 to 8. *Hatched boxes* indicate the period of aortic cross-clamping. For clarity, records were offset and aligned at the time of removal of the aortic clamp. *(From Rocke DA, Gaffin SL, Wells MT, et al. Endotoxemia associated with cardiopulmonary bypass.* J Thorac Cardiovasc Surg. *1987;93:832.)*

Normally, intestinal flora contain a large amount of endotoxin from gram-negative microorganisms.[98] The average human colon contains approximately 25 billion nanograms of endotoxin, which is an enormous quantity when 300 ng endotoxin is toxic to humans.[33,34] The leakage of live bacterial cells into the bloodstream can result in infection as these viable bacteria multiply.[99] However, many of the bacteria in the intestine are dead, and thus endotoxin also can enter the bloodstream contained within cell membrane fragments of dead bacteria. In this case, infection per se does not develop. Instead, endotoxin may initiate a systemic inflammatory response through potent activation of macrophages and other proinflammatory cells.[100] A plasma endotoxin concentration of only 1 ng/mL has been reported to be lethal in humans.[101]

On entry to the bloodstream, endotoxin forms complexes with numerous intravascular compounds including high-density lipoprotein, LPS-binding protein, and endotoxin-specific immunoglobulins. Endotoxin has been linked to dysfunction in every organ system of the body and may be the key initiating factor in the development of systemic inflammation.[12,82–84,93]

Normal Host Defenses Against Endotoxemia

Early Tolerance

If endotoxemia is deleterious to patients, it would be logical to assume that patients have defense mechanisms against this ubiquitous toxin. Tolerance to endotoxin was studied extensively by Greisman and Hornick in the early 1970s.[102] Two distinct types of tolerance to endotoxin exist and are classified as *early tolerance* and *late tolerance.*[102] Early tolerance to endotoxin represents a reduction in the proinflammatory effects of LPS when it is administered several hours after an earlier infusion of LPS.[103] It appears to result from an LPS-induced refractory state of macrophages in which they release less TNF in response to endotoxin. This early refractive state shows no LPS specificity and can be overcome with increased doses of endotoxin. The degree of this tolerance is directly proportional to the dose and hence the intensity of the initial LPS-induced inflammatory state. Early tolerance begins within hours of LPS exposure and decreases almost to baseline within 2 days. It cannot be transferred with plasma. Early tolerance may protect the host from lethal systemic inflammation after an overwhelming exposure of LPS.

Late Tolerance

Late tolerance to endotoxin is caused by the synthesis of immunoglobulins (ie, antibodies) directed against the offending LPS.[102] Late tolerance begins approximately 72 hours after exposure to LPS, timing that correlates with the appearance of the early-appearing immunoglobulin M (IgM) class of antibodies. This form of tolerance persists for at least 2 weeks and correlates with the presence of serum immunoglobulins. In contrast to early tolerance, the late response is not proportional to the intensity of the initial LPS-induced inflammatory response but is related to the immunogenicity of the initial LPS. Furthermore, late tolerance does not generally protect against a subsequent challenge with a dissimilar type of LPS. In other words, late tolerance is most pronounced when the same (ie, homologous) LPS serotype is used for both the initial and the subsequent challenge. It is not definitively understood how antiendotoxin antibodies responsible for late tolerance confer protection from LPS-induced systemic inflammation. Proposed mechanisms include increased clearance of endotoxin into the reticuloendothelial system, as well as direct neutralization through binding.

Understanding of the host's normal humoral defense against endotoxin is further complicated by the numerous serotypes of endotoxin.[98] Serotype-specific antibodies (ie, antibodies synthesized in response to a particular LPS) exhibit high-affinity binding to and protection from the specific serotype of endotoxin. These serotype (O-specific) antiendotoxin antibodies, however, do not recognize the many possible

variations of endotoxin O-polysaccharide side chains and thus are ineffective at conferring protection against the numerous serotypes of endotoxin likely to be encountered in the clinical setting. Conversely, antibodies directed against the well-conserved inner core structure of endotoxin should theoretically be cross-reactive against many clinically relevant serotypes of endotoxin. Cardiac surgical patients are exposed to a wide variety of endotoxin types. For example, at least 164 O-antigens exist for *Escherichia coli,* the gram-negative bacteria most commonly isolated in high-risk surgical patients and patients in the intensive care unit (ICU).[104,105]

Criticisms of Endotoxin as a Causative Factor

Several criticisms of the theory that endotoxemia is an important cause of postoperative morbidity have been expressed. A common criticism relates to the low incidence of culture-proven bacteremia in surgical and ICU patients.[106–109] Endotoxemia, however, is clearly prevalent in these patients and usually exists in the setting of negative blood culture results.[10,11,24,38,41,64,65,85–95] In fact, studies attempting to detect endotoxemia probably underestimate its incidence given its intermittent nature.

The failure of two antilipid A monoclonal antibodies (HA-1A, Centocor, Malvern, Pennsylvania; and E5, Xoma, Berkeley, California) to improve outcome on an "intention-to-treat" basis in ICU patients with established sepsis also has been used to suggest that endotoxemia is not clinically relevant.[110,111] These monoclonal antibodies may not bind to endotoxin with high affinity, and this may partly explain their lack of demonstrable efficacy.[112] In addition, these antibodies were tested in patients with established sepsis and organ failure, which comprise an entirely different setting from that of elective surgical patients, who are more likely to benefit from prophylaxis with endotoxin-neutralizing drugs. Arguing against the clinical relevance of endotoxin is the negative result of a trial of prophylactic administration of a lipid A antagonist (E5564) in cardiac surgical procedures.[113]

Splanchnic Perfusion

Splanchnic hypoperfusion appears to be an important cause of systemic inflammation.[114–117] The gut is one of the most susceptible organs to hypoperfusion during conditions of trauma or stress.[117–119] In the 1960s, Price and associates[118] removed 15% of the blood volume from healthy volunteers and caused a 40% reduction in splanchnic blood volume. In this study, cardiac output (CO), blood pressure (BP), and HR did not change from baseline. A study was conducted by Hamilton-Davies and colleagues[120] in which 25% of the blood volume was removed from six healthy volunteers. Gastric mucosal perfusion, as measured by saline tonometry, was the first variable to decline (in five of the six subjects). Stroke volume also decreased; however, routinely measured cardiovascular variables such as HR, BP, and CO did not change significantly enough from baseline values to cause suspicion of a hypovolemic state. Based on these types of studies, the Advanced Trauma Life Support (ATLS) course teaches that a 15% blood loss (class I hemorrhage) rarely results in changes in HR, BP, or urine output.[121] Significant decreases in systolic BP are late signs of shock, which typically occurs after class III hemorrhage (30–40% blood loss).

These studies suggest that during periods of hypovolemia, the gut vasoconstricts, thus shunting blood toward "more vital organs" such as the heart and brain.[117–119] In addition to hypovolemia, endogenously released vasoconstrictors during CPB, such as angiotensin II, thromboxane A_2, and vasopressin, also may result in decreased splanchnic perfusion.[122–125] Vasoconstrictors, such as phenylephrine, are routinely administered by anesthesiologists and perfusionists to increase BP and are likely to reduce gut perfusion further. Oudemans-van Straaten and associates[89] measured intestinal permeability and endotoxin levels in 23 patients during cardiac surgical procedure. Intestinal leak was measured by the amount of orally administered cellobiose present in the patients' urine. Intestinal permeability increased during the surgical procedures and correlated with circulating endotoxin levels. Administration of ephedrine, low central venous pressures, and less fluid balance during the operations also were associated with intestinal permeability; this finding confirms the theory that gut perfusion is reduced by vasoconstrictors, as well as by hypovolemia. Evidence also indicates that systemic endotoxemia may worsen intestinal permeability, thus exacerbating splanchnic hypoperfusion and initiating a vicious cycle.[126]

Several studies observed a high incidence of splanchnic hypoperfusion during cardiac operations, and some of these studies showed an association between abnormal gut perfusion during cardiac surgical procedures and postoperative complications.[10,87,88,127–130] Fiddian-Green and Baker[127] used saline tonometry to measure gastric mucosal perfusion in 85 cardiac surgical patients. Half (49%) of these patients developed evidence of abnormal perfusion, and all serious postoperative complications (eight patients, including five deaths) developed in this group. Gastric tonometry was shown in this and in two other studies to be a more sensitive predictor of adverse postoperative outcome compared with more routinely used global measures such as CO, BP, HR, and urine output.[128,130] A study using air tonometry demonstrated an increased gastric mucosal partial pressure of carbon dioxide in 52% of cardiac surgical patients. Thirty-five percent of these patients with abnormal perfusion developed postoperative complications, in contrast to 5% in the group without evidence of hypoperfusion.[130]

Studies that have failed to demonstrate an association between splanchnic hypoperfusion and adverse postoperative outcome are limited, in part, by small sample size, insensitive measures of postoperative morbidity, and deviation from validated methodology of tonometry.[87,88] Tonometric measurements of gastric mucosal perfusion during hypothermic CPB have not been validated in terms of their ability to predict postoperative morbidity.

Postoperative Complications Attributable to Inflammation

Types of Complications

Many postoperative complications are attributed to an exaggerated systemic proinflammatory response to surgical trauma. A common misunderstanding relates to the types of postoperative complications that may be attributable to systemic inflammation and, in particular, splanchnic hypoperfusion. Many of the complications that are thought to be linked to splanchnic hypoperfusion do not involve the gastrointestinal system. Because splanchnic hypoperfusion may cause injury through a systemic inflammatory response, it would be expected that every organ system of the body potentially would be involved.[131] For example, endotoxin has been reported to have adverse effects on the pulmonary, renal, cardiac, and vascular systems.[41,46,83,84,132–135] It affects the coagulation system and may be both antihemostatic, thus potentially explaining bleeding, and prothrombotic.[83,132,136] Prothrombotic effects may account for some cases of postoperative stroke, deep vein thrombosis, and pulmonary emboli. Circumstantial evidence also indicates that systemic inflammation may worsen neurologic injury.[137] Activation of inflammatory cascades has been shown to worsen neurologic injury in numerous animal models.

Infections are common after cardiac surgical procedures and increase hospital length of stay and cost.[107,138,139] Infecting bacteria may arise from translocation across the patient's gastrointestinal tract.[107,114,116] Surgical wounds (sternum and lower extremity) and the respiratory tract are common sources of postoperative infection.[140] Infections of prosthetic heart valves are less common but represent a devastating complication.[141] Infections are probably not caused by the direct effects of inflammation, but rather secondary effects on host immunity may predispose to this complication.[142]

Widespread activation of the complement system results in depletion of complement factors, which are crucial to the effective opsonization of bacterial pathogens.[143,144] Systemic activation and degranulation of neutrophils render these cells less capable of destroying bacteria by phagocytosis. CPB leads to reductions in immunoglobulin levels through denaturation of these and other proteins.[144–148] Antibody

production by B lymphocytes (plasma cells) is depressed after cardiac surgical procedures.[149] Cell-mediated immunity, revealed by decreased T-lymphocyte function, appears to be impaired after cardiac operations.[150] Thus reduced antibody levels, as well as reduced B- and T-cell function in the post-CPB period, may lead to increased infection rates after cardiac surgical procedures.

Incidence of Complications

The "low" mortality rate after cardiac surgical procedures also has been cited as evidence that splanchnic hypoperfusion, endotoxemia, and systemic inflammation result in only "rare" complications. As discussed earlier, it is clear that death[1] and morbidity[3,151] are still significant problems after cardiac operations. In addition, many studies report only frank organ failures or catastrophes and do not take into account less severe forms of organ dysfunction that do not lead to admission to an ICU but nevertheless cause suffering and increase hospital length of stay.

For example, a series by Huddy and colleagues[152] of 4473 cases involving CPB demonstrated a very low incidence rate (0.78%) of "gastrointestinal complications." In a series of 3129 patients, Christenson and associates[153] reported an incidence rate of 2.3% for major gastrointestinal complications after CABG procedures. The low incidence of major gastrointestinal complications (ie, perforation, necrotic bowel, major gastrointestinal bleeding) is often used to call into question the clinical relevance of splanchnic hypoperfusion. Growing evidence, however, indicates that less severe forms of splanchnic dysfunction (eg, ileus, nausea, anorexia, and abdominal distention) are clinically relevant and increase hospital length of stay.

Some series of postoperative complications have broadened their scope. In a series of 572 patients, Corwin and colleagues[154] reported the incidence of renal failure requiring dialysis (1%), as well as the incidence of renal dysfunction not requiring dialysis (6.3%). This study demonstrates that organ dysfunction is common postoperatively, despite a low incidence of organ failure.

Similarly, the incidence rate of acute respiratory distress syndrome after cardiac operations was reported to be very low (<2%) in several series.[155,156] The incidence of less severe pulmonary dysfunction appears to be much greater, however, as many as 7% of patients require supplemental oxygen 11 days postoperatively (Bennett-Guerrero E, unpublished data). Furthermore, a high incidence of postoperative pulmonary dysfunction, as measured by diagnostic tests, gives further support to the hypothesis that many patients have abnormal pulmonary physiology potentially attributable to systemic inflammation.[157–159]

Potential Therapies for the Prevention of Inflammation-Related Complications

Numerous strategies and pharmacologic agents have been demonstrated to reduce laboratory indices of complement activation and cytokinemia. Many of these studies, however, have been too small to detect improvements in clinically meaningful postoperative outcomes. All interventions that have been tested in large phase III trials have failed to demonstrate meaningful clinical improvement, as discussed in following sections. Currently, no therapies in widespread clinical use are available to prevent or treat organ dysfunction resulting from systemic inflammation; however, several approaches are discussed.

Steroid Administration

Steroids have been demonstrated to attenuate the release of proinflammatory cytokines, mitigate complement activation, and increase antiinflammatory mediators during cardiac surgical procedures.[37,86,160–169] The effect of steroids on the SIRS response during cardiac operations is among the most thoroughly studied of all interventions. No less than 3 metaanalyses focused on this intervention have been published, with more than 50 trials included.[170–172] Each metaanalysis suggested a trend toward benefit of steroids on morbidity and possibly mortality and called for large definitive trials to be undertaken.

The first large randomized controlled trial published in this area was the Dexamethasone for Cardiac Surgery Study (DECS).[173] This trial randomized 4494 adult patients to dexamethasone or placebo in 8 centers in the Netherlands. The DECS demonstrated that dexamethasone had no effect on the primary outcome of death, myocardial infarction, stroke, new renal failure, or respiratory failure (risk ratio [RR] for dexamethasone, 0.83; 95% confidence interval [CI], 0.67 to 1.01). However, a prespecified subgroup analysis suggested a benefit of steroids on the primary outcome in the subgroup of high-risk patients, defined as patients with a European System for Cardiac Operative Risk Evaluation score (EuroSCORE) of 5 or higher (RR, 0.77; 95% CI, 0.61 to 0.98). Further publications from the DECS group also demonstrated no impact on postpericardiotomy syndrome, new-onset atrial fibrillation, or postoperative cognitive decline.[174–176]

The Steroids in Cardiac Surgery trial followed on the heels of the DECS and randomized 7507 high-risk patients (EuroSCORE ≥6) to methylprednisolone or placebo. The dosing protocol used in the Steroids in Cardiac Surgery trial had been demonstrated to attenuate the biomarkers of inflammation in a published pilot study.[169] In fact, unpublished data from the group demonstrated what was thought to be a more favorable balance across a broad selection of proinflammatory and antiinflammatory mediators measured, with lower levels of IL-6, IL-8, TNF-α and increased levels of IL-10 (Fig. 9.7). The Steroids in Cardiac Surgery trial results were presented at the 2014 American College of Cardiology Conference, and publication is pending. The Steroids in Cardiac Surgery trial failed to demonstrate benefit of methylprednisolone on the risk of death (RR for methylprednisolone, 0.87; 95% CI, 0.70 to 1.07) or on the composite of death, myocardial injury, stroke, renal failure, and respiratory failure (RR, 1.03; 95% CI, 0.95 to 1.11) in patients with an elevated EuroSCORE.[177]

With both the DECS and the Steroids in Cardiac Surgery trial demonstrating no benefit of steroid prophylaxis on important clinical outcomes, the use of steroids in the field will likely disappear, and broader questions regarding the clinical relevance of the systemic inflammation are raised.

Role of Cardiopulmonary Bypass Technique

Although heparin-coated circuits have many theoretic advantages, evidence that their use during cardiac operations results in fewer clinically significant adverse complications is scant. Steinberg and associates[54] found no difference in cytokine levels or markers of complement activation between patients randomized to a heparin-coated circuit and patients randomized to a traditional circuit. Borowiec and colleagues,[25] however, observed lower levels of myeloperoxidase and lactoferrin (markers of inflammation) in patients undergoing CPB with a heparin-coated circuit. Other investigators reported reduced plasma levels of cytokines or neutrophil proteases in patients subjected to CPB using heparin-coated circuits; however, no improvement in outcome was observed in these small studies[23,53,178,179] (see Chapters 31 and 32). A metaanalysis involving 3434 patients from 41 randomized trials demonstrated reductions in blood transfusion and durations of mechanical ventilation, ICU stay, and hospital length of stay, findings that provide some support for this intervention.[180]

Centrifugal vortex blood pumping has been shown to result in reduced complement and neutrophil activation, as well as reduced hemolysis during cardiac surgical procedures compared with standard roller blood pumping.[181,182] Centrifugal vortex blood pumping, however, did not significantly prevent increases in cytokines in 17 pediatric patients randomized to this bypass technique.[58]

A randomized study of 15 patients suggested that pulsatile-flow CPB may result in less endotoxemia than CPB involving nonpulsatile flow.[94] Levine and associates[125] randomized 20 patients to pulsatile versus nonpulsatile flow and observed a less marked increase in vasopressin levels (an endogenous vasoconstrictor) in patients perfused with pulsatile flow. Taylor and colleagues[122] demonstrated increased levels of the endogenously produced vasoconstrictor angiotensin II in patients (n = 24) randomized to nonpulsatile flow CPB as compared with pulsatile flow. Watkins and associates[124] observed fewer marked

alterations in thromboxane B_2 and prostacyclin levels in patients (n = 16) randomized to pulsatile CPB. These studies evaluating pulsatile flow suggest that splanchnic perfusion may be better preserved with pulsatile flow because of less endogenously mediated vasoconstriction. Quigley and colleagues,[52] however, reported a lack of endotoxemia and pathologic cytokinemia in an uncontrolled study of patients who underwent nonpulsatile CPB. These investigators claimed that the use of "adequate flow and perfusion pressures" during CPB accounted for their findings.

The role of membrane oxygenators as a means of reducing systemic inflammation-related complications also is controversial. Less complement activation has been observed with the use of membrane oxygenators; however, other studies found no difference.[62,74,161,183–187] The use of membrane oxygenators was associated with better pulmonary function as compared with the use of a bubble oxygenator, although whether the difference observed reflected reduced systemic inflammation in the protocol group is unclear.[185] Butler and associates[62] randomized 20 patients undergoing cardiac surgical procedures to either a membrane oxygenator or a bubble oxygenator. IL-6 levels peaked 4 hours postoperatively, yet no significant differences were observed between groups in IL-1 or IL-6 levels or in intrapulmonary shunting. This study failed to show a difference in postoperative outcome, possibly because of short CPB durations (<1 hour), as well as the small sample size, which makes detecting a clinically significant difference in postoperative complications unlikely. Host defenses may be better maintained with the use of membrane oxygenators.[186]

Whether hypothermia during CPB affects systemic inflammation is also controversial.[40,51,76,188–190] Hypothermia has been shown to reduce

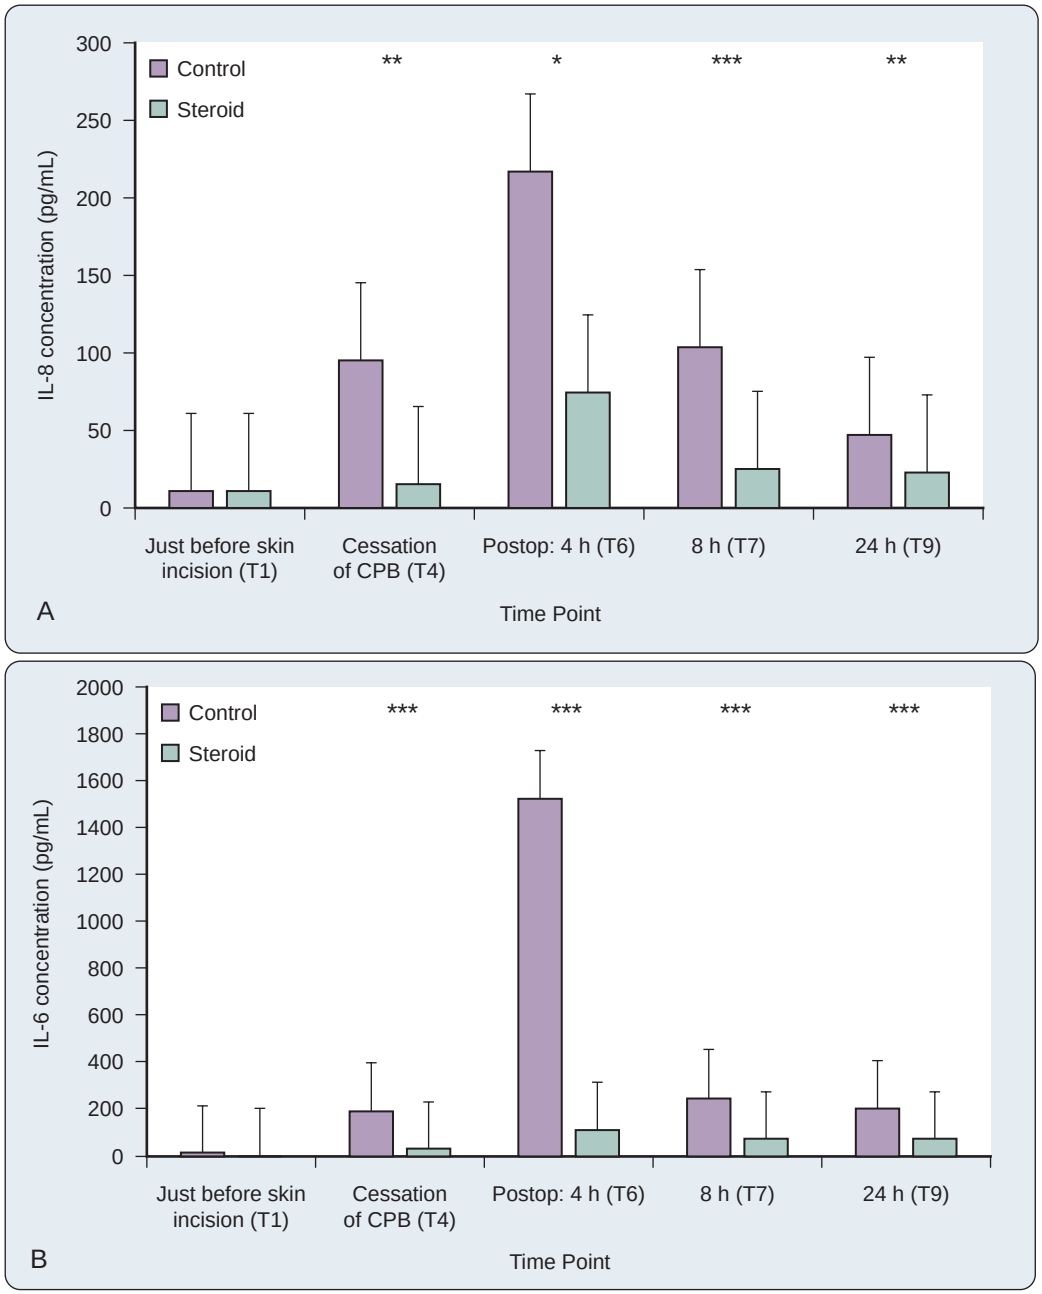

Fig. 9.7 Impact of methylprednisolone on (A) interleukin-6 *(IL-6),* (B) IL-8, (C) tumor necrosis factor-alpha *(TNF-alpha),* and (D) IL-10, from Randox's Evidence Investigator Platform9.8. *CPB,* Cardiopulmonary bypass; *$P < .05$; **$P < .01$; ***$P < .005$. *(Data from Dr. Richard Whitlock.)*

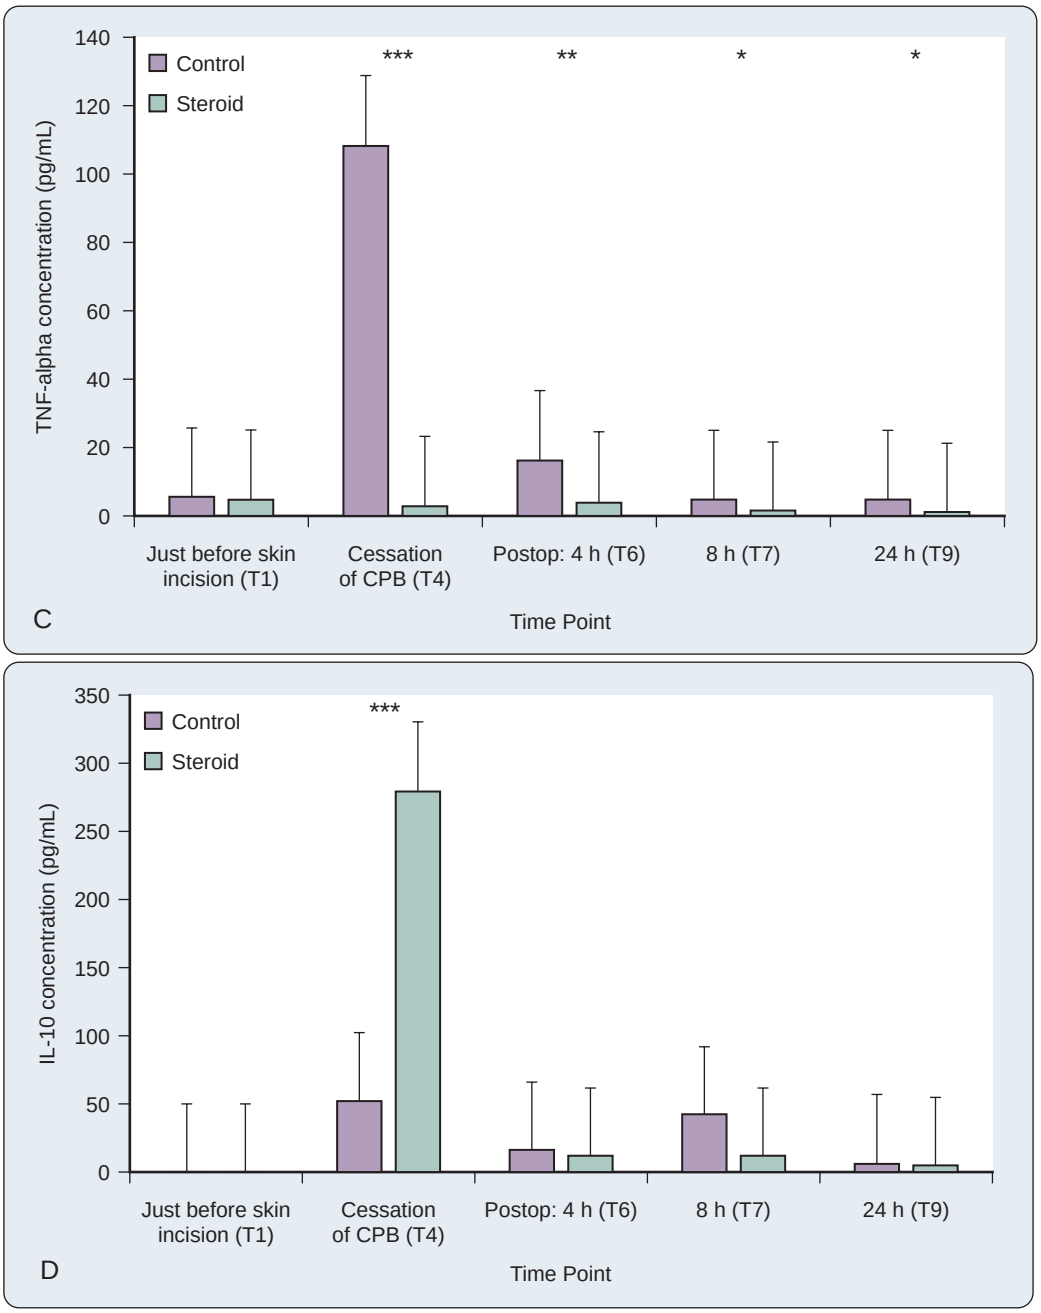

Fig. 9.7, cont'd

markers of complement activation.[76] Another study demonstrated reduced markers of inflammation, such as TNF and IL-6, as well as decreased neutrophil activation in the hypothermia group.[189] In contrast, another study randomized 30 cardiac surgical patients to either normothermic or hypothermic CPB.[40] These investigators found no association between CPB temperature and plasma TNF levels at any time point in the perioperative period, a finding suggesting a limited role for temperature as an independent cause of proinflammatory cytokine release. In one of the largest randomized trials to date, 300 elective CABG-treated patients were randomized to either normothermic (35.5–36.5°C) or hypothermic (28–30°C) CPB.[191] No differences were seen in either short-term or longer term outcome, thus suggesting no benefit to intraoperative hypothermia. However, evidence indicates that perioperative hyperthermia may be detrimental to the brain.[192] These investigators also observed an association between greater levels of the proinflammatory cytokine IL-6 and postoperative hyperthermia, a finding suggesting a potential role of inflammation in the increases in temperature commonly observed after major operations.

Finally, current data suggest that use of CPB for cardiac surgical procedures may not itself be more deleterious than not using CPB for these operations. Results from initial randomized clinical trials did not suggest that outcomes were substantially different in patients undergoing on-pump versus off-pump CABG procedures.[193–197] Given the importance of this question, two large randomized trials were performed to assess the potential benefits of off-pump CABG. The first trial included 2203 cardiac surgical patients at 18 Veterans Affairs medical centers from 2002 to 2008 and randomized these patients to either on-pump or off-pump CABG. No benefit was found with regard to outcomes such as duration of mechanical ventilation, lengths of stay in the ICU or hospital, renal failure, or a composite end point of complications.[198] The second trial randomized 4752 patients who were to undergo CABG procedures to either off-pump or on-pump

technique. No benefit was demonstrated for the primary outcome of death, nonfatal stroke, nonfatal myocardial infarction, or new renal failure (HR for the off-pump group, 0.95; 95% CI, 0.79 to 1.14).[199] Systemic inflammation was not specifically studied in these trials, but these data suggest that systemic inflammation attributable to CPB may have a more modest role in determining clinical outcome than previously thought.

Complement Inhibition

The results from several large, randomized clinical trials in which complement activation is selectively blocked have become available.[79–81] For example, in the largest randomized, double-blind clinical trial conducted to date, 3099 adults undergoing CABG procedures at 205 hospitals in North America and Western Europe were enrolled.[80] Patients were randomized to placebo or to a 24-hour infusion of pexelizumab, which is a recombinant, humanized, single-chain antibody fragment that binds to human C5 complement and prevents its activation. The administration of pexelizumab resulted in rapid and complete inhibition of complement activation. The primary outcome variable (death or myocardial infarction within 30 days) did not achieve statistical significance ($P = .07$). The subset of patients undergoing CABG plus valve did demonstrate a statistically significant difference ($P = .03$) in this outcome. This finding is somewhat contradictory to that of the previous phase IIb trial (n = 914), which enrolled patients undergoing CABG or valve operations, or both, and did not show a significant difference with regard to the end point of death or myocardial infarction.[79] This previous trial did achieve significance in the subset of patients undergoing isolated CABG, which was the apparent justification for studying isolated CABG operations in the larger phase III trial. These results suggest that complement activation may not play as large a role in the development of systemic inflammation-mediated morbidity as previously thought.

Ultrafiltration

Removal of excess fluid with ultrafiltration has been proposed as a method for eliminating proinflammatory mediators during cardiac surgical procedures, particularly in the pediatric population.[46,200] It is unclear in studies performed thus far whether the beneficial effects of ultrafiltration are caused by one or some combination of the following factors: prevention of initiation of inflammation, removal of inflammatory mediators, or removal of excessive fluid alone. In one study, Journois and colleagues[201] randomized 20 pediatric cardiac surgical patients to either a control group or high-volume, zero-fluid balance ultrafiltration. Measured TNF, IL-1, IL-10, myeloperoxidase, and C3a levels were lower in the protocol group compared with the control group. These investigators suggested that hemofiltration may have some beneficial effects that are not the result of water removal alone. Patients in the ultrafiltration group had less postoperative fever, reduced perioperative blood loss, a shorter time to extubation, and a lower postoperative alveolar-arterial oxygen gradient, findings suggesting, but not proving, a causal relationship between proinflammatory cytokinemia and several clinically meaningful end points. The small sample size of this study precludes any conclusions from being made regarding other outcomes such as the incidence of multiple organ dysfunction syndrome or hospital length of stay.

In an interesting study, 192 cardiac surgical patients were randomized to placebo (no steroids or ultrafiltration), steroid administration without ultrafiltration, or hemofiltration without steroids.[202] The study arm randomized to ultrafiltration without steroids showed a reduction in time to extubation; however, steroid administration was not effective compared with placebo. These data are promising, but the small number of subjects per arm of the study and the limited number of positive outcomes reported make it unclear whether ultrafiltration should be used more routinely.

Leukocyte Depletion

Removal of leukocytes during CPB with an inline leukocyte filter has been proposed as a method for reducing the concentration of activated leukocytes. This, in turn, may prevent inflammatory-mediated postoperative complications. This technology was well reviewed by Warren and associates,[203] who, in their review of 63 studies, concluded that this procedure may have some modest benefits, but the low quality of evidence from the predominantly small trials precluded any definitive conclusions on this matter. For example, patients randomized to leukocyte depletion (n = 20) had better oxygenation after CPB; however, no differences were noted in other outcomes measured.[204] A prospective randomized study of patients (N = 50) receiving inline leukocyte filtration demonstrated decreased leukocytes; however, postoperative arterial blood gases, pulmonary vascular resistance, ventilator time, and hospital length of stay were no different between groups.[205] Another study demonstrated no difference in postoperative complications or in the plasma levels of neutrophil proteases in patients undergoing leukocyte depletion with an inline filter.[206]

Davies and colleagues[207] used another method of leukocyte depletion in which they removed platelets and leukocytes by plasmapheresis from patients before cardiac operations. These patients, compared with the control group, demonstrated reduced postoperative thoracic drainage, decreased allogeneic blood product administration, and improved pulmonary function. This technique is not in widespread clinical use because of a lack of studies confirming its findings, as well as the time and cost involved in performing plasmapheresis.

The techniques described earlier differ from the issue of administration of leukocyte-reduced packed red blood cells. This method of minimizing a patient's exposure to leukocytes involves filtering collected blood either at the time of donation (fresh filtered) or before its release by the blood bank (stored filtered).[208] Van de Watering and colleagues[209] reported results from a large (N = 914) randomized clinical trial in which patients undergoing cardiac surgical procedures were randomized to receive allogeneic red cells without buffy coat, fresh-filtered allogeneic red cells, or stored filtered units. Patients randomized to either filtration group experienced a significant reduction in postoperative mortality ($P = .015$); however, this effect was most robust in patients administered more than three transfusions. The differences among groups in the incidence of infection did not achieve statistical significance ($P = .13$). No differences among groups were found in ICU or hospital length of stay in those patients in the overall study population or in the subset administered more than three units. These data are from a randomized trial and therefore should be more heavily weighted. Data from some retrospective cohort studies have shown no benefit of leukocyte reduction.[210,211]

Aprotinin and Other Serine Protease Inhibitors

Aprotinin, a 58–amino acid serine protease inhibitor isolated from bovine lung, has been shown in numerous studies to decrease bleeding associated with cardiac surgical procedures. It antagonizes numerous proteolytic enzymes including plasmin and kallikrein, and it may have some antiinflammatory effects,[14,212] although a metaanalysis found no beneficial effect of aprotinin on systemic markers of inflammation.[213] The blood-sparing effects of aprotinin were apparently discovered serendipitously while it was being evaluated as an antiinflammatory agent in cardiac surgical patients. Despite more than 45 randomized clinical trials conducted to date, few data support the hypothesis that aprotinin administration reduces postoperative complications attributable to excessive systemic inflammation. In these trials, numerous surrogate markers of postoperative morbidity, such as the duration of postoperative tracheal intubation, ICU stay, and hospital length of stay, were not reported to be improved in aprotinin-treated patients. One large trial was completed in 2331 cardiac surgical patients at 19 Canadian centers.[214] Patients were randomized to aprotinin, aminocaproic acid, or tranexamic acid. No benefit of aprotinin was observed with regard to complications such as respiratory failure, renal failure, or multisystem organ failure, and the study was terminated early because of an increase in mortality rates in aprotinin-treated patients (RR for aprotinin, 1.53; 95% CI, 1.06 to 2.22). The findings from this trial, as well as from several previous observational studies, led to market withdrawal of aprotinin.

Tumor Necrosis Factor Antagonists

Soluble TNF receptor proteins antagonize the toxic effects of LPS-induced lethality in mice.[215] These agents are ineffective in the treatment of sepsis or septic shock but have not been tested in the setting of cardiac surgery.[216] Anti-TNF monoclonal antibodies have also been studied in ICU patients with sepsis; however, these antibodies have not yet been tested prophylactically in cardiac surgical patients.[69] A study involving prophylactic administration would allow for the antibody to be present before the TNF and thus determine whether TNF has overall harmful or beneficial effects. If TNF and other cytokines are essential to the healing process, complete inhibition of their effects may result in worse, rather than improved, postoperative outcomes. Well-designed, large clinical trials could resolve these controversial issues.

E5564

E5564 is a synthetically derived lipid A analogue that is a potent Toll-like receptor 4–directed endotoxin antagonist.[217] It does not have lipid A agonist properties, and even in high doses it does not cause signs or symptoms of endotoxemia or systemic inflammation in humans and animals. Healthy volunteers were administered E5564 before a standard challenge dose of reference endotoxin (4 ng/kg). Single E5564 doses of 50 to 250 μg blocked or attenuated all the effects of LPS in a dose-dependent manner. All E5564 dose groups had statistically significant reductions in increased temperature, HR, CRP levels, white blood cell count, and cytokine levels (TNF-α and IL-6) compared with placebo ($P < .01$).[217] This drug has shown promising results in critically ill patients with sepsis; however, results from a phase II trial in cardiac surgical patients were disappointing.[113] In this trial, 152 cardiac surgical patients at 9 centers in the United States were randomized to receive placebo or ascending doses of E5564. Blocking lipid A with eritoran did not result in any overt beneficial effects on markers of systemic inflammation (IL-6, IL-8, or CRP) or measures of organ injury. These results call into question the potential clinical relevance of lipid A in this setting.

Pentoxifylline

Pentoxifylline is a nonspecific phosphodiesterase inhibitor similar in chemical structure to theophylline, a common antiinflammatory used to treat asthma. Pentoxifylline has multiple rheologic and antiinflammatory properties, but the exact mechanism of its pharmacologic effects is poorly understood. Clinically, pentoxifylline is approved by the US Food and Drug Administration to treat intermittent claudication, presumably by increasing red cell deformability, which may improve oxygen delivery to ischemic tissues. Animal studies showed that treatment with pentoxifylline significantly attenuates endothelial damage and the formation of oxygen radicals after ischemia/reperfusion, prevents fever after the administration of LPS, and prevents leakage of bacteria from the gut during hemorrhagic shock. Clinical research studies using pentoxifylline have been performed in the setting of lung transplantation, cardiac surgery, and anemia requiring red blood cell transfusion.

In an initial study, Hoffman and associates[218] randomized 40 patients with an Acute Physiology and Chronic Health Enquiry (APACHE) II score of 19 or higher after cardiac surgical procedures to placebo or pentoxifylline (1.5 mg/kg per hour for 48 hours). In this study, patients administered pentoxifylline had significantly fewer days on mechanical ventilation, less need for hemofiltration, and a shorter ICU length of stay. In a historic control study, Thabut and colleagues[219] administered pentoxifylline to 23 consecutive patients undergoing lung transplantation. Compared with historic controls, patients administered pentoxifylline experienced less allograft dysfunction, and a significant reduction in 60-day mortality rates was noted. Other small studies also suggested possible benefit[220,221]; however, these results have not been confirmed in a large, multicenter trial.

Ethyl Pyruvate

Ethyl pyruvate is a novel antiinflammatory agent.[222,223] It was shown to protect the intestinal mucosa from mesenteric ischemia and reperfusion in rats and improve survival in murine models of acute endotoxemia and bacterial peritonitis. Results from a phase II trial in cardiac surgical patients were disappointing.[224] In this trial, 102 high-risk cardiac surgical patients were randomized to receive placebo or ethyl pyruvate at 13 centers in the United States. Administration of ethyl pyruvate did not result in any overt beneficial effects on markers of systemic inflammation (TNF-α, IL-6, or CRP) or measures of organ injury.

Statins

Statins are routinely used to reduce cholesterol levels in patients at risk for cardiovascular disease; however, the antiinflammatory effects of these drugs have received significant attention.[225] Investigators have speculated that prophylactic statin administration before surgical procedures may have beneficial effects. One trial randomized 497 vascular surgical patients to placebo or fluvastatin daily from randomization to 30 days postoperatively.[226] Patients randomized to the statin exhibited lower levels of the inflammatory markers IL-6 and CRP, and they also had reduced myocardial ischemia ($P = .01$). All-cause mortality rates were lower in the statin-treated patients (2.4% vs 4.9%); however, this difference did not achieve statistical significance ($P = .14$). No similar large trials have been conducted in cardiac surgery, but a metaanalysis was completed of 8 trials involving a total of 638 such patients.[227] This analysis showed that statin use decreased levels of IL-6, IL-8, CRP, and TNF-α, although no improvement in clinical outcomes was reported. At this point, the use of statins in cardiac surgery must be investigational until additional data are obtained to support this indication.

N-*Acetylcysteine*

This agents is used to prevent radiocontrast-induced nephropathy and as an antidote for acetaminophen overdose. Its antiinflammatory and antioxidant properties have been studied in the ICU setting and in cardiac surgical patients, with mixed results. A metaanalysis of *N*-acetylcysteine to ameliorate postoperative morbidity included 1338 patients from 13 trials.[228] This analysis suggested that *N*-acetylcysteine may have a beneficial effect with regard to postoperative atrial fibrillation, but the agent did not appear to be beneficial with regard to other postoperative complications.

Other Potential Antiendotoxin or Antiinflammatory Agents

Other potential approaches to preventing endotoxin-related complications involve the use of either synthetic or naturally occurring antiendotoxin compounds. *Bactericidal/permeability-increasing protein (BPI)* is a neutrophil granule protein that has been shown to have endotoxin-neutralizing and bactericidal activity in animal models. A human recombinant version, $rBPI_{21}$, neutralized endotoxin-mediated toxicity in humans.

A recombinant version of an antiendotoxin factor, *endotoxin-neutralizing protein,* is another agent that has been shown to protect animals from endotoxin-mediated toxicity.[229] Reconstituted high-density lipoprotein neutralized some of the toxic effects of endotoxin during an experimental model of human endotoxemia.[230]

Polymyxin B neutralizes the toxic effects of endotoxin, although toxicity has prevented prophylactic intravenous use.[231] *Dextran-polymyxin B* is a variation of polymyxin B that has been reported to have antiendotoxin properties, as well as minimal toxicity in animal models.

Soluble TNF receptor proteins antagonize the toxic effects of LPS-induced lethality in mice. This agent was not effective in the treatment of sepsis or septic shock but has not been tested in the setting of cardiac surgery.[215]

Role of Anesthetic Agents and Vasoactive Agents

Anesthetic agents, defined here as drugs that induce hypnosis, amnesia, muscle relaxation, or regional anesthesia, have not been shown to result in clinically meaningful reductions in systemic inflammation after cardiac surgical procedures. Numerous studies have evaluated the effect of these agents on the immune system, with varied results;

however, no studies have reported a difference in outcome with one technique versus another. Ketamine is a promising agent that has been studied largely as an adjunct to reduce postoperative pain in noncardiac operations. In an initial study in cardiac surgical procedures, administration of a low dose (0.25 mg/kg) of ketamine before CPB prevented an increase in IL-6 for 7 days postoperatively.[232] In addition, ketamine administration inhibited TNF production and leukocyte adherence in animal models and suppressed oxygen radical production in vitro. These results were confirmed in another small study of patients undergoing CPB.[233] However, no outcome data exist from large outcome trials, so it is unknown whether this intervention reduces clinically relevant complications.

All general anesthetic agents can reduce splanchnic perfusion indirectly through a depression of myocardial function and a reduction in CO and hence oxygen delivery to the splanchnic mucosa.[234,235] Isoflurane theoretically may be better than halothane, enflurane, or propofol because of its vasodilating properties, which may preserve splanchnic blood flow and blood volume.[234–237] A prospective randomized study of cardiac surgical patients demonstrated better splanchnic perfusion in patients with anesthesia maintained with isoflurane in contrast to patients with anesthesia with propofol or enflurane.[238]

Although not definitively supported yet, evidence indicates that splanchnic hypoperfusion and endotoxin-induced inflammation can be prevented in the operating room by strategies familiar to clinicians. Strategies involve the use of fluid loading to maximize stroke volume,[129] as well as the use of adequate levels of vasodilating volatile anesthetic agents. Inodilating agents, such as milrinone, amrinone, dopexamine, and dobutamine, may be more protective of splanchnic perfusion than inoconstricting agents, such as epinephrine, norepinephrine, and dopamine. Patients randomized to enoximone administration during cardiac surgical procedures demonstrated lower endotoxin levels, a finding suggesting a beneficial effect on the barrier function of the gut.[91] Endotoxemia is probably a more sensitive marker of loss of barrier function than gastric mucosal hypoperfusion because these patients still had decreases in calculated gastric mucosal pH (pHi). When tested in vitro, amrinone was a potent inhibitor of endotoxin-induced TNF production at clinically relevant drug concentrations, thus suggesting an additional advantage to the use of this phosphodiesterase inhibitor.[239] Dopamine is often touted as preserving splanchnic blood flow; however, responses to this agent are unpredictable, with vascular resistance increasing in some patients at low doses (3 to 5 μg/kg per minute).

Selective Digestive Decontamination

Selective digestive decontamination represents a possible approach to limiting the incidence and severity of systemic inflammation. The technique attempts to reduce the total amount of endotoxin exposure by reducing the reservoir of endotoxin normally contained within the gut. Martinez-Pellús and associates[65] conducted a prospective, open, randomized, controlled trial in 80 cardiac surgical patients. Patients were randomized to either a control group or up to 3 days of preoperative selective digestive decontamination accomplished with the administration of oral nonabsorbable antibiotics (polymyxin E, tobramycin, amphotericin B). Patients in the protocol group demonstrated much lower gut bacterial counts, as well as lower blood levels of endotoxin and the proinflammatory cytokine IL-6 in the operating room and the postoperative unit. The study was not designed with sufficient power to determine whether this technique affects outcomes such as mortality and morbidity. Nevertheless, a trend toward improved outcome (mortality, hospital length of stay) was observed in the protocol group. In contrast, Bouter and colleagues[240] found no beneficial effects of selective digestive decontamination on clinical outcome or blood levels of TNF-α, IL-6, or IL-10 in 78 cardiac surgical patients.

Summary

A large body of circumstantial evidence strongly suggests that systemic inflammation is an important cause of mortality and morbidity after cardiac surgical procedures. However, all therapies that have been shown to alter the inflammatory milieu of patients to what investigators perceive as a more favorable state have failed to demonstrate clinical benefit in large clinical trials. At this point, the need exists to question whether ongoing efforts to improve outcomes through suppression of inflammation are wise, at least until the pathophysiology is better understood.

Pharmacology of Anesthetic Drugs

LAEBEN LESTER, MD | NANHI MITTER, MD | DAN E. BERKOWITZ, MD | DANIEL NYHAN, MD

KEY POINTS

1. In patients, the observed acute effect of a specific anesthetic agent on the cardiovascular system represents the net effect on the myocardium, coronary blood flow, and vasculature; electrophysiologic behavior; and neurohormonal reflex function. Anesthetic agents within the same class may differ from one another quantitatively and qualitatively. The acute response to an anesthetic agent may be modulated by the patient's underlying pathology or pharmacologic treatment, or both.
2. Volatile agents cause dose-dependent decreases in systemic blood pressure. For halothane and enflurane, this mainly results from depression of contractile function, and for isoflurane, desflurane, and sevoflurane, pressure changes result from decreases in systemic vascular responses. Volatile anesthetics cause dose-dependent depression of contractile function that is mediated at a cellular level by attenuating calcium currents and decreasing calcium sensitivity. Decreases in systemic vascular responses reflect various effects on endothelium-dependent and endothelium-independent mechanisms.
3. Volatile agents determine coronary blood flow by their effect on systemic hemodynamics, myocardial metabolism, and coronary vasculature. When these variables were controlled in studies, the anesthetics exerted only mild direct vasodilatory effects on the coronary vasculature.
4. In addition to causing acute coronary syndromes, myocardial ischemia can manifest as myocardial stunning, preconditioning, or hibernating myocardium. Volatile anesthetics can attenuate myocardial ischemia development through mechanisms that are independent of myocardial oxygen supply and demand and can facilitate functional recovery of stunned myocardium. Volatile agents also can simulate ischemic preconditioning, a phenomenon described as anesthetic preconditioning; the mechanisms of which are similar but not identical.
5. Intravenous induction agents (ie, hypnotics) belong to various drug classes, including barbiturates, benzodiazepines, *N*-methyl-D-aspartate receptor antagonists, and α_2-adrenergic receptor agonists. Although they all induce hypnosis, their sites of action and molecular targets are different, and their cardiovascular effects partially depend on the class to which they belong.
6. Studies of isolated cardiac myocytes, cardiac muscle tissue, and vascular tissue have demonstrated that induction agents inhibit cardiac contractility and relax vascular tone by inhibiting the mechanisms that increase intracellular calcium ion (Ca^{2+}) concentration. This may be offset by mechanisms that increase myofilament Ca^{2+} sensitivity in the cardiac myocyte and vascular smooth muscle, which can modulate cardiovascular changes. However, the cumulative effects of induction agents on contractility, vascular resistance, and vascular capacitance are mediated predominantly by their sympatholytic effects. Induction agents should be used judiciously and with extreme caution in patients with shock, heart failure, or other pathophysiologic circumstances in which the sympathetic nervous system is paramount in maintaining myocardial contractility and arterial and venous tone.
7. Opioids have diverse chemical structures, but all retain an essential T-shaped component necessary stereochemically for the activation of the μ-, κ-, and δ-opioid receptors. These receptors are not confined to the nervous system and have been identified in the myocardium and blood vessels where endogenous opioid proteins can be synthesized.
8. Acute exogenous opioid administration modulates many determinants of central and peripheral cardiovascular regulation. However, the predominant clinical effect is mediated by attenuation of central sympathetic outflow.
9. Activation of the δ-opioid receptor can elicit preconditioning, which is mediated by signaling pathways that involve G-protein–coupled protein kinases, caspases, nitric oxide, and other chemicals. In contrast with ischemia in homeotherms, hibernation is well tolerated in certain species. This phenomenon may partially depend on mechanisms that are activated by opioids or opioid-like molecules.

An enormous body of literature has described the protean effects of different anesthetic agents on the heart and the pulmonary and systemic regional vascular beds. More publications have been spawned by the great interest in anesthesia-induced preconditioning (APC). However, the prodigious literature detailing the influence of anesthetic agents on the myocardium has not always been consistent[1–3] because of the challenges inherent in quantitating the direct effects of volatile agents on the myocyte and myocardium and because of confounding variables such as the effects on coronary blood flow (CBF), the systemic vasculature, and the baroreceptor reflex arc.

In this chapter, volatile agents, intravenous anesthetics (ie, fixed agents), and opioids (ie, narcotics) are discussed in terms of their acute

BOX 10.1 VOLATILE ANESTHETIC AGENTS

- All volatile anesthetic agents cause dose-dependent decreases in systemic blood pressure, which for halothane and enflurane predominantly result from attenuation of myocardial contractile function and which for isoflurane, desflurane, and sevoflurane predominantly result from decreases in systemic vascular resistance.
- Volatile agents obtund all components of the baroreceptor reflex arc.
- The effects of volatile agents on myocardial diastolic function are not well characterized and await the application of emerging technologies that have the sensitivity to quantitate indices of diastolic function.
- Volatile anesthetics lower the arrhythmogenic threshold to catecholamines. However, the underlying molecular mechanisms are not well understood.
- When confounding variables are controlled (eg, systemic blood pressure), isoflurane does not cause coronary steal by a direct effect on coronary vasculature.
- The effects of volatile agents on systemic regional vascular beds and on the pulmonary vasculature are complex and depend on many variables, including the specific anesthetic, precise vascular bed, and vessel size and whether endothelial-dependent or endothelial-independent mechanisms are being investigated.

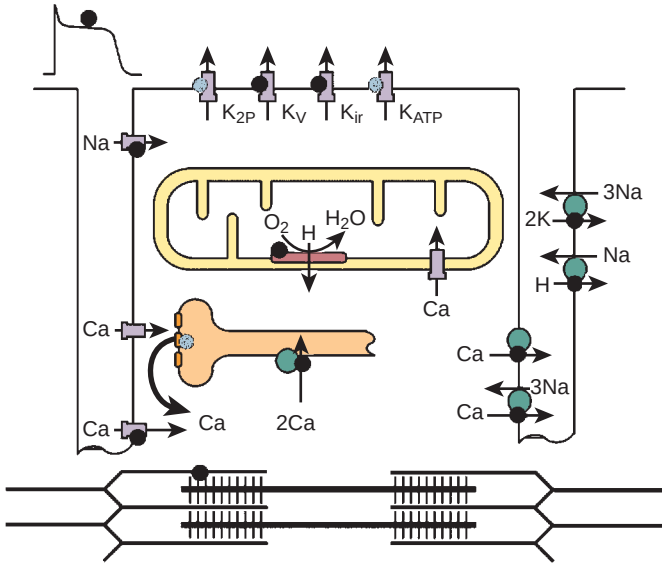

Fig. 10.1 Sites of action of volatile anesthetics in a ventricular myocyte. *Black circles* indicate inhibitory actions; *small green circles* indicate stimulatory actions. *(From Hanley PJ, ter Keurs HEDJ, Cannell MB, Excitation-contraction in the heart and the negative inotropic action of volatile anesthetics.* Anesthesiology. *2004;101:999.)*

and delayed effects on the cardiovascular system (CVS). The acute effects on myocardial function, electrophysiology, coronary vasoregulation, systemic and pulmonary vasoregulation, and the baroreceptor reflex are described. Discussion of the delayed effects focuses on APC.

Volatile Agents

Acute Effects

Myocardial Function

The influence of volatile anesthetics on contractile function has been investigated extensively in several animal species and in humans using various in vitro and in vivo models.[4–11] It is widely agreed that volatile agents cause dose-dependent depression of contractile function (Box 10.1). Different volatile agents are not identical in this regard, and the preponderance of information indicates that halothane and enflurane exert equal but more potent myocardial depression than isoflurane, desflurane, or sevoflurane, in part because of reflex sympathetic activation with the latter agents. In the setting of preexisting myocardial depression, volatile agents have a greater effect than in normal myocardium.[12,13] Early studies indicating that volatile agents did not have a deleterious effect on function in the setting of acute myocardial infarction (AMI) likely reflected the fact that the limited infarction did not compromise overall myocardial function.[14,15]

At the cellular level, volatile anesthetics exert their negative inotropic effects mainly by modulating sarcolemmal L-type Ca^{2+} channels, the sarcoplasmic reticulum (SR), and contractile proteins. L-type Ca^{2+} currents are decreased, and SR Ca^{2+} release is secondarily depressed (Figs. 10.1 and 10.2).[16] The contractile response to lower Ca^{2+} levels is further attenuated in the presence of volatile agents. The response is decreased by volatile agents at any given Ca^{2+} level because volatile agents decrease Ca^{2+} sensitivity (Fig. 10.3).[16]

The mechanisms by which anesthetic agents modify ion channels are not completely understood. Ion channels usually are studied in ex vivo circumstances in which they may be altered by multiple modulating influences. Moreover, the studies frequently used nonhuman tissue, and well-recognized species differences make extrapolation to humans difficult.[17] Nitrous oxide directly causes mild myocardial depression and sympathetic activation.[18]

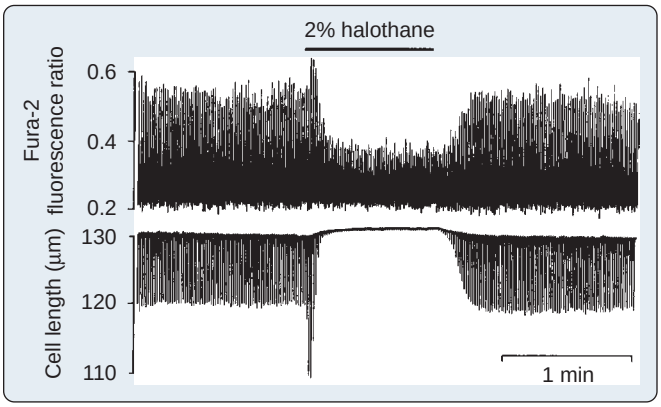

Fig. 10.2 Fura-2 fluorescence *(top trace)*, a ratiometric fluorescent dye that binds to free intracellular calcium and provides an index of calcium ion (Ca^{2+}) concentration, and cell length *(bottom trace)*, an index of contraction, were measured simultaneously in an electrically stimulated rat ventricular myocyte. Application of halothane initially induced a transient increase in the Ca^{2+} transient amplitude and twitch force before the Ca^{2+} signals and contraction decreased. *(From Harrison SM, Robinson M, Davies LA, et al. Mechanisms underlying the inotropic action of halothane on intact rat ventricular myocytes.* Br J Anaesth. *1999;82:609.)*

Even in the setting of normal systolic function, diastolic dysfunction occurs with increasing frequency in the elderly, and it is an important cause of congestive heart failure (CHF).[19–25] Diastolic dysfunction and its more severe clinical counterpart, diastolic heart failure, have protean causative factors and can be mechanistically complex[23] (Box 10.2). The mechanisms underlying these conditions can be categorized as those involving alterations in myocardial relaxation (eg, SR Ca^{2+} handling, phospholamban), those related to intrinsic properties of myocardial tissue (eg, myocyte cytoskeletal elements), and those that are extramyocardial (eg, loading conditions).

Indices of diastolic function were not readily and reliably measured noninvasively in the past, but there has been a relatively recent recognition of diastolic dysfunction and diastolic heart failure compared

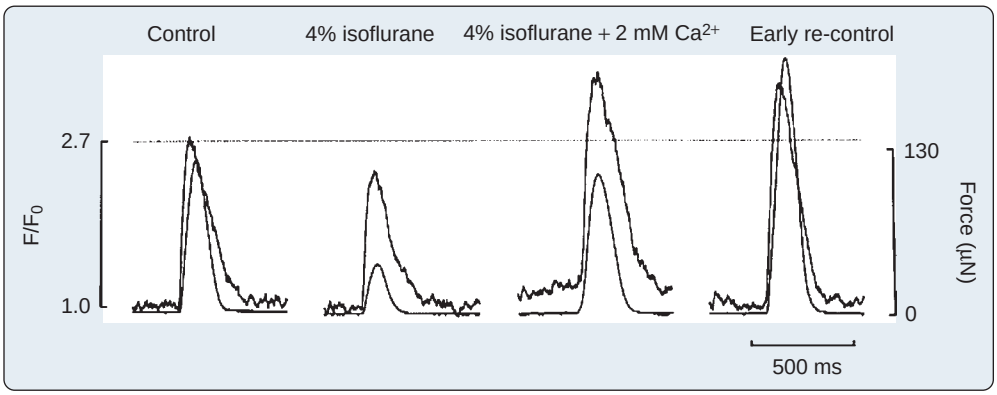

Fig. 10.3 Simultaneous measurement of force (*F*) and normalized fluo-3 fluorescence signals F/F_0, a fluorescence indicator of intracellular Ca^{2+}, in a rat cardiac trabecula. Application of isoflurane decreased force and Ca^{2+}. Restoration of the Ca^{2+} transient amplitude by an increase in external Ca^{2+} did not recover force, indicating that the anesthetic decreased Ca^{2+} responsiveness of the contractile proteins in addition to decreasing Ca^{2+} availability. *(From Hanley PJ, Loiselle DS. Mechanisms of force inhibition of halothane and isoflurane in intact rat cardiac muscle.* J Physiol. *1998;506:231.)*

with perturbations in systolic function. This likely explains the relative paucity of literature detailing the modulating effects of volatile agents on diastolic function. There is reasonable agreement in the literature that volatile agents prolong isovolumic relaxation in a dose-dependent manner.[21,22,26–30]

The effects of volatile agents on chamber stiffness are more controversial. For example, halothane has been reported to decrease compliance and have no effect on myocardial stiffness.[21,22,26,28–31] The effect of nitrous oxide on diastolic function has not been investigated in a manner that critically rules out confounding variables. At a molecular level, alterations in relaxation likely reflect modulation of Ca^{2+} currents, including SR Ca^{2+} reuptake mechanisms. Paradoxically, in the setting of reperfusion injury and Ca^{2+} overload, the volatile agent sevoflurane improves indices of diastolic relaxation and attenuates myoplasmic Ca^{2+} overload.[32]

Further studies may illuminate the specific binding sites and mechanisms by which volatile anesthetics exert their negative inotropic and lusitropic effects. Ongoing work by Wei Dong Gao and colleagues suggests that isoflurane and the intravenous agent propofol bind directly to the myofilaments actin and myosin, resulting in myocardial depression that is independent of calcium concentration (Fig. 10.4).[33]

Cardiac Electrophysiology

Volatile anesthetics reduce the arrhythmogenic threshold for epinephrine. For volatile agents, the order of sensitization is halothane > enflurane > sevoflurane > isoflurane = desflurane.

The molecular mechanisms underlying the effect of volatile anesthetics are poorly understood. Anesthetic-induced modulation of ion channels is important mechanistically in excitation-contraction coupling (discussed earlier), in preconditioning (discussed later), and in modulating automaticity and arrhythmia generation[17] (Table 10.1). Although the effects of a particular volatile agent on a specific cardiac ion channel may be characterized, the information often cannot be extrapolated for use in clinical situations. This partly reflects issues such as species differences and ex vivo studies, but it also recognizes the impossibility of predicting the arrhythmogenic effect that can ensue after modulation with a particular volatile agent. This is one of the lessons garnered from experience with antiarrhythmic drugs such as encainide and flecainide.[34] Even in the clinical setting, not all volatile agents have the same effect.[35]

Coronary Vasoregulation

Volatile anesthetics modulate several determinants of myocardial oxygen supply and demand. They also directly modulate the myocyte's response to ischemia. Studies investigating the effects of volatile agents on coronary vasoregulation should be interpreted in this context.

TABLE 10.1 Effects of Volatile Anesthetics

Anesthetic Gas	*Target*	*Effect*	*Cardiac Side Effects*
Halothane, isoflurane, sevoflurane	L-type Ca^{2+} current	Inhibition	Reduced contractility,[a] shortened AP and refractory time
Halothane	β-Adrenergic regulation of L-type Ca^{2+} current	Complex interference	Enhanced proarrhythmicity compared with sevoflurane (?)
Halothane, isoflurane, xenon	Voltage-dependent transient outward K^+ current	Inhibition	Shortened AP duration, AP duration mismatch within the heart
Halothane, isoflurane, sevoflurane	Voltage-dependent sustained outward K^+ current	Inhibition	Delayed repolarization, mismatch of AP duration[a]
Isoflurane, sevoflurane	ATP-dependent K^+ current	Enhancement	Myocardial preconditioning
Halothane, isoflurane, sevoflurane	Fast Na^+ current	Inhibition	Slowed conduction,[a] induction of tachyarrhythmias (?)

[a]Effects of paramount importance.

Animal studies indicate that halothane has little direct effect on the coronary vasculature.[36–38] Clinical studies investigating the effect of halothane also indicate that it has minimal or mild coronary vasodilator effects.[39–42] The effect of isoflurane on coronary vessels was controversial and dominated much of the relevant literature in the 1980s and early 1990s. Current assessments of the effects of isoflurane have been succinctly detailed by Tanaka and colleagues.[43] Several reports indicated that it caused direct coronary arteriolar vasodilatation in vessels with diameters of 100 µm or less and that isoflurane could cause coronary steal in patients with steal-prone coronary anatomy. The patients had significant coronary stenosis in a vessel serving a region of ischemic myocardium, in which vessels were presumably maximally dilated because of local metabolic autoregulation, and had isoflurane-induced vasodilatation in adjacent vessels in nonischemic zones that reduced flow through collateral vessels, diverting coronary flow away from the ischemic region.[44,45] Several animal and human studies in which potential confounding variables were controlled found that isoflurane did not cause coronary steal.[46–52] Studies of sevoflurane and desflurane showed similar results that were consistent with a mild direct coronary vasodilator effect of these agents.[53,54]

Ultimately, CBF in the setting of normal systemic hemodynamics is controlled by coronary vascular smooth muscle tone, which can be modulated directly (ie, endothelium independent) or indirectly through the endothelium (ie, endothelium dependent). Teleologically, it can be predicted that in vital organs, control of blood flow is predominantly local, acting through endothelium-dependent or endothelium-independent mechanisms.

Volatile agents can modulate mechanisms underlying vascular tone. Halothane and isoflurane have been shown to attenuate endothelial-dependent tone by receptor-dependent and receptor-dependent plus -independent mechanisms, respectively, in coronary microvessels.[55] Several volatile agents cause coronary vasodilation through mechanisms that depend on ATP-sensitive K^+ (K^+_{ATP}) channels.[55–58] Sevoflurane-induced K^+ and Ca^{2+} channel–mediated increases coronary collateral blood flow.[59] The effects in vivo typically are modest because local control mechanisms are likely to predominate.

Systemic Regional and Pulmonary Vascular Effects

Volatile agents can modulate vascular tone. The specific result, however, can be influenced by the agent under study, the vascular bed being investigated, the vessel size and type within the vascular bed, the level of preexisting vascular tone, patient age, and indirect effects of the agents, such as anesthesia-induced hypotension and reflex autonomic nervous system (ANS) activation.

All volatile anesthetics decrease systemic blood pressure (BP) in a dose-dependent manner. With halothane and enflurane, the decrease in systemic BP primarily results from decreases in stroke volume (SV) and cardiac output (CO), whereas isoflurane, sevoflurane, and desflurane decrease overall systemic vascular resistance (SVR) while maintaining CO. However, these overall effects belie the multiple effects in the various regional vascular beds. Within the systemic noncoronary vasculature, aortic and mesenteric vessels have been the best studied.

Reversible inhibition of endothelium-dependent relaxation in aortic and femoral vessels was first demonstrated for halothane and then was demonstrated for enflurane, isoflurane, and sevoflurane in capacitance and resistance vessels.[55,60–64] However, these observations mask the differential effects of volatile agents on underlying endothelium-dependent mechanisms. Halothane and enflurane decrease agonist- (ie, bradykinin-) and ATP-induced Ca^{2+} increases in bovine endothelial cells, whereas isoflurane does not.[65] In contrast, isoflurane does attenuate histamine-induced Ca^{2+} influx into human endothelial cells.[66]

Alterations in endothelium-dependent mechanisms by volatile agents are not confined to attenuation of agonist-dependent and -independent activation of endothelial nitric oxide synthase (eNOS) and nitric oxide (NO) release but also may extend to other mechanisms. For example, the effects of sevoflurane on endothelial cell function may be partially because of sevoflurane-induced changes in endothelin 1 (ET1) production and in the redox milieu of the endothelial cells (ie, increased superoxide anion production).[67]

The effect of volatile agents on vascular smooth muscle mechanisms is equally complex and varies among agents. In endothelial cell–denuded aortic rings, halothane decreases sarcolemmal Ca^{2+} influx through voltage-dependent calcium channels and SR Ca^{2+} release, but sevoflurane does not.[68] Sevoflurane also inhibits angiotensin II–induced vascular smooth muscle contraction in aortic rings.[69] In mesenteric vessels, sevoflurane accentuates endothelium-dependent mechanisms and attenuates endothelium-independent mechanisms in the presence of norepinephrine.[70] Studies of the influence of volatile agents on vascular smooth muscle Ca^{2+} currents indicate that halothane and enflurane stimulate SR release and reuptake from the caffeine-sensitive pool. In contrast, halothane, enflurane, and isoflurane increase calcium-induced calcium release (CICR) mechanisms, but sevoflurane decreases CICR mechanisms.[71] Volatile agents also modulate Ca^{2+} sensitivity. In mesenteric vessels, halothane relaxation is largely mediated by Ca^{2+} and myosin light-chain desensitizing mechanisms.[72]

The pulmonary circulation has unique features that must be taken into account when interpreting studies of this vascular bed. In addition to issues that also apply to systemic vascular beds (eg, vessel size), the pulmonary vasculature is a low-resistance bed (ie, requires preconstriction to access vasoactive effects), is not rectilinear (ie, changes in flow can change certain parameters used to calculate resistance), is contained within the chest and subject to extravascular pressures (ie, that are not atmospheric and change during the respiratory cycle), and exhibits the unique vascular phenomenon of hypoxia-induced vasoconstriction. Volatile agents modulate the baseline pulmonary vasculature and multiple vasoactive mechanisms that control pulmonary vascular tone.

The effect of volatile anesthetics is agent specific. For example, halothane causes flow-independent pulmonary vasoconstriction.[73] In contrast, the hypoxic pulmonary vasoconstrictor response does not appear to be altered by sevoflurane and desflurane.[74] The pulmonary vascular endothelial response appears to be impaired by the volatile agents halothane and isoflurane.[75,76]

Pulmonary vascular smooth muscle regulatory mechanisms also can be modified by volatile agents. Halothane, enflurane, and isoflurane attenuate pulmonary vasodilation induced by K^+_{ATP} channel activation.[77,78] Although the effects of various volatile agents on K^+_{ATP} channel activation are similar, β-adrenergic receptor–induced pulmonary vasodilatation is differently modulated. Halothane and isoflurane potentiate the vasodilatory response, but enflurane has no effect.[79]

Baroreceptor Reflex

All volatile agents attenuate the baroreceptor reflex. Baroreceptor reflex inhibition by halothane and enflurane is more potent than that observed with isoflurane, desflurane, or sevoflurane, each of which has a similar effect.[80,81] Each component of the baroreceptor reflex arc (eg, afferent nerve activity, central processing, efferent nerve activity) is inhibited by volatile agents. Inhibition of afferent nerve traffic in part results from baroreceptor sensitization,[82,83] whereas attenuation of efferent activity in part results from ganglionic inhibition as manifested by differential preganglionic and postganglionic nerve activity.[82–84]

Delayed Effects

Reversible Myocardial Ischemia

Prolonged ischemia results in irreversible myocardial damage and necrosis (Box 10.3). Depending on the duration and sequence of ischemic insults, shorter durations of myocardial ischemia can lead to preconditioning or myocardial stunning (Fig. 10.5).[85] Stunning, first described in 1975, occurs after brief ischemia and is characterized by myocardial dysfunction in the setting of normal restored blood flow and by an absence of myocardial necrosis.[86] Ischemic preconditioning (IPC) was first described by Murry and coworkers[87] in 1986 and is characterized by an attenuation of infarct size after sustained ischemia if the period of sustained ischemia is preceded by a period of brief ischemia (Fig. 10.6). This effect is independent of collateral flow. Short periods of ischemia followed by reperfusion can lead to stunning or preconditioning with a reduction in infarct size (Fig. 10.7).[85]

Work in the 1970s indicated that volatile anesthetic agents attenuated ST-segment elevations in the setting of short-duration ischemia and limited infarct size and lactate production after prolonged ischemia.[88,89] The effects seemed to be independent of the main determinants of myocardial oxygen supply and demand, suggesting that the volatile agents might be exerting a beneficial effect at the level of the myocyte.

On resolution of the isoflurane coronary steal controversy, the first description of the salutary effects of volatile agents on the consequences of brief ischemia was published in 1988. Warltier and coworkers[90] described the beneficial effects of halothane and isoflurane in facilitating recovery of contractile function in stunned myocardium (Fig. 10.8). It was almost a decade later before the effects of volatile agents on preconditioning were outlined[2,3] and the term *APC* was used[1] (Fig. 10.9).

BOX 10.3 VOLATILE AGENTS AND MYOCARDIAL ISCHEMIA

- Volatile anesthetic agents can attenuate the effects of myocardial ischemia (ie, acute coronary syndromes).
- Nonacute manifestations of myocardial ischemia include hibernating myocardium, stunning, and preconditioning.
- Halothane and isoflurane facilitate the recovery of stunned myocardium.
- Preconditioning, an important adaptive and protective mechanism in biologic tissues, can be provoked by protean nonlethal stresses, including ischemia.
- Volatile anesthetic agents can mimic preconditioning (ie, anesthetic preconditioning), which can have important clinical implications and provide insight into the cellular mechanisms of action of these volatile agents.

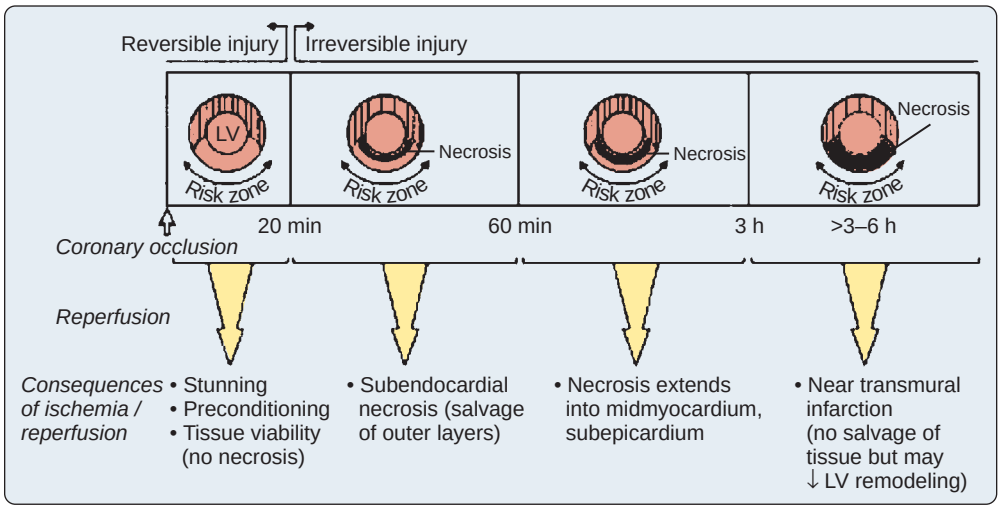

Fig. 10.5 Effects of ischemia and reperfusion on the heart based on studies using an anesthetized canine model of proximal coronary artery occlusion. Periods of ischemia of less than 20 minutes followed by reperfusion are not associated with development of necrosis (ie, reversible injury). Brief ischemia and reperfusion results in stunning and preconditioning. If the duration of coronary occlusion is extended beyond 20 minutes, necrosis develops from the subendocardium to subepicardium over time. Reperfusion before 3 hours of ischemia salvages ischemic but viable tissue. Salvaged tissue may demonstrate stunning. Reperfusion beyond 3 to 6 hours in this model does not reduce myocardial infarct size. Late reperfusion may still have a beneficial effect on reducing or preventing myocardial infarct expansion and left ventricular *(LV)* remodeling. *(From Kloner RA, Jennings RB. Consequences of brief ischemia: stunning, preconditioning, and their clinical implications, part I.* Circulation. *2001;104:2981.)*

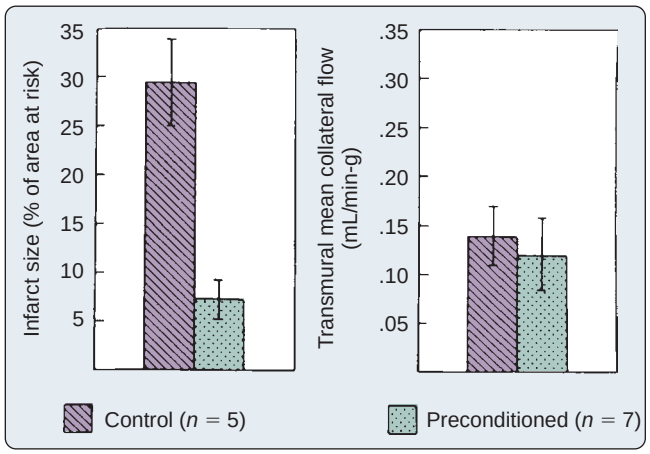

Fig. 10.6 Infarct size and collateral blood flow in a 40-minute study. Infarct size as a percentage of the anatomic area at risk in the control *(purple)* and preconditioned *(green)* hearts *(left)*. Infarct size in control animals averaged 29.4% of the area at risk. Infarct size in preconditioned hearts averaged only 7.3% of the area at risk (preconditioned vs control, $P < .001$). Transmural mean collateral blood flow *(right)* was not significantly different in the two groups. The protective effect of preconditioning was independent of the two major baseline predictors of infarct size: area at risk and collateral blood flow. *Bars* represent the group mean ± standard error of the mean. *(From Warltier DC, al-Wathiqui MH, Kampine JP, et al. Recovery of contractile function of stunned myocardium in chronically instrumented dogs is enhanced by halothane or isoflurane.* Anesthesiology. *1988;69:552.)*

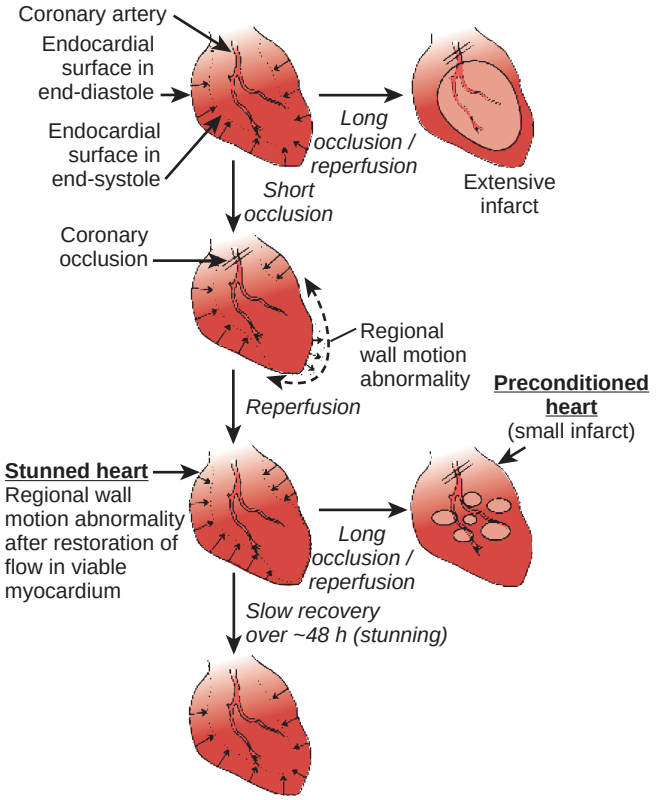

Fig. 10.7 Short coronary artery occlusions result in stunning, in which the regional wall motion abnormality is prolonged despite reperfusion and viable myocardial cells. Brief episodes of ischemia and reperfusion precondition the heart. When the heart is then exposed to a longer duration of ischemia and reperfusion, myocardial infarct size is reduced. *(From Kloner RA, Jennings RB. Consequences of brief ischemia: stunning, preconditioning, and their clinical implications, part I.* Circulation. *2001;104:2981.)*

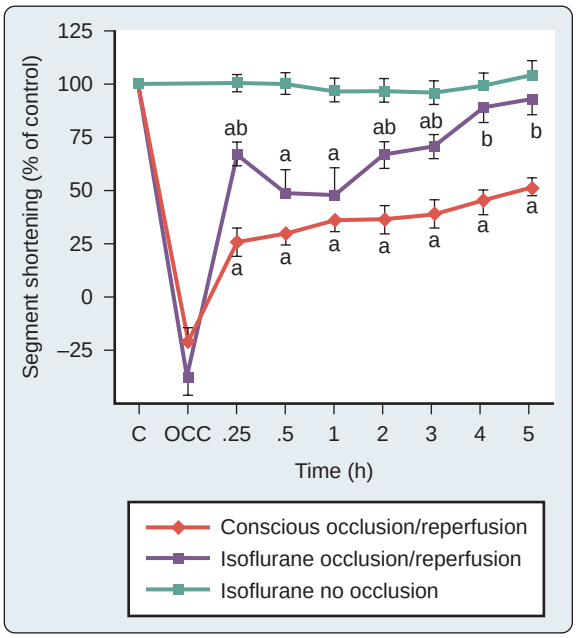

Fig. 10.8 Segment shortening data are expressed as a percentage of the control mean ± standard error of the mean during coronary artery occlusion *(OCC)* and at various times after reperfusion in conscious dogs *(red)* and in dogs anesthetized with isoflurane *(purple)*. Comparisons are made at various time points with animals anesthetized with isoflurane but not undergoing coronary artery occlusion and reperfusion *(green)*. A significant ($P < .05$) difference *(a)* was found for dogs anesthetized without occlusion *(green)* versus those undergoing conscious occlusion *(red)* or those undergoing occlusion during anesthesia *(purple)*. A significant ($P < 9.95$) difference *(b)* was found for dogs undergoing conscious occlusion *(red)* versus those undergoing occlusion during anesthesia (*purple*). The control state *(C)* indicates the awake, unsedated state *(red)* or a stable hemodynamic state after 2 hours of isoflurane anesthesia (*black* and *green*). *(From Warltier DC, al-Wathiqui MH, Kampine JP, et al. Recovery of contractile function of stunned myocardium in chronically instrumented dogs is enhanced by halothane or isoflurane.* Anesthesiology. *1988;69:552.)*

The phenomenon of and the mechanisms underlying IPC are the focus of extensive investigation. IPC has the following characteristics:

- It results in two periods (ie, windows) of protection. The first (ie, early or classic) occurs at 1 to 3 hours, and the second (ie, late or delayed) occurs 24 to 96 hours after the preconditioning stimulus.
- It also occurs in noncardiac tissue (eg, brain, kidney).
- It is ubiquitous across species.
- It is most pronounced in larger species with lower metabolism and slower heart rates (HRs).
- It seems to be important clinically because angina within the 24-hour period preceding an AMI is associated with an improved outcome (Fig. 10.10).[91]
- It is mediated by multiple endogenous signaling pathways[92,93] (Fig. 10.11).

As might be predicted from the time frame of delayed IPC, it is in part mediated by transcriptional and posttranslational mechanisms[92] (Fig. 10.12). Preconditioning also can be triggered by events other than ischemia (eg, cellular stressors, pharmacologic agonists, anesthetic agents) (see Fig. 10.12).[92]

The benefits of IPC are not necessarily confined to and may not include limitation of infarct size. They depend on the specific trigger, the species under study, and the type (ie, classic or delayed) of IPC. For example, rapid pacing affords protection against arrhythmias but not against infarct evolution. In contrast, cytokine-induced IPC limits infarct size but has no effect on arrhythmias.[92] Although there are fundamental mechanisms common to various triggers of IPC, the

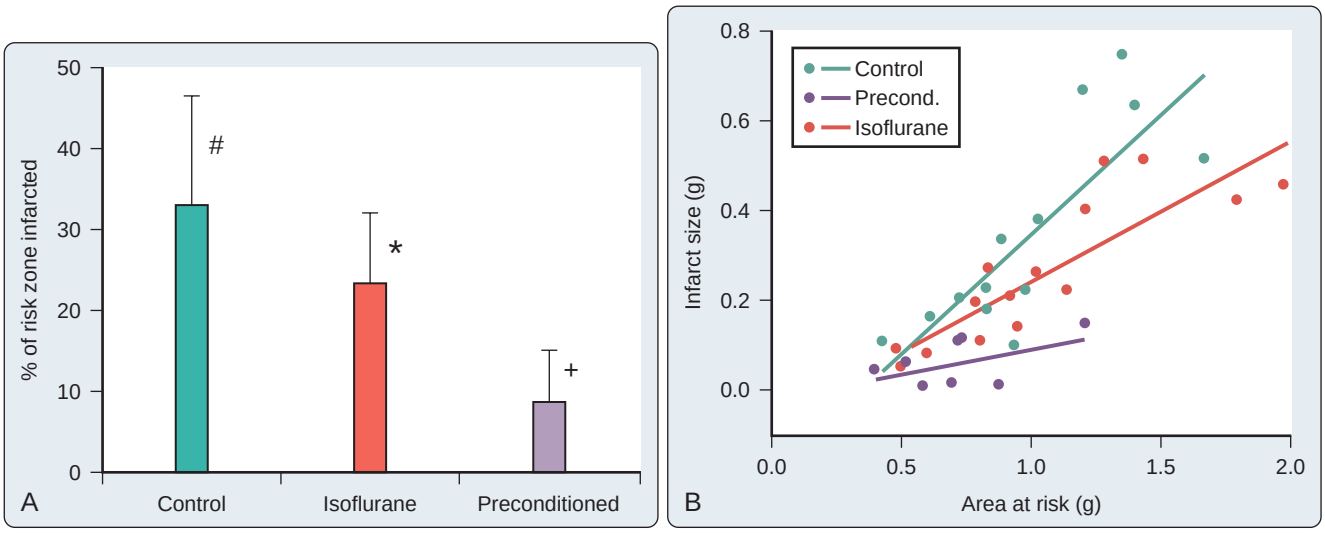

Fig. 10.9 (A) Infarct size (mean ± standard deviation) is expressed as a percentage of the area at risk in rabbit hearts that were not pretreated (control group: $n = 13$), exposed to 5 minutes of preconditioning (ischemic preconditioned group: $n = 8$), or exposed to 15 minutes of 1.1% isoflurane (isoflurane group: $n = 15$) before 30 minutes of anterolateral coronary occlusion. Statistical analysis of the groups ($^{\#},^{*},^{+}$) showed that the relationship between infarct size and area at risk was different in each group ($P < .05$). (B) Relationship between infarct size and myocardium at risk for the three groups in grams (g). This was a statistically significant difference in line elevation but not in slope. *(From Cason BA, Gamperi AK, Slocum RE, et al. Anesthetic-induced preconditioning: previous administration of isoflurane decreases myocardial infarct size in rabbits.* Anesthesiology. *1997;87:1182.)*

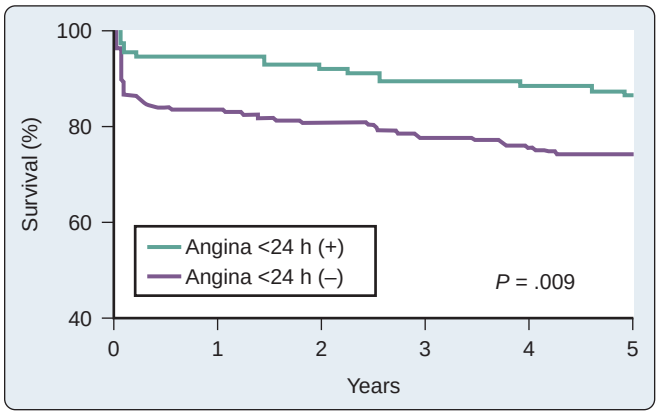

Fig. 10.10 Five-year survival curves for patients with *(green)* and those without *(purple)* prodromal angina in the 24 hours before infarction. *(From Ishihara M, Sato K, Tateishi H, et al. Implications of prodromal angina pectoris in anterior wall acute myocardial infarction: acute angiographic findings and long-term prognosis.* J Am Coll Cardiol. *1997;30:970.)*

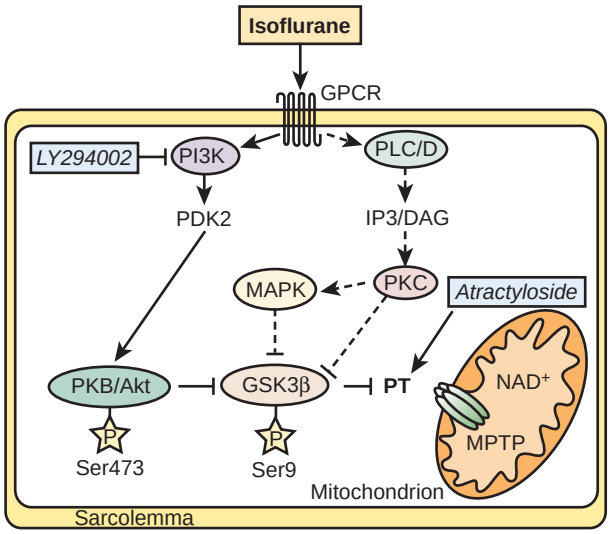

Fig. 10.11 Investigated signaling pathways *(solid lines)*. During early reperfusion, multiple signaling cascades inhibit the master switch kinase, glycogen synthase kinase 3β *(GSK3β)*, which converges the prosurvival pathways and prevents permeability transition *(PT)* in mitochondria. In addition to other kinases, protein kinase B *(PKB)/Akt* represents a key enzyme in the reperfusion injury salvage kinase cascade requiring phosphorylation at *Ser473* for full activation. Phosphorylated PKB/Akt subsequently inactivates its downstream target GSK3β by phosphorylation at *Ser9*. *LY294002* inhibits phosphatidylinositol 3-kinase *(PI3K)*. *Atractyloside* induces opening of the mitochondrial permeability transition pore *(MPTP)*. *Arrows* indicate positive activity; *lines with blunted ends* indicate inhibition. *DAG*, Diacylglycerol; *GPCR*, G-protein–coupled receptor; *IP3*, inositol 1,4,5-triphosphate; *MAPK*, mitogen-activated protein kinase; *NAD^+*, nicotinamide adenine dinucleotide; *PDK2*, phosphatidylinositol-dependent kinase 2 (ie, Ser473 kinase); *PKC*, protein kinase C; *PLC/D*, phospholipase C/D. *(From Feng J, Lucchinetti E, Ahuja P, et al. Isoflurane postconditioning prevents opening of the mitochondrial permeability transition pore through inhibition of glycogen synthase kinase 3β.* Anesthesiology. *2005;103:987–995.)*

different triggers of IPC modulating different end points suggest that there also exist mechanistic differences across triggers. APC may not be identical to IPC mechanistically.

Induced ischemia in a region of the body away from the heart (ie, remote ischemic preconditioning [RIPC]) has myocardium-protective effects in animals and has shown promising results in humans.[94–96] A randomized, controlled trial of RIPC (ie, three cycles of 5 minutes of an inflated BP cuff to 200 mm Hg on the upper extremity followed by 5 minutes of reperfusion with the cuff deflated) enrolling patients undergoing coronary artery bypass grafting (CABG) showed a mortality benefit with the intervention.[95] Metaanalyses show mixed results, with some showing insufficient evidence and others suggesting benefit.[94,97,98]

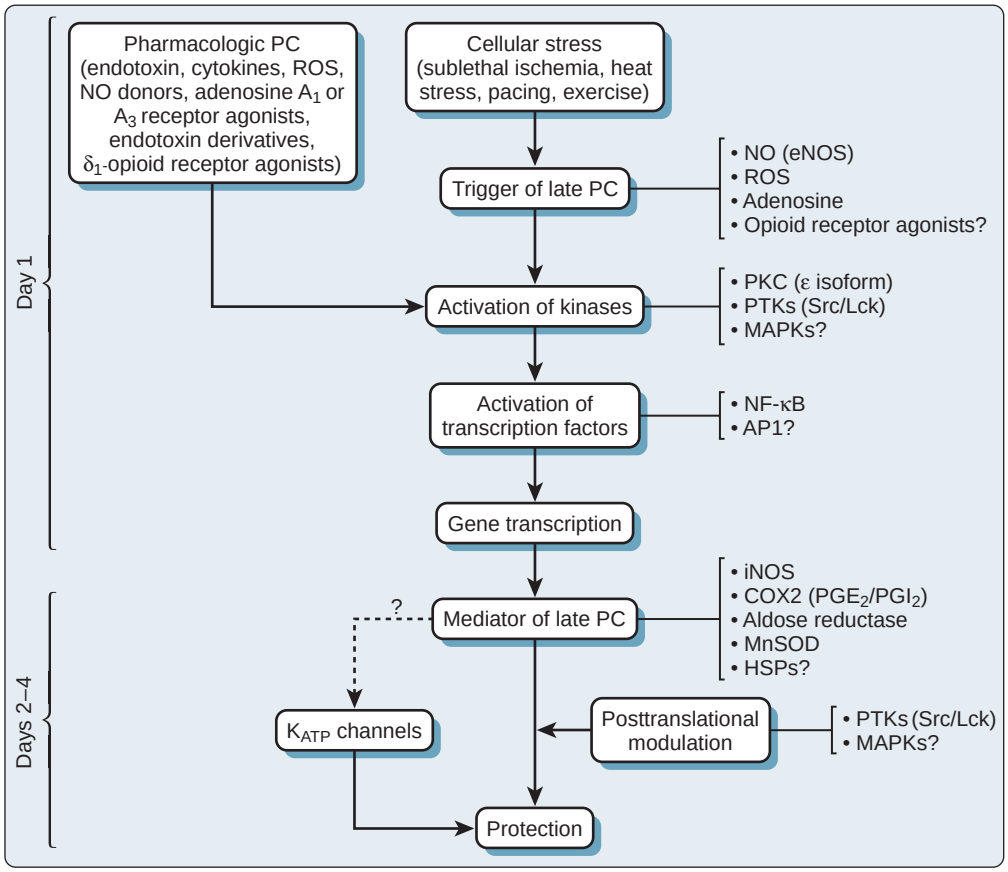

Fig. 10.12 Schematic representation of the cellular mechanisms underlying late preconditioning *(PC)*. A nonlethal cellular stress (eg, reversible ischemia, heat stress, ventricular pacing, exercise) causes release of chemical signals (eg, nitric oxide *[NO]*, reactive oxygen species *[ROS]*, adenosine, opioid receptor agonists) that serve as triggers for the development of late PC. These substances activate a complex signal transduction cascade that includes the ε isoform of protein kinase C *(PKC)*, Src or Lck protein tyrosine kinases *(PTKs)*, and probably other kinases. Similar activation of PKC and downstream kinases can be elicited pharmacologically by a wide variety of agents, including naturally occurring and often noxious substances (eg, endotoxin, interleukin-1, tumor necrosis factor-α or -β, leukemia inhibitor factor, or ROS) and clinically applicable drugs (eg, NO donors, adenosine A_1 or A_3 receptor agonists, endotoxin derivatives, or δ_1-opioid receptor agonists). Recruitment of PKC and distal kinases leads to activation of nuclear factor-κB *(NF-κB)* and almost certainly other transcription factors, resulting in increased transcription of multiple cardioprotective genes and synthesis of many cardioprotective proteins that serve as comediators of protection 2 to 4 days after the PC stimulus. The mediators of late PC include inducible nitric oxide synthase *(iNOS)*, cyclooxygenase 2 *(COX2)*, aldose reductase, and manganese superoxide dismutase *(MnSOD)*. Among the products of COX2, prostaglandin E_2 and I_2 (*PGE_2* and *PGI_2*) appear to be the most likely effectors of COX2-dependent protection. Increased synthesis of heat shock proteins *(HSPs)* is unlikely to be a mechanism of late PC, although the role of posttranslational modification of preexisting HSPs remains to be determined. The occurrence of cardioprotection on days 2 to 4 requires the activity of PTKs and possibly p38 mitogen-activated protein kinases *(MAPKs)*, potentially because iNOS and other mediators need to undergo posttranslational modulation to confer protection against ischemia. Opening of K^+_{ATP} channels is also essential for the protection against infarction (but not against stunning) to occur. The exact relationships among iNOS, COX2, aldose reductase, MnSOD, and K^+_{ATP} channels are unknown, although evidence suggests that COX2 may be downstream of iNOS (ie, COX2 is activated by NO). *AP1*, Activator protein 1; *PTK*, protein tyrosine kinases. *(From Bolli R. The late phase of preconditioning.* Circ Res. *2000;87:972.)*

The endogenous cannabinoids and the cannabinoid receptors, identified as the sites of action of Δ^9-tetrahydrocannabinol (THC) and other compounds found in marijuana, contribute to IPC and RIPC in animals. In a rat model, antagonism at the CB_2 receptor, but not the CB_1 receptor, reversed the cardioprotective effects of RIPC.[99] In a mouse model of ischemia and reperfusion, agonism at the CB_2 receptor was cardioprotective.[100] It is unknown whether cannabinoid signaling is involved in volatile anesthetic–induced IPC. Future investigations of the cannabinoid system and the CB_2 receptor in particular should elucidate whether they are pharmacologic targets for activating IPC.

Preconditioning and Postconditioning Anesthetic Agents

Preconditioning and postconditioning anesthetics is an area of intense investigation, as reflected in two issues of *Anesthesiology* that were predominantly devoted to the subject.[101,102] After the initial description of APC,[1–3] subsequent investigations indicated that volatile agents could elicit delayed (ie, late) and classic (ie, early) preconditioning.[103,104] APC is dose dependent,[105–107] exhibits synergy with ischemia in affording protection,[108,109] and perhaps not surprisingly in view of the differential uptake and distribution of volatile agents, requires different time intervals between exposure and the maintenance of a subsequent benefit that is agent dependent.[43]

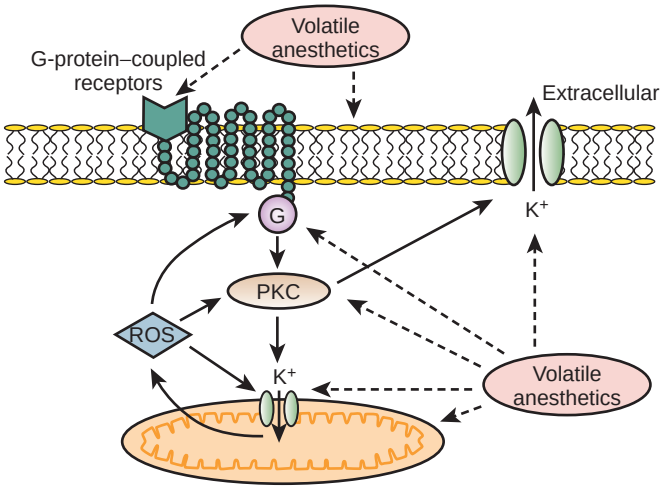

Fig. 10.13 Multiple endogenous signaling pathways mediate volatile anesthetic–induced myocardial activation of an end-effector that promotes resistance against ischemic injury. Mitochondrial K^+_{ATP} channels have been implicated as the end-effector in this protective scheme, but sarcolemmal K^+_{ATP} channels may also be involved. A trigger initiates a cascade of signal transduction events, resulting in protection. Volatile anesthetics signal through adenosine and opioid receptors, modulate G proteins *(G)*, stimulate protein kinase C *(PKC)* and other intracellular kinases, or directly stimulate mitochondria to generate reactive oxygen species *(ROS)* that ultimately enhance K^+_{ATP} channel activity. Volatile anesthetics may also directly facilitate K^+_{ATP} channel opening. *Dotted arrows* delineate the intracellular targets that may be regulated by volatile anesthetics; *solid arrows* represent potential signaling cascades. *(From Tanaka K, Ludwig LM, Kersten JR, et al. Mechanisms of cardioprotection by volatile anesthetics.* Anesthesiology. *2004;100:707.)*

The contributions of sarcolemmal and mitochondrial K^+_{ATP} channels in IPC have been extensively investigated, demonstrating that mitochondrial K^+_{ATP} channels play a critical role in this process. Volatile agents that exhibit APC activate mitochondrial K^+_{ATP} channels, and specific mitochondrial K^+_{ATP} channel antagonists block this effect. The precise contributions of sarcolemmal versus mitochondrial K^+_{ATP} channel activation to APC remain to be elucidated (Fig. 10.13).[43]

The original descriptions of APC indicated that volatile agents could trigger preconditioning without concurrent ischemia during the triggering period[1–3] (see Fig. 10.9). However, studies of mitochondrial activation (through mitochondrial K^+_{ATP} channels), indicate that volatile agents on their own do not activate mitochondria but do potentiate the effects of direct mitochondrial K^+_{ATP} channel openers[107] (Fig. 10.14). These apparent inconsistencies are likely explained by the presence of multiple parallel and redundant pathways activated during APC and IPC[104] (see Fig. 10.13). For example, the adenosine A_1 and δ_1-opioid G-coupled receptors can trigger IPC. Pharmacologic blockade of these receptors attenuates the positive effects of volatile agents.[106,110] Protein kinase C (PKC) and the nuclear signaling pathway (ie, mitogen-activated protein kinase [MAPK]) are important signaling pathways in preconditioning, and volatile agents have been shown to modulate PKC translocation.[111]

Oxidant stress is a central feature of reperfusion. Depending on the specific moiety, the enzymatic source, and most importantly, the oxidant stress load, it may trigger preconditioning or mediate reperfusion injury. Indirect and direct evidence indicate that volatile agents can increase oxidant stress to levels that trigger preconditioning.[112–114]

Activation of eNOS also plays a role, as does depolarization of the mitochondrial internal membrane.[115] It may prevent opening of the mitochondrial permeability transition pore (MPTP) and inhibit Na^+/H^+ exchange, attenuating Ca^{+2} overload and cell edema.[115] Inhibition of mitochondrial permeability by APC may decrease myocyte death, and PKC appears to play a role in IPC-induced delay of MPTP opening.[116,117] One study demonstrated that isoflurane activated PKC-dependent signaling pathways, resulting in the delay of MPTP opening,[118] suggesting a possible mechanism for isoflurane in APC. Ge and colleagues[119] demonstrated that NO could act as a trigger of preconditioning and a mediator for isoflurane-induced cardiac protection in mouse hearts. The finding implies that an eNOS-dependent mechanism prevents the opening of the MPTP, although other pathways, including glycogen synthase kinase-3β, have been implicated (Fig. 10.15).[93,119]

Mitochondrial activation attenuates ischemia-induced oxidant stress, favorably modulates mitochondrial energetics, decreases cytochrome *c* egress into the cytoplasm, and attenuates mitochondrial and cytoplasmic Ca^{2+} overload. Mitochondrial cytochrome *c* release is an important mechanism underlying caspase activation and the apoptotic process[120] (Fig. 10.16). Whether by Ca^{2+}-mediated or apoptotic mechanisms, or both, volatile agents attenuate cell death in models of APC[109] (Fig. 10.17). Although the mechanisms of mitochondrial activation have been aggressively studied, they remain incompletely understood. These salutary effects of volatile agents seem to have a clinical correlate[109] (Fig. 10.18).

The use of volatile anesthetics can alter outcomes after cardiac surgery. A metaanalysis by Landoni and associates[121] demonstrated a significant reduction in postoperative myocardial infarction after cardiac surgery and significant advantages with respect to postoperative cardiac troponin release, inotrope requirements, time to extubation, intensive care unit stay, hospital stay, and survival. Another metaanalysis by Bignami and colleagues[122] demonstrated that the use of volatile anesthetics was beneficial in terms of mortality rates after cardiac surgery. The duration of the volatile anesthetic exposure seemed to have an impact; the longer the exposure, the greater the effect. De Hert and coworkers[123] demonstrated the cardioprotective effects of volatile anesthetics if used throughout the surgical procedure rather than only before and after cardiopulmonary bypass (CPB).

Further studies are necessary to delineate the role of the anesthetic regimen on outcomes after cardiac surgery and elucidate the mechanisms behind this protection. Whether it involves mechanisms that are associated with APC remains unclear.

Intravenous Induction Agents

The drugs discussed in this section are induction agents and hypnotics. The drugs belong to different classes (ie, barbiturates, benzodiazepines, *N*-methyl-D-aspartate [NMDA] receptor antagonists, and α_2-adrenergic receptor agonists). Their effects on the CVS depend on the class to which they belong. These effects have been studied at a cellular, tissue, organ, and whole-animal level. Although a detailed discussion of the molecular mechanisms underlying each agent is beyond the scope of this chapter, a focused appraisal of well-established effects of specific drugs is given. Although sophisticated pharmacologic studies dissecting the signal transduction pathways can provide insights into mechanisms, they cannot fully predict the response of an intact organism. Because propofol is the most common induction agent, literature for this agent is used as the paradigm for discussing mechanisms by which cardiovascular regulation is altered by intravenous agents. A summary of the cardiovascular effects of each induction agent is provided later in the chapter.

Unlike the inhalation anesthetic agents that augment IPC, there is no good evidence that intravenous hypnotic agents demonstrate these protective effects. There is, however, emerging evidence that propofol, the mainstay of induction agents, may enhance antioxidant activity in the heart and may prevent lipid peroxidation after ischemia and reperfusion, offering a potential protection of the heart.[124]

Acute Cardiac Effects

Myocardial Contractility

To understand the effect of intravenous anesthetics on integrated cardiovascular responses is to understand the effect on the various factors that regulate the force of contraction of the heart. If the heart in

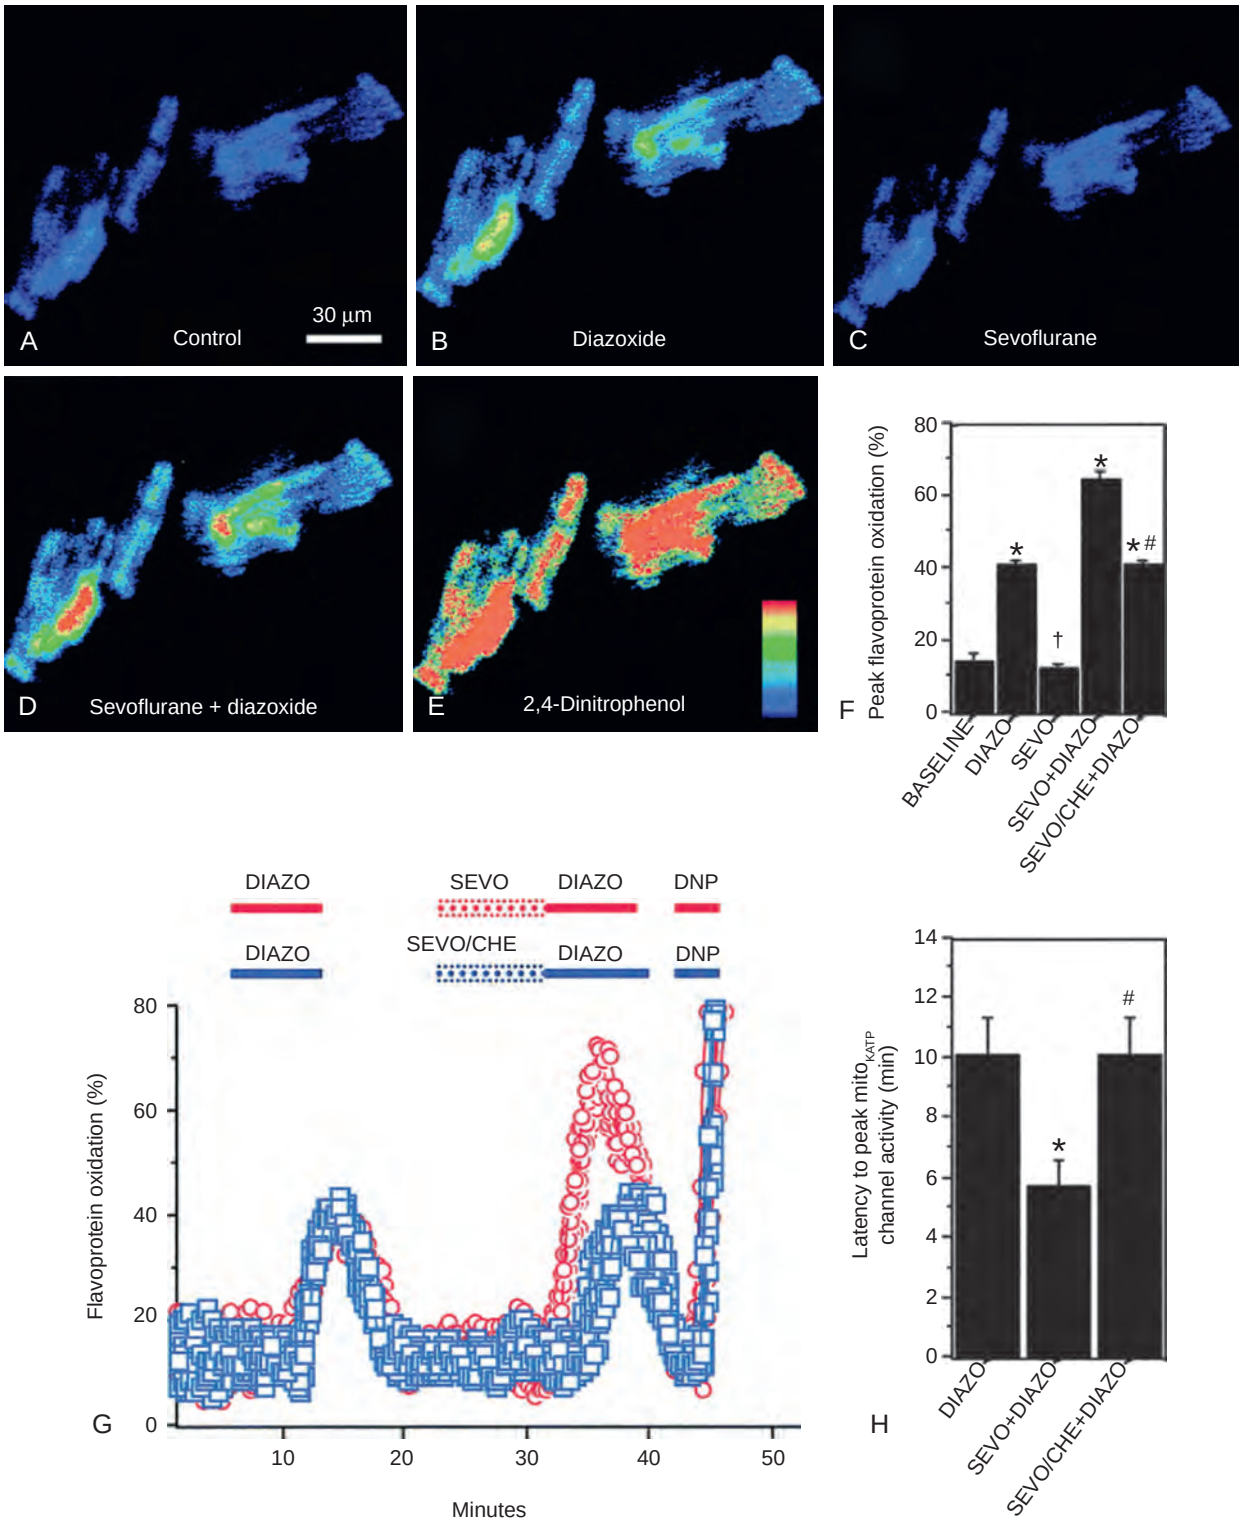

Fig. 10.14 Effect of sevoflurane (*SEVO*; 2.8% [vol/vol]) on diazoxide *(DIAZO)*–induced flavoprotein oxidation in myocytes excited at 480 nm. Similar results were obtained for isoflurane. An artificial color scale was used to visualize the relative intensity of emitted fluorescence at 530 nm; *blue* indicates reduced flavoproteins, and *red* indicates fully oxidized flavoproteins. (A) At baseline. (B) At 100 µm for DIAZO (same cells). (C) At 2 minimal alveolar concentration (MAC) of SEVO. (D) At 100 µm for DIAZO preceded by 2 MAC of SEVO. *Red* indicates intense local oxidation by mitochondrial clusters. (E) At 100 µm for 2,4-dinitrophenol *(DNP)*. (F) Mean percentages of peak flavoprotein fluorescence depending on the drugs exposed to myocytes. $*P < .0001$ versus baseline or SEVO + DIAZO versus DIAZO alone. $^{\#}P$ value is not significantly different from DIAZO; $^{\dagger}P$ value is not significantly different from baseline. SEVO/CHE indicates concomitant treatment of myocytes with SEVO and chelerythrine (CHE) at 2 µm before exposure to DIAZO. (G) Time-lapse analysis of alterations in fluorescence intensity in individual myocytes expressed as percentage of DNP-induced fluorescence. *Blue squares* and *red circles* indicate values from eight different experiments. (H) Latency to peak activation of mitochondrial K^{+}_{ATP} ($mitoK^{+}_{ATP}$) channels in response to the various treatment regimens. $*P < .001$ versus DIAZO; $^{\#}P$ value is not significant versus DIAZO. Data are mean ± standard deviation. *(From Zaugg M, Lucchinetti E, Spahn DR, et al. Volatile anesthetics mimic cardiac preconditioning by priming the activation of mitochondrial KATP channels via multiple signaling pathways.* Anesthesiology. *2002;97:4.)*

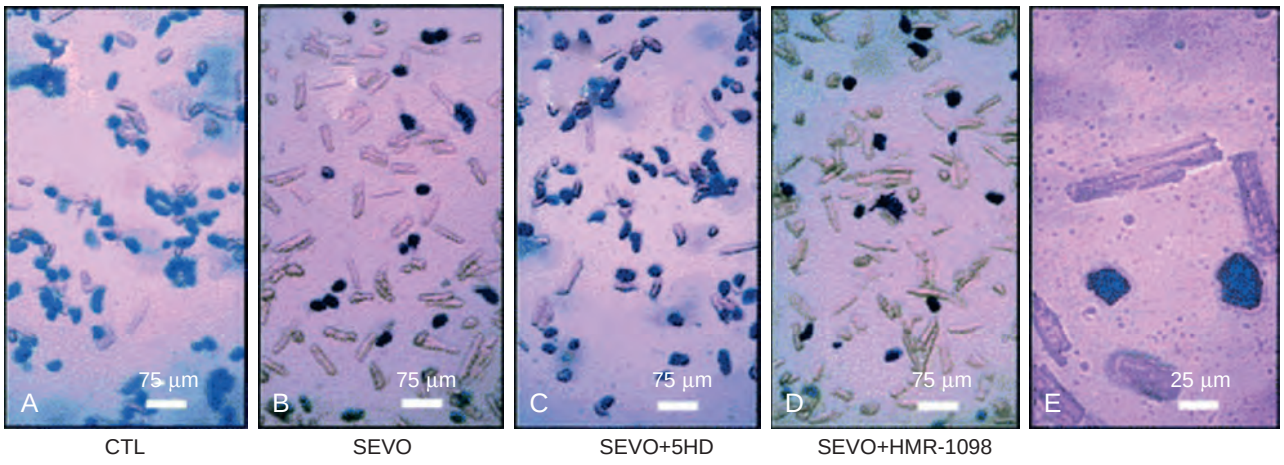
They cause proapoptotic members of the *BCL2* family, such as *BAX* and *BAK*, to open new pores or modify existing channels in the mitochondrial membrane, releasing cytochrome *c (Cyt c)* and other proteins that lead to caspase activation and cell death. BCL2, which is antiapoptotic, blocks the pore or channel opening. *AIF*, Apoptosis-inducing factor; *IAP*, inhibitors of apoptosis. *(From Finkel E. The mitochondrion: is it central to apoptosis?* Science. *2001;292(5517):624–626.)*

isolation is considered (ie, not coupled to the vasculature and not regulated by the autonomic system), the best methodologies for examining the effects of anesthetic agents involve using isolated myocytes and muscle tissue preparations in which the effect of the anesthetic drugs on contractile force or tension or on myocyte or sarcomere shortening can be determined.

The studies of propofol remain controversial about whether there is a direct effect on myocardial contractile function at clinically relevant concentrations. The weight of evidence, however, suggests that the drug has a modest negative inotropic effect, which may be mediated by inhibition of L-type Ca^{2+} channels or modulation of Ca^{2+} release from the SR. The effect of propofol may be mediated at multiple sites in the cardiac myocytes (see Fig. 10.4).

Effects of the agents may be species dependent, further confounding the literature regarding mechanisms. For instance, van Klarenbosch and colleagues[125] demonstrated that in contrast with use in rats, propofol directly depresses myocardial contractility in isolated muscle preparations from guinea pigs, probably by decreasing transsarcolemmal Ca^{2+} influx. However, there was little influence of propofol on Ca^{2+} handling by the SR or on the contractile proteins in rats. In one of the few human studies using isolated atrial muscle tissue (Fig. 10.19), no inhibition of myocardial contractility was found in the clinical concentration ranges of propofol, midazolam, and etomidate. Thiopental showed strong negative inotropic properties, whereas ketamine showed slight negative inotropic properties (Fig. 10.20). Negative inotropic effects may partially explain the cardiovascular depression on induction of anesthesia with thiopental but not with propofol, midazolam, and etomidate. Improvement of hemodynamics after induction of anesthesia with ketamine cannot therefore be explained by intrinsic cardiac stimulation but is a function of sympathoexcitation.[126]

The effect of drugs such as propofol may be affected by the underlying myocardial pathology.[127,128] For instance, Sprung and coworkers[128] determined the direct effects of propofol on the contractility of human nonfailing atrial and failing atrial and ventricular muscles obtained from the failing human hearts of transplant recipients or from nonfailing hearts of patients undergoing CABG. They concluded that propofol exerted a direct negative inotropic effect in nonfailing



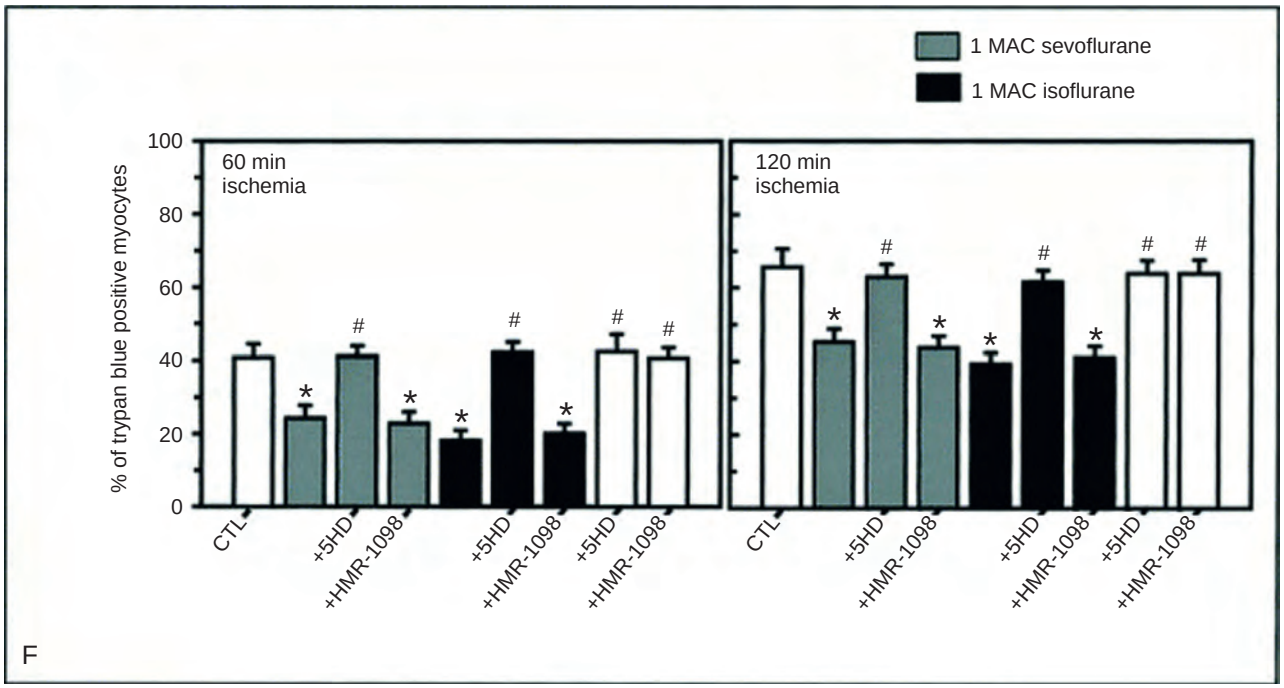


Fig. 10.17 Effects of the specific mitochondrial K^+_{ATP} (mitoK^+_{ATP}) channel blocker 5-hydroxy-decanoate *(5HD)* and the specific sarcolemmal K^+_{ATP} (sarcK^+_{ATP}) channel blocker *HMR-1098* on sevoflurane *(SEVO)*– and isoflurane *(ISO)*–mediated protection at 1 minimal alveolar concentration *(MAC)* against 60 or 120 minutes of ischemia in myocytes as assessed by trypan blue staining. (A) Control *(CTL)* myocytes after 60 minutes of ischemia. Myocytes stained *dark blue* indicate irreversible cell damage. (B) Myocytes exposed to SEVO before ischemia. Most myocytes retain their rod-shaped morphology. (C) Myocytes exposed to 5HD and SEVO before ischemia. The protective effect of SEVO is abolished. (D) Myocytes exposed to HMR-1098 and SEVO before ischemia. The protection by SEVO is unaffected. (E) Representative trypan blue–positive and –negative myocytes after exposure to ischemia seen at higher magnification. (F) Trypan blue–positive myocytes are indicated as a percentage of total viable myocytes before ischemia. The CTL group represents myocytes exposed to 60 or 120 minutes of ischemia alone. Data are mean ± standard deviation. $^*P < .0001$ versus respective CTL; $^\#P$ value is not significant versus respective CTL. *(From Zaugg M, Lucchinetti E, Spahn DR, et al. Volatile anesthetics mimic cardiac preconditioning by priming the activation of mitochondrial K(ATP) channels via multiple signaling pathways.* Anesthesiology. *2002;97:4.)*

and failing human myocardium, but only at concentrations larger than typical clinical concentrations.

Negative inotropic effects are reversible with β-adrenergic stimulation, suggesting that propofol does not alter the contractile reserve but may shift the dose responsiveness to adrenergic stimulation. The negative inotropic effect of propofol is at least partially mediated by decreased Ca^{2+} uptake into the SR, but the net effect of propofol on contractility is insignificant at clinical concentrations because of a simultaneous increase in the sensitivity of the myofilaments to activator Ca^{2+}.[128]

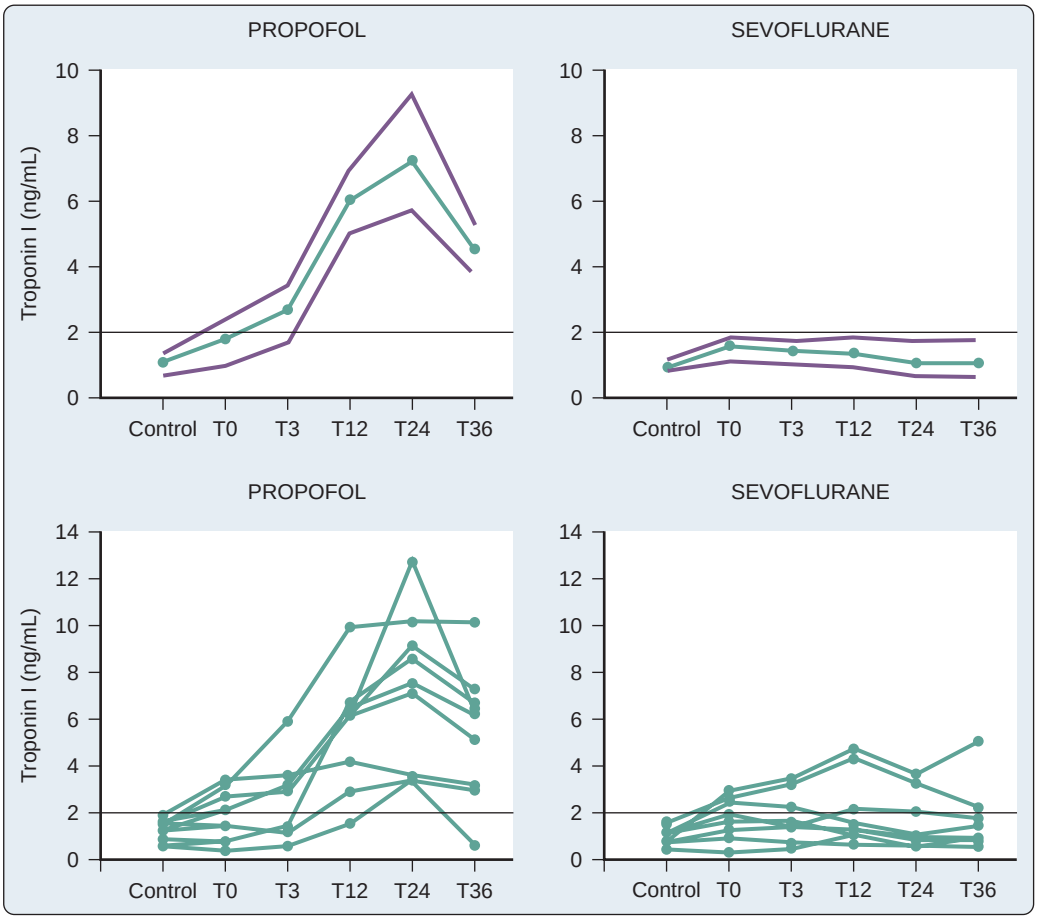

Fig. 10.18 Cardiac troponin I concentrations in the propofol and sevoflurane groups before surgery *(Control)*, at arrival in the intensive care unit *(T0)*, and after 3 *(T3)*, 12 *(T12)*, 24 *(T24)*, and 36 *(T36)* hours. *Top,* Median values *(green)* with 95% confidence intervals *(purple). Bottom,* Evolution of the individual values. Concentrations were significantly greater with propofol. In the propofol group, all patients had troponin concentrations greater than the cutoff value of 2 ng/mL *(gray line). (From de Hert S, ten Broecke PW, Mertens E, et al. Sevoflurane but not propofol preserves myocardial function in coronary surgery patients.* Anesthesiology. *2002;97:42.)*

Molecular Mechanisms: Adrenergic Signaling, Ca^{2+} Influx, and Ca^{2+} Sensitivity

A drug such as propofol may alter cardiac contractility by several molecular mechanisms. Propofol may inhibit cardiac L-type calcium current by interacting with the dihydropyridine-binding site[129] (Fig. 10.21A), with resultant alteration in developed tension (see Fig. 10.21B). Propofol may alter adrenergic signaling in cardiac myocytes. Experiments using membranes and cardiac preparations isolated from rat heart demonstrate that relatively high concentrations of propofol (25 to 200 µmol/L) are required to antagonize β-adrenoceptor binding and tissue responsiveness.[130] Kurokawa and colleauges[131] observed that clinically relevant concentrations of propofol-attenuated β-adrenergic signal transduction in cardiac myocytes by inhibition of cyclic adenosine monophosphate (cAMP) production (Fig. 10.22). The inhibitory site of action of propofol appears to be upstream of adenylyl cyclase and involves activation of PKCα, an isoform of the enzyme that plays a role in regulating contractility.

Although propofol may decrease contractile response to adrenergic stimulation, there is emerging evidence that it may enhance myofilament sensitivity to Ca^{2+}. Propofol caused a leftward shift in the extracellular Ca^{2+}-shortening relationship, suggesting that propofol increases the sensitivity of myofibrillar actomyosin ATPase to Ca^{2+} (ie,

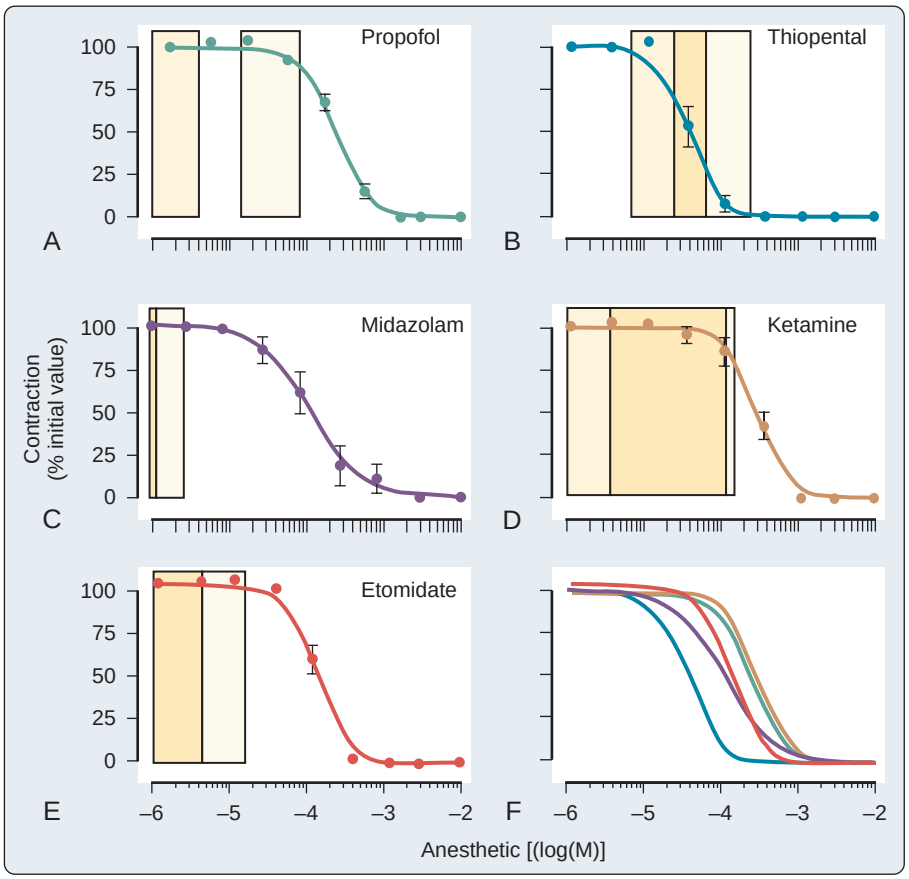

Fig. 10.20 Comparative effects of increasing concentrations of anesthetic on isometric contractions of human atrial tissue induced by field stimulation. Data are mean ± standard error of the mean. Curves were plotted using logistic regression. *Circles* indicate the clinical concentration range during anesthesia. Tan areas represent the total concentration and *white areas* show the free fraction. (A) Propofol ($n = 16$). (B) Thiopental ($n = 7$). (C) Midazolam ($n = 7$). (D) Ketamine ($n = 9$). (E) Etomidate ($n = 9$). (F) Combined plot shows the concentration–response curves of the five anesthetics. *(From Gelissen HP, Epema AH, Henning RH, et al. Inotropic effects of propofol, thiopental, midazolam, etomidate, and ketamine on isolated human atrial muscle.* Anesthesiology. *1996;84:397.)*

increases myofilament Ca^{2+} sensitivity) (Fig. 10.23). This is mediated in part by increasing pH through PKC-dependent activation of Na^+/H^+ exchange or by a PKC-dependent pathway involving the phosphorylation of myosin light chain 2 (MLC2).[132]

Integrated Cardiovascular Responses

The use of combined conductance-manometric catheters allows simultaneous measurement of pressure and volume in the ventricle and precise determination of the effects of anesthetic agents on integrated cardiovascular responses. Parameters include load-independent measures of contractility (eg, slope of the end-systolic pressure-volume relationship, end-systolic elastance [E_{es}]) and indices of ventricular-vascular coupling (eg, ratio of arterial elastance to ventricular elastance [E_a/E_{es}]) (see Chapters 6 and 13).

In one study, the effects of propofol and pentobarbital on integrated cardiovascular function were assessed in pigs at baseline and after an acute increase in ventricular afterload.[133] At baseline, E_{es} was lower during pentobarbital compared with propofol anesthesia, suggesting a greater negative inotropic effect for barbiturates than propofol (Fig. 10.24). However, the responses to ventricular afterload induced by aortic banding were maintained in the pentobarbital-anesthetized animals, whereas the responses were markedly attenuated in the propofol-anesthetized pigs, suggesting attenuation of the baroreflex responses with propofol. A decrease in arterial pressure with propofol is consistent with the drug acting as a vasodilator.

There is a question about what represents a clinically relevant dose of intravenous induction agents. Although coronary concentrations of propofol have been the major contributor to myocardial depression, they were a less significant contributor to the hypotension caused by this drug.[124]

Propofol affects ventricular and atrial function.[125] Propofol depresses contractility of the left atrial myocardium and reduces the active left atrial contribution to left ventricular filling in vivo. Compensatory decreases in chamber stiffness contribute to relative maintenance of left atrial reservoir function during the administration of propofol.

Oxidative Stress

Oxidative stress remains an important pathophysiologic mechanism for cellular injury in critically ill patients and represents an imbalance between the production of free radicals and the enzymatic defense system that removes them (Box 10.4). This has potential therapeutic implications because these agents are used routinely for sedation in the intensive care unit, in which disease processes associated with increased oxidative stress are treated.

Animal data suggest that propofol decreases postischemic myocardial mechanical dysfunction, infarct size, and histologic evidence of

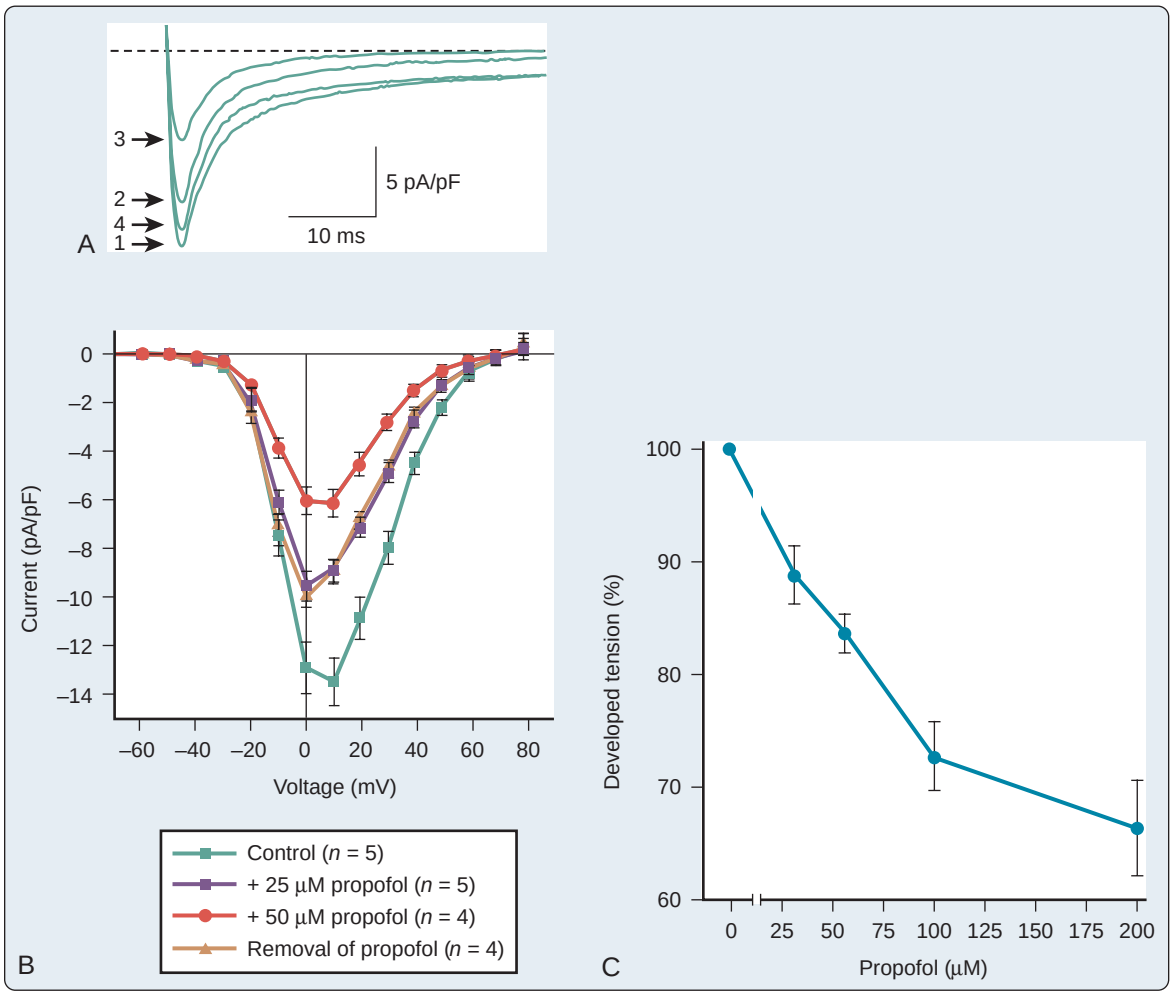

Fig. 10.21 (A) Current-voltage (I-V) relationship of peak cardiac L-type calcium current ($I_{Ca,L}$) as monitored before and during exposure to propofol. Cultured rat ventricular myocytes were clamped at –70 μV. $I_{Ca,L}$ was elicited by 200-ms pulses from the holding potential of –70 μV to potentials between –60 and +80 μV in 10-μV increments. Propofol dose-dependently decreased calcium current. (B) Representative current traces of $I_{Ca,L}$ by current density pA/pF in response to depolarizing pulses to 0 μmol/L from a holding potential of –70 μV. As shown in the legend below the graph, traces were obtained (1) before exposure to propofol, during treatment with (2) 25 μmol/L and (3) 50 μmol/L propofol, and (4) after recovery. (C) Effects of propofol on developed tension in papillary muscle isolated from the rat heart. Preparations (n = 4) were bathed in an oxygenated Krebs-Henseleit solution at 37°C and paced electrically at 1 Hz. The anesthetic was added to the bathing solution cumulatively. *Vertical bars* represent standard error of the mean. Values on the ordinate indicate the percentage of the developed tension recorded immediately before adding propofol (0.64 ± 0.15 g). Propofol dose-dependently decreases twitch tension. *(From Zhou W, Fontenot HJ, Liu S, et al. Modulation of cardiac calcium channels by propofol.* Anesthesiology. *1997;86:670.)*

BOX 10.4 INTRAVENOUS INDUCTION AGENTS

- Oxidative stress is an important pathophysiologic mechanism for cellular injury in critically ill patients and represents an imbalance between the production of free radicals and the enzymatic defense system that removes them.
- Propofol and midazolam act as free radical scavengers at near-therapeutic doses and suggest a role for propofol in modulating injury. This has therapeutic implications because the agents are used routinely for sedation in the intensive care unit, where patients with disease processes associated with increased oxidative stress are treated.
- Evidence does not support propofol or other induction agents as preconditioning-inducing agents.
- The effects of intravenous anesthetic agents may not be solely mediated by directly modulating vascular tone through alteration of the contractile state of the vascular smooth muscle. They also may alter vascular smooth muscle proliferation and modulate pathways that are important in angiogenesis.
- Administration of these anesthetic agents by the anesthesiologist may have effects that last long after the drugs have disappeared from the circulation.

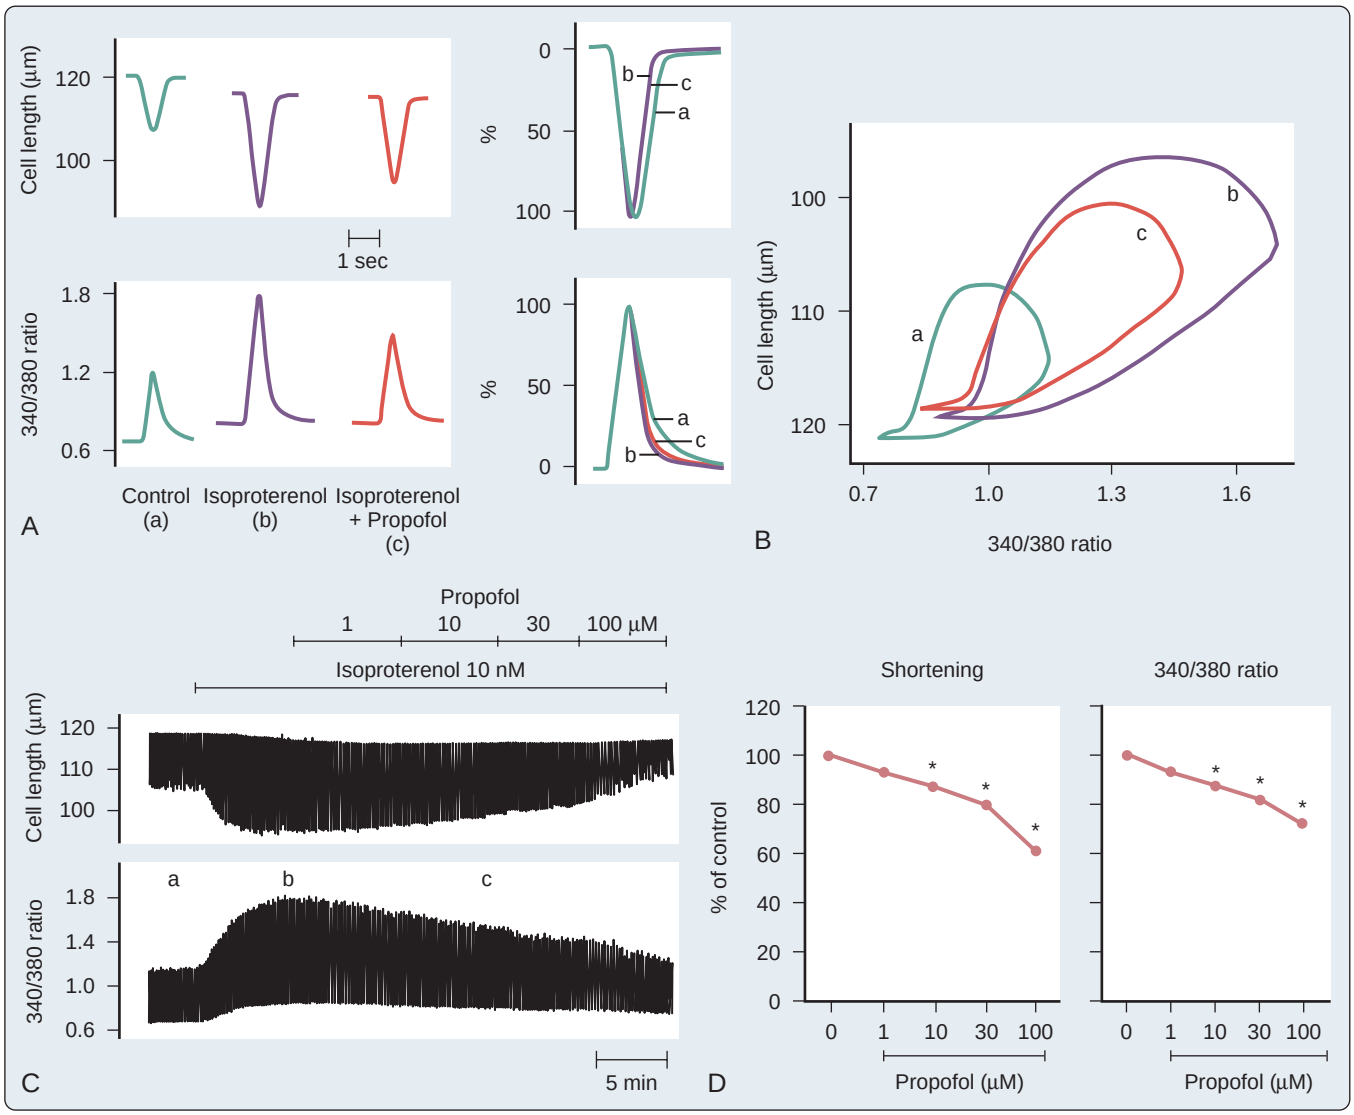

Fig. 10.22 (A and B) Original traces depict the dose-dependent effects of propofol on shortening and intracellular Ca^{2+} concentration, $[Ca^{2+}]_i$, after exposure to isoproterenol (10 nM) in a rat isolated ventricular myocyte. Calcium concentration was measured as the 340/380 ratio by dual wave spectrofurometry. (C and D) Summarized data for the effects of propofol on isoproterenol-stimulated increases in shortening and $[Ca^{2+}]_i$. Results are expressed as a percentage of the control. Propofol inhibits β-adrenergic–mediated contractility in a dose-dependent system. Significant changes (*) are shown. *(From Kurokawa H, Murray PA, Damron DS. Propofol attenuates beta-adrenoreceptor-mediated signal transduction via a protein kinase C-dependent pathway in cardiomyocytes.* Anesthesiology. *2002;96(3):688–698.)*

injury[134–140] (Fig. 10.25). Propofol has a chemical structure similar to that of phenol-based free radical scavengers (eg, vitamin E) and may therefore act as a free radical scavenger.[141,142] Studies by Tsuchiya and colleagues[143,144] demonstrated in vitro the potential for propofol and midazolam to act as free radical scavengers at near-therapeutic doses. Propofol also impairs the activity of neutrophils by inhibiting the oxidative burst and may modulate injury at the critical phase of reperfusion by reducing free radicals, Ca^{2+} influx, and neutrophil activity.[145]

Microsomes prepared from animals anesthetized with propofol demonstrate a significantly increased resistance to lipid peroxidation.[146] The evidence does not support propofol as an APC-inducing agent because protection was observed when the heart was treated with propofol solely during reperfusion rather than before or during the ischemic insult,[139] although the addition of glibenclamide, a K^+_{ATP} channel blocker, does not abolish the protection afforded by propofol.[140] There is little evidence for other intravenous induction agents having protective effects on the heart. Ketamine may block IPC[147–149] by deactivating sarcolemmal K^+_{ATP} channels.[150]

Vasculature

As with the heart, the physiologic actions of anesthetics in the vasculature represent a summation of their effects on the central ANS, direct effects on the vascular smooth muscle, and modulating effects on the underlying endothelium. An exhaustive review of the effects of each agent on isolated and integrated vascular function is beyond the scope of the chapter, but an overview of the effects of some commonly used agents on vasoregulation is presented.

Despite clear effects of anesthetics on vascular smooth muscle and endothelial function, controversy and diversity regarding mechanisms arise because of the species of animals studied, the vessel bed examined, and the drug dosage used. The effects may be significantly

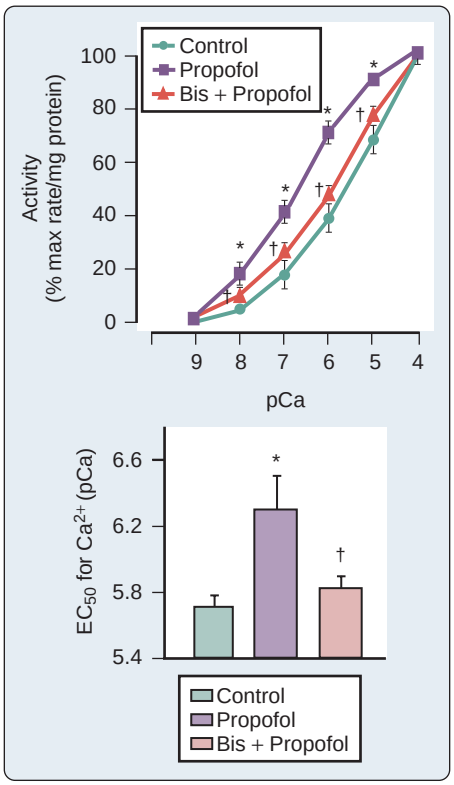

Fig. 10.23 *Top,* Summarized data depict the effects of bisindolylmaleimide I (Bis) or aprotinin kinase C inhibition on the propofol-induced leftward shift (30 μm) in actomyosin ATPase activity in isolated myofibrils. *Bottom,* Summarized data depict the increase (*$P < .05$ vs control) in the median effective concentration (EC_{50}) value for Ca^{2+} induced by propofol and inhibition of this effect (†$P < .05$ vs propofol) after pretreatment with Bis. Propofol increased myofilament Ca^{2+} sensitivity by a protein kinase C–dependent receptor. *(From Kanaya N, Gable B, Murray PA, et al. Propofol increases phosphorylation of troponin I and myosin light chain 2 via protein kinase C activation in cardiomyocytes.* Anesthesiology. *2003;98:1363.)*

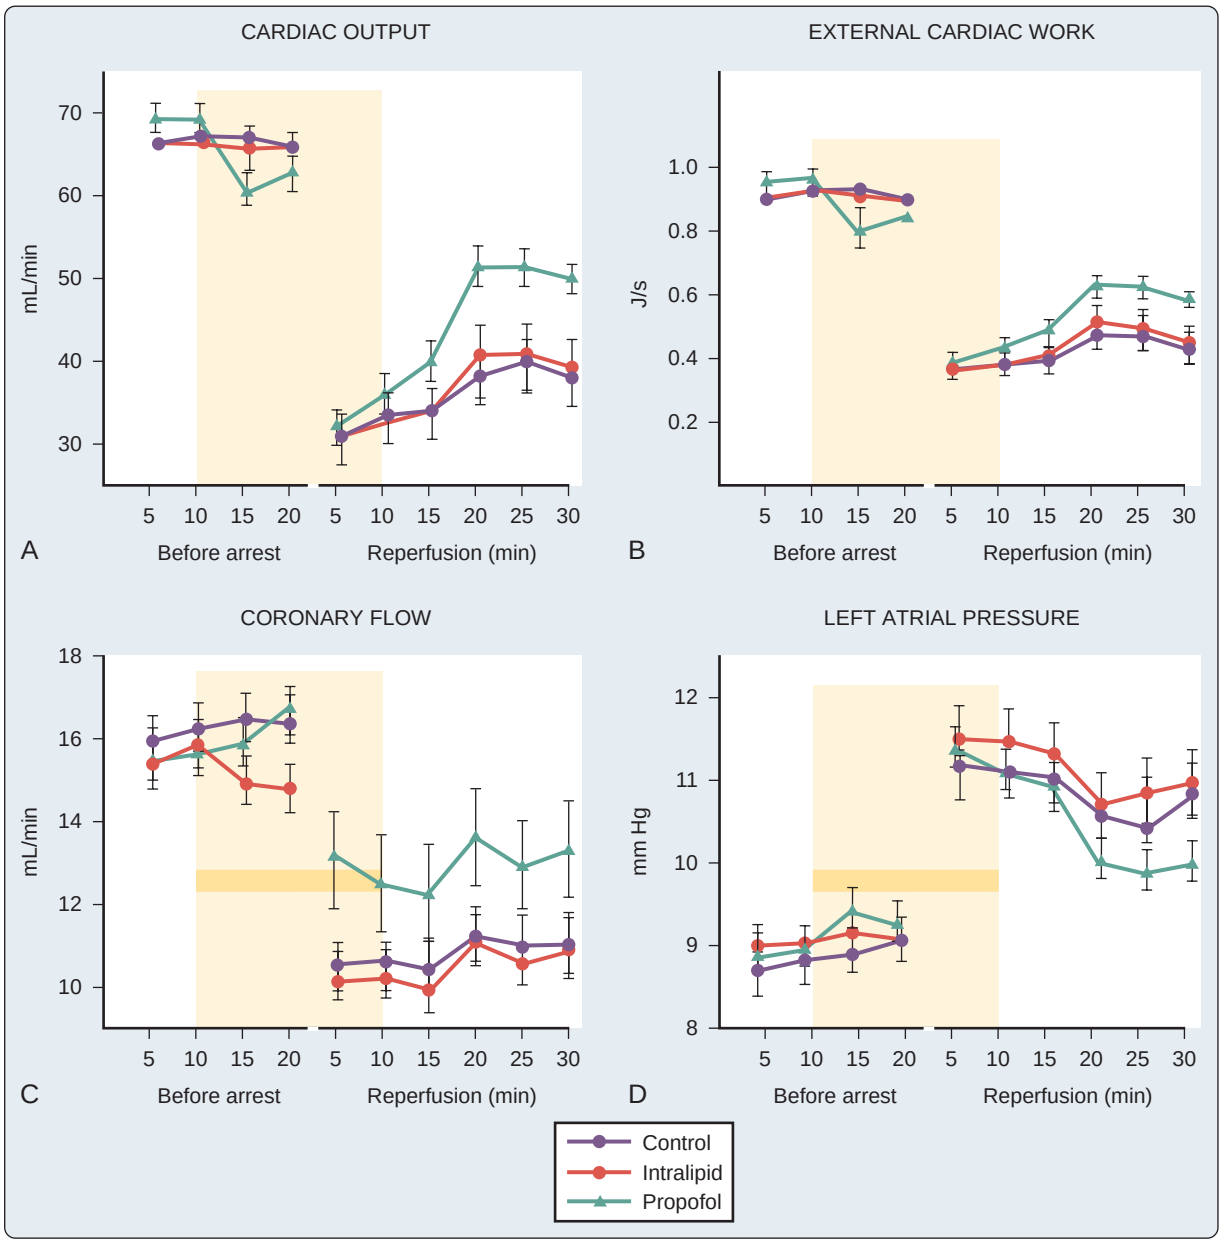

Fig. 10.25 Cardiac function of the isolated working rat heart subjected to cold cardioplegic arrest and subsequent reperfusion. (A) Cardiac output. (B) External cardiac work. (C) Coronary flow. (D) Left atrial pressure. Propofol (4 g/mL dissolved in intralipid emulsion) or intralipid alone was added 10 minutes after initiation of the working heart mode and washed out after 10 minutes into the working heart reperfusion. Data are plotted as mean ± standard error of the mean *(error bars)* for the separate heart preparations: control, intralipid, and propofol (n = 12, 12, and 14, respectively). *Shaded area* represents the period during which test agents were present. The break in the plots represents a 60-minute cold cardioplegic arrest and 10 minutes of initial Langendorff reperfusion. An increase in cardiac output (A) and a decrease in left atrial pressure (D) in propofol-perfused hearts demonstrate the protective effect of the drug. *(From Ko SH, Yu CW, Lee SK, et al. Propofol attenuates ischemia-reperfusion injury in the isolated rat heart.* Anesth Analg. *1997;85:719.)*

different in vessels from animals that develop disease phenotypes such as hypertension and diabetes. Although the effects of anesthetics on a variety of signal transduction pathways are invariably seen with high concentrations of the agents, their clinical relevance remains unclear.

Systemic Vasoregulation

Propofol decreases SVR in humans. This was demonstrated in a patient with an artificial heart in whom the CO remained fixed.[151] The effect is predominantly mediated by alterations in sympathetic tone, but in isolated arteries, propofol decreases vascular tone and agonist-induced contraction (discussed later). Propofol mediates these effects by inhibition of Ca^{2+} influx through voltage- or receptor-gated Ca^{2+} channels and inhibition of Ca^{2+} release from the intracellular Ca^{2+} stores regulated by the ryanodine receptor.[152–155]

Most of the experimental data obtained in isolated studies have focused on conduit arteries (eg, rat aorta), but some properties of the resistance arteries differ from the rat bioassay. Modulation of

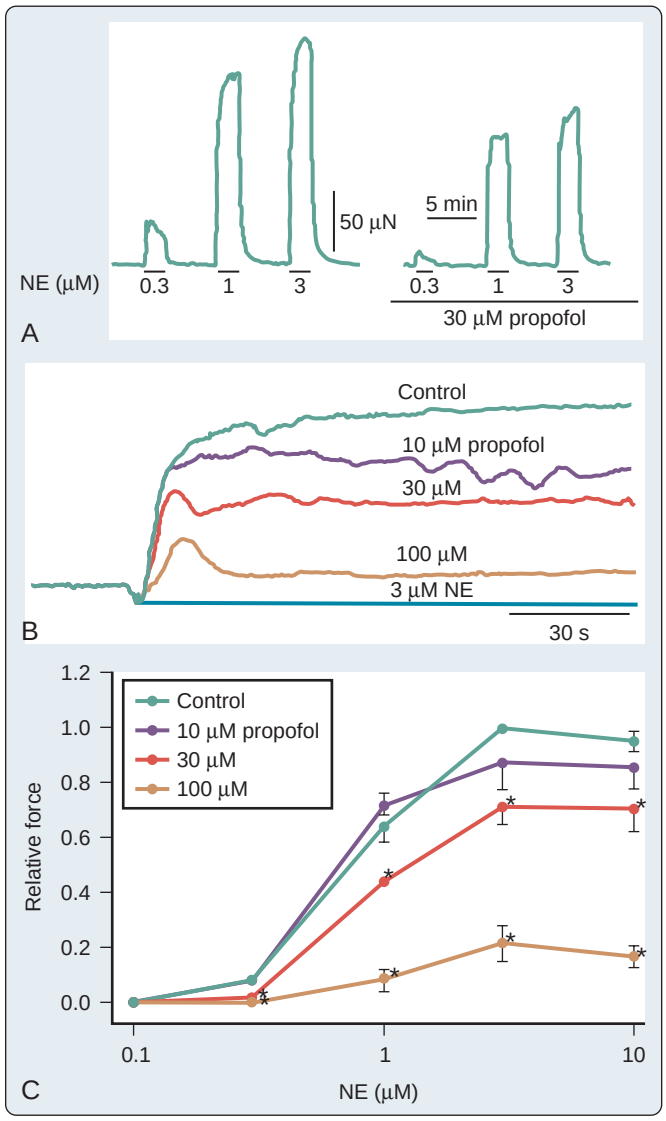

Fig. 10.26 (A–C) Effects of propofol on norepinephrine *(NE)*–induced increases in intracellular Ca^{2+} concentration and force in smooth muscle of the rabbit mesenteric resistance artery. *(From Imura N, Shiraishi Y, Katsuya H, et al. Effect of propofol on norepinephrine-induced increases in [Ca^{2+}] and force in smooth muscle of the rabbit mesenteric resistance artery.* Anesthesiology. *1998;88:1566.)*

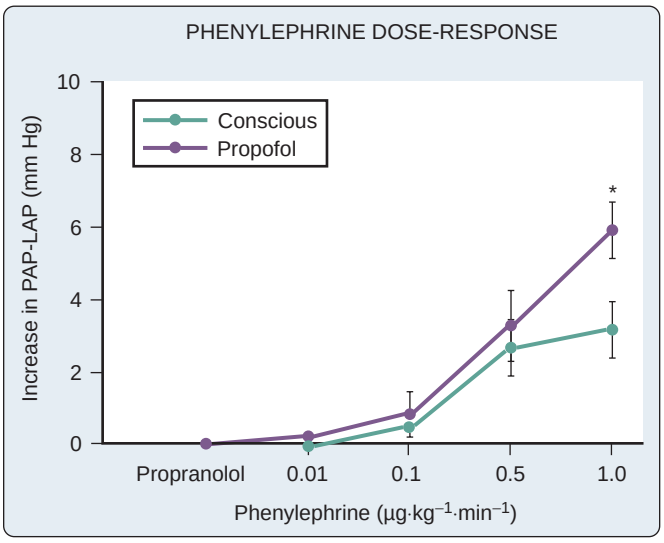

Fig. 10.27 Pulmonary vascular effects of propofol at baseline, during elevated vasomotor tone, and in response to sympathetic and adrenoreceptor activation. *LAP*, Left atrial pressure; *PAP*, pulmonary artery pressure. *(From Kondo U, Kim SO, Nakayama M, et al. Pulmonary vascular effects of propofol at baseline, during elevated vasomotor tone, and in response to sympathetic alpha- and beta-adrenoreceptor activation.* Anesthesiology. *2001;94:815.)*

vasoconstriction by vascular smooth muscle may be mediated by an alteration in endothelium-independent vasodilation[153] or an alteration in the sensitivity of the myofilaments to Ca^{2+}, primarily mediated by Rho activation (ie, activation of Rho kinase). In an elegant study examining the effects of propofol on resistance arteries, Imura and coworkers[156] examined the effect of propofol on simultaneous measurements of force and in mesenteric resistance arteries. The investigators concluded that propofol attenuated norepinephrine-induced contraction through inhibition of Ca^{2+} release and Ca^{2+} influx through L-type Ca^{2+} channels, partially explaining the effects of propofol on vascular adrenergic signaling (Fig. 10.26). Propofol may modulate vascular tone by interfering with other signaling pathways involved in vasoregulation, such as ET1.[156,157] Propofol also may attenuate the myogenic tone or response in pressure-flow autoregulation.[158]

Pulmonary Vasoregulation

The effects of induction agents on pulmonary vasoregulation may have important implications for the management of patients whose primary pathologies involve the pulmonary circulation when they undergo cardiothoracic surgery (ie, primary pulmonary hypertension for lung transplantation and chronic thromboembolic disease for pulmonary endarterectomy). The effects may be important for patients with right ventricular failure.[159] In modulating hypoxic pulmonary vasoconstriction, induction agents may affect intraoperative alveolar-arterial (A-a) gradients, particularly during one-lung ventilation.

Murray and colleagues[160,161] systematically studied the effects of anesthetic agents on pulmonary vasoregulation. They found that propofol attenuated endothelium-dependent vasodilatation[160] through a mechanism involving NO and endothelium-dependent hyperpolarizing factor.[161] In vascular smooth muscle, the effect appears somewhat different in the pulmonary circulation. Rather than attenuate vasoconstriction and thereby decrease tone, propofol appears to increase the sensitivity of the contractile myofilaments to Ca^{2+},[154] and it potentiates the effect of catecholamines on pulmonary artery smooth muscle cells[162,163] (Fig. 10.27).

Endothelial Function

Propofol modulates the function of the endothelium, altering the underlying tone of the vessels. The data about the direction and mechanism underlying this effect are widely divergent and depend on the vascular bed, species, and experimental conditions. Early studies suggested that propofol-mediated vasodilatation was a function of stimulation of NO and vasodilator prostanoids from the endothelium.[148] Other studies demonstrated an inhibitory effect of propofol and ketamine, but not of midazolam, on endothelium-dependent relaxation.[164] The suppressive effect of ketamine on endothelium-dependent relaxation appears to be mediated by suppression of NO formation, whereas that of propofol may be mediated in part by suppression of NO function.

In a rabbit mesenteric resistance artery preparation, Yamashita and colleagues[165] demonstrated that propofol inhibits prostacyclin-mediated, endothelium-dependent vasodilatation by inhibition of vascular hyperpolarization (Fig. 10.28). The inhibition of hyperpolarization and inhibition of relaxation appear to be mediated by the blockade of ATP-sensitive K^+ channels. Although the clinical implications of these findings are unclear, it may be predicted based on the data that the effects of propofol on the vasculature may be significantly

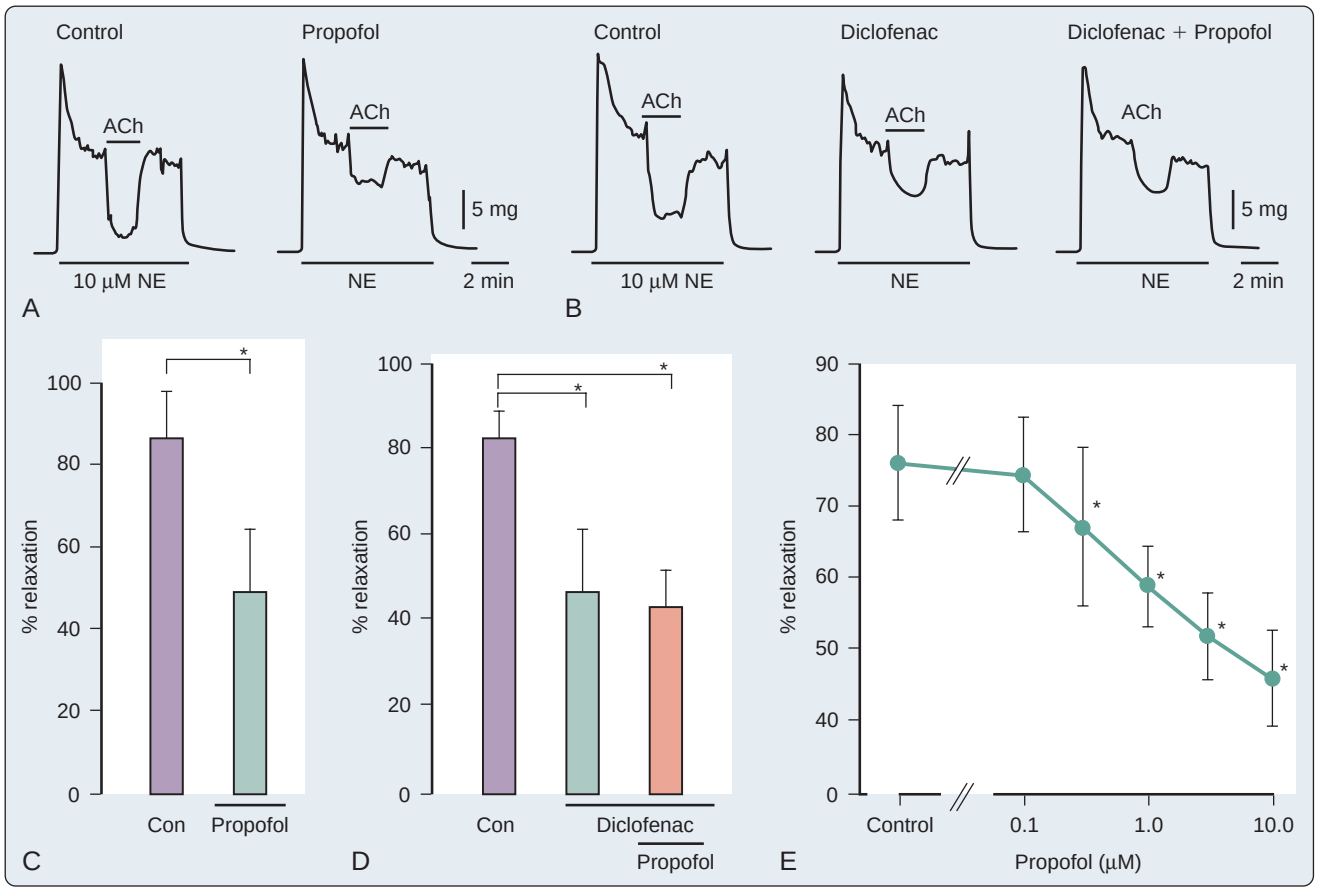

Fig. 10.28 (A–E) Inhibitory effects of propofol on acetylcholine *(ACh)*–induced, endothelium-dependent relaxation and prostacyclin synthesis in rabbit mesenteric resistance arteries. *Con*, Control; *NE*, norepinephrine; significant difference (*) from control ($P < .05$). *(From Yamashita A, Kajikuri J, Ohashi M, et al. different in patients in whom endothelial dysfunction, such as hypertension and atherosclerosis, is a significant factor.

Gursoy and associates[166] described the dose-dependent vasorelaxation produced by intravenous anesthetic agents on human radial artery grafts. The relaxant properties of thiopental and ketamine were more potent than those of etomidate and propofol. These observations may have implications for the perioperative management of coronary artery graft vasospasm.[166]

Sympathetic and Parasympathetic Nervous System

In human in vivo studies, it appears that the cumulative effects of propofol on peripheral arterial venous capacitance are mediated primarily by its effects on the sympathetic nervous system (SNS). In a well-designed study in which the effect of a local infusion of propofol into the brachial artery was compared with systemic intravenous administration with induction of anesthesia, direct brachial infusion had little effect on resistance and capacitance, whereas the effect of intravenous administration was similar to the effect observed with sympathectomy induced by stellate ganglion block (Fig. 10.29). The peripheral vascular effects of propofol appear to be mediated primarily by reduced sympathetic vasoconstrictor nerve activity.[167]

In another elegant study, Sellgren and coworkers[168] measured the effect of propofol on the SNS using percutaneous recordings of muscle sympathetic nerve activity. The researchers demonstrated a profound decrease in SNS activity with a reciprocal increase in blood flow (measured by laser Doppler) with propofol-induced anesthesia. Sympathetic baroreflex sensitivities were also depressed by propofol, highlighting the profound effect of this agent on central sympathetic modulation of integrated cardiovascular function. The precise locations of the central modulation by propofol were investigated by Yang and colleagues,[169,170] who demonstrated that propofol principally inhibited the vasomotor mechanism in the dorsomedial and ventrolateral medulla to effect its hypotensive actions.

The implications of these effects are significant in that sympathoinhibition is amplified in patients in whom the level of SNS activity is high. Caution is indicated in the administration of these agents to patients with shock, CHF, or other pathophysiologic conditions in which the SNS is paramount in maintaining arterial and venous tone.

Remodeling and Cell Proliferation

The literature suggests that the effects of intravenous anesthetic agents may not be solely mediated by direct modulation of vascular tone through alteration of the contractile state of the vascular smooth muscle. Some studies suggest that intravenous anesthetics may alter vascular smooth muscle proliferation and modulate pathways that are important in angiogenesis. For example, Shiga and associates[171] demonstrated the effect of ketamine (but not propofol) on inhibiting vascular smooth muscle proliferation through a PKC-dependent pathway. However, midazolam (but not ketamine) released vascular endothelial growth factor, a growth factor important in angiogenesis and cellular proliferation, from vascular smooth muscle cells.[172] The clinical importance of these findings remains unstudied and unclear, but they emphasize that the administration of these agents and others

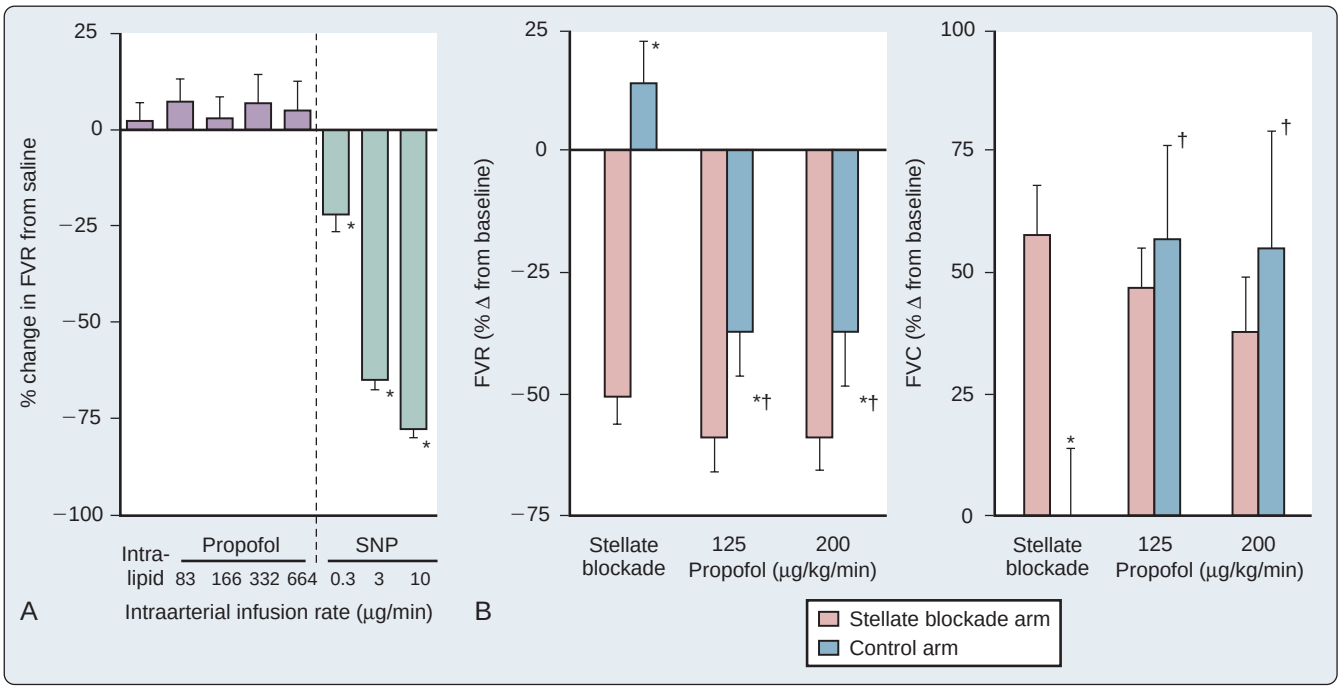

Fig. 10.29 (A) Change in forearm vascular resistance *(FVR)* during brachial artery infusions of intralipid, propofol, and sodium nitroprusside *(SNP)*. Intraarterial infusions of propofol did not change FVR, whereas intraarterial infusions of SNP significantly reduced FVR. Data are expressed as the percentage change from saline and are shown as the mean ± standard error of the mean (SEM). *$P < .05$ indicates a significant change from saline. (B) Percentage changes from awake baseline in FVR and forearm venous compliance *(FVC)* in the left arm after stellate blockade and in the control unblocked arm before and during propofol anesthesia. Stellate blockade decreased FVR and increased FVC on the side of the blockade. During propofol anesthesia, there was no further arterial or venous dilation in the sympathectomized arm, but significant dilation occurred in the unblocked control arm. Data are mean ± SEM. *$P < .05$ indicates a significant difference between arms; †$P < .05$ indicates a significant change from prepropofol baseline. *(From Robinson BJ, Ebert TJ, O'Brien TJ, et al. Mechanisms whereby propofol mediates peripheral vasodilation in humans. Sympathoinhibition or direct vascular relaxation?* Anesthesiology. *1997;86:64.)*

by the anesthesiologist may have effects that last well after the drug has disappeared from the body.

Individual Agents

Thiopental

General Characteristics

Thiopental has survived the test of time as an intravenous anesthetic drug (Box 10.5). Since Lundy introduced it in 1934, thiopental remained the most widely used induction agent for decades because of the rapid hypnotic effect (ie, one arm-to-brain circulation time), highly predictable effect, lack of vascular irritation, and general overall safety.[173]

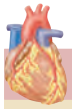
The induction dose of thiopental is less for older than for younger healthy patients.[174] Pharmacokinetic analyses[175–177] confirm the findings from the early classic studies of Brodie and Mark[178] relating the awakening from thiopental to rapid redistribution. Thiopental has a distribution half-life ($t_{½}\alpha$) of 2.5 to 8.5 minutes, and the total body clearance varies according to sampling times and techniques from 0.15 to 0.26 L/kg per hour.[167–169,171,172] The elimination half-life ($t_{½}\beta$) varies from 5 to 12 hours.[176,177,179,180]

Barbiturates[181] and drugs such as propofol[182] have increased volumes of distribution (V_d) when used during CPB. Young (<13 years) patients seem to have a greater total clearance and quicker plasma thiopental clearance than do adults, which theoretically might result in earlier awakening, especially after multiple doses.[183] Because of the affinity of fat for this drug, its relatively large V_d, and its low rate of hepatic clearance, thiopental can accumulate in tissues, especially if given in large doses over a prolonged period.

Cardiovascular Effects

The hemodynamic changes produced by thiopental have been studied in healthy patients[174,184–190] and in patients with cardiac disease (Table 10.2).[191–196] The principal effect is a decrease in contractility,[188,189,197] which results from reduced availability of calcium to the myofibrils.[198] There is also an increase in HR.[174,185,187–189,194–197] The cardiac index (CI) is unchanged[185,193–196] or reduced,[184,186,189] and the mean arterial pressure (MAP) is maintained[185,195,196,199] or slightly reduced.[186,187,193–195] In the dose range studied, no relationship between plasma thiopental and hemodynamic effect was found.[174] Early hemodynamic investigations demonstrated that thiopental (100 to 400 mg) significantly decreased CO (24%) and systemic BP (10%), presumably by reducing venous return because of an increase in venous capacitance.[186,200]

Mechanisms for the decrease in CO include direct negative inotropic action; decreased ventricular filling, resulting from increased venous capacitance; and transiently decreased sympathetic outflow from the central nervous system (CNS). The 10% to 36% increase in HR that accompanies thiopental administration probably results from the baroreceptor-mediated sympathetic reflex stimulation of the heart. Thiopental produces dose-related negative inotropic effects that appear to result from a decrease in calcium influx into the cells and a resultant diminished amount of calcium at sarcolemma sites.[201,202] Patients who had compensated heart disease and received 4 mg/kg of thiopental had a greater (18%) BP decline than did other patients without heart disease. The 11% to 36% increase in HR encountered



BOX 10.5 INTRAVENOUS ANESTHETICS

Thiopental
- Thiopental decreases cardiac output by
  - A direct negative inotropic action
  - Decreased ventricular filling resulting from increased venous capacitance
  - Transiently decreasing sympathetic outflow from the central nervous system
- Because of these effects, caution should be used when thiopental is given to patients who have left or right ventricular failure, cardiac tamponade, or hypovolemia.

Midazolam
- Small hemodynamic changes occur after the intravenous administration of midazolam.

Etomidate
- Etomidate is the drug that changes hemodynamic variables the least. Studies in noncardiac patients and those who have heart disease document remarkable hemodynamic stability after administration of etomidate.
- Patients who have hypovolemia, cardiac tamponade, or low cardiac output probably represent the population for whom etomidate is better than other induction drugs, with the possible exception of ketamine.

Ketamine
- A unique feature of ketamine is stimulation of the cardiovascular system with the most prominent hemodynamic changes, including significant increases in heart rate, cardiac index, systemic vascular resistance, pulmonary artery pressure, and systemic artery pressure. These circulatory changes increase myocardial oxygen consumption with an appropriate increase in coronary blood flow.
- Studies have demonstrated the safety and efficacy of induction with ketamine in hemodynamically unstable patients, and it is the induction drug of choice for patients with cardiac tamponade physiology.

Dexmedetomidine
- Dexmedetomidine is a highly selective, specific, and potent adrenoreceptor agonist.
- α_2-Adrenergic agonists can safely reduce anesthetic requirements and improve hemodynamic stability. They can enhance sedation and analgesia without producing respiratory depression or prolonging the recovery period.

in patients with coronary artery disease (CAD) who were anesthetized with thiopental (1 to 4 mg/kg) is potentially deleterious because of the obligatory increase in myocardial oxygen consumption ($M\dot{V}o_2$).

Despite the well-known potential for cardiovascular depression when thiopental is given rapidly in large doses, the drug has minimal hemodynamic effects in healthy patients and in those who have heart disease when it is given slowly or by infusion. Significant reductions in cardiovascular parameters occur in patients who have impaired ventricular function. When thiopental is given to patients with hypovolemia, there is a significant reduction in CO (69%) and a large decrease in BP, which indicate that patients without adequate compensatory mechanisms may have serious hemodynamic depression with a thiopental induction.[203] Thiopental produces greater changes in BP and HR than midazolam when used for induction of American Society of Anesthesiologists (ASA) class III (ie, severe systemic disease) and class IV (ie, severe systemic disease that is life-threatening) patients.

Uses in Cardiac Anesthesia

Thiopental can be used safely for the induction of anesthesia in normal patients and in those who have compensated cardiac disease. Because of the negative inotropic effects, increase in venous capacitance, and dose-related decrease in CO, caution should be used when thiopental is given to patients who have left or right ventricular failure, cardiac tamponade, or hypovolemia. The development of tachycardia is a potential problem in patients with ischemic heart disease.

A controversial additional use for thiopental infusion is for putative cerebral protection during CPB in patients undergoing selected cardiac operations.[204] However, the cerebral protective effect of thiopental during CPB has been challenged by Zaidan and coworkers,[205] who demonstrated no differences in outcome between thiopental and control patients undergoing hypothermic CPB for CABG. Although the administration of a barbiturate during CPB may result in myocardial depression necessitating additional inotropic support, the study by Ito and associates[206] suggested beneficial effects of a thiopental infusion during CPB in maintaining peripheral perfusion, which allowed more uniform warming, decreased base deficit, and decreased requirements for postoperative pressor support.

Midazolam

General Characteristics

Midazolam, a water-soluble benzodiazepine, was synthesized in the United States in 1975, in contrast to most new anesthetic drugs, which are synthesized and first tested in European countries. It is unique

TABLE 10.2 Induction Agents and Hemodynamic Changes

Parameter	*Thiopental (%)*	*Midazolam (%)*	*Etomidate (%)*	*Propofol (%)*	*Ketamine (%)*

among benzodiazepines because of its rapid onset, short duration of action, and relatively rapid plasma clearance.[207] Although controversial, the dose for induction of general anesthesia is between 0.05 and 0.2 mg/kg and depends on the premedication and speed of injection.[208–211]

The pharmacokinetic variables of midazolam reveal that it is cleared significantly more rapidly than diazepam and lorazepam. The rapid redistribution of midazolam and high rate of liver clearance account for its relatively short hypnotic and hemodynamic effects. The $t_{1/2}\beta$ is about 2 hours, which is at least tenfold less than for diazepam.[212–216]

Cardiovascular Effects

The hemodynamic effects of midazolam have been investigated in healthy subjects,[187,217,218] in ASA class III patients,[219] and in patients who have ischemic[200–227] and valvular[219] heart disease (VHD). Table 10.2 summarizes the hemodynamic changes after induction of anesthesia with midazolam. Only small hemodynamic changes occur after intravenous administration of midazolam (0.2 mg/kg) in premedicated patients who have CAD.[223,225] Potentially important changes include a decrease in MAP of 20% (ie, 102 to 81 mm Hg) and an increase in HR of 15% (ie, 55 to 64 beats/min).[223] The CI is maintained.[223,225] Filling pressures are unchanged or decreased in patients who have normal ventricular function,[223,225] but they are significantly decreased in patients who have an increased pulmonary capillary wedge pressure (PCWP = 18 mm Hg).[224] There seems to be little effect of different doses on hemodynamics: 0.2,[225] 0.25,[222] and 0.3 mg/kg[227] all produce similar effects.

Sedation with midazolam (0.05 mg/kg) in patients undergoing cardiac catheterization is devoid of any hemodynamic effect.[220] Marty and colleagues[221] showed that induction with 0.2 mg/kg produced a 24% reduction in CBF and a 26% reduction in MVo_2 in patients with CAD. As in patients with ischemic heart disease, the induction of anesthesia in patients with VHD is associated with minimal changes in CI, HR, and MAP after midazolam.[220] When intubation follows anesthesia induction with midazolam, significant increases in HR and BP occur, because midazolam is not an analgesic.[187,225–227] Adjuvant analgesic drugs are required to block the response to noxious stimuli.

Midazolam appears to affect the capacitance vessels more than diazepam does, at least during CPB, when decreases in venous reservoir volume of the pump are greater with midazolam than with diazepam. Diazepam decreases SVR more than midazolam during CPB.[228]

Midazolam (0.15 mg/kg) and ketamine (1.5 mg/kg) have proved to be a safe and useful combination for rapid-sequence induction for emergency surgery.[190] This combination was superior to thiopental alone because it caused less cardiovascular depression, more amnesia, and less postoperative somnolence. If midazolam is given to patients who have received fentanyl, significant hypotension may occur, as seen with diazepam and fentanyl.[229] However, midazolam routinely is combined with fentanyl for induction and maintenance of general anesthesia during cardiac surgery without adverse hemodynamic sequelae.[230,231]

Uses

Midazolam is distinctly different from the other benzodiazepines because of its rapid onset, short duration, water solubility, and failure to produce significant thrombophlebitis. It is therefore one of the mainstays of anesthesia in the cardiac operating room.

Etomidate

General Characteristics

Etomidate is a carboxylated imidazole derivative that was synthesized by Godefroi and coworkers in 1965.[232] In animal experiments, it was found that etomidate had a safety margin four times greater than that of thiopental.[233] The recommended induction dose of 0.3 mg/kg has pronounced hypnotic effects. Etomidate is moderately lipid soluble[234] and has a rapid onset (ie, 10 to 12 seconds) and a brief duration of action.[235–237] It is hydrolyzed primarily in the liver and in the blood.[238]

The administration of etomidate in a buffered solution was accompanied by a burning sensation in about 40% of cases and myoclonic movements in about 40% to 50%.[237] The myoclonic movements were not associated with an epileptiform pattern on the electroencephalogram.[234]

Etomidate infusion and single injections directly suppress adrenocortical function, which interferes with the normal stress response.[237–239] Blockade of 11β-hydroxylation mediated by the imidazole radical of etomidate results in decreased biosynthesis of cortisol and aldosterone.[240–242] The clinical significance of etomidate-induced adrenal suppression remains undetermined.

Cardiovascular Effects

In comparative studies with other anesthetic drugs, etomidate is usually described as the drug that changes hemodynamic variables the least.[243–249] Studies of noncardiac patients[245,248,250] and those who have heart disease[195,243,246,247,251,252] document the remarkable hemodynamic stability after administration of etomidate (see Table 10.2). In healthy subjects or patients who have compensated ischemic heart disease, HR, pulmonary artery pressure (PAP), PCWP, left ventricular end-diastolic pressure, right atrial pressure (RAP), CI, SVR, pulmonary vascular resistance (PVR), rate of left ventricular pressure rise in early systole (dP/dt), and systolic time intervals are not significantly changed after doses of 0.15 to 0.30 mg/kg.[195,243,244,252] Compared with other anesthetics, etomidate produces the least change in the balance of myocardial oxygen demand and supply. Systemic BP remains unchanged in most series[243,244,246,249] but may be decreased 10% to 19%[247,251,253] in patients who have VHD.

Dose-related changes have been demonstrated in the dog and were attributed to three possible causes: decreased CNS sympathetic stimulation, autoregulation due to decreased regional O_2 consumption, and decreased SV due to reduced venous return.[254]

A dose-dependent direct negative inotropic effect of etomidate was demonstrated in dogs, although at equianesthetic doses, it was one-half as pronounced as that of thiopental.[201] Determining the effects of anesthetic agents on myocardial contractility is difficult in vivo because of concomitant changes in HR, preload, and afterload. The effects may be evaluated in vitro, although this does not accurately represent what is occurring in the myocardium as a whole. Riou and associates[255] studied the effect of etomidate on intrinsic myocardial contractility using left ventricular papillary muscle and an electromagnetic lever system. Etomidate induced a slightly positive inotropic effect, as manifested by increased maximum shortening velocity. It appears, however, that propylene glycol, the solvent in which etomidate is available, may result in SR dysfunction with a slight negative inotropic effect in some clinical conditions.

Intravenous etomidate (0.3 mg/kg), used to induce general anesthesia in patients with AMI undergoing percutaneous coronary angioplasty, did not alter the HR, MAP, and rate-pressure product, demonstrating the remarkable hemodynamic stability of this agent.[256,257] However, VHD may influence the hemodynamic responses to etomidate. Whereas most patients can maintain their BP, patients with aortic and mitral VHD had significant decreases of 17% to 19% in systolic and diastolic BP[247,251] and had decreases of 11% and 17% in PAP and PCWP, respectively.[251] CI in patients who had VHD and received 0.3 mg/kg remained unchanged[194,247] or decreased 13%.[251] There was no difference in response to etomidate between patients who had aortic valve disease and those who had mitral valve disease.[251]

Wauquier[257] anticipated the widespread clinical use of etomidate in their investigation, in which they compared the effects of etomidate and thiopental in hypovolemic dogs. In a hemorrhagic shock model, dogs were bled to an MAP of 40 to 45 mm Hg and then given etomidate (1 mg/kg) or thiopental (10 mg/kg). There was significantly more hemodynamic depression in the thiopental group and increased

survival for the etomidate group. Whether this is true in humans is not known, but clinical evidence suggests that etomidate is useful in patients with hypovolemia.

Uses

In certain situations, the advantages of etomidate outweigh the disadvantages. Emergency uses include situations in which rapid induction is essential. Patients who have hypovolemia, cardiac tamponade, or low CO probably represent the population for whom etomidate is better than other drugs, with the possible exception of ketamine. The brief hypnotic effect means that additional analgesic or hypnotic drugs, or both, must be administered. Etomidate offers no real advantage over most other induction drugs for patients undergoing elective surgical procedures.

Ketamine

General Characteristics

Ketamine is a phencyclidine derivative whose anesthetic actions differ so markedly from barbiturates and other CNS depressants that Corssen and Domino[258] labeled its effect *dissociative anesthesia.* The properties of ketamine and its use in anesthesia have been completely reviewed.[199] Although ketamine produces rapid hypnosis and profound analgesia, respiratory and cardiovascular functions are not depressed as much as with most other induction agents.

Disturbing psychotomimetic activity (ie, vivid dreams, hallucinations, or emergence phenomena) remains a problem. Preliminary data suggest the possibility of a protective effect against postoperative cognitive dysfunction in patients undergoing cardiac surgery, and a study conducted by Hudetz and colleagues[259] suggested that ketamine attenuated the postoperative delirium seen in cardiac surgical patients after surgery.

Cardiovascular Effects

The hemodynamic effects of ketamine have been examined in noncardiac patients,[247,260–265] critically ill patients,[266] geriatric patients,[267] and patients who have a variety of heart diseases.[262,268–270,272–278] Table 10.2 contains the range of hemodynamic responses to ketamine. A unique feature of ketamine is stimulation of the CVS. The most prominent hemodynamic changes are significant increases in HR, CI, SVR, PAP, and systemic artery pressure. These circulatory changes increase $M\dot{V}o_2$ with an apparently appropriate increase in CBF.[268,277] Although global increases in $M\dot{V}o_2$ occur, there is some evidence that the increased work may be borne primarily by the right ventricle because of significantly greater increases in PVR than SVR[279]; however, both ventricles demonstrate increased work.

The hemodynamic changes observed with ketamine are not dose related in the relatively small dose ranges examined; there is no significant difference between changes after intravenous administration of 0.5 and 1.5 mg/kg.[280] A second dose of ketamine produces hemodynamic effects opposite to those of the first.[276] The cardiovascular stimulation seen after ketamine induction of anesthesia (2 mg/kg) in a patient who has VHD is not observed with the second administration, which is accompanied instead by decreases in the BP, PCWP, and CI.

Ketamine produces similar hemodynamic changes in healthy patients and those who have ischemic heart disease.[264] In patients who have increased PAP (eg, mitral valvular disease), ketamine appears to cause a more pronounced increase in PVR than in SVR. Marked tachycardia after administration of ketamine and pancuronium also can complicate the induction of anesthesia in patients who have CAD or VHD with atrial fibrillation.[281] In a study of patients undergoing elective CABG, the use of S-(+)-ketamine did not lead to increased cardiac troponin T levels after surgery when used in combination with propofol.[282]

The mechanism responsible for ketamine's stimulation of the circulatory system remains enigmatic. The direct effects of ketamine on the myocardium remain controversial. Riou and associates[283] demonstrated that ketamine has a dual opposing action on the myocardium: a positive inotropic effect, probably due to increased Ca^{2+} influx, and an impairment of SR function. The impairment is significant only at supratherapeutic ketamine concentrations or in cardiomyopathic myocardium,[284] and it overcomes this positive inotropic effect only under these circumstances. Myocardial depression has been demonstrated in isolated rabbit hearts,[285] intact dogs, and isolated dog heart preparations.[286,287] Although the precise site of cardiovascular stimulation is unknown, Ivankovich and colleagues[288] showed that small doses of ketamine injected directly into the CNS result in immediate hemodynamic stimulation. Ketamine also causes the sympathoneuronal release of norepinephrine, which can be measured in venous blood.[268,280,289] Blockade of the effect is possible with barbiturates, benzodiazepines,[280,288–290] and droperidol.[269]

Animal work supports the hypothesis that the primary hemodynamic effect of ketamine is central and not peripheral.[291–298] The role of ketamine's cocaine-like neuronal inhibition of norepinephrine reuptake has not been defined in its overall influence on the CVS.[299,300] It also is unknown whether ketamine exerts the same effect centrally, preventing reuptake of norepinephrine in the brain.

One of the most common and successful approaches to blocking ketamine-induced hypertension and tachycardia is prior administration of benzodiazepines. Diazepam, flunitrazepam, and midazolam successfully attenuate the hemodynamic effects of ketamine.[190,270,273,290,301–303] For example, in a study involving 16 patients with VHD, ketamine (2 mg/kg) did not produce significant hemodynamic changes when preceded by diazepam (0.4 mg/kg).[270] The HR, MAP, and rate-pressure product were unchanged, but there was a slight but significant decrease in CI.[270]

Hatano and associates[302] reported their experience with 200 cardiac surgical patients in whom the administration of diazepam (0.3 to 0.5 mg/kg) and then a ketamine infusion (0.7 mg/kg per hour) provided a stable hemodynamic course during induction, intubation, and incision. The combination of diazepam and ketamine rivals the high-dose fentanyl technique with regard to hemodynamic stability. No patient had hallucinations, although 2% had dreams and 1% had recall of events in the operating room.[302]

Levanen and colleagues[304] suggested that premedication with 2.5 μg/kg of intramuscular dexmedetomidine before ketamine-based anesthesia was as effective as midazolam in blocking the hemodynamic effects of ketamine and was more effective in reducing adverse CNS effects. Because of the propensity of dexmedetomidine to produce bradycardia, concomitant use of an anticholinergic agent was suggested.

Studies have demonstrated the safety and efficacy of induction with ketamine (2 mg/kg) in hemodynamically unstable patients who required emergency operations.[266,305,306] Most patients were hypovolemic because of trauma or massive hemorrhage. Ketamine induction was accompanied in most patients by the maintenance of BP and presumably of CO.[266,305] In patients who have an accumulation of pericardial fluid with or without constrictive pericarditis, induction with ketamine (2 mg/kg) maintains CI and increases BP, SVR, and RAP.[307,308] The HR in this group of patients was unchanged by ketamine, probably because cardiac tamponade already produced a compensatory tachycardia.

Uses

In adults, ketamine is probably the safest and most efficacious drug for patients who have decreased blood volume or cardiac tamponade. Undesired tachycardia, hypertension, and emergence delirium may be attenuated with benzodiazepines.

Propofol

Propofol was introduced into clinical practice in 1986. It is an alkylphenol with hypnotic properties. The pharmacokinetics of propofol has been evaluated by numerous investigators and been described by two-compartment[309,310] and three-compartment[311,312] models.

Cardiovascular Effects

The hemodynamic effects of propofol have been investigated in ASA class I (ie, normal and healthy) and class II (ie, mild systemic disease) patients,[313] elderly patients,[314,315] patients with CAD and good left ventricular function,[316,317] and patients with impaired left ventricular function (see Table 10.2). Numerous studies have compared the cardiovascular effects of propofol with the most commonly used induction drugs, including the thiobarbiturates and etomidate.[318–322] However comparison of the study findings is difficult because of variations in anesthetic techniques, drug dosages, and techniques for measuring data. It is clear that systolic arterial pressure declines 15% to 40% after intravenous induction with 2 mg/kg and maintenance infusion with 100 µg/kg per minute of propofol. Similar changes are seen in diastolic arterial pressure and MAP.

The effect of propofol on HR varies. Most studies have demonstrated significant reductions in SVR (ie, 9% to 30%), CI, SV, and LVSWI after propofol. Although controversial, the evidence points to a dose-dependent decrease in myocardial contractility. In a double-blind, randomized, controlled trial, Bendel and associates[323] compared the effects of propofol and etomidate in patients undergoing elective aortic valve surgery for aortic stenosis. They concluded that propofol was twice as likely to result in hypotension during the induction of patients with severe aortic stenosis compared with etomidate.[323]

It has been suggested that propofol increases triglyceride levels.[324–326] In 2007, Oztekin and coworkers[327] conducted a study evaluating the effect of propofol and midazolam on lipid levels early in the postoperative period in patients undergoing CABG surgery. Serum triglyceride levels and very-low-density lipoproteins were significantly increased in patients receiving intraoperative propofol infusions 4 hours after surgery. It remains to be seen what effect this increase has on clinical outcomes and postoperative course.[327]

Uses

In a study of the cerebral physiologic effects of propofol during CPB, Newman and colleagues[328] found that when given during nonpulsatile CPB, propofol produced statistically significant reductions in cerebral blood flow and cerebral metabolic rate in a coupled manner without adverse effects on the cerebral arteriovenous oxygen content difference or jugular bulb venous saturation. The coupled reductions in cerebral blood flow and cerebral metabolic rate suggest the potential for propofol to reduce cerebral exposure to emboli during CPB.

The effect of propofol on hypoxic pulmonary vasoconstriction was minimal in thoracic surgical patients undergoing one-lung ventilation. Compared with isoflurane, maintenance of anesthesia with propofol resulted in a lower CI and right ventricular ejection fraction but avoided the threefold increase in shunt fraction observed with isoflurane on commencement of one-lung ventilation.[329]

Dexmedetomidine

Dexmedetomidine, the pharmacologically active D-isomer of medetomidine, is a highly selective, specific, and potent adrenoreceptor agonist. Medetomidine has a considerably greater α_2/α_1 selectivity ratio than does the classic prototype α_2-adrenergic agonist clonidine in receptor-binding experiments. Compared with clonidine, it is more efficacious as an α_2-adrenoreceptor agonist. It has effectively reduced volatile anesthetic requirements in experimental animals as measured by the minimal alveolar concentration (MAC), and it can be a complete anesthetic in sufficiently high doses. The exact mechanisms of function and reduced anesthetic requirement are unknown but are thought to involve actions at presynaptic and postsynaptic α_2-adrenoreceptors in the CNS.

Cardiovascular Effects

The cardiovascular effects of dexmedetomidine are dose related. Furst and Weinger[330] demonstrated that an increase in systemic BP was associated with the pretreatment of rats with high-dose dexmedetomidine and that dexmedetomidine had little effect on arterial blood gases in spontaneously ventilating rats, consistent with minimal respiratory depression. Canine studies with medetomidine in doses of 30 µg/kg given intravenously or 80 µg/kg given intramuscularly showed decreases in HR and CO with increased SVR after drug administration. The intravenous administration of 5 to 10 µg/kg of medetomidine to anesthetized, autonomically blocked dogs suggested that the decline in CO was not mediated by decreased contractility but rather by the effects of increased vascular resistance and decreased HR. At high doses, the increase in SVR most likely results from the activation of peripheral postsynaptic α_2-adrenoreceptors in vascular smooth muscle.

In human studies, ASA class I women who received low-dose premedication with 0.5 µg/kg of dexmedetomidine demonstrated modest decreases in BP and HR. Intramuscular dexmedetomidine in a dose of 2.5 µg/kg administered 45 minutes before induction of a ketamine-N_2O-oxygen anesthetic resulted in effective attenuation of the cardiostimulatory effects of ketamine but also in increased intraoperative and postoperative bradycardia.[304] The use of perioperative intravenous infusions of low-dose dexmedetomidine in vascular patients at risk for CAD produced lower preoperative HR and systolic BP and less postoperative tachycardia, but it also resulted in a greater intraoperative requirement for pharmacologic intervention to support BP and HR. The precise cause of this effect is unknown, but it may reflect the attenuation of sympathetic outflow from the CNS.

Some controversy exists about whether the hemodynamic effects of dexmedetomidine are influenced by the background anesthetic. In conscious animals, the hypotensive effect of the drug dominates, but with the addition of potent inhalation anesthetics, MAP remains unchanged or increased, which implies a different mechanism of interaction of inhalation agents for this class of anesthetics. Dexmedetomidine has little effect on respiration, with minimal increase in arterial carbon dioxide tension ($PaCO_2$) after administration to spontaneously ventilating dogs. It has a potential advantage over other respiratory depressant anesthetics. Antinociceptive effects of medetomidine are mediated by suppression of responses of the pain-relay neurons in the dorsal horn of the spinal cord.

Uses

Clinical studies have suggested that α_2-adrenergic agonists can safely reduce anesthetic requirements and improve hemodynamic stability. These agents may enhance sedation and analgesia without producing respiratory depression or prolonging the recovery period. Barletta and associates[331] compared postoperative opioid requirements in patients undergoing cardiac surgery who received intraoperative propofol with those receiving dexmedetomidine. Although dexmedetomidine resulted in lower opioid use compared with propofol, it did not translate to a shorter duration of mechanical ventilation, but it did result in significantly greater sedation-related costs.[331]

Levanen and coworkers[304] suggested that dexmedetomidine might be an effective alternative to benzodiazepines in attenuating the postanesthetic delirium effects of ketamine. Because α_2-adrenergic agonists potentially inhibit opiate-induced rigidity, they may be of use as adjuvants with high-dose opioid anesthetics for cardiac surgery. In contrast with other anesthetic adjuvants such as the benzodiazepines, the α_2-adrenoreceptor agonist dexmedetomidine does not further compromise cardiovascular or respiratory status in the presence of high-dose opioids.

The use of dexmedetomidine as a sedative adjunct in the management of patients after surgery in the intensive care unit is becoming increasingly popular.[332] The idea that the type and amount of agent used intraoperatively can influence the postoperative course, specifically neuropsychologic events, is emerging as an important paradigm.[333] The management of patients after surgery is covered extensively in Chapters 37, 38, and 39. In summary, pharmacologic evidence suggests dexmedetomidine may be useful as an adjuvant in cardiac anesthesia.

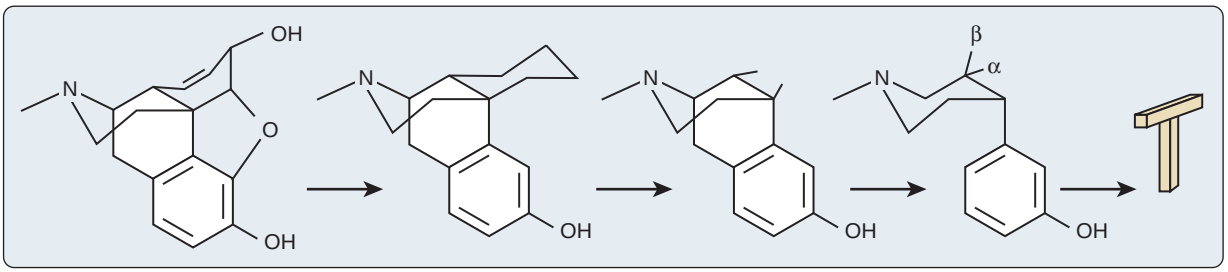

Fig. 10.30 Synthetic opioids are produced by successive removal of ring structures from the five-ring phenanthrene structure of morphine. A common core, envisaged as a T shape, is shared by all opioids. A piperidine ring (which is thought to confer opioid-like properties to a compound) forms the crossbar, and a hydroxylated phenyl group forms the vertical axis. *(From Ferrante FM. Opioids. In: Ferrante FM, VadeBoncouer TR, eds.* Postoperative Pain Management. *New York: Churchill Livingstone; 1992:149.)*

Opioids in Cardiac Anesthesia

Terminology and Classification

Various terms are commonly used to describe morphine-like drugs that are potent analgesics. The word *narcotic* is derived from the Greek word for "stupor" and refers to any drug that produces sleep. In legal terminology, it refers to any substance that produces addiction and physical dependence. Its use to describe morphine or morphine-like drugs is misleading and should be discouraged.

Opiates refer to alkaloids and related synthetic and semisynthetic drugs that interact stereospecifically with one or more of the opioid receptors to produce a pharmacologic effect. The more encompassing term, *opioid,* also includes the endogenous opioids and is used in this chapter. Opioids may be agonists, partial agonists, or antagonists.

A wide diversity in chemical structure exists among the naturally occurring, semisynthetic, and synthetic opioids. Opium contains several important alkaloid constituents, which may vary markedly in their pharmacologic actions. The five major alkaloid constituents of opium can be separated into two groups based on differences in their chemical structure. The phenanthrene derivatives include morphine, codeine, and the convulsogenic compound thebaine, which is used as a chemical precursor in the development of many clinically useful semisynthetic opioid compounds such as oxycodone. The benzylisoquinoline derivatives of opium include the phosphodiesterase inhibitor, smooth muscle relaxant papaverine, and the antitussive compound noscapine.

Modification of the morphine molecule, although simultaneously preserving the basic five-ring structure, results in semisynthetic compounds that also exhibit analgesic effects (eg, hydromorphone, heroin). Progressive removal of the rings results in synthetic opioids. As long as the common core or T shape is retained stereochemically and is shared by these synthetic derivatives, opioid properties are retained. The piperidine ring forms the crossbar and the hydroxyl phenyl group forms the vertical axis of the T shape (Fig. 10.30).

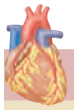
Opioid Receptors

The idea of opioid receptors was stated in the pioneering work of Beckett and Casy,[334] which in 1965 allowed Portoghese[335] to postulate the existence of separate opioid receptors by correlating analgesic activity with the chemical structure of many opioid compounds (Box 10.6). The concept of multiple opioid receptors is accepted, and several subtypes of each class of opioid receptors have been identified. Through biochemical and pharmacologic methods, the μ, δ, and κ receptors have been characterized.[336–338] Pharmacologically, the δ-opioid receptors consist of two subtypes: δ_1 and δ_2.[339–342] Table 10.3 lists the opioid receptors and their associated agonists and antagonists.

The μ-, κ-, and δ-opioid receptors have been cloned, and experimental data indicate that they belong to the family of G-protein–coupled receptors.[343–346] Three steps have been identified in the opioid-induced transmembrane signaling process: recognition by the receptor of the extracellular opioid agonist, signal transduction mediated by the G protein, and altered production of an intracellular second messenger (Fig. 10.31). The opioid receptors preferentially couple to a pertussis toxin–sensitive G protein (ie, G_i/G_o subunits) to influence one or more of three second-messenger pathways: cytoplasmic-free Ca^{2+} $[Ca^{2+}]_i$, the phosphatidylinositol-$[Ca^{2+}]_i$ system, and the cyclic nucleotide cAMP.

The actions of opioids are primarily inhibitory. Opioids close N-type, voltage-operated Ca^{2+} channels and open Ca^{2+}-dependent inwardly rectifying K^+ channels. This results in hyperpolarization and a reduction in neuronal excitability.[347] The κ receptors may act only on Ca^{2+} channels.[348] Evidence indicates that P/Q-type Ca^{2+} channels may be inhibited by μ-opioid but not δ-opioid receptors.[349] These effects may be mediated through direct coupling between the G protein and ion channels or indirectly through changes in intracellular Ca^{2+} levels. The Ca^{2+} fluxes and their consequences, such as calmodulin activation, are altered by opioids. Ca^{2+} ions are essential in nociception, and Ca^{2+} channel blockers potentiate opioid analgesia[350,351] and reduce fentanyl requirements during cardiac surgery.[352] Opioid-induced inhibition of adenylyl cyclase and the resultant decrease in the concentration of cAMP may be responsible for modulation of neurotransmitter release (eg, substance P).

Opioids have excitatory effects that involve disinhibition of interneurons and direct excitation of neurons. Nanomolar concentrations acting through G proteins stimulate adenylyl cyclase activity in certain neurons.[353] Another important stimulatory effect is a transient increase in cytoplasm-free Ca^{2+} due to Ca^{2+} influx through L-type Ca^{2+} channel



BOX 10.6 OPIOIDS

- The μ-, κ-, and δ-opioid receptors and endogenous opioid precursors have been identified in cardiac and vascular tissue.
- The functional roles of opioid precursors and opioid receptors in the cardiovascular system of persons with pathophysiologic conditions (eg, congestive heart failure, arrhythmia) are areas of ongoing investigation.
- The predominant cardiovascular effect of exogenously administered opioids is attenuation of central sympathetic outflow.
- Endogenous opioids and opioid receptors (especially the δ_1-opioid receptor) are likely important contributors to early and delayed preconditioning in the heart.
- Plasma drug concentrations are profoundly altered by cardiopulmonary bypass as a result of hemodilution, altered plasma protein binding, hypothermia, exclusion of the lungs from the circulation, and altered hemodynamics that likely modulate hepatic and renal blood flow. The specific effects are drug dependent.

TABLE 10.3 Agonist and Antagonist Drugs for μ-, κ-, and δ-Opioid Receptors

Opioid Receptor	*Agonists*	*Antagonists*
μ	Morphine Fentanyl Levorphanol Methadone	Naloxone Naltrexone β-Funaltrexamine (β-FNA)[a] Nalbuphine[b]
κ	U-50,488H Ethylketocyclazocine (EKC) Spiradoline (U-62,066E) U-69,593	Nor-binaltorphimine (nor-BNI) MR-2266 Naloxone
δ	(−)TAN-67 7-Spiroindinooxymorphone (SIOM) (+)-4-[((αR)- α (2S,5R)-4-Allyl-2,5-dimethyl-1-piperazinyl)-3-methoxy-benzyl]-*N*,*N*-diethylbenzamide chloride (SNC 80)	Naltrindole 7-Benzylidene-naltrexone (BNTX) Naltriben

[a]β-FNA is an irreversible opioid receptor antagonist.
[b]Nalbuphine is an opioid receptor antagonist with partial agonist properties.

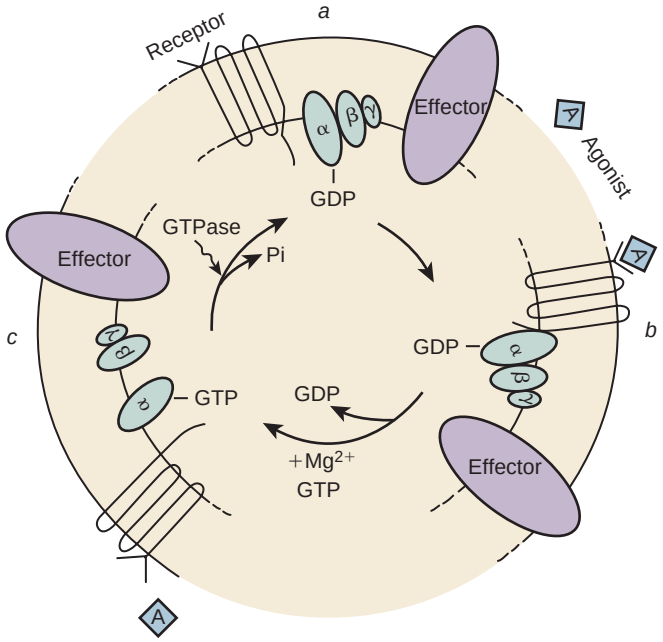


Fig. 10.31 Simple scheme for G-protein signal transduction. From the unliganded state (*a*), receptor binds agonist A (eg, epinephrine, acetylcholine), which produces a change (*b*) in the receptor and G protein interaction, allowing guanosine triphosphate *(GTP)* in the presence of Mg^{2+} to replace guanosine diphosphate *(GDP)* on the α subunit. The activated GTP α subunit and the βγ subunits dissociate, and one or both interact with effectors (eg, adenylyl cyclase, K^+ channel). Alternatively, free βγ may bind other α subunits. The intrinsic *GTPase* activity of the α subunit hydrolyzes GTP to GDP, releasing inorganic phosphate *(Pi)*, and α-GDP recombines with βγ (*c*), ending the activation cycle. Nonhydrolyzable analogues of GTP, such as Gpp(NH)p or GTP-γS, produce persistent activation of α subunits and persistent dissociations of α from βγ because activation cannot be reversed by hydrolysis of these nucleotide analogues to GDP.

openings and mobilization of Ca^{2+} from inositol triphosphate–sensitive intracellular stores.[354] The μ agonists also may stimulate Ca^{2+} entry into neurons through G-protein–coupled activation of phospholipase C to increase inositol 1,4,5-triphosphate formation due to Ca^{2+} influx through L-type Ca^{2+} channel openings.[354–356]

TABLE 10.4 Endogenous Opioid Peptide Precursors and Opioid Peptide Products Involved in Cardiovascular Regulation and Function

Precursor	*Opioid Peptide*	*Receptor*[a]
Proenkephalin[b]	Met-enkephalin Leu-enkephalin	δ > μ ≫> κ
POMC[c]	β-Endorphin	μ ≈ δ ≫ κ
Prodynorphin[d]	Dynorphin A Dynorphin $A_{(1–8)}$ Dynorphin B	κ ≫> μ > δ κ ≫ μ > δ κ ≫> μ > δ
Pronociception	Nociception	ORL1

ORL1, Opioid receptor-like 1; *POMC*, proopiomelanocortin.
[a]The affinity of the opioid peptide for its receptor is qualitatively described in this table for the μ-, κ-, and δ-opioid receptor subtypes found in the central nervous system.[544]
[b]An additional opioid peptide product from this precursor that exhibits relevant cardiovascular actions in MERF.[545]
[c]An additional POMC peptide cleavage product is adrenocorticotropic hormone, which is converted to α-melanocyte–stimulating hormone–related peptides in cardiac tissue.[546]
[d]Additional active peptides include leumorphin, α-neoendorphin, and β-neoendorphin.[544]

Opioid receptors involved in regulating the CVS have been localized centrally to the cardiovascular and respiratory centers of the hypothalamus and brainstem and peripherally to cardiac myocytes, blood vessels, nerve terminals, and the adrenal medulla. Opioid receptors are differentially distributed between atria and ventricles. The highest specific receptor density for binding of κ-opioid agonists is in the right atrium and least in the left ventricle.[357,358] As with the κ-opioid receptor, distribution of the δ-opioid receptor favors atrial tissue and the right side of the heart more than the left.[359] Data confirming the presence of the μ-opioid receptor subtype in the heart are less conclusive, and most researchers think that this receptor subtype is not present in cardiac tissue.[357,358,360,361]

Whether the differences in receptor location are important cannot be determined because it has not been shown whether the receptors are differentially located in cardiac muscle or cardiac nerves or are expressed on immunomodulatory cells within the heart. Based on these studies, the ability of opioid agonists to produce cardioprotection is most likely the effect of δ- and κ-opioid receptor stimulation, and studies appear to support a role for the δ-opioid receptor as the primary receptor responsible for IPC.

Endogenous Opioids in the Heart

Myocardial cells can synthesize, store, and release opioid-receptor peptides.[362] Opioid-receptor peptides may be secreted from nerves that innervate the heart or produced in myocardial tissue. Regardless of the manner of production, the peptides are devoid of activity until they undergo enzymatic proteolysis of the precursor by convertases into one or more active peptide products. The large stores of endogenous opioid peptide (EOP) precursors, which reside in the myocardial tissue, include proenkephalin, proendorphin, and prodynorphin.

The EOP system consists of the peptides endorphin, dynorphin, and enkephalin and their associated μ-, δ-, and κ-opioid receptors (Table 10.4). These opioid peptides and receptors are widely distributed in the body, and all have complex actions. In the heart, κ- and δ-receptor agonists inhibit ventricular contractility without altering atrial function.[359] A study of the actions of peptides on electrical and mechanical properties of the isolated rat heart showed that δ- and κ-opioid receptor agonists could directly depress cardiac function.[363] The rate of vagal firing is regulated by opioid peptides.[364] Vagal bradycardia is inhibited by the administration of the intrinsic cardiac opioid heptapeptide Met-enkephalin-Arg-Phe (MERF), presumably by the activation of δ-opioid receptors on prejunctional cardiac vagal nerves or parasympathetic ganglia, reducing acetylcholine release.[365] EOPs therefore mediate direct and indirect actions in various regions of the heart. In addition to complex differences in the general tissue

distribution of opioid receptors, cardiac opioid peptide function is complicated by the fact that receptor expression is modulated by physiologic states and disease.

Several investigators have demonstrated that certain opioid peptides are released during stressful situations into the peripheral circulation.[366,367–369] The peptides can modulate the ANS.[370] In the heart, opioid peptides (Leu- and Met-enkephalins) have been shown to increase with age[371–373] and disease.[374–377] EOPs are involved in the modulation of hypertension and other cardiovascular conditions such as CHF and appear to be involved in arrhythmogenesis.[378] Myocardial ischemia and reperfusion can induce synthesis and release of opioid peptides.[377,379–384] Several studies have demonstrated that levels of circulating β-endorphins are greater in patients with acute myocardial ischemia or those undergoing angioplasty.[379,382,383,385]

Although κ-receptor agonists have no effect on cardiovascular indices in healthy humans,[386] activation of δ and κ receptors during CHF decreases myocardial mechanical performance and alters regional blood flow distribution.[380] The mechanism for the negative inotropic effects is thought to be an increase of intracellular free Ca^{2+} by increasing the mobilization of calcium from intracellular stores due to increased production of inositol 1,4,5-triphosphate. The increase in Ca^{2+} concentration may manifest in cardiac arrhythmias, whereas depletion of Ca^{2+} from intracellular stores is responsible for a reduction in contractility.[380,387]

In patients with acute heart failure, concentrations of EOPs are increased,[388] whereas concentrations are decreased in patients with chronic heart failure. This has been interpreted as exhaustion of the opioid system.[389] Many studies suggest that EOPs mediate depression of myocardial function in CHF states.[367,388,390,391] Clinically, increased levels of EOPs (ie, β-endorphin, Met-enkephalin, and dynorphin) have been found in CHF patients, and they may correlate with severity. Naloxone administration to CHF patients increased BP and HR, suggesting a homeostatic regulatory role for EOPs.

Not all clinical studies suggest that inhibition of opioid peptides benefits patients with acute and chronic heart failure.[389] Oldroyd and colleagues[392] found that plasma levels of β-endorphins were normal in patients with acute and chronic heart failure and did not correlate with the severity of heart failure observed in their study.[392] They also found that naloxone administration did not alter cardiopulmonary exercise in these patients and suggested that EOP inhibition was not likely to have any therapeutic potential.

Cardiac Effects of Opioids

At clinically relevant doses, the cardiovascular actions of opioid analgesics are limited. The role that endogenously or exogenously administered opioids play in the regulation of the CVS is difficult to interpret because the physiologic effects they impart depend on pharmacologic variables such as dose, site, and route of administration; receptor specificity; and species. The actions opioids exhibit are mediated by opioid receptors located centrally in specific areas of the brain and nuclei that regulate the control of cardiovascular function and peripherally by tissue-associated opioid receptors. Opioids exhibit a variety of complex pharmacologic actions on the CVS[367] (Fig. 10.32).

Most of the hemodynamic effects of opioids in humans can be related to their influence on sympathetic outflow from the CNS. Evidence shows that sympathetic overactivity favors the genesis of life-threatening ventricular tachyarrhythmias, and its control has protective effects during acute myocardial ischemia.[393] Imbalance of the ANS, characterized by increased sympathetic activity and reduced vagal activity, results in myocardial electrical instability and promotes ischemic events. Pharmacologic modulation of the sympathetic activity by centrally or peripherally acting drugs elicits cardioprotective effects. Opioid-receptor agonists such as fentanyl exhibit significant central sympathoinhibitory effects.[394]

Fentanyl and sufentanil enhance the calcium current that occurs during the plateau phase (ie, phase 2) of the cardiac action potential and depress the outward potassium current responsible for terminal

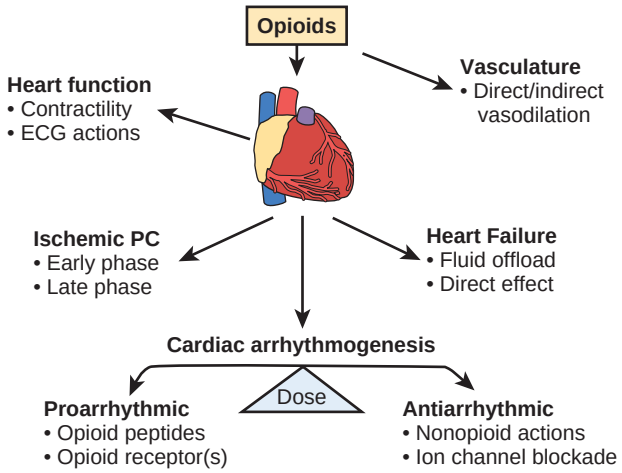

Fig. 10.32 Actions of opioids on the heart and cardiovascular system. Actions may involve direct opioid receptor–mediated actions, such as the involvement of the δ-opioid receptor in ischemic preconditioning *(PC)*, or indirect, dose-dependent, nonopioid-receptor–mediated actions, such as ion channel blockade associated with the antiarrhythmic actions of opioids. *ECG*, Electrocardiogram.

repolarization,[395] resulting in a significant prolongation of the duration of the action potential. Blair and coworkers[396] suggested that the cardiac electrophysiologic effects of fentanyl and sufentanil represented a direct membrane effect resembling that produced by class III antiarrhythmic drugs. In patients, large doses of opioids prolong the QT interval of the electrocardiogram.[395] Although generally proarrhythmic, this effect has been cited to explain the antiarrhythmic properties of opioids, particularly in the setting of myocardial ischemia.[292] Fentanyl (60 μg/kg) and sufentanil (10 μg/kg) significantly increased the ventricular fibrillation threshold in dogs after coronary artery occlusion.[397]

With the exception of meperidine, all opioids produce bradycardia, although morphine given to unpremedicated, healthy persons may cause tachycardia. The mechanism of opioid-induced bradycardia is central vagal stimulation. Premedication with atropine can minimize but not totally eliminate opioid-induced bradycardia, especially in patients taking β-adrenoceptor antagonists. Although severe bradycardia should be avoided, moderate slowing of the HR may be beneficial in patients with CAD by decreasing myocardial oxygen consumption.

Isolated heart or heart muscle studies have demonstrated dose-related inotropic effects for morphine, meperidine, fentanyl, and alfentanil.[398–401] However, these effects occurred at concentrations a hundred to several thousand times those found clinically. In canine hearts, the direct intracoronary injection of fentanyl in concentrations up to 240 ng/mL produced no changes in myocardial mechanical functions.[402]

Morphine produced dose-related decreases in the contractility of atria obtained from nonfailing and failing human hearts, but the concentration-response curve was significantly shifted to the right for preparations from failing hearts[403] (Fig. 10.33). The negative inotropic effects induced by morphine in failing and nonfailing preparations were not antagonized by naloxone, indicating that opioid receptors do not play a part in this cardiac effect of morphine. One explanation may be an interaction with β-adrenoceptors, unrelated to the binding of opioids to opioid receptors. Opioids inhibit β-adrenoceptor–sensitive adenylyl cyclase.[404]

Hypotension can occur after even small doses of morphine and is primarily related to decreases in SVR. The most important mechanism responsible for these changes is histamine release. The amount of histamine release is reduced by slow administration (<10 mg/min). Pretreatment with a histamine H_1 or H_2 antagonist does not block these reactions, but they are significantly attenuated by combined H_1

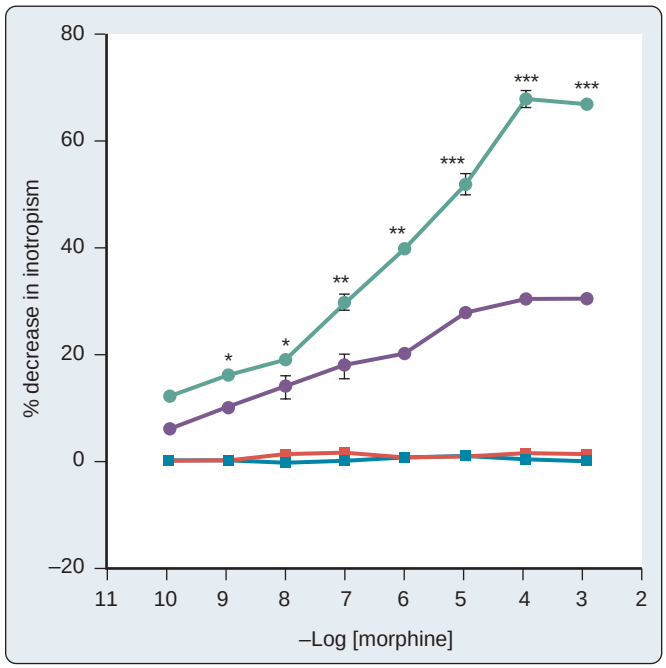

Fig. 10.33 Concentration-response curves for morphine *(circles)* in isolated electrically stimulated human right atrial strips from nonfailing *(green circles)* and failing *(purple circles)* hearts (*squares* indicate control). Average auricular inotropism (mean ± standard error of the mean [SEM)]) was 0.90 ± 0.05 g for nonfailing hearts and 0.89 ± 0.02 g for failing hearts. *$P < .05$; **$P < .01$; ***$P < .001$ versus failing heart. Each point represents the mean ± SEM of eight experiments for each experimental group.

TABLE 10.5 Effects of Arylacetamide κ-Opioid Agonists on Heart Rate, Blood Pressure, and Electrocardiographic Measures

Drug[a]	*Heart Rate*	*Blood Pressure*	*PR*	*QRS*	*RSh*	*QT*
U-50,488H	1.5	>32	20	>32	16	32
U-62,066E	4.0	8.0	15	25	2.0	10
PD117,302	5.5	0.50	3.0	7.5	1.0	6.0

[a]The nonopioid actions of structurally related arylacetamide κ-opioid receptor agonists were examined in pentobarbital-anesthetized rats. Heart rate, blood pressure, and electrocardiographic (ECG) measures (in milliseconds) were determined as D_{25}, the intravenous dose (μmol/kg/min) producing a 25% change in the given response. This measure allowed determination of the differential actions of the arylacetamides on ECG measures, an index of drug action on cardiac ion channels ($n = 6$). The drug dose produced a 25% change from controls in intact animals for six determinations per measure. All drugs consistently reduced the heart rate but had various D_{25} doses for blood pressure reduction. PD117,302 {(±)-*N*-methyl-*N*-[2-(1-pyrrolidinyl) cyclohexyl]benzo[b]thiophene-4-acetamide monohydrochloride} produced evidence of sodium channel blockade (ie, changes in the PR, QRS, and RSh measures) and potassium channel blockade (ie, changes in the QT interval) at lower D_{25} values than either of the other two drugs.

and H_2 antagonist pretreatment.[405] Neither morphine nor fentanyl in clinically relevant concentrations blocks α-adrenergic receptors in isolated vascular tissue studies.[406,407]

Opioids may directly act on vascular smooth muscle, independent of histamine release. In the isolated hind limbs of dogs anesthetized with halothane, high doses of alfentanil (500 μg/kg), fentanyl (50 μg/kg), and sufentanil (6 μg/kg) caused decreases in SVR of 48%, 48%, and 44%, respectively. Neither pretreatment with naloxone nor denervation changed the responses, and it was concluded that the three opioids produced vasodilation by a direct action on vascular smooth muscle.[408] Although fentanyl-induced relaxation in the rat aorta may be mediated by α-adrenergic receptors, this effect occurs only at concentrations several hundred times greater than those encountered clinically.[409]

The effects of κ-agonists on BP have been examined[410] and shown to be dose, species, and route dependent.[410,411] U-50,488H, for example, displays a markedly different cardiovascular profile when injected intravenously compared with direct injection into the CNS. In anesthetized dogs, κ-agonists produce dose-related decreases in BP, HR, peak systolic pressure, and cardiac contractility when administered intravenously. The cardiovascular responses to both opioid agonists were abolished by previous administration of naloxone.[412] In addition to reducing BP, κ-opioid agonist dose-dependently reduced the HR in anesthetized rats.[410] This suggests an effect on the reflex mechanisms that regulate the HR during hypotension or direct action on the electrical or mechanical properties responsible for normal cardiac contractility. The κ-opioid agonists slightly depress the HR and BP at low doses and are not inhibited by naloxone, suggesting a lack of involvement of opioid receptors and a possible direct effect on cardiac muscle.[411] In anesthetized rats, the cardiovascular responses to κ-opioid agonists in the presence of opioid antagonists were not changed.[411,413,414] It was concluded from these studies and others[415] that because opioid receptor antagonists did not block these responses, they were not mediated by opioid receptors.

Opioid-receptor agonists and antagonists block ion channels that constitute the genesis of the action potential in neurons. Voltage-gated Na^+ channels are responsible for the initiation of membrane depolarization and conduction of action potentials in electrically excitable cells, resulting in contraction of the heart or transmission of electrical impulses in nerves. K^+ channels are responsible for repolarization of the cell membrane and cessation of action potentials in excitable cells. Morphine and naloxone block the propagation of action potentials in many nerve and cardiac muscle preparations by directly inhibiting voltage-dependent Na^+ and K^+ currents.

In addition to the opioid receptor–independent actions of U-50,488H and related κ-opioid agonists on BP and HR (ie, actions not blocked by opioid-receptor antagonists), these drugs produce changes in the electrocardiogram indicative of a drug interaction with cardiac ion channels.[410,416] Table 10.5 summarizes the action of several κ-opioid agonists and their actions on BP, HR, and the PR, QRS, RSh, and QT intervals on rat electrocardiograms. The electrocardiographic changes, including PR interval prolongation, QRS widening, and increased amplitude of the RSh, are indicative of cardiac Na^+ channel blockade. Widening of the QT interval, an index of cardiac repolarization, suggests K^+ channel blockade.

The results of studies of opioid drugs such as sufentanil[395] and morphine[417] corroborate the suggestion of interaction of κ-opioids with cardiac K^+ channels. However, the opioid receptor–independent nature of the ion channel blockade may not be isolated to Na^+ and K^+ channels and may include L-type Ca^+ channels found in cardiac muscle. The use of Ca^{2+} fluorescent techniques for measurement of cardiac myocyte contractility suggested that the negative inotropic actions of κ-opioid agonists also may result from inhibition of L-type Ca^{2+} currents.[418,419] While investigating the possible cardiotoxic effects produced by opioids in human poisoning, Wu and colleagues[420] found that opioids such as meperidine and dextropropoxyphene exert negative inotropic actions in cardiac muscle by blockade of Ca^{2+} currents in myocytes in the presence of naloxone.

Ischemic Preconditioning

Myocardial IPC is a phenomenon that occurs in cardiac muscle in which brief periods of ischemia (usually <5 minutes) render the muscle tolerant to tissue damage that occurs during a subsequent period of ischemia after an interlude of perfusion[94] (Fig. 10.34). The phenomenon occurs in many species and is mediated by a well-defined intracellular cascade.[421] The intercellular mediator or IPC-induction trigger appears to be diverse and involves opioids and other substances.

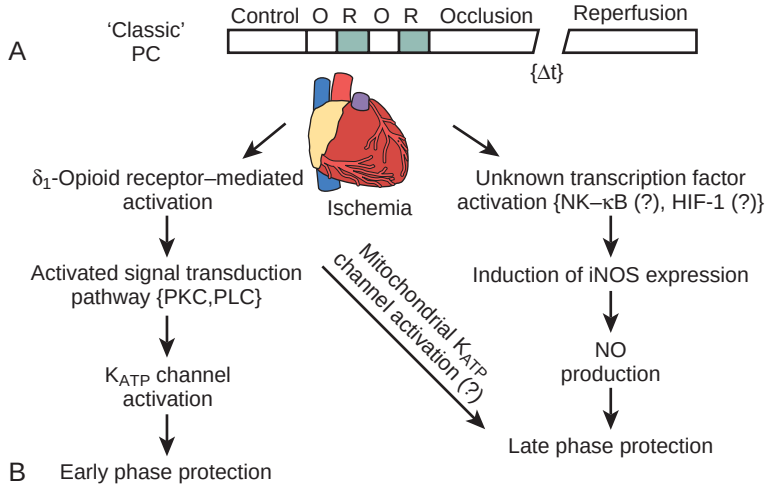

Fig. 10.34 (A) Typical protocol bar that may be used in experiments that investigate the effects of agents on ischemic preconditioning *(PC)* in the heart. Similar protocols have been used to study opioid receptor–mediated cardioprotective mechanisms in the rat and other mammalian species. Studies may investigate the effects of ischemic PC on ischemia or reperfusion arrhythmias of various durations in length (Δt). Ischemic PC usually involves a sequence of coronary artery occlusion *(O)* followed by reperfusion *(R)* cycles. Two cycles are depicted before coronary artery occlusion followed by reperfusion. This type of protocol may be easily amenable to modification; the protocol shown is a simplified protocol bar. (B) The schematic diagram shows the molecular pathways involved in the protective effects of ischemic PC in the heart. Brief periods of ischemia provide an early and late phase of protection to the heart from subsequent episodes of prolonged or permanent ischemia. Activation of G-protein–coupled δ_1-opioid receptors is involved in both protective phases. Activation of the δ_1-opioid receptor activates intracellular signal transduction pathways, including protein kinase C *(PKC)*, phospholipase C *(PLC)*, and related kinase pathways. Activation of these pathways results in phosphorylation of proteins such as the K^+_{ATP} channel on the myocyte cell surface and the myocyte mitochondrial cell surface. Opening of these ion channels mediates the early phase of cardioprotection that lasts 2 to 3 hours after the ischemic episode. The late phase of cardioprotection that results from the brief episodes of ischemia may be mediated by activation of oxygen-sensitive transcription factors such as nuclear factor-κB *(NF-κB)* and hypoxia-inducible factor 1 *(HIF-1)*. These factors subsequently induce the expression of inducible nitric oxide synthase *(iNOS)* and the production of nitric oxide *(NO)*, the putative mediator of the protective effect on the heart observed 24 to 48 hours after the ischemic episode. δ_1-Opioid receptor stimulation also may produce a late cardioprotective effect that may result from activation of mitochondrial K^+_{ATP} channels. *(From Murry CE, Jennings RB, Reimer KA. Preconditioning with ischemia: a delay of lethal cell injury in ischemic myocardium.* Circulation. *1986;74:1124.)*

The nature of IPC may not be consistent among the species examined despite a common end result.

In vivo studies show that IPC can reduce the size of an infarct resulting from prolonged ischemia.[422] There also is a reduction in damage to myocardial intracellular structure, a decrease in the dysfunction of the cardiac contractile machinery, and a direct reduction in arrhythmias associated with IPC.[422,423] The ability of IPC to limit myocardial damage occurs chronologically in two distinct phases. The first or early phase provides a window of protection to the heart muscle that occurs soon after IPC and declines with time during the first 3 hours of reperfusion. The late or delayed phase of IPC provides a second window of protection to heart muscle that emerges after 24 hours of reperfusion and may last up to 72 hours[424–426] (see Chapter 7).

Importance of Opioid Receptors in Early Preconditioning

The involvement of opioids in IPC resulted from recognition of their value at increasing survival time and tissue preservation before surgical transplantation and their possible role in enhancing tolerance to hypoxia.[427,428] The first evidence demonstrating a role for opioids in early IPC was published by Schultz and associates[429] in the intact, blood-perfused rat heart. The investigators demonstrated that the nonselective opioid receptor antagonist naloxone completely antagonized the ability of IPC to reduce infarct size whether administered before the IPC stimulus or after the IPC stimulus just before the index ischemia. The results suggested that endogenous opioids served as a trigger and end-effector of IPC in rat hearts (Fig. 10.35). Chien and Van Winkle[430] found similar results in the rabbit heart with the use of the active enantiomer (−)naloxone. Schulz and coworkers[431] also determined the role of endogenous opioids in mediating IPC and myocardial hibernation in pig hearts and observed that naloxone blocked IPC but not the effects of short-term hibernation. The data suggest that an opioid receptor mediates the effect of endogenous opioids to elicit IPC in the rat, rabbit, and pig.

Takashi and colleagues[432] performed a study in isolated adult rabbit cardiomyocytes to determine the EOPs responsible for the cardioprotective effect observed during and after IPC. They found that Met-enkephalin, Leu-enkephalin, and Met-enkephalin-Ang-Phe (MEAP) reduced the incidence of cell death, suggesting that the enkephalins are the most likely candidates for triggers and distal effectors of IPC in the rabbit heart. Huang and associates[433,434] studied the role of δ-opioid receptor activation in reducing myocardial infarct size in human and rat hearts. Their studies indicated that endogenous adrenergic receptor activation and downstream signaling were important mediators in attenuating infarct size.[433,434]

Cardioprotective Effects of Exogenous Opioid Agonists

In 1996, Schultz and colleagues[435] were the first to demonstrate that an opioid could attenuate ischemia-reperfusion damage in the heart.

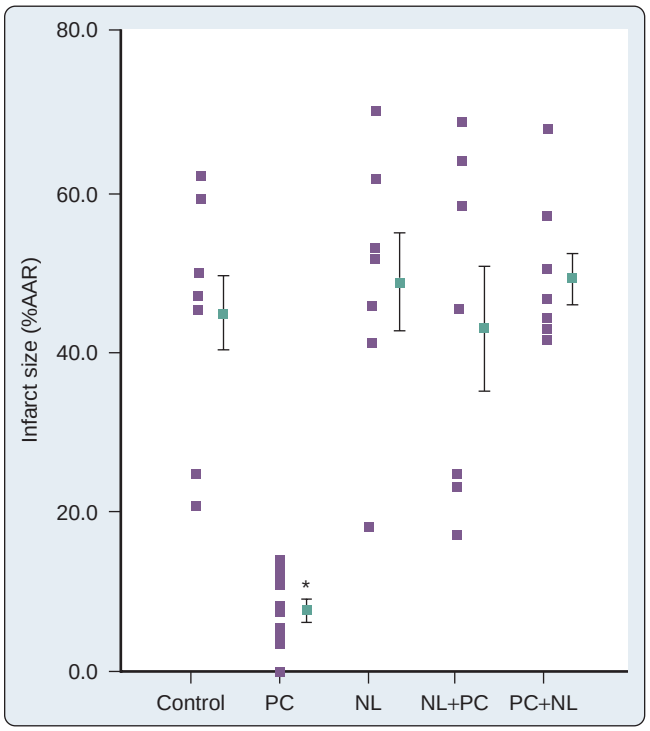

Fig. 10.35 Infarct size is expressed as a percentage of the area at risk *(AAR)* in intact rat hearts subjected to vehicle *(Control)*, ischemic preconditioning *(PC)*, naloxone *(NL)* in the absence of PC, NL treatment before PC *(NL+PC)*, and NL treatment after PC *(PC+NL)* before the index ischemic period. Green squares indicate the mean ± standard error of the mean for each group. *$P < .05$ versus the control group. *(From Schultz JJ, Rose E, Yao Z, et al. Evidence for involvement of opioid receptors in ischemic preconditioning in rat heart.* Am J Physiol. *1995;268:157.)*

Morphine at the dose of 300 µg/kg was given before left anterior descending coronary artery occlusion for 30 minutes in rats in vivo. The infarct area or area at risk was diminished from 54% to 12% by this treatment. The infarct-reducing effect of morphine has been shown in hearts in situ, isolated hearts, and cardiomyocytes.[432,436,437] Morphine also improved postischemic contractility.[438] It is now accepted that morphine provides protection against ischemia-reperfusion injury.

Gross and coworkers[439] reported a significant reduction in infarct development in rats after administration of morphine or a selective δ-opioid receptor ligand at reperfusion. The effects are mediated through glycogen synthase kinase-β and the phosphatidylinositol 3-kinase pathway.[439] There is also evidence to suggest that remifentanil, when added to a standard anesthetic regimen, may reduce myocardial damage after CABG (Fig. 10.36).[440]

Fentanyl has been studied in a limited fashion and has had mixed results as far as its ability to protect the myocardium.[438,441,442] This may be because of differences in species studied or fentanyl concentrations, or both. Pentazocine and buprenorphine improved postischemic contractility in rabbits in vitro.[438] Overall, the effects of opioids other than morphine have not been sufficiently investigated to allow conclusions to be drawn.

Schultz and colleagues[443] showed that IPC's reduction of infarct size was mediated by the δ_1-opioid receptor but not the δ_2-, µ-, or κ-opioid receptor. The effects of IPC were blunted by the selective δ_1-opioid receptor antagonist 7-benzylidenenaltrexone (BNTX) but not the δ_2-opioid receptor antagonist naltriben. They also showed that cardioprotection was not induced by the administration of the selective µ-opioid receptor agonist [D-Ala2, *N*-methyl-Phe4, Gly5-ol]enkephalin (DAMGO) and that PC was not attenuated by the µ-opioid receptor antagonist β-funaltrexamine (β-FNA).[443] In the same study, they excluded involvement of the κ-opioid receptor because a κ-selective antagonist could not reverse the effects of IPC to reduce infarct size. These data suggest that the δ_1-opioid receptor is the primary opioid receptor involved in IPC in the intact rat heart.

Although exogenous activation of the δ-opioid receptor subtype by highly specific agonists before ischemia reduces infarct size in several species, including rats,[443] rabbits,[444] and swine,[445] the role of κ-opioid receptors in preconditioning has been a subject of much controversy. Cao and associates[446,447] found that the cardioprotective effects caused by κ-opioid receptor stimulation were abolished with a calcium-activated potassium channel (K_{Ca}) blocker. This is consistent with reports that the protective effects of the κ-opioid receptor are mediated through a K_{Ca} channel pathway as seen in IPC.[446,447]

Preischemic administration of selective κ-opioid receptor agonists can reduce infarct size and ischemia-induced arrhythmias in the isolated rat heart. Conversely, specific activation of the κ-opioid receptor before ischemia can increase infarct size[427] and arrhythmias[448] and induce an antipreconditioning-like state in rats. It has been proposed that the κ-opioid receptor agonists exert a biphasic effect on the myocardium, producing proarrhythmic and antiarrhythmic effects in the rat.[393] It is unclear whether selective or nonselective activation of the κ-opioid receptor subtype is beneficial during preconditioning, and although conflicting information exists for the rat, the role of opioid receptor subtypes in IPC and pharmacologic preconditioning in other species is even more limited. Further studies are needed to address the role of the κ-opioid receptor in arrhythmias.

Signaling Pathways Involved in Opioid-Induced Cardioprotection

Opioid-induced cardioprotection and IPC appear to share a common pathway. The δ-opioid receptor and the mitochondrial K^+_{ATP} channel appear to be involved in the beneficial effects observed. Additional studies show that the cardioprotective effect of IPC and δ_1-opioid receptor activation are mediated through a G_i-protein–coupled receptor and may involve NO.[443,449,450] G-protein–coupled receptors have an established role in the attenuation of ischemia-reperfusion injury, mainly by activation of κ- and δ-opioid receptors.[451,452] The mechanisms underlying this effect include apoptotic pathways and restriction of internucleosomal DNA fragmentation.[453]

While investigating signaling pathways involved in opioid-induced protection, it was observed that morphine produced a cardioprotective effect in isolated rabbit hearts that was blocked by pretreatment with a nonselective PKC inhibitor. Jang and coworkers[449] demonstrated the activation of δ-opioid receptors and their role in postconditioning. This effect occurs by modulation of the MPTP and signaling through an NO- and PKC-mediated pathway (Fig. 10.37). The beneficial effects were eliminated by a G_i-protein inhibitor, a PKC inhibitor,[437,441,454,455] and a selective mitochondrial K^+_{ATP} channel blocker.[436,441,454,456,457] Studies also have demonstrated the role of inducible nitric oxide synthase (iNOS) as an upstream mediator of cyclooxygenase 2 (COX2). In iNOS gene *(NOS2)* knockout mice, morphine-mediated cardioprotection is attenuated, and some reports suggest iNOS and COX2 are required only during the mediation phase and not in the trigger phase.[458,459] Fig. 10.38 is a schematic summary of the major pathways involved in acute opioid-induced cardioprotection.

Role of Opioids in Delayed Preconditioning

It appears that opioid receptors are involved in delayed cardioprotection through activation of the δ- and κ-opioid receptors. Fryer and colleagues[460] demonstrated that TAN-67, a δ_1-opioid agonist, also induced cardioprotection during the second window of IPC. They found no protective effect to reduce infarct size 12 hours after administration of the selective δ_1-opioid receptor agonist, but it produced a marked cardioprotective effect at 24 to 48 hours after drug administration, which disappeared at 72 hours (Fig. 10.39). The cardioprotective effects were blocked by pretreatment with a selective δ_1-opioid receptor antagonist, a nonselective K^+_{ATP} channel antagonist, and a mitochondrial-selective K^+_{ATP} channel blocker. These results suggest that δ_1-opioid receptor

activation 24 to 48 hours before an ischemic insult results in a delayed cardioprotective effect that appears to be mediated by the mitochondrial K^+_{ATP} channel.

Wu and colleagues[461] demonstrated that κ-opioid receptor–induced cardioprotection occurred in two phases. The first window occurred about 1 hour after receptor activation, and the second developed 16 to 20 hours after administration in isolated ventricular myocytes.

Opioids and Cardioprotection in Humans

Although the animal and cell work reviewed imply a cardioprotective effect by opioid receptor activation, it is important to demonstrate that a similar system exists in humans and whether the studies can be extrapolated to the clinical world. Tomai and associates[462] demonstrated that naloxone abolished the reduction in ST-segment elevation normally observed during a second balloon inflation during coronary angioplasty. In naloxone-treated patients, the severity of cardiac pain and time to onset at the end of the second balloon inflation were similar to those of the first inflation, whereas in the placebo-treated patients, the severity of cardiac pain during the second inflation was reduced, and the time to onset of pain was lengthened compared with the first inflation. The findings suggest a preconditioning-like effect in humans undergoing coronary angioplasty that may be attenuated by the opioid antagonist naloxone.

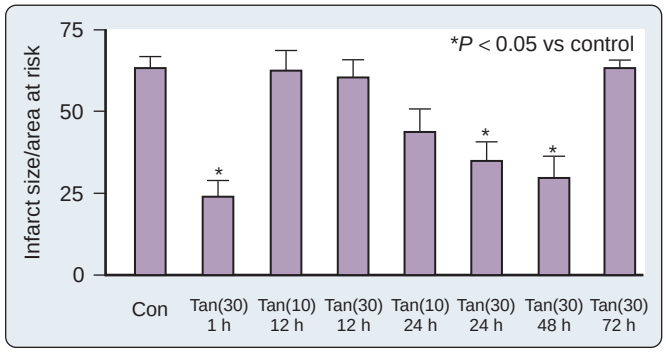

Fig. 10.39 Infarct size is expressed as a percentage of the area at risk in rats administered 10 or 30 mg/kg of TAN-67 1, 12, 24, 48, or 72 hours before 30 minutes of ischemia and 2 hours of reperfusion. A 1-hour pretreatment with TAN-67 produced a significant reduction in infarct size or area at risk. Pretreatment with both doses of TAN-67 12 hours before ischemia and reperfusion or low-dose TAN-67 24 hours before ischemia and reperfusion had no significant effect on infarct size or area at risk. However, pretreatment with the large dose of TAN-67 24 to 48 hours before ischemia and reperfusion significantly reduced the infarct size or area at risk. This cardioprotective effect was lost after 72 hours of pretreatment. All values are the mean ± standard error of the mean. *(From Fryer RM, Hsu AK, Ells JT, et al. Opioid-induced second window of cardioprotection. Potential role of mitochondrial KATP channels.* Circ Res. *1999;84:846.)*

Xenopoulos and coworkers[463] similarly showed that intracoronary morphine (15 μg/kg) mimics IPC as assessed by changes in ST-segment shifts in humans undergoing percutaneous transluminal coronary angioplasty. Bell and colleagues[456] demonstrated that δ-opioid receptor stimulation mimics IPC in human atrial trabeculae by K^+_{ATP} channel activation. These results are encouraging and suggest a possible clinical use for opioids in the therapy of acute or chronic myocardial ischemia.[456]

Cardioplegia and hypothermia provide considerable myocardial protection against the induced ischemia of cardiac surgery. However, in certain high-risk subgroups and to some extent in all patients, current methods of cardioprotection are still suboptimal, and there continues to be poor myocardial tolerance to ischemia. Myocardial ischemia often is evidenced by perioperative ventricular dysfunction, myocardial stunning, and poor functional recovery after an ischemic episode, which may lead to a poor surgical outcome (see Chapters 36 and 38). Postsurgical myocardial ischemic changes include hypothermia, intracellular acidosis, hypoxia, depletion of energy stores, and cellular volume shifts, all of which adversely affect myocardial

contractility. Hibernating animals demonstrate cellular and molecular cardiac changes during hibernation that closely parallel those seen in hypothermic cardioplegic arrest. However, the changes are well tolerated in the myocardium of the hibernating mammals for months at a time, whereas the duration of induced ischemia tolerated surgically is limited. This process is induced by a hibernation-induction trigger molecule, which has an opioid basis.[464] Opioid peptides can induce mammalian hibernation and may provide protection against the adverse effects of hypothermic myocardial ischemia, providing potential therapeutic applications during CPB and protection of organs for heart transplantation.

Bolling and associates[465,466] showed in animal studies the δ-opioid receptor agonist [D-Ala2, D-Leu5]enkephalin (DADLE) protected hearts that were subjected to 18 hours of cold storage at 4°C or 2 hours of global ischemia in the presence of a standard cardioplegic solution. Another study[467] provided evidence that pentazocine, a δ-opioid agonist, enhanced the myocardial protection of standard cardioplegia at temperatures ranging from 0°C to 34°C. Subsequently, Kevelaitis and colleagues[468] showed that stimulation of δ-opioid receptors improved recovery of cold-stored rat hearts to a state similar to IPC. The investigators showed that opioid-induced cardioprotection was mediated through K^+_{ATP} channel activation.[468]

Although the initial success of cardiopulmonary resuscitation (CPR) is on average 39% (range, 13% to 59%), most victims die within 72 hours, primarily because of heart failure or recurrent ventricular fibrillation, or both. CPR therefore yields a functional survival rate of only 1.4% to 5%.[469–471] Myocardial function is substantially impaired after successful resuscitation from cardiac arrest, prompting investigation of the use of opioid-receptor agonists to improve functional outcome. Fang and colleagues[472] demonstrated that pharmacologic activation of δ-opioid receptors significantly reduced $M\dot{V}o_2$ during the global myocardial ischemia of cardiac arrest. A follow-up study in rats demonstrated that the nonselective δ-opioid receptor agonist pentazocine strikingly reduced the severity of postresuscitation myocardial dysfunction and increased the duration of postresuscitation survival.[472]

Opioid analgesics are used widely for the treatment of pain. Although these agents are predominantly agonists of μ-opioid receptors, crosstalk with δ-opioid receptors has been demonstrated. However, the US Food and Drug Administration has not approved these drugs for use in patients with unstable angina or who are predisposed to myocardial infarction, probably due to the limited research in humans on the importance of opioid receptors in the myocardium and the high potential for dependence, abuse, and respiratory depression. Future avenues of research should focus on the identification of orally active compounds with high affinity for δ-opioid receptors to be used as cardioprotective agents because these drugs are currently lacking.

Opioids in Cardiac Anesthesia

A technique of anesthesia for cardiac surgery involving high doses of morphine was developed in the late 1960s and early 1970s. The technique was based on the observation by Lowenstein and colleagues[473] that patients requiring mechanical ventilation after surgery for end-stage VHD tolerated large doses of morphine for sedation without discernible circulatory effects. When they attempted to administer equivalent doses of morphine as the anesthetic for patients undergoing cardiac surgery, they discovered serious disadvantages, including inadequate anesthesia (even at doses of 8 to 11 mg/kg), episodes of hypotension related to histamine release, and increased intraoperative and postoperative blood and fluid requirements. Attempts to overcome these problems by combining lower doses of morphine with a variety of supplements (eg, N_2O, halothane, diazepam) proved unsatisfactory, resulting in significant myocardial depression, with decreases in CO and hypotension.[474]

However, Murphy and coworkers[475] demonstrated that morphine resulted in better myocardial function after CABG surgery than using fentanyl. For the protective effects mediated by IPC, it appears that morphine may have some benefit over fentanyl,[475] but the use of morphine has to be weighed against the multitude of other deleterious effects during the management of cardiac surgical patients.

Because of the problems associated with the use of morphine, other opioids were investigated in an attempt to find a suitable alternative. The use of fentanyl in cardiac anesthesia was first reported by Stanley and Webster in 1978.[476] Since then, there have been extensive investigations of fentanyl, sufentanil, and alfentanil in cardiac surgery. The fentanyl group of opioids has proved to be the most reliable and effective for producing anesthesia for patients with valvular disorders and CABG (see Chapters 20 and 21).

A major advantage of fentanyl and its analogues for patients undergoing cardiac surgery is their lack of cardiovascular depression, which is important during anesthesia induction, when episodes of hypotension can be critical. Cardiovascular stability may be less evident during surgery; in particular, the period of sternotomy, pericardiectomy, and aortic root dissection may be associated with significant hypertension and tachycardia. During and after sternotomy, arterial hypertension increases in SVR and decreases in CO frequently occur.[477,478] Variability in hemodynamic responses to surgical stimulation, even with similar doses of fentanyl, probably reflects differences in the patient populations studied by different investigators. One factor is the influence of β-blocking agents. In patients anesthetized with fentanyl while undergoing CABG, 86% of those not taking β-blockers became hypertensive during sternal spread compared with only 33% of those who were taking β-blockers.[479]

The opioids may produce different degrees of hemodynamic stability during surgery. One study concluded that fentanyl and sufentanil provided similar hemodynamic stability during induction, whereas alfentanil caused hemodynamic instability and myocardial ischemia.[480] Alfentanil also may be less effective in suppressing reflex sympathetic and hemodynamic responses to stimuli than fentanyl or sufentanil.[481] In patients undergoing valvular surgery, all three opioids provided satisfactory anesthesia.[482] However, controversy still surrounds the best choice of anesthetic, at least for CABG. Two studies involving more than 2000 patients anesthetized with inhalation agents (ie, fentanyl or sufentanil) came to the conclusion that the choice of anesthetic did not significantly influence the outcome after CABG, although the type of anesthetic continues to remain a topic of controversy with respect to postoperative outcomes.[121–123,483,484]

The degree of myocardial impairment influences the response. Critically ill patients or patients with significant myocardial dysfunction appear to require lower doses of opioid for anesthesia. This may reflect altered pharmacokinetics in the patients. A decrease in liver blood flow resulting from decreased CO and CHF reduces plasma clearance. Patients with poor left ventricular function may develop greater plasma and brain concentrations for a given loading dose or infusion rate than patients with good left ventricular function. Patients with depressed myocardial function may lack the ability to respond to surgical stress by increasing CO in the face of progressive increases in SVR.[485]

An infusion of alfentanil (125-μg/kg bolus followed by 0.5 mg/kg per hour) has been compared with fentanyl (100 μg/kg) or sufentanil (20 μg/kg) by bolus injection as the sole anesthetic for patients undergoing valvular surgery.[482] No differences in hemodynamic effects were found in the study, and it was concluded that all three opioids could provide satisfactory anesthesia for valve replacement surgery (see Chapter 19).

Sufentanil appears to offer more stable anesthesia with less hemodynamic disturbance than fentanyl,[486] and it has been used successfully for cardiac transplantation.[487,488] In patients undergoing mitral or aortic valve surgery, sufentanil (total dose, 9.0 ± 0.4 μg/kg) resulted in less need for supplements and vasodilators than fentanyl (113 ± 11 μg/kg), but sufentanil produced more hypotension during induction.[489] Howie and associates[490] compared a fentanyl/isoflurane/propofol regimen with remifentanil/isoflurane/propofol for fast-track anesthesia. Significantly more patients in the fentanyl regimen experienced hypertension during skin incision and maximal sternal spread compared with patients in the remifentanil regimen. There was no

difference between the groups in time to extubation, discharge from the intensive care unit, electrocardiographic changes, catecholamine levels, or cardiac enzymes. The remifentanil-based anesthetic (ie, bolus followed by continuous infusion) resulted in less need for anesthetic interventions compared with the fentanyl regimen.[490]

Samuelson and colleagues[491] compared hemodynamic and stress responses in patients with CAD anesthetized with sufentanil/oxygen or enflurane/nitrous oxide and oxygen. Both techniques were satisfactory and resulted in stable hemodynamics, but considerable fine-tuning was required when enflurane was administered. The postoperative hemodynamic effects were compared in patients who received sufentanil (25 µg/kg) or fentanyl (100 µg/kg) for anesthesia for CABG.[492] Patients who received sufentanil had a more stable course, with higher CO, lower SVR, and a lower incidence of hypertension. The two groups had similar values for time to awakening, response to verbal commands, and extubation.

Collard and coworkers[493] compared the intraoperative hemodynamic profiles and recovery characteristics of propofol/alfentanil with those of fentanyl/midazolam in elective coronary artery surgery. Cardiovascular parameters and time to extubation were recorded. Throughout surgery, hemodynamic profiles were comparable between groups except after intubation, when the MAP was significantly lower in the propofol/alfentanil group. This group also required less inotropic support, and extubation was performed earlier.

Murphy and associates[494] compared the long-acting opioid methadone with fentanyl in a randomized, double-blind clinical trial and showed improved pain scores, decreased morphine requirements, and enhanced patient-perceived quality of pain management with methadone. Previous studies in rats have shown methadone to have myocardial protective effects similar to morphine.[495] With increased emphasis on patient satisfaction, more frequent use of methadone in cardiac surgery is possible.

Effects of Cardiopulmonary Bypass on Pharmacokinetics and Pharmacodynamics

The pharmacokinetics of drugs in cardiac anesthesia is well covered by Wood.[496] This section focuses on the effects of CPB on pharmacokinetics as the most relevant area for the cardiac anesthesiologist.

Institution of CPB has profound effects on the plasma concentration, distribution, and elimination of administered drugs. The major factors responsible are hemodilution and altered plasma protein binding, hypotension, hypothermia, pulsatile versus nonpulsatile flow, isolation of the lungs from the circulation, and uptake of anesthetic drugs by the bypass circuit. These changes result in altered blood concentrations, which also depend on the particular pharmacokinetics of the drug administered (Table 10.6).

TABLE 10.6 Effects of Cardiopulmonary Bypass on Drug Disposition

Pharmacokinetic Process	*Pathophysiology*	*Pharmacokinetic Sequelae*
Absorption	Hypotension and alterations in regional blood flow or perfusion	Reduced oral or intramuscular absorption
Distribution	Lung sequestration	Decreased volume of distribution
	Decreased pulmonary blood flow	Decreased pulmonary drug distribution and increased systemic drug levels
	Hypotension, altered regional blood flow	Decreased volume of distribution
	Decreased protein binding	Increased volume of distribution
	Hemodilution Dilution of binding proteins	
	Postoperative increased α_1-acid glycoprotein	Decreased volume of distribution
	Postoperative increased protein binding	Interpretation of postoperative drug levels difficult
Elimination	Decreased hepatic blood flow	Decreased drug clearance
	Hypothermia	Decreased intrinsic clearance (decreased hepatic metabolism)
	Decreased renal blood flow and hypothermia	Decreased renal function

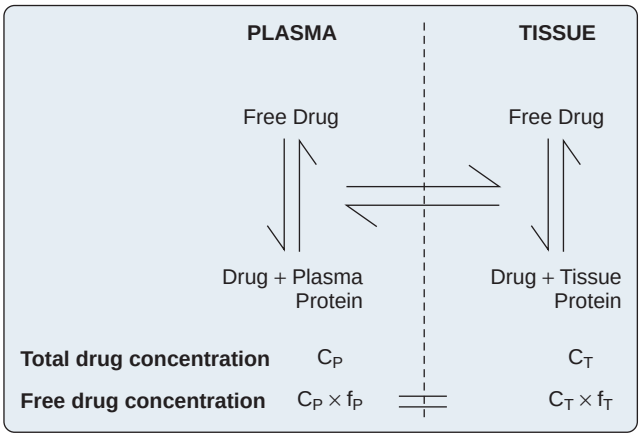

Fig. 10.40 Relationship between free drug concentration in plasma and tissue. The free concentration in plasma equals the total concentration (C_P) × the free fraction in plasma (f_P). The free concentration in tissue equals the total concentration in tissue (C_T) × the free fraction in tissue (f_t).

Hemodilution

At the onset of CPB, the circuit priming fluid is mixed with the patient's blood. In adults, the priming volume is 1.5 to 2 L, and the prime may be crystalloid or crystalloid combined with blood or colloid. The overall result is a reduction in the patient's hematocrit to approximately 25% with an increase in plasma volume of 40% to 50%. This decreases the total blood concentration of any free drug in the blood. When CPB is initiated, there is an immediate reduction in the levels of circulating proteins such as albumin and α_1-acid glycoprotein. This affects the protein binding of drugs because of alteration in the ratio of bound-to-free drug in the circulation. Introduction of retrograde autologous priming and low-volume CPB circuits has decreased these effects.

In the blood, free (ie, unbound) drug exists in equilibrium with bound (ie, bound to plasma proteins) drug. The free drug interacts with the receptor to produce the drug effect (Fig. 10.40). Drugs primarily are bound to the plasma protein albumin and α_1-acid glycoprotein. Changes in protein binding are of clinical significance only for drugs that are highly protein bound. The degree of drug-protein binding depends on the total drug concentration, the affinity of the protein for the drug, and other substances that may compete with the drug or alter the drug's binding site. If the drug has a high degree of plasma protein binding, hemodilution results in a relatively larger increase in the free fraction than for a drug with a low affinity for plasma protein binding.

The effect of heparin administration on plasma protein binding is important. Heparin results in lipoprotein lipase and hepatic lipase release, which hydrolyzes plasma triglycerides into nonesterified fatty acids. They can bind competitively to plasma proteins and result in displacement of bound drug, increasing the concentration of the unbound fraction.[496]

The consequences of acute hemodilution by the pump prime on drug disposition can be summarized as follows:

1. Because plasma drug concentration is reduced without any change in the amount of drug in the body, the apparent V_d increases acutely but by a relatively small amount.
2. After acute hemodilution, drug redistribution from tissues may occur to bring free drug concentrations in plasma and tissues back into equilibrium. The magnitude of this flux of drug depends on the relative amounts in tissues and plasma and on the degree of protein binding change.
3. Focus on total drug concentration of the free fraction and free concentration change may give misleading information on the expected change in the drug effect.
4. For drugs whose plasma and red cell partitioning is not equal, blood and plasma clearance no longer bears the same relation to each other after hemodilution and must be distinguished.
5. Heparin has an effect on the measurement of drug protein binding.

There may be marked changes in acid-base balance during CPB, resulting in changes in ionized and unionized drug concentrations, which affect drug binding. CPB may be conducted using pH-stat or alpha-stat blood gas management. The change in pH with either management scheme may affect organ blood flow.[497,498] pH management may affect the degree of ionization and protein binding of certain drugs, leading to increased or decreased free (active) drug concentrations.

Blood Flow

Hepatic, renal, cerebral, and skeletal perfusion is reduced during CPB, and the use of vasodilators and vasoconstrictor agents to regulate arterial pressure may further change regional blood flow. Alterations in regional blood flow distribution have implications for drug distribution and metabolism. The combination of hypotension, hypothermia, and nonpulsatile blood flow significantly affects distribution of the circulation, with a marked reduction in peripheral flow and relative preservation of the central circulation.[499,500]

CPB may be conducted with or without pulsatile perfusion. Nonpulsatile perfusion is associated with altered tissue perfusion.[501] Nonpulsatile flow and decreased peripheral perfusion from CPB, hypothermia, and administration of vasoconstrictors may result in cellular hypoxia and probable intracellular acidosis. This may affect the tissue distribution of drugs whose tissue binding is sensitive to pH. On reperfusion, rewarming, and reestablishment of normal cardiac (pulsatile) function, redistribution of drugs from poorly perfused tissue is likely to add to the systemic plasma concentration because basic drugs have been trapped in acidic tissue. The degree to which pulsatile perfusion altars drug pharmacokinetics is not well studied.

Hypothermia

Hypothermia commonly is used and can reduce hepatic and possibly renal enzyme function.[502] Hypothermia depresses metabolism by inhibiting enzyme function and reduces tissue perfusion by increasing blood viscosity and activation of autonomic and endocrine reflexes to produce vasoconstriction. Hepatic enzymatic activity is decreased during hypothermia, and there is marked intrahepatic redistribution of blood flow with the development of significant intrahepatic shunting. Hypothermia reduces metabolic drug clearance and has been shown to reduce the metabolism of propranolol and verapamil.

Altered renal drug excretion occurs as a result of decreased renal perfusion, glomerular filtration rate, and tubular secretion. In dogs, glomerular filtration rate is decreased by 65% at 25°C.[503]

Sequestration

When normothermia is reestablished, reperfusion of tissue may lead to washout of drug sequestered during the hypothermic CPB period, which may explain the increase in opioid plasma levels during the rewarming period.[504–506]

Many drugs bind to components of the CPB circuit, and their distribution may be affected by changes in circuit design, such as the use of oxygenators (ie, gas exchange devices) from different manufacturers. In vitro, various oxygenators bind lipophilic agents such as volatile anesthetic agents, propofol, opioids, and barbiturates[498,507–511] This phenomenon has never been demonstrated to be important in vivo, likely because any drug removed by the circuit is replaced from the much larger tissue reservoir.

During CPB, the lungs are isolated from the circulation with the pulmonary artery blood flow being interrupted. Basic drugs (eg, lidocaine, propranolol, fentanyl) that are taken up by the lungs are sequestered during CPB, and the lungs can serve as a reservoir for drug release when systemic reperfusion is established.[504] After the onset of CPB, plasma fentanyl concentrations decrease acutely and then plateau. However, when mechanical ventilation of the lungs is instituted before separation from CPB, plasma fentanyl concentrations increase. During CPB, pulmonary artery fentanyl concentrations exceed radial artery levels, but when mechanical ventilation resumes, the pulmonary artery-to-radial ratio is reversed, suggesting that fentanyl is being washed out from the lungs.

Specific Agents

Opioids

The total drug concentration of all opioids decreases on commencing CPB (Table 10.7). The degree of decrease is greater with fentanyl, because a significant proportion of the drug adheres to the surface of the CPB circuit.[408,509,512] Inadequate anesthesia has been described when fentanyl was used as the major anesthetic agent.[513] There is high first-pass uptake of fentanyl by the lungs,[500,514] and reperfusion of the lungs at the end of CPB results in increased fentanyl concentrations (Figs. 10.41 and 10.42).

Total drug concentration is decreased least with opioids that have a high V_d, when the addition of the prime volume is less important, and for drugs that can equilibrate rapidly to minimize the dilutional effect. In this respect, sufentanil, which has the most stable total drug concentrations, may offer advantages. Free alfentanil concentrations remain relatively stable throughout CPB, and the pharmacologically active concentrations remain unchanged. The bound concentration changes, reflecting concentration changes in albumin and α_1-acid glycoprotein, to which alfentanil is predominantly bound.[515–517] Elimination of fentanyl and alfentanil was prolonged by CPB, whereas that of morphine was unchanged. Data on the elimination of sufentanil after

TABLE 10.7 Effect of Cardiopulmonary Bypass on Opioid Disposition

	Concentration				
Opioid	*Start of CPB*	*During CPB*	*Clearance*	*Half-Life*	*Volume of Distribution*
Fentanyl	Decreased	Relatively stable or increased near end of CPB	—	Increased	—
Alfentanil	Decreased total alfentanil concentration; no change in free concentration	Gradual increase in total concentration near end of CPB	Unchanged	Increased	Increased
Sufentanil	Decreased	Gradual increase	—	—	—

CPB, Cardiopulmonary bypass.
Data from Buylaert WA, Herregods LL, Mortier EP, Bogaert MG. Cardiopulmonary bypass and the pharmacokinetics of drugs, *Clin Pharmacokinet.* 1989;17:10.

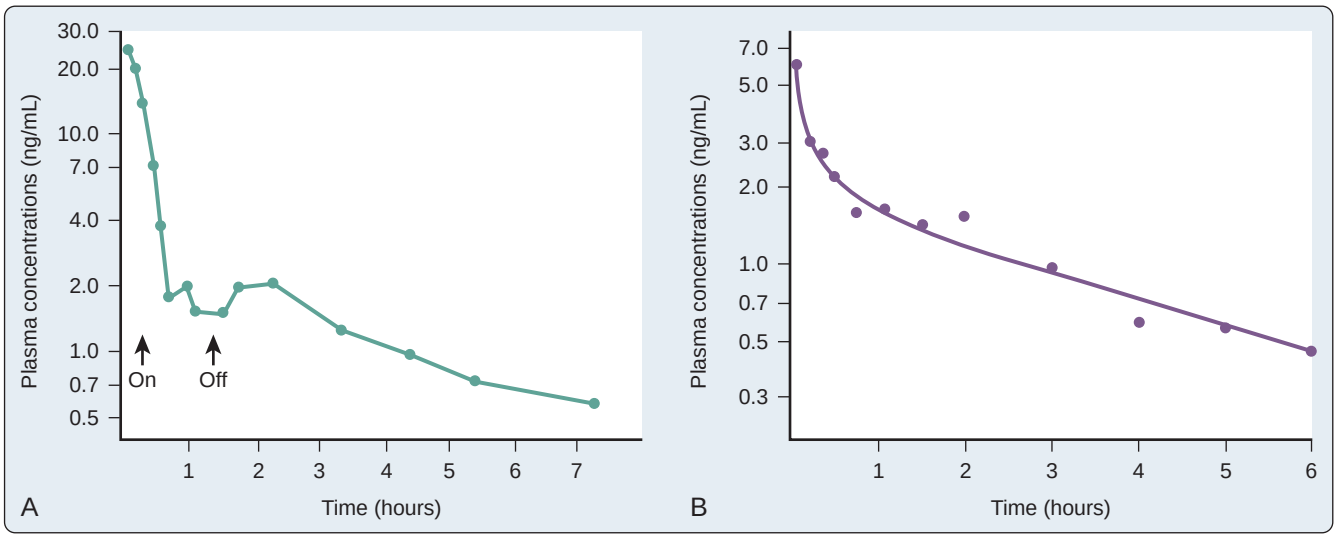

Fig. 10.41 Effect of cardiopulmonary bypass (CPB) on the disposition of a single bolus injection of fentanyl. The time course of plasma fentanyl concentrations is shown after injection of a 500-µg intravenous bolus at time zero. (A) Data from a cardiac surgery patient. Times of CPB are indicated by *arrows*. (B) Data from a vascular surgery control patient. *(From Koska AJ, Romagnole A, Karmer WG. Effect of cardiopulmonary bypass on fentanyl distribution and elimination.* Clin Pharmacol Ther. *29:100, 1981.)*

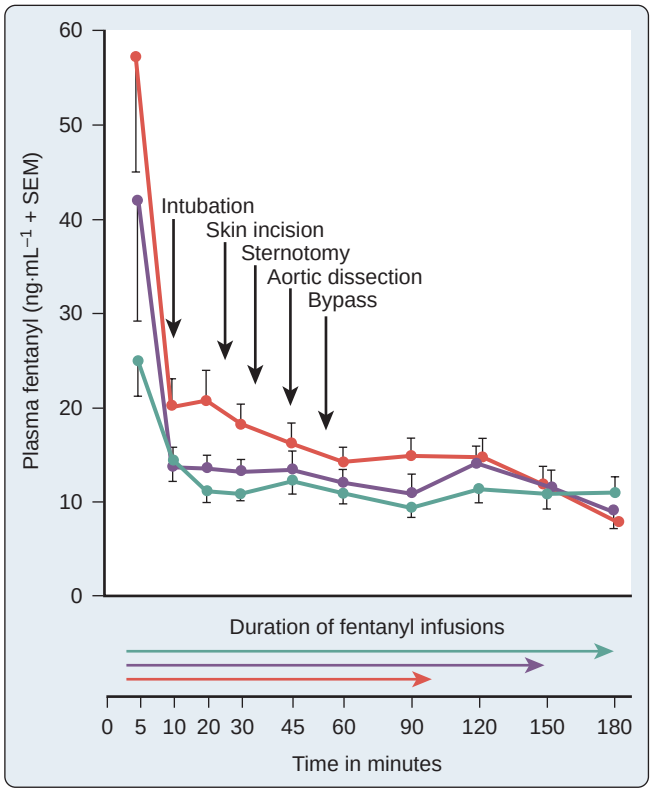

Fig. 10.42 Effect of cardiopulmonary bypass (CPB) on plasma fentanyl concentrations when fentanyl is administered at various constant-rate infusions for aortocoronary surgery. Plasma fentanyl concentrations and durations of fentanyl infusion are shown for three groups of patients: those given 30 µg/kg followed by 0.3 µg/kg per minute *(green)*; those given 40 µg/kg followed by 0.4 µg/kg/min *(purple)*; and those given 50 µg/kg followed by 0.5 µg/kg/min *(red)*. *SEM*, Standard error of the mean. *(From Sprigge JS, Wynands JE, Whalley DG, et al. Fentanyl infusion anesthesia for aortocoronary bypass surgery: plasma levels and hemodynamic response.* Anesth Analg. *1982;61:972.)*

CPB are inadequate. Based on the available pharmacokinetic information, alfentanil may be the most suitable opioid for CPB because free concentrations are stable during CPB and its half-life is much less prolonged than that of fentanyl.

Benzodiazepines

The total concentration of benzodiazepines decreases on commencing CPB. Because the drugs are more than 90% protein bound, changes in free concentrations are greatly influenced by changes in protein concentrations or factors such as acid-base balance that influence protein binding. This is particularly pertinent in the context of CPB, but no studies have commented on free versus total concentrations of benzodiazepines.

Diazepam has a very long elimination half-life, even in non-CPB patients, and it is cumulative after CPB.[518] Midazolam has a shorter elimination half-life. It increases with age and is significantly longer for CPB patients than for patients undergoing other types of major surgery (Fig. 10.43). The elimination half-life is prolonged in 6% of patients.[519,520] However, the half-life of midazolam is shorter than that of the other benzodiazepines; and in small doses, elimination is rapid in most patients. It is the suitable benzodiazepine for use by repeated boluses or infusion. The elimination half-life of lorazepam is unchanged by CPB but is longer than that of midazolam.

Intravenous Anesthetic Agents

Total drug concentrations of thiopental and methohexital decrease on commencing CPB, but the active free concentrations are remarkably stable[516,521] (Fig. 10.44). Clearance of thiopental is halved during CPB, but its elimination half-life after CPB is unknown. Elimination of methohexital remains unchanged after CPB. Conflicting results have been obtained for propofol[522,523] (Fig. 10.45). The total concentration of propofol may decrease on commencing CPB with an increase in the free fraction, or the total concentration may remain unchanged. A prolonged elimination half-life was demonstrated in one study,[522] but the redistribution half-life was short, concentrations decreased rapidly after stopping the drug, and patients made a rapid recovery. The free active concentrations of these drugs usually remain unchanged, but their actions may be prolonged.

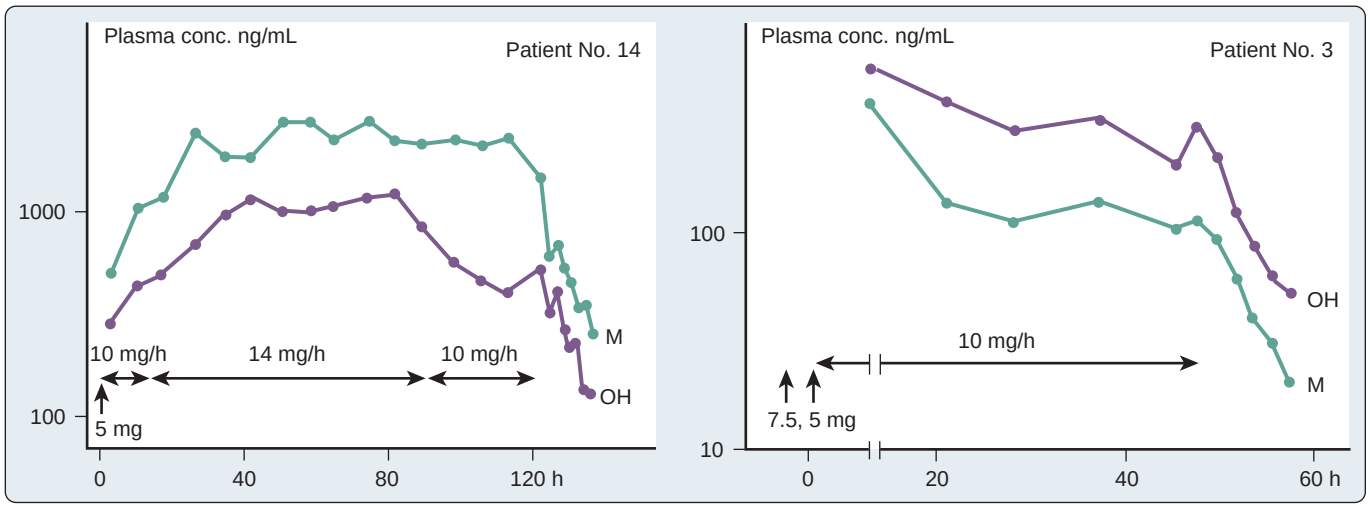

Fig. 10.43 Variations of concentrations of midazolam and its metabolite in the intensive care unit. Notice the difference in the two scales for concentration for the panels. *Left,* Concentrations of midazolam *(M)* are slightly higher than those of its metabolite *(OH). Right,* Midazolam concentrations are lower than those of the metabolite. *(From Vree TB, Shimoda M, Driessen JJ, et al. Decreased plasma albumin concentration results in increased volume of distribution and increased elimination of midazolam in intensive care patients.* Clin Pharmacol Ther. *1989;46:537.)*

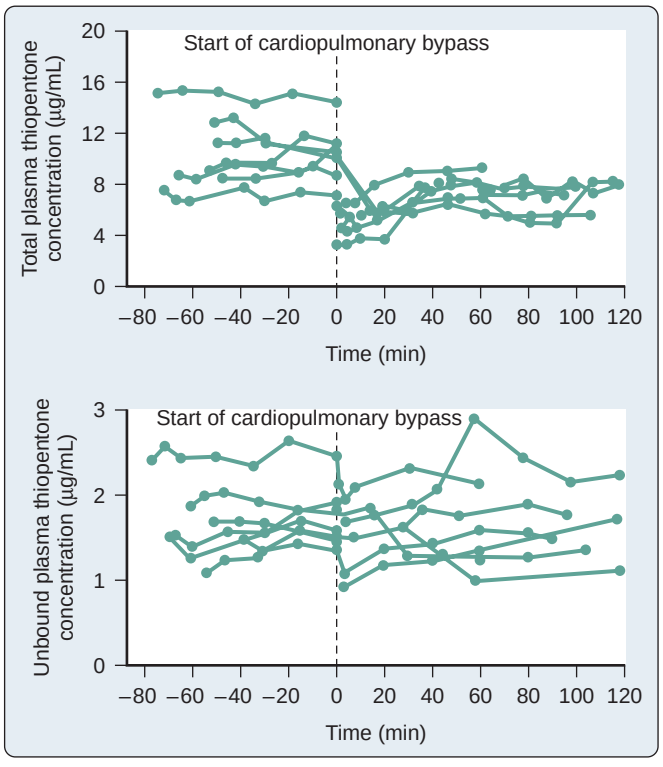

Fig. 10.44 Effect of cardiopulmonary bypass on plasma thiopental concentrations during continuous infusion. *Top,* Total plasma thiopental concentrations. *Bottom,* Unbound (free) plasma thiopental concentrations. The zero time point is considered the start of bypass. *(From Morgan DJ, Crankshaw DP, Prideaux PR, et al. Thiopentone levels during cardiopulmonary bypass: changes in plasma protein binding during continuous infusion.* Anaesthesia. *1986;41:4.)*

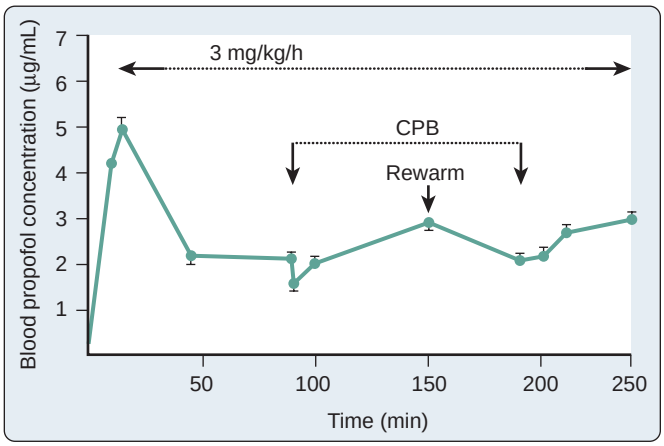

Fig. 10.45 Blood propofol concentrations during coronary artery surgery and cardiopulmonary bypass *(CPB).* A two-stage propofol infusion (10 mg/kg/h for 30 minutes followed by 3 mg/kg/h thereafter) was administered. Time scale shows the mean time taken to specific events such as the onset of CPB, induced hypothermia (25–27°C), and the end of bypass. *Bars* represent mean concentrations ± standard error of the mean. *(From Russell GN, Wright EL, Fox MA, et al. Propofol-fentanyl anaesthesia for coronary artery surgery and cardiopulmonary bypass.* Anaesthesia. *1989;44:205.)*

Volatile Anesthetic Agents

The effect of CPB on MAC remains uncertain. Some researchers have shown that CPB reduces the MAC of enflurane by as much as 30% in animal studies, whereas others have failed to demonstrate any reduction.[521–526] Several groups have shown variation in MAC with temperature and found reduced volatile concentrations were required at lower temperatures.[525,527–529]

The effect of CPB with cooling on the uptake of volatile anesthetics administered to the oxygenator depends on three factors: the blood/gas solubility of the agent and opposing effects of cooling in increasing blood/gas solubility of blood compared with hemodilution, which decreases the solubility of volatile anesthetics[530]; the increased solubility in tissue of volatile anesthetics due to hypothermia; and uptake by the oxygenator.[531] CPB produces changes in the blood/gas partition coefficient that depend on the prime used and the temperature. The coefficient is the ratio of the concentration of an inhaled anesthetic in blood to the concentration in gas that is in contact with the blood when the partial pressure in both compartments is equal.

Factors that alter the solubility of volatile anesthetics in blood and other tissues include lipid concentration, osmolarity, and hematocrit.

The changes in blood composition after the addition of a crystalloid prime tend to decrease blood solubility, favoring a more rapid attainment of steady state and a lower blood concentration of volatile agent for a given inspired concentration. However, hemodilution with a plasma prime increases solubility because volatile agents are more soluble in albumin than red blood cells.[532] Blood solubility also is inversely proportional to temperature. This relationship is linear but different for individual agents, with a range of 4% to 4.9% per 1°C decrease in body temperature.[533] Hemodilution with a crystalloid prime and hypothermia have opposite effects on the blood/gas partition coefficient. The predicted net change in solubility for isoflurane when the hematocrit is reduced from 40% to 20% and temperature is reduced from 37°C to 28°C is 2%.[534]

Volatile agents can bind to a variety of plastics,[535] which may account for some of the decrease in concentrations on commencing CPB. A volatile agent started during hypothermic CPB takes longer to equilibrate, and agents already in use need to equilibrate, potentially changing the depth of anesthesia, until equilibration is complete. Because these agents are metabolized to a small degree and washout is fast, the duration of action is not prolonged after CPB.[536,537]

Neuromuscular Blockers

CPB influences the concentrations and response relationships of neuromuscular blockers during hypothermia.[538] The requirements for neuromuscular blockade are significantly reduced as a result of several pharmacokinetic and pharmacodynamic effects. Cooling influences nerve conduction in the mobilization of acetylcholine from the nerve vesicles[539] and modifies cholinergic receptors. Cooling affects cholinesterase enzyme activity, which is temperature dependent. The most important effect of cooling is decreased mobilization of acetylcholine, which has been demonstrated in vitro and in animal models.[540,541] During hypothermia, less muscle relaxant is needed to obtain the same amount of muscle relaxation obtained in normothermic conditions. Cooling alters the mechanical properties of the muscle and has potentially significant effects on electrolytes, which modulate the contractile response.

CPB causes hemodilution, which may result in an initial decrease in the free drug concentration. The albumin concentration is also decreased during CPB, and although the total drug concentration may be decreased as a result of hemodilution, the free drug concentration may be increased if the drug is partially bound to albumin. This phenomenon may occur with neuromuscular blockers such as rocuronium.[542]

Hypothermia inhibits the hepatic clearance of steroidal neuromuscular blocking agents, although it seems to promote renal clearance. This may explain why the durations of action of steroidal neuromuscular blocking agents such as rocuronium and vecuronium, which depend on liver clearance, are more prolonged under hypothermic conditions than the durations of agents that depend on renal clearance (eg, pancuronium and pipecuronium).[543]
