from ECMO.[50] Weaning is not commenced until after cardiac rest for at least 24 to 48 hours to facilitate recovery. After successful cardiac rest and recovery, the arterial monitor should demonstrate pulsatility on low doses of an inotrope and a mean arterial pressure of at least 60 mm Hg.[51] Metabolic disturbances should be corrected, and lung function should be adequate to increase the chance of successful weaning. If cardiac function has recovered but lung function remains compromised, conversion to VV ECMO should be considered.

Pump flows are systematically decreased over a period of hours under echocardiographic and hemodynamic guidance. As circuit flows decrease in increments of 0.5 to 1 L/min, preload increases and afterload decreases, facilitating cardiac ejection. If hemodynamic parameters are met and organ and limb perfusion are satisfactory, the patient is evaluated on a 1-L/min flow for up to 1 hour before decannulation. During this low-flow period, extra heparin should be given to prevent pump thrombosis. Several parameters have been proposed and studied to predict successful ECMO weaning and decannulation,[51–53] but in our experience, serial echocardiographic assessment, a left ventricular ejection fraction of at least 20% to 25%, and a multidisciplinary approach are important to maximize successful liberation from VA EMCO support.[52,54]

Management of Venovenous ECMO

Indications for Venovenous ECMO

According to the ECLS registry (see Fig. 33.1), the most rapidly growing aspect of ECLS remains VV ECMO, spurred on by the CESAR trial results and the 2009–2010 H1N1 pandemic.[16,17] In the key data published, ECMO duration averaged 9 to 10 days, and it was initiated within the first 7 days of mechanical ventilation; mortality rates ranged from 21% to 37%.[16,17] VV ECMO is considered in patients with life-threatening but potentially reversible respiratory failure who otherwise do not have contraindications to ECLS.[55]

The Murray score played a key role in determining the need for ECMO support in the CESAR trial. The score is based on the assessed severity of respiratory failure. It uses four criteria (Table 33.2): PaO_2/FIO_2 ratio, positive end-expiratory pressure (PEEP), dynamic lung compliance, and the number of quadrants infiltrated on the chest radiograph.[29,56] In this trial, a Murray score greater than 3.0 was the

TABLE 33.2 Murray Lung Injury Score for Grading ARDS Severity

	ARDS Severity				
Parameter	*0*	*1*	*2*	*3*	*4*
Consolidation on chest radiograph (no. of quadrants)	0	1	2	3	4
PEEP (cm H_2O)	≤5	6–8	9–11	12–14	≥15
PaO_2/FIO_2	300	225–299	175–224	100–174	<100
Compliance (mL/cm H_2O)	≥80	60–79	40–59	20–39	≤19

ARDS, Acute respiratory distress syndrome; *FIO_2*, fraction of inspired oxygen; *PaO_2*, arterial partial pressure of oxygen; *PEEP*, positive end-expiratory pressure.

key criterion for patient enrollment in addition to uncompensated hypercapnia with a pH lower than 7.20.[57]

As described in the 2013 ELSO guidelines,[48] VV ECMO recommendations are based on the impending mortality risk. For patients with a 50% risk of death (ie, PaO_2/FIO_2 <150 on FIO_2 >90% and/or Murray score of 2–3), ECMO should be considered. When the anticipated risk of death approaches 80% (PaO_2/FIO_2 <100 on FIO_2 >90% and/or Murray score 3–4 despite optimal care for ≥6 hours), VV ECMO is indicated.

In addition to ARDS, the ELSO guidelines also recommend VV ECMO for severe air leak syndromes, for CO_2 retention in mechanically ventilated patients despite a high (>30 cm H_2O) plateau pressure (Pplat), and for miscellaneous patient conditions such as airway support in a patient listed for lung transplantation and a patient with acute respiratory failure unresponsive to optimal care.[58–60] The ongoing Extracorporeal Membrane Oxygenation for Severe Respiratory Distress Syndrome (EOLIA) trial uses a set of three criteria, and a patient must meet at least one:

1. PaO_2/FIO_2 ratio greater than 50 with an FIO_2 greater than 0.8 for more than 3 hours despite optimization of mechanical ventilation (MV) and despite possible recourse to the usual adjunctive therapies (eg, nitric oxide [NO], recruitment maneuvers, prone position, high-frequency oscillating [HFO] ventilation, almitrine infusion)
2. PaO_2/FIO_2 ratio greater than 80 with an FIO_2 greater than 0.8 for more than 6 hours despite optimization of MV and despite possible recourse to usual adjunctive therapies (eg, NO, recruitment maneuvers, prone position, HFO ventilation, almitrine infusion)
3. pH less than 7.25 for more than 6 hours (ie, respiratory rate increased to 35 breaths per minute) resulting from MV settings adjusted to keep Pplat less than 32 cm H_2O (ie, tidal volume reduction by steps of 1–4 mL/kg and then PEEP reduction to a minimum of 8 cm H_2O).

Table 33.3 summarizes the current ECLS options for respiratory failure.[46]

Contraindications for Venovenous ECMO

Aside from the inability to anticoagulate for ECMO, there are no absolute contraindications. Conditions that are recognized to have poor outcomes on ECMO according to the ELSO guidelines are considered to be relative contraindications and include high-pressure ventilation (end-expiratory plateau pressure >30 cm H_2O) for more than 7 days, high FIO_2 requirements (>0.8) for more than 7 days, nonrecoverable conditions such as major central nervous system (CNS) bleeding or trauma, malignancy, immunosuppression, and limited vascular access.[58]

Age and body mass index (BMI) as contraindications vary by center and country. Age greater than 65 years is considered a contraindication in some countries.[61] BMI does present practical limitations related to cannulation and maximal pump flows. Tulman and collaborators suggest that patients with BMIs greater than 35 may develop early hemolysis from flow-related issues resulting from elevated driveline pressures.[62]

TABLE 33.3 Available ECLS Strategies for Respiratory Failure

Strategy	*Principal Indications*
VV ECMO standard (femoral vein–femoral vein)	Default strategy for complete extracorporeal respiratory support
VV ECMO (dual-lumen cannula)	Complete or partial respiratory support predominantly Bridge to lung transplantation
VV ECMO high flow (SVC and IVC access)	Complete respiratory support for larger patients (eg, male >90 kg)
VV ECMO high flow with two oxygenators in parallel	Complete respiratory support for very large patients (eg, male >120 kg)
Femoral VV with pump (iLA Activve, Novalung, Hechingen, Germany)	Complete or partial respiratory support
Pulmonary artery–left atrium pumpless with oxygenator (iLA; Novalung)	Bridge to lung transplantation Salvage for refractory hypoxia during complete respiratory support on VV ECMO Salvage for severe pulmonary hypertension with normal left heart
Femoral arteriovenous pumpless (iLA, Novalung)	Partial respiratory support only if patient is hemodynamically very stable
VV ECCOR (Hemolung, Alung Technologies, Pittsburgh, PA)	Partial respiratory support

Venovenous ECMO Cannulation Strategies

VV ECMO cannula configuration should maximize flow and minimize recirculation. As Sidebotham and colleagues[63] emphasize, the former can be maximized by placement of a long, multiport (>50 cm), 23- to 29-Fr drainage cannula in the inferior vena cava (IVC) and the latter minimized by returning oxygenated blood directly to the RA and directed flow through the tricuspid valve (away from the IVC, as demonstrated in Fig. 33.8).

Standard ECMO cannula design uses wire-reinforced polyurethane (ie, resistant to kinking or collapse), and kits include guidewires (>2 m) to facilitate the Seldinger technique. Commonly used cannulas include the HLS (Maquet Cardiovascular) and Avalon Elite (Avalon Laboratories, Rancho Dominquez, CA). Cannulation is described elsewhere, but a few key principles are summarized here. There are three commonly used VV ECMO cannulation options (Fig. 33.9):

1. Femorofemoral option: Venous drainage is achieved by a femorally introduced cannula. The cannula tip is placed 5 to 10 cm below the IVC-RA junction. Return occurs through a long (>50 cm) cannula inserted into the contralateral femoral vein and advanced until its tip lies in the RA directed toward the tricuspid valve (see Fig. 33.9B).
2. Femoroatrial option: Venous drainage is achieved through a femorally inserted cannula placed 5 to 10 cm below the RA-IVC junction. Oxygenated blood is typically returned through a 20-cm long, 17- to 19-Fr cannula placed in the right internal jugular vein (RIJV) at the SVC-RA junction (see Fig. 33.9A). In a modification of this technique (ie, atriofemoral cannulation), the drainage cannula is placed in the RA through the RIJV with oxygenated blood returned though the femoral vein, and the cannula is advanced to mid-IVC. This technique produces more recirculation than femoroatrial ECMO and is not recommended.[63,64]
3. Single cannula option: Advances in cannula design led to the creation of dual-lumen, 27- and 31-Fr catheters (Avalon Elite, Bi-caval Dual Lumen Catheters, Avalon Laboratories) for exclusive RIJV placement. The cannula is advanced until the tip lies in the mid-IVC, just distal to the hepatic vein (Fig. 33.10; see Fig. 33.9C). Drainage occurs from the SVC and IVC. The return lumen opens 10 cm from the tip of the cannula and is designed to return blood back to the RA.[64] Imaging during insertion is commonly assisted by transesophageal echocardiography (TEE) and fluoroscopy. Positioning is critically important; if the distal tip or the return jets (directed toward the tricuspid valve) are not accurately placed, low flows and significant recirculation can occur. Advantages of this cannula include technical simplicity with one catheter, low rates of recirculation if appropriately positioned, easier use of prone positioning, easier aeromedical transport, and the ability to mobilize and ambulate patients with long durations of ECLS (ie, walking or awake ECMO) (discussed later). Initial experience is encouraging, but longer-term experience is needed.[65] Tulman and associates described disadvantages with this technique that include a limited range of catheter sizes, the need for expert TEE or fluoroscopic

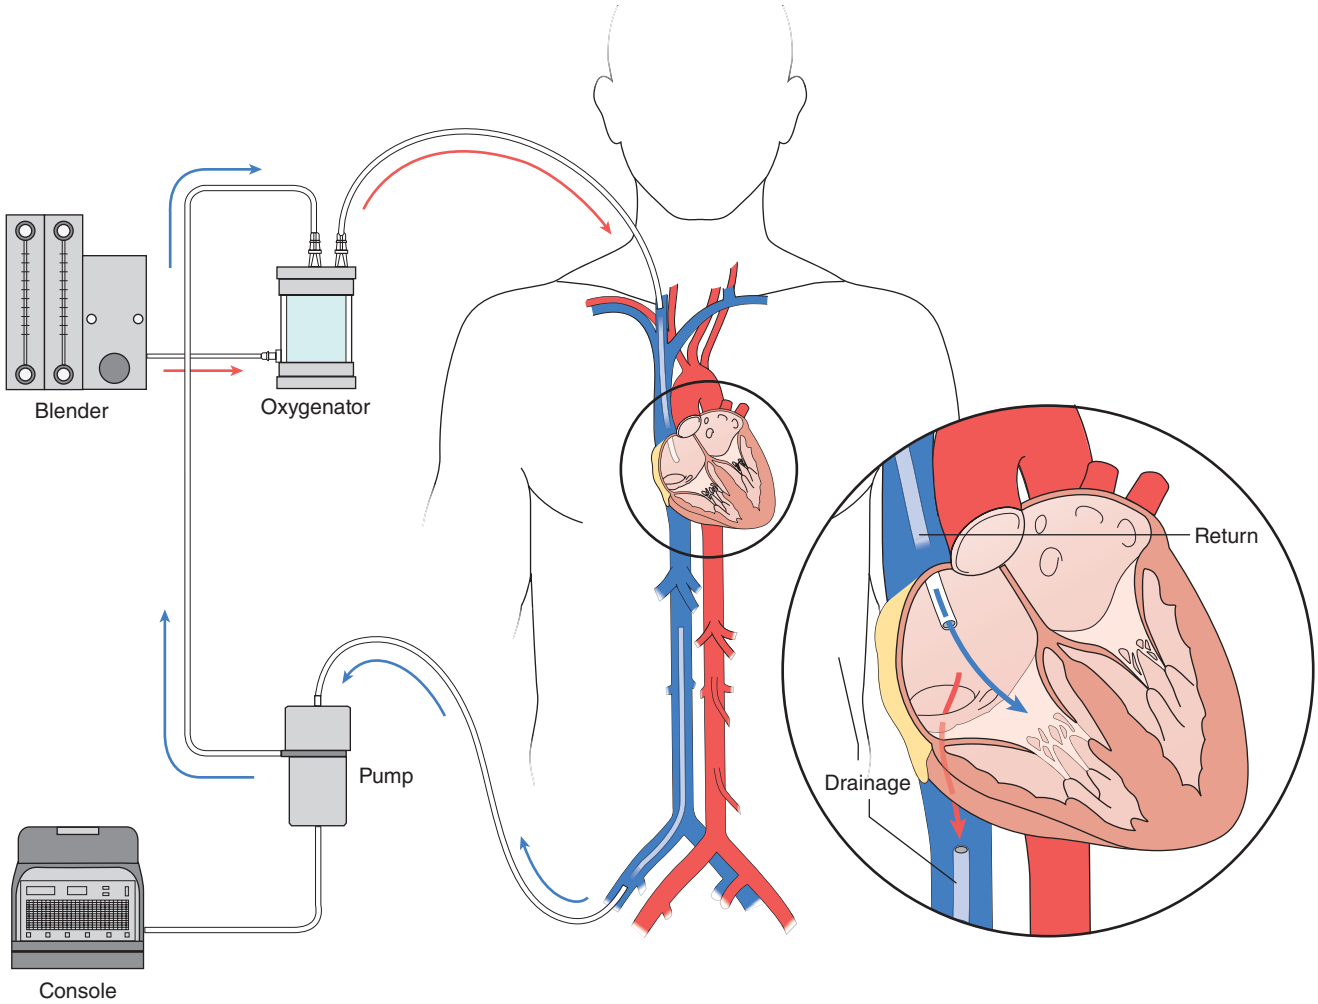

Fig. 33.8 Peripheral bicaval cannulation veno-venous ECMO standard cannulation and circuit.

guidance during insertion, relative instability of the catheter in the neck, and the potential for cerebral venous congestion with malposition.[62]

Care of Patients on Venovenous ECMO

The standard of care requires intravenous administration of 5000 U of heparin when the guidewires are in place during percutaneous insertion, and the dose should be titrated to an activated coagulation time (ACT) greater than 160 seconds. Most patients requiring ECMO are intubated, deeply sedated, and mechanically ventilated at this point, but they may require additional neuromuscular blockade and opiates. Sidebotham and coworkers[63] suggest that awake VV ECMO may be indicated in two situations: acute airway compromise needing emergent ECMO and acute cardiogenic shock needing VA ECMO because anesthesia induction may precipitate cardiac arrest. Compared with VA ECMO, VV ECMO has a lower risk of arterial injury and lower extremity ischemia.

Initial Venovenous ECMO Management

After cannulation has been performed along with heparinization, ECMO is commenced by unclamping the circuit and slowly increasing flows to the target range. For VV ECMO, key parameters used to determine pump flows are Sa_{O_2} and Sd_{O_2} (ie, oxygen saturation of blood in the VV ECMO drainage cannula).[66] The European Consensus Conference data suggest that for ideal oxygenation in VV ECMO, the pump blood flow should be 60% or greater of the calculated cardiac output (CO), with an arterial saturation goal of 88% or greater and a sweep gas rate that produces a Pa_{CO_2} between 30 and 40 mm Hg.[58] The 2013 ELSO guidelines for VV ECMO also recommended a sweep gas flow titrated to maintain Pa_{CO_2} at 40 mm Hg.[49] Unlike VA ECMO, VV ECMO does not provide added hemodynamic support. The need for pressors, inotropes, vasodilators, and volume replacement does not change.

Ventilator settings for VV ECMO can vary based on clinical pathophysiology. Current ELSO guidelines recommend rest settings, with F_{IO_2} as low as possible (<40%) and the avoidance of plateau pressures greater than 25 mm Hg.[48] Typical rest settings consist of pressure-controlled ventilation with low respiratory rates, very low tidal volumes, low F_{IO_2}, peak inspiratory pressure no higher than 25 cm H_2O, and PEEP of 10 to 15 cm H_2O.

A progressive, tapered sedation plan should be instituted for all VV ECMO patients with moderate to heavy sedation for the first 24 hours. The goal is minimal to no sedation to accompany a plan to extubate or perform tracheotomy within 3 to 5 days of VV ECMO commencement.[58] Most ECMO centers have protocols for management of temperature, blood volume, and nutrition; infection prevention; patient positioning; and management of bleeding. For VV ECMO patients with the primary goal of CO_2 removal (eg, status asthmaticus, chronic obstructive pulmonary disease [COPD] exacerbation), the goal should be a gradual reduction in blood CO_2 to avoid acid-base and neurologic complications. Recommendations from ELSO suggest an arterial P_{CO_2} reduction rate of 20 mm Hg/hour.

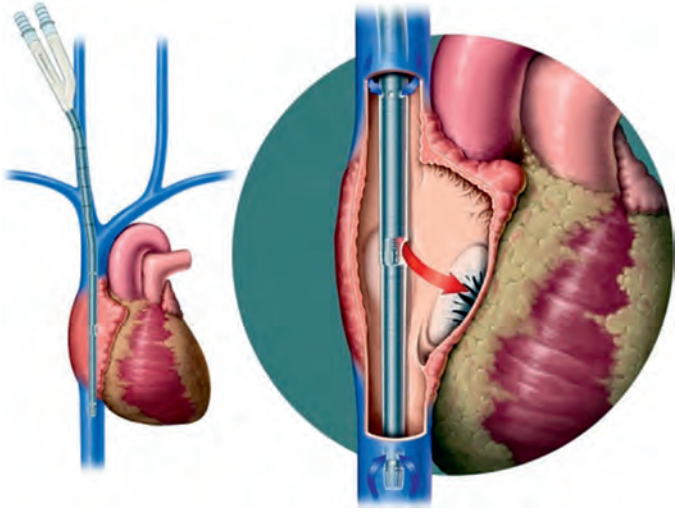

Fig. 33.10 Single-cannula, dual-lumen venovenous ECMO.

Analogous to CPB, ECMO creates significant alterations in drug pharmacokinetics that require dose adjustments, particularly in the ICU setting. With additional multisystem organ dysfunction, systemic inflammatory response, hemodilution from the circuit, and acute renal failure that is associated with critically ill patients, drug responses can be difficult to predict, and possibilities range from drug toxicity to lack of effect.[67] The increased volumes of distribution, decreased drug elimination, and sequestration of drugs in the ECMO circuit contribute to altered pharmacokinetics.

Most of the relevant data are found in the neonatal and pediatric literature.[68,69] Lipophilic agents (eg, fentanyl) and highly protein-bound drugs tend to be significantly sequestered in the ECMO circuit, whereas hydrophilic agents (eg, morphine) tend to be affected by hemodilution. Circuit priming with crystalloid-, colloid-, and blood-containing solutions contribute to the hemodilution and affect hydrophilic agents more than lipophilic agents. Other factors that are associated with critical illness (eg, pH alterations) affect drug protein binding, distribution, and elimination and alterations in the renin-angiotensin system.[70,71]

Data suggest that ECMO circuit design makes a difference in drug sequestration, with older circuits generating more drug losses.[72] Wildschut and colleagues, using neonatal and pediatric circuits, compared roller pumps with centrifugal pumps and two types of oxygenators (ie, silicone membrane and hollow fiber). They demonstrated significantly more drug losses with roller pumps equipped with membrane oxygenators compared with the newer centrifugal pumps with polypropylene hollow-fiber oxygenators.[73]

Weaning From Venovenous ECMO

Weaning from ECMO is a complex process. The question of when a VV ECMO patient should be weaned should be posed daily with each clinical assessment. For most patients, recovery can take 1 to 3 weeks. Possibilities for recovery or discontinuation due to futility should be explained to the family before ECMO institution. Patients should be carefully watched for signs of potential irreversibility, such as fluid overload refractory to aggressive diuresis and progressively worsening pulmonary hypertension (PH). Sidebotham and colaborators[63] suggested that right ventricular failure in conjunction with a mean pulmonary artery pressure that is more than two-thirds of systemic pressure usually indicates irreversibility.

The decision to discontinue VV ECMO for futility should be considered if there is no hope of organ recovery or replacement, particularly in the setting of irreversible and permanent brain, heart, lung, and other organ failure. VV ECMO patients with improving chest radiographs, improving lung compliance, reduced airway resistance, reduced extravascular lung fluid, and improving oxygen saturations (with lower circuit flows) in conjunction with reduced SvO_2 suggest a potential for weaning. According to ELSO guidelines, after the native lung is supporting 50% to 80% of gas exchange, ECMO weaning can be actively considered. In terms of improved gas exchange, most centers contemplate weaning from VV ECMO when $PaCO_2$ and PaO_2 are acceptable on moderate ventilator support (ie, FIO_2 of 50% or less, PEEP of 10 cm H_2O, peak inspired pressures of 25 to 30 cm H_2O, and ventilatory rate of 10 to 16 breaths per minute). In practice, circuit flows are dropped to 1 to 2 L/min, and the flow of sweep gas is stopped.

VV ECMO weaning durations are not established. Weaning trials can be 1 to 6 hours or longer. Key monitoring issues include hemodynamic stability (ie, standard parameters, including TEE to monitor cardiac function with or without inotropes and vasopressors), serial arterial blood gas measurements, and assessment of respiratory mechanics, particularly if the patient is on spontaneous assisted ventilation. If the patient meets all criteria, circuit flows are reduced to zero, the cannulas are clamped, and decannulation takes place.

Expanded Indications for Venovenous ECMO

The resurgence of VV ECMO can be largely attributed to its success in the management of H1N1-induced respiratory failure. The rapid advances in circuit and oxygenator technology ensure a far greater use of ECLS in the future. With smaller cannulas and more efficient, portable circuits, the opportunities to use VV ECMO for rapid CO_2 removal will continue to increase.

ECMO in Thoracic Surgery

Depending on the surgical indications, cannulation options, and patient pathophysiology, ECMO can be a versatile tool for providing complete cardiopulmonary support (ie, VA ECMO) or respiratory support alone (ie, VV ECMO). VV ECMO is preferred for adults with respiratory failure with little or no cardiac decompensation. Congenital diaphragmatic hernia is a typical, life-threatening condition that has a well-documented association with ECMO use. Data attesting to its successful use exists in the pediatric literature. Studies have shown that ECMO use in these patients, regardless of timing, improves survival compared with no ECLS.[74,75] In a 2009 outcome analysis of neonates with congenital diaphragmatic hernia treated with VV ECMO and VA ECMO, Guner and associates found both techniques comparable, but VV ECMO had the added benefit of carotid artery preservation in neonates.[76]

The use of ECMO in the trauma setting is increasing; particularly for cases of penetrating chest trauma with transfusion-associated acute lung injury and posttraumatic ARDS, for which VV ECMO has been lifesaving.[77] Mediastinal masses with the associated high risk of airway compression and collapse are well-established indications for elective or emergent VV ECMO, which can be instituted in awake and upright patients.[78] Pulmonary thromboendarterectomy, a high-risk procedure for the surgical management of recurrent pulmonary emboli, has benefitted from the use of VV ECMO and VA ECMO preoperatively and as a bridge[79] and postoperative ECLS (see Chapter 26).[80]

There is growing interest in the use of ECMO for airway surgery, particularly in situations with a high risk of airway collapse. Published case reports indicate successful use of VV ECMO with femoral cannulation for tracheal resections, bronchial repairs, tracheal papilloma resections, and tracheal injury from blunt trauma.[80–82]

VV ECMO is also used for the surgical management of severe lung infections, facilitating emergent surgery in high-risk patients. In 2010, Brenner and coworkers[83] published a successful case of thoracotomy and decortication on VV ECMO support (ie, femoral-jugular) in a critically ill young man with ventilator-associated pneumonia and a large empyema. Souilamas and colleagues reported the successful use of VV ECMO in a patient with severe bronchopulmonary aspergillosis resistant to medical treatment who had borderline pulmonary function and was not a candidate for traditional one-lung anesthesia. VV ECMO was implemented using an Avalon cannula, and uncomplicated lung resection was performed with weaning of VV ECMO support 12 hours postoperatively.[84] VV ECMO support has also been reported in the repair of large bronchopleural fistulas. Video-assisted thoracoscopic repair was performed in a postpneumonectomy patient who was not a candidate for one-lung ventilation.[85]

Because of the increasing use of ECMO, its utility for thoracic surgical procedures and associated outcomes are being reported. All procedures for ECMO patients are high risk, largely because of the possibility of coagulopathy and bleeding. Joshi and associates from the United Kingdom published the largest retrospective series, which reviewed 569 ECMO patients over a 16-year period.[86] They found that the most common primary thoracic operation was hemothorax evacuation, which was performed in 63% of patients. The most common thoracotomy indication for ECMO patients was bleeding after chest drain insertion (58%), followed by uncontrolled air leak (47%) and pleural effusion (21%). Although the overall rate of thoracotomy among ECMO patients was 3.2%, the in-hospital mortality rate was significant at 39%. The investigators concluded that experienced thoracic surgical expertise was needed in all ECMO centers.[86]

Venovenous ECMO in Accidental Hypothermia

ECMO is becoming an increasingly attractive option for rapid rewarming of patients with profound accidental hypothermia. VA ECMO is the gold standard for rapid treatment,[87] and it has improved survival rates.[88] Compared with conventional CPB, ECMO has certain key advantages. A relatively shorter setup time with the smaller portable circuits allows use outside the operating room and interhospital transport. Lower levels of systemic anticoagulation and percutaneous Seldinger-guided access contribute to its relatively greater use recently.

Although the primary technique used is VA ECMO with femoral-femoral cannulation, VV ECMO has been used in selective cases.[89] VV ECMO can also be used instead of VA ECMO for upper body hypoxemia that occurs in patients on prolonged VA ECMO. When myocardial function recovers faster than pulmonary function, the recovering heart ejects poorly oxygenated blood into the ascending aorta and proximal branches, whereas the more distal aorta is perfused by well-oxygenated blood from the VA ECMO circuit. This is best monitored by an arterial catheter and pulse oximeter in the right upper extremity to detect proximal arterial desaturation. A prompt switch to VV ECMO usually is indicated in this situation [90]

Venovenous ECMO in Pulmonary Hypertension

VA ECMO is typically used in hemodynamically unstable patients with severe PH and acute heart failure, and it has been used as a bridge to lung, heart, and heart-lung transplantation.[91–93] VV ECMO has been used successfully in the setting of acute right ventricular failure after pulmonary embolism and thromboendarterectomy[79,94] as a bridge and for postoperative support until recovery (see Chapter 26). In a 2011 study of patients with chronic thromboembolic PH that was surgically managed, Mayer and coworkers found an overall incidence of ECMO use of 3.1%, a 16.7% incidence of persistent PH after treatment, and a 9.6% incidence of reperfusion pulmonary edema.[95]

VV ECMO also has been used in acute PH crises to help unload the right ventricle. In situations with significant left-to-right intracardiac shunting, VV ECMO has been successfully used to manage acute right ventricular failure.[96] VV ECMO and atrial septostomy have been used to treat acute right ventricular failure and severe pulmonary venoocclusive disease.[97,98]

Using VV ECMO to treat acute lung failure (ie, acutely impaired gas exchange, with hypoxemia, hypercapnia, and respiratory acidosis) of any cause is becoming increasingly popular. Tsushima and colleagues suggested that the annual incidence of acute lung failure was approximately 190,000 cases per year in the United States alone.[99] The use of ECMO in these patients has dramatically increased because of advances in circuit technology (eg, portable ECMO system [Cardiohelp]) and improved interhospital transport, including the ability to safely transport critically ill patients by air.[100,101]

VV ECMO for acute lung failure has been widely used in Europe, as described by Schmid and associates for a large series of patients in Germany.[102] Over a 3-year period, 176 patients with acute lung failure refractory to conventional management were supported with VV ECMO. All patients underwent peripheral cannulation, predominantly femoral-jugular, and the Cardiohelp system was used for 20. For 59 patients, ECMO was placed at another hospital. The mean duration of VV ECMO support was 12.0 ± 9.0 days (range, 1–67 days), and 7% were extubated while on ECMO. The overall survival rate was 56%, with 33% of patients dying during mechanical support and 11% dying after weaning.

Trauma patients had the best outcomes. Sepsis and multiorgan failure were the leading causes of death. Outcomes were also better for patients who had VV ECMO placed in another facility, which was attributed to their relatively younger age and earlier ECMO support (mean, 4 vs 7 days). There was no correlation between BMI, sex, duration of mechanical ventilation before ECMO, and severity of lung injury as demonstrated by gas exchange indices (eg, hypoxia, hypercapnia) between survivors and nonsurvivors. Risk factors that did affect survival included renal failure, advanced age, and multiple organ failure. In their series, the worst outcomes were seen for patients with H1N1 pneumonia.[102]

Venovenous ECMO as a Bridge to Lung Transplantation

Lung transplantation is still the gold standard for selected end-stage lung failure patients (see Chapter 25). The past decade has witnessed a dramatic increase in the number of lung transplantations and a significant improvement in 1-year survival rates, increasing from 75% to more than 80%.[103] Although the lung allocation score, which replaced the accrued time method of lung donor distribution, has reduced the overall mortality rates of wait-listed patients for lung transplantation,[104] certain subsets of critically ill patients, such as those with resistant PH and idiopathic pulmonary fibrosis with secondary PH, have not obtained the same wait list survival benefit as others and remain at high risk for decompensation because they are not candidates for prolonged mechanical ventilation.[104,105]

Mortality rates for patients on mechanical ventilation awaiting lung transplantation remain high. Stern and coworkers reported a 90% mortality rate for patients with idiopathic pulmonary fibrosis on mechanical ventilation.[106] Prolonged mechanical ventilation can be detrimental for patients with severe emphysema needing lung transplantation; high airway pressures can lead to pneumothorax and predispose to significant air leaks. Ventilator-induced lung injury can worsen PH and predispose to ventilator-associated pneumonia, which can be fatal for subsets of patients with cystic fibrosis.[107] The use of VV ECMO in these patients remains a controversial topic due to the cost-benefit analysis.

Some recent case series have reported encouraging short- and medium-term survival rates for the bridge-to-lung transplantation group. Lang and associates[108] reviewed their single-institution data on the use of VV ECMO used as a bridge to lung transplantation for 38 patients between 1988 and 2011. In this group, 34 patients eventually underwent lung transplantation, and 4 patients died on ECMO awaiting transplantation. The 1-, 3-, and 5-year survival rates were not significantly worse than for other lung transplant recipients undergoing elective transplantation without ECMO bridging.[108]

In a retrospective review of lung transplantation candidates receiving awake ECMO support as a bridge to transplantation, Fuehner and collaborators[109] described slightly different outcomes from those found in other studies. Outcomes were compared for 26 ECMO patients and 34 controls who received conventional mechanical ventilation. The overall survival rates at 6 months after transplantation was 50% for the conventional-ventilation group and 80% for the VV ECMO group.[109]

The issue of the survival of mechanically ventilated patients who require lung transplantation also has been studied by Mason and colleagues.[110] Focusing on a group of 15,934 patients who underwent lung transplantation between 1987 and 2008, they identified 586 patients who were receiving mechanical ventilation at the time of lung transplantation and 51 who were on ECMO. The 1-year survival rate was 50% for ECMO patients, 62% for those on ventilator support, and 79% for those not requiring either. Bermudez and coworkers[111] from the University of Pittsburgh reported a 16% mortality rate for 17 VV ECMO patients who underwent transplantation.

As more centers begin to use earlier and awake ECMO strategies, more experience is needed with bridging critically ill patients because long-term data is lacking. The choice between VV ECMO and VA ECMO as a bridge is largely based on whether patients have associated hemodynamic instability or severe PH. Both factors are likely to mandate the use of VA ECMO. Multiorgan failure, sepsis, significant nutritional debility, uncontrolled bleeding, and uncontrolled infection are usually considered contraindications to VV ECMO as a bridge to transplantation.

Awake ECMO

The concept of using ECMO earlier and as a substitute for mechanical ventilation has developed significant momentum in the past decade. It has been spurred by improvements in circuit technology and development of less invasive, more user-friendly ECMO.[5,112] As Iotti and associates[112] suggest, the term *awake ECMO* indicates the use of ECMO without mechanical ventilation.

Fig. 33.11 Awake or walking ECMO.

For the lung transplantation population, awake ECMO has the advantage of avoiding the sequelae that accompany prolonged intubation and mechanical ventilation, such as muscle deconditioning and hospital acquired or ventilator associated infections.[113] It allows the patient to ambulate and exercise under supervision, which aids pretransplantation rehabilitation (Fig. 33.11).[114] As Iotti and associates suggest,[112] awake ECMO can be used early as a planned alternative to mechanical ventilation in patients such as those with cystic fibrosis or idiopathic pulmonary fibrosis, for whom the associated risks may be unacceptable, or used in patients with established or resolving respiratory failure as a means to weaning from mechanical ventilation. Most publications on awake ECMO describe lung transplantation patients[109,115,116] patients with life-threatening COPD exacerbations,[117] and as a bridge to recovery for patients with acute lung failure.[118]

VV ECMO is considered the ideal technique for nonintubated patients. It can remove CO_2 and significantly rescue the work of breathing and oxygen consumption.[119] Various cannulation options using local or general anesthesia have been described. Garcia and colleagues[120] described use of the jugular, bicaval, double-lumen, 23-Fr Avalon Elite cannula. They obtained an oxygen transfer rate of 100 mL/min at a flow of 2.5 L/min in a spontaneously breathing adult.[120]

The interventional lung assist (iLA) membrane ventilator is marketed by Novalung (Hechingen, Germany). This pumpless arteriovenous bypass approach has been used in awake patients primarily for CO_2 removal but also as a bridge to lung transplantation.[121] The low-gradient device is designed for femoral access and return and allows complete CO_2 removal in hemodynamically stable patients. Its use has been described in patients with severe asthma,[122] ARDS from H1N1 infection,[123] and a bridge to lung transplantation.[124]

For patients with severe PH, a modification of the cannulation approach (ie, pulmonary artery–left atrial approach) for ECMO has been used as a bridge to lung transplantation.[125,126] CO_2 removal of 200 to 250 mL/min has been described, but its oxygenation capacity is minimal, defining its use primarily as a means to treat severe hypercapnia, not hypoxemia.[127,128] Awake VA ECMO has also been suggested, particularly in the setting of severe PH and right ventricular failure.

BOX 33.3 VENOVENOUS ECMO COMPLICATIONS

Oxygenator failure	10.2%

Factor	*Effect*
Circuit flow rate	Lower flow rates should trigger higher levels of anticoagulation.
Platelet count	Platelet counts less than 100 may increase the risk for bleeding.
Bleeding	Active hemorrhage may require anticoagulation discontinuation.
Hypothermia	Reduced platelet function may increase the risk of bleeding.
Antiplatelet agents	Reduced platelet function may increase the risk of bleeding.
Thrombophilic conditions (eg, cancer)	May increase the levels of anticoagulation required
Heparin-induced thrombocytopenia	Require novel anticoagulants and increased risk of pump thrombosis

Mojoli and associates[129] described a small series of 16 patients in whom VA ECMO was used for primary cardiogenic shock as a bridge to recovery or to transplantation. For these patients, 29% of 3514 hours on VA ECMO were awake hours, and 4 of 16 patients were never intubated. Larger studies are needed, but experienced centers have demonstrated that awake ECMO is feasible and may reduce mortality rates for selected patients.

Ventilatory support on awake ECMO can range from simple nasal cannula oxygen to noninvasive ventilation. High-volume awake ECMO centers support the use of helmet continuous positive airway pressure (CPAP) with active humidification, which has better flow characteristics compared with mask CPAP, and it is better tolerated by awake and ambulating patients.[130]

Complications of Venovenous ECMO

ECMO is used to treat critically ill neonates, infants, and adults worldwide, with a trend toward earlier use in high-risk patients. Despite the high-risk population, overall outcomes suggest that almost 50% of patients who have received ECMO survive to discharge from the hospital.[12] Improvements in pump circuitry allow longer periods of extracorporeal circulatory support.

Complications from ECMO can be devastating, and troubleshooting circuit issues can be challenging in an unstable patient.[131] ECMO complications can arise from the circuit or be patient related (Box 33.3). Complications are discussed further in the following sections.

Anticoagulation for ECMO

Contact of the blood with the nonendothelial surfaces of the ECMO circuit activates the coagulation cascade to form clots within the circuit. The clots can disrupt the function of the membrane oxygenator, inhibit pump function, and embolize to vital organs.

Maintenance of an ECMO circuit for a prolonged period may require anticoagulants to prevent thrombosis.[132] Heparin infusion is the most commonly used anticoagulant in patients without a contraindication. Clinicians can use heparin-bonded circuits to reduce the risk of thrombus formation and lower the level of anticoagulation needed in the immediate period after circuit implementation. In addition to reducing the risk of thrombus formation, heparin-bonded circuits reduce inflammation by decreasing complement and granulocyte activation.[12,133] Newer PMP membrane oxygenators have biocompatible coatings that can reduce inflammation and thrombus formation. Patients with heparin-induced thrombocytopenia should avoid contact with heparin-bonded circuits, and the circuit should be changed to a non–heparin-bonded circuit. Direct thrombin inhibitors may be used to systemically anticoagulate patients on ECMO, but they are second-line therapy due to the difficulty in controlling bleeding.[134]

The level of anticoagulation required to prevent thrombosis depends on many factors (Table 33.4). Bleeding remains one of the most common complications associated with ECMO, which must be factored into the anticoagulation level maintained. Bleeding complications for ECMO patients include cannula site bleeding, gastrointestinal hemorrhage, surgical site bleeding, cardiac tamponade, pulmonary hemorrhage, and CNS bleeds.[131] Antithrombogenic coating has become standard in ECMO circuits. It allows patients to be maintained on low levels of anticoagulation for prolonged periods.[135] ECMO circuits tend to cause thrombocytopenia because of a combination of dilution and platelet damage.

The ACT is a simple, rapidly performed test that has been the traditional monitor for anticoagulant levels in ECMO patients (see Chapter 19).[134] In patients on high-dose heparin, the ACT is used because the activated partial thromboplastin time (aPTT) is not useful. To measure the ACT, whole blood is mixed with an activator (ie, celite or kaolin) to provide a functional test for anticoagulation. The test result is reported as the duration in seconds, with longer times reflecting higher degrees of anticoagulation. Factors that affect the ACT include coagulation factor deficiencies, hypothermia, and platelet count and function. The ACT correlates poorly with pediatric and adult heparin levels, whereas aPTT levels correlate more closely with heparin levels and are considered more desirable.

Occasionally, bleeding or thrombosis occurs that does not correlate with the level of anticoagulation measured by the ACT or aPTT. For these patients, an anti-Xa level can be used to measure heparin activity.[136] An anti-Xa level of 03 to 0.7 U/mL is considered appropriate for patients on ECMO.[137] If the heparin dose required is exceedingly high, the antithrombin III level may be below 50%, and administering plasma or recombinant antithrombin III should be considered.[134]

Complications in ECMO

Circuit-Related Complications

Circuit thrombi and blood clots can form from blood and tubing interactions. Thrombi can occur anywhere in the circuit and have devastating consequences. Constant vigilance with an appropriate plan for anticoagulation, especially in longer ECMO runs, is warranted. In the case of flow abnormalities, pump head thrombosis must be ruled out, and it can be suggested by a sudden change in the sound from the pump, hemolysis, or thrombocytopenia.[138] Evidence suggests that the most common equipment-related complication for ECMO patients is clot formation.[139,140] Immediate system exchange is warranted in these situations.

A retrospective review by Lubnow and colleagues[140] studied technical complications during VV ECMO and illustrated the need for vigilance. Using the Regensburg ECMO Registry of patients on VV

ECMO ($N = 265$), 31% of VV ECMO patients required one or more system exchanges. Life-threatening acute mechanical failure of the VV ECMO circuit occurred in 10% of patients, and acute thrombosis of the oxygenator or blood pump occurred in 35%. More than 50% of cases showed preceding, significant alterations in gas exchange, laboratory values (ie, increased D-dimers, decreased fibrinogen, decreased platelet count, lactate dehydrogenase level elevation, and an increase in plasma free hemoglobin), or increased resistance to blood flow through the circuit. Pump exchanges were urgent in 45% of cases. They concluded that most ECMO circuit system changes were predictable and could be anticipated by regular inspection of the ECMO circuit; daily monitoring of gas exchange, coagulation indices, and hemolysis parameters; and assessment of pressure drops in the ECMO circuit.

Circuit fractures can occur, and their effects depend on size and location. If they are on the venous side of the circuit, air aspiration and gas embolism can occur. Immediate replacement of the affected portion of the circuit or the entire apparatus may be indicated.

Gas embolism can be a sudden, devastating complication. It is usually caused by creation of a significant negative pressure and air entrainment in the circuit.[141] Cavitation, in which gas is forced out of the liquid medium by a circuit obstruction, can also lead to gas embolism. Treatment must be immediate, with prompt circuit shutoff and clamping, simultaneous full ventilator support, and circuit de-airing.

Patient-Related Complications

Neurologic complications in ECMO patients remain a significant cause of morbidity and mortality. For these high-risk patients, many pre-ECLS factors (eg, low CO, hypoxia, acidosis, infection) and ECLS-related factors (eg, bleeding, multisystem failure) should be considered.

About 50% of ECMO use is for neonates and pediatric patients, a group that has the highest incidence of neurologic complications. For neonates treated with VV ECMO, ELSO data indicate a 9.0% incidence of clinical seizures and a 7.4% incidence of intracranial hemorrhage. For the pediatric VV ECMO group, data show a 5.2% incidence of clinical seizures and a 6.2% incidence of intracranial hemorrhage.[142]

Although adults comprise a smaller group of ECMO patients, the data show a lower incidence of neurologic complications with VV ECMO compared with VA ECMO. According to cumulative ELSO data, adult VV ECMO patients have a 1.0% incidence of clinical seizures and a 3.8% incidence of intracranial hemorrhage. Adults on VA ECMO have a 1.7% incidence of seizures and a 2.4% incidence of intracranial hemorrhage.[142] Rollins and coworkers[143] suggested that adults were predominantly supported with VV ECMO, which has been associated with lower rates of neurologic complications. Long-term functional neurologic outcome data for adults and children need more study.

Data on outcomes from the use of ECMO for cardiac support continues to grow. VA ECMO ELSO data show survival rates of 39% for neonates, 39% for adults, and 49% for pediatric patients, with lower survival rates after cardiopulmonary resuscitation (28% for adults, 41% for children, and 39% for neonates).[142] Among cardiac patients supported by VA ECMO, adults tend to have the lowest incidence of neurologic complications compared with neonates, with a 2% incidence of seizures, 3.7% incidence of infarction, and 2% incidence of intracranial hemorrhage.[142] Long-term neurodevelopmental data from the neonatal and pediatric literature[144,145] show a 50% incidence of moderate to severe cognitive delays and a 12% to 25% incidence of neuromotor delay in long-term survivors needing VA ECMO. In this group, chromosomal abnormalities, time to lactate normalization, and high inotrope scores predict poor cognitive outcomes.[144,145]

In a 2013 metaanalysis of complications and deaths related to ECMO[146] that included 1763 adults, Zangrillo and colleagues[146] found an in-hospital mortality rate of 54% and suggested that VV ECMO was safer than VA ECMO; possibly due to the lack of arterial involvement. The most common complications in ECMO patients were renal failure requiring ultrafiltration (52%), bacterial pneumonia (33%), bleeding (33%), oxygenator dysfunction requiring replacement (29%), sepsis (26%), hemolysis (18%), liver dysfunction (16%), leg ischemia (10%), venous thrombosis (10%), central nervous complications (8%), gastrointestinal bleeding (7%), aspiration pneumonia (5%), and disseminated intravascular coagulation (5%).

Bleeding is common in ECMO patients, particularly from cannulation sites due to systemic anticoagulation. Arterial cannulation presents a higher bleeding risk compared with venous ECMO. All ECMO patients are monitored with daily indices of coagulation status such as ACT, PT, aPTT, and platelet counts and with thromboelastography as indicated, especially before an invasive procedure. Other than cannulation site bleeding, mucosal bleeding can occur from the airway to stomach, colon or rectum, and bladder with minor, repeated trauma or instrumentation. Gastrointestinal bleeding can be a source of significant morbidity.

Anemia can be an issue because the circuit is usually primed with a crystalloid solution that causes dilution of blood cells. Thrombocytopenia is common, with up to a 40% reduction from baseline in the first few hours on ECMO.[147] Platelet transfusion thresholds can vary, but ELSO guidelines recommend 80,000 as the minimum platelet count for ECLS. Heparin-induced thrombocytopenia can occur on ECMO, and in its most severe form, it can be associated with white arterial thrombi and profoundly reduced platelet counts, mandating the use of alternative agents such as argatroban.[148] Hemolysis can trigger coagulopathy and is suggested by pink urine and an elevated level of plasma-free hemoglobin.[149] The level can be raised by thrombus in the circuit and red cell trauma resulting from excessive suction from the centrifugal pump.

Summary

The reemergence of ECMO as an option for patients with severe cardiopulmonary failure has increased its availability. Trials are investigating the utility of ECMO in treating various diagnoses, but much more research needs to be performed to clarify the indications, inclusion criteria, and management paradigms of this technology.[132] As ECMO use becomes more common, centers of excellence with high volumes will emerge as the safest locations to deploy this high-risk therapy.

Blood and Fluid Management During Cardiac Surgery

COLLEEN G. KOCH, MD, MS, MBA | KEYVAN KARKOUTI, MD, FRCPC, MSc | SIMON C. BODY, MD

KEY POINTS

1. Practice guidelines are useful tools to guide patient management in the setting of wide practice variations or costly therapies.
2. Practice guidelines often are not effective in changing clinical practice for a variety of reasons.
3. Effective guidelines require effective implementation and the tools to follow the guidelines.
4. ABO and Rh blood groups are defined by the presence or absence of surface antigens on the red blood cell membrane.
5. The purpose of crossmatching is to reduce the mixing of patient and donor antigens and antibodies that elicit immune reactions.
6. Transfusion-related complications can be immune mediated (eg, graft-versus-host disease, transfusion-related acute lung injury) or nonimmune mediated (eg, infectious transmission, transfusion-associated circulatory overload).
7. Genetic variations affect circulating levels of coagulation factors and platelet numbers.
8. It is likely that genetic variation influences the risk for perioperative hemorrhage.
9. Reoperation for bleeding is associated with increased postoperative morbidity and mortality.
10. Implementation of a massive transfusion protocol and consideration of a higher fresh frozen plasma–to–red blood cell ratio may improve hemorrhage and patient outcomes.
11. Factor replacement with recombinant factor VIIa is effective for the treatment of refractory bleeding in the perioperative setting, but it may be associated with an increased risk of thrombotic complications.
12. Human fibrinogen concentrates are approved for use in patients with dysfibrinogenemias. Use in patients with low-normal levels of fibrinogen undergoing surgery is uncertain and may place the patient at risk for thrombotic complications.
13. Prothrombin complex concentrates are prepared from pooled plasma and contain four vitamin K–dependent clotting factors: II, VII, IX, and X.
14. Appropriate volume replacement to avoid tissue hypoperfusion is more important than the choice of colloid or crystalloid.
15. Despite decades of research, there are no blood substitutes approved for clinical use in the United States.
16. Anemia while on cardiopulmonary bypass has been associated with increased perioperative renal injury and patient morbidity. However, the results of observational studies are not entirely consistent, and a specific cutoff value for a safe hematocrit while on cardiopulmonary bypass has not been determined.

Appropriate perioperative blood and fluid management is critical to the care of patients undergoing cardiac surgical procedures. A conservative strategy to minimize the use of red blood cells (RBCs) and component therapy is strongly recommended. Transfusion guidelines have been developed to assist clinicians with transfusion decisions, as have clinical studies examining the use of component therapy and choice of fluid therapy for maintaining adequate intravascular volume. This chapter reviews transfusion guidelines as they apply to cardiothoracic surgical patients, examines genetic background of blood type groupings, explains immunologic and nonimmunologic-related complications associated with RBC transfusion, and explores risk factors and treatment strategies for perioperative bleeding.

Transfusion Guidelines

Rationale for Guidelines

Clinical guidelines are a ubiquitous part of medicine. They are "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances."[1] The US National Guideline Clearinghouse (http://www.guideline.gov) includes more than 2480 recently generated guidelines. Guidelines are valuable methods for reducing practice variations and errors, and they ensure efficient use of health care resources.[2] Despite the availability of well-constructed guidelines, clinicians often are reluctant to implement them in daily practice. Several studies have shown that guidelines may do little to change practice behavior.[3]

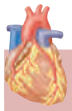
Formulation of Guidelines

Groups developing guidelines require support from a national or international society that can endorse and disseminate the guidelines. Committee members should be recognized experts in the field and be assisted by people with expertise in guideline preparation. American Heart Association guidelines are the model for well-crafted guidelines that were developed using well-conducted, peer-reviewed studies as their evidence base (Box 34.1).

Guidelines can be based on a spectrum of evidence from case reports, series without control groups, or randomized, controlled trials. The Society of Thoracic Surgeons and Society of Cardiovascular Anesthesiologists Transfusion Guidelines were published in 2007[4] and are a good example of well-crafted guidelines, but they were based on limited available evidence. There were 57 recommendations in the guidelines. Only 13 were level A evidence (ie, best level of evidence), 27 were level B (ie, limited evidence), and 17 were level C (ie, very limited evidence). Only 7 were class I recommendations (ie, benefit strongly outweighs risk), 18 were class IIa (ie, benefit outweighs risk), 23 were class IIb (ie, benefit may outweigh risk), and 10 were class III (ie, risk outweighs benefit).[5] The relatively low level of evidence for the guidelines likely is reflected by the lack of wide implementation by clinicians.

Implementation of Guidelines

To be effective, guidelines should be widely disseminated using commercial marketing tools. Anesthesia and surgical societies have been comparatively slow in adopting guidelines. Although the Society of Thoracic Surgeons and Society of Cardiovascular Anesthesiologists Transfusion guidelines were widely distributed throughout societies and to the perfusion community, many practitioners were not aware of the content of the guidelines. Several other studies have found a similar lack of awareness of other guidelines.[6,7]



BOX 34.1 REQUIREMENTS FOR SUCCESSFUL GUIDELINE DEVELOPMENT AND IMPLEMENTATION

Guideline Writing Group Formation
Support at a societal level
Perception of a need to define practice standards
Senior leadership for guideline preparation
Statistical support for examination of evidence

Guideline Preparation
Sufficient evidence base for guideline preparation
Sufficient expertise for guideline preparation
Dedicated time and effort for guideline generation
Dissemination to content and structure experts for commentary

Guideline Dissemination
Wide dissemination using an authoritative journal in the field
Wide dissemination using traditional and nontraditional mechanisms such as Web sites, conferences, and special interest groups

Guideline Conformity at the Local Institutional Level
Senior leadership within the institution
Incorporation of guidelines into the local context of clinical practice
Providing practitioners with the resources to conform to the guidelines
Providing practitioners with timely, accurate, and pertinent feedback on measured conformity with guidelines

Other factors may hinder effective implementation by practitioners, such as guidelines that are too complicated or lack rigorous scientific evidence as a basis. In other fields, such as general medicine practices, several studies have demonstrated low rates of change in response to guidelines.[8–10] In the surgical environment that relies on multispecialty teams, the entire team must understand the rationale for practice guideline implementation. However, it is equally important that guidelines remain flexible enough to permit a degree of patient-specific departures from specified prevention, diagnostic, and treatment protocols.[11]

Other key components for successful implementation of guidelines lie in senior institution leadership and endorsement[12] and practice-specific feedback about performance. Implementation of guidelines in cardiac surgery has been poor,[13,14] but focused implementation of guidelines at single institutions has been successful.[15,16] Quality improvement initiatives used in industry such as Total Quality Management and Six Sigma, which appear applicable to surgical processes, depend on collection of verifiable data on processes.[17,18] The notion that clinicians can improve cardiac surgical care and the performance of individual members of the team without proper timely feedback is not reasonable. Real-time feedback has been particularly effective.[19]

In summary, individuals involved in the management of cardiac surgical patients are obligated to provide the best possible clinical care, often by consulting guidelines. Societies have a key role in endorsement, dissemination, and use of guidelines to improve care.

Blood Groups and Transfusion

ABO Blood Groups

ABO and Rh blood groups are the most well known of more than 30 antigen-based classifications of human blood types. The ABO blood group system is based on identification of A and B antigens on RBCs, and it was originally described by Janský and Landsteiner.[20] Wide variation exists in the frequency of the ABO groups across different populations. For example, group B is the most common type among Asians but uncommon among whites.[21]

The ABO blood grouping is defined by presence or absence of surface antigens on the RBC membrane. The *ABO* gene is located on chromosome 9q34.2 and has three principal isoforms (ie, A, B, and O) that are determined by single nucleotide polymorphisms (SNPs) and single-base deletions in the *ABO* gene (Table 34.1). Four missense SNPs determine the structural and functional differences between the A and B transferases. The different transferases result from four amino acid substitutions at amino acid positions (codons) 176, 235, 266, and 268, and they usually occur together. Two SNPs (ie, L266M and G268A) change the substrate specificity of the ABO enzyme for galactose. The protein produced by the *ABO* gene is not the antigen. Instead, O, A, and B antigens are formed by the action of three glycosyltransferases (ie, isoforms) encoded by the *ABO* gene that modify a cell membrane glycoprotein (ie, H antigen).[22]

The O blood group results from a single base deletion (261delG) in exon 6 of the *ABO* gene that causes a frameshift mutation and translation of a truncated ABO protein, the O isoform. Because it has

TABLE 34.1 Genetic Profiles of the ABO Blood Groups

ABO gene exon	6	7	7	7	7
Nucleotide position	261	526	703	796	803
Common allele[a]	G	C	G	C	G
Rare allele[a]	del	G	A	A	C
Amino acid position	118	176	235	266	268
Blood group O	Deleted	Deleted	Deleted	Deleted	Deleted
Blood group A	Leucine	Arginine	Glycine	Leucine	Glycine
Blood group B	Leucine	Glycine	Serine	Methionine	Alanine

[a]Nitrogenous bases are given for the specified nucleotide positions.

no enzymatic activity, the H antigen is unmodified, and the A and B antigens are not created.[23]

In the A transferase, the amino acids are leucine (L) and glycine (G) at codons 266 and 268, respectively. The A isoform (ie, L266 and G268) encodes a glycosyltransferase (ie, A transferase) that bonds α-*N*-acetylgalactosamine to the H antigen, producing the A antigen of the ABO blood group system. Individuals who exclusively synthesize A isoforms have blood group A and have the genotype AA (ie, homozygotes with the same A allele on both chromosomes) or AO (ie, heterozygotes with an A allele only on one chromosome).[23]

In the B transferase, the amino acids are methionine (M) and alanine (A) at codons 266 and 268, respectively. The B isoform (ie, M266 and A268) encodes a glycosyltransferase (ie, B transferase) that joins α-D-galactose to the H antigen, creating the B antigen. Blood group B individuals have the genotype BB (ie, homozygotes) or BO (ie, heterozygotes). Individuals who express both A and B isoforms of the ABO gene (ie, A allele on one chromosome 9 and B allele on the other chromosome 9) are blood group AB.[23]

Other variations in the *ABO* gene can create functionally similar antigens. For example, the A(2) isoform, comprising only 20% of group A individuals, is caused by deletion of a protein-coding termination point, extending the enzyme by 21 extra amino acids and altering its specificity. These structural differences reflect the different catalytic activities of the enzymes encoded by the A(1) and A(2) alleles and result in different antigenic properties of A(1) and A(2) antigens.[24] Different molecular mechanisms may be responsible for seemingly identical ABO blood groups. For example, the B3 phenotype may be caused by a missense mutation (D291N), a splicing mutation (B303), or the combination of a missense mutation and a single nucleotide deletion (V277M and 1060delC).

ABO blood groups also can be measured by genotyping the variants in the *ABO* gene instead of measuring the presence or absence of the A and B antigens. The ABO antigens are also expressed on the surface of many other cells types, indicating the importance of ABO crossmatching of organ transplants. Several other rare variants of the ABO gene that change activity or specificity, or both, of the enzyme have been identified and generate several rare blood groups.[25]

Anti-A and anti-B antibodies (ie, isohemagglutinins) are IgM antibodies that appear in the first years of life. Early in the postnatal period, the immune system generates IgM antibodies against ABO antigens even when they are absent from the individual's RBCs. If present in the fetus, the IgM antibodies are too large to cross the placenta and are not a relevant cause of hemolytic disease of the newborn. The antibodies are thought to be produced in response to infantile exposure to influenza virus and gram-negative bacteria. Antibodies usually are not generated against the H antigen. An individual with blood group A therefore makes IgM antibodies against the B antigen. An individual with blood group B makes IgM antibodies against the A antigen. An individual with blood group AB does not make IgM antibodies against the A and B antigens. An individual with blood group O makes IgM antibodies against the A and B antigens.[23]

If an individual with blood group A receives group B RBCs, anti-B IgM isohemagglutinins in the recipient plasma bind to the B antigen on donor RBCs, generating a locus for complement-mediated lysis of transfused donor RBCs and generating a hemolytic transfusion reaction. Similar events occur in group O and B individuals receiving RBCs containing non–self-antigens. However, blood group AB individuals do not generate anti-A and anti-B antibodies, and they can receive RBCs from all groups and are universal RBC recipients.[23]

Rhesus Blood Groups

The rhesus (Rh) blood group system consists of about 50 blood group antigens, among which five antigens—D, C, c, E, and e—are the most important. The proteins that carry the Rh antigens form a transmembrane transporter complex that resembles NH_3 and CO_2 transporters of evolutionary origin.[26] The proteins are encoded by two adjacent genes on chromosome 1p36.13-p34.3: the *RHD* gene that encodes the RhD protein with the frequent D antigen and the *RHCE* gene that encodes the RhCE protein with the C, E, c, and e antigens.[27] The term *Rh factor* refers only to the D antigen that is normally present. Unlike the ABO system, the absence of the normally present D antigen is called the *d antigen,* but there is no protein corresponding to the d antigen. Lowercase *d* indicates the absence of the D antigen, often as a result of the deletion of the gene or other variants that prevent expression of the antigenic protein on RBCs.[27] To be Rh negative, the individual must have the gene absent on both chromosomes.

The frequency of Rh-negative individuals ranges from about 16% in white populations to less than 1% in Asian populations.[28] Rh incompatibility of an RhD-negative mother and RhD-positive fetus is the predominant cause of hemolytic disease of the newborn, which occurs when maternal IgG anti-RhD antibodies pass through the placenta into the fetal circulation and cause hemolysis of RhD antigen-positive fetal RBCs.[29]

Other Blood Groups

At least 30 other antigens are expressed on the RBC surface, defining the Kell-Cellano, MNS, Lewis, and other blood groups. These blood groups are capable of causing transfusion reactions, although most are less common and produce less severe transfusion reactions than ABO incompatibility. Several can produce hemolytic disease of the newborn.[29]

The Kell-Cellano antigens are variants of a transmembrane glycoprotein encoded by *ET3* on chromosome 7q33. In contrast to many other blood groups, the function of the enzyme is known, and it is responsible for producing endothelin 3, a potent bioactive peptide with many biologic roles. There are several variants of the gene, of which K_1 (Kell) and K_2 (Cellano) are the most common and result from an SNP generating a Thr193(K_2) from the more frequent Met193(K_1) isoform. Kell incompatibility is second to Rh incompatibility for generation of hemolytic disease of the newborn.[29]

The MNS antigens are variants of two genes, glycophorin A (containing the *M* and *N* alleles) and glycophorin B (containing the *S* and *s* alleles), adjacent to each other on chromosome 4q28-q31. The glycophorins are the most common sialoglycoproteins on the RBC membrane, but their function is not clear. Unlike most other blood group systems in which individual SNPs or deletions create the antigens, the MNS antigens are created by complex rearrangements of the protein structure that generate antigens.[30]

The Lewis blood group antigens are structurally similar to the ABO and the H blood group systems. The antigens are generated by variants in the fucosyl transferase gene *(FUT3)*, residing on chromosome 19p13.3; they act on the Lewis antigens in a similar fashion to the galactose transferase function of the *ABO* gene acting on the H antigen. The Lewis antigens are not synthesized in erythrocyte progenitor cells like the ABO antigens and are more likely created in the gut. The Le-a or Le-b antigens circulate in plasma bound to serum lipoproteins and are adsorbed to circulating erythrocytes, usually only after birth.[31]

Crossmatching

The use of citrate and refrigeration and a nascent understanding of blood incompatibility during World War I enabled the development of blood banking.[32] The first US hospital blood bank was created at Cook County Hospital in 1937.[32] About 16 million units of blood were transfused in the United States in 2008.[33]

Crossmatching of donor blood products to an individual recipient is a sequence of procedures performed to prevent transfusion reactions. American Association of Blood Banks' *Standards for Blood Banks and Transfusion Services* defines the procedures performed before blood is transfused to a recipient. The first laboratory component for the recipient blood specimen is a *type and screen*, which consists of two separate tests.[34] First, the recipient's ABO and RhD blood groups are determined (ie, typed) by using commercially produced anti-A and anti-B antibodies that react with the A or B antigens, if present, on the

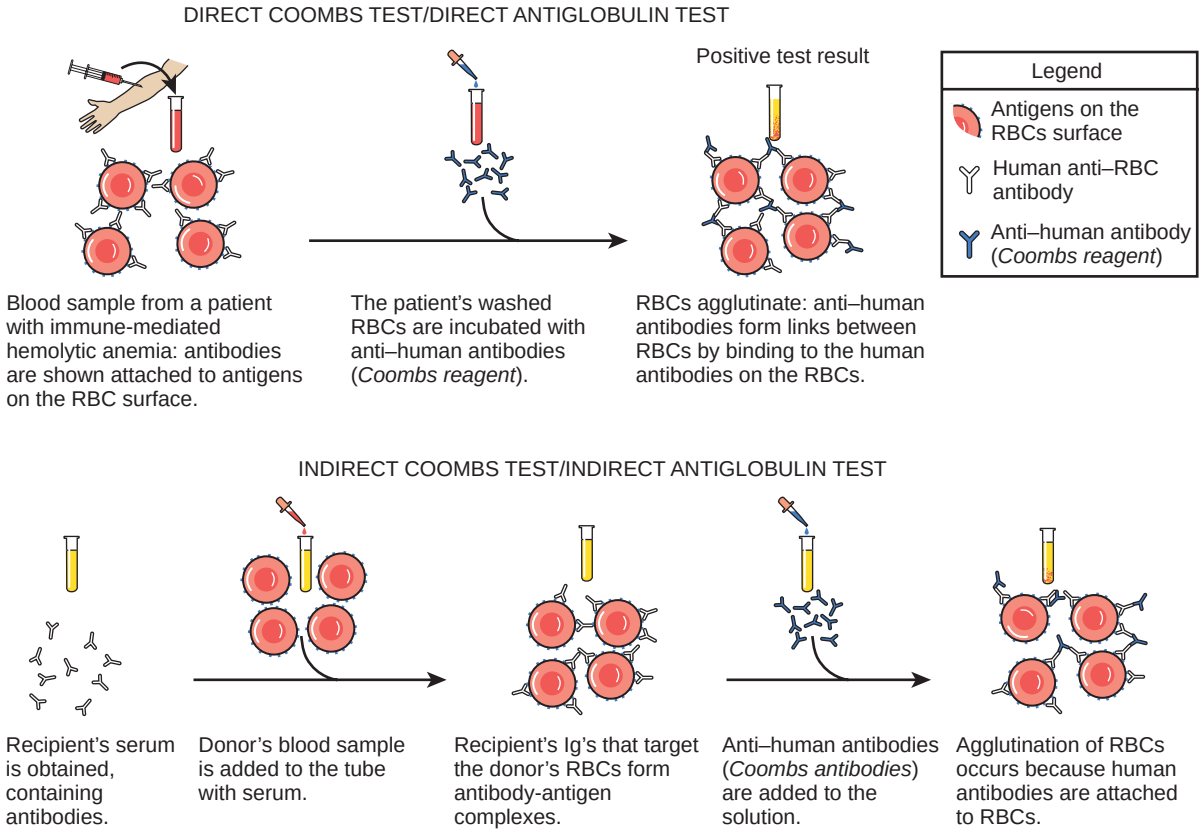


Fig. 34.1 Indirect and direct Coombs (antiglobulin) tests. The recipient's serum or plasma is separately mixed with three or more commercially available type O washed red blood cells *(RBCs)* that express about 20 of the most clinically significant RBC antigens to detect unexpected antibodies. The recipient's serum and reagent RBCs are incubated at 37°C for 30 minutes and examined. Spun cells are then washed and tested with antihuman immunoglobulin and reexamined for hemolysis or agglutination. When antibodies bind to RBC surface antigens, the cells agglutinate during incubation with an anti–human globulin (ie, Coombs reagent), and the indirect Coombs test result is positive. *(Modified from Wikipedia: Coombs test schematic. Updated March 2006.* http://en.wikipedia.org/wiki/File:Coombs_test_schematic.png.*)*

recipient's RBCs, causing the RBCs to agglutinate. The RhD antigen is tested in the same manner, with commercially available anti-D antibodies mixed with the recipient's RBCs.[34]

In the second step, antibody screening is done to identify whether the recipient has formed antibodies to nonself blood groups, such as Duffy, MNS, Kell, Kidd, and P system antigens, using an updated version of the classic Coombs test, also called the *indirect antiglobulin test* (Fig. 34.1). The recipient's serum or plasma is mixed separately with three or more commercially available type O washed RBCs that express about 20 of the most clinically significant RBC antigens to detect unexpected RBC antibodies.

If transfusion is required, the recipient sample that is already typed and screened is crossmatched with donor units. Provided recipient antibodies were not identified on the type and screen, it is possible to perform a crossmatch serologically using an immediate spin crossmatch or perform an electronic match. If clinically significant antibodies have been found on the type and screen, electronic crossmatching is not sufficient, and an antiglobulin crossmatch must be performed.[34] An electronic or computerized crossmatch is performed by identifying donor units on hand that have appropriate ABO and RhD blood groups for the recipient.[35] Electronic crossmatching can be used only if a patient has a negative antibody screen, which means that they do not have any active RBC atypical antibodies. It is assumed that the proper testing (ie, type and screen) of the recipient and donor blood is sufficient to identify clinically important incompatibility and to identify matching donor blood.[36]

When serologic crossmatching (ie, immediate-spin crossmatch) is performed, RBCs from an ABO- and RhD-compatible RBC unit are mixed with the recipient's plasma. The mixture is centrifuged and examined for hemolysis or agglutination. Agglutination is considered a positive reaction, indicating that the donor unit is incompatible for that specific patient. If both are absent, ABO compatibility is verified, and the RBC unit issued. This procedure is repeated for each donor RBC unit. If agglutination or hemolysis occurs, additional screening of the recipient's plasma is performed to identify the unexpected antibodies.[36] Performing a serologic crossmatch over electronic crossmatching before transfusing RBCs is preferred by some laboratories because it detects rare ABO errors and detects most recipient IgM antibodies to antigens on donor RBCs.[37] In an emergency, *uncrossmatched blood* can be transfused and the risk for a serious transfusion reaction minimized by administration of type O and RhD-negative RBCs.[38]

Because plasma contains the anti-ABO, RhD, and other antibodies of the donor, only ABO and RhD-compatible units are transfused. The recipient and donor unit must undergo a type and screen; however, crossmatching is not performed. Platelets have ABO antigens on their surface. However, ABO compatibility for platelet transfusion is desirable but not required because of the relatively small volume of plasma in a bag of platelets. If ABO-incompatible platelets are administered for operational reasons, the recipient may have a positive direct antiglobulin test result, but significant hemolysis is rare. A donor-recipient ABO mismatch may result in poor function of donor platelets after transfusion.[39–41]

Complications of Transfusion

Immediate Immune-Mediated Complications

Hemolytic transfusion reaction is the result of complement-mediated destruction of transfused RBCs, usually because of incompatibility of antigen on the transfused RBCs with antibody in the recipient's circulation. The most common cause of acute hemolytic reactions is transfusion of ABO-incompatible blood; rarely, undetected serologic incompatibility is a cause of acute hemolysis.[42]

Transfusion has been associated with greater pulmonary morbidity after cardiac surgery.[43] Transfusion-related acute lung injury (TRALI) occurs when increased permeability of the pulmonary endothelium causes pulmonary edema, usually within a few hours of transfusion. Hypotension and fever also may occur.[44,45] TRALI accounts for most transfusion-associated deaths in the United States.[45,46] The specific cause of TRALI is unknown, but in many cases, it is associated with antibodies in donor plasma directed toward the recipient's leukocyte or neutrophil antigens.[45,46] These antibodies are seen more frequently in multiparous women and individuals who have had a prior transfusion.[47]

Transfusion of blood components, especially products containing high volumes of plasma such as fresh frozen plasma (FFP), is associated with the greatest risk of TRALI.[47] Plasma from women is typically used for processed protein fractions rather than transfusion. No routinely available pretransfusion testing is available.

Immune-mediated platelet destruction is the result of recipient antibodies to the human leukocyte- or platelet-specific antigens on transfused platelets. Most cases of immune-mediated platelet destruction occur in individuals who have had several prior platelet transfusions. For some patients, platelet matching may be required.[41]

Anaphylactoid reactions rarely occur in transfusion of IgA-containing plasma in a blood product given to IgA-deficient patients who have anti-IgA antibodies. The reaction is characterized by hypotension, bronchospasm, and laryngeal edema.[48]

Febrile nonhemolytic reactions are relatively common and typically manifest by a temperature increase of 1°C or more during or shortly after transfusion. They may result from antibodies to white blood cells or from high levels of cytokines in transfused blood products.[49]

Delayed Immune-Mediated Complications

Delayed hemolytic reactions occur in patients who have had previous exposure to incompatible blood but who do not have circulating antibodies. Reexposure to the antigen provokes delayed production of antibody that reaches a significant circulating level while the transfused RBCs are still present in the circulation, usually 2 to 14 days after transfusion.[50]

Graft-versus-host disease (GVHD) is a rare condition that occurs when viable donor T lymphocytes in the transfused blood product successfully engraft in the recipient. Normally, donor T cells are recognized as foreign by the recipient's immune system. However, in immunocompromised patients and rarely when the donor is homozygous and the recipient is heterozygous for an HLA haplotype (as occurs in directed donations from first-degree relatives), the recipient's immune system is not able to destroy the donor T cells. This can result in GVHD. Irradiation of the donor unit prevents T-cell proliferation and GVHD.[51,52]

Nonimmune Complications

Transmission of infectious disease may occur with transfusion despite standard blood-banking operational procedures. Routine testing of donor blood is performed for Chagas disease, hepatitis B and C, human immunodeficiency viruses types 1 and 2, human T-lymphotropic virus, syphilis, West Nile virus, and in some situations, cytomegalovirus.[33] Bacterial contamination occurs rarely and manifests by fever and hemodynamic instability after transfusion of the blood product.[53] Circulatory overload, hypothermia, and metabolic and electrolyte derangements may occur with high-volume transfusions.[54]

Transfusion and Morbidity Outcomes

Morbidity and Mortality

Although transfusion of RBCs is necessary for some patients, its use has been associated with a dose-dependent greater prevalence of morbidity after cardiac surgery.[55] Greater rates of postoperative infectious complications, prolonged postoperative ventilatory support, renal injury, and reductions in short- and long-term survival are more common for patients transfused with RBCs.[43,55–57] Greater rates of bacteremia, septicemia, and deep and superficial sternal wound infections are higher for transfused patients. Some investigators hypothesize that this results from downregulation of the immune system.[56,58–60]

A metaanalysis by Rohde and colleagues examined the association between RBC transfusion strategies and health care–associated infection.[59] The investigators reported reduced risk of health care–associated infections for patients who had a restrictive RBC transfusion strategy compared with a liberal transfusion strategy. They posited that implementation of restrictive strategies might have the potential to lower the incidence of health care–associated infections. The relative risk for the association between transfusion strategy and serious infection was 0.82 (95% confidence interval [CI], 0.72 to 0.95).[59]

Transfusion has been related to increased development of postoperative atrial fibrillation due to the influence of RBC transfusion on inflammation. RBC transfusion results in a direct infusion of inflammatory mediators and augments the inflammatory response to cardiopulmonary bypass (CPB) and cardiac surgery.[61,62]

Work by Clifford and colleagues characterized the epidemiology of pulmonary complications related to perioperative transfusion (ie, transfusion-associated circulatory overload [TACO] and TRALI).[63,64] In a noncardiac surgical population, the researchers found an overall 4.3% incidence of TACO, with increasing age, total intraoperative fluid balance, and increasing amounts of transfused products also related to TACO development. They highlighted the importance of recognizing TACO because circulatory overload due to transfusion was the second most common complication related to transfusion.[64]

In a separate investigation of a non-cardiac surgery population, the investigators examined the epidemiology of TRALI and found that it was the leading cause of death related to transfusion. They reported no reductions in the occurrence of TRALI despite TRALI reduction efforts over time. The rate of TRALI was 1.3% in 2004 and 1.4% in 2011.[63]

Length of Storage Duration and Morbidity

Storage duration of the RBC product may contribute to adverse outcomes. A series of structural and functional changes occur with increasing RBC storage. Some changes are reversible, others are not, and together they may result in decreased microvascular tissue flow.[65–67] One investigation reported that transfusion of RBCs stored longer than 14 days was associated with a greater risk for death and complications after cardiac surgery.[68] A laboratory investigation by Sweeney and coworkers[69] found increased thrombin generation for RBC units of increasing storage duration, suggesting a cause for increased complications observed with transfusion of RBCs of increased storage duration.

Steiner and colleagues reported results from a randomized, controlled trial that assessed the effects of RBC storage on patients undergoing cardiac surgery.[70] The primary outcome was the multiple organ dysfunction score (MODS) through day 7; the change in MODS was similar for the fresh and old blood groups. The study was not powered for assessing postoperative mortality.

Genetic Causes of Hemorrhage

The coagulation system can be thought of as being highly optimized for rapid cessation of hemorrhage. There likely has been a strong evolutionary pressure toward rapid coagulation and wound healing. There must be an equally highly developed system that prevents overwhelming coagulation of the entire blood volume in response to a trivial intravascular insult. There was likely little or no pressure to avoid a

deep venous thrombosis in older age because most individuals did not live beyond 40 years until a few centuries ago. Similarly, there has been no evolutionary pressure to successfully undergo blood exposure to foreign surfaces such as the CPB circuit.

Because severe bleeding abnormalities are strongly selected against evolutionarily, they are rare. A sentinel example is the hemophilias, in which a rare variant causes production of a nonfunctional protein with severe consequences. In contrast, trivial abnormalities have not undergone marked evolutionary pressures and are likely to be more common. A good example is the wide but seemingly unimportant heritable variation seen in the circulating level of many coagulation proteins.[71–74]

In some individuals, the coagulation system is not optimized to achieve rapid coagulation. Most abnormalities are a quantitative deficiency of a normal protein or a qualitatively defective (ie, hypofunctional) protein in normal concentrations. The measurement of protein concentration and activity are importantly different. Protein concentrations usually are measured by the amount of binding of a manufactured antibody against a portion of the protein (ie, antigen). Antibody-based assays detect quantitative deficiencies of the protein but cannot detect qualitative defects unless the antibody is specifically directed against the structural abnormality of the protein. The function of a protein usually is measured by the enzyme or other functional activity of the protein, often by measuring the amount of enzyme product formed. Results of activity-based assays may be reduced because the amount of the protein is reduced or its activity is reduced, and the cause of reduced function likely must include the measurement of the amount of protein using a quantitative assay.

Genetic causes of impaired coagulation can be thought of as a qualitative defect arising from abnormal protein structure because of a coding genetic variant or a quantitative defect arising from abnormal and usually reduced production of a normal protein because of a noncoding (promoter) genetic variant. This rudimentary approach gives a basic understanding of the genetic mechanisms of coagulation disorders.

The overall effect of a genetic variant on the individual or surgical population is a product of the frequency of the genetic variant and its biologic effect.[75] Rare variants such as the hemophilias are problematic for single individuals, but the overall effect on daily practice is low. A more common variant may have greater effects. Similarly, for two variants of equal frequency, the one with a low biologic effect has less overall influence than the one with a higher biologic effect. No frequent variants with high biologic effect on coagulation have been identified.[74]

Variation in Coagulation Protein Levels

Several studies have demonstrated the strong heritability of levels of plasma proteins and platelet levels in normal populations.[73,76–79] This type of research is undertaken by examining the plasma level of coagulation proteins in multigenerational families and estimating the within-family variation compared with the whole-population variation.[80] In accordance with the strong evolutionary importance of coagulation function, there is similar strong inheritance within families, with up to 70% of the variation in plasma protein levels determined by genetic heritability. Similar heritability of platelet count and platelet volume has been observed.[81,82]

Genetic variation associated with the circulating level of a coagulation protein is usually in or around the gene for that coagulation protein. For example, the circulating level of plasminogen activator inhibitor 1 (PAI-1) principally is determined by a common promoter variant that alters the binding of the transcription factor inhibitor.[72,73] Similarly, the circulating level of thrombin-activated fibrinolysis inhibitor is determined by two variants,[83] and circulating prothrombin levels are determined by a single variant.[84] However, some coagulation protein levels are regulated by genetic variation that is not in or around the protein's gene. Platelet count and platelet volume are regulated by genes that would not be intuitive choices.[81,82]

Hemophilias

Hemophilias are well-known examples of a rare, severe genetic disorder of coagulation. Hemophilia A (ie, factor VIII deficiency) is the most common hemophilia, occurring in about 1 in 5000 male births.[85] Hemophilia B (ie, factor IX deficiency) occurs in about 1 in 34,000 male births. Both genes lie on the X chromosome, meaning that in males, only one copy of the chromosome is present, and a single variant may result in hemophilia, which is often called a *sex-linked* or *X-linked disease*. Female hemophiliacs must have two copies of the rare variant, an event that usually occurs only in consanguineous births in which the father has hemophilia. Although most hemophilias are maternally inherited, about 30% are spontaneous mutations not found in the mother.

An obvious question is why females do not have twice the factor VIII and IX levels as male individuals. In females, one of the X chromosomes is usually inactivated and does not generate messenger RNA for translation of proteins. However, it is possible for female carriers to have mild hemophilia because of lyonization (ie, inactivation) of the X chromosome that carries the normal gene, leaving the abnormal gene as the most active. Women may experience menorrhagia because of the bleeding tendency.

Hemophilia C is an autosomal genetic disorder (not an X-linked trait) involving a lack of functional clotting factor XI. Hemophilia C is not completely recessive because heterozygous individuals also have increased bleeding.[86]

The *F8* gene encodes factor VIII of the intrinsic pathway. Factor VIII is a cofactor for factor IXa, which converts factor X to the activated form Xa. There are almost 700 known coding variations of the *F8* gene, many of which have been seen in only one individual or family. More than 170 variations produce severe forms of hemophilia A, and more than 180 produce milder forms.[87,88] Some mutations change one amino acid; many have little effect on protein function because only one amino acid is changed, often to a similar type of amino acid.[89] Others cause a frameshift mutation that usually truncates the protein and markedly reduces its function. Another severe mutation is an inversion of a portion of the genome, and the sequence of a portion of the protein is back-to-front, with a marked reduction in function. Rarely, the entire gene is deleted so that quantitative and qualitative assays show the absence of factor VIII. The diagnosis of hemophilia A is based on reduced factor VIII activity, prolonged activated partial thromboplastin time except in mild disease, and a normal prothrombin time (PT) and platelet count.[89]

The *F9* gene encodes the vitamin K–dependent factor IX of the intrinsic pathway. Factor IX is activated by factor XI to factor IXa. Because hemophilia B is less common than hemophilia A, fewer mutations have been described, but the mechanisms of protein dysfunction caused by genetic variations are similar. The diagnosis of hemophilia B is made by reduced factor IX activity, prolonged activated partial thromboplastin time except in mild disease, and a normal PT and platelet count.[89]

Hemophilia is not a contraindication for cardiac surgery, but it is an absolute indication for involvement of a hematologist and blood banker. Most experience has been with small case series or single case reports, but all emphasize the need for prolonged factor therapy and subsequent excellent outcomes. For hemophilia A, the factor VIII activity level should be corrected to 100% of normal for cardiac surgery, although some hematologists use 50% to 70% of normal as a goal. One unit of factor VIII is the normal amount of factor VIII in 1 mL plasma. Because the volume of distribution of factor VIII is that of plasma, the amount of factor VIII in an individual is about 50 mL/kg. The factor VIII dose needed to correct the level is calculated as follows[90,91]:

$$\text{Units factor VIII} = (\text{weight in kg}) \cdot (50\ \text{mL plasma/kg}) \cdot (\text{desired \% factor VIII level} - \text{current \% of factor VIII level})/100\%$$

Approximately 30% of people with severe hemophilia A develop antibodies to transfused factor VIII. These antibodies (ie, inhibitors)

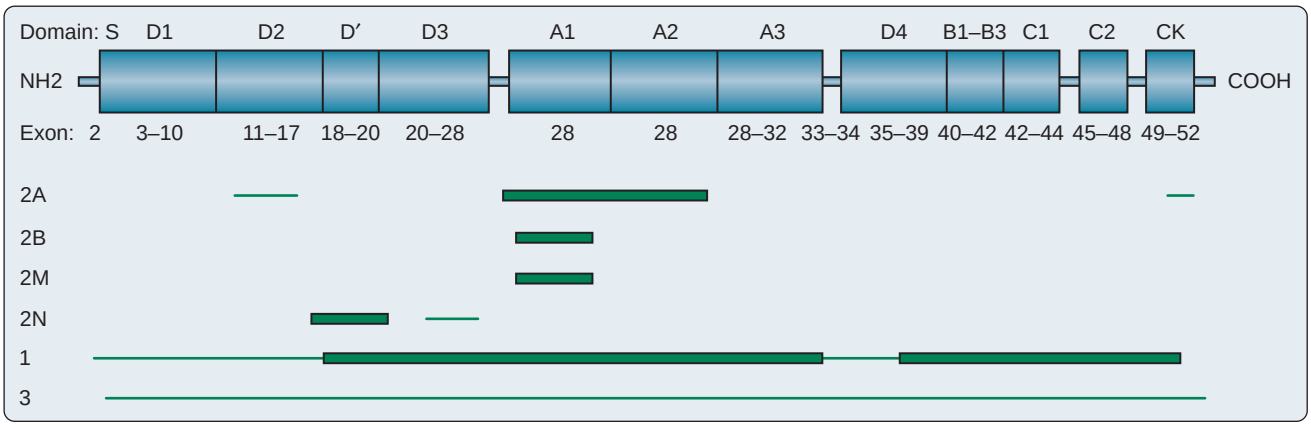

Fig. 34.2 Location of von Willebrand factor (vWF) mutations by von Willebrand disease (vWD) type. *Thick lines* indicate the approximate position of exons where mutations are most prevalent; *thin lines* indicate exons with mutations of lower frequency. Mutations that result in type 2 vWD affect vWF function and cluster in domains primarily disrupted by missense mutations. *(From* http://www.ncbi.nlm.nih.gov/books/NBK7014/; GeneReviews [Internet]. von Willebrand disease. http://www.ncbi.nlm.nih.gov/bookshelf/br.fcgi?book=gene&part=von-willebrand*)*

bind to transfused factor VIII and reduce its activity, increasing the doses of factor VIII required.[92] The next dose should be administered 6 to 12 hours after the initial dose, together with repeated factor VIII activity monitoring with the goal of keeping the trough activity greater than 50%. During hemorrhage, cryoprecipitate and FFP can be given to restore levels of factor VIII, other coagulation factors, and blood volume. 1-Deamino-8-D-arginine vasopressin (DDAVP) at a dose of 0.3 μg/kg can be used in mild or moderate hemophilia A. It works by increasing circulating factor VIII and von Willebrand factor (vWF) levels. DDAVP works only when some normal factor VIII activity is present and usually with only modest success.[93]

For hemophilia B, the factor IX activity level should be corrected to 100% of normal for cardiac surgery, although some hematologists use 50% to 70% of normal as a goal. One unit of factor IX is the normal amount of factor IX in 1 mL plasma. Unlike factor VIII, the volume of distribution of factor IX in an individual is 100 mL/kg. The factor IX dose needed to correct the level is calculated as follows[94]:

$$\text{Units factor IX} = (\text{weight in kg}) \cdot (100\ \text{mL plasma/kg}) \cdot (\text{desired \% of factor IX level} - \text{current \% of factor IX level})/100\%$$

The next dose should be administered 12 to 24 hours after the initial dose, together with repeated factor IX activity monitoring with the goal of keeping the trough activity greater than 50%. During hemorrhage, FFP can be given to restore levels of factor IX, other coagulation factors, and blood volume. DDAVP is not effective.[93]

Von Willebrand Disease

Von Willebrand disease (vWD) is the most common inherited coagulation abnormality, occurring in about 1% of individuals.[95] vWD also can be an acquired disease. It arises from quantitative (ie, reduced amounts of usually normal protein) or qualitative (ie, normal amounts of a defective protein) deficits of vWF, which is a multimeric plasma glycoprotein produced by endothelium and platelets. The protein binds factor VIII (ie, platelet GPIb receptor), the activated form of the GPIIb/IIIa receptor, and collagen.[96]

Unlike the serine proteases of the intrinsic and extrinsic pathways of the coagulation system, vWF is not an enzyme and functions by binding to other proteins.[96] It has an important role in platelet adhesion to exposed subendothelial collagen by binding to exposed collagen and to the GPIb receptor of circulating platelets, especially in high-shear environments such as arterial bleeding. vWF decelerates platelets from rapid flow by uncoiling; it appears to be the critical initiator of platelet adhesion in high-flow environments. Platelet adhesion initiates rapid platelet activation, with switching of the most common platelet receptor, GPIIb/IIIa, from a quiescent protein that poorly binds to fibrinogen and fibrin to an activated protein that strongly binds fibrinogen and fibrin. vWF also can bind to activated GPIIb/IIIa receptors expressed on activated platelets.

There are four types of hereditary vWD caused by mutations in the *VWF* gene (Fig. 34.2).[97,98] Other factors, including having an O blood group, increase the clinical severity of vWD. Type 1 vWD (60–80% of cases) is a mild quantitative defect of normal vWF. Affected individuals have about 10% to 50% of normal vWF levels and often have low levels of factor VIII. The disease is inherited in an autosomal dominant fashion, and most individuals are heterozygous who possess one copy of the abnormal gene, with variants principally found between exons 18 and 28.[99] Rarely, homozygotes (ie, two copies of the abnormal gene) have extremely low levels of vWF. Most heterozygotes have normal or near-normal coagulation and are identified by having abnormal bleeding after tooth extraction or surgery or having menorrhagia.[100]

Type 2 vWD (20–30% of cases) is a qualitative defect with four subtypes: 2A, 2B, 2M, and 2N.[95] Type 2A vWD is caused by decreased activity but normal levels of vWF. The vWF multimers are structurally abnormal and usually small. In contrast to hemophilia, type 2A vWD is inherited in an autosomal dominant fashion and is caused by variants in exons 12 to 16, 28, and 52 of the gene. Type 2B vWF is a rare gain-of-function defect leading to spontaneous binding to platelets and subsequent rapid clearance of the platelets and large vWF multimers. Patients with this subtype should not receive desmopressin because it can induce platelet aggregation. Type 2M vWD is characterized by a platelet function defect caused by a decrease in high-molecular-weight multimers. Type 2N vWD is caused by the inability of vWF to bind factor VIII; it has an autosomal recessive inheritance pattern and is most often associated with variants in exons 18 to 20. Type 2N vWD produces a normal vWF antigen level and normal functional test results, but it has a low factor VIII levels. This probably has led to some 2N patients being misdiagnosed in the past as having hemophilia A, and it should be suspected if the patient has the clinical findings of hemophilia A but a pedigree suggesting autosomal rather than X-linked inheritance.[95]

Type 3 vWD is caused by a quantitative lack of vWF and premature proteolysis of factor VIII, similar to type 2A vWD, but in an autosomal recessive fashion. Type 3 is the most severe form of vWD because individuals are homozygous for the defective gene and protein. They

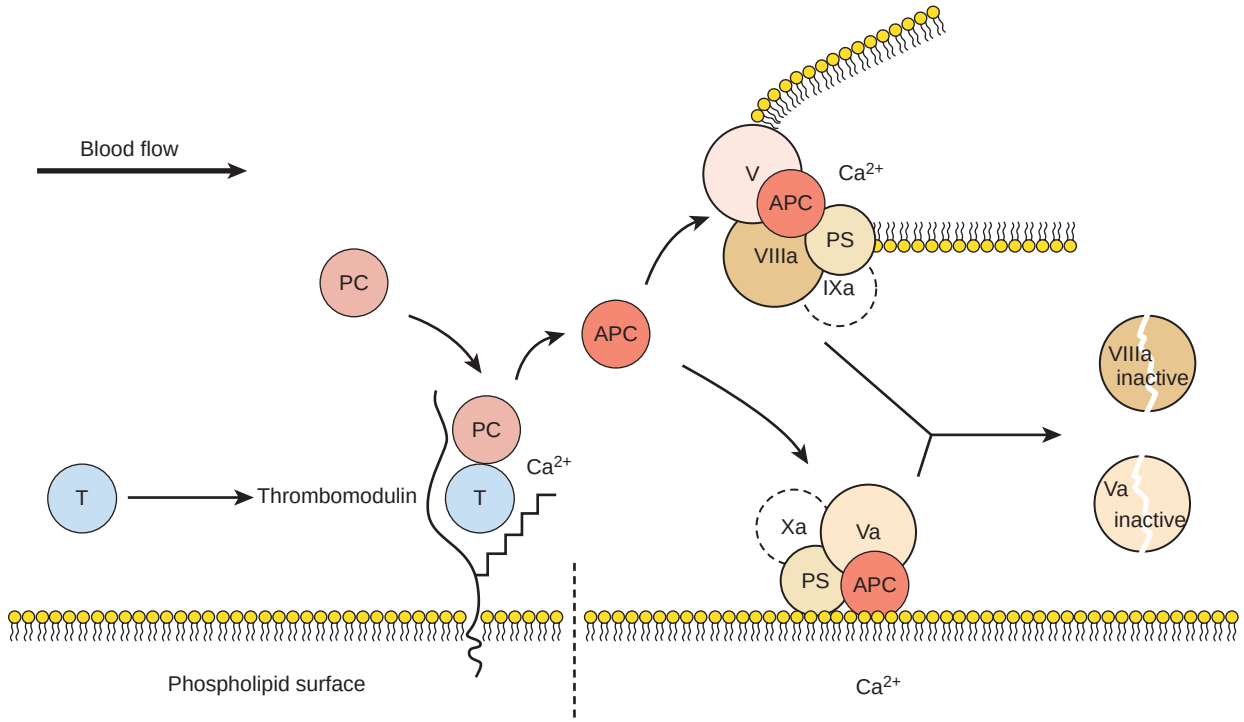

Fig. 34.3 Protein C anticoagulant pathway. Activated protein C functions as a circulating anticoagulant that degrades factors Va and VIIIa. This effectively downregulates the coagulation cascade and limits clot formation to sites of vascular injury. *APC,* Activated protein C, *PC,* protein C; *PS,* protein S; *T,* thrombin. *(From Wikipedia. Protein C anticoagulant.* http://en.wikipedia.org/wiki/File:Protein_C_anticoagulant.jpg.)

have no detectable vWF antigen and may have sufficiently low factor VIII that they have hemarthroses, similar to hemophilia.[100]

Acquired vWD can occur in patients with autoantibodies. In this case, the function of vWF is not inhibited, but the vWF-antibody complex is rapidly cleared from the circulation by antibody binding. A form of vWD occurs in patients with aortic valve stenosis, leading to gastrointestinal bleeding (ie, Heyde syndrome).[101] This form of acquired vWD may be more prevalent than currently thought. Acquired vWD also has been described in cases of Wilms tumor and hypothyroidism.

Laboratory diagnosis is based on a usually normal hemoglobin level, activated partial thromboplastin time, and partial PT but a reduced quantity of vWF measured by an antigenic assay, reduced vWF-ristocetin cofactor (vWF:RCo) assay, or reduced functional factor VIII assay result.[97] If abnormalities in these three tests are identified, specialized coagulation studies may be performed to determine the subtype of vWD. Bleeding can be treated with plasma-derived clotting factor concentrates containing vWF and factor VIII. Depending on the vWD type, mild bleeding episodes usually respond to DDAVP.[102]

Platelet-type vWD (ie, pseudo-vWD) is an autosomal dominant type of the disease caused by gain-of-function coding mutations of the vWF receptor (ie, GPIb) on platelets, not of the vWF gene.[98] GPIb is a dimeric protein that is part of the larger complex (ie, GPIb/V/IX), which forms the full vWF receptor on platelets. The loss of large vWF multimers is similar to that seen in type 2B vWD, but genetic testing of the vWF gene does not find mutations. The hyperresponsiveness of the platelet receptor results in increased interaction with vWF in response to minimal or no stimulation in vivo. This leads to a decline in plasma vWF levels and typically to a decreased or low normal platelet count.[96] Replacement therapy in the form of VIII/vWF preparations or drugs aimed at increasing the release of endogenous vWF exacerbate the condition and lead to further reduction of the platelet count. Platelet transfusions are therapeutic.

Factor V

Normal factor Va and its cofactor, factor Xa, are the first members of the *final common pathway* (ie, thrombin pathway) and combine to form the prothrombinase complex.[103,104] The prothrombinase complex catalyzes the conversion of prothrombin (ie, factor II) to thrombin (ie, factor IIa). To produce thrombin, the prothrombinase complex cleaves two peptide bonds in prothrombin. The action of factor Va is terminated by cleavage by activated protein C (aPC) (Fig. 34.3).

Factor V Leiden is a common SNP that results in a factor V variant that cannot be easily degraded by aPC.[105] The nucleotide variant (G1691A) results in conversion of an arginine to a glycine (Arg506Gln). This amino acid is normally the cleavage site for aPC, and the protein change markedly reduces the activity of aPC on factor Va.[104] When factor Va remains active, it facilitates overproduction of thrombin, leading to excess fibrin generation and excess clotting. It creates a gain of function by inhibiting the termination of factor Va. Clotting is almost always venous, resulting in deep vein thrombosis or pulmonary embolus.[104]

About 5% of whites in North America have factor V Leiden.[105] The SNP is less common in Hispanics and African Americans, and it is rare in Asians. About 30% of people who have a deep vein thrombosis or pulmonary embolism, especially younger patients, carry the SNP. Having the SNP and having other risk factors for deep vein thrombosis, including smoking, taking oral contraceptives, pregnancy, and recent surgery, markedly increase risk. Efforts to show that the prothrombotic factor V Leiden variant results in less bleeding have been mixed.[106,107]

Cold Agglutinins

Cold agglutinin disease is rare (about 2 cases per 100,000 people). Causes include a lymphoma-induced monoclonal gammopathy, renal cell carcinoma, and infection; but most commonly, no cause is found.[108] Cold agglutinins are usually IgM autoantibodies that react

at cold temperatures with RBC polysaccharide antigens. Low titers (1:16) of cold agglutinins often are found in the sera of healthy individuals, but high titers of cold agglutinins (>1:1000 at 4°C) can lead to hemagglutination and thrombosis at low temperatures, followed by complement activation and subsequent hemolysis on rewarming.[109,110] Screening for cold agglutinins before cardiac surgery is not warranted because of their rarity.[109]

In contrast to the warm agglutinins, patients with cold agglutinins do not respond to steroids or splenectomy but sometimes respond to the monoclonal antibody rituximab.[108] Rituximab destroys normal and malignant B lymphocytes and is used to treat B-cell lymphomas and rheumatoid arthritis. It specifically targets the CD20 antigen expressed on B cells. The exact function of CD20 is unclear, although it has been determined that CD20 has a nonredundant role in generating optimal B-cell immune responses.[108]

Variation in Platelet Count and Volume

There are wide variations in platelet counts and volumes in normal individuals undergoing surgery. Platelet function is often markedly depressed from purposeful administration of antiplatelet agents such as aspirin, clopidogrel, and other drugs.

Mean platelet volume is a measurement of the average size of platelets found in blood and is positively correlated with platelet count and function and with adverse thrombotic outcomes. Genetic variants associated with mean platelet volume and platelet count have been identified in or near *WDR66, ARGHEF3, TAOK1, TMCC2, TPM1, PIK3CG, EHD3, ATXN2, PTPN11, AK3*, and other genes.[82] Few of these associations are intuitive or supported by well-understood biologic mechanisms; nevertheless, they indicate the complexity and importance of genetic causes of normal coagulation function.

Bleeding After Cardiac Surgery

Do genetics affect bleeding after cardiac surgery? For many of the well-identified bleeding diatheses mentioned earlier, the answer is yes. However, clinicians rarely encounter these patients in their practice. More commonly, they see a patient who is bleeding for no apparent reason—without a surgical bleeding site, without a drug cause, and with normal or near-normal coagulation test results. The reason for this in an individual patient is almost never known, and the patient is treated symptomatically until the bleeding stops. It is possible, although unproved, that these patients have a genetically inherited bleeding diathesis. Few studies have examined this question, and their limited findings are unreplicated[107,111–113] (see Chapter 35).

Reoperation for Bleeding

Reexploration for bleeding is a serious complication, which significantly impacts the postoperative course by increasing morbidity and mortality rates. Approximately 2% to 4% of patients undergoing cardiac surgery require reoperation for bleeding with greater reported rates for more complex procedures. An investigation evaluating incidence, risk factors, and outcomes for 528,686 coronary artery bypass grafting (CABG) patients requiring reoperation for bleeding from the Society of Thoracic Surgeons National Cardiac Database (2004–2007) reported a 2.4% rate of reoperation. Risk factors for reoperation were older age, male sex, comorbidity such as peripheral vascular and cerebrovascular disease, chronic lung disease, renal insufficiency, heart failure, previous interventions, urgent or emergent surgery, preoperative intra–aortic balloon pump, percutaneous coronary intervention less than 6 hours before CABG, and thienopyridine use less than 24 hours before surgical intervention. Patients requiring reoperation had a greater risk for morbidity such as septicemia, stroke, and prolonged ventilatory support after surgery. The risk-adjusted mortality rate was significantly greater for patients requiring reoperation: 5.9% versus 1.97%. Risk was not increased for patients receiving aspirin therapy less than 24 hours before surgery.[114]

Additional studies have characterized risk factors for reoperation and its relation to patient outcome. Moulton and associates[115] identified a 4.2% reoperation rate and identified increasing age, renal insufficiency, reoperations, and prolonged CPB time as risk factors for this complication. Antiplatelet drugs (eg, preoperative aspirin) and preoperative use of heparin or thrombolytic agents were not significant predictors. The investigators reported that the incidence of death, renal failure and sepsis, and the need for prolonged ventilatory support were significantly greater for patients who underwent reoperation for bleeding.[115] Choong and collaborators[116] reported that the demographic and comorbidity risk factors previously described, cessation of aspirin within 4 days of surgery, preoperative use of clopidogrel, lack of antifibrinolytic agents during surgery, type of operation, and CPB duration were risk factors for postoperative bleeding necessitating reexploration.

In a contemporary cohort of patients, Karthik and colleagues[117] examined risk factors for reoperation and effect of time delay on morbidity after surgery. The rate of reoperation in their investigation was 3.1%. Factors associated with the need for reoperation included demographics such as increasing age, smaller body mass index, and nonelective surgery. They similarly reported that reoperation was associated with increased morbidity, hemodynamic instability, and transfusion of RBCs and component therapy. Among the 89 patients requiring reoperation, 31 had a greater than 12 hours time delay to reexploration; there were four deaths in delayed-reoperation group. The investigators concluded that mortality outcomes were worse if the time delay was greater than 12 hours after surgery and recommended an early reexploration policy for bleeding.[117]

Ranucci and coworkers[118] reported an increased risk for reoperation. They found that much of the morbidity risk was attributable to the amount of RBCs transfused. Delay for reoperation was related to risk only if the delay involved excess use of blood products.

Hall and associates[119] sought to differentiate coagulopathy from hemorrhage due to surgery in patients undergoing reoperation for bleeding. Both groups had increased morbidity and mortality rates compared with those not requiring reoperation. Excess risk was attributed to more hemodynamic instability, transfusions, and inotropic support, which were more common in patients undergoing reoperation. The investigators recommended normalization of coagulation profiles within 4 hours of intensive care unit admission, and if significant bleeding persisted with a normal coagulation profile, reexploration should be undertaken.[119]

Ratios in Resuscitation: Implications for Massive Transfusion in Cardiac Surgery

Patients requiring massive transfusion in the perioperative period may become coagulopathic due to loss, hemodilution, consumption of coagulation factors, and insufficient component replacement. Hypothermia is common in the perioperative period and can cause platelet dysfunction by its effect on platelet activation and adhesion.[120] Hypothermia also may contribute to reductions in clotting factor functional activity.[121–123] Development of acidosis may act synergistically with hypothermia to further worsen coagulopathy through its impact on pH-sensitive enzyme complexes involved in the clotting cascade.[124–126] Choice of volume administration (eg, starches) may further worsen coagulopathy in patients.[127]

Traditionally, a step-wise approach has been recommended for the massively bleeding patient, starting with fluid replacement (using crystalloids with or without colloids), followed in order by RBCs, plasma, cryoprecipitate, and platelet transfusions according to the amount of blood loss relative to the patient's blood volume (Fig. 34.4).[128]

A different approach that uses greater FFP-to-platelet-to-RBC ratios has been proposed. These proposals are based on publications that reported improved outcomes after traumatic injury for patients receiving a greater ratio of blood products to RBC early in the course of resuscitation.[129–132]

Borgman and colleagues[129] recommended implementation of massive transfusion protocols consisting of a 1:1 ratio of FFP to RBC,

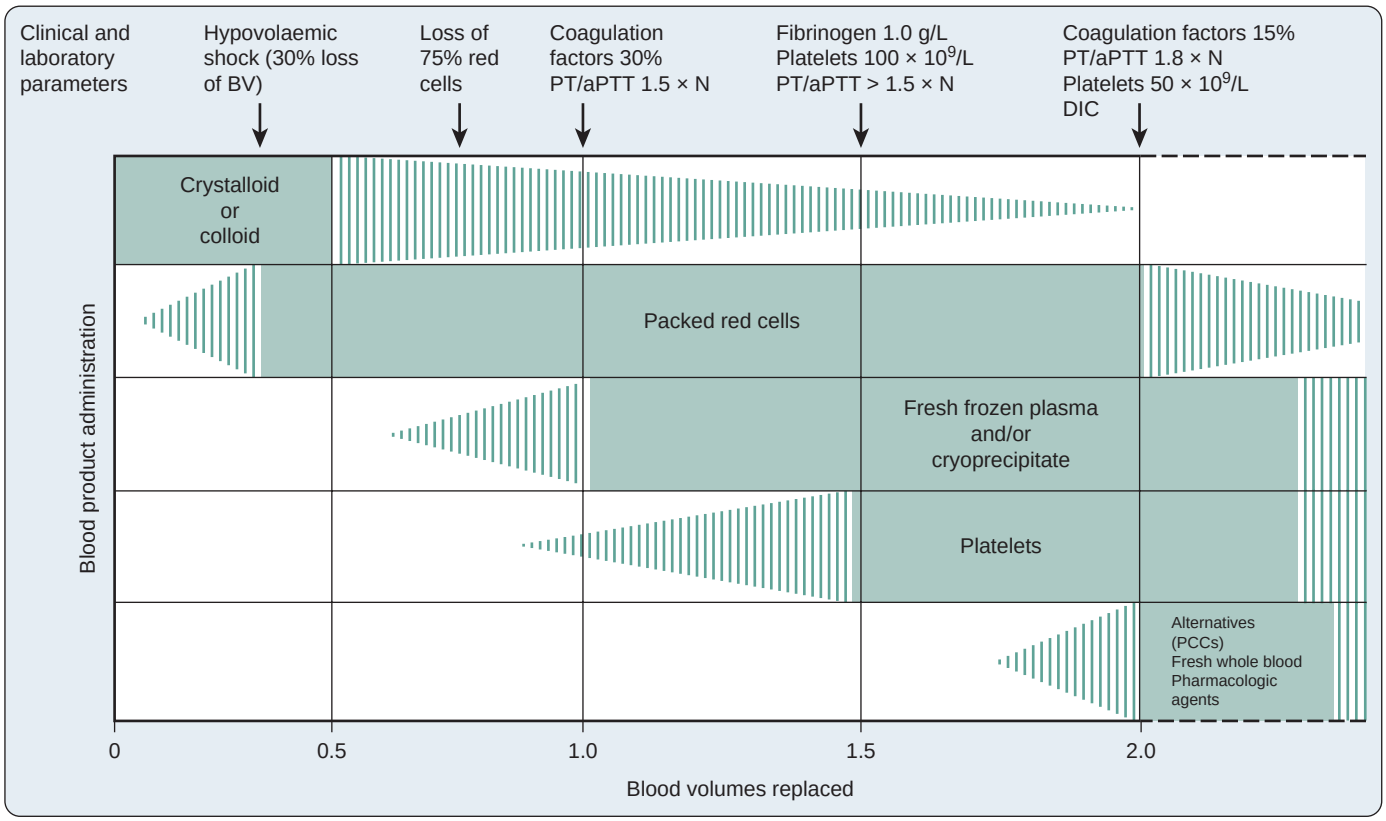

Fig. 34.4 Transfusion therapy for massive hemorrhage. *(Modified from Erber WN. Massive blood transfusion in the elective surgical setting. aPTT*, activated partial thromboplastin time; *BV*, blood volume; *DIC*, disseminated intravascular coagulation; *N*, normal; PCCs, prothrombin complex concentrates; *PT*, prothrombin time. *(From Erber WN. Massive blood transfusion in the elective surgical setting.* Transfus Apher Sci. *2002;27:83–92.)*

using evidence of improved survival and possibly less use of RBCs primarily from the trauma literature. Holcomb and coworkers[130] recommended a massive transfusion protocol that included a 1:1:1 ratio of FFP, platelets, and RBCs to improve patient outcomes. They analyzed four groups based on high and low plasma- and platelet-to-RBC ratios. The combination of high plasma-to-RBC and high platelet-to-RBC ratios was associated with decreased truncal hemorrhage and increased 6-hour, 24-hour, and 30-day survival rates.

In a subsequent prospective, observational study, Holcomb and associates found that the use of higher amounts of plasma and platelets relative to RBC transfusions during the first 6 hours after admission was associated with reduced mortality rates for trauma patients.[133] The risk of death was three to four times higher among patients with ratios less than 1:2 compared with those with ratios of 1:1 or higher.

Others have suggested a U-shaped curve depicting higher mortality rates at low and higher FFP-to-RBC ratios and better outcomes when the ratio was 1:2 or 1:3. A 1:1 ratio of FFP to RBC reduced coagulopathy but failed to improve survival, prompting the investigators to caution against adopting the 1:1 ratio without further testing.[134] An important limitation of observational studies in assessing transfusion ratios is that results may be influenced by survival bias; the most severely injured patients do not survive long enough to receive FFP or platelets, which are often not immediately available.[135]

In a computer simulation model of dilutional coagulopathy, Hirshberg and colleagues[136] reported that current massive transfusion protocols used for bleeding patients underestimate dilution of clotting factors to correct dilutional coagulopathy. The researchers provided a sensitivity analysis of a wide range of replacement protocols by programming their model to administer FFP and platelets after transfusion of a predefined number of RBC units. The model was calibrated to data from 44 patients. They determined that the optimal replacement ratios were 2:3 for plasma and 8:10 for platelets with RBC[136] (Figs. 34.5 and 34.6).

The most definitive study on the transfusion ratios was a randomized trial that compared mortality rates for patients who received plasma, platelets, and RBCs in a 1:1:1 ratio or a 1:1:2 ratio.[137] This multicenter study included 680 severely injured patients who were predicted to require massive transfusion on admission to the trauma unit. The two groups had similar 24-hour (13% vs 17%, respectively; $P = .12$) and 30-day mortality rates (22% vs 26%; $P = .26$), which were the primary outcomes. (The critical level for significance was 0.044, accounting for two interim analyses.) Among the predefined outcomes, the only significant benefit in the high-ratio group was in the subjective outcome of *achieving hemostasis* (86% vs 78%; $P = .006$), although this did not translate into a reduced 30-day mortality rate due to exsanguination or any other benefits. The high-ratio group consumed substantially more plasma (median, 7; interquartile range [IQR], 3–13 units vs median, 5; IQR, 2–10 units; $P < .001$) and platelets (median, 12; IQR, 6–18 units vs median, 6; IQR, 0–12 units; $P < .001$).

Using empiric transfusion ratios is not beneficial and increases transfusions in trauma, and by extension, their use in cardiac surgery cannot be recommended, particularly in the era of point-of-care coagulation testing that allow rapid identification of coagulation defects[138–140] (see Chapter 19). It is, however, likely that protocols for massive transfusion improve outcomes by improving access and availability of blood products irrespective of their content. Riskin and colleagues[141] emphasized the importance of expeditious product availability because a survival benefit did not appear related to any alteration in the volume or ratio of blood components used.

Replacement Therapy

Factor VIIa

Recombinant factor VIIa (rFVIIa, NovoSeven, Novo Nordisk, Bagsværd, Denmark) is approved for the treatment of bleeding in patients with hemophilia A or B with inhibitors against factors VIII and IX. Factor VII acts locally at the site of vessel injury by binding to tissue factor on subendothelial cells and facilitates transformation of factors IX and X to active forms, ultimately resulting in a thrombin burst and clot formation.[142,143] A laboratory investigation examined the effect of rFVIIa-mediated thrombin generation on platelet adhesion and aggregation at normal and reduced platelet counts. The results suggested that administration of rFVIIa in patients with or without thrombocytopenia enhanced platelet deposition and aggregation at the site of vascular injury, which may in part explain the efficacy of rFVIIa in thrombocytopenic patients.[144]

Off-label use of rFVIIa has been reported as a rescue therapy for patients with hemorrhage refractory to conventional therapy. However, the safety of rFVIIa in the cardiac surgical setting has not been clarified. Safety concerns are related to the risk for thrombosis, and reports of thrombotic events have tempered consideration for use in patients beyond rescue therapy, such as prophylactically in patients at high risk for bleeding to avoid blood transfusion.

Since the early 2000s, there have been numerous case reports and case series on the use of rFVIIa in cardiac surgery. Most suggest that rFVIIa is effective in reducing bleeding and decreasing RBC and component therapy requirements in the setting of refractory bleeding. Several, however, have reported increased complication rates associated with rFVIIa use.

In a comprehensive evaluation of off-label use of rFVIIa in Canada, Karkouti and coworkers[145] found that rFVIIa administration (median dose of approximately 60 μg/kg) was associated with significant reductions in transfusion without increases in deaths or major morbid events. They also found that the drug might be more effective given early in the course of bleeding after correction of identifiable coagulation defects.

The Australian and New Zealand Hemostasis Registry found that rFVIIa (median dose of approximately 90 μg/kg) was associated with fewer blood product transfusions.[146] They reported an 11.5% incidence of thromboembolic adverse events, but lacking a control group, they could not determine the relative contribution of rFVIIa versus patients' underlying risk status to the high complication rate. Reduced bleeding occurred in 86% of cases, but the rate was lower for patients whose pH was less than 7.1 before therapy. Patients in whom rFVIIa was effective had reduced mortality rates. Review of the US Food and Drug Administration Adverse Event Reporting System found a total of 431 adverse events related to the use of rFVIIa, among which 185 were thromboembolic events.[147]

In a phase II, randomized, placebo-controlled, dose-escalation trial that included 172 bleeding cardiac surgical patients, Gill and associates[148] reported that patients who received rFVIIa had fewer transfusions after randomization and fewer reoperations for bleeding. However, they also reported an increase in serious adverse events for patients randomized to rFVIIa compared with placebo. Although this increase was not significantly different, it was concerning. Soon after the publication of this study, the manufacturer of rFVIIa ceased further research of rFVIIa use in cardiac surgery.

Prevailing evidence suggests that rFVIIa is effective in refractory bleeding after cardiac surgery but that it does increase the risk of thromboembolic events. This has generated a dichotomy in approach. Although some think that its use should be limited to clinical studies,[149,150] others maintain that it is appropriate to consider its use in the setting of life-threatening, refractory bleeding.[151–153]

Fibrinogen Concentrates

Human fibrinogen concentrates have been used for substitution therapy in cases of hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia. Accumulating data suggest that fibrinogen, which is both the precursor of fibrin and a cofactor in platelet aggregation,[154,155] plays a critical role in hemostasis, especially in bleeding patients with an acquired fibrinogen deficiency.[156–159] Clinical use of fibrinogen concentrates is based on the supposition that plasma fibrinogen concentrations may become critically reduced somewhat early in a bleeding patient and that this may contribute to the coagulopathy associated with hemorrhage. A functional fibrinogen deficiency may develop with excessive hemodilution.

Normal plasma fibrinogen levels vary from 1.5 to 4.5 g/L,[154,160] and the minimum or critical fibrinogen level that is needed for proper clot formation in bleeding patients is unknown. The traditional critical level for fibrinogen replacement is 0.8 to 1.0 g/L, but several studies have found that clot formation and strength are impaired and that blood loss and transfusion rates are increased when fibrinogen levels are substantially higher than 1.0 g/L.[155,161–169] Later guidelines recommend that the critical level should be increased to between 1.5 and 2.0 g/L.[159]

Because of the importance of fibrinogen in clot formation, some have proposed that the fibrinogen target should be near the upper level of the normal range. Karlsson and collaborators[170] hypothesized that preoperative fibrinogen plasma concentrations within the reference range may be a limiting factor for hemostasis. In a pilot study, the investigators randomized CABG patients with preoperative plasma fibrinogen levels less than 3.8 g/L to an infusion of 2 g fibrinogen concentrate or placebo. End points were vessel occlusion assessed by multislice computed tomography, blood loss, transfusion, and hemoglobin levels 24 hours after surgery. One subclinical vein graft occlusion was reported in the fibrinogen group, with similar global measures of hemostasis assessed by thromboelastography. The fibrinogen group had lower postoperative blood loss and greater hemoglobin concentrations. The study authors appropriately addressed the concern of creating a prothrombotic state with increased incidence of graft occlusion. They were not able to clarify the mechanism behind the reduced bleeding. Fibrinogen plasma levels were increased in the fibrinogen group immediately after infusion, but there were no differences between the groups 2 hours after surgery, and measures of hemostasis also were similar.[170]

In another placebo-controlled pilot study, Rahe-Meyer and colleagues[171] reported a reduction in transfusions with administration of fibrinogen concentrate to a target of approximately 4.0 g/L (using point-of-care fibrinogen assays to estimate fibrinogen levels). A larger multicenter confirmatory study,[171a] however, did not find any benefits with this strategy.[171a] Of note, the median pretreatment fibrinogen level in this study was 1.9 g/L (SD 0.66 g/L), and many of the subjects did not have fibrinogen deficits. This study illustrates that fibrinogen supplementation is not an appropriate first-line therapy in bleeding patients who do not have fibrinogen deficits.

Where indicated, correction of fibrinogen deficits can be accomplished with administration of FFP, cryoprecipitate, and plasma-derived fibrinogen concentrates.[157,172,173] Benefits of fibrinogen concentrates over FFP and cryoprecipitate include viral inactivation, rapid reconstitution, accurate dosing, and a lower volume of administration for equivalent fibrinogen supplementation.

A theoretical model developed by Collins and coworkers suggests that to raise the fibrinogen concentration from 0.9 to 2.0 g/L requires 41 units of cryoprecipitate (ie, 4 g of fibrinogen concentrate) and that it cannot be achieved with FFP transfusion.[174] Data on the safety of fibrinogen concentrate is limited. Fassl and associates[175] used propensity score matching to compare the outcomes of 190 patients who received fibrinogen concentrates (median dose of 2 g) with 190 patients who did not receive fibrinogen concentrates during cardiac surgery. They found no significant between-group differences in 1-year mortality or thromboembolic cardiac event rates (hazard ratio = 0.57; 95% CI, 0.25 to 1.17; $P = .1$ in favor of the fibrinogen group).

Factor XIII

Factor XIII is the terminal enzyme in the coagulation cascade, and it is necessary for cross-linking of fibrin monomers to form a stable and strong fibrin clot.[176,177] Cardiac surgery with CPB leads to a reduction in plasma factor XIII levels, and an association between low factor XIII levels and increased bleeding has been found in some settings, including cardiac surgery.[178–182] Preliminary studies indicated that administration of factor XIII may improve clot strength and reduce blood loss in cardiac surgery, but a multicenter, randomized, phase II study that included 409 cardiac surgical patients at moderate risk for transfusion did not find factor XIII supplementation to be efficacious in reducing transfusions.[183]

Prothrombin Complex Concentrates

Prothrombin complex concentrates (PCCs) are virally inactivated, lyophilized products that are prepared from pooled plasma and primarily contain the vitamin K–dependent coagulation factors II, VII, IX, and X (Table 34.2).[184] Other components include coagulation inhibitors proteins C and S, heparin, and antithrombin. After reconstitution with small amounts of water, PCCs can be administered rapidly without the need for thawing or blood group matching.

Four-factor PCCs are approved for rapid reversal of oral vitamin K antagonists in patients requiring emergency surgery or invasive procedures. Recommended dosage is based on factor IX content, ranging from 25 to 50 IU of factor IX per 1 kg of body weight, depending on the patient's international normalized ratio (INR) (eg, 25 IU/kg for INR 2.0–3.9; 50 IU/kg for INR 4.0–5.9; 50 IU/kg for INR >5.9).[184] In a phase IIIb study that randomized 181 patients who needed rapid vitamin K antagonist reversal before urgent surgical or invasive procedures to a four-factor PCC or FFP, Goldstein and collaborators[185] found that the four-factor PCC was more efficacious and potentially safer than FFP. Rapid INR reversal was achieved in 55% of the PCC group compared with 10% of the FFP group (difference of 45%; 95% CI, 32–56%). Deductively defined adverse events were similar between the two groups, but the PCC group had fewer adverse events related to the study treatment (9% vs 17%; $P = .2$) and had fewer fluid overload or similar cardiac events (3% vs 13%; $P = .05$).[185]

Three-factor PCCs contain low levels of factor VII, and activated PCCs such as FEIBA, a factor VIII inhibitor bypassing agent, contain trace amounts of activated factor VII and X. These products are primarily indicated for the prevention and treatment of hemophilia-related bleeding.[186] There may be a role for PCCs in the management of surgical coagulopathy instead of FFP outside of vitamin K antagonist reversal; however, data on safety and efficacy are limited.[186,187]

Volume Replacement: Colloids and Crystalloids

Maintenance of intravascular volume is a common goal for perioperative management in cardiovascular surgery. Merits of specific choices for fluid therapy to replace ongoing fluid loss continue to be debated. Although there may be theoretical advantages of using colloid or crystalloid for volume replacement, clinical trial data do not definitively support one over the other in terms of mortality outcomes. Both have distinct advantages and disadvantages.[188] More important than the choice of volume replacement is appropriate volume replacement to avoid tissue hypoperfusion.

Volume of distribution for a particular fluid administered depends on fluid composition. Saline-based crystalloids usually result in expansion of the plasma volume by approximately 200 to 250 mL for each 1 L administered; glucose-based solutions expand the plasma volume by approximately 60 to 70 mL for each 1 L infused; and colloid solutions result in expansion of the plasma volume similar to the volume infused. Within the semisynthetic colloid solutions, there is variation in the degree of plasma volume expansion and a differential influence on hemostasis and inflammatory processes.[189,190]

Those favoring crystalloids for volume replacement have found problems with hemostasis, adverse reactions, and greater risk of volume overload with colloidal fluids. Those favoring colloids highlight larger volumes of crystalloid required to achieve volume resuscitation, tissue edema, and a potential for reduction in tissue oxygen delivery.[191] It is unclear whether the type of fluid therapy for hypovolemia affects development of pulmonary edema. Verheij and colleagues[192] reported that type of fluid given to patients with pulmonary vascular injury without fluid overloading did not influence pulmonary vascular permeability or pulmonary edema.

A key characteristic of colloid solutions is their persistence within the intravascular space, which is determined by rate of loss from the circulation.[190] Albumin is monodisperse substance (ie, uniformity of particle molecular weight), whereas semisynthetic colloids are polydisperse substances (ie, wide distribution of particle molecular weight). The molecular weight of a colloid has pharmacokinetic implications in terms of degree of oncotic effect, viscosity, intravascular persistence, and initial degree of volume expansion. In addition to molecular weight, other properties of colloids such as surface charge affect the degree of loss through capillary endothelium and the rate of glomerular filtration.[189,190,193]

Albumin is derived from pooled human plasma and has minimal side effects or contraindications. Results from the Saline versus Albumin Evaluation (SAFE) trial, which randomized 7000 critically ill medical and surgical patients to 4% albumin or normal saline, provided evidence on the safety of albumin in critically ill patients. The groups had similar mortality outcomes at the 28-day follow-up and similar secondary outcomes of length of stay, ventilatory requirements, and renal replacement therapy.[194–196]

Semisynthetic colloids are dissolved in a crystalloid carrier solvent consisting of isotonic or hypertonic saline or glucose or an isotonic balanced electrolyte solution. Clinical data provide supportive evidence in terms of patient outcomes for colloids with a balanced solvent solution mirroring the composition of plasma.[189,190] Semisynthetic colloids increase the risk of bleeding, largely because of hemodilution of clotting factors, reductions in factor VIII/vWF (also caused by hemodilution), and functional platelet abnormalities.[189,190,195,197,198] A retrospective chart review concluded that intraoperative use of hetastarch in cardiac surgery requiring CPB increased bleeding and transfusion requirements.[199]

A laboratory investigation examined the effect of fluid resuscitation with three colloids (ie, Hextend, Dextran 70, and 5% albumin) on coagulation and uncontrolled bleeding in rabbits subjected to a splenic injury. Although the prothrombin and partial thromboplastin times were prolonged in all rabbits, thromboelastography and thrombin generation assays identified more severe coagulopathy with Hextend and Dextran 70 than with albumin. Their results suggested resuscitation with albumin-maintained coagulation function, decreased blood loss, and improved survival time compared with synthetic colloids.[200]

Lang and coworkers[201] examined the impact of volume replacement with 6% hydroxyethyl starch or Ringer lactate solutions on tissue oxygen tension during and after major surgical procedures. Patients who received 6% hydroxyethyl starch had improved tissue oxygenation compared with a crystalloid-based volume replacement strategy. Improvements in tissue oxygen tension in the hydroxyethyl starch–treated group were thought to result from improved microperfusion and less endothelial swelling.

Jacob and associates[190] examined the impact of albumin, hydroxyethyl starch, and saline as resuscitation fluids on vascular integrity in an isolated guinea pig perfused heart model. The study authors hypothesized that fluid extravasation might lead to myocardial edema and consequent reduction in ventricular function. Albumin more effectively prevented fluid extravasation in the heart than crystalloid or artificial colloid, and this effect was partly independent of colloid osmotic pressure. Others have found that using albumin for the CPB prime better preserved platelet counts than a crystalloid prime and more favorably influenced colloid oncotic pressure, positive fluid balance, and postoperative weight gain.[202]

Blood Substitutes

Risks associated with RBC transfusion in terms of morbidity, mortality, survival, and availability of supply have spurred development of alternatives to blood transfusion for decades. Ideal characteristics of a blood substitute include long shelf life, no need to crossmatch, immediate availability, and lack of toxic side effects.[203] Hemoglobin-based oxygen carriers (HBOCs) are engineered human, animal, or recombinant hemoglobin products in a cell-free hemoglobin preparation. There are no approved products in the United States.[204,205] Perfluorocarbon-based oxygen carriers are aqueous emulsions of a perfluorocarbon derivative that dissolve relatively large amounts of oxygen and usually require patients to breathe oxygen-enriched air.[204]

Failure to bring a product to the clinical arena has been attributed to toxicity-related issues. First-generation HBOCs had issues with the way oxygen was carried and released from RBCs. Several adverse events have been reported in clinical trials of oxygen carriers, including death, stroke, hypertension, anemia, and abdominal pain.[206] Others have reported adverse effects that included rash, diarrhea, hemoglobinuria, elevated lipase levels, vasoconstrictive effects, and increased hemostatic effects because of the reversal of inhibition effect of nitric oxide on platelet aggregation. Free plasma hemoglobin generates reactive oxygen species and is a potent scavenger of nitric oxide[205] (Table 34.3).

In a review of oxygen carriers, Winslow[206] found the solutions caused vasoconstriction, which has been one of the limiting factors for clinical use. Vasoconstriction may be caused by scavenging nitric oxide by hemoglobin or an oversupply of oxygen from free hemoglobin through facilitated diffusion. An understanding of the proposed mechanisms of vasoconstriction (ie, oversupply theory) led to new product development involving modification of hemoglobin with a lower P_{50} (ie, oxygen tension at which hemoglobin is 50% saturated) and increased molecule size, reducing the release of oxygen in resistance vessels and resultant vasoconstriction.[207]

Yu and colleagues[208] described profound vasoconstrictor side effects that limited the clinical utility of HBOCs, and they attributed this side effect to nitric oxide scavenging. The investigators found that by inhaling nitric oxide, changes occur in body stores of nitric oxide metabolites without producing hypotension and may prevent hypertensive side effects of HBOC infusion. Others have reported the nitric oxide–scavenging properties of HBOCs as a likely mechanism of vasoconstriction associated with infusion and proposed modifications that could ameliorate this side effect.[209,210]

A basic science working group from the National Heart, Lung, and Blood Institute Division of Blood Diseases and Resources provided recommendations for a basic science focus in the area of blood substitutes. The working group highlighted impediments to further HBOC product development due to the significant side effects of excessive cardiovascular and cerebrovascular events and death.[211]

Lowest Hematocrit on Cardiopulmonary Bypass

Anemia while on CPB and transfusion of RBCs have been associated with adverse perioperative outcomes. Hemodilution due to fixed priming volume and pre-CPB fluid administration contribute to anemia and transfusion need.[212,213] Minimum hematocrit values less than or equal to 14% on CPB have been associated with postoperative deaths of CABG patients; and for high-risk patients, values less than 17% increase mortality risk.[214] The morbidity risk associated with hemodilutional anemia is thought to result from inadequate oxygen delivery leading to organ dysfunction.[215]

The lowest hematocrit while on CPB is a risk factor for postoperative low-output syndrome and renal failure. Ranucci and coworkers[216] reported a cutoff hematocrit value of 23% for renal failure and 24% for development of the low-output syndrome. RBC transfusion also was associated with renal failure and the low-output syndrome in their investigation. The risk for renal injury further increased when RBC transfusions were associated with a nadir hematocrit of less than 23% while on CPB.

Swaminathan and associates[217] reported more perioperative renal injury with hemodilution, targeting CPB hematocrit levels of 22% to 24%. The investigators highlighted the renal benefits of hemodilution related to reductions in blood viscosity and improved regional blood flow. However, a well-defined cutoff value for hemodilution has not been clarified. They were unable to find an "elbow" for a cutoff between the hematocrit and a change in creatinine values. The significant association between the lowest CPB hematocrit and a change in creatinine values was highly influenced by body weight in their investigation.[217] Others have reported that hemodilution while on CPB to hematocrit values less than 24% and associated renal injury were further exacerbated by longer CPB times and RBC transfusion.[215]

Karkouti and collaborators[218] suggested a U-shaped relationship between the nadir hematocrit while on CPB and renal failure requiring dialysis. Moderate hemodilution (ie, hematocrit values between 21% and 25%) were associated with the lowest risk for acute renal failure; risk increased as nadir hematocrit concentrations decreased to

[a]Not all clinical trials conducted by commercial sponsors have been published, and the published results are not synonymous with line listings that would be found in a comprehensive final study report. For each paper, editorial decisions were made about what information should be included or excluded and data presentation (numbers vs percentages), making derivation of the number of subjects experiencing an event and aggregation of information to derive a comprehensive list of adverse events difficult and potentially incomplete. Not all studies were controlled. Not all enzyme elevations were captured as adverse events, and in some instances, the number of subjects experiencing enzyme elevations was not captured. Differences in reporting methods may have resulted in counting subjects more than once in each category of events (ie, rows).

less than 21% or were greater than 25%. In congenital heart surgery, Jonas and colleagues[219] reported that lower hematocrit strategies (21% ± 2.9%) compared with higher hematocrit strategies (28% ± 3.2%) were associated with higher serum lactate levels 60 minutes after CPB, greater percentage of increase in total body water on postoperative day 1, and at 1 year of age, worse scores on the Psychomotor Development Index. The study authors concluded that a lower hematocrit strategy was associated with increased risk for developmental impairment.

Loor and colleagues examined the relationship between a lower nadir hematocrit and postoperative complications in more than 7000 cardiac surgical patients who did not receive RBC transfusions. A lower nadir hematocrit was associated with higher mortality rates and more postoperative morbidity.[220] It appeared that after the threshold of a hematocrit of less than 24% was reached, risk increased. A separate study by the same group of investigators examined the risks of a single exposure to anemia, a single RBC transfusion, and both exposures. They reported exposure to both anemia and RBC transfusion was associated with the highest risk of poor outcomes. The lowest risk was with neither exposure; the risk of a single exposure to anemia or transfusion depended on the organ system. For example, the kidneys were more sensitive to anemia exposure, as reflected by a decrease in the estimated glomerular filtration rate, and the lungs were more sensitive to an RBC transfusion exposure.[221]

DeFoe and coworkers[222] reported a risk-adjusted increased risk for mortality, need for an intraaortic balloon pump, and return to CPB after initial separation for a nadir hematocrit while on CPB. Smaller patients and those with lower preoperative hematocrit values were at greater risk for lower CPB values. They reported trends toward increasing risk for death among patients with hematocrit values less than 23%, and for those with hematocrit values less than 19%, the mortality rate was almost twice as high as for patients with hematocrit values of 25% or more.[222] Others have reported the association between hemodilution to hematocrit values of 24%, RBC transfusion, and increased risk of renal and splanchnic injury.[223]

Not all investigations have reported adverse consequences with lower nadir hematocrit values while on CPB; von Heymann and associates[224] examined oxygen delivery, oxygen consumption, and outcomes for low-risk CABG patients assigned CPB hematocrit values of 20% or 25%. They reported similar oxygen delivery, oxygen consumption, blood lactate levels, and clinical outcome measures for the two groups. They concluded that CPB hematocrit values of 20% were adequate to maintain calculated whole-body oxygen delivery above critical levels.

Similarly, Berger and collaborators randomized patients to profound hemodilution with CPB hematocrit values between 19% and 21% or standard values of 24% to 26%. They reported similar changes in intestinal permeability and cytokine release for the two groups and concluded that CPB hematocrit values between 19% and 21% did not adversely affect outcomes.[225]

Orlov and colleagues[226] described the clinical utility of using the oxygen extraction ratio as an adjunct to hemoglobin concentration for guiding RBC transfusion decisions in cardiac surgery. They suggested that a normal oxygen extraction ratio in patients with anemia and no evidence of organ dysfunction indicated adequate tissue oxygen delivery and that by incorporating this measure into the transfusion decisions, RBC transfusions could be reduced.

Variations in transfusion practice reflect the continuing controversy about when to transfuse RBCs.[227,228] Although a single trigger is not ideal, it is often what initiates transfusion discussions in the perioperative period. Several publications have described liberal versus restrictive transfusion strategies. Many have reported similar outcomes, with the study authors supporting a more restrictive approach.

An editorial highlighted the complexity of the issue of when to transfuse. It suggested that there may an adaptive response to anemia up to the point of organ damage and that the point may vary by patient, organ system, and level of anemia. Without a way to measure when a tissue bed is signaling stress related to tissue hypoxia, the definitive answer on when to transfuse remains uncertain.[229]

Conclusions

Proper blood and fluid management in the perioperative period are critical to the care of cardiac surgical patients and can significantly influence patient outcomes. A better understanding of the role of genetics in perioperative bleeding may enable a more proactive approach to patients before surgical intervention. Technologic advances in the measurement of tissue oxygenation will allow better, evidenced-based decisions about transfusion in the future.

Transfusion Medicine and Coagulation Disorders

BRUCE D. SPIESS, MD, FAHA | SARAH ARMOUR, MD | JAY HORROW, MD, FAHA | JOEL A. KAPLAN, MD, CPE, FACC

KEY POINTS

1. It is easiest to think of coagulation as a wave of biologic activity occurring at the site of tissue injury consisting of initiation, acceleration, control, and lysis.
2. Hemostasis is part of a larger body system: inflammation. The protein reactions in coagulation have important roles in signaling inflammation.
3. Thrombin is the most important coagulation modulator, interacting with multiple coagulation factors, platelets, tissue plasminogen activator, prostacyclin, nitric oxide, and various white blood cells.
4. The serine proteases that compose the coagulation pathway are balanced by serine protease inhibitors, termed *serpins*. Antithrombin is the most important inhibitor of blood coagulation, but others include heparin cofactor II and alpha I antitrypsin.
5. Platelets are the most complex part of the coagulation process, and antiplatelet drugs are important therapeutic agents.
6. Heparin requires antithrombin to anticoagulate blood and is not an ideal anticoagulant for cardiopulmonary bypass. Newer anticoagulants are actively being sought to replace heparin.
7. Protamine can have many adverse effects. Ideally, a new anticoagulant will not require reversal with a toxic substance such as protamine.
8. Antifibrinolytic drugs are often given during cardiac surgery; these drugs include ε-aminocaproic acid and tranexamic acid.
9. Recombinant factor VIIa is an off-label "rescue agent" to stop bleeding during cardiac surgery, but it can also be prothrombotic, which is an off-label use of the drug.
10. Every effort should be made to avoid transfusion of banked blood products during routine cardiac surgery. In fact, bloodless surgery is a reality in many cases. Patient blood management, including techniques to reduce coagulation precursors, has been shown to be cost effective and to have better outcomes than routine surgery.
11. The evolving risks of transfusion have shifted from viral transmission to transfusion-related acute lung injury (TRALI) and immunosuppression. Those patients who receive allogeneic blood have a measurable increased rate of perioperative serious infection (approximately 16% increase per unit transfused).
12. Cardiac centers that have adopted multidisciplinary blood management strategies have improved patient outcomes and decreased costs. The careful application of these strategies in use of coagulation drugs and products is very beneficial.
13. Whole blood viscoelastic testing in conjunction with platelet count and fibrinogen concentration laboratory testing is of value in guiding coagulation therapy. All available testing modalities are most effective when teams have discussed and created accepted algorithms for care of the bleeding patient in their institution.
14. New purified human protein adjuncts are replacing FFP and cryoprecipitate with four-agent prothrombin complex concentrate (PCC) and human lyophilized fibrinogen.

Coagulation and bleeding assume particular importance when surgery is performed on the heart and great vessels using extracorporeal circulation. This chapter provides an understanding of the depth and breadth of hemostasis relating to cardiac procedures, beginning with coagulation pathophysiology. The pharmacology of heparin and protamine follows. This background is then applied to treatment of the bleeding patient. Coagulation monitoring is covered in Chapter 19, and fluid and blood management is further discussed in Chapter 34. This chapter will, however, point out how monitoring can help with appropriate coagulation management decisions under certain circumstances.

Overview of Hemostasis

Blood cannot coagulate to stop hemorrhage unless there is closure of large vessels. Any vascular structure larger than 50 μm cannot contract enough to allow platelets and proteins to perform their actions. Superb, meticulous surgical technique is the single most important variable in decreasing postoperative bleeding/blood transfusion requirements. Those centers with surgeons who are not only fast, but willing to spend a few extra minutes conserving blood by detailed hemostasis, will exhibit better outcomes.

Proper hemostasis requires the participation of innumerable biologic elements (Box 35.1). This section groups them into four topics

to facilitate understanding: coagulation factors, platelet function, the endothelium, and fibrinolysis. The reader must realize this is for simplicity of learning, and that in biology, the activation creates many reactions (perhaps >800) and control mechanisms, all interacting simultaneously. The interaction of the platelets, endothelial cells, and proteins to either activate or deactivate coagulation is a highly buffered and controlled process. It is perhaps easiest to think of coagulation as a wave of biologic activity occurring at the site of tissue injury (Fig. 35.1).[1] Although there are subcomponents to coagulation itself, the injury/control leading to hemostasis is a four-part event: initiation, acceleration, control, and lysis (recanalization/fibrinolysis). The initiation phase begins with tissue damage, which really is begun with endothelial cell destruction or dysfunction. This initiation phase leads to binding of platelets, as well as protein activations; both happen nearly simultaneously, and each has feedbacks into the other. Platelets adhere, creating an activation or acceleration phase that gathers many cells to the site of injury. From that adhesion a large number of events of cellular/protein messaging cascade. As the activation phase ramps up into an explosive set of reactions, counter-reactions are spun off, leading to control proteins damping the reactions. It is easiest, conceptually, to think of these control mechanisms as analogous to a nuclear reactor. The activation phase would continue to grow and overcome the whole organism unless control rods were inserted (eg, thrombomodulin, proteins C and S, and tissue plasminogen activator [t-PA]) to stop the spread of the reaction. The surrounding normal endothelium acts quite differently from the disturbed (ischemic) endothelium. Eventually, the control reactions overpower the acceleration reactions and lysis comes into play. The diagram in Fig. 35.1 shows lysis as a relatively quick process, but it can take from 24 hours to days to have its full effects. A key concept is that hemostasis is part of a larger body system: inflammation. Most, if not all, of the protein reactions of coagulation control have importance in signaling inflammation leading to other healing mechanisms. Entire books have been written merely to examine these fascinating interactions. It is no wonder that cardiopulmonary bypass (CPB) has such profound inflammatory effects when it is considered that each of the activated coagulation proteins and cell lines then feeds into upregulation of inflammation.

During cardiac surgery, the endothelium (locally and systemically) is disturbed.[2] The coronary arteries are made either partially or fully ischemic for periods with cardioplegia (perfused CPB being relatively rare today). Little known is that high concentrations of potassium are particularly insulting to endothelial cells. Ischemia/reperfusion injury is, therefore, the norm for every cardiac surgical case using CPB.[3] Systemic ischemia and reperfusion occur throughout every capillary bed because micro-air, thrombus, and fat emboli are by-products of CPB[4] (see Chapters 31–35 and 40). It is quite possible that transfusion of red blood cell (RBC) products, through blocking of the microcirculation, actually may contribute to ischemia/reperfusion injury. Transfusion has been shown to evoke endothelial cell hyper-reactivity mediated through erythrocyte cell membrane microparticles liberated during blood bank storage.[4] Furthermore, the dysfunctional erythrocytes given during transfusion may plug the microcirculation and probably contribute to endothelial cell dysfunction.

The coagulation proteins and platelets are both hemodiluted and consumed during CPB. Platelets are activated/inhibited by various means. Coagulation dysfunction in cardiac surgery has been studied for more than 60 years. The complexity of the myriad number of dysfunctions should impress the student of this area. Unfortunately, when a patient is bleeding in the operating room (OR) or intensive care unit (ICU), there is no universal way to quickly sort out the causative events. Furthermore, the interventions are limited; yet an educated and planned approach (algorithm-driven transfusion/coagulation intervention) does decrease unnecessary transfusion and influences subsequent bleeding.

BOX 35.1 COMPONENTS OF HEMOSTASIS

- Coagulation factor activation
- Platelet function
- Vascular endothelium
- Fibrinolysis and modulators of coagulation

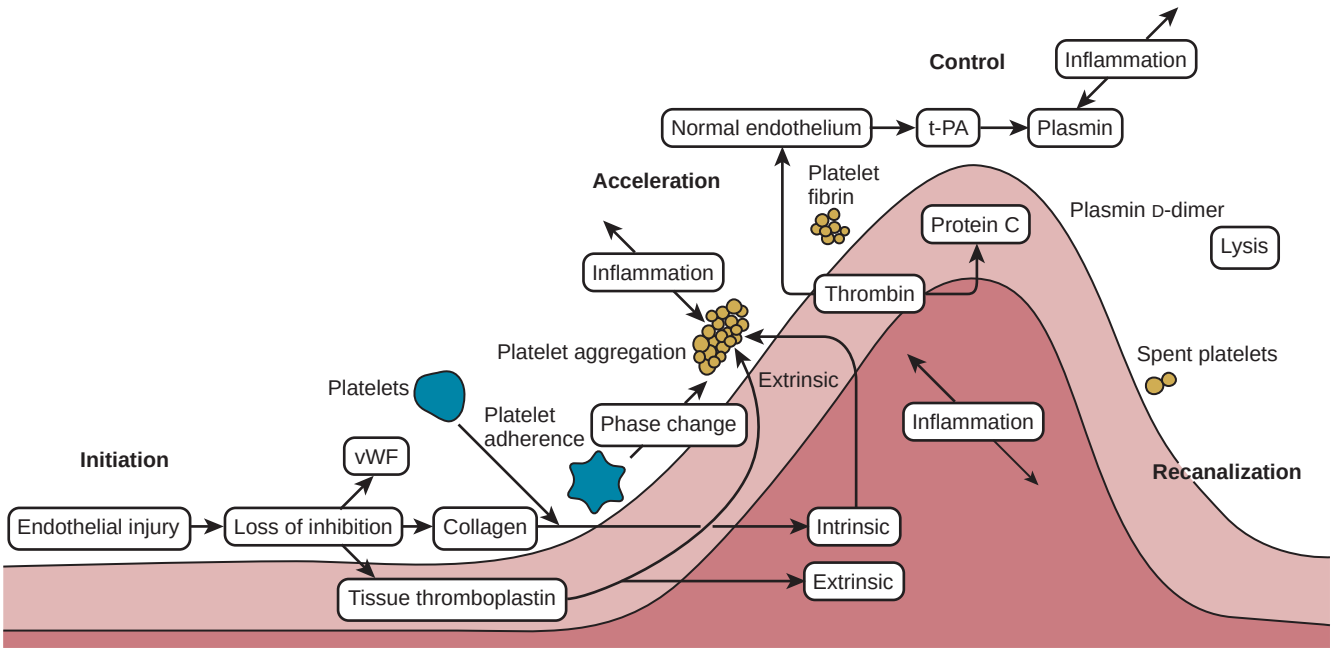

Fig. 35.1 Coagulation is a sine wave of activity at the site of tissue injury. It goes through four stages: initiation, acceleration, control, and lysis/recanalization. *t-PA,* Tissue plasminogen activator; *vWF,* von Willebrand factor. *(Redrawn from Spiess BD. Coagulation function and monitoring. In: Lichtor JL, ed.* Atlas of Clinical Anesthesia. *Philadelphia: Current Medicine; 1996.)*

Protein Coagulation Activations

Coagulation Pathways

The coagulation factors participate in a series of activating and feedback inhibition reactions, ending with the formation of an insoluble clot.[5] A *clot* is the sum total of platelet-to-platelet interactions, leading to the formation of a platelet plug (initial stoppage of bleeding). The cross-linking of platelets to each other by way of the final insoluble fibrin leads to a stable clot. Clot is not simply the activation of proteins leading to more protein deposition. Clinicians have been shaped in their thinking about coagulation by the historic way that coagulation proteins were discovered and the resulting coagulation tests (prothrombin time [PT] and activated thromboplastin time). It is that teaching of the coagulation cascade, with resultant monitoring technology, that has led to some transfusion behaviors. The way coagulation has been classically taught (separate protein cascades) is not the way coagulation proceeds biologically.

With few exceptions, the coagulation factors are glycoproteins (GPs) synthesized in the liver, which circulate as inactive molecules termed *zymogens.* Factor activation proceeds sequentially, each factor serving as substrate in an enzymatic reaction catalyzed by the previous factor in the sequence. Hence this reaction sequence classically has been termed a *cascade* or *waterfall.* Cleavage of a polypeptide fragment changes an inactive zymogen to an active enzyme often by creating a conformational change of the protein exposing an active site. The active form is termed a *serine protease* because the active site for its protein-splitting activity is a serine amino acid residue. Many reactions require the presence of calcium ion (Ca^{2+}) and a phospholipid surface (platelet phosphatidylserine). The phospholipids occur most often either on the surface of an activated platelet or endothelial cell and occasionally on the surface of white cells. So anchored, their proximity to one another permits reaction rates profoundly accelerated (up to 300,000-fold) from those measured when the enzymes remain in solution. The factors form four interrelated *arbitrary* groups (Fig. 35.2): the contact activation, intrinsic, extrinsic, and common pathways. They were so labeled historically by the human need for order. In biology, they are all highly interactive, occur simultaneously on the surface of cells, and have feedback loops with cross-reactions.

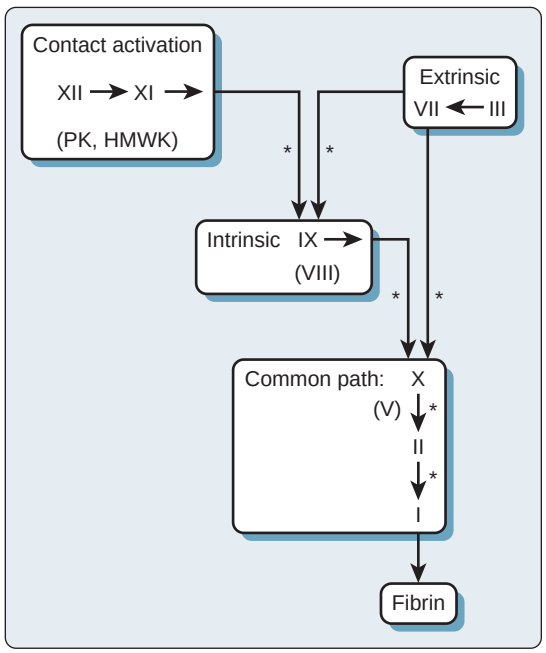

Fig. 35.2 Depiction of coagulation protein activation sequence. *Asterisks* denote participation of calcium ion. *HMWK,* High-molecular-weight kininogen; *PK,* prekallikrein.

When you look at the coagulation cascade with its multiple arrows, one cannot see which direction some reactions are flowing or which is the predominant reaction.

Contact Activation

Factor XII, high-molecular-weight kininogen (HMWK), prekallikrein (PK), and factor XI form the contact or surface activation group. The in vivo events that activate factor XII remain unconfirmed, because this seems to be built to recognize foreign surfaces. Clinicians do know that ex vivo contact with ionically charged surfaces will activate factor XII. Because factor XII autoactivates by undergoing a shape change in the presence of a negative charge, in vitro coagulation tests use glass, silica, kaolin, and other compounds with negative surface charge (see Chapter 19). The glycocalyx of endothelial cells has a repelling charge for coagulation proteins. One potential in vivo mechanism for factor XII activation is disruption of the endothelial cell layer, which exposes the underlying negatively charged collagen matrix. Activated platelets also provide negative charges on their membrane surfaces. HMWK anchors the other surface activation molecules, PK and factor XI, to damaged endothelium or activated platelets. Factor XIIa cleaves both factor XI, to form factor XIa, and PK, to form kallikrein. Fig. 35.3 depicts the events of surface activation.

This system interlinks to the complement cascade and fibrinolytic process as follows. Kallikrein converts HMWK to bradykinin, which activates the complement proteins. Kallikrein also may convert plasminogen to plasmin (see later). This latter function is quite weak, however, and of unknown significance in vivo.

It was rather tempting historically to attribute all coagulation abnormalities of cardiac surgery to activation of the contact system. This seemed an obvious explanation for the coagulopathy of CPB. The circuits are most often made of polyvinylchloride with a negatively charged surface. Today, it is known that the effects of contact activation in the entire scheme of CPB coagulation dysfunction are actually quite small. Of note, patients with completely absent factor XII do just fine and do not exhibit excess bleeding, nor are they particularly devoid of microvascular bleeding after CPB. Therefore the presence or absence of factor XII in the evolution of humankind seems to not be critical for survival. It also should reveal that the surface activation mechanism is not the driving force behind the bleeding/consumptive coagulopathy of CPB.

Intrinsic System

Intrinsic activation forms factor XIa from the products of surface activation. Factor XIa splits factor IX to form factor IXa, with Ca^{2+} required for this process. Then factor IXa activates factor X with help from Ca^{2+}, a phospholipid surface (platelet-phosphatidylserine), and a GP cofactor, factor VIIIa. Fig. 35.4 displays a stylized version of factor X activation. Please note that the phospholipids and GP cofactors are on the surface of platelets.

Extrinsic System

Activation of factor X can proceed independently of factor XII by substances classically thought to be extrinsic to the vasculature (hence the name). This is of historic interest because today it is known that the expression of tissue factor is actually a highly regulated event in endothelial cells. Any number of endothelial cell insults can lead to the production of tissue factor by the endothelial cell.[3–10] At rest, the endothelial cell is quite antithrombotic. However, with ischemia, reperfusion, sepsis, or cytokines (particularly interleukin [IL]-6), the endothelial cell will stimulate its production of intracellular nuclear factor-κB and send messages for the production of messenger RNA for tissue factor production.[6] This can happen quickly and the resting endothelial cell can turn out large amounts of tissue factor. It is widely held today that the activation of tissue factor is what drives many of the abnormalities of coagulation after cardiac surgery, rather than contact activation.[7,8] In some tissues, cells outside the vasculature contain large amounts of tissue factor. They are released when cells are damaged/ruptured. Thromboplastin, also known as tissue factor, released from

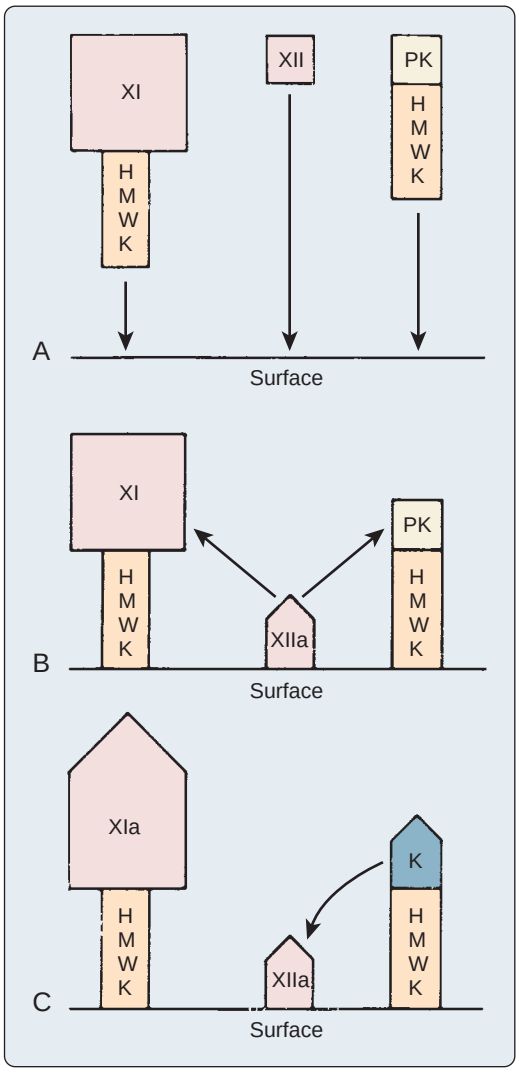

Fig. 35.3 (A–C) Activation of the contact factors XII, XI, and prekallikrein (PK). The cofactor, high-molecular-weight kininogen (HMWK), binds factor XI and PK to the endothelial surface. Kallikrein (K) amplifies factor XII activation. *(From Colman RW, Marder VJ, Salzman EW, Hirsh J. Overview of hemostasis. In: Colman RW, Hirsh J, Marder VJ, Salzman EW, eds.* Hemostasis and Thrombosis. *3rd ed. Philadelphia: JB Lippincott; 1994:3.)*

tissues into the vasculature, acts as a cofactor for initial activation of factor X by factor VII. Factors VII and X then activate one another with the help of platelet phospholipid and Ca^{2+}, thus rapidly generating factor Xa. (Factor VIIa also activates factor IX, thus linking the extrinsic and intrinsic paths.)

Thromboplastin straddles the extravascular cell membrane, with its extracellular portion available to bind factor VIIa. Cytokines (particularly tumor necrosis factor-α and IL-6) and endotoxins can stimulate its expression on endothelium.[9,10] Thromboplastin anchors factor VIIa to the cell surface, thus facilitating activation of factor X. The amount of available factor Va also seems to be quite important for the adequate functioning of the normal coagulation cascades.

Common Pathway

Using membrane phospholipids (phosphatidylserine) as a catalyst site, Ca^{2+} as a ligand, and factor Va as cofactor, factor Xa splits prothrombin (factor II) to thrombin (factor IIa). The combination of factors Xa, Va, and Ca^{2+} is termed the *prothrombinase complex*—a critical step. Factor Xa anchors to the membrane surface (of platelets) via Ca^{2+}. Factor Va, assembling next to it, initiates a rearrangement of the complex,

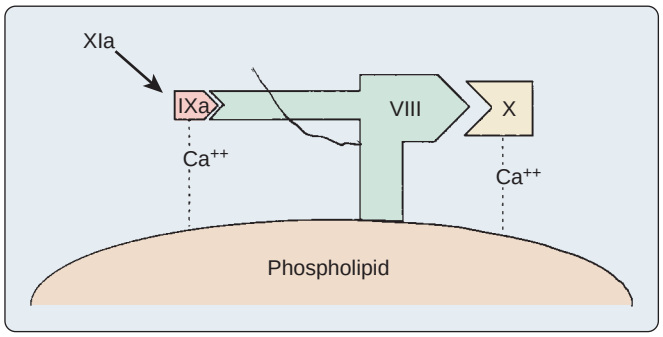

Fig. 35.4 Factor VIII facilitates the activation of factor X by factor IXa. Calcium tethers the molecules to the phospholipid surface. *(From Horrow JC: Desmopressin and antifibrinolytics.* Int Anesthesiol Clin. *1990;28:230.)*

vastly accelerating binding of the substrate, prothrombin. Most likely, the factor Xa formed from the previous reaction is channeled along the membrane to this next reaction step without detaching from the membrane.

Fig. 35.5 depicts the steps involved in formation of thrombin from its precursor, prothrombin. The by-product, fragment F1.2, serves as a plasma marker of prothrombin activation. An alternative scheme generates a different species, meizothrombin, involved more specifically in activation of coagulation inhibitors.[11]

Thrombin cleaves the fibrinogen molecule to form soluble fibrin monomer and polypeptide fragments termed *fibrinopeptides A* and *B*. Fibrin monomers associate to form a soluble fibrin matrix. Factor XIII, activated by thrombin, cross-links these fibrin strands to form an insoluble clot. Patients with lower levels of factor XIII have been found to have more bleeding after cardiac surgery.[11,12]

Vitamin K

Those factors that require calcium (II, VII, IX, X) depend on vitamin K to add between 9 and 12 γ-carboxyl groups to glutamic acid residues near their amino terminal. Calcium tethers the negatively charged carboxyl groups to the phospholipid surface (platelets), thus facilitating molecular interactions. Some inhibitory proteins also depend on vitamin K (proteins C and S) for their functional completion.

Modulators of the Coagulation Pathway

Thrombin, the most important coagulation modulator, exerts a pervasive influence throughout the coagulation factor pathways. It activates factors V, VIII, and XIII; cleaves fibrinogen to fibrin; stimulates platelet recruitment, creates chemotaxis of leukocytes and monocytes; releases t-PA, prostacyclin, and nitric oxide from endothelial cells; releases IL-1 from macrophages; and with thrombomodulin, activates protein C, a substance that then inactivates factors Va and VIIIa.[12] Note the negative feedback aspect of this last action (Fig. 35.6). Coagulation function truly centers on the effects of thrombin as far reaching accelerant. The platelets, tissue factor, and contact activation all are interactive and activated by a rent in the surface of the endothelium or through the loss of endothelial coagulation control. Platelets adhere to a site of injury and, in turn, are activated, leading to sequestration of other platelets. It is the interaction of all of those factors together that eventually creates a critical mass of reacting cells and proteins, which in turn, leads to clot formation. Once enough platelets are interacting together, with their attached surface concomitant serine protease reactions, then a thrombin burst is created. Only when enough thrombin activation has been encountered in a critical time point is a threshold exceeded, and the reactions become massive—much larger than the sum of the parts. It is thought that the concentration and ability of platelets to react fully affect the ability to have a critical thrombin burst. CPB may affect the ability to get that full thrombin burst because it reduces platelet number, decreases platelet-to-platelet interactions, and decreases the concentration of protein substrates.

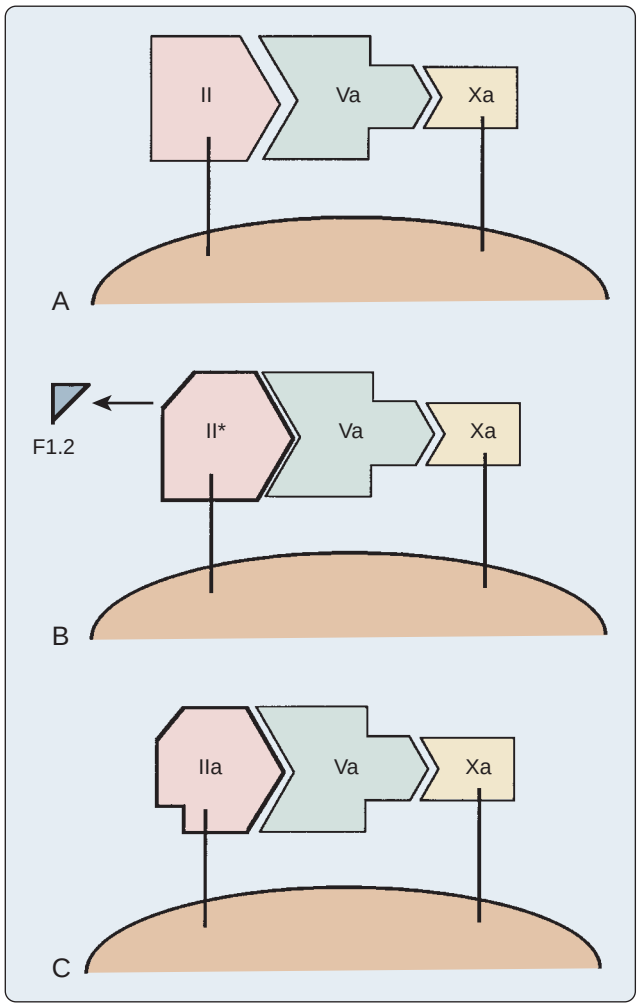

Fig. 35.5 Activation of prothrombin by factor Xa proceeds in a multistep fashion. (A) On the phospholipid surface, the prothrombinase complex consists of prothrombin (factor II), factor Xa, and factor Va. (B) The first activation step in which the prothrombin fragment F1.2 is split from prothrombin to form prethrombin (II*). (C) Molecular rearrangement of prethrombin yields thrombin.

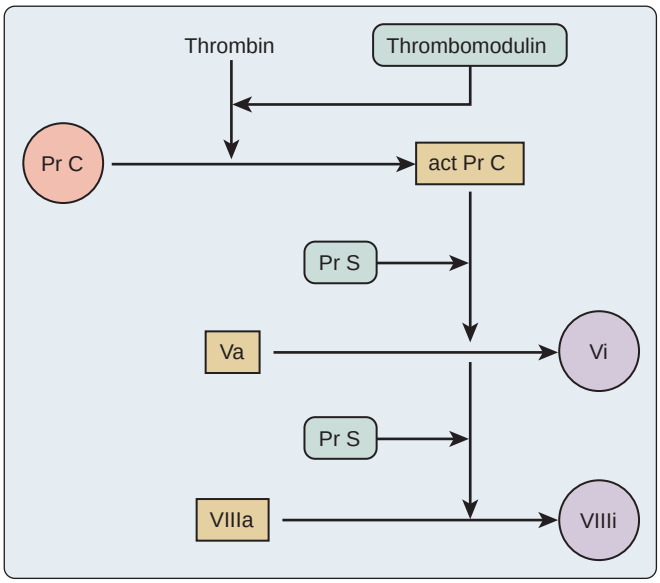

Fig. 35.6 Modulating effects of protein C on coagulation. Thrombomodulin from endothelial cells accelerates thrombin activation of protein C *(Pr C)*. In the presence of protein S *(Pr S)*, activated protein C [(act Pr C)a] inactivates factors V and VIII. Protein C and protein S are vitamin K dependent.

The many serine proteases that compose the coagulation pathways are balanced by serine protease inhibitors, termed *serpins*.[13] Thus a biologic yin and yang leads to an excellent buffering capacity. It is only when the platelet-driven thrombin burst so overwhelms the body's localized anticoagulation or inhibitors that clot proceeds forward. Serpins include α_1-antitrypsin, α_2-macroglobulin, heparin cofactor II, α_2-antiplasmin, antithrombin (AT; also termed *antithrombin III* [AT III]), and others.

AT III constitutes the most potent and widely distributed inhibitor of blood coagulation. It binds to the active site (serine) of thrombin, thus inhibiting action of thrombin. It also inhibits, to a much lesser extent, the activity of factors XIIa, XIa, IXa, and Xa; kallikrein; and the fibrinolytic molecule, plasmin. Thrombin bound to fibrin is protected from the action of AT, thus partially explaining the poor efficacy of heparin in treating established thrombosis. AT III is a relatively inactive zymogen. To be most effective, AT must bind to a unique pentasaccharide sequence contained on the wall of endothelial cells in the glycosaminoglycan surface known as heparan; the same active sequence is present in the drug heparin.

An important point is that activated AT III is active only against free thrombin (fibrin-bound thrombin cannot be seen by AT III).[14] Prothrombin circulates in the plasma but is not affected by heparin-AT III complexes; it is only thrombin, and thrombin does not circulate freely. Most thrombin in its active form is either bound to GP binding sites of platelets or in fibrin matrices. When blood is put into a test tube and clot begins to form (such as in an activated coagulation time [ACT]), 96% of thrombin production is yet to come. Most thrombin generation is on the surface of platelets and on clot-held fibrinogen. Platelets, through their GP binding sites and phospholipid folds, protect activated thrombin from attack by AT III. Therefore the biologic role of AT III is to create an anticoagulant surface on endothelial cells. It is not present biologically to sit and wait for a dose of heparin before CPB.

CPB dilutes AT III substantially, and the further consumption of AT III during CPB (thrombin generation) leads, in some patients, to profoundly low levels of this important inhibitor.[15] Research work adding AT III back to the CPB circuit has shown promise in that by doing so there is better preservation of serine protease proteins and platelets. The level of AT III on entry to the ICU, and probably over the first few days, has been shown to affect the risk of thrombotic events.[15-17] A large trial of added AT III to CPB is underway to assess whether supplementation will reduce thrombotic events without increasing bleeding. Congenital AT III deficiency can lead to in utero fetal destruction if the fetus is homozygous for the abnormal AT III. However, patients who are heterozygous for AT III abnormalities have about 40% to 60% of normal AT III activity. They have a particularly high risk for deep vein thrombosis. Low AT III levels have been described during extracorporeal membrane oxygenation, and the addition of AT III to the extracorporeal membrane oxygenation circuit has been effective in improving outcome and decreasing bleeding in some circumstances.[18] How useful it would be in which patients on CPB is not clear because only small trials have been performed, but these have been encouraging and a single larger trial is underway.[19,20] Both human AT III concentrate (harvested from multiple plasma donors and pasteurized) and a pharmaceutically engineered, goat milk–produced AT III (slightly different structure than human AT III) are commercially available.

Heparin cofactor II also inhibits thrombin, once it is activated. Although large doses of heparin activate heparin cofactor II, dermatans on endothelial cell surfaces activate it far more effectively, suggesting dermatans as alternative drugs to heparin.[21] Dermatan sulfates are not available for use today in the United States.

TABLE 35.1 The Coagulation Pathway Proteins, Minimal Amounts Needed for Surgery, and Replacement Sources

Factor	*Activated By*	*Acts On*	*Minimal Amount Needed*	*Replacement Source*	*Alternate Name and Comments*
XIII	IIa	Fibrin	<5%	FFP, CRYO	Fibrin-stabilizing factor; not a serine protease, but an enzyme
XII	Endothelium	XI	None	Not needed	Hageman factor; activation enhanced by XIIa
XI	XIIa	IX	15%–25%	FFP	Plasma thromboplastin antecedent
X	VIIa or IXa	II	10%–20%	FFP, 9C	Stuart-Prower factor; vitamin K dependent
IX	VIIa or XIa	X	25%–30%	FFP, 9C, PCC	Christmas factor; vitamin K dependent
VIII	IIa	X	>30%	CRYO, 8C, FFP	Antihemophilic factor; a cofactor; RES synthesis
VII	Xa	X	10%–20%	FFP, PCC	Serum prothrombin conversion accelerator; vitamin K dependent
V	IIa	II	<25%	FFP	Proaccelerin; a cofactor; RES and liver synthesis
IV	—	—	—	—	Calcium ion; binds II, VII, IX, X to phospholipid
III	—	X	—	—	Thromboplastin/tissue factor; a cofactor
II	Xa	I	20%–40%	FFP, PCC	Prothrombin; vitamin K dependent
I	IIa	—	1 g/L	CRYO, FFP	Fibrinogen; activated product is soluble fibrin
vWF	—	VIII	See VIII	CRYO, FFP	von Willebrand factor; endothelial cell synthesis

Unless otherwise specified, all coagulation proteins are synthesized in the liver. Note that there is no factor VI. For von Willebrand factor, cryoprecipitate or fresh frozen plasma (FFP) is administered to obtain a factor VIII coagulant activity >30%. *8C,* Factor VIII concentrate; *9C,* purified factor IX complex concentrate; *CRYO,* cryoprecipitate; *PCC,* prothrombin complex concentrate; *RES,* reticuloendothelial system.

Another serpin, *protein C,* degrades factors Va and VIIIa. Like other vitamin K–dependent factors, it requires Ca^{2+} to bind to phospholipid. Its cofactor, termed *protein S,* also exhibits vitamin K dependence. Genetic variants of protein C are less active and lead to increased risk for deep vein thrombosis and pulmonary embolism. When endothelial cells release thrombomodulin, thrombin then accelerates by 20,000-fold its activation of protein C[22] (see Fig. 35.6). Activated protein C also promotes fibrinolysis through a feedback loop to the endothelial cells to release t-PA.[23]

Regulation of the extrinsic limb of the coagulation pathway occurs via tissue factor pathway inhibitor (TFPI), a glycosylated protein that associates with lipoproteins in plasma.[24] TFPI is not a serpin. It impairs the catalytic properties of the factor VIIa–tissue factor complex on factor X activation. Both vascular endothelium and platelets appear to produce TFPI.[25,26] Heparin releases TFPI from endothelium, increasing TFPI plasma concentrations by as much as sixfold, which should be viewed as a biologic indicator of how poor heparin is as an anticoagulant. TFPI is not tested for in routine coagulation testing. It may be that some individuals with certain types of TFPI or who have very large amounts of circulating TFPI could be at risk for severe adverse bleeding after cardiac surgery.[27–32] This area is just beginning to be examined today both in terms of whether TFPI is responsible for abnormal bleeding and whether its genetic variants have abnormal bleeding or thrombosis.

von Willebrand factor (vWF), a massive molecule composed of disulfide-linked glycosylated peptides, associates with factor VIII in plasma, protecting it from proteolytic enzymes. It circulates in the plasma in its coiled inactive form.[33] Disruption of the endothelium either allows for binding of vWF from the plasma or allows for expression of vWF from tissue and from endothelial cells. Once bound, vWF uncoils to its full length and exposes a hitherto cryptic domain in the molecule. This A-1 domain has a very high affinity for platelet GPs. Initially, vWF attaches to the glycoprotein Iα (GPIα) platelet receptor, which slows the platelet forward movements against the shear forces of blood flow. Shear forces are activators of platelets. As the platelet's forward movement along the endothelial brush border is slowed (because of vWF attachment), shear forces actually increase; thus the binding of vWF to GP1 acts to provide a feedback loop for individual platelets, further activating them. The activation of vWF and its attachment to the platelet are not enough to bind the platelet to the endothelium, but it creates a membrane signal that allows for early shape change and expression of other GPs, GPIb, and GPIIb/IIIa. Then secondary GPIb binding connects to other vWF nearby, binding the platelet and beginning the activation sequence. It bridges normal platelets to damaged subendothelium by attaching to the GPIb platelet receptor. An ensuing platelet shape change then releases thromboxane, β-thromboglobulin, and serotonin, and exposes GPIIb/IIIa, which binds fibrinogen.

Deficiency States

Decreased amounts of coagulation proteins may be inherited or acquired. Deficiencies of each part of the coagulation pathway are considered in turn. Table 35.1 summarizes the coagulation factors, their activation sequences, and vehicles for factor replacement when deficient.

Contact Activation

Although decreased amounts of factor XII, PK, and HMWK can occur, these defects do not have clinical sequelae. The autosomal dominant deficiency of factor XI is very rare.[34] However, its incidence among Ashkenazi Jews is as high as 0.1% to 0.3%.[35] Most of these patients require factor replacement with fresh-frozen plasma (FFP) for surgery. Spontaneous bleeding does not occur, but increased bleeding after a surgical event or trauma is possible. Factor XI concentrations do not directly correlate with bleeding after trauma or surgery, suggesting that factor XI deficiency can be easily overcome by activation of platelets, factor IX, and other signaling mechanisms. An FFP dose of 10 mL/kg (700 mL or roughly 4 units of FFP) will yield target concentrations of only 20% activity, and it is often given for this rare deficiency. Note that the amount of FFP required to get to a 20% level might well dilute platelets and red cells and put complex cardiac patients into a fluid overload situation.

Intrinsic System

Hemophilia occurs worldwide, with a prevalence of 1 in 10,000. Hemophilia A, which constitutes about 80% to 85% of cases, originates from decreased activity of factor VIII. Because platelet function remains normal, minor cuts and abrasions do not bleed excessively. Joint and muscle hemorrhages ensue from minor trauma or, seemingly, spontaneously. Airway issues include epistaxis and obstruction from bleeding into the tongue. The bleeding time and prothrombin time (PT) remain normal, whereas the activated partial thromboplastin time (aPTT) is prolonged.[35] Desmopressin, a synthetic analog of vasopressin, will increase factor VIII activity by releasing vWF from endothelial cells, except in patients with severe hemophilia A who have too little functional factor VIII available for vWF.[36] Major surgery requires replenishment of factor VIII functional activity to greater than 80% of normal with FFP, cryoprecipitate (cryo), or factor VIII concentrate.[37] Factor VIII concentrate is the preferred method today. After surgery, factor VIII concentrations should be maintained greater than 30% for 2 weeks with repeat doses. Current plasma-derived concentrates are solvent detergent and heat-treated to remove lipid-coated viruses (human immunodeficiency virus [HIV], hepatitis B, human T-lymphotropic virus [HTLV]. However, this was not historically the case, and in Europe during the early parts of the HIV/acquired immune deficiency syndrome (AIDS) crisis, most individuals with hemophilia who contracted HIV/AIDS were exposed to it through

contaminated products. A recombinant product also is available but costs about three times that of the plasma-derived one.

Factor IX deficiency manifests as hemophilia B, constituting 15% to 20% of all hemophilia cases. Patients present with symptoms identical to those with hemophilia A. No study has demonstrated a salutary effect of desmopressin here. Prothrombin complex (factor IX) concentrates will replenish levels, but consumptive coagulopathy remains a possible complication, stemming from the presence of activated coagulation factors, principally factor VIIa, in the preparation.[38] Purified factor IX concentrate, a plasma-derived, solvent detergent and heat-treated product, currently constitutes the replacement vehicle of choice for patients with hemophilia B.[39] Recombinant pure factor IX concentrate will be available, but at considerable expense (factor VIIa is now available as well). Consultation with an experienced hematologist aids in the care of patients with hemophilia undergoing surgery.

Extrinsic System

Inheritance of factor VII deficiency follows an autosomal recessive pattern, with a prevalence of 1 in 500,000. Although factor VII deficiency may mimic hemophilia in presentation, most often, clinical bleeding is absent and surgery is well tolerated without replacement. The PT is elevated, whereas the PTT is normal. When necessary, replacement of factor VII levels to 10% to 20% of normal with FFP suffices.

Common Pathway

Deficiency of either factor V or factor X, both extremely rare autosomal recessive disorders, increases both the PT and PTT. The bleeding time is normal in factor X deficiency but prolonged in one-third of patients with factor V deficiency. The bleeding time prolongation arises from the role of factor V in platelet function.[40] Prothrombin complex concentrate (PCC) or FFP supplies prothrombin, factor V, and factor X. Numerous inherited abnormalities (polymorphisms) of prothrombin and fibrinogen occur, with varying characteristics. Cryoprecipitate, which contains 250 mg of fibrinogen and 100 units of factor VIII per 10-mL bag, as well as vWF and factor XIII, treats inherited or acquired disorders of fibrinogen. Many of the prothrombin and fibrinogen polymorphisms are associated with hypercoagulability and, perhaps, accelerated atherosclerosis rather than bleeding. Therefore they may be seen in CABG surgery that serves as a selection process for people with inherited hypercoagulability. There is no consensus yet on how to handle these cases in the OR.

Liver Disease

Hepatic compromise decreases the circulating amounts of factors II, VII, and X, but the level of factor IX is often normal. Decreases in factor V are variable. Factor VIII levels, in contrast, can reach as much as five times normal in acute hepatitis. Factors XIII, XII, and XI, HMWK, and PK suffer mild decreases. Administration of FFP restores these factors to normal levels. Liver disease also leads to decreases in the production of AT III and protein S. Therefore the buffering capacity of coagulation is thrown off. A small change in activation could, therefore, lead to a large and diffuse whole-body event such as consumptive coagulopathy.

Warfarin

Administration of this vitamin K antagonist affects plasma levels of factors II, VII, IX, and X, as well as proteins C and S.[41] Protein C has the shortest half-life, followed by factors VII (6 hours), IX (24 hours), X (2 days), and II (3 days).[42] Substantial PT prolongation and some aPTT prolongation accompany warfarin therapy. For immediate restoration of clotting function, FFP has been given in the past as the standard of care. Today, the recommendation is for the use of a PCC (20–25 μg/kg) or factor VIIa (20 μg/kg) as pharmaceuticals.[42-44] Studies have shown that these create immediate reversal and the normalization of coagulation function that lasts at least 24 hours. There is no reason why these agents cannot be given prior to CPB or even during full heparinization on CPB. The use of PCC will not reverse heparin's effect, nor will it make the patient intrinsically hypercoagulable. Thus if a patient comes to the OR with a prolonged INR and has been taking warfarin up until surgery, reversal can be immediate and blood loss during the dissection phase before CPB can be reduced. Physicians appear concerned about giving a PCC, but it will not in itself make the patient intrinsically hypercoagulable. The contents of the available 4 protein PCCs are shown in Table 34.3. These have been available in Europe for a number of years but are just now being adopted across the United States.

Parenteral vitamin K or cessation of warfarin suffices if the patient has several days before surgery. Clinicians should be extremely careful in administering these compounds if a patient is suspected of having heparin-induced thrombocytopenia (HIT). Treatment with commercially available factor VIIa or PCC restores PT to normal and appears to stop bleeding when warfarin therapy has not had time to be reversed. The use of factor VIIa or PCC for this intervention before surgery is effective and, perhaps, worthwhile because it avoids the use of FFP (very real risk for TRALI). The time scale of factor VIIa or PCC effectiveness may not be as long as if one normalized circulating levels through FFP administration, but that has not been studied. It makes sense, therefore, that if the PT is prolonged again approximately 8 to 12 hours after a dose of factor VIIa or PCC, redosage of the drugs could be given.

Inherited Thrombotic Disorders

A number of genetic abnormalities lead to thrombosis. The most prevalent (2%–5%) in European-derived populations is factor V Leiden, in which a point mutation at residue 1691 on factor V renders it resistant to inactivation by activated protein C. Venous thromboembolism risk increases sevenfold in heterozygotes and 80-fold in homozygotes, but episodes are less severe than in other thrombotic disorders. Pregnancy and oral contraceptives greatly exacerbate the thrombotic tendency.

Congenital AT III deficiency (1:1000 patients) causes venous thromboembolism and heparin resistance. This autosomal dominant disorder involves three types: absence of AT (type I), dysfunctional AT (type II), and AT with dysfunction limited to a reduced response to heparin (type III). Clinical presentation begins at age 15 or later, with venous thrombosis occurring with surgery, pregnancy, or bed rest. Replacement AT III is now available for use in the United States.

Protein C or S deficiencies, if homozygous, present at birth as neonatal purpura fulminans. Protein C deficiency heterozygotes demonstrate 40% to 60% protein C activity and present with venous thrombosis beginning in adolescence. The role of reduced concentrations of protein S in causing thrombosis has come into question. Together, deficiencies of AT, protein C, and protein S account for 10% to 15% of inherited thrombosis.[45]

Deficiency of heparin cofactor II is rare. Its role in thrombosis is uncertain. Other conditions that cause thrombosis are dysfibrinogenemia with lysis-resistant fibrinogen, plasminogen deficiency, t-PA deficiency, excess plasminogen activator inhibitor 1 activity (plasminogen activator inhibitor 1 inhibits t-PA), and homocysteinemia.

Homocysteinemia is the mild heterozygous state of cystathione β-synthetase deficiency, known as homocystinuria in its more serious homozygous form. Increased plasma concentrations of homocysteine induce endothelial cell tissue factor activity, stimulate factor V activation, and impair protein C activation, all of which contribute to thrombosis. Folic acid and vitamins B_6 and B_{12} reduce homocysteine plasma concentrations.[46] AT has been used to treat homocystinuria and its thrombosis situations as well. Elevated homocysteine levels prior to CABG surgery makes these patients particularly hypercoagulable.[47]

Platelet Function

Most clinicians think first of the coagulation proteins when considering hemostasis. Although no one element of the many that participate in hemostasis assumes dominance, platelets may be the most complex.[48,49] Without platelets, there is no coagulation and no hemostasis, so it could be argued that they are most important. Without the proteins, there is hemostasis, but it lasts only about 10 to 15 minutes because the platelet plug is inherently unstable and breaks apart under the shear stress of the vasculature. Platelets provide phospholipid for

coagulation factor reactions; contain their own micro-skeletal system and release coagulation factors; secrete active substances affecting themselves, other platelets, the endothelium, and other coagulation factors; and alter shape (through active actin-myosin contraction) to expose membrane GPs essential to hemostasis. Their cell signaling is highly regulated, is present in other cell lines (RBCs, leukocytes, and endothelial cells), and has been intensively studied. Platelets have perhaps as many as 30 to 50 different types of cell receptors, with many ways of these being activated and inhibited.

The initial response to vascular injury is formation of a platelet plug. Good hemostatic response depends on proper functioning of platelet adhesion, activation, and aggregation. This section first discusses these aspects and then follows with the effects of platelet disorders and platelet-inhibiting pharmaceuticals. Clinicians talk about platelet dysfunction, which is largely overarching and grossly too general a term. The complexity that is platelet function really needs careful study.

Platelet Adhesion

Capillary blood exhibits laminar flow, which maximizes the likelihood of interaction of platelets with the vessel wall. Red cells and white cells stream near the center of the vessels and marginate platelets. However, turbulence causes reactions in endothelium that lead to the secretion of vWF, adhesive molecules, and tissue factor. Shear stress is high as fast-moving platelets interact with the endothelium. When the vascular endothelium becomes denuded or injured, the platelet has the opportunity to contact vWF, which is bound to the exposed collagen of the subendothelium. A platelet membrane component, GPIb, attaches to vWF, thus anchoring the platelet to the vessel wall. Independently, platelet membrane GPIa and GPIIa and IX may attach directly to exposed collagen, furthering the adhesion stage.[49–51]

After activation (see later), additional adhesive mechanisms come into play. Release of selectin GPs from α-granules allows their membrane expression, thus promoting platelet-leukocyte adhesion. This interaction ultimately may allow expression of tissue factor on monocytes, thus amplifying coagulation.[51]

The integrin GPs form diverse types of membrane receptors from combinations of 20 α and 8 β subunits.[52,53] One such combination is GPIIb/IIIa, a platelet membrane component that initially participates in platelet adhesion. Platelet activation causes a conformational change in GPIIb/IIIa, which results in its aggregator activity.

Platelet adhesion begins rapidly—within 1 minute of endothelial injury—and completely covers exposed subendothelium within 20 minutes.[50] It begins with decreased platelet velocity when GPIb/IX and vWF mediate adhesion, followed by platelet activation, GPIIb/IIIa conformational change, then vWF binding and platelet arrest on the endothelium at these vWF ligand sites.[49,51]

Adhesion requires margination of platelets; high hematocrits concentrate RBCs in the central regions of a vessel, promoting marginal placement of platelets. Dilute hematocrit (eg, post-CPB) impairs this effect, thus adversely affecting platelet adhesion. Low hematocrit also may affect platelet prostaglandin levels because RBCs are required for preprocessing of arachidonic acid before platelets make thromboxane. Because of rheology, RBC transfusions have been thought by some to improve hemostasis. However, transfusion should not be used primarily to achieve this goal because RBC concentrates carry a high concentration of cytokines and platelet-activating factor, which may contribute to platelet dysfunction or consumptive coagulopathy. Some of the most recent data-based studies looking at only several units of blood transfusion have noted that when transfusion is used, the postoperative chest tube output is greater. That finding is, however, fundamentally different from the observation that if a patient is bleeding and has a particularly low hematocrit, the use of RBCs may well increase margination of platelets.

Platelet Activation and Aggregation

Platelet activation results after contact with collagen, when adenosine diphosphate (ADP), thrombin, or thromboxane A_2 binds to membrane receptors, or from certain platelet-to-platelet interactions. Platelets then release the contents of their dense (δ) granules and α granules. Dense granules contain serotonin, ADP, and Ca^{2+}; α granules contain platelet factor V (previously termed platelet factor 1), β-thromboglobulin, platelet factor 4 (PF4), P-selectin, and various integrin proteins (vWF, fibrinogen, vitronectin, and fibronectin). Simultaneously, platelets use their microskeletal system to change shape from a disk to a sphere, which changes platelet membrane GPIIb/IIIa exposure. Released ADP recruits additional platelets to the site of injury and stimulates platelet G protein, which in turn, activates membrane phospholipase. This results in the formation of arachidonate, which platelet cyclooxygenase converts to thromboxane A_2. Other platelet agonists besides ADP and collagen include serotonin, a weak agonist, and thrombin and thromboxane A_2, both potent agonists. Thrombin is by far the most potent platelet agonist, and it can overcome all other platelet antagonists, as well as inhibitors. In total, more than 70 agonists can produce platelet activation and aggregation.

Agonists induce a graded platelet shape change (the amount based on the relative amount of stimulation), increase platelet intracellular Ca^{2+} concentration, and stimulate platelet G protein. In addition, serotonin and thromboxane A_2 are potent vasoconstrictors (particularly in the pulmonary vasculature). The presence of sufficient agonist material results in platelet aggregation. Aggregation occurs when the integrin proteins (mostly fibrinogen) released from α granules form molecular bridges between the GPIIb/IIIa receptors of adjacent platelets (the final common platelet pathway).

Platelet Disorders

Dysfunctional vWF produces von Willebrand disease (vWD), an autosomal dominant disorder of variable expressivity.[36,54] With an incidence of 1.4 to 5 cases per 1000 population, vWD is the most common inherited coagulopathy. Patients present with mucocutaneous hemorrhages rather than hemarthroses. Common symptoms include epistaxis, ecchymoses, and excessive bleeding after trauma, with surgery, or during menses. Because vWF concentrations vary greatly with time, symptoms have variable expressivity. Desmopressin reverses the prolonged bleeding time in patients with mild vWD.[55] As with hemophilia A, severe cases of vWD do not benefit from desmopressin therapy. In one rare class of vWD (type IIB, 3%–5% of vWD), desmopressin aggregates platelets, inducing thrombocytopenia and worsening rather than helping hemostasis. Table 35.2 summarizes features of the more common types of vWD. When blood products are needed, cryoprecipitate constitutes the replacement vehicle of choice in vWD, although recent factor VIII concentrates retain vWF activity and have been used successfully during cardiac surgery.

The addition of agonist (ADP or collagen) to platelets allows measurement of platelet aggregation in vitro. In Glanzmann thrombasthenia, the GPIIb/IIIa receptor is absent, preventing aggregation. However, ristocetin, a cationic antibiotic similar to vancomycin, can agglutinate platelets directly via GPIb receptors and vWF. Absence of the GPIb receptor, Bernard–Soulier syndrome, prevents adhesion and agglutination with ristocetin, but aggregation to ADP is normal, because the GPIIb/IIIa receptor is intact. Patients with vWD also exhibit impaired platelet adhesion and normal aggregation. Decreased amounts of vWF antigen distinguish it from the Bernard–Soulier syndrome. In platelet storage pool deficiency, impairment of dense granule secretion yields no ADP on adhesion. In vitro addition of collagen will not aggregate platelets because of absence of ADP release, whereas added ADP will initiate some aggregation. Table 35.3 summarizes these diagnostic findings. Uremia impairs the secretory and aggregating functions of platelets, resulting in an increased bleeding time. However, the most common effect of renal dysfunction is hypercoagulability. It is only with severe uremia that the platelets are poisoned. It is, therefore, a common misconception in the OR that a patient with mild-to-moderate renal failure will be at increased risk for bleeding. The utilization of thromboelastography (TEG) can help in deciding whether the extent of renal failure is causing hypocoagulability. The cause and clinical significance remain poorly defined (see Chapter 19).

TABLE 35.2 Major Types of von Willebrand Disease

Classification	*Prevalence Rate*	*vWf:Ag*	*R:Co*	*Molecular Pathology*
I (Classic)	70%–80%	Decreased	Decreased	Normal multimers; decreased quantity
IIA	10%–12%	Decreased	Decreased	Intermediate and large multimers decreased
IIB	3%–5%	Decreased	Near normal	Abnormal, large multimers that bind platelets
III	1%–3%	None	None	No vWF present
Platelet-type	0%–1%	Decreased	Decreased	Normal vWF; platelet glycoprotein Ib receptors bind large multimers

Prostaglandins and Aspirin

Endothelial cell cyclooxygenase synthesizes prostacyclin, which inhibits aggregation and dilates vessels. Platelet cyclooxygenase forms thromboxane A_2, a potent aggregating agent and vasoconstrictor. Aspirin irreversibly acetylates cyclooxygenase, rendering it inactive. Low doses of aspirin, 80 to 100 mg, easily overcome the finite amount of cyclooxygenase available in the nucleus-free platelets. However, endothelial cells can synthesize new cyclooxygenase. Thus with low doses of aspirin, prostacyclin synthesis continues, whereas thromboxane synthesis ceases, decreasing platelet activation and aggregation. High doses of aspirin inhibit the enzyme at both cyclooxygenase sites.[53]

Reversible platelet aggregation is blocked by aspirin, as the platelet cyclooxygenase is inhibited. However, the more powerful agonists that yield the calcium release response can still aggregate and activate platelets, because cyclooxygenase is not required for those pathways (Fig. 35.7).

In many centers, a majority of the patients presenting for CABG will have received aspirin within 7 days of surgery in hopes of preventing coronary thrombosis.[56–59] Platelets have a life span of approximately 9 days, so the idea of taking somebody off aspirin for 5 to 7 days seems reasonable in that the majority of platelets circulating will not have cyclooxygenase poisoned by aspirin. Aspirin is a drug for which an increased risk for bleeding often has been demonstrated.[60] Although most early research studies stated that aspirin leads to increased bleeding, since the mid-1990s, that early impression has not been confirmed. Today, it probably is more likely that, in some patients, a mild-to-moderate increased risk for bleeding is possible.

Unfortunately, most of the early studies of aspirin were not blinded, and it may be that the pervading belief that aspirin caused increased bleeding was actually self-fulfilling. Since the early 1990s, there have been a number of therapeutic changes, including use of lower doses and greater use of antifibrinolytics. These changes alone may have decreased the overall risk for bleeding from aspirin. Follow-up prospective studies have, thus, yielded varied results. In the largest cohort of 772 men, aspirin increased bleeding after CABG by 33%,[59] and a group of 101 aspirin-taking patients bled 25% to 56% more than a control group.[60] In another study, the need to explore the mediastinum for excessive bleeding nearly doubled (factor of 1.82) in patients taking aspirin.[61] However, many other studies have not shown increased bleeding with aspirin.[62–67] Although a single aspirin can irreversibly inhibit platelet cyclooxygenase for the life of the platelet, aspirin-related bleeding after surgery usually requires more extensive exposure to the drug. Early use of aspirin after CABG surgery has been shown to decrease thrombosis and infarction.[67]

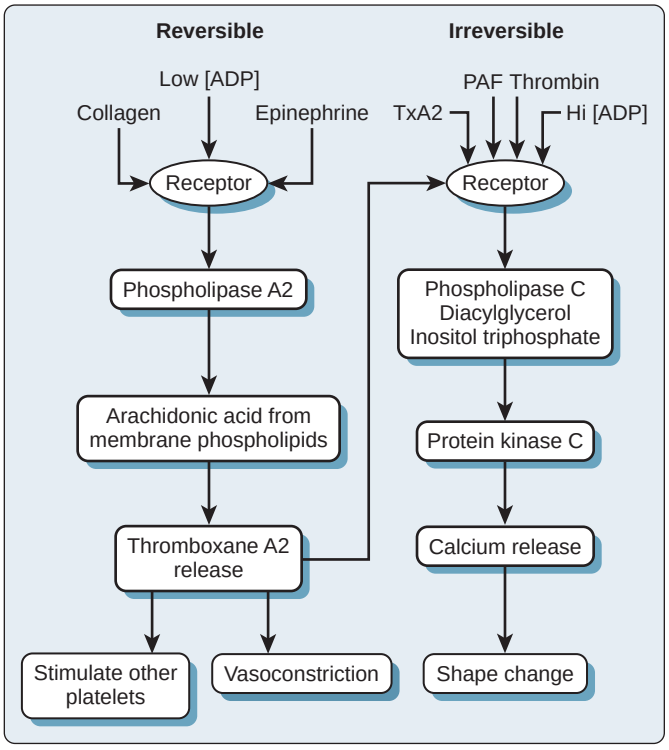

Fig. 35.7 Pathways for reversible *(left column)* and irreversible *(right column)* platelet aggregation. Note the different agents that activate distinct receptors. Aspirin inhibits reversible platelet aggregation via the phospholipase A_2 pathway by affecting the arachidonic acid enzyme cyclooxygenase, but it does not prevent more powerful agonists from aggregating platelets by directly stimulating phospholipase C pathway receptors. *(Adapted from Kroll MH, Schafer A: Biochemical mechanisms of platelet activation.* Blood. *1989;74:1181.)*

Drug-Induced Platelet Abnormalities

Many other agents inhibit platelet function. β-Lactam antibiotics coat the platelet membrane, whereas the cephalosporins are rather profound but short-term platelet inhibitors.[68] Many cardiac surgeons may not realize that their standard drug regimen for antibiotics may be far more of a bleeding risk than aspirin. Hundreds of drugs can inhibit platelet function. Calcium channel blockers, nitrates, and β-blockers are ones commonly used in cardiac surgery. Nitrates are effective

antiplatelet agents, and that may be part of why they are of such benefit in angina, not only for their vasorelaxing effect on large blood vessels. Nonsteroidal antiinflammatory drugs reversibly inhibit both endothelial cell and platelet cyclooxygenase. In addition, anecdotal reports of platelet inhibition, without clear confirmatory studies, exist for many pharmaceuticals, including dextran, and for innumerable foods (eg, onion, garlic, alcohol) and spices (eg, ginger, turmeric, cloves).[26]

Rofecoxib (Vioxx), a cyclooxygenase 2 (COX-2) inhibitor, was withdrawn from the US market because of its cardiovascular risk profile (a small increase in associated acute myocardial infarctions).[69] This COX-2 inhibitor has the highest selectivity for COX-2 versus COX-1 and thus leads to an imbalance between thromboxane A_2 and prostacyclin production. The other COX-2 inhibitors are currently also undergoing cardiovascular investigation.

In addition to the partial inhibitory effects of aspirin and the other drugs mentioned earlier, new therapies that inhibit platelet function in a more specific manner have been developed. These drugs include platelet adhesion inhibitor agents, platelet-ADP-receptor antagonists, and GPIIb/IIIa receptor inhibitors (Table 35.4).[70]

Adhesion Inhibitors

Dipyridamole (Persantine) and cilostazol (Pletal) alter platelet adhesion by various mechanisms, including cyclic adenosine monophosphate, phosphodiesterase III, and thromboxane A_2 inhibition. Dipyridamole has been used with warfarin in some patients with artificial valves and with aspirin in patients with peripheral vascular disease.

Adenosine Diphosphate Receptor Antagonists

Clopidogrel (Plavix), prasugrel (Effient), and ticlopidine (Ticlid) are thienopyridine derivatives that inhibit the ADP receptor pathway to platelet activation. They have a slow onset of action because they must be converted to active drugs, and their potent effects last the lifetime of the platelets affected (5–10 days). Clopidogrel and prasugrel are the preferred drugs. They are administered orally once daily to inhibit platelet function and are quite effective in decreasing myocardial infarctions after percutaneous coronary interventions (see Chapter 3). The combination of aspirin and clopidogrel has led to increased bleeding but is sometimes used in an effort to keep vessels and stents open. Recently, two new nonthienopyridine ADP P_2Y_{12} inhibitors have become available. Ticagrelor is a direct-acting oral drug, and cangrelor is a short-acting intravenous agent. The latter drug may be a very valuable bridging drug for use in the PCI laboratory and perioperative period.[71] The TEG and now the RoTEM (a modified TEG) with ADP or other additives can be used to determine the degree of inhibition caused by these drugs. Other new tests are coming onto the market to allow testing for relative platelet inhibition caused by thienopyridines. Some of these are modifications of platelet flow cytometry or automated platelet aggregometers. Verify Now (Accumetrics, San Diego, CA) and the PFA-100 (Siemens USA, Deerfield, IL) have been used in dosing clopidogrel for cardiology procedures. These platelet function tests are now finding their way into hospitals, and some facilities are starting to use them before or after surgery.[72–78] In at least one study, the use of the Verify Now P_2Y_{12} test has been shown to have predictive value for early graft thrombosis.[79] Modification of the TEG with platelet mapping have been used to define the amount of platelet inhibition by aspirin and P_2Y_{12} antagonists[80–84] (see Chapter 19).

Glycoprotein IIb/IIIa Receptor Inhibitors

GPIIb/IIIa receptor inhibitors are the most potent (>90% platelet inhibition) and important platelet inhibitors because they act at the final common pathway of platelet aggregation with fibrinogen, no matter which agonist began the process. All of the drugs mentioned earlier work at earlier phases of activation of platelet function. These drugs are all administered by intravenous infusion, and they do not work orally. The GPIIb/IIIa inhibitors often are used in patients taking aspirin because they do not block thromboxane A_2 production. The dose of heparin usually is reduced when used with these drugs (ie, percutaneous coronary intervention to avoid bleeding at the vascular puncture sites). Platelet activity can be monitored to determine the extent of blockade. Excessive bleeding requires allowing the short-acting drugs to wear off, while possibly administering platelets to patients receiving the long-acting drug abciximab (see Table 35.4). Most studies have found increased bleeding in patients receiving these drugs who required emergency CABG.

Vascular Endothelium

The cells that form the intima of vessels provide an excellent nonthrombogenic surface. Characteristics of this surface, which may account for its nonthrombogenicity, include negative charge; incorporation of heparan sulfate in the grid substance; the release of prostacyclin, nitric oxide, adenosine, and protease inhibitors by endothelial cells; binding and clearance of activated coagulation factors both directly, as occurs with thrombin, and indirectly, as evidenced by the action of

TABLE 35.4 Antiplatelet Therapy

Drug Type	*Composition*	*Mechanism*	*Indications*	*Route*	*Half-Life*	*Metabolism*
Aspirin	Acetylsalicylic acid	Irreversible COX inhibition	CAD, AMI, PVD, PCI, ACS	Oral	10 days	Liver, kidney
NSAIDs	Multiple	Reversible COX inhibition	Pain	Oral	2 days	Liver, kidney
Adhesion inhibitors (eg, dipyridamole)	Multiple	Block adhesion to vessels	VHD, PVD	Oral	12 hours	Liver
ADP receptor antagonists						
-Clopidogrel (Plavix), prasugrel (Effient)	Thienopyridines	Irreversible	AMI, CVA, PVD, ACS, PCI	Oral	5 days	Liver
-Ticagrelor (Brilinta)	Nonthienopyridine	Reversible	AMI, CVA, PVD, ACS, PCI	Oral	3–5 days	Liver
-Cangrelor (Kengreal)	Nonthienopyridine	Reversible	AMI, CVA, PVD, ACS, PCI	IV	3–5 min	Blood
PAR-1 inhibitors						
-Vorapaxar (Zontivity)	PAR-1 antagonist	Irreversible—inhibits thrombin-induced platelet activation	AMI, PVD	Oral	20 hr–4 wk	Liver
GPIIb/IIIa receptor inhibitors						
Abciximab (ReoPro)	Monoclonal antibody	Nonspecific—binds to other receptors	PCI, ACS	IV	12–18 hours	Plasma proteinase
Eptifibatide (Integrilin)	Peptide	Reversible—specific to GPIIb/IIIa	PCI, ACS	IV	2–4 hours	Kidney
Tirofiban (Aggrastat)	Nonpeptide-tyrosine derivative	Reversible—specific to GPIIb/IIIa	PCI, ACS, AMI, PVD	IV	2–4 hours	Kidney

ACS, Acute coronary syndrome; *AMI*, acute myocardial infarction; *CAD*, coronary artery disease; *COX*, cyclooxygenase; *CVA*, cerebrovascular disease; *IV*, intravenous; *NSAID*, nonsteroidal antiinflammatory drug; *PAR-1*, protease-activated receptor; *PCI*, percutaneous coronary intervention; *PVD*, peripheral vascular disease; *VHD*, valvular heart disease.

thrombomodulin to inactivate factors Va and VIIIa via protein C; and stimulation of fibrinolysis.

Nitric oxide vasodilates blood vessels and inhibits platelets. Its mechanism involves activation of guanylate cyclase with eventual uptake of calcium into intracellular storage sites. Prostacyclin (prostaglandin I_2) possesses powerful vasodilator and antiplatelet properties. Endothelium-derived prostacyclin opposes the vasoconstrictor effects of platelet-produced thromboxane A_2. Prostacyclin also inhibits platelet aggregation, disaggregates clumped platelets, and at high concentrations, inhibits platelet adhesion. Prostacyclin increases intracellular concentrations of cyclic adenosine monophosphate, which inhibits aggregation. Thromboxane acts in an opposite manner. The mechanism of prostacyclin action is stimulation of adenylyl cyclase, leading to reduced intracellular calcium concentrations. Some vascular beds (eg, lung) and atherosclerotic vessels secrete thromboxane, endothelins, and angiotensin, all vasoconstrictors, as well as prostacyclin. Activation of platelets releases endoperoxides and arachidonate. These substances, used by nearby damaged endothelial cells, provide substrate for prostacyclin production.[5]

The endothelial cell also participates in coagulation factor activation. Playing a role similar to that of platelet phospholipid, the endothelial surface facilitates activation of factor IX. Thrombospondin, a substance formed in endothelial cells and platelets, helps complete platelet aggregation and binds plasminogen. The latter effect decreases the amount of locally available plasmin, thus inhibiting fibrin breakdown.

Fibrinolysis

Fibrin breakdown, a normal hematologic activity, is localized to the vicinity of a clot. It remodels formed clot and removes thrombus when endothelium heals. Like clot formation, clot breakdown may occur by intrinsic and extrinsic pathways. As with clot formation, the extrinsic pathway plays the dominant role in clot breakdown. Each pathway activates plasminogen, a serine protease synthesized by the liver, which circulates in zymogen form. Cleavage of plasminogen by the proper serine protease forms plasmin. Plasmin splits fibrinogen or fibrin at specific sites. Plasmin is the principal enzyme of fibrinolysis, just as thrombin is principal to clot formation. Plasma normally contains no circulating plasmin because a scavenging protein, α_2-antiplasmin, quickly consumes any plasmin formed from localized fibrinolysis. Thus localized fibrinolysis, not systemic fibrinogenolysis, accompanies normal hemostasis.

Extrinsic Fibrinolysis

Endothelial cells synthesize and release t-PA. Both t-PA and a related substance, urokinase plasminogen activator, are serine proteases that split plasminogen to form plasmin. The activity of t-PA magnifies on binding to fibrin. In this manner, also, plasmin formation remains localized to sites of clot formation. Epinephrine, bradykinin, thrombin, and factor Xa cause endothelium to release t-PA, as do venous occlusion and CPB.[85] Fibrinolysis during and after CPB is discussed later.

Intrinsic Fibrinolysis

Factor XIIa, formed during the contact phase of coagulation, cleaves plasminogen to plasmin. The plasmin so formed then facilitates additional cleavage of plasminogen by factor XIIa, forming a positive feedback loop. Kallikrein also can activate plasminogen; the physiologic importance of this pathway for fibrin breakdown has not been established.

Exogenous Activators

Streptokinase (made by bacteria) and urokinase (found in human urine) both cleave plasminogen to plasmin but do so with low fibrin affinity. Thus systemic plasminemia and fibrinogenolysis, as well as fibrinolysis, ensue. Acetylated streptokinase plasminogen activator complex provides an active site, which is not available until deacetylation occurs in blood. Its systemic lytic activity lies intermediate to those of t-PA and streptokinase. Recombinant t-PA (Alteplase) is a second-generation agent that is made by recombinant DNA technology and is relatively fibrin specific.

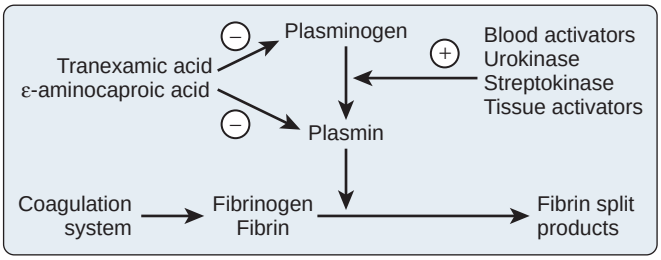

Fig. 35.8 The fibrinolytic pathway. Antifibrinolytic drugs inhibit fibrinolysis by binding to both plasminogen and plasmin. Intrinsic blood activators (factor XIIa), extrinsic tissue activators (tissue plasminogen activator, urokinase plasminogen activator), and exogenous activators (streptokinase, acetylated streptokinase plasminogen activator complex) split plasminogen to form plasmin. *(From Horrow JC, Hlavacek J, Strong MD, et al: Prophylactic tranexamic acid decreases bleeding after cardiac operations.* J Thorac Cardiovasc Surg. *1990;99:70.)*

Clinical Applications

Fig. 35.8 illustrates the fibrinolytic pathway, with activators and inhibitors. Streptokinase, acetylated streptokinase plasminogen activator complex, and t-PA find application in the lysis of thrombi associated with myocardial infarction. These intravenous agents "dissolve" clots that form on atheromatous plaque. Clinically significant bleeding may result from administration of any of these exogenous activators or streptokinase.[86]

Fibrinolysis also accompanies CPB. This undesirable breakdown of clot after surgery may contribute to postoperative hemorrhage and the need to administer allogeneic blood products. Regardless of how they are formed, the breakdown products of fibrin intercalate into sheets of normally forming fibrin monomers, thus preventing cross-linking. In this way, extensive fibrinolysis exerts an antihemostatic action. Factor XIII is an underappreciated coagulation protein. It circulates and, when activated, cross-links fibrin strands and protects fibrin from the lytic actions of plasmin. It has been known for some time that low levels of factor XIII are associated with increased hemorrhage after CPB. Factor XIII levels are reduced by hemodilution, but it also appears that there is active destruction in some patients with CPB. Several new studies have begun testing adding factor XIII to patients and assessing bleeding.[87–89] The problem, however, is that currently there is no good way to assess factor XIII levels. Clearly, factor XIII will be quite expensive, and using it for most patients may well be ill advised.

Heparin

In 1916, in the course of experiments to determine whether the phospholipid component of cephalin caused clotting, a second-year medical student, Jay McLean, instead discovered a substance derived from liver that prolonged coagulation.[90] His mentor, William Howell, named this substance *heparin* (after *hepatic* for "liver"). Heparin has been used almost exclusively as the anticoagulant for CPB for more than 50 years.

Pharmacology

Chemical Structure

In the 1920s, Howell's group isolated heparin and identified it as a carbohydrate containing glucuronic acid residues. In the 1930s, Jorpes demonstrated a hexosamine component to heparin (glucosamine, in particular) that is present in a ratio of 1:1 with glucuronic acid. Of greater importance, he discovered that heparin contains many sulfate groups—two per uronic acid residue—making it one of the strongest acids found in living things. In the 1950s, Jorpes' group identified the sulfate groups at the N-position on glucosamine, where solely acetyl groups previously were thought to reside. In the 1960s, they corrected

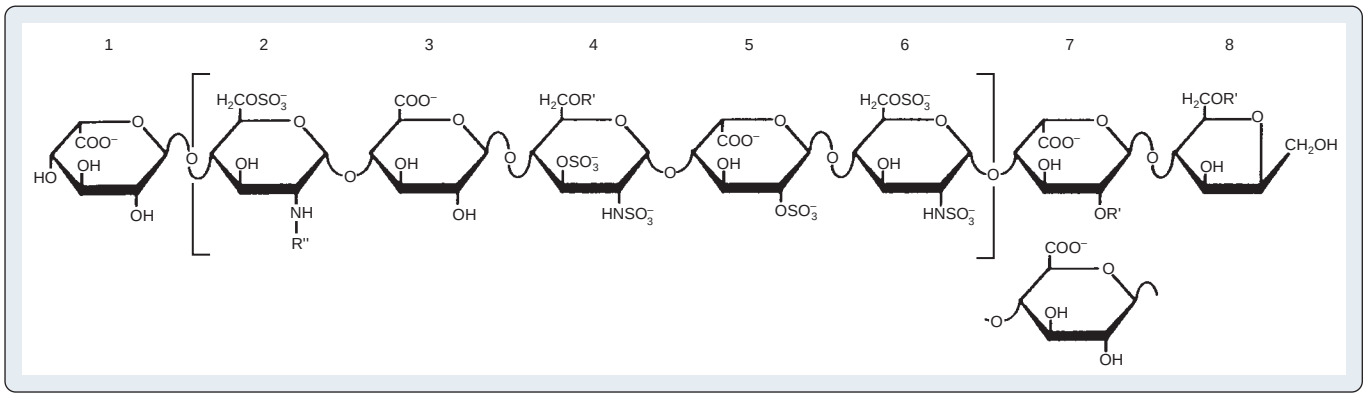

Fig. 35.9 An octasaccharide fragment of heparin, a substituted alternating copolymer of iduronic acid and glucosamine. The leftmost sugar is iduronic acid. Note the numerous sulfate groups and the acetyl substitution on the second sugar. Variations in sugar substitutions and in chain length produce molecular heterogeneity. Brackets indicate the pentasaccharide sequence that binds to antithrombin. *(From Rodén L. Highlights in the history of heparin. In: Lane DA, Lindahl U, eds.* Heparin. *Boca Raton, FL: CRC Press; 1989:1.)*

identification of the uronic acid as L-iduronic acid, an epimer of D-glucuronic acid, and refined its structural detail.[90]

The *N*-sulfated-D-glucosamine and L-iduronic acid residues of heparin alternate in copolymer fashion to form chains of varying length (Fig. 35.9). As a linear anionic polyelectrolyte, the negative charges being supplied by sulfate groups, heparin demonstrates a wide spectrum of activity with enzymes, hormones, biogenic amines, and plasma proteins. A pentasaccharide segment binds to AT.[91,92] Heparin is a heterogenous compound; the carbohydrates vary in both length and side-chain composition, yielding a range of molecular weights from 5000 to 30,000, with most chains between 12,000 and 19,000.[92] Today, the standard heparin is called *unfractionated heparin (UFH)*.

Heparin Versus Heparan

Heparan, a glycosaminoglycan found in the connective tissue and the coating of the endothelial surfaces of nearly all species, can be distinguished from heparin by the following characteristics: (1) a predominance of glucuronic acid over iduronic acid and (2) *N*-acetylation, rather than *N*-sulfation, of more than 20% of glucosamine residues. Bound to cellular proteins, heparan resides inside cells, on cell surfaces, and in the extracellular matrix.[90–95]

Source and Biologic Role

Heparin is found mostly in the lungs, intestines, and liver of mammals, with skin, lymph nodes, and thymus providing less plentiful sources.[94] Abundance of heparin in tissues rich in mast cells suggests these as the source of the compound. Its presence in tissues with environmental contact suggests a biologic role relating to immune function. Heparin may assist white blood cell movements in the interstitium after an immunologic response has been triggered. Mollusks have no coagulation system yet possess heparin, arguing against a biologic role in hemostasis. It is clear that heparin, per se, was never intended biologically to be circulating in large dosages throughout the vascular tree.

Most commercial preparations of heparin now use pig intestine, 40,000 pounds of which yield 5 kg heparin.[90] Prevention of postoperative thrombosis constituted the initial clinical use of heparin in 1935 by Best, Jaques, and colleagues in Toronto, and by Craford in Stockholm.[91]

Potency

Heparin potency is determined by comparing the test specimen against a known standard's ability to prolong coagulation.[96] Current United States Pharmacopeia (USP) and British Pharmacopoeia (BP) assays use a PT-like method on pooled sheep's plasma obtained from slaughterhouses. The plasma commonly is contaminated with tissue extracts or other hemostatically active substances. The European Pharmacopoeia's method, an aPTT on fresh sheep's plasma, is superior to that of the USP.[97] Modern research assays use human FFP, an aPTT-like method, and require linear log versus log plots of standard and test samples.[96]

UFH dose should not be specified by weight (milligrams) because of the diversity of anticoagulant activity expected from so heterogenous a compound. Unfortunately, because of the flawed USP assay, even units of activity often do not reflect clinical effects. As originally defined, 1 unit of heparin prolongs the clotting of cat's blood for only 24 hours at 0°C.[98] Milligram usage, introduced in 1937 as a Swedish standard, was superseded by the first international standard, in which 130 units of activity corresponded to 1 mg. The fourth international standard uses a porcine mucosal preparation.[96]

One USP unit of heparin activity is the quantity that prevents 1.0 mL of citrated sheep's plasma from clotting for 1 hour after addition of calcium.[99] Units cannot be cross-compared among heparins of different sources, such as mucosal versus lung, or low-molecular-weight heparin (LMWH) versus UFH, or even lot to lot, because the assay used may or may not reflect actual differences in biologic activity. None of these measures has anything to do with the effect of a unit on anticoagulation effect for human cardiac surgery.

Pharmacokinetics and Pharmacodynamics

The heterogeneity of UFH molecules produces variability in the relation of dose administered to plasma level of drug. In addition, the relation of plasma level to biologic effect varies with the test system. A three-compartment model describes heparin kinetics in healthy humans: rapid initial disappearance, saturable clearance observed in the lower dose range, and exponential first-order decay at greater doses[99–101] (Fig. 35.10). The rapid initial disappearance may arise from endothelial cell uptake.[101,102] The reticuloendothelial system, with its endoglycosidases and endosulfatases, and uptake into monocytes, may represent the saturable phase of heparin kinetics. Finally, renal clearance via active tubular secretion of heparin, much of it desulfated, explains heparin's exponential clearance.

Male sex and cigarette smoking are associated with more rapid heparin clearance.[103] The resistance of patients with deep vein thrombosis or pulmonary embolism to heparin therapy may be caused by the release from thrombi of PF4, a known heparin antagonist.[104,105] Chronic renal failure prolongs elimination of high, but not low, heparin doses.[103] Chronic liver disease does not change elimination.[106,107]

Loading doses for CPB (200–400 U/kg) are substantially greater than those used to treat venous thrombosis (70–150 U/kg). Plasma heparin levels, determined fluorometrically, vary widely (2–4 units/

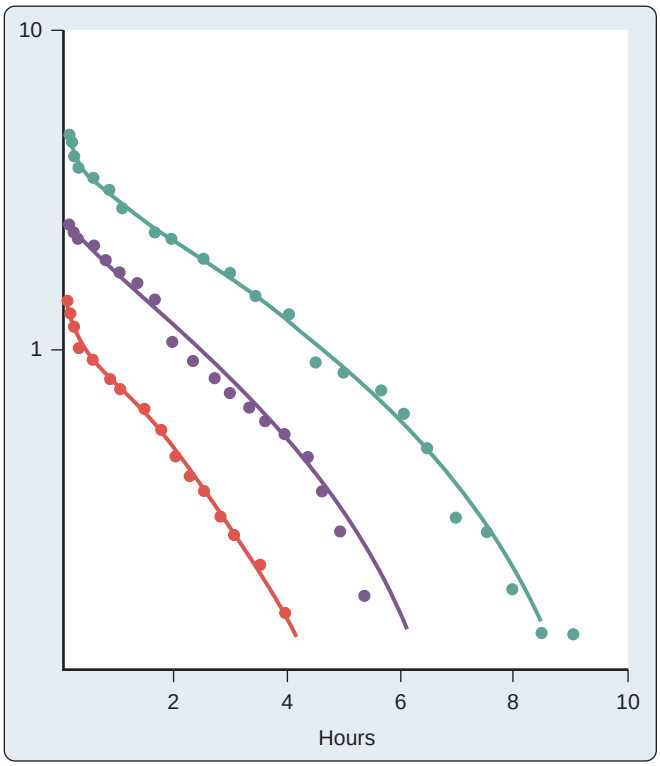

Fig. 35.10 Decay of heparin anticoagulant activity (U/mL on a logarithmic scale) after injections of 75, 150, and 250 U/kg to a single healthy volunteer. Note the rapid initial decline in all curves and nonlinearity at greater doses.

Note continued presence of these markers of thrombin activity despite heparin administration. *FPA,* Fibrinopeptides A; *FPB,* fibrinopeptides B. *(From Tanaka K, Takao M, Yada I, et al. Alterations in coagulation and fibrinolysis associated with cardiopulmonary bypass during open heart surgery.* J Cardiothorac Anesth. *1989;3:181.)*

mL) after doses of heparin administered to patients about to undergo CPB.[107,108] The ACT response to these doses of heparin displays even greater dispersion. Gravlee and colleagues[109] identified thrombocytosis and advanced age as causing a decreased ACT response to administered heparin. This effect may arise from alterations in pharmacokinetics, pharmacodynamics, or both. Interpatient variability in heparin response (pharmacodynamics) does affect the clotting time[109,110]; however, the clinical response to heparin administered to various patients is more consistent than suggested by in vitro measurements.

Although not substantiated formally, most clinicians would agree that hypothermia prolongs the effect of heparin. Precise documentation remains impeded by inability to warm the patient's blood immediately to 37°C for standardized measurement of its ACT. Delayed metabolism or excretion, or both, most likely account for the prolongation of heparin presence during systemic hypothermia, whereas prolongation of the ACT more likely relates to decreased activity of coagulation enzymatic processes (see later).

Actions and Interactions

Heparin exerts its anticoagulant activity via AT III, one of the many circulating serine protein inhibitors (serpins), which counter the effects of circulating proteases.[111,112] The major inhibitor of thrombin and factors IXa and Xa is AT III; that of the contact activation factors XIIa and XIa is α_1-proteinase inhibitor; kallikrein inhibition arises mostly from C1 inhibitor. AT activity is greatly decreased at a site of vascular damage, underscoring its primary role as a scavenger for clotting enzymes that escape into the general circulation.

AT inhibits serine proteases even without heparin. The extent to which heparin accelerates AT inhibition depends on the substrate enzyme; UFH accelerates the formation of the thrombin-AT complex by 2000-fold but accelerates formation of the factor Xa-AT complex by only 1200-fold[112] (Table 35.5). In contrast, LMWH fragments

TABLE 35.5 Some Coagulation Factor Inhibitors and the Effects of Heparin

Factor	*Major Inhibitor*	*Acceleration of Antithrombin Activity by Heparin*
Kallikrein	C1 inhibitor	—
XIIa	α_1-Proteinase inhibitor	—
Xia	α_1-Proteinase inhibitor	40-fold
Xa	Antithrombin	1,200-fold
IXa	Antithrombin	10,000-fold
IIa	Antithrombin	2,000-fold

preferentially inhibit factor Xa. Enzyme inhibition proceeds by formation of a ternary complex consisting of heparin, AT, and the proteinase to be inhibited (eg, thrombin, factor Xa). For UFH, inhibition of thrombin occurs only on simultaneous binding to both AT and thrombin. This condition requires a heparin fragment of at least 18 residues.[111–113] A pentasaccharide sequence binds to AT (see Fig. 35.9). LMWHs, consisting of chains 8 to 16 units long, preferentially inhibit factor Xa. In this case, the heparin fragment activates AT, which then sequentially inactivates factor Xa; heparin and factor Xa do not directly interact.[114–116]

Several investigators have demonstrated continued formation of fibrinopeptides A[116,117] and B[118] (Fig. 35.11), as well as prothrombin fragment F1.2 and thrombin-AT complexes,[119] despite clearly acceptable anticoagulation for CPB by many criteria. These substances indicate thrombin activity. The clinical significance of this ongoing thrombin activity has had limited study. The ACT must be more prolonged to prevent fibrin formation during cardiac surgery compared with during extracorporeal circulation without surgery because surgery

itself incites coagulation. UFH in conjunction with AT appears to work in plasma only on free thrombin. When considering what is known today about thrombin burst and thrombin activity, heparin appears to be relatively inefficient because there is not much free thrombin. Thrombin is held on the surface of activated platelets at various GP binding sites including the GPIIb/IIIa site. Most thrombin is fibrin bound, and heparin-AT complexes do not bind at all to this thrombin unless the level of heparin is pushed far above what is used routinely for CPB. The idea behind using heparin for CPB is that by creating a large circulating concentration of activated AT, whenever a thrombin molecule is produced, an available AT molecule will be there to immediately bind to it before it can have any further activating effect. Clearly, that is unrealistic with the knowledge that thrombin exerts its main activity by binding to the surface of platelets.

Bovine Versus Porcine Preparations

Bovine lung heparin contains greater amounts of iduronic acid and sulfoamino groups than pork mucosal heparin. Because endothelial endoglycosidases degrade heparin at sulfoamino groups, elimination of beef lung heparin proceeds more quickly than that of pork mucosal heparin. Its AT III affinity and anticoagulant activity are less than those of porcine heparin. Either preparation can establish suitable anticoagulation for CPB. Beef lung heparin may be more amenable to protamine neutralization than the pork mucosal preparation because it exerts less anti–factor Xa activity.[120,121] HIT is less common with pork heparin (see later). This information may be of historic value only because bovine heparin is no longer available in the United States.

Heparin Resistance

In the course of continuous infusions of UFH to treat venous thrombosis, some patients experience development of tachyphylaxis, requiring increasing amounts of heparin to maintain the laboratory measurement of anticoagulation, the aPTT, at its designated therapeutic level. In some reports, up to 22% of patients do not adequately respond to heparin and are termed *heparin resistant.*[121–124] To most practitioners, that number seems high, but the definition of what constitutes heparin resistance is highly variable from institution to institution. Likewise, patients receiving UFH infusions exhibit a much-diminished ACT response to full anticoagulating doses of UFH for CPB (200–400 U/kg). With widespread use of heparin infusions to treat myocardial ischemia and infarction, heparin resistance or, more appropriately, "altered heparin responsiveness" has become more problematic during cardiac surgery (Box 35.2).[125,126]

Mechanism

Although several observations suggest that decreased levels of AT III mediate heparin resistance, these observations lack sufficient evidence to establish this relation.[126] In one study of 500 CABG patients, 21% demonstrated heparin resistance, and 65% of these responded to added AT III; this translates into 35% being nonresponders.[122] First, a patient with congenital AT III deficiency displayed heparin resistance[127]; this hardly proves that all heparin resistance stems from AT III deficiency. Second, of six patients with venous thrombosis, three receiving heparin infusions displayed a 25% shorter half-life for AT III compared with the three untreated patients.[128] Accelerated AT III consumption could have resulted from the thrombotic process rather than the heparin infusion. Third, plasma levels of AT III decreased by 17% to 33% during heparin administration by intravenous or subcutaneous routes[129–134] It is possible that this measurement resulted merely from formation of heparin-AT complexes. Perhaps accelerated elimination of AT III arises from some modification of the protein during or after its interaction with heparin.[133] Also, it has been postulated that excesses of platelet activity, releases of PF4, could neutralize heparin in these patients. That has yet to be studied, as has a great deal to do with hypercoagulable states in cardiac surgery.[135]

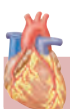
Hemodilution accompanying CPB decreases AT levels to about 66% or even half of normal levels.[107] There are, however, outlier patients who have profoundly low AT levels. It is possible to see AT III levels as low as 20% of normal, and these levels correspond to levels seen in septic shock and diffuse intravascular coagulation.[15] However, supplemental AT may not prolong the ACT, which means that the heparin available has been bound to sufficient or available AT. The only way that the ACT would be prolonged is if there is excess heparin beyond available AT. Reports of heparin resistance for CPB ascribe its occurrence variously to the use of autotransfusion,[135] previous heparin therapy,[136–139] infection,[140,141] and ventricular aneurysm with thrombus.[139–150] The differential diagnosis also includes hypereosinophilia, oral contraceptive therapy, consumptive coagulopathy, thrombocytosis, and congenital AT deficiency.[138] Heparin resistance also might occur in patients with subclinical thrombotic processes releasing PF4.

The individual anticoagulant response to heparin varies tremendously.[143] Some presumed cases of heparin resistance may represent nothing more than this normal variation. Regardless of cause, measurement of each individual's anticoagulant response to heparin therapy for CPB is warranted.[144] Heparin resistance helps focus the debate regarding whether anticoagulation monitoring should measure heparin concentrations or heparin effect; the goal of anticoagulation is not to achieve heparin presence in plasma but to inhibit the action of thrombin on fibrinogen, platelets, and endothelial cells (see Chapter 19). Therefore the effect of heparin usually is measured.

Treatment

Most commonly, additional heparin prolongs the ACT sufficiently for the conduct of CPB. Amounts up to 800 U/kg may be necessary to obtain an ACT of 400 to 480 seconds or longer. Although administration of FFP, which contains AT,[144] should correct AT depletion (Fig. 35.12) and suitably prolong the ACT,[145] such exposure to transfusion-borne infectious diseases should be avoided whenever possible. The use of FFP is outdated and the guidelines by The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists (STS/SCA) call for the use of AT concentrate. The use of 2 units of FFP might increase the circulating AT levels by roughly 10% to 15%. Today, the risks of blood transfusion have shifted away from blood-borne viral transmission, with TRALI being noted as the greatest mortality-associated event with transfusion. FFP and platelet transfusions carry the greatest risk for TRALI.[146–148] Although TRALI has not been studied in relation to use of FFP for heparin resistance, it makes great sense to use one of the AT products. This modality is reserved for the rare refractory case. Rather than administer FFP, centers normally accepting only ACTs of 480 seconds or longer for CPB might consider accepting 400 seconds or less, or administering AT III concentrate.[145–149]

AT concentrate specifically addresses AT deficiency.[15–18,145] Two products are available for utilization. One is a recombinant DNA engineered product made from goat's milk and the other is a purified human plasma harvest derivative. There are currently no head-to-head studies to recommend one over the other at this time. The literature supports success in treating heparin resistance during cardiac surgery.[126,150] A multicenter study on the efficacy of using a recombinant human AT in heparin-resistant patients undergoing CPB was published.[151] The patients received 75 U/kg recombinant human AT, which was effective in restoring heparin responsiveness in most



BOX 35.2 PROBLEMS WITH HEPARIN AS AN ANTICOAGULANT FOR CARDIOPULMONARY BYPASS

patients. However, some patients still required FFP, and the patients bled more than did a control group after surgery.

Heparin Rebound

Several hours after protamine neutralization for cardiac surgery, some patients experience development of clinical bleeding associated with prolongation of coagulation times. This phenomenon is often attributed to reappearance of circulating heparin. Theories accounting for "heparin rebound" include late release of heparin sequestered in tissues, delayed return of heparin to the circulation from the extracellular space via lymphatics, clearance of an unrecognized endogenous heparin antagonist, and more rapid clearance of protamine in relation to heparin.[152,153] Studies demonstrating uptake of heparin into endothelial cells suggest that these cells may slowly release the drug into the circulation once plasma levels decline with protamine neutralization.[102] It is questionable how much heparin rebound contributes to actual bleeding. This phenomenon may be caused by TFPI release from the surface of endothelial cells or other causes of bleeding.

Incidence and Timing

Although initial reports placed the incidence of heparin rebound after cardiac surgery at about 50%, modifications in the timing and amount of protamine administration decreased the incidence.[153–155] Heparin rebound can occur as soon as 1 hour after protamine neutralization.[137] When present, prolonged coagulation times or more direct evidence of circulating heparin may persist for 6 hours or longer.[107,154–158]

Treatment and Prevention

Although still debated by a few, most clinicians accept heparin rebound as a real phenomenon. However, clinical bleeding does not always accompany heparin rebound. When it does, administration of supplemental protamine will neutralize the remaining heparin (Box 35.3). Can the initial protamine dose be adjusted to prevent heparin rebound? Available studies yield conflicting results. All six patients who received protamine based on the estimated amount of *remaining* heparin developed heparin rebound, compared with none of six who received protamine based on the total administered dose of heparin.[154,155] However, 42% of patients receiving large, fixed doses of both drugs experienced heparin rebound and increased bleeding compared with patients whose doses were titrated to clotting assays[155] (Fig. 35.13). Likewise, patients receiving smaller doses of protamine bled less than those receiving protamine doses based on the total amount of heparin administered.[158] In contrast, a fourth study recommended that the ratio of protamine given to heparin remaining be as much as 1.6 mg/100 units.[108]

BOX 35.3 CONSIDERATIONS IN DETERMINING THE PROPER DOSE OF PROTAMINE TO REVERSE HEPARIN

- The proper dose is broad and difficult to determine exactly.
- The dose should be determined by a measurement of coagulation.
- The dose should be administered over at least 10 minutes.
- Excess protamine is a mild antithrombin agent; it may well lead to bleeding itself.

It should be noted that in vitro work shows that as little as one-third the heparin dose is all the protamine that is actually required to reverse the heparin in a test tube. It is still difficult to know exactly what the best heparin reversal dose is by protamine. Some effort at titration with a heparin dose–response curve seems worthwhile.

Although larger initial doses of protamine may decrease the likelihood of heparin rebound, two potential complications of protamine over dosage must be considered: adverse cardiovascular sequelae of protamine administration and the anticoagulant effects of protamine itself. Although protamine is an in vitro anticoagulant, doses up to 6 mg/kg in volunteers, in the absence of heparin, do not prolong the clotting time.[159] However, doses four times in excess of a neutralizing dose doubled the ACT in dogs.[160] The dose after CPB that causes anticoagulation in patients remains unknown. Clinical studies comparing fixed-ratio protamine doses with protocols that gauge protamine dose to remaining heparin activity and protamine drug lot potency demonstrated decreased doses of protamine, decreased chest tube drainage after surgery, and fewer transfusions.[160–162]

Heparin Effects Other Than Anticoagulation

UFH was never biologically intended to circulate freely in plasma.[162–164] As such, it has a number of underappreciated and untoward effects. All too often the effects of CPB have been asserted as causing a coagulopathy; however, the effect of heparin contributing to this has not been widely studied. This is because there has not been an alternative anticoagulant to compare with heparin until now. In the future, there may be better anticoagulants to use during cardiac surgery (see later).

Heparin exerts its anticoagulant activity by activating a binding site on AT III, and without AT, heparin has no intrinsic anticoagulation effect. AT does have anticoagulant effects of its own, but its ability to bind to thrombin is increased 100- to 2000-fold by the presence of the pentasaccharide sequence of heparin. Less than one-third of all mucopolysaccharides present in a dose of heparin contain the active pentasaccharide sequence. The other molecules may have a number of adverse properties.

Heparin binds AT III during CPB, and through ongoing thrombin generation, the AT III levels are decreased over time, as well as via hemodilution. Thus the AT III levels may become quite low, in the range seen during disseminated intravascular coagulopathy, septic shock, and eclampsia.[15,164–167] AT III is not able to be constitutively increased by production. Therefore the level at the beginning of a CPB case is all that is available. The liver will manufacture more AT III, but it may take 1 to 3 days to return to normal after cessation of CPB. In at least one study in which AT III was repleated to normal, the levels of coagulation proteins were much improved after CPB in patients who received exogenous AT III.[15,144]

UFH chelates calcium.[168] When a large bolus dose of heparin is given, there is a slow and steady decline in blood pressure, probably because of decreased vascular resistance and decreased preload. Both

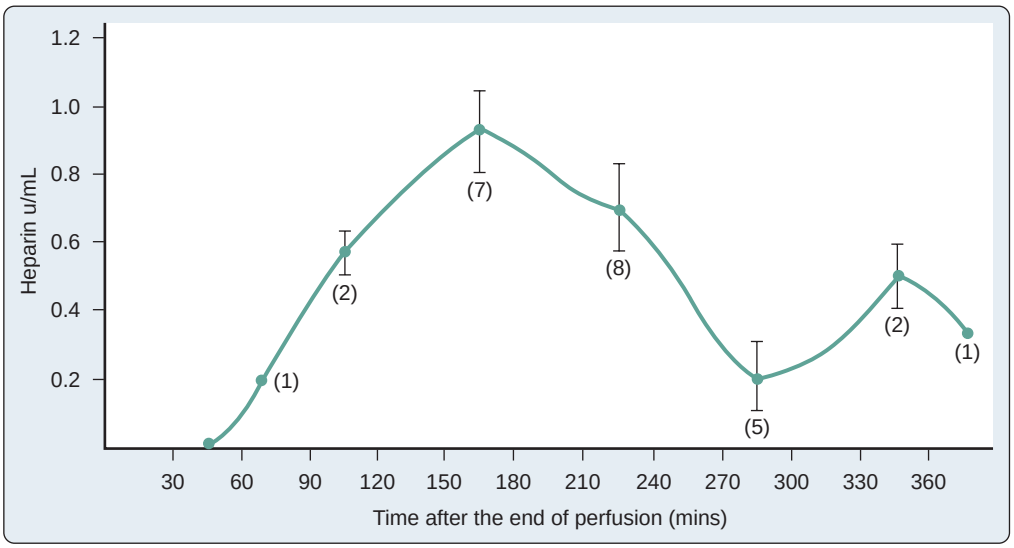

Fig. 35.13 Heparin rebound measured by protamine titration in 10 of 24 patients given heparin by a fixed-time protocol. Parentheses denote number of patients. *(From Kaul TK, Crow MJ, Rajah SM, et al. Heparin administration during extracorporeal circulation.* J Thorac Cardiovasc Surg. *1979;78:95.)*

arterial and venous vessels are dilated by the decrease in the calcium level. The heparin is given while patients are being prepared for CPB, and numerous mechanical events (ie, catheters being inserted into the right atrium and vena cava and arrhythmias) can be blamed for the hypotension, rather than the heparin itself.

Heparin, even in very small doses, partially and reversibly activates platelets and forces them to express many, if not all, of their GP binding sites.[169,170] This fact alone makes clinicians wonder whether there is not a better anticoagulant that might not do this. Heparan, the endothelial analog of heparin, does not break off freely into the circulation; if it does, it is immediately neutralized by platelets through expression of PF4 and adsorption. Thus it makes sense that platelets seeing loose heparin would suspect a site of tissue injury nearby and, therefore, an evolutionary advantage would be created by making these cells react and get ready to create a thrombus. Every coagulation activation is also an inflammatory signal. The fact that platelets take this reactive step means that they are now primed to become highly reactive or contribute to the inflammatory events or have their receptors targeted by other subsequent events. After CPB, platelets have many of their membrane GPs either destroyed or competitively occupied by a number of products of inflammation produced during CPB. The expression of binding sites in response to heparin, therefore, is important and probably has profound implications.

Heparin causes the competitive release of some heparan from endothelial cells and the release of TFPI.[27,28] Endothelial cells all over the body change from being anticoagulant producing to rapidly producing tissue factor. What role large doses of heparin have in this whole-body event is hard to define, but it is known that heparin also causes the release of single-chain urokinase from endothelial cells.[171] The amount of fibrinolysis caused by heparin infusion is not as great as the release of t-PA, which probably is mediated by cytokines as a result of the inflammatory reactions. When released from mast cells, heparin promotes leukocyte chemotaxis and movement through the interstitium.[162,163] However, it is unclear whether heparin upregulates or decreases white cell activations.[163]

Heparin is important for a number of angiogenesis and repair activities of tissue, and these effects may have something to do with its antineoplastic effect.[164] Heparin also affects lipid, sodium and potassium, and acid-base metabolism. These effects are not usually seen acutely but come into play when patients have been on heparin infusions for days in the ICU.

The immunologic effects of heparin are profound. The next section discusses HIT, but recent work shows that 30% to 50% of cardiac surgery patients have heparin antibodies present in their blood by the time of hospital discharge.[172,173] The clinical implications of these prevalent antibodies remain unknown and are the subject of investigation.

Heparin-Induced Thrombocytopenia

Heparin normally binds to platelet membranes at GPIb and other sites and aggregates normal platelets by releasing ADP.[172,173] A moderate, reversible HIT, now termed *type I,* has been known for half a century.[174] The fact that heparin actually triggers an acute decline in platelet count should be considered a biologic event, because heparin, even in trace amounts, triggers the expression of many different platelet GPs. This has been termed *activation of platelets,* but it is not total activation. Heparin's prolongation of the bleeding time probably is related to activation of the platelets, as well as heparin binding to the GPIb surface. It may be that a number of platelets adhere to endothelial cells simply because of their expression of these GP binding sites. Margination, particularly within the pulmonary vasculature, may be an event of HIT type I.

In contrast with these predictable effects of heparin, occasionally patients experience development of progressive and severe thrombocytopenia (<100,000/mm^3), sometimes accompanied by a debilitating or fatal thrombosis (HIT with thrombosis [HITT]). This syndrome is termed *type II heparin-induced thrombocytopenia (HIT II).* A platelet count in excess of 100,000/mm^3 does not mean that HIT II is not present. A decline in platelet count in excess of 30% to 50% over several days in a patient who is receiving or who has just finished receiving heparin is probably caused by HIT II.

Mechanism

These patients with HITT demonstrate a heparin-dependent antibody, usually IgG, although others are described, which aggregates platelets in the presence of heparin.[172,173] During heparin therapy, measured antibody titers remain low because of antibody binding to platelets. Titers rise after heparin therapy ceases; but paradoxically, antibody may be undetectable a few months later.[175] Two other features are unexpected: first, the antibody does not aggregate platelets in the presence of excess heparin; and second, not all re-exposed patients experience development of thrombocytopenia.[176–178]

The platelet surface contains complexes of heparin and PF4. Affected patients have an antibody to this complex. Antibody binding activates platelets via their FcγII receptors and activates endothelium[179–181] (Fig. 35.14). The activation of the platelet surface triggers a secondary

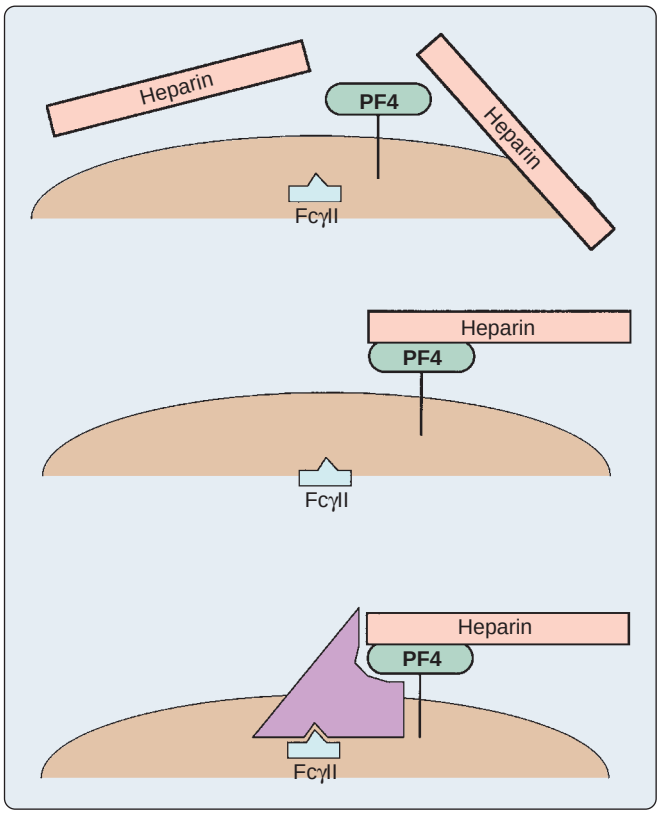

Fig. 35.14 Presumed mechanism of the interaction among heparin, platelets, and antibody in heparin-induced thrombocytopenia. *Top,* Platelet factor 4 (*PF4*) released from platelet granules is bound to the platelet surface. *Middle,* Heparin and PF4 complexes form. *Bottom,* The antibody binds to the PF4-heparin complex and activates platelet FcγII receptors.

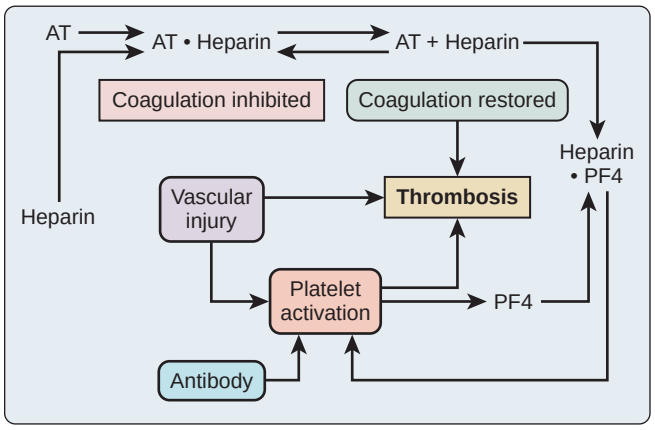

Fig. 35.15 Mechanism of thrombosis accompanying heparin-induced thrombocytopenia. Normally, heparin and antithrombin (*AT*) form a complex that inhibits coagulation. Platelet factor 4 (*PF4*), released from platelets on activation, binds heparin and drives the dissociation reaction of the AT-heparin complex to the right, restoring coagulation locally. Restored coagulation mechanisms and activated platelets form thrombus in the presence of vascular injury. *(Adapted from Parmet JL, Horrow JC: Hematologic diseases. In: Benumof J, ed.* Anesthesia and Uncommon Diseases. *3rd ed. Philadelphia: WB Saunders Company; 1997.)*

thrombin release. Platelets can attach to each other, creating what is known as a white-clot syndrome, but if secondary thrombin generation is created through antibody activation of the platelets, then a fibrin clot can be the result. In the absence of heparin, the heparin-PF4 antigen cannot form. However, there seems to be some sort of continuum between idiopathic thrombocytopenia and HIT.

In the absence of an endothelial defect, the only responses to the antibody-antigen interaction are platelet consumption and thrombocytopenia. Atheroma rupture, endovascular interventions such as balloon angioplasty, vascular surgery, and other procedures that disrupt endothelium can provide a nidus for platelet adhesion and subsequent activation. PF4, released with platelet activation, binds to heparin locally, thus not only removing the inhibition of coagulation but also generating additional antigenic material (Fig. 35.15). Clumps of aggregated platelets thrombose vessels, resulting in organ and limb infarction. Amputation, death, or both often occur with established HITT. The presence of heparin-PF4 antibodies recently has been associated with other adverse effects. It appears that if a patient undergoes cardiac surgery with positive antibodies, the risk for mortality or MI, or both, may at least double.

Incidence and Diagnosis

Estimates of the true incidence of HIT are confounded by different diagnostic thresholds for platelet count, varying efforts to detect other causes, and incomplete reports.[182,183] After 7 days of therapy with UFH, probably 1% of patients experience development of HIT; after 14 days of therapy, the prevalence rate is 3%.[181] Using a platelet count of 100,000/mm^3, multiple reports comprising more than 1200 patients revealed an overall incidence rate of HIT of 5.5% with bovine heparin and 1.0% with porcine heparin.[172] Other recent research has found the preoperative incidence rate of enzyme-linked immunosorbent assay (ELISA)–positive patients to be between 6.5% to 10%. This means that antibodies are present, and that may not mean that thrombocytopenia is occurring. Of great interest is that many more patients develop positive tests for ELISA antibodies by days 7 to 30 after cardiac surgery. Somewhere between 25% and 50% of patients develop these antibodies.[172] In a study of patients after cardiac surgery wherein all patients were screened for HIT antibodies, the group also looked for platelet counts well less than the patient's baseline[184]; 21 of 153 patients (14%) tested positive for antibodies by heparin-induced platelet activation (HIPA) testing. Those patients with a low platelet count and a high HIT antibody titer after surgery were at very high risk for mortality (59%). Therefore a decline in platelet count or persistence of a low platelet count after cardiac surgery should be considered HIT until proved otherwise and taken very seriously. Anticoagulation with alternative non-triggering anticoagulants is imperative.[184] Warfarin should be avoided until such time as the platelet count is recovered and vitamin K therapy can be instituted; this is because the use of warfarin compounds will decrease protein C, which has been known to trigger an HITT crisis.

In the bivalirudin trials, wherein patients thought to have HIT were given an alternative anticoagulant, the presence of antibodies after surgery was associated with adverse events. Particularly worrisome were the presence of a low platelet count or a blunted return toward a normal platelet count after surgery.[185–188]

Some particular lots of heparin may be more likely to cause HIT than others.[189] HIT can occur not only during therapeutic heparin administration but with low prophylactic doses, although the incidence is dose related. Even heparin flush solution or heparin-bonded intravascular catheters can incite HIT.[189–193] Cases of platelet-to-platelet adhesion creating a "white clot" in otherwise normal patients have been observed in the oxygenator and the reservoir of CPB machines. The fact that such events have been reported even when all other tests appeared normal signals the unpredictable nature of the heparin-PF4 antibody, as well as the biologic activity of UFH.

Although HIT usually begins 3 to 15 days (median, 10 days) after heparin infusions commence, it can occur within hours in a patient previously exposed to heparin. Platelet count steadily decreases to a nadir between 20,000 and 150,000/mm^3. Absolute thrombocytopenia is not necessary; only a significant decrease in platelet count matters,

as witnessed by patients with thrombocytosis who experience development of thrombosis with normal platelet counts after prolonged exposure to heparin. Occasionally, thrombocytopenia resolves spontaneously despite continuation of heparin infusion.[194]

Clinical diagnosis of HIT requires a new decrease in platelet count during heparin infusion. Laboratory confirmation is obtained from several available tests. In the serotonin release assay, patient plasma, donor platelets, and heparin are combined. The donor platelets contain radiolabeled serotonin, which is released when donor platelets are activated by the antigen-antibody complex. Measurement of serotonin release during platelet aggregation at both low and high heparin concentrations provides excellent sensitivity and specificity.[177]

A second assay measures more traditional markers of platelet degranulation in a mixture of heparin, patient plasma, and donor platelets.[195] The most specific test is an ELISA for antibodies to the heparin-PF4 complex.[172,173,195,196]

The type, source, and lot of heparin used affect the outcome of these tests. The heterogenous nature of heparin demands that a lot-specific drug be used in serotonin release assays, especially when used to determine suitability of future administration. For example, if LMWH administration is planned for a patient who experienced development of HIT II with UFH, testing of patient plasma with the lot of LMWH to be given should precede its administration.

Measurement of platelet-associated IgG is poorly specific for HIT because of numerous other causes of antiplatelet IgG. This test should not be used in the diagnosis of HIT.

Heparin-Induced Thrombocytopenia With Thrombosis

The incidence rate of HITT is 1.7% with bovine heparin and 0.3% with porcine heparin; thus thrombosis accompanies more than one in five cases of HIT.[172,173] It is clear that the longer patients are on heparin, the more likely it is that they will develop antibody; and with the knowledge that today close to 50% of cardiac patients develop antibodies, it is possible that a significant number of long-term or early mortalities might be because of undiagnosed HITT.[172] In several studies in the catheterization laboratory, it has been shown that if HITT antibodies are present before the performance of angioplasty, the mortality and combined morbidity are greatly increased, perhaps double or more.[197,198] One study has been conducted in almost 500 patients undergoing CABG surgery looking for the presence of antibodies and outcome. The incidence rate of antibody-positive patients was approximately 15%, and their length of stay in the hospital and mortality were more than doubled. Occasional rare situations in which the CPB circuit suddenly clots or when early graft thrombosis or whole-body clotting occurs may all be variants of HITT, but none of these cases can be readily studied because they are so rare.[198,199] If such an occurrence does happen, HITT should be in the differential diagnosis. The occurrence of thrombosis at first seems a paradox. However, HITT has as its hallmark a huge thrombin burst that can occur all over the body. With such massive thrombin generation, the triggering of thrombosis is natural. Thrombosis may then activate the fibrinolytic system to produce a picture of consumptive coagulopathy.[189]

Between 15% and 30% of patients who experience development of HITT will have severe neurologic complications, require amputation of a limb, or die. Lower limb ischemia constitutes the most frequent presentation. Venous clots occur probably as frequently as arterial ones but are not detected as often. Unfortunately, no test predicts the thrombosis component of HIT; thrombosis should be anticipated in the presence of vascular injury, such as puncture sites for catheterization.

The 4Ts system (thrombocytopenia, timing, thrombosis, and other [lack of other reasons]) has been used to increase the index of suspicion with regard to HIT.[200] The use of this scoring system is quite effective, but after cardiac surgery, the decline in platelet count is expected for at least 24 hours. If platelet count stays down after that time, then suspicion for HIT should be high. A study of critically ill patients (noncardiac) using the 4Ts showed an incidence rate of 4.1% for HIT. Low scoring appears to be reliable, whereas high and intermediate scoring showed patients with antibody-positive tests.

Treatment and Prevention

In the absence of surgery, bleeding from thrombocytopenia with HIT is rare. In contrast with other drug-induced thrombocytopenia, in which severe thrombocytopenia commonly occurs, more moderate platelet count nadirs characterize HIT. Platelet transfusions are not indicated and may incite or worsen thrombosis. Heparin infusions must be discontinued, and an alternative anticoagulant should be instituted. LMWHs can be tested in the laboratory using serotonin release before patient administration. Although thrombosis may be treated with fibrinolytic therapy, surgery often is indicated. No heparin should be given for vascular surgery. Monitoring catheters should be purged of heparin flush, and heparin-bonded catheters should not be placed. Antiplatelet agents, such as aspirin, ticlopidine, or dipyridamole, which block adhesion and activation and, thus, PF4 release, provide ancillary help (see Table 35.4).

The patient presenting for cardiac surgery who has sustained HIT in the past presents a therapeutic dilemma. Antibodies may have regressed; if so, a negative serotonin release assay using the heparin planned for surgery will predict that transient exposure during surgery will be harmless. However, no heparin should be given at catheterization or in flush solutions after surgery.[172,173]

Patients with HIT who require urgent surgery may receive heparin once platelet activation has been blocked with aspirin and dipyridamole[171–209] or, in the past, the prostacyclin analog iloprost.[205–208] Unfortunately, iloprost is no longer available. The problem with this strategy is obtaining sufficient blockade of platelet activity. The ultrashort-acting platelet blocking agent cangrelor would seem perfect to create "platelet anesthesia."

Another alternative, delaying surgery to wait for antibodies to regress, may fail because of the variable offset of antibody presence and the unpredictable nature of platelet response to heparin rechallenge. Plasmapheresis may successfully eliminate antibodies and allow benign heparin administration.[209] Finally, methods of instituting anticoagulation without heparin may be chosen (see later). Of these, the alternative thrombin antagonists pose the greatest risk for uncontrolled bleeding, whereas LMWHs and heparinoids afford the greatest chance of success.[209]

LMWH heparin, as an alternative to UFH, has been used for urgent surgery.[210–217] Although LMWHs also can induce thrombocytopenia, and by displaying different antigenic determinants, they may prove acceptable alternatives for patients who experience development of HIT from UFH. Box 35.4 summarizes the therapeutic options available for urgent cardiac surgery in patients with HIT. For additional information on HIT, see recent reviews.[172,173,218]

Alternative Modes of Anticoagulation

The hemostatic goal during CPB is complete inhibition of the coagulation system. Unfortunately, even large doses of heparin do not provide this, as evidenced by formation of fibrinopeptides during surgery.[117–119] Despite being far from the ideal anticoagulant, heparin still performs better than its alternatives. Heparans, dermatans, and other glycosaminoglycans with minimal antihemostatic properties may replace heparin in the future. Current substitutes for heparin include ancrod, a proteinase obtained from snake venom that destroys fibrinogen; heparin fragments, which provide less thrombin inhibition than the parent, unfractionated molecule; direct factor Xa inhibitors; and direct thrombin inhibitors (Box 35.5).

Ancrod

Ancrod abnormally cleaves fibrinogen, resulting in its rapid clearance by the reticuloendothelial system. Thrombin, thus, has no substrate on which to act. Proper patient preparation for CPB (plasma fibrinogen, 0.4–0.8 g/L) requires more than 12 hours. Fig. 35.16 demonstrates

BOX 35.4 THERAPEUTIC OPTIONS FOR ANTICOAGULATION FOR BYPASS IN PATIENTS WITH HEPARIN-INDUCED THROMBOCYTOPENIA

1. Ancrod
2. Low-molecular-weight heparin or heparinoid (test first!)
3. Alternative thrombin inhibitor (hirudin, bivalirudin, argatroban)
4. Use a single dose of heparin, promptly neutralize with protamine, *and*
   a. Delay surgery so antibodies can regress; *or*
   b. Use plasmapheresis to decrease antibody levels; *or*
   c. Inhibit platelets with iloprost, aspirin and Persantine, abciximab, or RGD blockers

In all cases:

1. No heparin in flush solutions
2. No heparin-bonded catheters
3. No heparin lock intravenous ports

No agent is currently indicated for anticoagulation in cardiopulmonary bypass. *RGD,* Receptor glycoprotein derived.

BOX 35.5 POTENTIAL REPLACEMENTS AS AN ANTICOAGULANT FOR CARDIOPULMONARY BYPASS

- Ancrod
- Low-molecular-weight heparins
- Factor Xa inhibitors
- Bivalirudin or other direct thrombin inhibitors (hirudin, argatroban)
- Platelet receptor inhibitors

BOX 35.6 PROPERTIES OF UNFRACTIONATED HEPARIN

1. Anti*thrombotic*[a]—prevents thrombus formation in vivo
2. Anti*coagulant*[a]—prolongs clotting time in vitro
3. Anti*hemostatic*—promotes bleeding
4. Anti*platelet*—activates platelets

[a]Properties of an ideal agent.

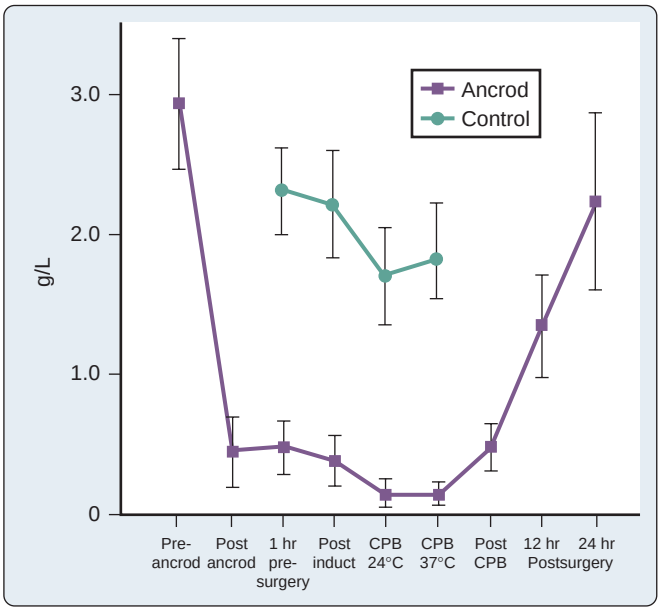

Fig. 35.16 Plasma fibrinogen concentrations (normal, 1.5 to 4.5 g/L) in 20 patients who received snake venom (Ancrod; *squares*) and 20 patients who received heparin (control; *circles*) for anticoagulation during cardiopulmonary bypass (CPB). Note the slow return of plasma fibrinogen, despite administration of 9.3 ± 16.3 SD units of cryoprecipitate and 5.6 ± 3.1 units of fresh frozen plasma to the Ancrod group. *(From Zulys VJ, Teasdale SJ, Michel ER, et al. Ancrod [Arvin] as an alternative to heparin anticoagulation for cardiopulmonary bypass.* Anesthesiology. *1989;71:870.)*

the extent of fibrinogen depletion (from normal value of 1.5–4.5 g/L) and repletion for cardiac surgery using ancrod.[219] Replenishment of fibrinogen via hepatic synthesis is slow; cryoprecipitate, fibrinogen, or FFP administration will speed restoration of coagulation. Patients anticoagulated in this fashion bleed more and require more cryoprecipitate and FFP compared with heparin-anticoagulated patients. One case was done with ancrod in which the coagulation activation was carefully studied.[220] Unbridled thrombin production led to massive platelet activation with a secondary precipitous decline in platelet count. No clot formed, but a gray slime of platelets adhered to the wall of the oxygenator and the reservoir. The platelet count declined to less than 1000/mm^3. However, transfusion with platelet concentrates and cryoprecipitate reestablished normal coagulation, and the patient had less than 500 mL of blood loss for the first 24 hours. No neurologic deficits occurred. However, ancrod is not commercially available in the United States.[219]

Low-Molecular-Weight Heparins

Thrombin inhibition requires chains longer than 18 saccharide units, and aPTT activity follows anti–factor IIa activity more closely than it does anti–factor Xa activity.[114] Thrombin must bind to a portion of the heparin chain for AT to inhibit it. In contrast, factor Xa inhibition by AT does not require interaction of factor Xa with the heparin molecule. Only about 1% to 2% of standard heparin consists of low-molecular-weight (molecular weight, 6000–7000) fragments.[103] Short polysaccharide chains of heparin can be synthesized, or extracted from standard heparin, but both processes cost much more than depolymerization of standard heparin utilizing nitric acid, peroxides, or the enzyme heparinase. Preparations of LMWH formed by these methods include fraxiparine, dalteparin, and enoxaparin.

Standard heparin can inhibit thrombus formation in vivo (antithrombotic activity) and prolong in vitro clotting tests (anticoagulant activity). It also leads to clinical bleeding (antihemostatic activity). Box 35.6 highlights these definitions. LMWHs may dissociate these activities, displaying greater antithrombotic activity and less antihemostatic activity.[103] Unfortunately, coagulation tests sensitive to thrombin inhibition and insensitive to inhibition of factor Xa, namely, the aPTT and ACT, do not adequately monitor the antithrombotic effects of LMWHs. For additional information regarding LMWHs, there are several good reviews.[212–223]

LMWHs have undergone clinical trials for antithrombosis after orthopedic procedures and for prevention of deep vein thrombosis.[223–226] The traditional LMWHs, such as enoxaparin, have not been used for CPB cases because of a limited ability of protamine to neutralize them.[227,228]

Heparinoids

Danaparoid (Orgaran), a mixture of LMWHs and dermatans, can provide anticoagulation for CPB, but lack of readily available

monitoring and sure neutralization limit its application to cases in which UFH clearly is contraindicated.[229] Dermatans alone might prove suitable, but much more investigative work must first occur.[7] Case reports of these agents have shown severe bleeding and, in some cases, death from hemorrhage after cardiac surgery. It appears at this point that dermatan sulfate will not be used for cardiac surgery, and danaparoid was removed from the US market.

Fondaparinux (Arixtra) is a synthetic pentasaccharide identical to that in heparin. It is a primary factor Xa inhibitor that requires AT III, which does not affect thrombin, platelets, or fibrinolytic activity. It is being used for prophylaxis of deep vein thrombosis after surgery, but it does not alter routine coagulation tests (requires a factor Xa assay).[230] Since 2008, there have been some reports of patients with HIT not responding successfully to therapy with fondaparinux.[231,232] Supratherapeutic dosages for fondaparinux were required to inhibit binding of antibodies to platelets. Danaparoid in very low concentrations increased PF4 antibodies; however, in therapeutic concentrations, it decreased production of antibodies. There is no direct antidote for either of these agents, but patients may respond to factor VIIa (see later).

Direct Thrombin Inhibitors

Hirudin, a single-chain polypeptide containing 65 amino acids with a molecular weight of 7000 and produced by the medicinal leech *Hirudo medicinalis,* binds directly to thrombin without need of a cofactor or enzyme, inhibiting all the proteolytic functions of thrombin. This inhibition includes actions on fibrinogen; factors V, VIII, and XIII; and platelets.

Modifications of hirudin include hirugen, a synthetic peptide containing residues 53 to 64 of the native hirudin, and Hirulog, formed by attaching the amino acid sequence d-phe-pro-arg-pro-(gly) to the amino-terminal end of hirugen. Hirugen inhibits the action of thrombin on fibrinogen, but not on factor V. Hirulog has full inhibitory properties but is slowly cleaved by thrombin itself to a hirugen-like molecule.

Hirudin depends on renal excretion; renal failure prolongs its elimination half-life of 0.6 to 2.0 hours. Although there are no known direct neutralizing agents for these drugs, administration of prothrombin complex may partially restore coagulation by enhancing thrombin generation. Clinical trials of hirudin compounds have yielded mixed results. It has been used for patients with HITT, but the longer half-life of approximately 90 minutes means that many of these patients bleed after cardiac surgery.[233] Hirudin is highly antigenic and will lead to immune complexes being created to itself in about 40% of patients. If it is used a second time, the overall incidence rate of anaphylaxis may be as high as 10% of all patients who have received it before. Currently, it is not recommended to use hirudin as a primary agent to perform CPB even if a patient has HIT antibodies.

New direct thrombin inhibitors are now available (Fig. 35.17). These include argatroban and bivalirudin. Argatroban, a derivative of L-arginine, is a relatively small molecule and functions as a univalent direct thrombin inhibitor.[234–249] It binds at the active cleavage site of thrombin and stops thrombin's action on serine proteases. It is completely hepatically cleared and has a reported half-life of 45 to 55 minutes with prolongation when liver function is depressed or liver blood flow is decreased. One case report examined argatroban's half-life after CPB. It was found to be prolonged to 514 minutes in a patient undergoing heart transplantation. This led to the use of massive transfusion (55 units of RBCs, 42 units of FFP, 40 units of cryoprecipitate, 40 units of platelets, as well as 3 doses of factor VIIa).

There is no reversal agent for argatroban, although factor VIIa has been given to increase thrombin generation. It has been approved by the US Food and Drug Administration (FDA) for anticoagulation in the face of HITT, but there has not been, to date, a large-scale, prospective, randomized trial for cardiac surgery or any type of comparison with heparin/protamine. Some case reports do exist of successful usage of argatroban in patients with HITT both on- and off-pump with

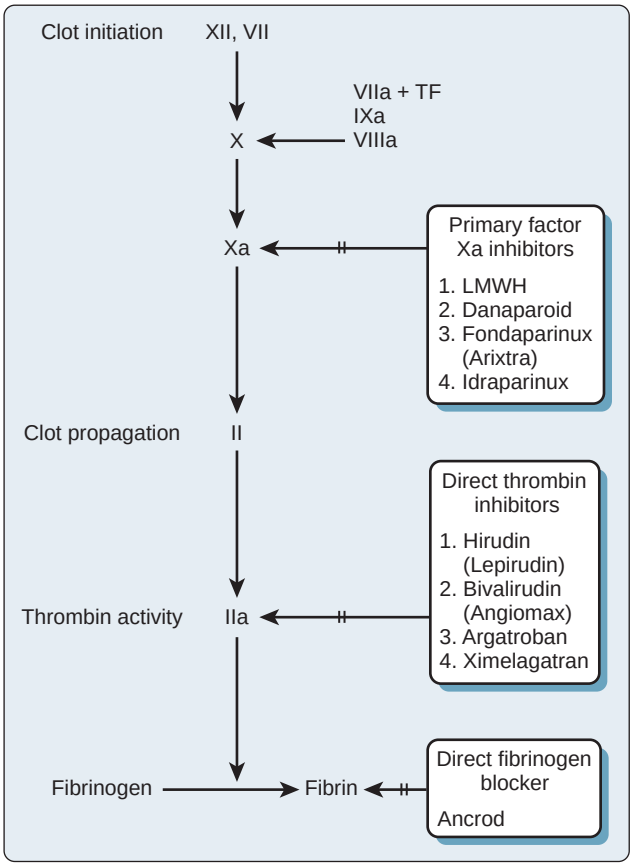

Fig. 35.17 Alternatives to heparin. New modes of anticoagulation are shown in the boxes on the right side of the figure where they inhibit either factor Xa, thrombin, or fibrinogen. *LMWH,* Low-molecular-weight heparin.

acceptable amounts of postoperative bleeding.[236–240] The dosing for off-pump cases has been reported to be about 2 to 3 μg/kg/min, with a goal of an ACT longer than 200 seconds.[239,240] For on-pump cases, the dose is at least doubled (5–10 μg/kg/min), with an effort to achieve an ACT of 300 to 400 seconds.[242] There is no safe and effective dose that has been clinically studied, so any use of this drug for cardiac surgery is off-label and based on experience, as well as case reports. Successful case completions have been noted without undue excess bleeding. However, as noted earlier in the transplant case, some very large bleeds have been encountered. Some cases of thrombosis also have occurred.[241–246] It has been more commonly used in the ICU for patients with hypercoagulable syndromes and HITT.[237,238] Argatroban is a viable direct thrombin inhibitor for use in the cardiac catheterization laboratory. It is far more likely that anesthesiologists will encounter the drug either in the ICU being used for patients with HIT or in patients who have come from the catheterization laboratory directly to the ORs.

Bivalirudin is a bivalent synthetic 20-amino acid peptide based on the structure of hirudin (previously called *Hirulog*).[250–259] Pharmacologists have taken the active amino acids at either end of the hirudin molecule and biosynthesized them. One active site competitively binds to the fibrinogen-binding site of thrombin; the other end of the molecule, the amino-terminal sequence, binds to the active serine cleavage site of thrombin. The two sequences of amino acids are connected together by a tetraglycine spacer. This fully manufactured molecule is highly specific for thrombin and has the unique property that it binds to both clot-bound and free thrombin. Heparin binds only to free plasma thrombin. Bivalirudin has a shorter half-life than argatroban and hirudin; the $t_{1/2}$ is approximately 20 to 25 minutes (with normal renal function and not on CPB). One of the most unique

features of bivalirudin is that its binding to thrombin is reversible and the molecule itself is cleaved by thrombin.

Like the other direct thrombin inhibitors, bivalirudin also has no reversal agent analogous to protamine, so when it is used, it must wear off. Bivalirudin undergoes destruction by the molecule to which it binds and deactivates, thrombin; it is destroyed by thrombin (proteolytic cleavage). The more thrombin activation that is present (ie, the less bivalirudin that is present), the shorter is the half-life. Only about 20% of the molecular activity is eliminated by renal clearance.[250] In mild-to-moderate renal failure, the effect on bivalirudin clearance is thought to be small, but bleeding in patients with renal failure has been noted.

Several clinical trials of bivalirudin for cardiology procedures or cardiac surgery have been completed and published.[251–259] Two pivotal trials aiming for FDA approval of bivalirudin for cardiac surgery with known/suspected HIT were conducted several years ago.[187,188] In trials comparing bivalirudin with either heparin/protamine alone or heparin plus the use of a GP IIb/IIIa inhibitor for percutaneous interventions, bivalirudin was found to have at least equal or better safety and less bleeding than either of the other therapies. When compared with heparin/protamine alone in percutaneous coronary intervention, bivalirudin was found to be superior, not just in bleeding, but also in terms of morbidity and mortality (as a combined end point).[258] In a trial of 100 off-pump routine CABG patients without suspected HIT, patients were randomized to receive either bivalirudin or heparin/protamine, and bleeding and outcome were equal between the groups.[251] These patients underwent recatheterization at 3 months, and it was found that the bivalirudin patients had overall better flow down their grafts than did the patients who had received heparin/protamine. That finding is consistent with the work noted in the HIT section earlier wherein the presence of antibodies bodes poorly for postoperative complications. It also suggests that heparin-protamine in the face of ischemia and reperfusion may lead to adverse thrombotic outcomes with or without heparin-PF4 antibodies. This trial, in conjunction with subsequent trials, raises questions with regard to heparin-protamine and suggests that for off-pump CABG, a more routine usage of bivalirudin might produce improved outcomes.

A phase I/II safety trial of bivalirudin in 30 on-pump CABG patients has also shown good safety, but no comparison was conducted to look at advantages against heparin/protamine. When used, the doses for CPB have been a 0.50- to 0.75-mg/kg bolus followed by an infusion at 1.75 to 2.5 mg/kg/hr titrated to the ACT (target, 2.5 times baseline). The CPB system also was primed with 50 mg, and no stasis can be allowed in the CPB circuit because of metabolism of bivalirudin during CPB. The infusion is stopped about 15 to 30 minutes before CPB is discontinued, and patients bleed for up to 4 to 6 hours. OPCAB cases have used similar doses to ACT targets of 350 to 450 seconds.[253,254] There certainly are some tricks to using bivalirudin for cardiac cases. The drug itself is broken down by thrombin, and thrombin is produced by CPB, as well as through tissue destruction. Any blood left alone without a continuous infusion of bivalirudin will, because of its generation of thrombin, overcome the anticoagulation of bivalirudin in time. Therefore it is expected that stagnant blood in the mediastinal or the chest cavities, or both, will clot. This is alarming to the first-time user of bivalirudin and completely different from what is seen in cases with heparin anticoagulation. Also, the use of mediastinal suction during bypass is not recommended because the mediastinum is a source of a great deal of thrombin activity. Suctioning that back into the CPB reservoir has led to clots being present in a hard-shell reservoir, wherein there is stasis or incomplete mixing of bivalirudin. Once the patient is separated from CPB, it is important to make a decision regarding whether the patient is likely to need to return to bypass. The bypass system, if left stagnant, will have ongoing production of thrombin. Over time, that thrombin will overcome the bivalirudin present in the plasma. Therefore within 10 minutes of separation from CPB, it is wise to decide to either drain the blood from the pump, process it through a cell-saver machine, or reestablish flow and have a slow infusion of bivalirudin into the pump. The reestablishment of flow can be easily accomplished by reattaching the ends of the venous and arterial cannulae. If it is necessary to reestablish CPB, the system should be maintained warm and either a bolus (25 to 50 mg) of bivalirudin should be put into the pump or the infusion that had been running to the patient should be switched to the pump.[252] Furthermore, some surgeons have suggested that in areas of stasis, such as in an internal mammary artery, it is important to flush the artery every 10 to 15 minutes to allow for new bivalirudin to be perfused, or clot could build up in the "dead end" if it is clamped. The other option is to not completely clamp off the internal mammary artery until just before it is to be anastomosed.

There has been some confusion regarding how best to monitor anticoagulation with bivalirudin for cardiac surgery. Originally, Koster and colleagues [233,255] utilized the ecarin clotting time (ECT) to follow circulating levels of bivalirudin. The ECT has a straight-line dose-response relation in the critical range between 300 and 550 seconds. The ACT has a less specific and more variable relation. With circulating bivalirudin concentrations of 10 to 15 μg/mL, the ECT will be 400 to 450 seconds. It is known that clot will not be able to be generated with a bivalirudin concentration greater than 3 to 5 μg/mL, so a level of 10 to 12 will be well greater than a therapeutic threshold to ensure that fibrin formation does not occur on bypass. The dose-responsiveness of bivalirudin is highly predictable. There is no secondary reaction necessary such as with AT III and UFH. Therefore, when bivalirudin is given, there is an absolute amount of AT available. Debates among researchers have gone forward as to whether ACT or ECT monitoring is even necessary at all. The consensus is that ACT will work (the ECT is no longer commercially available). The other reason for using an ACT is that during CPB, if a drug pump malfunctions or the infusion is somehow disconnected, it is important to know that earlier rather than later. If the ACT begins to elevate to more than 500 seconds, then the team really does not know whether to back off on the bivalirudin infusion, stop it altogether, or attribute the effect to some other ACT-prolonging situation such as hemodilution or hypothermia. It is known that hypothermia retards the production of thrombin, but no studies have been done of bivalirudin half-lives in the face of mild-to-moderate hypothermia.

The two trials of bivalirudin in the face of known or suspected HIT antibodies did show effectiveness and safety.[187,188] The CABG Hit On- and Off-Pump Safety and Efficacy (CHOOSE) study and the Evaluation of Patients During Coronary Artery Bypass Operation: Linking Utilization of Bivalirudin to Improved Outcomes and New Anticoagulant Strategies (EVOLUTION) trial were performed as parts of a program to get bivalirudin approved for patients undergoing cardiac surgery with known or suspected HIT. EVOLUTION (ON and OFF) trials randomized patients to receive either heparin-protamine or bivalirudin as the primary anticoagulant regimen for either on- or off-pump CABG surgery. In EVOLUTION-OFF, 157 patients were scheduled for OPCAB at 21 centers. The dosing of bivalirudin was 0.75 mg/kg as a bolus and 1.75 mg/kg/h while the grafts were being prepared and anastomosed. Heparin was dosed to reach an ACT target of 300 seconds and reversed with protamine. There were no differences in death, myocardial infarction, or need for repeat revascularization. However, there was a significant reduction in strokes seen with the use of bivalirudin. Bleeding was about the same with both groups. In the EVOLUTION-ON trial, 150 patients underwent a number of cardiac procedures at the 21 sites. There were, again, no major differences in procedural success (death, MI, need for redo) in the heparin versus bivalirudin groups. There was a statistically, but clinically insignificant, difference (78 mL) in blood loss at 2 hours and not at 24 hours with bivalirudin.

The CHOOSE trials undertook to use bivalirudin in patients with known or suspected HIT. In the CHOOSE-ON trial, 50 patients were enrolled. Immediate success of surgery was achieved in 94% of patients (treated with bivalirudin); at 30 days, success was 86%, and at 12 weeks that had decreased to 82%. Unfortunately, only historic controls could be examined to compare, and conjecture comes into play as to what might happen in such a high-risk group with known/suspected HIT.

Bleeding and transfusion were greater in patients who received bivalirudin. In a single German center with a large experience using bivalirudin, 40 patients had heparin antibodies.[253] These investigators noted that their procedural success rate was 99.4%; however, they did have an increased use of transfusion in those patients who received bivalirudin.

In the face of HITT syndrome, case reports continue to show effectiveness and utility of bivalirudin.[250,255,256] This is an off-label use of the drug because it has not been FDA approved. In animal studies, bivalirudin does not activate platelets, and those animals that have received the drug for CPB have a better platelet count at the end of surgery. Other inflammatory mediators such as cytokines also may be decreased with bivalirudin administration as compared with heparin/protamine administration. Heparin, even in small doses, activates platelets to express their binding sites, whereas bivalirudin seems to leave the platelets quiescent. It also has no cross-reactivity with any immunoglobulin that is present to heparin/PF4 and does not produce an immune response of its own, which can be seen with hirudin.

New Oral Anticoagulants

The introduction of new oral anticoagulants (NOAC) that specifically target thrombin (factor IIa or FIIa) or factor Xa has increased the complexity of coagulation management in patients presenting for cardiac and noncardiac surgery. These NOACs or target-specific oral anticoagulants (TSOACs) include one FIIa inhibitor, dabigatran (Pradaxa), and three factor Xa inhibitors—rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa)—that are increasingly encountered in clinical practice. These drugs are prescribed in place of warfarin or LMWH for the prevention and treatment of thromboembolism in various clinical settings.[260] Advantages for patients include shorter half-life, more favorable risk-benefit profile, and fixed daily dosing without the need for frequent laboratory tests because of more predictable pharmacokinetics (Table 35.6). Dabigatran has been found unsuitable for patients with artificial valves in place, because it caused more bleeding and thromboembolic episodes than warfarin.[261] Dabigatran has a half-life of 12 to 14 hours, whereas the factor Xa inhibitors half-lives range from 5–15 hours. Dabigatran is 80% excreted by the kidneys, whereas the factor Xa inhibitors are protein bound and metabolized by cytochrome P450s in the liver.

These medications do not require regular laboratory testing as occurs with warfarin. In fact, they have variable effects on the various coagulation tests. The preferred tests are the direct thrombin time or an ECT for dabigatran and the anti–factor Xa assays for the other drugs. In an emergency, an aPTT with calibrated reagents can be used for dabigatran and a dilute PT for the factor Xa agents.[262]

In the case of surgical bleeding, patients can be treated with the usual blood products. In addition, the PCCs can be used, with or without FVIIa, to further improve coagulation in life-threatening situations. The four factor PCCs (eg, Kcentra) have been approved by the FDA for warfarin reversal and have had some positive results with the factor Xa inhibitors (see Chapter 34). The best ways to treat bleeding with dabigatran are to either prevent its absorption from the stomach with charcoal or to remove it from the blood with hemodialysis. Extensive work is leading to reversal agents for these NOACs. Idarucizumab (Praxbind) is a fully humanized antibody fragment that has completely reversed dabigatran in clinical trials. It has been studied in more than 100 patients who are either bleeding or undergoing surgery in the RE-VERSE AD phase III trial.[263] The thrombin time and coagulation time have been normalized very rapidly and sustained for 24 hours, whereas the plasma levels of dabigatran have been lowered significantly. Reversal agents are also being developed for the factor Xa inhibitors (eg, andexanet alfa, PER 977), but these are at earlier stages of development.

TABLE 35.6 New Oral Anticoagulants

	Dabigatran	*Rivaroxaban*	*Apixaban*	*Edoxaban*
Action	IIa Inhibitor	II Inhibitor	Xa Inhibitor	Xa Inhibitor
Administration	bid	daily	bid	daily
Peak plasma level	2 h	2–4 h	1–4 h	1–2 h

Renal exc.	80%	35%	25%	50%
Protein bind	35%	90%	87%	—

Nonthrombogenic Surface

Considered the holy grail of extracorporeal circulation, an artificial surface that does not incite thrombus formation remains undiscovered. The endothelial surface, which the artificial one should mimic, performs a host of biochemical functions related to antithrombosis. Two that appear crucial are (1) secretion of substances that inhibit both platelet activation and aggregation and (2) surface and matrix adsorption of heparin and heparan, which may locally potentiate AT.[264]

Heparin may be immobilized onto surfaces by ionic bonding onto cationic surfactants. Unfortunately, both heparin and surfactant leach off the coated surface on exposure to blood. Covalent binding or surface grafting of heparin provides a more stable preparation. A properly heparin-bonded surface should bind AT sufficiently to prevent fibrinogen-induced platelet adhesion. Heparin-coated CPB tubing reduces the need for systemic heparin but has not been sufficiently effective to replace systemic anticoagulation.[265–270] Other approaches include increasing surface hydrophilicity with polyethylene oxide and sequestration of the thrombogenic surface by endothelialization, albumin activation, or phospholipid mimicking. New materials might permit cardiac surgery with minimal doses of heparin or even without it (see Chapters 31–33).

Protamine

Pharmacology

Protamine neutralizes heparin-induced anticoagulation. This section considers the history, pharmacology, and clinical use of protamine during cardiovascular surgery, including toxic and idiosyncratic adverse effects. Alternatives to protamine complete the discussion.

History

Miescher, investigating cell nuclei in 1868, discovered and named protamine, a nitrogenous alkaline substance in sperm heads of salmon. Composed of nearly two-thirds arginine, protamines contain many positive charges (Fig. 35.18). Their biologic role is to associate with the negatively charged phosphate groups of nucleic acids[269] (Fig. 35.19).

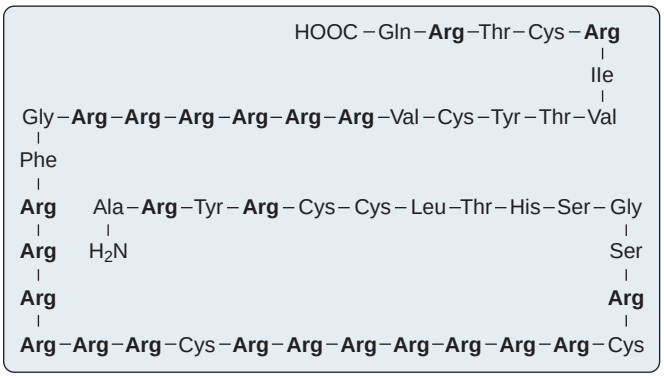

Fig. 35.18 The complete amino acid sequence of protamine from steer. Note the abundance of arginine residues (50% for this species). *(Modified from Coelingh JP, Monfoort CH, Rozijn TH, et al. The complete amino acid sequence of the basic nuclear protein of bull spermatozoa.* Biochim Biophys Acta. *1972;285:1.)*

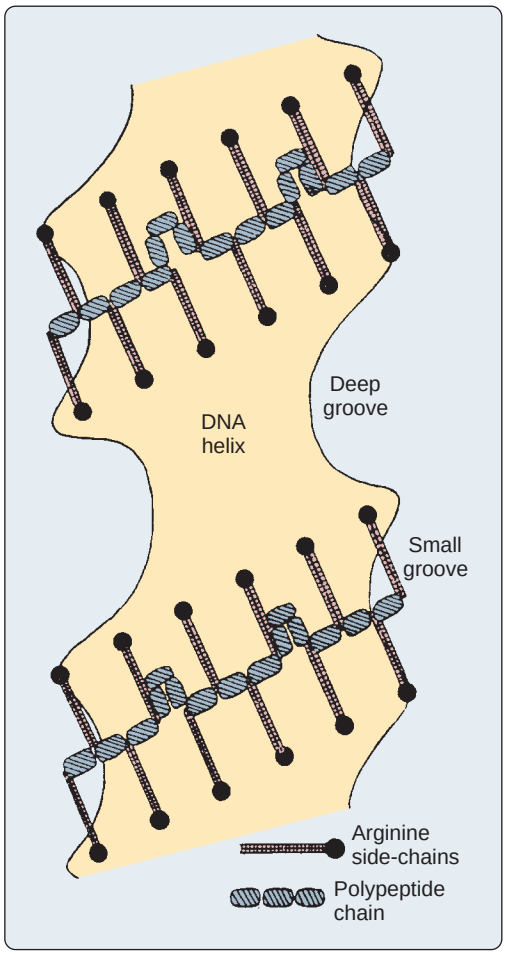

Fig. 35.19 The polypeptide chain of protamine with its arginine residues seen residing in the small groove of the DNA helix. *(From Wilkins MHF: Physical studies of the molecular structure of deoxyribonucleic acid and nucleoprotein.* Cold Spring Harbor Symp Quant Biol. *1956;21:83.)*

In 1936, Hagedorn and colleagues used protamine to delay the absorption of insulin administered subcutaneously. They (correctly) chose protamine, hoping that its alkaline pH would maintain insulin in an ionized, slowly absorbed state. When others attempted to mix protamine with heparin to make a long-acting subcutaneous preparation for thrombosis prophylaxis, they obtained a white precipitate instead of a useful mixture. Chargaff and Olson[271] recognized that this precipitate represented the salt of polycationic protamine and polyanionic heparin. They established protamine as the neutralizing drug for heparin's anticoagulant effect. Jaques[272,273] developed the in vitro protamine titration test for blood heparin levels and documented adverse circulatory effects from protamine.

Source and Preparation

Most vertebrate species synthesize a protamine residing in the heads of sperm. Human protamine closely resembles that of other species.[274] Salmon milt provides the pharmaceutical source of protamine. The crushed gonads of male salmon undergo a crude extraction and filtration process using salt and alcohol. The final product, a dried powder, commonly is reconstituted as a 10-mg/mL solution. Like insulin and some other protein products, it is stable without refrigeration for several weeks. Protamine is available as sulfate and chloride salts. Protamine chloride may have a more rapid onset compared with protamine sulfate.[275] Nevertheless, clinical study reveals no superiority of one preparation over the other.[276]

BOX 35.7 BASIS FOR VARIABILITY IN PROTAMINE DOSE

- Ratio of protamine to heparin
- Amount of heparin to neutralize
- Heparin rebound
- Protamine overdose

Uses and Actions

Two long-acting insulin preparations contain protamine. Protamine-zinc insulin contains 10 to 15 µg protamine per unit of insulin, whereas NPH (neutral protamine Hagedorn) insulin contains 3 to 6 µg/unit. The former compound, with more protamine, exhibits a 36-hour duration, compared with 24 hours for the NPH insulin. Both heparin and protamine alter cell division and influence angiogenesis and tumor size.[277,278] However, these effects have not yet developed into therapeutic modalities. In addition, both protamine and its substitute polycation, hexadimethrine, possess broad antimicrobial activity, suggesting application as a topical antibiotic.[279]

Neutralization of heparin-induced anticoagulation remains the primary use of protamine. Formation of complexes with the sulfate groups of heparin forms the basis for this "antidote" effect. Protamine neutralizes the AT effect of heparin far better than its anti–factor Xa effect.[120] This distinction may arise from the need for thrombin, but not factor Xa, to remain complexed to heparin for AT to exert its inhibitory effect. Because porcine mucosal heparin has more potent anti–factor Xa activity than bovine lung heparin,[280] today's available heparin may prove to be more difficult to neutralize with protamine. Protamine's poor efficacy in neutralizing anti–factor Xa activity limits the utility of LMWH compounds as anticoagulants for CPB.

Protamine exhibits antihemostatic properties by affecting platelets and by releasing t-PA from endothelial cells.[120] Thrombocytopenia follows protamine administration in dogs and in humans.[281–284] Heparin-protamine complexes inhibit thrombin-induced platelet aggregation.[285] In addition, protamine appears to bind to thrombin, inhibiting its ability to convert fibrinogen to fibrin.[286] Initial attempts to document an in vivo antihemostatic effect of protamine proved unsuccessful.[154] Rapid degradation of protamine by circulating proteases may account for this discrepancy.

Administration, Distribution, and Fate

Neutralization of heparin occurs by intravenous injection of protamine. Subcutaneous administration is limited to prolongation of insulin absorption. Presumably, these highly charged polycations distribute only to the extracellular space.

In the presence of circulating heparin, protamine forms large complexes with heparin.[287] Excess protamine creates larger complexes. The reticuloendothelial system may then dispose of these particles by endocytosis. Although this action has not been proved, macrophages in the lung may constitute the site for elimination of these complexes because intravenous administration of protamine permits formation of heparin-protamine complexes in the pulmonary circulation first. Protamine also may bind to circulating plasma proteins, the significance of which remains unclear.[288] Proteolytic degradation of the protamine complexed to heparin conceivably results in free heparin. Protamine degradation in vivo proceeds by the action of circulating proteases, among them carboxypeptidase N, an enzyme that also clears anaphylatoxins and kinin pathway products.[289] The time course of protamine disappearance from plasma in patients remains poorly investigated.

Dosage

The recommended dose of protamine to neutralize heparin varies widely. Box 35.7 lists factors accounting for this variability. The first

factor is the proper ratio of protamine to heparin. Reports of the optimal ratio of milligrams of protamine to units of heparin cite values as low as zero (ie, they do not neutralize heparin)[290] to as much as 4 mg/100 units.[168] This variability has been accounted for by differences in timing, temperature, and other environmental factors; choices for coagulation tests and outcome variables; and speculation and unproven assumptions. Second, the basis for calculating protamine dose, the total amount of heparin given or the amount remaining in the patient, must be determined. Protamine titration tests at the conclusion of CPB can determine the amount of heparin remaining in the patient. With automated versions of this test and simple assumptions regarding the volume of distribution of heparin, the amount needed to neutralize the heparin detected in the patient's vasculature can be calculated. However, this technique may invite heparin rebound, the third concern (see Chapter 19).

An alternative regimen splits a 1 mg/100 units calculated dose of protamine into two separate doses: an initial dose (75% of the total) after CPB, with the remainder after reinfusion of blood from the bypass circuit. This regimen prevented increased plasma heparin levels and prolongation of the aPTT, compared with a control group.[291] The ACT remained unchanged, perhaps a reflection of its insensitivity to small amounts of circulating heparin. Protamine chloride did not prove superior to protamine sulfate in preventing the occurrence of heparin rebound.[276]

A system using coagulation test tubes that contain lyophilized heparin and protamine matched by lot to that administered to the patient permits calculation of dosages to account for variations arising from patient and pharmaceutical factors. It results in increased doses of heparin and decreased doses of protamine compared with those calculated by weight alone. Nevertheless, decreased bleeding and less use of allogeneic blood products result.[161]

Finally, lest fear of heparin rebound prompt the clinician to administer protamine in excess, gross overdosage may likely anticoagulate patients. Dogs given excess protamine exhibited a dose-dependent prolongation of the ACT, with the ACT nearly doubling after a protamine dose four times that needed to neutralize heparin. At a tenfold dose, the aPTT prolonged and thrombocytopenia developed[160] (Fig. 35.20). Without prior heparin, the coagulation test abnormalities occurred at lower protamine doses. The cautious clinician realizes that the protease enzyme system that degrades protamine can be saturated. Prolongation

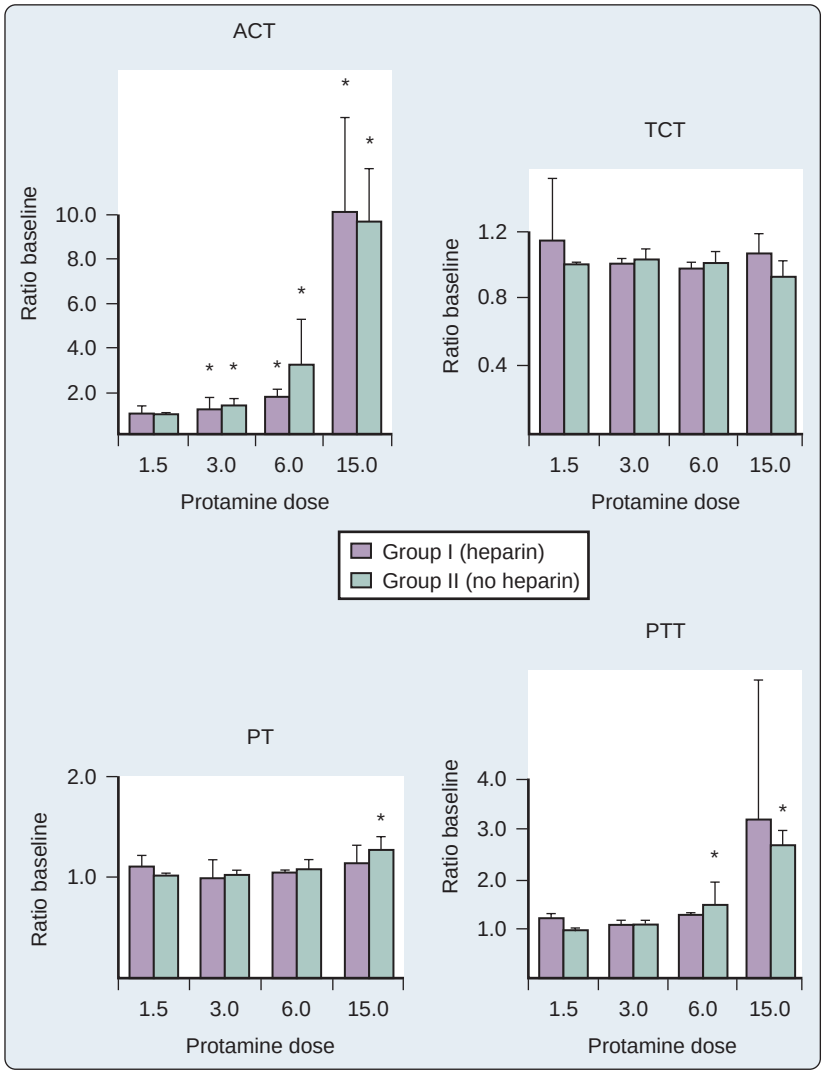

Fig. 35.20 Effect on the activated coagulation time (*ACT*), thrombin clotting time (*TCT*), prothrombin time (*PT*), and activated partial thromboplastin time (aPTT) of protamine dose (in mg/kg) given to dogs 10 minutes after 150 U/kg heparin *(dark bars)* or without prior heparin *(light bars)*. Error bars represent standard deviation (SD). *Asterisks* denote statistical significance compared with baseline values. *(From Kresowik TF, Wakefield TW, Fessler RD, Stanley JC. Anticoagulant effects of protamine sulfate in a canine model.* J Surg Res. *1988;45:8.)*

of coagulation times may conceivably result from protamine overdose, as well as from unneutralized heparin. Fortunately, the safe range of protamine dose regarding neutralization of anticoagulation is large; therefore the prudent clinician will not hesitate to administer a small additional dose of protamine should incomplete neutralization or heparin rebound be suspected, while limiting administration so as not to overwhelm the proteases that degrade protamine.

Adverse Reactions

The potential for a deleterious response to protamine administration raises serious questions and difficult choices in clinical care before, during, and after cardiac operations. This section presents the spectrum of adverse reactions, the presumed mechanism for each, and treatment options. These adverse events can be reduced with proper clinical technique. Thus a clinical perspective at the end of this section discusses preventive measures to guard against untoward responses. The causes of hypotension after protamine (rapid administration, anaphylactic reaction, and pulmonary vasoconstriction) are considered in turn.

Rapid Administration

Peripheral Cardiovascular Changes

Jaques determined initially that systemic hypotension from protamine administered to dogs required a rapid (15-second) injection. Subsequent studies confirmed that hypotension accompanies intravenous protamine.[273,292–299] However, repeat doses are benign when given slowly or rapidly within 4 to 6 hours of an initial reaction unless heparin is given before the second dose.[293,300] Pulmonary arterial pressures also increase.[293,301] Although increased pulmonary arterial pressure and pulmonary vascular resistance follow protamine predictably in dogs, pigs, and sheep, humans respond in a more idiosyncratic fashion. Decreased systemic vascular resistance accompanies the systemic hypotension,[281,296,297] whereas venous return and cardiac filling pressures decrease.[296,287] Rapid volume administration may avert systemic hypotension in both dogs and humans.[296,302]

Slow administration of a neutralizing dose over 5 minutes or longer rarely will engender cardiovascular changes[303] Systemic hypotension from rapid injection in humans has been ascribed to pharmacologic displacement of histamine from mast cells by the highly alkaline protamine, similar to the mechanism by which curare, morphine, and alkaline antibiotics (eg, vancomycin and clindamycin) cause hypotension. However, protamine alone, in concentrations similar to those expected in vivo, fails to release histamine from minced animal lung tissue,[304] or from dispersed human mast cells.[305] More recent investigations linked hypotension to the release of nitric oxide from endothelium.[306]

Effects on Cardiac Inotropy

Cardiac output (CO) predictably decreases after rapid administration to animals when preload is allowed to decrease.[281,292,294,295,299,301] Most human studies document no change in CO with rapid[307–309] or slow administration.[310–314] When volume infusion accompanies protamine, CO increases[302]; however, the effects of protamine on CO do not assess its impact on inotropy, which constitutes only one of many determinants of CO.

Initial reports indicated a myocardial depressant effect.[292,294,295,297] Studies using strips of myocardium bathed in concentrated protamine solutions produced similar results[315–318]; clinically relevant bath concentrations yielded conflicting results regarding depressed myocardial mechanics.[319–321] One study suggested that only concentrated noncomplex protamine would compromise patients clinically.[318] Another suggested that patients with established ventricular compromise might suffer further degradation of contractile performance on exposure to unbound protamine.[322] The mechanism may relate to altered membrane ion conductances that increase intracellular calcium.[322] Well-conducted studies in intact organisms revealed no effect of protamine on contractility in animals[298,313,323] or humans[293,323–329] (Fig. 35.21).

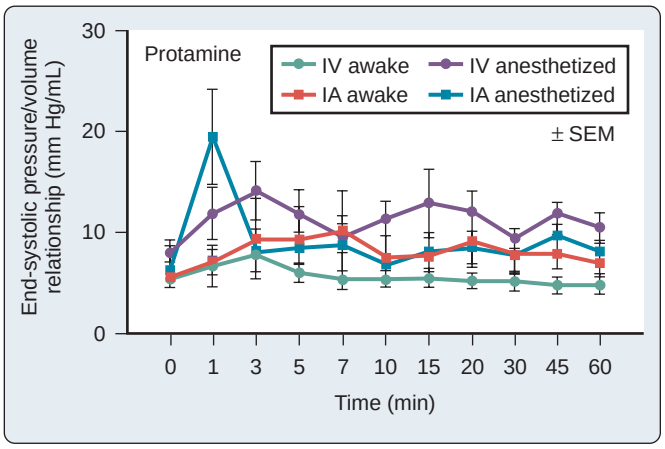

Fig. 35.21 Effect of protamine infusion to dogs on a measure of inotropic state, the end-systolic pressure-volume relation. Neither route of administration (intra-aortic [*IA*], intravenous [*IV*]) nor the presence of anesthesia modified the absence of an effect of protamine on inotropic state. *(From Taylor RL, Little WC, Freeman GL, et al. Comparison of the cardiovascular effects of intravenous and intraaortic protamine in the conscious and anesthetized dog.* Ann Thorac Surg. *1986;42:22.)*

Left-Sided Injection

Based on early reports claiming protection from adverse responses, injection of protamine directly into the left side of the circulation (left atrium or aortic root) became popular.[326,327] Some subsequent animal investigations confirmed a left-sided advantage[328,329]; others demonstrated no advantage[323,330] or more compromised hemodynamics[331–333] compared with a control right-sided group. Left-sided injection provides no protection from pulmonary hypertension.[331] In humans, the published evidence weighs against left-sided injection; three separate investigations in a total of 130 patients demonstrated more hypotension from left-sided than right-sided injection.[309,332,333] The clinician must consider that left-sided injection also increases the risk for systemic particulate and air embolization.

Platelet Reactions

The most underappreciated reaction to protamine is thrombocytopenia. The heparin-protamine complex activates the microcirculation. For a quick graphic example, the reader should merely mix heparin and protamine in a well or syringe. A milky precipitate is observed that grows into larger beads of precipitate. It is clear that when protamine is administered, it binds heparin wherever it comes into contact with it. It may find heparin attached to the surface of platelets and then coat the surface of the platelets with heparin-protamine complexes. It also is possible that heparin and protamine could form cross-links between platelets because the protamine is polycationic and can bind a number of heparin molecules. The end result is a decrease in platelet count within 10 to 15 minutes of administration of protamine. The usual is roughly a 10% decline in platelet count, but it can be larger, when normalization of coagulation is expected. It appears that the platelets are sequestered by the reticuloendothelial and pulmonary vasculature. It is unclear whether those patients with the largest drop in platelets develop the worst bleeding or whether they are at the greatest risk for pulmonary vasoconstriction and pulmonary hypertension secondary to thromboxane release. The sequestered platelets come back into the circulation over the next few hours, and by 1 to 4 hours, the platelet count returns toward normal.

Anaphylactoid Reaction

Allergy, Anaphylaxis, and Adverse Responses

Not all adverse responses to protamine are allergic reactions. Rapid protamine injection decreases blood pressure just as morphine induces nausea; neither side effect is allergic. Immediate hypersensitivity

allergic reactions involve release of vasoactive mediators resulting from antigen-antibody interaction. The broader term *anaphylactoid reactions* includes not only severe immediate hypersensitivity allergy, termed *anaphylaxis,* but also other life-threatening idiosyncratic responses of nonimmunologic origin[334–336] (Fig. 35.22). The initial classification of protamine reactions split the anaphylactoid category (type II) into three subsets: anaphylaxis (IIA), nonimmunologic anaphylactoid reaction (IIB), and delayed noncardiogenic pulmonary edema (IIC).[336] The last two are poorly defined phenomena. Complement-mediated nonimmunologic effects do occur but are not discussed here.[337] This section deals mainly with allergic responses and polycation lung injury.[336–338]

Diabetes Mellitus

Patients receiving protamine-containing insulin develop antibodies to protamine. Between 38% and 91% of these patients demonstrate an antiprotamine IgG[339–341]; far fewer patients develop an antiprotamine IgE. Do these antibodies cause adverse responses to protamine administration? Few patients with diabetes actually experience development of hemodynamic compromise from protamine.[341] The numerous case reports of patients with diabetes who had adverse responses to protamine reflected either a truly increased incidence of adverse response in this population or merely a reporting bias, because cases in nondiabetics are not published.[342–353] Retrospective attempts to determine the risk for protamine reaction in diabetes patients yield diverse results.[354,355] A case-control study found a 95-fold increase in risk relative to patients taking NPH insulin,[356] whereas prospective studies [341,357] demonstrated no increased risk. Table 35.7 displays these data. If risk is increased, it remains quite small (0.6%).[341]

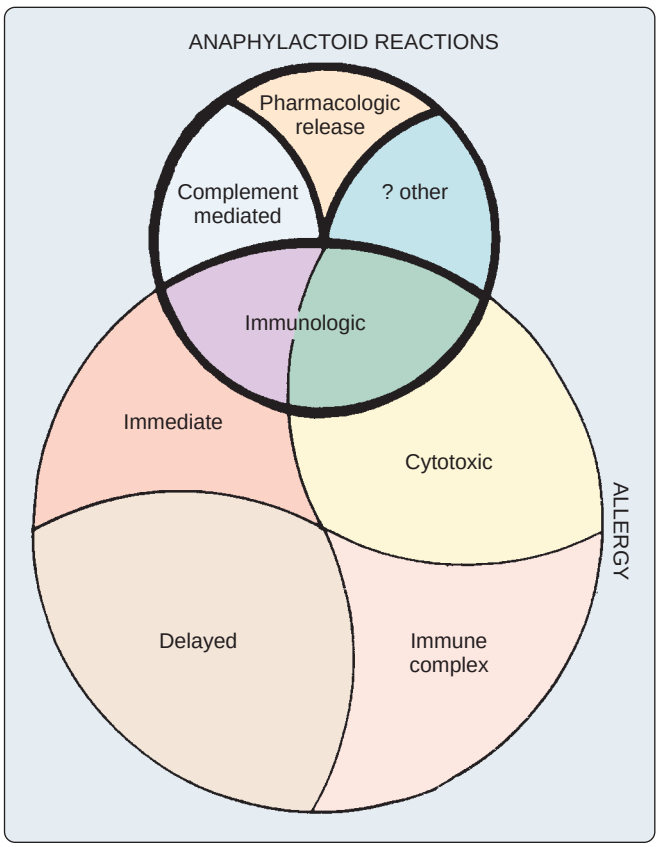

Fig. 35.22 Venn diagram depicting the spectrum of allergy and of anaphylactoid reactions. Anaphylaxis to protamine is an immunologic-type anaphylactoid reaction classified as an immediate allergic reaction. *(From Horrow JC: Protamine allergy.* J Cardiothorac Vasc Anesth. *1988;2:225.)*

Prior Exposure to Protamine

Previous protamine exposure may occur at catheterization,[344,358] at prior vascular surgery,[342,345] at dialysis,[359] or during blood component donation,[360] although modern techniques for the latter two procedures no longer use heparin and protamine. Multiple exposures at intervals of about 2 weeks maximize the chance of an allergic response.[361]

A single intravenous exposure to protamine will engender an IgG or IgE antibody response in 28% of patients.[362] Nevertheless, many thousands of patients each year receive protamine at both catheterization and then later at surgery without sequelae. They offer evidence of the safety of this sequence and the rarity of intravenous exposure to protamine generating clinically significant antibodies.

Fish Allergy

Salmon is a vertebrate or true fish (also known as "fin" fish), as opposed to shellfish, which are invertebrates. Patients allergic to fin fish can respond to protamine with anaphylaxis. Several case reports support this statement.[363,364] As with patients with diabetes, patients with fish allergy followed prospectively do not exhibit an adverse response to protamine challenge.[341] One of this chapter's authors (J.H.) has documented negative skin tests in several patients with fish allergy in whom subsequent protamine administration was benign, as well as a positive skin test in one patient who did not receive protamine (unpublished data). Because skin tests have high sensitivity and poor specificity, negative results suggest lack of allergy. No data link shellfish and protamine allergies.

Vasectomy

Within 1 year of vasectomy, 22% of men develop cytotoxic (IgG) antibody to human protamine, which may cross-react with salmon protamine because of similarity among protamines.[365] These autoantibodies exist in weak titers, however. Prospective studies demonstrate that patients with prior vasectomy receive protamine during cardiac surgery without adverse response.[365,366] Case reports of vasectomy-related protamine allergy[367] display insufficient evidence to demonstrate a causal relation[336,368]; thus vasectomy remains only a theoretic risk for protamine allergy.

Noncardiogenic Pulmonary Edema

Systemic hypotension accompanied by massive pulmonary capillary leak, accumulation of alveolar fluid, decreased pulmonary compliance, wheezing, and pulmonary edema can occur after CPB. Originally attributed to protamine, these rare responses occur sporadically at least 20 minutes after protamine administration.[348,369–372] Others have

TABLE 35.7 Studies on the Incidence of Protamine Reactions (Type Unspecified)

Authors	*Type*	*Size*	*Situation*	*Nondiabetics*	*Diabetics, No Insulin*	*Diabetics-NPH*
Stewart et al[354]	Retrospective	651	Catheterization	0.50%	0.0%	27.0% (4/15)
Gottschlich et al[355]	Retrospective	2996	Catheterization	0.07%	—	2.9% (2/68)
Levy et al[304]	Prospective	3245	Surgery	0.06%	—	0.6% (1/160)
Weiss et al[356]	Case control	27	Various	25 × (IgG)[a]	—	95 × (IgE)[b]

[a]Nondiabetics who sustained an adverse response to protamine were 25 times more likely to demonstrate an antiprotamine IgG than nondiabetics who did not suffer an adverse protamine response.

[b]Diabetics taking NPH insulin who sustained an adverse response to protamine were 95 times more likely to demonstrate an antiprotamine IgE than NPH-taking diabetics who did not suffer an adverse protamine response.

attributed the problem to administration of banked blood products[373,374] or other substances.[375] CPB itself activates complement via the alternate pathway, which can (but usually does not) result in leukocyte aggregation, free radical formation, and lung injury.[34,376]

Many polycations, including protamine, hexadimethrine, and polylysine, can directly induce delayed pulmonary vascular damage.[376] Verapamil may attenuate polycation injury via its inhibitory effects on calcium channels.[377] The delayed noncardiogenic pulmonary edema seen clinically might arise from protamine, from administration of leukocytes that accompany banked blood products,[374] or from CPB.[378,379] Perhaps the marked decrease in occurrence of this phenomenon since 2000 arises from less frequent use of FFP, more widespread administration of calcium channel blockers perioperatively, or both.

Pulmonary Vasoconstriction

Clinical Features

Several years after PACs achieved common usage and case reports sensitized clinicians to adverse responses to protamine, Lowenstein and colleagues[380] reported a series of patients in whom protamine caused systemic hypotension, decreased left atrial pressure, increased rather than decreased pulmonary arterial pressure, and right ventricular distention and failure. This syndrome resembles the predictable response seen in certain laboratory animals.[380–384] Unlike in anaphylaxis, plasma histamine levels do not change during this idiosyncratic, catastrophic pulmonary vasoconstriction,[382] thus justifying a separate classification for this unusual response.[383]

The duration of pulmonary hypertension may vary substantially from brief episodes[384] (Fig. 35.23) to those requiring reinstitution of CPB.[380,384,385] Rechallenge with protamine immediately after recovery from this type III reaction can be benign,[384] similar to the results in laboratory animals. However, because rechallenge could induce repeat pulmonary vasoconstriction, it is best avoided whenever possible.

Proposed Mechanism

Animal models of type III protamine responses demonstrate that heparin must precede the protamine,[386] that heparin–protamine complexes activate the complement pathway,[387] and that blockade of complement activation attenuates pulmonary damage.[388] Furthermore, leukocytes respond to complement activation by forming free radicals, which stimulate the arachidonate pathway.[377,389] Blockade of this pathway mitigates the pulmonary response,[390,391] whereas antihistamines do not.[331,382]

Unlike the immediate pulmonary damage induced by heparin-protamine complexes, polycations alone (eg, poly-l-lysine) induce pulmonary damage in a more delayed fashion. Polycation-induced injury probably involves pulmonary macrophages and arachidonate metabolites.[377,387,392–395] Heparin-protamine complex size varies with the molar ratios of heparin and protamine present[348]; an excess of protamine forms larger complexes.[287] Rapid protamine administration in humans may not predictably cause pulmonary hypertension because, unlike those of the pig and sheep, human lungs do not contain large numbers of macrophages.[348,377] Polycations can block nitric oxide synthetase, leading to speculation that this pathway also participates in the development of pulmonary vasoconstriction. Fig. 35.24 summarizes the speculative mechanisms of various adverse responses to protamine.

Treatment and Prevention

Theoretically, slow administration should limit type III reactions because large heparin-protamine complexes would less likely form. Slow dilute infusion (see later) has decreased this adverse response to protamine.

Some have suggested routine administration of antihistamines to prevent protamine-induced circulatory changes. For type III reactions, in which histamine has no mechanistic role, such a plan should fail. Indeed, antihistamines confer no advantage in general.[396] Hydrocortisone or aminophylline prophylaxis may lessen any circulatory changes with protamine administration, but for nonspecific reasons.[397,398]

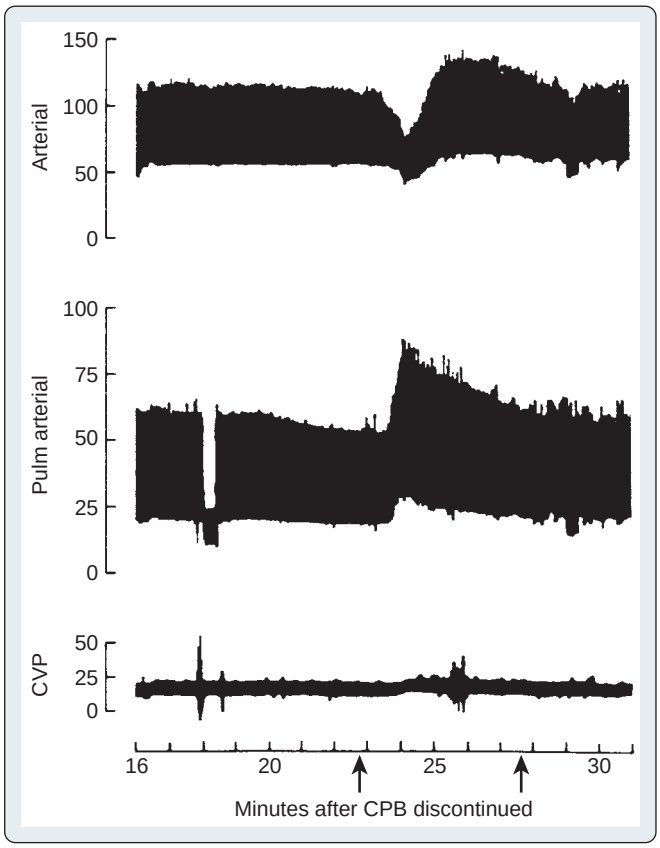

Fig. 35.23 Example of a type III protamine reaction of brief duration. Compressed waveforms of radial arterial, pulmonary arterial, and central venous pressures (*CVP;* all in mm Hg) demonstrate sudden systemic hypotension and pulmonary hypertension soon after administration of 10 mg protamine sulfate (arrow at 23 minutes after bypass). Note lack of adverse response to an additional 10 mg protamine sulfate 5 minutes later. *(From Horrow JC. Thrombocytopenia accompanying a reaction to protamine sulfate.* Can Anesth Soc J. *1985;32:49.)*

On detection of sudden pulmonary hypertension and systemic hypotension, protamine infusion should cease, as should administration of any cardiovascular depressant. Administration of a heparin bolus should be considered in an attempt to reduce heparin-protamine complex size.[385] Excess heparin would theoretically attract protamine away from large complexes to yield a larger number of smaller size particles. If hemodynamics have not deteriorated sufficiently to warrant immediate reinstitution of CPB, 70 U/kg of heparin should be tried first, then 300 U/kg if that fails. Inotropic support should be selected so as not to worsen the pulmonary hypertension; isoproterenol (0.1–0.2 μg/kg bolus followed by 0.1–0.3 μg/kg/min) or milrinone appear best suited for this purpose. Milder cases may revert without intervention,[384] merely by halting protamine administration,[399] a highly desirable outcome insofar as the treatments outlined earlier all extract a price, whether it be arrhythmias from inotropes or bleeding from heparin. Rechallenge with protamine should be avoided.

Guidelines for Clinical Use

The most important principle in avoiding adverse responses to protamine is to administer the drug slowly. Dilution aids this goal by limiting the impact of an undetected rapid administration. A neutralizing dose (3 mg/kg, or 21 mL on average of 10 mg/mL solution) can be added to 50 mL clear fluid; then the diluted drug can be administered into a central vein by a small-drop infusion (60 drops/mL) over 10 to 15 minutes. It is important to provide a carrier flow

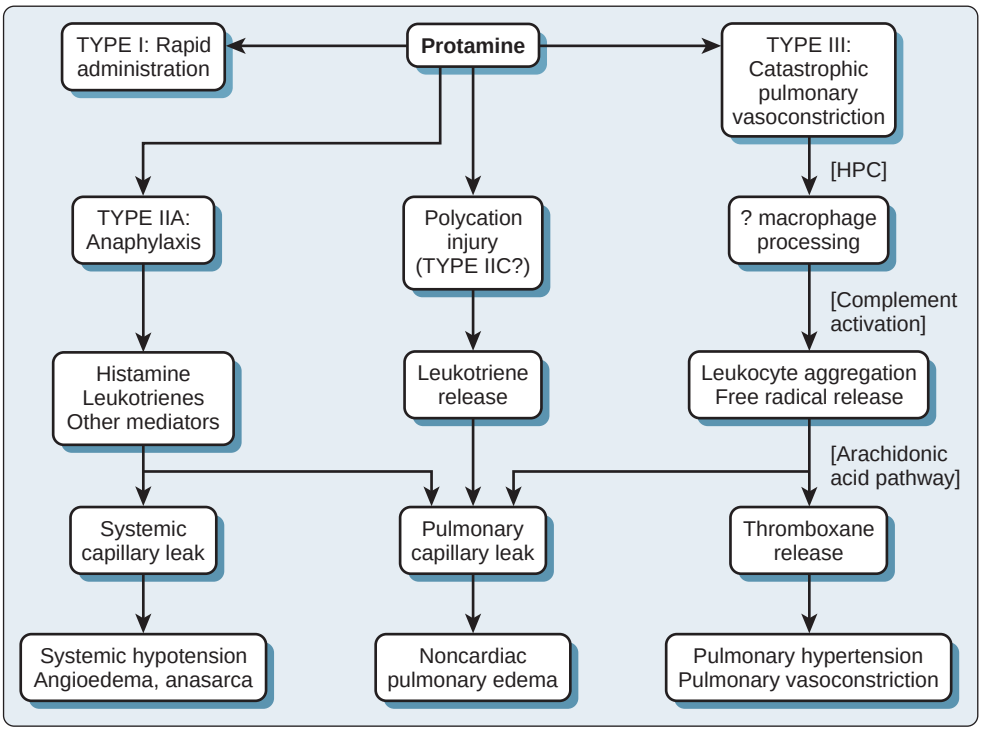

Fig. 35.24 Speculative mechanisms of some protamine reactions to heparin-protamine complex (*HPC*). *(From Horrow JC: Heparin reversal of protamine toxicity: have we come full circle?* J Cardiothorac Vasc Anesth. *1990;4:539.)*

when administering by peripheral vein so that the long tubing does not slowly fill with drug rather than the drug entering the patient. Additional doses of undiluted protamine are given from small syringes (5 mL) at a maximum rate of 20 mg/min to adults. Proper choice of materials (small syringes, small-drop administration sets, and use of diluent) helps protect against too-rapid drug delivery. Slow administration should decrease the likelihood of a type I and III adverse response. However, anaphylactic response (type IIA) may occur at any delivery rate. Preparation for groups at risk to receive protamine is discussed in the following sections.

Patients With Diabetes

No screening test predicts an adverse response to protamine; serum IgE levels are nonspecific; and skin tests do not correlate with antiprotamine antibody measurements.[400,401] Using too concentrated a protamine solution in performing skin tests may produce false-positive results.[402,403] Antiprotamine antibody determinations, available by radio allergosorbent test or ELISA, appear equally nonspecific and are expensive.[400,401] Although most patients with diabetes have antiprotamine immunoglobulin (38% to 91%), most receive protamine without adverse sequelae (>99.4%).

Vasectomy and Patients With Fish Allergy

Like patients with diabetes, vasectomy patients demonstrate antibodies but show a benign response to protamine. All skin tests on vasectomy patients by these authors have displayed negative results and benign responses to protamine after CPB, including one who demonstrated an anaphylactoid reaction at catheterization, probably arising from radiocontrast administration.

Patients with strong evidence by history or laboratory tests of allergy to fin fish are uncommon. After CPB, these patients receive 1 mg protamine diluted in 50 mL intravenous fluid over 10 minutes. If hemodynamics do not deteriorate, the neutralizing dose is administered as previously outlined. Otherwise, protamine is withheld. Skin testing may predict this allergy but would not change the approach, because false-positive skin tests are common, and too few reported cases of protamine–fin fish cross-allergy exist to warrant more aggressive drug administration to those demonstrating negative skin tests. Heparin has been successfully neutralized in a patient with a history of fin fish anaphylaxis and positive skin tests to protamine by using the enzyme heparinase I (Neutralase). This case is unpublished.

Prior Reaction to Protamine

For patients with prior reaction to protamine, skin testing, radio allergosorbent test, and ELISA are appropriate, because negative responses provide greater comfort in attempting a rechallenge. If the historic or laboratory evidence for protamine sensitivity is poor, then a challenge as described for patients with fish allergy may be attempted. Otherwise, an alternative to protamine should be chosen. Availability of a safe alternative would save the cost of these tests and any prolonged hospitalization that accompanies them.

Alternatives to Protamine

This section discusses techniques for neutralizing heparin other than with administration of protamine. Substitutes for protamine in long-acting insulin preparations are not considered.

Hexadimethrine

This synthetic polycation (Fig. 35.25) is 1.1 to 2.0 times more potent than protamine.[404,405] Hexadimethrine (Polybrene) engenders the same biologic responses as protamine when administered rapidly: systemic hypotension, decreased systemic vascular resistance, and rapid disappearance from plasma.[405,406] Pulmonary hypertension occurs after hexadimethrine neutralization of UFH.[407] Patients allergic to protamine have received hexadimethrine without adverse effects.[344]

After reports of renal toxicity, hexadimethrine was withdrawn from clinical use in the United States.[408,409] Animal studies confirmed glomerular injury from hexadimethrine. Urinary excretion of lactic dehydrogenase, aspartase aminotransferase, and other enzymes occurs.[410] Binding of the polycation to the carboxyl groups of proteoglycans in the glomerular basement membrane probably mediates this

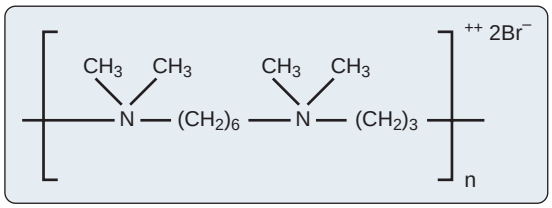

Fig. 35.25 Hexadimethrine, a synthetic polycationic polymer. *(From Horrow JC: Protamine. A necessary evil. In: Ellison N, Jobes DR, eds.* Effective Hemostasis in Cardiac Surgery. *Philadelphia: WB Saunders Company; 1988:15.)*

injury.[411] Although protamine also causes renal toxicity, larger doses are required.[412,413] Hexadimethrine appears unlikely to replace protamine for routine clinical use.[414]

Platelet Factor 4

Platelets contain the potent antiheparin compound PF4. An early attempt to neutralize heparin by platelet concentrate transfusion in two patients produced poor results, however. Despite 18 units of platelets and 400 mL of FFP, 1 patient bled 4 L, whereas 12 units of platelets and 1100 mL of FFP accompanied more than 2 L of blood loss in another.[341]

Rather than bind to heparin electrostatically, like protamine, PF4 utilizes lysine residues at its C termini to neutralize heparin. Both native and recombinant PF4 effectively neutralize heparin in rats without adverse effects at one-fifth the potency of protamine, that is, 5 mg/100 U heparin.[105] In heparinized human blood, recombinant PF4 was half as potent as protamine in restoring the ACT and whole-blood clotting time.[415] Doses of 2.5 and 5.0 mg/kg of recombinant PF4 neutralized the 5000 units of heparin given for cardiac catheterization.[416] Doses of 5 mg/kg of recombinant PF4 to a small number of patients successfully neutralized the 300 U/kg of heparin given for CPB.[417]

Does PF4 avoid the adverse effects of protamine? Kurrek and colleagues[418] demonstrated pulmonary hypertension in lambs when neutralizing heparin with PF4. The lamb, like the dog, responds predictably to protamine with increased pulmonary artery pressures, and thus serves as a model for predicting the idiosyncratic effects of protamine in humans. Those patients likely to respond to protamine with pulmonary hypertension might respond likewise to PF4.[418] Another less likely explanation is that PF4 constitutes a foreign protein to the lamb, thus engendering the adverse pulmonary hemodynamic response.[419] Further clinical work on PF4 as a protamine substitute appears to have slowed.

Interposed Filters

The enzyme, heparinase, bonded to an exit filter of an experimental bypass circuit and interposed at the conclusion of CPB, decreased blood heparin levels within two passes[420]; current filters achieve 90% heparin removal with a single pass.

A modification of this concept uses a hollow-fiber filter to which protamine has been immobilized. Although not a true alternative to protamine, the protamine filter traps heparin extracorporeally, limiting tissue interaction with heparin-protamine complexes.[421,422] This "protamine filter" attenuates both thrombocytopenia and leucopenia. The clinical efficacy and safety of this technique have not yet been clearly demonstrated. Heparin removal proceeds slowly, requiring 10 minutes to remove half of circulating heparin.

Methylene Blue

This positively charged chemical dye binds to heparin in an electrostatic fashion similar to that of protamine. Sloan and colleagues[423] administered 2 mg/kg to a patient who had sustained a severe reaction to protamine, successfully restoring the ACT and aPTT, and decreasing chest tube output. Follow-up work ex-vivo confirmed a potential benefit.[424] However, more rigorous laboratory testing[425] and a clinical trial of ascending doses of methylene blue to neutralize heparin administered for elective CPB demonstrated no efficacy whatsoever in restoring the ACT to normal.[426] Furthermore, doses greater than 6 mg/kg resulted in moderate-to-severe pulmonary hypertension, necessitating administration of inotropic support.[427] Methylene blue, an inhibitor of nitric oxide synthetase, predictably increases pulmonary and systemic vascular resistances at greater doses. Methylene blue should not be used to neutralize heparin.

Omit Neutralization

Heparin activity will decay spontaneously with time because of drug elimination. Castaneda omitted heparin neutralization in 92 patients[290]; despite lower doses of heparin and meticulous hemostasis, most of those patients bled excessively. Another patient in whom heparin was not neutralized bled 5 L over 13 hours and required more than 15 units of blood products.[427] Although this option avoids exposure to protamine, hemodynamic instability and consumptive coagulopathy may result from massive hemorrhage.

Heparinase

Systemic administration of the enzyme heparinase I, produced by *Flavobacterium,* resulted in a return of the ACT to normal in an ex vivo model,[428] animal models of CPB,[428] and healthy volunteers.[429] Initial investigation in patients undergoing elective CABG operations confirmed the utility of heparinase in neutralizing heparin-induced anticoagulation.[430]

Because the enzyme remains in the vasculature for some time after administration (the half-life is 12 minutes in healthy subjects), should an immediate need arise to reinstitute CPB, patients would require not only repeat doses of heparin, but an infusion of heparin to counter the lingering effects of the enzyme. All work on the development of heparinase has stopped after failure of initial clinical trials.

Designer Polycations

DeLucia, Wakefield, and associates[431,432] generated a series of artificial polycation molecules to neutralize heparin. Unfortunately, adverse effects appear to correlate with the ability to neutralize UFH. However, some of the polycations developed can neutralize LMWH species without adverse sequelae. Much more investigation must precede clinical trials. The future may be in using the new direct thrombin inhibitors and completely avoiding the need for protamine.

Bleeding Patient

After cardiac surgery, some patients bleed excessively (probably about 20%). Prompt diagnostic and therapeutic action will avoid impaired hemodynamics from hemorrhage, decreased oxygen-carrying capacity from anemia, and impaired hemostasis from depletion of endogenous hemostatic resources. Many factors govern whether a particular patient will experience excessive bleeding after cardiac surgery. This section details the causes, prevention, and management of the bleeding patient (see Chapters 19 and 31–34).

Although many different criteria can define excessive bleeding, chest tube drainage of more than 10 mL/kg in the first hour after operation or a total of more than 20 mL/kg over the first 3 hours after operation for patients weighing more than 10 kg is considered significant. Also, any sudden increase of 300 mL/hr or greater after minimal initial drainage in an adult usually indicates anatomic disruption warranting surgical intervention.

Patient Factors

The medical history can reveal information relevant to hemostasis. Any patient with a personal or family history of abnormal bleeding after surgery deserves specific coagulation testing for an inherited disorder. Routine PT, aPTT, and bleeding times probably offer little as screening tests.[433–435] The bleeding time has been investigated in a metaanalysis of more than 800 published articles, and it was concluded that it has no correlation with postoperative coagulopathic bleeding.[435] The other

routine tests have less than a 50% accuracy for predicting who will bleed and who will have normal chest tube outputs.

The TEG has been tested extensively both alone and in conjunction with a number of other tests including PT, platelet count, and fibrinogen. The TEG has been shown to have the best predictive accuracy for postoperative bleeding.[436–443] In work using an algorithm based on the TEG and other tests, blood product utilization was cut considerably.[442] Chest tube bleeding was not different, but the TEG did predict which patients might bleed abnormally. Work with TEG monitoring has shown that it can detect both hypocoagulable and hypercoagulable states. New additives to the testing make it sensitive to the ADP-receptor platelet antagonists, as well as the IIb/IIIa inhibitors (see Chapter 19).

Concurrent systemic disease affects hemostasis during surgery as well. Uremia from renal failure results in platelet dysfunction. Severe hepatic compromise impairs every aspect of hemostasis: PK and most coagulation factors circulate in decreased concentration; additional sialic acid residues on fibrinogen and other coagulation factors impair clotting function; splenomegaly induces thrombocytopenia; maldistribution of vWF multimers impairs platelet adhesiveness and aggregation; impaired clearance of endogenous plasminogen activators accentuates fibrinolysis; and decreased levels of coagulation inhibitors induce a consumptive coagulopathy.[444]

Medications significantly affect surgical bleeding. Many patients taking aspirin or other platelet-inhibiting drugs regularly cannot halt that therapy within 7 days of surgery. No antidote can correct the platelet defect. Fortunately, most patients taking aspirin within 7 days of surgery do not exhibit excessive bleeding. The new antiplatelet drugs can all lead to postoperative bleeding (see Table 35.4).

Patients taking warfarin require 2 to 5 days without therapy for correction of the international normalized ratio. Patients for urgent surgery may receive parenteral vitamin K, FFP, or PCC, which corrects the warfarin defect more quickly. Some patients may receive thrombolytic therapy for acute ischemic events just before surgery. Systemic fibrinogenolysis resulting from use of nonspecific thrombolytic agents such as streptokinase should respond to antifibrinolytic therapy with ε-aminocaproic acid (EACA) or tranexamic acid (TA).

Insult of Cardiopulmonary Bypass

More so than patient factors, CPB itself acts to impair hemostasis. Bypass activates fibrinolysis, impairs platelets, and affects coagulation factors. Hypothermia, used in most centers during CPB, adversely affects hemostasis as well.

Fibrinolysis

Numerous investigations support the notion that CPB activates the fibrinolytic pathway.[445,446] Despite clinically adequate doses and blood concentrations of heparin, coagulation pathway activity persists. Formation of prothrombin and fibrinopeptide fragments and thrombin-AT complexes document continued thrombin activity in this setting (see Fig. 35.11). The site of thrombin activity probably resides in the extracorporeal circuit, which contains a large surface of thrombogenic material. Thrombin activation results in fibrinolytic activity; activation of fibrinolysis may be localized to those external sites of fibrin formation. Plasminogen activator concentrations increase during CPB, whereas levels of its inhibitor plasminogen activator inhibitor 1 remain unchanged. This scenario is consistent with activation of fibrinolysis during CPB. Neither of the labels "primary" or "secondary" applies to the fibrinolysis peculiar to CPB.

Does fibrin formation during CPB constitute a consumptive coagulopathy? It is not a systemic event. Presuming that plasminogen activation occurs only where fibrin is formed (extracorporeally), a systemic fibrinogenolytic state should not ensue. Should α_2-antiplasmin become overwhelmed by plasmin formation, however, systemic manifestations may result. Previous generations of oxygenators may have engendered systemic fibrinogenolysis more easily because of their more thrombogenic designs. In these (now more uncommon) instances of fibrinolysis, the TEG may demonstrate clot lysis. Even when fibrinolysis remains limited to the sites of extravascular fibrin formation, the fibrin degradation products so formed might impair hemostasis. In many cases, the mild fibrinolytic state engendered during CPB resolves spontaneously with little clinical impact.

Platelet Dysfunction

Thrombocytopenia occurs during CPB as a result of hemodilution, heparin, hypothermia-induced splenic sequestration of platelets, and platelet destruction from the blood-gas and blood-tissue interfaces created by cardiotomy suction, filters, and bubble oxygenators.[447–450] Platelet count rarely declines to less than 50,000/mm^3, however.

Not only does the number of platelets decrease during CPB, but remaining platelets become impaired by partial activation. Fibrinogen and fibrin, which adhere to artificial surfaces of the extracorporeal circuit, form a nidus for platelet adhesion and aggregation. A reduced content of platelet α-granules constitutes the evidence for partial activation[447]; nearly one-third of circulating platelets undergo α-granule release during CPB.[448] Bypass also depletes platelet GP receptors Ib and IIb/IIIa.[448–450] These platelets cannot respond fully when subsequent hemostatic stimuli call for release of granule contents. Use of frequent cardiotomy suction and bubble oxygenators aggravates the extent of platelet activation.

Activation of the fibrinolytic system may contribute to platelet dysfunction. Local formation of plasmin affects platelet membrane receptors.[450] Antifibrinolytic medications preserve platelet function and prevent some platelet abnormalities that occur during CPB[451] (Fig. 35.26).

Clotting Factors

Denaturation of plasma proteins, including the coagulation factors, occurs at blood-air interfaces. Liberal use of cardiotomy suction and prolonged use of bubble oxygenators potentially impair coagulation by decreasing coagulation factor availability. Hemodilution also decreases factor concentrations. However, rarely do coagulation factor levels decline to less than the thresholds for adequate formation of fibrin in adult surgery. In infants, however, the smallest achievable pump priming volumes can dilute factors to less than 30% of normal levels.

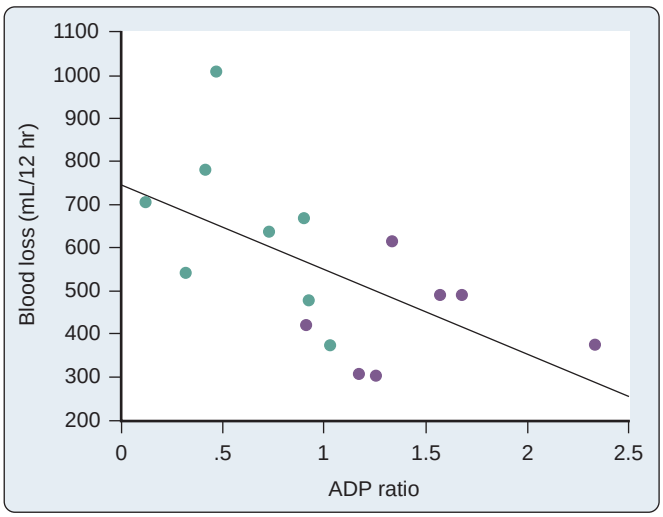

Fig. 35.26 Antifibrinolytics may aid hemostasis by platelet preservation. Here, blood loss appears as a function of platelet adenosine diphosphate (*ADP*), expressed as a ratio (after bypass/before bypass). *Purple circles* represent patients who received prophylactic tranexamic acid. Placebo-treated patients appear as *green circles*. Note that the antifibrinolytic afforded less bleeding after operation and greater platelet ADP. *(From Soslau G, Horrow JC, Brodsky I. The effect of tranexamic acid on platelet ADP during extracorporeal circulation.* Am J Hematol. *1991;38:113.)*

Hypothermia

Hypothermia potentially affects hemostasis in many ways. First, the splanchnic circulation responds to hypothermia with sequestration of platelets.[452,453] After warming, the accompanying thrombocytopenia reverses over 1 hour. Second, transient platelet dysfunction occurs, evidenced by a platelet shape change, increased adhesiveness, inhibition of ADP-induced aggregation, and decreased synthesis of both thromboxane and prostacyclin.[454,455] Third, a specific heparin-like inhibitor of factor Xa becomes more active[456]; protamine cannot neutralize this factor, which might be heparan. Fourth, hypothermia slows the enzymatic cleavage on which activation of coagulation factors depends. Many biologic phenomena display a 7% attenuation of activity for each decrease of 1°C in temperature.[457] Although coagulation factor structure remains unaltered, formation of fibrin may be sluggish when the patient is cold. Fifth, hypothermia accentuates fibrinolysis[455]; the fibrin degradation products so formed then impair subsequent fibrin polymerization. Cold-induced injury of vascular endothelium can release thromboplastin, which then incites fibrin formation and activates fibrinolysis. Table 35.8 summarizes these effects.

Prevention of Bleeding

The possible transmission of serious viral illness and impairment of immune function during transfusion of blood products may generate great concern among clinicians and patients. Many techniques attempt to limit viral exposure, including donation of autologous blood or directed blood, blood scavenging during and after surgery, and efforts to limit perioperative hemorrhage (Table 35.9). Advances in blood banking have decreased infectious disease transmission.[458] Blood sterilization techniques may render such concerns moot.[459]

Preoperative Factors

What can be done before surgery to minimize the extent of bleeding during and after surgery? Existing disorders of hemostasis must be identified and treated. The bleeding diathesis of uremia responds to hemodialysis, RBC transfusion, and administration of desmopressin.[460,461] Because impaired hemostasis from hepatic failure may respond to intravenous desmopressin, preoperative verification of an appropriate response will permit proper administration of this drug after protamine neutralization of heparin after CPB.[462] Likewise, patients with hematologic disorders potentially amenable to desmopressin therapy, such as hemophilia and vWD, should receive desmopressin before surgery to determine the extent of response, if any.[463] When specific factor replacement is indicated, withholding it until after neutralization of heparin will provide less extensive exposure to allogeneic blood products.

Administration of platelet-inhibiting drugs should cease before surgery. Two to three days should elapse for nonsteroidal antiinflammatory medications, which cause reversible inhibition of cyclooxygenase. Seven to ten days are required for regeneration of platelets after administration of aspirin, which irreversibly acetylates cyclooxygenase and some other platelet inhibitors (see Table 35.4).

TABLE 35.8 Antihemostatic Effects of Hypothermia

Hemostatic Component	*Effect of Hypothermia*
Factors	Increased anti–factor Xa activity; heparan?
	Slows enzymes of the coagulation cascade
Platelets	Splanchnic sequestration
	Partial activation
Fibrinolysis	Enhanced
Endothelium	Tissue factor release

TABLE 35.9 Ways to Prevent Excessive Bleeding in Decreasing Order of Importance

Intervention[b]	*Purpose*
Ligatures	Repair all vascular trespass
Neutralize	Heparin fully neutralized
Blood pressure	Avoid hypertension after aortotomy
Suction	Limit cardiotomy suction
Drugs	Cease platelet-inhibiting drugs in advance
Preoperative	Diagnose and treat first
Oxygenator	Membrane oxygenators for long cases
ε-Aminocaproic acid (EACA)	Antifibrinolytic prophylaxis
Temperature	Rewarm sufficiently
Go	Act with deliberate speed (tardiness begets bleeding)
Intravenous	Limit fluids, hemoconcentrate, and diurese
Extracorporeal circuit	Minimize volume

[a]These maneuvers do not all apply to the treatment of excessive bleeding after operation.
[b]The entries in this column form a mnemonic device: the initial letters of each entry, when rearranged, form the words STOP BLEEDING.

Physical Factors

Hypothermia still forms an essential component of organ protection during CPB in many centers. Sufficient rewarming with adequate distribution of heat from central to intermediate and peripheral zones should help prevent hypothermia-induced impairment of hemostasis.

Incomplete surgical hemostasis may occur from a slipped ligature, unclipped vessel branch, loose anastomosis, unattended open vessel at the wound edge, or sternal wire placed through the internal mammary artery. Because few fresh aortic suture lines fail to leak at high systemic pressures (systolic pressure > 180 mm Hg or mean arterial pressure > 120 mm Hg), control of hypertension after CPB promotes hemostasis (see Chapter 38).

Limiting the intensity and frequency of use of the cardiotomy suction fosters platelet preservation during CPB and improves hemostasis after surgery.[464] Selection of a membrane rather than a bubble-type oxygenator for cases involving prolonged CPB limits platelet destruction and fibrinolysis, thus aiding hemostasis.[465]

A small priming volume of the extracorporeal circuit restricts the extent of hemodilution. Hemodilution engenders bleeding not only by providing decreased concentrations of clotting factors and platelets, but also by decreasing the margination of platelets, making them less available for adhesion and aggregation. Other measures that help include regulating cardioplegia volumes, restricting intravenous fluids, administering mannitol or loop diuretics, and providing hemoconcentration with filtration devices during CPB (see Chapter 32).

Removal of platelet-rich plasma at the induction of anesthesia for return to the patient after CPB by plasmapheresis supplies autologous, functional thrombocytes when they are most needed.[466,467] Previously, some centers collected autologous whole blood from patients at the beginning of surgery, reinfusing it after CPB, with controversial benefit.[468–470]

Speed of surgery receives less attention now than in the past, when the therapeutic index of available anesthetics was less favorable. However, patients undergoing short surgery enjoy several advantages. Shorter CPB duration preserves platelet function and limits the coagulant stimulus for subsequent fibrinolysis; more rapid closure after CPB limits tissue exposure to the hypothermic OR environment.

Pharmacologic Factors

Heparin and Protamine

Too little heparin invites active fibrin formation during CPB with consumption of clotting factors and platelets, and excessive activation of the fibrinolytic system; too much heparin risks postoperative heparin rebound. With too little protamine, the remaining unneutralized heparin impairs hemostasis by its anticoagulant action. Doses of protamine excessive enough to overwhelm the endogenous proteases may exert an anticoagulant effect, as well as invite polycation-induced lung injury and pulmonary vasoconstriction. The optimal approach uses coagulation testing to estimate the appropriate heparin

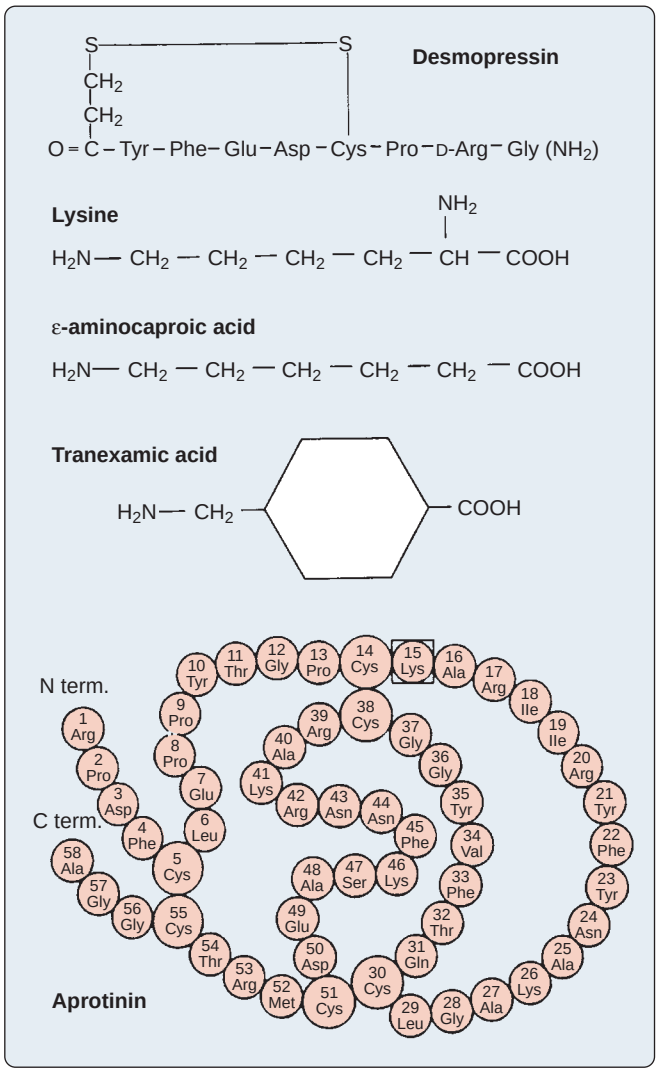

Fig. 35.27 Molecular configurations of drugs used to decrease surgical bleeding. For comparison, the amino acid lysine is also depicted. *(Modified from Horrow JC: Desmopressin and antifibrinolytics. Int Anesthesiol Clin 28:230, 1990; and Fritz H, Wunderer G. Biochemistry and applications of aprotinin, the kallikrein inhibitor from bovine organs.* Drug Res.*1983;33:479.)*

and protamine doses, and confirm both adequate anticoagulation and its neutralization.

Desmopressin

Desmopressin, an analog of vasopressin (Fig. 35.27), provides more potent and longer-lasting antidiuretic activity than vasopressin, with little vasoconstriction (Box 35.8). Like the parent compound and like epinephrine and insulin, desmopressin releases coagulation system mediators from vascular endothelium. Factor VIII coagulant activity increases 2- to 20-fold and is maximal about 30 to 90 minutes after injection.[471–473] Factor XII levels also increase. In response to desmopressin, endothelium releases the larger multimers of vWF, as well as t-PA and prostacyclin. The latter two compounds potentially thwart clot formation and stability. Nevertheless, the overall effect of desmopressin is procoagulant, perhaps because of the impact of factor VIII and vWF.

The optimal dose of desmopressin is 0.3 μg/kg. Intravenous, subcutaneous, and intranasal routes are all acceptable. After plasma redistribution with an 8-minute half-life, metabolism in liver and kidney and urinary excretion yield a plasma half-life of 2.5 to 4 hours.[461] Levels of

BOX 35.8 USEFUL DRUGS TO REDUCE BLEEDING DURING CARDIAC SURGERY

- Tranexamic acid or epsilon aminocaproic acid
- Recombinant factor VIIa
- Desmopressin

factor VIII persist in plasma long after desmopressin excretion because of the release of vWF. Depletion of vWF stores in endothelial cells accounts for the drug's tachyphylaxis. Rapid intravenous administration decreases systemic blood pressure and systemic vascular resistance, possibly by prostacyclin release or stimulation of extrarenal vasopressin V_2 receptors.[474–478] The antidiuretic action of the drug poses no problem in the absence of excessive free water administration.[479]

Specific applications of desmopressin's hemostatic benefit include uremia, cirrhosis, aspirin therapy, and surgery of various types. Correction of prolonged bleeding times in patients with uremia follows desmopressin administration, making desmopressin the treatment of choice for bleeding emergencies in uremia.[461] Administration of desmopressin to patients with cirrhosis also shortens prolonged bleeding times.[462] Desmopressin corrected the aspirin-induced prolongation in bleeding time in 2 patients and 10 healthy volunteers.[480] It is also effective in some rare platelet disorders.[471] Evidence of a hemostatic effect during surgery is varied. Early success in adolescents undergoing Harrington rod placement was not confirmed with subsequent studies.[481]

Initial reports of a hemostatic effect during cardiac surgery were largely unsubstantiated by subsequent investigations.[482–488] vWF activity increased in both control and desmopressin-treated patient groups, thus explaining the absence of a salutary effect of desmopressin on blood loss[486,487] (Fig. 35.28). Desmopressin-induced release of t-PA does not overcome its hemostatic action during cardiac surgery because antifibrinolytic therapy fails to uncover an additional hemostatic effect of desmopressin.[488]

Which subgroups of patients undergoing cardiac surgery might benefit from desmopressin? Certainly, those with uremia or cirrhosis benefit. Those who display decreased maximum amplitude on TEG for whatever reason constitute a third group.[488–491] The heparinase-augmented TEG permits timely identification of patients in this subgroup.

Desmopressin afforded no hemostatic benefit to patients taking aspirin before cardiac surgery,[488,489] and the bulk of evidence currently points away from desmopressin as a prophylactic hemostatic agent for patients undergoing elective cardiac surgery.[490,491]

Synthetic Antifibrinolytics

Synthetic antifibrinolytics, simple molecules (see Fig. 35.27), and analogs of the amino acid lysine, bind to plasminogen and plasmin, thus inhibiting binding of plasminogen at the lysine residues of fibrinogen. Antifibrinolytics may be administered intravenously or orally and undergo renal concentration and excretion with a plasma half-life of about 80 minutes. Effective fibrinolysis inhibition requires an intravenous loading dose of 10 mg/kg for TA followed by 1 mg/kg/hr or 50 mg/kg of EACA followed by infusion of 25 mg/kg/hr.[492,493] Infusion rates require downward adjustment when serum creatinine concentration is increased. Plasma concentrations of TA achieve greater values with decreasing glomerular function. The author's practice is to administer only a loading dose of TA to patients with serum creatinine concentrations in excess of 2.0 mg/dL. Antifibrinolytics are not given to patients with significant upper urinary tract bleeding or consumptive coagulopathy because they prevent the clot lysis needed for continued patency of the ureters or circulatory system, respectively. However, they can also halt ongoing consumption.[494]

Pharmacokinetic studies demonstrated a need to readminister a bolus of EACA on institution of CPB.[493,495] This may not apply to

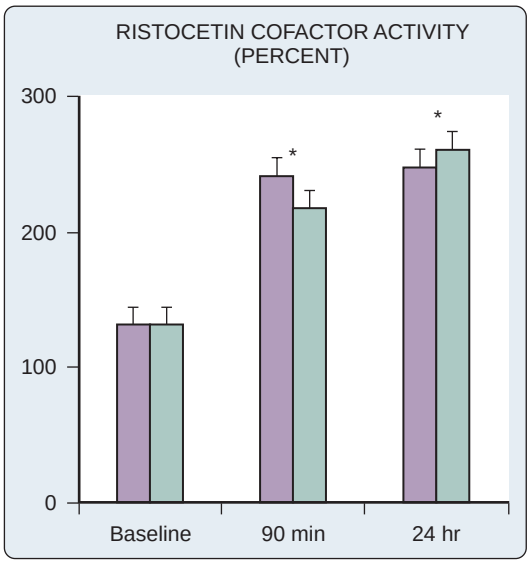

Fig. 35.28 At 90 minutes and 24 hours after receiving desmopressin *(green bars)*, ristocetin cofactor (von Willebrand factor) activity was not different from a placebo-treated group *(purple bars)*. However, in each group, ristocetin cofactor activity increased *(asterisks)* from baseline values, possibly from surgical stress. Blood loss did not differ in the two groups. Error bars denote standard error of the mean. *(Modified from Hackmann T, Gascoyne RD, Naiman SC, et al: A trial of desmopressin [1-desamino, 8-D-arginine vasopressin] to reduce blood loss in uncomplicated cardiac surgery.* N Engl J Med. *1989;321:1437.)*

TA,[496] perhaps because of a larger volume of distribution of this drug, although definitive data are still lacking.

Antifibrinolytics aid clotting in patients with hemophilia and patients with vWD by blocking lysis of whatever clot can form.[497,498] Spontaneous bleeding after chemotherapy is decreased with oral TA.[499] Prostate surgery, well known for excessive bleeding from release of t-PA, responds beneficially to antifibrinolytic therapy.[500] Fibrinolysis contributes to bleeding during the anhepatic phase of liver transplantation; antifibrinolytic therapy proves useful in this setting.

Ongoing thrombin activity with varied activation of fibrinolysis plagues cardiac surgery. Fig. 35.11 demonstrates thrombin activity as reflected in continuing formation of fibrinopeptides despite adequate heparin anticoagulation. For decades, antifibrinolytics have been proposed as potential hemostatic agents during cardiac surgery. Initial investigations of the efficacy of synthetic antifibrinolytics as hemostatic agents during or after cardiac surgery lacked blinding, randomization, and control groups.[501–509] Most subsequent studies administered EACA after CPB. One study demonstrated a salutary effect in cyanotic children, but not in acyanotic children.[504]

Several investigations, using prophylactic antifibrinolytics, documented savings in blood loss, as well as in blood transfused in a general population of cardiac surgery patients[489,507–509] (Fig. 35.29). By commencing administration of TA before CPB, chest tube drainage in the first 12 hours after surgery decreased by 30%, and the likelihood of receiving banked blood within 5 days of operation decreased from 41% to 22%.[489] Prophylactic antifibrinolytics may spare platelet function by inhibiting the deleterious effects of plasmin,[510] but administration of very large doses of antifibrinolytics appears to offer no greater savings.[511] Cardiac surgery patients undergoing repeat operation may benefit particularly from prophylactic antifibrinolytic administration.[512,513]

Some recent reports noted that TA is associated with increased risks for seizure. This has been known for some time in the neurosurgical literature; it is considered unwise to place TA directly on the surface of the brain. The mechanism for this potential neurologic toxicity is unknown.[514–517]

Aprotinin

Bovine lung provides the source of the 58-residue polypeptide serine protease inhibitor aprotinin.[518,519] Aprotinin inhibits a host of proteases, including trypsin, plasmin, kallikrein, and factor XIIa activation of complement[519] (Fig. 35.30). The adult intravenous dose for surgical hemostasis is 2 million kallikrein inhibitor units (KIU) for both patient and CPB circuit, followed by 600,000 KIU/hr.[520,521] The elimination half-life of aprotinin, 7 hours, is considerably longer than that of the synthetic antifibrinolytics; after 6 days, aprotinin continues to be excreted in the urine. Volume-loaded rats respond to aprotinin with decreases in glomerular filtration rate, renal plasma flow, and sodium and potassium excretion.

After the serendipitous discovery of unusually dry surgical fields while investigating high-dose aprotinin for respiratory distress syndrome, Royston and colleagues[522] documented more than a fourfold reduction in blood loss during repeat cardiac surgery. Subsequent studies using high-dose aprotinin confirmed conservation of blood products and a reduction in bleeding, ranging from 29% to 50%.[523–525]

Although studies clearly demonstrated decreased fibrinolysis in aprotinin-treated patient groups, preservation of platelet GPIb or blockade of a plasmin-mediated platelet defect may better explain the hemostatic mechanism of aprotinin.

High-dose aprotinin alone prolonged the celite ACT, leading some investigators to limit use of heparin during CPB.[525] Reports of clot formation during CPB, however, mandated continued use of heparin despite administration of aprotinin. Most investigators simply avoided the celite ACT and used kaolin ACT. The kaolin ACT adsorbs about 98% of aprotinin and any intrinsic AT effect that aprotinin had was mitigated. It was recommended to use the kaolin ACT and keep the length of ACT time the same as if aprotinin was not being used.[526–530] An animal protein, aprotinin caused anaphylaxis, although uncommon (<1 in 1000)[531] Aprotinin cost significantly more than equivalent doses of synthetic antifibrinolytic drugs.[532] The group at Duke University analyzed overall cost-effectiveness of aprotinin therapy and found it highly cost-effective.[533,534] Aprotinin was voluntarily withdrawn from the market in 2008 after two reviews of adverse outcomes by the FDA. Published reports of an association between high-dose aprotinin utilization and renal dysfunction/failure occurred in 2005 and 2006. These publications arose from the Multicentered Study of Perioperative Ischemia EPI-II database.[535] The study was complex, involving more than 4300 cases, and used sophisticated statistical analysis. Unfortunately, the patients who received aprotinin had been selected to get that drug, as opposed to two other antifibrinolytics, by physician choice. This channeling of therapy meant that those patients who were more ill would get aprotinin. To separate out cause and effect from such data becomes impossible; yet, with elegant propensity analysis methods, weighting of certain covariates can be accounted for. The study, although landmark, was widely criticized for all the potential covariates not examined, such as sites (European countries had different practice patterns) and the use of FFP and platelet transfusions. At the same time, a separate report from the University of Toronto examined cases within their own institution.[536] Their study used aprotinin in only the sickest patients. From their large series, they carefully propensity-matched more than 400 patients to ones of similar age and risk in the overall group of 10,000. There was a propensity for those patients to have more renal dysfunction once the statistics controlled for the other confounders. A third study performed using the Medicare billing database also found that patients who received aprotinin had worse overall outcomes.[537] The use of billing databases has always been fraught with problems in that they are incomplete. Billing data are only summary information and give little of the medical history necessary when trying to balance risk in terms of covariates. Finally, Fergusson and colleague's[538] study in Canada (BART study) confirmed a greater 30-day mortality rate with use of aprotinin compared with either EACA or TA and led to the immediate withdrawal of the drug by the manufacturer.[539] Many questions remain about aprotinin and whether it should be available for high-risk cardiac surgical patients. Some clinicians believe that its withdrawal has led to more bleeding and use of blood products and drugs to improve coagulation, all of which have their own complications.

The aprotinin story continues as the BART trial was reanalyzed when it became apparent that 137 patients were excluded from the original analysis.[540] Health Canada reanalyzed the data with all of these patients included, and the signal for early mortality related to aprotinin disappeared. In some high-risk groups aprotinin seemed to confer an advantage. The European Commission reviewed the data again and lifted its ban on aprotinin noting that the analysis may well have been flawed.[541]

The revised STS/SCA guidelines do not reflect the changing nature of the controversy; rather they present BART as a final conclusive study before the reanalysis by Health Canada.[542] Others continue to question the data analysis in the BART study. At present, aprotinin has been allowed back on the market in Europe and Canada, but it is not marketed in the United States. Work is underway to find other kallikrein-inhibiting agents, but at the time this chapter went to publication, there were no studies in late stages of development.

Management of the Bleeding Patient

The initial approach to perioperative bleeding violates the medical paradigm of treatment based on diagnosis. The clinician must simultaneously initiate diagnostic tests, begin treating a presumed cause, and replace lost hemostatic resources (see Chapter 34). The all-encompassing ("shotgun") approach to bleeding after operation should be shunned. Avoiding it will simplify patient management and yield superior results.

Risks of Coagulation Products

The standard blood bank products available to the cardiovascular team include FFP, cryoprecipitate, and platelet concentrates (either pooled or apheresis single-donor platelets). It should be stated emphatically that there are no data to support the "clinical impression" of use of these agents as a prophylactic method to reduce bleeding.[542] For example, if a patient is known to be using a P_2Y_{12} inhibitor, the use of prophylactic platelet transfusions will not decrease the bleeding. These products should be used only if coagulation data from a laboratory point towards appropriate use or if a patient is bleeding severely enough that the team feels it necessary to attempt empiric therapy.

Platelet transfusions and FFP carry a higher risk of TRALI than do RBCs from the blood bank.[543–551] It is known that the causes of TRALI are manyfold and not limited to recipients receiving HLA antibodies towards their pulmonary endothelium. Indeed, it has been shown that cytokines, red cell microparticles, and CD-40L (a platelet proinflammatory protein) all contribute to leaking pulmonary capillaries.[543] In studies from the Mayo Clinic, platelet concentrates were the most highly associated with TRALI followed by FFP.[549] Recent work in cardiac surgery has demonstrated that the overall risk of TRALI is soberingly high.[544,550] In 688 patients prospectively studied with rigorous predefinition of TRALI, 16 definite cases were discovered (2.4% incidence).[551] Others have reported that between 1% and 8% of all patients for cardiac surgery get TRALI from transfusion. Those with TRALI have a 13- to 15.5-fold increase in major organ morbidity and mortality; mortality has been 20% to 55%.[544,546,550] FFP contains most of the serine proteases found in plasma. There is a small diminution of some of the labile factors, and if the units given have had cryoprecipitate withdrawn from them, they are known as fibrinogen poor plasma. The literature on FFP shows that it does little to reduce bleeding.[552,553] Even in known liver failure, when used prophylactically, FFP cannot be shown to reduce the risk of bleeding. It is only after 10 to 15 mL/kg of FFP that changes in clotting factors will be seen; for most patients, 4 to 6 units of FFP are required before serine protease levels rise. However, by giving this much FFP, RBC and platelets are diluted. The use of 2 units of FFP in a bleeding patient after CPB does nothing other than increase the risk of lung dysfunction. Yet in cardiac surgery, approximately 25% to 50% of patients receive FFP with the idea that it does "something," which is completely unsupported by evidence-based research.

Today, the use of 4-component PCC is the recommended therapeutic intervention to reverse the effects of warfarin or low clotting factor levels. The use of platelet concentrates makes a great deal of sense when a patient is bleeding and there is a proven or suspected platelet function or number deficit.[542] Prophylactic platelet transfusions have never been shown to be of utility. Platelets are harvested by ultra-centrifugation and stored in the blood bank at room temperature on a rocker that keeps them from aggregating. Platelet concentrates can be kept for only 5 days; therefore they are the blood product in shortest supply. Because they are kept at room temperature, they have the potential for growth of bacterial contamination. The risk of bacterial contamination is somewhere between 1/5000–20,000 units. The most common bacteria isolated from platelet bags are *Yersinia* and *Staphylococcus* strains. Today, the blood bank uses surrogate testing (pH) to improve the chances of detecting a septic unit before dispensing it clinically.

Platelet concentrates are most often white cell depleted. The lack of white cells is both good and bad. The bad aspect is that reduction of white cells may well increase the risk of bacterial growth. If white

cells are present in the platelet bags, the concentration of inflammatory cytokines can be 1000 times normal. High levels of cytokines have been implicated as one of the potential precursors of the "two hit" model for TRALI. Even with white cell reduction, the platelet concentrates are profoundly proinflammatory. The levels of CD-40L are very high and rise every day the platelets are kept in the blood bank. CD-40L is a proinflammatory cellular messenger protein that platelets release upon being stressed, and CD-40L has been implicated in causing TRALI.[543,554–556]

Live circulating normal platelets move through the blood stream in a quiescent resting state. They have multiple different transmembrane proteins that signal the surrounding cellular milieu. Bank platelets rapidly become partially or totally activated and release their alpha and dense granules, further activating other platelets. The contents of the granules have a number of highly vasoactive compounds within them, including serotonin, epinephrine, and adenosine. Depending on the age of the unit to be infused, 20% to 60% of the platelets are dysfunctional or undergoing apoptosis; once infused, they circulate for a rather short time. The result of this partial/total activation is that infusions of platelet concentrates, when they are not required, are very prothrombotic. Therefore if a patient is not bleeding and platelets are given, they increase the risk of myocardial infarction, strokes, and other thrombotic events.

A number of investigations have led to controversy about the use of platelet transfusions in cardiac surgery. In a study of approximately 1800 patients undergoing CABG surgery and participating in an early trial of aprotinin, the question of platelet transfusions was investigated.[557] This pharmaceutical phase III study was chosen because it had defined criteria for transfusion of blood products and very careful monitoring/follow-up on predefined complications. With multivariate analysis (accounting for more than 100 potential confounders), use of platelet transfusions had significant relationships to perioperative infections, pneumonia/respiratory failure/TRALI, use of vasopressors (more vasoplegia), stroke, and death. The odds ratios for stroke and death were between 2.5- and 3-fold higher than patients not receiving platelet transfusions. This paper led others to examine additional databases to answer the same question regarding platelet transfusions. Karkouti and colleagues found univariate relationships between platelet transfusions and many of the same adverse outcomes.[558] However, when RBC use was added into this multivariate model, platelet transfusion no longer stood out as a predictor of bad outcome. The Cleveland Clinic team examined their database in two separate papers.[559,560] In one, they examined the effects of transfusion on the risk of development of vasoplegia[560]; in the other, they examined morbidity and mortality as directly related to platelet transfusions.[559] Their findings were that RBCs, FFP, and platelet transfusions all correlated with the development of vasoplegia. However, when they looked at the same data using propensity matching techniques and tried to answer the platelet transfusion question alone, they found that platelet transfusions by themselves did not increase morbidity or mortality.

The biology of platelet concentrates suggest they are highly inflammatory, and their use should thus be reserved for patients who are bleeding and have a demonstrable platelet defect (number or function). No pharmaceutical or manmade product is available for use now or in the near future to replace a platelet transfusion.

Cryoprecipitate is a product that contains a very high concentration of fibrinogen and factor VIII. The product is manufactured from harvested plasma and represents the total available soluble fibrinogen in 1 unit of banked blood/plasma. That precipitate is packaged in approximately 15 mL of plasma. Unlike FFP, cryoprecipitate has a very low volume for the concentration of protein it delivers. Most often when used in cardiac surgery, a dose of cryo is from 10 donors representing the fibrinogen of 10 units of whole blood (roughly one circulating volume). Therefore if a patient is bleeding because of a low fibrinogen concentration or a dysfibrinogenemia, a single infusion of 10 units of cryo should restore the levels above 200 mg/dL. Cryo represents the exposure of 10 donors and still may carry viruses not tested for such as Epstein Barr virus and TTV virus, both of which can cause hepatic failure in immunocompromised hosts. The risk of TRALI from cryo may be lower than that from FFP, because it carries a lower volume of fluid and should have a lower HLA antibody load.

New work from Europe supports the concept of maintaining fibrinogen levels near normal by using a lyophilized human fibrinogen concentrate.[561–563] The fibrinogen concentrate is supplied as a powder, can be mixed with sterile water and injected with very small fluid volumes (900–1300 mg/50 mL). Many US centers have not been concerned about bleeding and fibrinogen being causative until the levels fell below 100mg/dL. However, patients with the fibrinogen maintained at 200 mg/dL or above have demonstrated better TEGs (MA) and RoTEM (MCF) tracings with decreased bleeding.[561] It was thought that low preoperative fibrinogen could be a marker for bleeding after cardiac surgery, but that has not been borne out. Furthermore, trials of giving fibrinogen concentrate pre-bypass have not been shown to be as effective as testing post-bypass with maintenance of fibrinogen concentrations at 200 to 250 mg/dL. The natural course postsurgery is that fibrinogen rises dramatically by day 3 to 5 as an acute phase reactant. If a patient exhibits microvascular bleeding and the fibrinogen is below 200 mg/dL, it makes sense to administer fibrinogen.

Determine the Cause

Anatomic sources of bleeding frequently present once systemic blood pressure achieves sufficient magnitude. Some clinicians prefer to identify these sources before chest closure with a provocative test, that is, allowing brief periods of hypertension. Generous chest tube drainage early after surgery suggests an anatomic source. Retained mediastinal clot may engender a consumptive coagulopathy. A widened mediastinum on chest radiograph suggests the need for surgical drainage.

Nonsurgical causes of bleeding (platelets, coagulation factors, and fibrinolysis) usually manifest as a generalized ooze. Inspection of vascular access puncture sites aids in this diagnosis. Bleeding from other areas not manipulated during surgery (stomach, bladder) also may occur.

Coagulation tests aid diagnosis. Because the PT and aPTT usually are prolonged by several seconds after CPB, only values more than 1.5 times control suggest factor deficiency. Increase of the ACT should first suggest unneutralized heparin, then factor deficiency. The PT is often obtained, and after cardiac surgery it is out of normal range 85% of the time.[564] It has been thought that the protamine-heparin complex binds to the lipid cofactors in the PT test and artificially prolongs PT.

A decreased platelet count, usually denoting hemodilution or consumption, requires correction with exogenous platelets in any bleeding patient. However, bleeding patients with insufficient functional platelets may demonstrate normal platelet counts early after operation. For this reason, clinicians have sought rapid diagnostic tests of platelet function and attempted correlation with bleeding after CPB (see Chapter 19).

Low plasma fibrinogen occurs from excessive hemodilution or factor consumption and is usually corrected with cryoprecipitate or FFP. The thrombin time is useful here; clinical laboratories can perform this test with rapid turnaround. A prolonged thrombin time denotes unneutralized heparin, insufficient fibrinogen, or high concentrations of fibrin degradation products. Finally, direct measurement of fibrin degradation products denotes fibrinolytic activity. In the absence of a cause for a consumptive coagulopathy, antifibrinolytic therapy may be useful.

Table 35.10 lists a treatment plan for excessive bleeding after cardiac surgery. Interventions appear not in order of likelihood, but rather by priority of consideration. Thus, surgical causes should be ruled out before seizing on the diagnosis of a consumptive coagulopathy. The priority will also vary among institutions, depending on the availability and cost of resources.[565] This table provides a simple algorithm for treating postoperative bleeding. More complete schemes present a daunting level of complexity that deters implementation (Fig. 35.31).

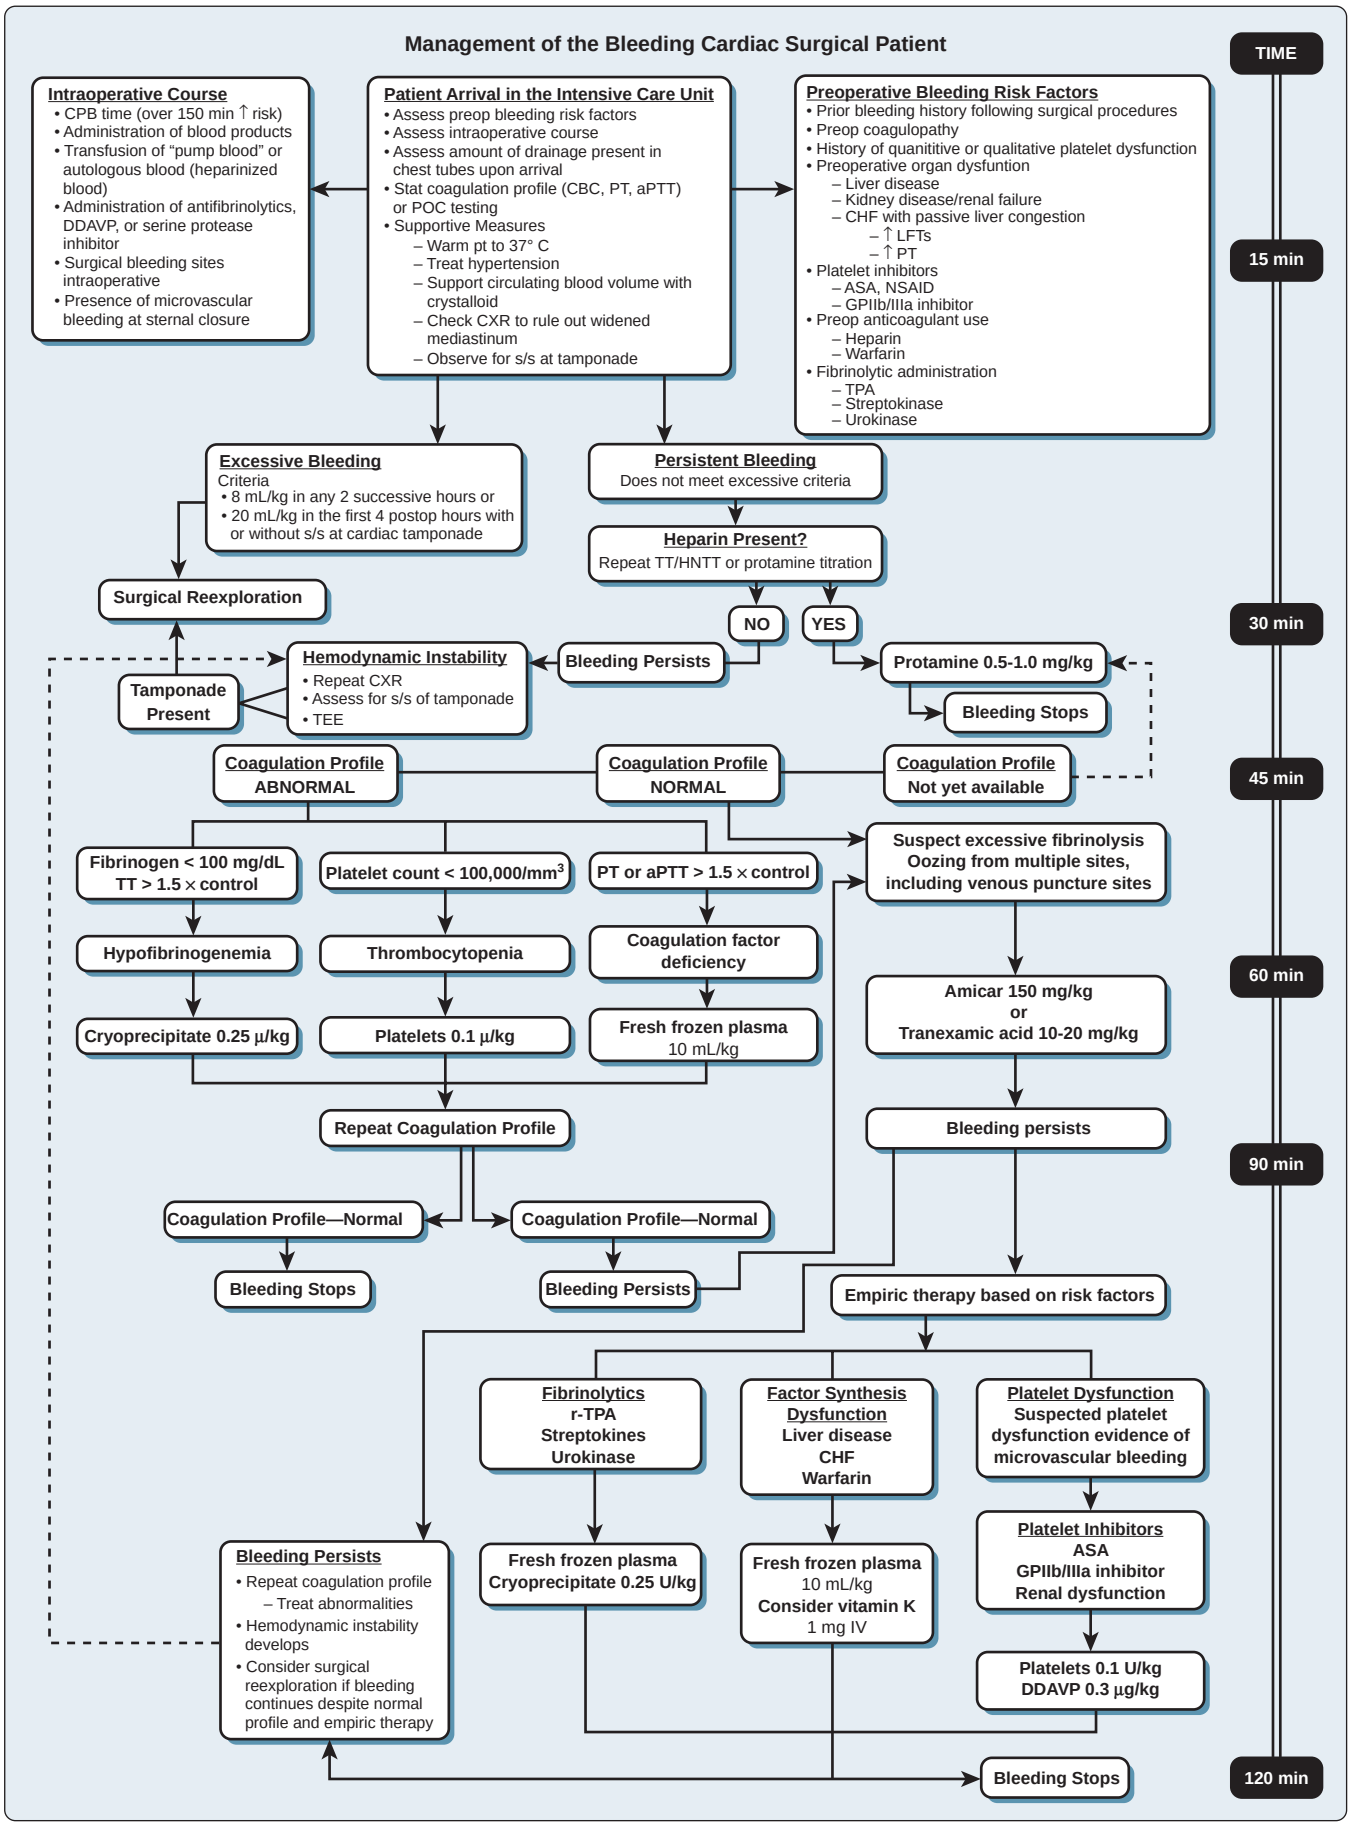

Fig. 35.31 Example of a scheme for treating excessive bleeding. *aPTT*, Activated partial thromboplastin time; *ASA*, acetylsalicylic acid; *CBC*, complete blood cell count; *CHF*, congestive heart failure; *CPB*, cardiopulmonary bypass; *CXR*, chest radiograph; *GP*, glycoprotein; *NSAID*, nonsteroidal antiinflammatory drug; *POC*, point of care; *PT*, prothrombin time; *r-TPA*, recombinant tissue plasminogen activator; *TEE*, transesophageal echocardiography; *t-PA*, tissue plasminogen activator. *(From Milas B, Johes D, Gorman R. Management of bleeding and coagulopathy after heart surgery.* Semin Thorac Cardiovasc Surg. *2000;12:326.)*

TABLE 35.10 Treatment Plan for Excessive Bleeding After Cardiac Surgery

Action	*Amount*	*Indication*
Rule out surgical cause	—	No oozing at puncture sites; chest radiograph
More protamine	0.5–1 mg/kg	ACT > 150 seconds or aPTT > 1.5 times control
Warm the patient	—	"Core" temperature < 35° C
Apply PEEP[a]	5–10 cm H_2O	—
Desmopressin	0.3 µg/kg IV	Prolonged bleeding time
Aminocaproic acid	50 mg/kg, then 25 mg/kg/hr	Increased D-dimer or teardrop-shaped TEG tracing
Tranexamic acid	10 mg/kg, then 1 mg/kg/hr	Increased D-dimer or teardrop-shaped TEG tracing
Platelet transfusion	1 U/10 kg	Platelet count < 100,000/mm^3
Fresh frozen plasma	15 mL/kg	PT or aPTT > 1.5 times control
Cryoprecipitate	1 U/4 kg	Fibrinogen < 1 g/L or 100 mg/dL
Fibrinogen	2 g	Fibrinogen < 100 mg/dL

ACT, Activated coagulation time; *aPTT*, activated partial thromboplastin time; *TEG*, thromboelastograph.
[a]Positive end-expiratory pressure (PEEP) is contraindicated in hypovolemia.

Adjunctive Therapy

Warming

Bleeding patients with core or intermediate zone temperatures less than 35°C will benefit from warming efforts, both passive (warm ambient temperature, adequate body coverings, low-ventilator fresh gas flows, airway heat and humidity exchangers) and active (heated humidifiers, warmed intravenous fluids, forced-air convective warming blankets). All too often, in the effort to maintain intravascular volume, ICU personnel administer liters of room-temperature (≤20°C) or refrigerated (0°C–4°C) fluids, which render patients hypothermic.

Positive End-Expiratory Pressure

One popular method to limit bleeding after cardiac surgery is application of positive end-expiratory pressure (5 to 10 cm H_2O).[566] A tamponade effect in the mediastinum may explain this salutary effect. Unfortunately, controlled studies have not confirmed this benefit.[567,568] In addition, excessive pressure impedes venous return, worsening hemodynamics in the patient with hypovolemia.

Blood Pressure

Maintenance of systemic blood pressure in the low-normal range promotes tissue perfusion while limiting leakage around suture lines. Adequate depth of anesthesia during surgery and sufficient postoperative analgesia and sedation should be verified before initiating vasodilator therapy (see Chapter 38).

36 Discontinuing Cardiopulmonary Bypass

LIEM NGUYEN, MD | DAVID M. ROTH, PhD, MD | JACK S. SHANEWISE, MD | JOEL A. KAPLAN, MD, CPE, FACC

KEY POINTS

1. The key to successful weaning from cardiopulmonary bypass (CPB) is proper preparation.
2. After rewarming the patient, correcting any abnormal blood gases, and inflating the lungs, make sure to turn on the ventilator.
3. To prepare the heart for discontinuing CPB, optimize the cardiac rate, rhythm, preload, myocardial contractility, and afterload.
4. The worse the heart's condition, the more gradually CPB should be weaned. If hemodynamic values are not adequate, immediately return to CPB. Assess the problem, and choose an appropriate pharmacologic, surgical, or mechanical intervention before trying to terminate CPB again.
5. Perioperative ventricular dysfunction usually is caused by myocardial stunning and is a temporary state of contractile dysfunction that should respond to positive inotropic drugs.
6. In addition to left ventricular dysfunction, right ventricular failure is a possible source of morbidity and mortality after cardiac surgical procedures.
7. The presence of diastolic dysfunction during the postbypass period may contribute to impaired chamber relaxation and poor compliance, resulting in reduced ventricular filling during separation.
8. Epinephrine is frequently chosen as an inotropic drug when terminating CPB because of its mixed α- and β-adrenergic stimulation.
9. Milrinone is an excellent inodilator drug that can be used alone or combined with other drugs such as epinephrine for discontinuing CPB in patients with poor ventricular function and diastolic dysfunction.
10. In patients with high preload and/or elevated systemic vascular resistance, vasodilators such as nitroglycerin, nicardipine, clevidipine, or nitroprusside may improve ventricular function.
11. Variable gene expression and genetic polymorphism in patients presenting for cardiac surgical procedures may provide the foundation for individualized tailoring of pharmacology based on molecular genotyping in the future.
12. Intraaortic balloon pump counterpulsation increases coronary blood flow during diastole and unloads the left ventricle during systole. These effects can help in weaning patients with poor left ventricular function and severe myocardial ischemia.

Cardiopulmonary bypass (CPB) has been used since the 1950s to facilitate surgical procedures of the heart and great vessels, and is a critical part of most cardiac operations. Managing patients undergoing CPB remains one of the defining characteristics of cardiac surgery and cardiac anesthesiology (see Chapters 31–35). Discontinuing CPB is a necessary part of every operation involving extracorporeal circulation. Through this process, the support of the circulation by the bypass pump and oxygenator is transferred back to the patient's heart and lungs. This chapter reviews important considerations for discontinuing CPB and presents an approach to managing this critical component of a cardiac operation, which may be routine and easy or extremely complex and difficult. The key to success in discontinuing CPB is proper preparation. The period during and immediately after weaning from CPB usually is busy for the anesthesiologist, and having to do tasks that could have been accomplished earlier in the operation is not helpful. The preparations for removing a patient from CPB may be organized into several parts: general preparations, preparing the lungs, preparing the heart, and final preparations.

General Preparations

Temperature

Because at least moderate hypothermia is used during CPB in most cardiac surgical cases, it is important that the patient is sufficiently rewarmed before attempts are made to wean the patient from CPB (Table 36.1).[1–3] Initiation of rewarming is a good time to consider whether additional drugs must be given to keep the patient anesthetized and to prevent shivering. Monitoring the temperature of a highly perfused tissue such as the nasopharynx is useful to help prevent overheating of the brain during rewarming. Cerebral hyperthermia may lead to neurologic injury and postoperative cognitive dysfunction. The central nervous system receives a greater proportion of warm blood, thus resulting in a more rapid increase in temperature compared with other sites such as the bladder, rectum, or axilla. This situation may lead to inadequate rewarming and temperature dropoff after CPB as the heat continues to distribute throughout the body.[4]

TABLE 36.1 General Preparations for Discontinuing Cardiopulmonary Bypass

Temperature	*Laboratory Results*
Adequately rewarm before weaning from CPB	Correct metabolic acidosis
Avoid overheating the brain	Optimize hematocrit
Start measures to keep patient warm after CPB	Normalize potassium
Use fluid warmer, forced air warmer	Consider giving magnesium or checking magnesium level
Warm operating room	Check calcium level and correct deficiencies

CPB, Cardiopulmonary bypass.

BOX 36.1 PREPARING THE LUNGS FOR DISCONTINUING CARDIOPULMONARY BYPASS

- Suction trachea and endotracheal tube.
- Inflate lungs gently by hand.
- Ventilate with 100% oxygen.
- Treat bronchospasm with bronchodilators.
- Check for pneumothorax and pleural fluid.
- Consider the need for positive end-expiratory pressure, intensive care unit ventilator, and nitric oxide.

Different institutions have various protocols for rewarming, but the important point is to warm gradually, avoiding hyperthermia of the central nervous system while providing enough heat to the patient to prevent significant dropoff after CPB (see Chapters 31 and 32). After CPB, the tendency is for the patient to lose heat, and measures to keep the patient warm (eg, fluid warmers, a circuit heater-humidifier, and forced-air warmers) should be set up and turned on before weaning from CPB is begun. The temperature of the operating room may need to be increased as well; this is probably an effective measure to keep a patient warm after CPB, but it may make the scrubbed and gowned personnel uncomfortable.

Laboratory Results

Arterial blood gases should be measured before the patient is weaned from CPB, and any abnormalities should be corrected. Severe metabolic acidosis depresses the myocardium and necessitates correction before separation from bypass.[5] The optimal hematocrit for weaning from CPB is controversial and probably varies from patient to patient.[6,7] It makes sense that sicker patients with lower cardiovascular reserve may benefit from a higher hematocrit (optimal is considered to be 30%), but the risks and adverse consequences of transfusion must be considered as well. The hematocrit should be measured and optimized before the patient is weaned from CPB (see Chapters 34 and 35). The serum potassium (K^+) level should be measured before weaning from CPB and may be high because of cardioplegia or low, especially in patients receiving loop diuretics. Hyperkalemia may make establishing an effective cardiac rhythm difficult and can be treated with sodium bicarbonate, ($NaHCO_3$), calcium chloride ($CaCl_2$), or insulin, but the levels usually decrease quickly after cardioplegia has been stopped. Low serum K^+ levels should be corrected before CPB is discontinued, especially if arrhythmias are present. Administration of magnesium (Mg^{2+}) to patients on CPB decreases postoperative arrhythmias and may improve cardiac function, and many centers routinely give all CPB-treated patients magnesium sulfate.[8,9] Theoretic disadvantages include aggravation of vasodilation and inhibition of platelet function.[10] If Mg^{2+} is not given routinely, the level should be checked before weaning from CPB, and deficiencies should be corrected. The ionized Ca (Ca^{2+}) level should be measured, and significant deficiencies should be corrected before discontinuing CPB. Many centers give all patients a bolus of $CaCl_2$ just before coming off CPB because it transiently increases contractility and systemic vascular resistance (SVR).[11] However, investigators have argued that this practice is to be avoided because Ca^{2+} may interfere with catecholamine action and aggravate reperfusion injury.[12]

Preparing the Lungs

As the patient is weaned from CPB and the heart starts to support the circulation, the lungs again become the site of gas exchange, by delivering oxygen and eliminating carbon dioxide. Before weaning from CPB, the patient's lung function must be restored (Box 36.1). The trachea should be suctioned and, if necessary, lavaged with saline solution to clear secretions. If the abdomen appears to be distended, the stomach should be suctioned so that gastric distention does not impair ventilation after CPB. The lungs are reinflated by hand gently and gradually, with sighs using up to 30 cm H_2O pressure, and then mechanically ventilated with 100% oxygen. Care should be taken not to allow the lungs to injure an in situ internal mammary artery graft as they are reinflated. The compliance of the lungs can be judged by their feel with hand ventilation; stiff lungs suggest more difficulty with oxygenation or ventilation after CPB. If visible, both lungs should be inspected for residual atelectasis, and they should be rising and falling with each breath. Ventilation alarms and monitors should be activated. If prolonged expiration or wheezing is detected, bronchodilators should be given. The surgeon should inspect both pleural spaces for pneumothorax, which should be treated by opening the pleural space. Examining the lung fields by transesophageal echocardiography (TEE) may assist in the detection of pleural effusions. This imaging technique is primarily performed by examining the lung fields just to the right and left of the heart in the midesophageal four-chamber view at 0 degrees. Any fluid present in the pleural spaces should be removed before attempting to wean the patient from CPB.

The apneic period during CPB has been suggested to contribute to ventilator-associated pneumonia and postoperative pulmonary dysfunction through a variety of mechanisms.[13,14] Continuing mechanical ventilation during CPB has been proposed as another option to attenuate the post-CPB impairment of lung function.[13,15] Results of several small trials that used continued ventilation during CPB were mixed, with some trials showing benefit and others showing no outcome difference.[1] At present, the evidence for intraoperative lung protection strategies such as continued ventilation is lacking and awaits larger randomized trials. In its most severe form, pulmonary dysfunction after CPB may require positive end-expiratory pressure, an intensive care unit–type ventilator, or nitric oxide (see Chapters 37, 39, and 41). If needed, this equipment should be obtained before attempting to wean the patient from CPB.

Preparing the Heart

Management of Intracardiac Air

During the bypass period, the heart is empty, cooled, and usually electrically silent to minimize consumption of adenosine triphosphate (ATP). Air is often introduced into the heart during the operation and can eventually cause deleterious effects during separation from CPB and in the postoperative period. TEE can be helpful in identifying and locating air in the heart and assisting in de-airing before CPB is discontinued. On TEE, air is often seen as echo-dense or bright foci floating to the highest point within the chamber.[1,16]

The time to begin looking with TEE for intracardiac air on CPB is usually after all the chambers and the aorta are closed and the aortic cross-clamp is removed. It is essential to identify macroscopic accumulations of air within the left side of the heart to minimize systemic emboli. With the patient in the supine position, air often is visualized in the left atrium along the interatrial septum, left atrial (LA) appendage, and near the entry points of the pulmonary veins. In the left ventricle and aortic root, air often accumulates along the apical portion

of the interventricular septum and right coronary sinus of Valsalva.[1] To scan for intracardiac air systematically, it may be useful to start in the midesophageal four-chamber view at 0 degrees and fully examine all aspects of the left atrium and ventricle, with special attention to the interatrial and interventricular septum. From this image plane, it may be useful to change the multiplane angle to approximately 120 to 145 degrees, to provide an additional image sector to examine the apical septum for air-fluid levels. As the heart ejects, close inspection of the left ventricular (LV) outflow tract (LVOT) and aortic root at this image plane may facilitate visualization of air emboli, mandating aggressive aspiration of the aortic root vent.

Although a correlation with the amount of intracardiac air seen with TEE and neurologic outcome has not been shown, one of the major concerns with systemic air emboli after CPB is the potential for cerebral injury (see Chapter 40). It is reasonable to proceed with the assumption that the less air pumped into the systemic circulation during and after CPB, the better. Another adverse consequence is the passage of air into the coronary circulation that leads to myocardial ischemia. In the supine patient, the right coronary artery takes off from the highest point of the aortic root, and intracoronary air is most commonly manifested by dramatic inferior ST-segment elevation and acute right-sided heart dysfunction. Saphenous vein grafts typically are anastomosed to the anterior aspect of the ascending aorta and are susceptible to air emboli as well. If this occurs while the patient is still on CPB or before decannulation, it is a simple matter to go back on CPB and wait a few minutes until the air clears from the coronary circulation, the ST segments normalize, and ventricular function improves before trying to wean the patient from CPB again. If, however, coronary air embolization occurs after decannulation, the hemodynamic status can quickly deteriorate to cardiac arrest. Smaller air emboli can be moved through the coronary vessels by acutely increasing the blood pressure with a vasopressor while dilating the coronary arteries with nitroglycerin (NTG). Perhaps the worst-case scenario is when a macroscopic air bubble in the left side of the heart is shaken loose while moving the patient from the operating table at the end of the case; acute right-sided heart failure (HF) and circulatory collapse may occur either then or while the patient is being transported to the intensive care unit.

Numerous maneuvers may be used to de-air the chambers.[1,17] They may include shaking the vented heart on partial CPB to jar loose any pockets of air, elevating and aspirating LV air directly from the apex, applying positive pressure to the lungs to squeeze air out of the pulmonary veins, and tipping the table from side to side to help the passage of bubbles through the heart to the ascending aorta where they are released through a vent. Additional air may appear in the left side of the heart during weaning from CPB as increasing flow through the pulmonary veins flushes air out from the lungs into the left atrium. Passage of air from the left atrium to the left ventricle may be facilitated with the head and right-side-down position, as well as from the left ventricle to the ascending aorta with the head and right-side up. It may be impossible to evacuate every last trace of air from the left side of the heart before discontinuing CPB, especially tiny bubbles trapped in the trabeculae of the left ventricle; it therefore becomes a matter of judgment and experience to know when enough is enough. The persistence of a macroscopic air-fluid level in the left side of the heart visible with TEE, however, suggests that more de-airing probably is needed before closing the vent in the ascending aorta and weaning from CPB. After adequate de-airing, preparing the heart to resume its function of pumping blood involves optimizing the determinants of cardiac output (CO). The five hemodynamic parameters that can be controlled are rate, rhythm, preload, contractility, and afterload (Table 36.2).

TABLE 36.2 Preparing the Heart for Discontinuing Cardiopulmonary Bypass

Hemodynamic Parameters	*Preparation*
Heart rate	Rate should be between 75 and 95 beats/min in most cases Treat slow rates with electrical pacing Treat underlying causes of fast heart rates Heart rate may decrease as the heart fills Control fast supraventricular rates with drugs, and then pace as needed Always have pacing immediately available during heart operations
Rhythm	Normal sinus rhythm is ideal Defibrillate if necessary when temperature >30°C Consider antiarrhythmic drugs if ventricular fibrillation persists more than a few minutes Try synchronized cardioversion for atrial fibrillation or flutter Look at the heart to diagnose atrial rhythm Try atrial pacing if atrioventricular conduction exists Try atrioventricular pacing for heart block
Preload	End-diastolic volume is the best measure of preload and can be seen with TEE Filling pressures provide a less direct measure of preload Consider baseline filling pressures Assess RV volume with direct inspection Assess LV volume with TEE Cardiac distention may cause MR and TR
Contractility	Carefully examine heart for air and employ de-airing maneuvers Assess and quantify RV function with direct inspection and TEE Assess and quantify LV function with TEE Inspect for new regional wall motion abnormalities Inspect for new or worsening valvular abnormalities Quantify cardiac output by TEE or PAC Assess need for inotropic agent
Afterload	Systemic vascular resistance is a major component of afterload Keep MAP between 60 and 80 mm Hg at full CPB flow Consider a vasoconstrictor if the MAP is low and a vasodilator if the MAP is high

CPB, Cardiopulmonary bypass; *LV,* left ventricular; *MAP,* mean arterial pressure; *MR,* mitral regurgitation; *PAC,* pulmonary artery catheter; *RV,* right ventricular; *TEE,* transesophageal echocardiography; *TR,* tricuspid regurgitation.

Heart Rate

Establishing an effective heart rate (HR) is a critical prerequisite and major determinant of CO. In most situations for adult patients, the HR should be between 75 and 95 beats/minute for weaning from CPB. It may be prudent to establish electrical pacing early in the weaning process to ensure a means to control the HR precisely. Lower rates theoretically may be desirable for hearts with residual ischemia or incomplete revascularization. Higher HRs may be needed for hearts with limited stroke volume (SV) such as after ventricular aneurysmectomy. Slow HRs are best treated with electrical pacing, but β-agonist or vagolytic drugs also may be used to increase the HR. Tachycardia before weaning from CPB is more worrisome and difficult to manage, and treatable causes such as inadequate anesthesia, hypercarbia, and ischemia should be identified and corrected. The HR often decreases as the heart is filled in the weaning process, and electrical pacing always should be immediately available during cardiac operations to treat sudden bradycardias. Supraventricular tachycardias should be electrically cardioverted if possible, but drugs such as β-antagonists or Ca^{2+} channel antagonists may be needed to control the ventricular rate if these arrhythmias persist, most typically in patients with chronic atrial fibrillation. If drug therapy decreases the HR too much, pacing may be used.

Rhythm

The patient must have an organized, effective, and stable cardiac rhythm before attempts are made to wean the patient from CPB. This rhythm can occur spontaneously after removal of the aortic cross-clamp, but the heart may resume electrical activity with ventricular fibrillation. If the blood temperature is greater than 30°C, the heart may be defibrillated with internal paddles applied directly to the heart by using 10 to 20 J. Defibrillation at lower temperatures may be unsuccessful

because extreme hypothermia can cause ventricular fibrillation.[18,19] If ventricular fibrillation persists or recurs repeatedly, antiarrhythmic drugs such as lidocaine, amiodarone, or Mg^{2+} may be administered to help achieve a stable rhythm. It is not unusual for the rhythm to remain unstable for several minutes immediately after cross-clamp removal, but persistent or recurrent ventricular fibrillation should prompt concern about impaired coronary blood flow. Because it provides an atrial contribution to ventricular filling and a normal, synchronized contraction of the ventricles, normal sinus rhythm is the ideal cardiac rhythm for weaning from CPB.[20] Atrial flutter or fibrillation, even if present before CPB, often can be converted to normal sinus rhythm with synchronized cardioversion, especially if antiarrhythmic drugs are administered. It often is helpful to look directly at the heart when any question exists about the cardiac rhythm. Atrial contraction, flutter, and fibrillation are easily seen on CPB when the heart is visible. Ventricular arrhythmias should be treated by correcting underlying causes such as K^+ or Mg^{2+} deficits and, if necessary, by administering antiarrhythmic drugs such as amiodarone.[9] If asystole or complete heart block occurs after cross-clamp removal, electrical pacing with temporary epicardial pacing wires may be needed to achieve an effective rhythm before weaning from CPB. If atrioventricular conduction is present, atrial pacing should be attempted because, as with normal sinus rhythm, it provides atrial augmentation to filling and synchronized ventricular contraction. Atrioventricular sequential pacing is used in patients with heart block, which may be temporarily present for 30 to 60 minutes as the myocardium recovers after cardioplegia and cross-clamp removal. Ventricular pacing remains the only option if no organized atrial rhythm is present, but this sacrifices the atrial "kick" to ventricular filling and the more efficient synchronized ventricular contraction of the normal conduction system[21,22] (see Table 36.2).

Preload

Once control of the rate and rhythm is established, priming the heart with volume or preload is the next step. Preload is the amount of stretch on the myocardial muscle fibers just before contraction. In the intact heart, the best measure of preload is end-diastolic volume. Less direct clinical measures of preload include LA pressure (LAP), pulmonary artery occlusion pressure, and pulmonary artery diastolic pressure, but the relationship between end-diastolic pressure and volume during cardiac surgical procedures may be poor[23,24] (see Chapters 6, 13, and 38). TEE is a useful tool for weaning from CPB because it provides direct visualization of the end-diastolic volume and contractility of the left ventricle[25,26] (see Chapters 14–16). TEE may also provide a means to calculate serial CO measurements during volume loading of the heart. In addition, diastolic filling indices (transmitral and pulmonary venous inflow) may assist in assessing fluid responsiveness and elevations in LA and LV filling pressures.[27,28] The process of weaning a patient from CPB involves increasing the preload (ie, filling the heart from its empty state on CPB) until an appropriate end-diastolic volume is achieved. When preparing to discontinue CPB, some thought should be given to the appropriate range of preload for the individual patient. The filling pressures before CPB may indicate what they need to be after CPB; a heart with high filling pressures before CPB may require high filling pressures after CPB to achieve an adequate preload.

Contractility

The contractile state of both the right and left sides of the heart should be considered individually before attempting to wean from CPB. The decision to institute inotropic support after CPB is complex, and intraoperative use of inotropes may be associated with higher mortality rates.[29] Some of the factors associated with the low CO syndrome (LCOS) or the need for inotropic support after CPB include preexisting right ventricular (RV) or LV dysfunction,[30–36] diastolic dysfunction,[37,38] elevated LV end-diastolic pressure (LVEDP),[30,32] advanced age,[30,32,34] prolonged CPB time,[37] and long aortic cross-clamp time[30,35,37] (Table 36.3). Assessment of the right ventricle may be easily attainable because the right-sided chambers are directly visible to the anesthesiologist. Direct visualization of the left ventricle is difficult, and TEE may be the only modality by which to visualize left-sided heart function directly. Both right-sided and left-sided heart function and the corresponding atrioventricular valves should be systematically examined by TEE. The use of TEE during gradual weaning from the pump may provide essential information on chamber filling and the contractile state.

TABLE 36.3 Summary of Factors Associated With the Use of Inotropic Drug Support or Low Cardiac Output Syndrome

Variable	*Odds Ratio*	*Reference*
Age (>60 y)	4.3	Butterworth et al., 1998[31]
Aortic cross-clamp time >90 min	2.32	Muller et al., 2002[36]
Bypass time (min)	3.40	Bernard et al., 2001[37]
CABG + MVR	3.607	McKinlay et al., 2004[35]
Cardiac index <2.5 L/m^2 per min	3.10	Ahmed et al., 2009[30]
CHF (NYHA class >II)	1.85	Muller et al., 2002[36]
CKD (stage 3–5; GFR <60 mL/1.73 m^2 per min	3.26	Ahmed et al., 2009[30]
COPD	1.85	Muller et al., 2002[36]
Diastolic dysfunction	4.31	Bernard et al., 2001[37]
Ejection fraction (%) <40	2.76	Ahmed et al., 2009[30]
Emergency operation	9.15	Ding et al., 2015[34]
Female sex	2.0	Alganrni et al., 2011[33]
LVEDP >20 mm Hg	3.58	Ahmed et al., 2009[30]
Myocardial infarction	2.01	Muller et al., 2002[36]
Moderate-to-severe mitral regurgitation	2.277	McKinlay et al., 2004[35]
Regional wall motion abnormality	4.21	McKinlay et al., 2004[35]
Repeat operation	2.38	McKinlay et al., 2004[35]

CABG, Coronary artery bypass graft; *CHF,* congestive heart failure; *CKD,* chronic kidney disease; *COPD,* chronic obstructive pulmonary disease; *GFR,* glomerular filtration rate; *LVEDF,* left ventricular end-diastolic pressure; *MVR,* mitral valve repair or replacement; *NYHA,* New York Heart Association.

A brief evaluation of cardiac function including both RV and LV contractility is achieved by a series of scan planes at the midesophageal level and advancing the probe into the transgastric position. The goal is to ascertain quickly the suitability of the heart to wean from CPB successfully. This goal may be achieved by scanning for RV and LV wall motion in the midesophageal (four-chamber view at 0 degrees, two-chamber view at 90 degrees, aortic long-axis view at 120 to 150 degrees, RV inflow-outflow at 45 to 60 degrees) and transgastric views (LV and RV short-axis view at 0 degree). If evidence of poor contractility is visualized on TEE, initiation or titration of inotropic agents can begin at this time. As the pump flow is gradually reduced, the ability of the heart to fill and eject is continuously assessed, and drug therapy is titrated as needed. Once the heart has demonstrated the ability to maintain adequate hemodynamic status, separation from CPB is commenced. At this point, serial volume transfusions from the venous reservoir can be carefully titrated as needed, and the heart's response to volume can be monitored by TEE.[25] After each volume bolus, assessments of biventricular function and the end-diastolic and end-systolic areas of the right and ventricles are critical to prevent overdistention and unwanted wall tension. Reinstitution of CPB is warranted if the heart begins to distend or displays inadequate function.

Because the use of intraoperative and postoperative inotropic support may be associated with increased mortality rates, the decision to initiate pharmacologic therapy should be made with caution.[29] A prudent approach, using a slow and gradual weaning process from the pump and assessing cardiac filling and biventricular contractility in a stepwise manner, may help reduce unnecessary use of inotropic agents. As the heart is allowed to fill gradually, if significant chamber distention or depression of contractility is evident on TEE or by direct visual inspection, the safest approach is to prevent cardiac distention by resuming CPB. At this point, the heart may benefit from a resting

period of 10 to 20 minutes on CPB, and then the decision to start inotropes may be warranted before the patient is weaned from CPB.

Extreme depression of contractile function of the myocardium despite adequate pharmacologic therapy may require mechanical support with an intraaortic balloon pump (IABP), ventricular assist device, or extracorporeal membrane oxygenator (see later and Chapters 28, 33, and 38).

Afterload

Afterload is the tension developed within the ventricular muscle during contraction. An important component of afterload in patients is the SVR (see Chapters 6, 13, and 38).[39] During CPB at full flow (usually ≈2.2 L/m^2 per min), mean arterial pressure (MAP) is directly related to SVR and indicates whether the SVR is appropriate, too high, or too low. Low SVR after CPB can cause inadequate systemic arterial perfusion pressure, and high SVR can significantly impair cardiac performance, especially in patients with poor ventricular function. SVR during CPB can be approximated by using the following equation:

$$\text{SVR (dynes} \cdot \text{s} \cdot \text{cm}^{-5}) = \text{MAP} \times 80 / \text{pump flow}$$

If the SVR is less than normal, infusion of a vasopressor may be needed to increase the SVR before attempting to wean the patient from CPB. If the MAP is high during CPB, vasodilator therapy may be needed.

Final Considerations and Preparations

The state of coagulation and the potential requirement for blood transfusion or component therapy must be considered before separation from CPB. Review of data from prebypass studies such as hemoglobin, platelet count, thromboelastography, and coagulation panels may help in recognizing preexisting coagulopathy and predict transfusion requirements in the presence of post-CPB bleeding after protamine administration. Risk factors that may be associated with higher rates of transfusion include emergency or urgent surgical procedures, reoperation, cardiogenic shock, older age, female sex, low body weight, and preoperative anemia.[40] Preoperative use of antiplatelet agents, warfarin, and novel anticoagulants may also portend higher transfusion rates and warrant special attention. Assessing coagulation status and the need for transfusion is an important consideration before attempting to wean a patient from CPB.

The final preparations before discontinuing CPB include leveling the operating table, resetting the pressure transducers to zero, ensuring the proper function and location of all monitoring devices, confirming that the patient is receiving only intended drug infusions, ensuring the immediate availability of resuscitation drugs and appropriate fluid volume, and verifying that the lungs are being ventilated with 100% oxygen (Table 36.4).

The surgeon must confirm that he or she has completed the necessary preparations in the surgical field before CPB is discontinued. Macroscopic collections of air in the heart should be evacuated as described in detail earlier before starting to wean the patient from CPB. This is also an appropriate time to reassess the five major determinants of CO by using all available monitors and TEE. Major sites of bleeding should be controlled, cardiac vent suction should be off, all clamps on the heart and great vessels should be removed, coronary artery bypass grafts (CABGs) should be checked for kinks and bleeding, and tourniquets around the caval cannulas should be loosened or removed before starting to wean a patient from CPB.

TABLE 36.4 Final Preparations for Discontinuing Cardiopulmonary Bypass

Anesthesiologist's Preparations	*Surgeon's Preparations*
Level operating table	Remove macroscopic collections of air from the heart
Reset transducers to zero	Control major sites of bleeding
Activate monitors	Ensure CABG is lying nicely without kinks
Check drug infusions	Turn off or remove cardiac vents
Have resuscitation drugs and fluid volume at hand	Take clamps off the heart and great vessels
Reestablish TEE or PAC monitoring	Loosen tourniquets around caval cannulas

CABG, Coronary artery bypass graft; *PAC,* pulmonary artery catheter; *TEE,* transesophageal echocardiography.

Routine Weaning From Cardiopulmonary Bypass

The perfusionist, the surgeon, and the anesthesiologist should communicate closely and clearly while weaning a patient from CPB, and the surgeon or the anesthesiologist should be in charge of the process. The anesthesiologist should be positioned at the head of the table, able to see the CPB pump and perfusionist, the heart, the surgeon, and the anesthesia monitor display readily. The TEE display also should be easily in view. Weaning a patient from CPB is accomplished by diverting blood back into the patient's heart by occluding the venous drainage to the CPB pump. The arterial pump flow is decreased simultaneously as the pump reservoir volume empties into the patient, and the heart's contribution to systemic flow increases. This can be accomplished most abruptly by simply clamping the venous return cannula and transfusing blood from the pump until the heart fills and the preload appears to be adequate. Some patients tolerate this method of discontinuing CPB, but many do not, and a more gradual transfer from the pump to the heart usually is desirable. The worse the function of the heart is, the slower the transition from full CPB to off CPB needs to be.

Before beginning to wean the patient from CPB, the perfusionist should communicate to the physicians involved the following three important parameters: (1) the current flow rate of the pump, (2) the volume in the pump reservoir, and (3) the oxygen saturation of venous blood returning to the pump from the patient. The flow along with MAP can be used to gauge the SVR of the patient before weaning from CPB. The current flow rate of the pump indicates the stage of weaning as it is decreased. Weaning is just beginning at full flow, is well under way when down to 2 or 3 L/minute in adults, and is almost finished at less than 2 L/minute. The reservoir volume indicates how much blood is available for transfer to the patient to fill the heart and lungs as CPB is discontinued. If the volume is low (<400 to 500 mL in adults), more fluid may need to be added to the reservoir before weaning from CPB. The oxygen saturation of the venous return ($S\bar{v}O_2$) gives an indication of the adequacy of peripheral perfusion during CPB. If the $S\bar{v}O_2$ is greater than 60%, oxygen delivery during CPB is adequate; if it is less than 50%, oxygen delivery is inadequate, and measures to improve delivery (eg, increase pump flow or hematocrit) or decrease consumption (eg, give more anesthetic agents or neuromuscular blocking drugs) must be taken before CPB is discontinued. An $S\bar{v}O_2$ between 50% and 60% is marginal and must be followed closely. As the patient is weaned from CPB, an increasing $S\bar{v}O_2$ suggests that the net flow to the body is increasing and that the heart and lungs will support the circulation; a declining $S\bar{v}O_2$ indicates that tissue perfusion is decreasing and that further intervention to improve cardiac performance will be needed before CPB is discontinued.

The actual process of weaning from CPB begins with partially occluding the venous return cannula with a clamp (Fig. 36.1). This may be done in the field by the surgeon or at the pump by the perfusionist. This maneuver causes blood to flow into the right ventricle. As the right ventricle fills and begins to pump blood through the lungs, the left heart begins to fill. When this occurs, the left ventricle begins to eject, and the arterial waveform becomes pulsatile. Next, the perfusionist gradually decreases the pump flow rate. As more of the venous return goes through the heart and less to the pump reservoir, it becomes necessary to decrease the pump flow gradually to avoid emptying the pump reservoir.

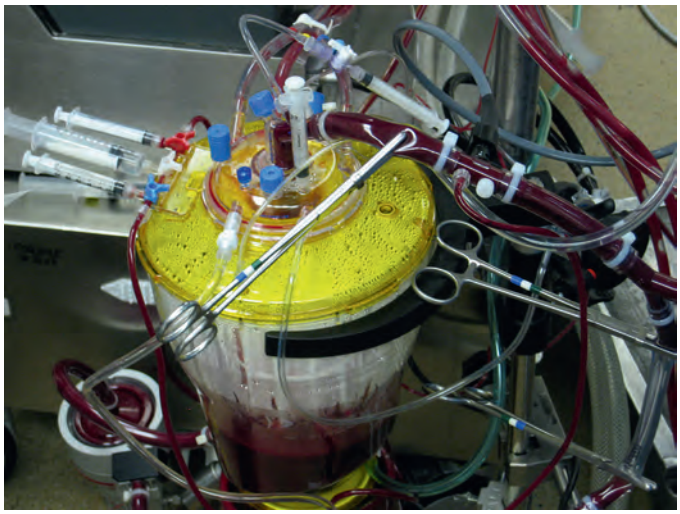

Fig. 36.1 The process of weaning from cardiopulmonary bypass is started by partially occluding the venous return cannula with a clamp.

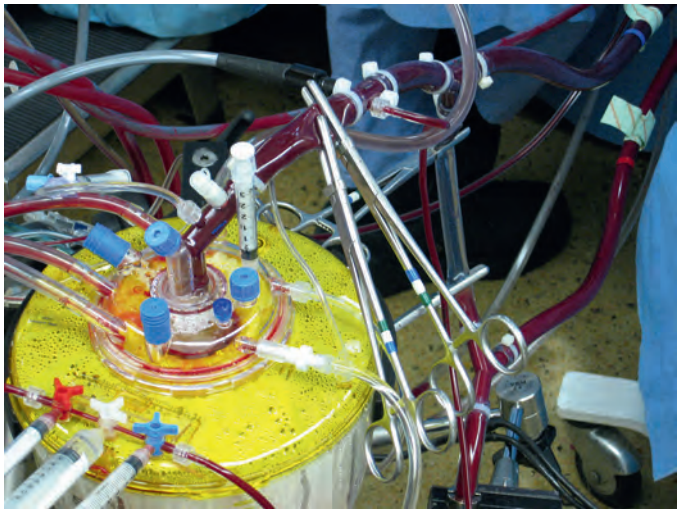

Fig. 36.2 When the venous return cannula is completely clamped, the patient is "off bypass."

One approach to weaning from CPB is to bring the filling pressure being monitored (eg, central venous pressure, pulmonary artery pressure, LAP) to a specific, predetermined level somewhat lower than may be necessary and then assess the hemodynamic status. Volume (preload) of the heart also may be judged by direct observation of its size or with TEE. Further filling is done in small increments (50–100 mL) while closely monitoring the preload until the hemodynamic status appears satisfactory as judged by the arterial pressure, the appearance of the heart, the trend of the $S\bar{v}O_2$, and CO measurements by TEE or pulmonary artery catheter. It typically is easy to see the right-sided heart volume and function directly in the surgical field and the left side of the heart with TEE; combining the two observations is a useful approach for weaning from CPB. Overfilling and distention of the heart should be avoided because they may stretch the myofibrils beyond the most efficient length and dilate the annuli of the mitral and tricuspid valves, thus rendering them incompetent, which can be detected with TEE. If the patient has two venous cannulas, the smaller of the two may be removed when the pump flow is half of the full flow rate to improve movement of blood from the great veins into the right atrium. When the pump flow has been decreased to 1 L/minute or less in an adult and the hemodynamics findings are satisfactory, the venous cannula may be completely clamped and the pump flow turned off. At this point, the patient is "off bypass" (Fig. 36.2).

This is a critical juncture in the operation. The anesthesiologist should pause a moment to make a brief scan of the patient and monitors to confirm that the lungs are being ventilated with oxygen, the hemodynamic status is acceptable and stable, the electrocardiogram shows no new signs of ischemia, the heart does not appear to be distending, and the drug infusions are functioning as desired. Further fine-tuning of the preload is accomplished by transfusing 50- to 100-mL boluses from the pump reservoir through the arterial cannula and observing the effect on hemodynamics. If acute failure of the circulation occurs, as evidenced by an unstable rhythm, falling arterial and rising filling pressures, or visible distention of the heart, the patient is put back on CPB by unclamping the venous return cannula and turning on the arterial pump flow. Once CPB has resumed, an assessment of the cause of failure to wean is made, and appropriate interventions are undertaken before attempting to wean the patient from CPB again. When the hemodynamic status appears to be stable and adequate, the surgeon may remove the venous cannula from the heart.

The next step in discontinuing CPB is to transfuse as much of the blood remaining in the pump reservoir as possible into the patient before removal of the arterial cannula. This technique is usually easier and quicker than transfusing through the intravenous infusions after decannulation. The blood in the venous cannula and tubing (usually ≈500 mL) may be drained into the reservoir for transfusion. The patient's venous capacitance can be increased by raising the head of the bed (ie, reverse Trendelenburg position) and/or giving NTG; more cautions is required with these maneuvers in patients with impaired cardiac function. Filling the vascular space with the patient's head up and while infusing NTG increases the ability to cope with volume loss after decannulation by allowing rapid augmentation of the central vascular volume by leveling the bed and decreasing the NTG infusion rate.

After discontinuing CPB, the anticoagulation by heparin is reversed with protamine. Depending on institutional preference, protamine may be administered before or after removal of the arterial cannula. Giving protamine before removal allows for continued transfusion from the pump and easier return to CPB if the patient has a severe protamine reaction (see Chapter 35). Giving protamine after removal of the arterial cannula may decrease the risk for thrombus formation and systemic embolization. After the infusion of protamine is started, pump suction return to the reservoir should be stopped to keep protamine out of the pump circuit in case subsequent return to CPB becomes necessary. Titrated dosing of protamine may be more effective in reducing postoperative bleeding compared with a standard protamine administration protocol.[41] Titrated dosing involves adjusting the protamine concentration to reflect measured circulating heparin levels. Protamine should be given slowly through a peripheral intravenous catheter over 5 to 15 minutes while the clinician watches for systemic hypotension and pulmonary hypertension, which may indicate that an untoward (allergic) reaction to protamine is occurring.[42–44] Technically flawed CABGs may thrombose after protamine administration, thus causing acute ischemia mimicking a protamine reaction.

When transfusion of the pump reservoir blood is completed, a thorough assessment of the patient's condition should be made before the arterial cannula is removed because after this is done, returning to CPB becomes much more difficult. The cardiac rhythm should be stable. Cardiac function and hemodynamic status, as assessed by arterial and venous filling pressures, CO, and TEE, should be satisfactory and stable. A more detailed and comprehensive TEE examination can be performed as time permits. RV free wall motion to assess RV function qualitatively can be obtained in the midesophageal four-chamber view (0 degrees) and midesophageal RV inflow-outflow view (45–60 degrees). In the midesophageal four-four-chamber view, RV function can also be quantified by measuring tricuspid annular systolic plane excursion (TAPSE) and comparing it with prebypass assessments.

Findings of interatrial septal bowing into the left atrium may indicate volume or pressure overload of the right atrium. Interventricular septal motion after CPB should be interpreted with caution because abnormal septal movement may be caused by several factors including epicardial pacing, stunned myocardium, volume or pressure overload,

and ischemia. The midesophageal four-chamber view at 0 degrees and the RV inflow-outflow view at 45 to 60 degrees may be used to assess for new or worsening tricuspid regurgitation, thereby indicating the possibility of RV dysfunction. Advancing the probe to the transgastric level allows for further evaluation of RV function in the short-axis view. After examining the right-sided chambers, all segments of the left side of the heart should be reviewed. This examination can be performed by using all sector planes in the midesophageal views (four-chamber view at 0 degrees, two-chamber at 90 degrees, and aortic long-axis view at 120–150 degrees) and transgastric views.

Special attention should be given to new regional wall motion abnormalities, systolic thickening, and excursion of all segments of the left ventricle, evidence of LVOT obstruction from systolic anterior motion of the mitral valve, new valvular abnormalities, and overall end-diastolic and systolic chamber dimensions. New regional wall motion abnormalities may signify a technically flawed CABG or intracoronary air. LVOT obstruction from systolic anterior motion may indicate the presence of inadequate chamber filling from hypovolemia and tachycardia or a hyperdynamic state of contractility. New valvular abnormalities may represent iatrogenic damage to the valvular apparatus, myocardial ischemia, volume overload, or ventricular dysfunction. It is also important to scan the aorta to rule out a new aortic dissection after aortic decannulation. As time permits, TEE can also be used to calculate SV and CO by Doppler interrogation of the LVOT and aortic outflow tract. Diastolic filling profiles of the left ventricle and left atrium may be obtained using transmitral and pulmonary venous inflow, respectively. Serial measurements of LA and LV inflow may allow for estimating filling pressures and chamber compliance.

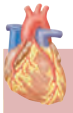
Adequate oxygenation and ventilation should be confirmed by arterial blood gas or pulse oximetry and capnography. Bleeding from the heart should be at a manageable level before removal of the arterial cannula. The perfusionist should not have to transfuse significant amounts of blood through the arterial cannula before removing it because keeping up with the blood loss through intravenous infusions alone may be difficult. Bleeding sites behind the heart may have to be repaired on CPB if the patient cannot tolerate lifting of the heart to expose the problem area. At the time of arterial decannulation, the systolic pressure should be lowered to between 85 and 100 mm Hg to minimize the risk for dissection or tearing of the aorta.[45] The head of the bed may be raised, or small boluses of a short-acting vasodilator may be given to lower the systemic blood pressure as necessary. Tight control of the arterial blood pressure may be needed for a few minutes until the cannulation site is secure. The routine process of discontinuing bypass is completed when removal of all cannulas is successful and full reversal of the anticoagulation is achieved.

Pharmacologic Management of Ventricular Dysfunction

Perioperative ventricular dysfunction usually is a transient state of contractile impairment that may require temporary support with positive inotropic agents. In a subset of patients, contractility may be significantly depressed such that combination therapy with positive inotropes and vasodilator agents is needed to improve CO and tissue perfusion effectively. The use of mechanical assist devices is reserved for conditions of overt or evolving cardiogenic shock.

Severe ventricular dysfunction, specifically the LCOS, occurring after CPB and cardiac operations differs from chronic congestive HF (CHF) (Box 36.2). Patients emerging from CPB have hemodilution, moderate hypocalcemia, hypomagnesemia, and altered K^+ levels. Depending on temperature and depth of anesthesia, these patients may demonstrate low, normal, or high SVR. Increasing age, female sex, decreased LV ejection fraction (LVEF), diastolic dysfunction, prolonged aortic cross-clamp time, and increased duration of CPB are associated with a greater likelihood that inotropic support will be needed after CABG procedures (see Table 36.3).[30,32,37,46]

Contractile dysfunction during or after cardiac operations can result from preexisting impairment in contractility or may be a new-onset condition. Abnormal contraction, especially in the setting of coronary artery disease (CAD), usually is caused by myocardial injury resulting in ischemia or infarction. The magnitude of contractile dysfunction corresponds to the extent and duration of injury. Brief periods of myocardial oxygen deprivation (<10 minutes) produce regional contractile dysfunction, which can be rapidly reversed by reperfusion. Extension of the ischemia to 15 to 20 minutes also is associated with restoration of cardiac function with reperfusion; however, this process is very slow and can take hours to days. This condition of postischemic reversible myocardial dysfunction in the presence of normal flow is referred to as *myocardial stunning*.[47–50] Irreversible cell injury occurs with longer periods of ischemia and produces myocardial infarction characterized by release of intracellular enzymes, disruption of cell membranes, influx of Ca^{2+}, persistent contractile dysfunction, and eventual cellular swelling and necrosis.[51]



BOX 36.2 RISK FACTORS FOR THE LOW CARDIAC OUTPUT SYNDROME AFTER CARDIOPULMONARY BYPASS

- Preoperative ventricular dysfunction
- Myocardial ischemia
- Poor myocardial preservation
- Reperfusion injury
- Inadequate cardiac surgical repair or revascularization

In addition to the previously described factors, RV dysfunction and RV failure are potential sources of morbidity and death after cardiac operations.[52–54] Numerous factors may predispose patients to the development of perioperative RV dysfunction, including CAD, RV hypertrophy, previous cardiac operation, and operative considerations such as inadequate revascularization or hypothermic protection. Technical and operative difficulties are associated with various cardiac surgical procedures (eg, right ventriculotomy), RV trauma, rhythm and conduction abnormalities, injury to the right ventricle during cessation of CPB, or protamine reaction.

The following discussion provides an overview of the pharmacologic approach to management of perioperative ventricular dysfunction in the setting of cardiac surgery. Management goals are described in Table 36.5. These are extensions of the routine preparations made for discontinuing CPB shown in Table 36.2.

Sympathomimetic Amines

Sympathomimetic drugs (ie, catecholamines) are pharmacologic agents capable of providing inotropic and vasoactive effects (Box 36.3). Catecholamines exert positive inotropic action by stimulation of the β_1- and β_2-receptors.[55–57] The predominant hemodynamic effect of a specific catecholamine depends on the degree to which the various α, β, and dopaminergic receptors are stimulated (Tables 36.6 and 36.7).

The physiologic effect of an adrenergic agonist is determined by the sum of its actions on α, β, and dopaminergic receptors. The effectiveness of any adrenergic agent is influenced by the availability and responsiveness of adrenergic receptors. Chronically increased levels of plasma catecholamines (eg, chronic CHF and long CPB time) cause downregulation of the number and sensitivity of β-receptors.[58] Acute depression of β-adrenergic receptor signaling has been reported following CPB.[59] Maintenance of normal acid-base status, normothermia, and electrolytes also improve the responsiveness to adrenergic-receptor stimulation.

The selection of a drug to treat ventricular dysfunction is influenced by pathophysiologic abnormalities, as well as by the physician's experience and preference. If LV performance is decreased primarily as a result of diminished contractility, the drug chosen should increase contractility. Although β-agonists improve contractility and tissue perfusion, their effects may increase myocardial oxygen consumption

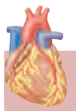
TABLE 36.5 Goals and Management of Cardiac Dysfunction

Variable	*Physiologic Management*
Heart rate and rhythm	Maintain normal sinus rhythm, avoid tachycardia; for tachycardia or bradycardia, consider pacing or chronotropic agents (atropine, isoproterenol, epinephrine), correct acid-base, electrolytes, and review current medications
Contractility	Assess hemodynamics, perform TEE to assess cardiac function, inspect for RWMA, rule out ischemia or infarction, inspect for dynamic outflow obstruction, consider inotropes; consider combination therapy with inotropes and/or vasodilators, and evaluate need for assist devices (IABP/LVAD/RVAD)
Preload	Assess end-diastolic volumes and chamber dimensions on TEE, rule out ischemia, significant valvular lesions, tamponade, and intracardiac shunts; reduce increased preload with diuretics or venodilators (nitroglycerin); monitor CVP, PCWP, and SV; consider using inotropes, IABP, or both
Afterload	Avoid increased afterload (increased wall tension), use vasodilators; avoid hypotension; maintain coronary perfusion pressure; consider IABP, inotropes devoid of α_1-adrenergic effects (dobutamine or milrinone), or both IABP and inotropes
Oxygen delivery	Increase Fio_2 and CO; check ABGs and chest radiograph; confirm adequate ventilation and oxygenation; correct acid-base disturbances

ABG, Arterial blood gas; *CO,* cardiac output; *CVP,* central venous pressure; *Fio_2,* fraction of inspired oxygen concentration; *IABP,* intraaortic balloon pump; *LVAD,* left ventricular assist device; *PCWP,* pulmonary capillary wedge pressure; *RVAD,* right ventricular assist device; *RWMA,* regional wall motion abnormality; *SV,* stroke volume; *TEE,* transesophageal echocardiography.

TABLE 36.6 Sympathomimetic Agents

	Dosage		Site of Action		
Drug	*Intravenous Bolus*	*Infusion*	*α*	*β*	*Mechanism of Action*
Dobutamine	—	2–20 μg/kg per min	+	++++	Direct
Dopamine	—	1–10 μg/kg per min	++	+++	Direct and indirect
Epinephrine	2–16 μg	2–10 μg/min Or 0.01–0.4 μg/kg per min	+++	+++	Direct
Ephedrine	5–25 mg	—	+	++	Direct and indirect
Isoproterenol	1–4 μg	0.5–10 μg/min Or 0.01–0.10 μg/kg per min		++++	Direct
Norepinephrine	—	2–16 μg/min Or 0.01–0.3 μg/kg per min	++++	+++	Direct



BOX 36.3 PHARMACOLOGIC APPROACHES TO VENTRICULAR DYSFUNCTION

($M\dot{v}o_2$) and reduce coronary perfusion pressure (CPP). However, if the factor most responsible for decreased cardiac function is hypotension with concomitantly reduced CPP, infusion of α-adrenergic agonists can increase blood pressure and improve diastolic coronary perfusion.

Catecholamines also are effective for treating primary RV contractile dysfunction, and all the β_1-adrenergic agonists augment RV contractility. Studies have documented the efficacy of epinephrine, norepinephrine, dobutamine, isoproterenol, dopamine, levosimendan, and phosphodiesterase fraction III (PDE III) inhibitors in managing RV contractile dysfunction. When decreased RV contractility is combined with increased afterload, agents that exert vasodilator and positive inotropic effects may be used, including epinephrine, isoproterenol, dobutamine, levosimendan, PDE III inhibitors, and inhaled nitric oxide or prostaglandins.[60–66]

Epinephrine

Epinephrine is an endogenous catecholamine that stimulates both α- and β-adrenergic receptors in a dose-dependent fashion.[56,57] The β-selective pharmacology of epinephrine is characterized by a higher binding affinity for the β-receptor at lower doses and a stronger preference for the α-receptor at higher doses. This provides the clinical basis for the biphasic response observed for epinephrine, in which at lower doses the hemodynamic effects are predominated by increased inotropy and chronotropy of the heart (β-effect), and at higher doses a vasopressor effect (α-effect) is primarily observed.[56,57]

Epinephrine is often used to facilitate the separation from CPB (Box 36.4). In the earliest studies, epinephrine infusion at 0.03 μg/kg per minute following CPB resulted in an increase in cardiac index (CI), MAP, and HR by 30%, 27%, and 11%, respectively, compared with baseline.[67]

In another study, epinephrine infusion at dosages of 0.01, 0.02, and 0.04 μg /kg per minute was shown to increase SV by 2%, 12%, and 22%, respectively, corresponding to an increased CI of 0.1, 0.7, and 1.2 L/m^2 per minute.[68] In the lower dose range (0.01–0.04 μg/kg per min), the effect on the HR was less pronounced, with a maximum increase of 10 beats/minute in this study. Lobato and colleagues[69] similarly demonstrated, during CABG procedures, an increase in CO with a negligible increase in HR following CPB in response to an infusion of epinephrine at a dose of 0.03 μg/kg per minute. In a study comprising patients receiving preoperative β-blockers, epinephrine at a higher dose of 0.1 μg/kg per minute produced significant increases in CI and HR of 24.1% and 14.1%, respectively, compared with placebo.[70]

TABLE 36.7 Hemodynamic Effects of Inotropes

[a]The indicated dosages represent the most common dosage ranges. For the individual patient, a deviation from these recommended doses may be indicated.
[b]Phosphodiesterase inhibitors are usually given as a loading dose followed by a continuous infusion: amrinone: 0.5 to 1.5 mg/kg loading dose, 5 to 10 μg/kg per minute continuous infusion; milrinone: 50 μg/kg loading dose, 0.375 to 0.75 μg/kg per minute continuous infusion.
[c]Levosimendan is usually administered as a loading dose followed by an infusion for 24 hours: 8 to 24 μg/kg loading dose, 0.1 to 0.2 μg/kg per minute (Toller W, Heringlake M, Guarracino F, et al. Preoperative and perioperative use of levosimendan in cardiac surgery: European expert opinion. *Int J Cardiol.* 2015;184:323–336.)
CO, Cardiac output; *dP/dt,* myocardial contractility; *HR,* heart rate; *$M\dot{v}o_2$*, myocardial oxygen consumption; *PCWP,* pulmonary capillary wedge pressure; *PVR,* pulmonary vascular resistance; *SVR,* systemic vascular resistance; ↑, mild increase; ↑↑, moderate increase; ↑↑↑, major increase; ↔, no change; ↓, mild decrease; ↓↓, moderate decrease.
Modified from Lehmann A, Boldt J. New pharmacologic approaches for the perioperative treatment of ischemic cardiogenic shock. *J Cardiothorac Vasc Anesth.* 2005;19:97–108.

The results of these studies suggest that elevations in HR may be an effect observed at higher doses. Moreover, epinephrine is also used frequently after cardiac operations to support the function of the "stunned" reperfused heart following CPB. During emergence from CPB, Butterworth and associates[71] showed that epinephrine (0.03 μg/kg per min) increased CI and SV by 14% without increasing HR. In summary, epinephrine (0.01–0.04 μg/kg per min) at certain doses effectively increases CO with minimal increases in HR following CPB (see Table 36.7).[67–69,71] (see Chapters 11 and 38).

Dobutamine

Dobutamine is a synthetic catecholamine that displays a strong affinity for the β-receptor and results in dose-dependent increases in CO and HR, as well as reductions in diastolic filling pressures.[61] Administration of dobutamine in cardiac surgical patients produced a marked increase in CI and HR in several studies.[61,67,71,72] In patients with the LCOS, dobutamine resulted in an increase in HR in excess of 25% and a significant concomitant decrease in SVR.[61,72] The effects of epinephrine (0.03 μg/kg per min) were compared with those of dobutamine (5 μg/kg per min) in 52 patients recovering from CABG procedures.[71] Both drugs significantly and similarly increased SV index (SVI), but epinephrine increased the HR by only 2 beats/minute, whereas dobutamine increased the HR by 16 beats/minute. In an observational study of 100 cardiac surgical patients, HR increased by an average of 1.45 beats/minute per μg/kg per minute of dobutamine.[73] In the randomized multicenter trial comparing dobutamine and milrinone in patients with low CI (<2.0 L/m^2 per min), CI increased by 55% versus 36% after 1 hour in the dobutamine-treated group compared with the milrinone-treated group.[61] The hemodynamic effects of dobutamine were also characterized by a 35% increase in HR (vs 10% with milrinone) and a 31% increase in MAP (vs 7% with milrinone). Dobutamine was also associated with significantly higher incidences of hypertension and new atrial fibrillation (18% vs 5%; $P < .04$).[61]

In addition to increasing contractility, dobutamine may have favorable metabolic effects on ischemic myocardium. Intravenous and intracoronary injections of dobutamine increased coronary blood flow in animal studies.[74] In paced cardiac surgical patients, dopamine increased oxygen demand without increasing oxygen supply, whereas dobutamine increased myocardial oxygen uptake and coronary blood flow. However, because increases in HR are a major determinant of $M\dot{v}o_2$, these favorable effects of dobutamine could be lost if dobutamine induces tachycardia. During dobutamine stress echocardiography, segmental wall motion abnormalities suggestive of myocardial ischemia can result from tachycardia and increases in $M\dot{v}o_2$ (see Chapters 1 and 2).[75]

Dopamine

Dopamine is an endogenous catecholamine and an immediate precursor of norepinephrine and epinephrine. Its actions are mediated by stimulation of adrenergic receptors and specific postjunctional dopaminergic receptors (D_1 receptors) in the renal, mesenteric, and coronary arterial beds.[56,57,76] Dopamine is unique in comparison with other endogenous catecholamines because of its effects on the kidneys. It has been shown to increase renal artery blood flow by 20% to 40% by causing direct vasodilation of the afferent arteries and indirect vasoconstriction of the efferent arteries.[77] This action results in increases in glomerular filtration rate and in oxygen delivery to the juxtamedullary nephrons. In low doses (0.5–3.0 μg/kg per minute), dopamine predominantly stimulates the dopaminergic receptors; at doses ranging from 3 to 10 μg/kg per minute, it activates most adrenergic receptors in a nonselective fashion; and at higher doses (>10 μg/kg per min), dopamine behaves as a vasoconstrictor. The dose-dependent effects of dopamine are not very specific and can be influenced by multiple factors such as receptor regulation, concomitant drug use, and interindividual and intraindividual variability.[56,57,67]

In patients undergoing cardiac surgical procedures, dopamine in the dose range of 2.5 and 5.0 μg/kg per minute was observed to produce significant increases in CI and HR.[72,78] Doses greater than 5 μg/kg per minute may result in significant increases in MAP and pulmonary vascular resistance (PVR) without increasing CO.[78] In patients with the LCOS following cardiac operations, dopamine produced a 57.9% increase in CI compared with baseline and a simultaneous increase in HR by 25.5% in one study.[79] Tarr and colleagues[72] compared the efficacies of dopamine, dobutamine, and enoximone for weaning from CPB in a randomized trial of 75 patients. Nine of the 25 patients randomly assigned to dopamine displayed a poor and inadequate hemodynamic response. The remaining 16 patients recorded an increase in CI of 25.7% and elevations in HR of 44.3%, with minimal increase in SVI after receiving dopamine. The CI in the dopamine-treated group was significantly lower than in patients treated with dobutamine.[72] In the early study by Steen and associates,[67] dopamine caused more frequent and less predictable degrees of tachycardia than dobutamine or epinephrine at doses that produced comparable improvement in contractile function. These studies suggest that the hemodynamic

effects of dopamine at lower doses are predominately characterized by marked elevations in HR and moderate increases in CI. At higher doses, increases in MAP and PVR predominate without an increase in CO. The propensity of dopamine to increase HR and induce tachyarrhythmias may limit its utility in the cardiac surgical patient emerging from CPB.

Norepinephrine

Norepinephrine is an endogenous catecholamine exhibiting potent α-adrenergic activity with a mild-to-modest effect on the β-adrenergic receptor.[56,57] The higher affinity for norepinephrine for the α-adrenergic receptor provides the basis for its powerful vasoconstrictor effect and less potent inotropic and chronotropic properties. The overall hemodynamic effects of norepinephrine are characterized by an increase in systolic, diastolic, and pulse pressure, with minimal net impact on CO and HR. In this regard, norepinephrine is used primarily to manage low SVR secondary to vasodilation after CPB. In this setting, norepinephrine has been used to increase MAP in patients receiving inotropic support. Norepinephrine has been used in combination with milrinone, dobutamine, or levosimendan to counteract systemic vasodilation and hypotension in patients following CPB.[80,81] Norepinephrine has also been reported in the management of sepsis. Meadows and associates[82] treated 10 patients with severe sepsis and hypotension unresponsive to volume expansion, dopamine, and dobutamine. Norepinephrine infusion (0.03–0.89 μg/kg per min) alone improved arterial blood pressure, LV stroke work index, urine output, and, in most cases, CI. Desjars and colleagues[83] studied the renal effects of prolonged norepinephrine infusion in hypotensive patients with sepsis. Norepinephrine (0.5–1.0 μg/kg per min) in combination with low-dose dopamine improved urine flow and renal function compared with dopamine alone.[83] Norepinephrine may be effective in restoring MAP in patients with a low SVR after CPB (ie, vasoplegia syndrome).[84] When cardiac dysfunction is primarily a result of decreased CPP, vasoconstrictors may be used to optimize performance.

Isoproterenol

Isoproterenol is a potent, nonselective β-adrenergic agonist, devoid of α-adrenergic agonist activity. Isoproterenol dilates skeletal, renal, and mesenteric vascular beds and decreases diastolic blood pressure.[56] The potent chronotropic action of isoproterenol, combined with its propensity to decrease CPP, limits its usefulness in patients with CAD. Applications include treatment of bradycardia (especially after orthotopic heart transplantation), pulmonary hypertension, and HF after surgical treatment of congenital cardiac disease.[85] Isoproterenol remains the inotrope of choice for stimulation of cardiac pacemaker cells in the management of acute bradyarrhythmias or atrioventricular heart block. Its use for this purpose during cardiac surgery is limited because artificial pacing is usually easily accomplished in this setting. This drug reduces refractoriness to conduction and increases automaticity in myocardial tissues. The tachycardia seen with isoproterenol is a result of direct effects of the drug on the sinoatrial and atrioventricular nodes and reflex effects caused by peripheral vasodilation. Isoproterenol is routinely used in the setting of cardiac transplantation for increasing automaticity and inotropy, as well as for its vasodilatory effect on the pulmonary arteries.

Phosphodiesterase Inhibitors

The PDE III inhibitors milrinone and amrinone (inamrinone), are bipyridine derivatives that increase cyclic adenosine monophosphate (cAMP), Ca^{2+} flux, and Ca^{2+} sensitivity of contractile proteins.[56,57] PDE III inhibitors increase the level of cAMP by inhibiting its breakdown within the cell; this action leads to increased myocardial contractility. These drugs have a unique site of action in that they do not bind and activate the adrenergic receptor. Their positive effects on inotropy are mediated primarily through an inhibition of the PDE enzyme and not through β-receptor stimulation. As a result, the effectiveness of the PDE III inhibitors is not altered by previous β-blockade, nor is it reduced in patients who may experience β-receptor downregulation.[58] In addition to their positive inotropic effects, these agents produce systemic and pulmonary vasodilation and improve diastolic relaxation (lusitropy). For these reasons, the term *inodilator* has been used to describe this class of drugs (Box 36.5).

BOX 36.5 INODILATOR DRUGS AND OTHER AGENTS

- Inamrinone
- Milrinone
- Dobutamine
- Epinephrine plus nitroprusside ("epipride")
- Levosimendan
- Nesiritide

Milrinone has been shown to increase CO without increasing overall $M\dot{v}o_2$. Monrad and colleagues[86] administered milrinone to patients with CHF; CI increased by 45%, but overall $M\dot{v}o_2$ did not change.[86] Several studies also suggested that milrinone may improve myocardial diastolic relaxation and compliance (ie, positive "lusitropic" effect) while augmenting coronary perfusion.[30,69,87,88] The proposed mechanism for this effect on diastolic performance is that by decreasing LV wall tension, ventricular filling is enhanced, and myocardial blood flow and oxygen delivery are optimized (see Table 36.7). The ability of short-term administration of milrinone to augment ventricular performance in patients undergoing cardiac surgical procedures was shown in the results from the European Milrinone Multicentre Trial Group.[89] In this prospective study, intravenous milrinone was studied in patients after CPB. All patients received a bolus infusion of milrinone at 50 μg/kg over 10 minutes, followed by a maintenance infusion of 0.375, 0.5, or 0.75 μg/kg per minute for 12 hours. Significant increases in SV and CI were observed. In addition, significant decreases in pulmonary capillary wedge pressure, central venous pressure, pulmonary artery pressure, MAP, and SVR were seen. Eighteen patients (14%) had arrhythmias, most of which occurred in the group receiving 0.75 μg/kg per minute. Two arrhythmic events were deemed serious; both were bouts of rapid atrial fibrillation occurring with the larger dose.

In another study, Bailey and associates[90] also showed that after CPB, a loading dose of milrinone at 50 μg/kg, followed by a continuous infusion of 0.5 μg/kg per minute, resulted in a significant increase in CO. Moreover, in a dose-escalation study, Butterworth and colleagues[91] investigated the pharmacokinetics and pharmacodynamics of milrinone in adult patients undergoing cardiac operations; milrinone (bolus doses of 25, 50, or 75 μg/kg) was given if the CI was less than 3.0 L/m^2 per minute after separation from CPB. All three bolus doses of milrinone significantly increased CI. The 50 and 75 μg/kg doses produced significantly greater increases in CI than did the 25 μg/kg dose. The 75 μg/kg dose produced increases in CI comparable to those observed with the 50 μg/kg dose, but the higher dose was associated with more hypotension, despite administration of intravenous fluid, blood, and a phenylephrine infusion. The initial redistribution half-lives were 4.6, 4.3, and 6.9 minutes, and the terminal elimination half-lives were 63, 82, and 99 minutes for the 25, 50, and 75 μg/kg doses, respectively. The results of these investigations suggest that for optimizing hemodynamic performance (while minimizing potential for arrhythmias), the middle dose range (ie, loading dose of 50 μg/kg) of milrinone may be most efficacious, with a continuous infusion of 0.5 μg/kg per minute, leading to a plasma concentration of more than 100 ng/mL. In patients with poor LV function, the loading dose should be given during CPB to avoid a decrease in MAP and to minimize the need for other inotropes on discontinuing CPB.[91–93]

Amrinone represents the first-generation PDE III inhibitor used to wean from CPB. Compared with dobutamine, amrinone was found to be more effective for separation from CPB, with observed increases

in SV and CO and decreases in SVR and PVR.[94,95] Gage and colleagues[96] reported that when amrinone was used in combination with dobutamine, CO was significantly increased compared with therapy with dobutamine alone. Thrombocytopenia has been a potential clinical concern with the administration of PDE III inhibitors. Currently, amrinone has been implicated in causing dose-dependent thrombocytopenia, thus limiting its utility in cardiac surgical procedures.[97,98] By contrast, the potential negative effects of PDE III inhibitors on platelets were not demonstrated with milrinone. George and associates[99] were unable to demonstrate any significant reduction in platelet count after 48 hours of milrinone infusion in cardiac surgical patients. Similarly, Kikura and colleagues[100] found that milrinone administration did not cause significant changes in platelet number or function in patients undergoing cardiac operations with CPB compared with controls.

In summary, the PDE III class of inodilators has a unique mechanism of action independent of the β-receptor. These agents combine increases in contractility with reductions in SVR and PVR. In addition, the properties that govern relaxation and compliance of the heart are enhanced with PDE III inhibitors and allow these drugs to improve diastolic filling. These unique properties render PDE III inhibitors particularly useful in patients with β-receptor downregulation, right-sided heart dysfunction, pulmonary hypertension, diastolic dysfunction, and the LCOS.[57]

Calcium Sensitizers

Levosimendan is a positive inotropic drug belonging to the unique class of Ca^{2+} sensitizers.[56,57] Levosimendan binds three distinct sites of action, and this property characterizes its unique tripartite mechanism of action and pharmacologic effects.[101] In the myocardium, levosimendan selectively binds troponin C through a Ca^{2+}-dependent binding site stabilizing the cross-bridging mechanism and resulting in positive inotropy. Levosimendan also specifically binds to the ATP-dependent K^+ channel (K^+/ATP) in cardiac mitochondria, governing its protective effects against ischemia and reperfusion injury. By regulating Ca^{2+} influx in the mitochondria, opening of the K^+/ATP channel attenuates infarct size as a result of ischemia-reperfusion injury.[102] The third site of action is at the level of the smooth muscle in the vasculature. At this site, levosimendan binds and opens K^+/ATP channels and thus leads to decreases in SVR and cardiac preload and afterload. The vasodilatory effect on the vasculature has been shown to increase coronary and renal blood flow. Levosimendan is unique in that it confers positive inotropy without an increase in cardiac bioenergetics.[103] The salutary effects on the myocardium are achieved through an observed decrease in overall cardiac workload, cardioprotective effects, lusitropy, and a net increase in myocardial oxygen supply.[101,103,104]

The pharmacokinetics and pharmacodynamics of levosimendan are unique in that an active metabolite is formed with potency and efficacy similar to those of the parent compound.[105,106] Following a loading dose, steady-state levels are reached at approximately 4 hours after drug infusion. However, an active metabolite known as OR-1986 peaks at 48 hours and remains active for more than 300 hours (12–14 days after the end of infusion). The active metabolite, OR-1986, is primarily responsible for the sustained increase in SVI, decrease in cardiac workload, and improved coronary and renal blood flow in patients with the LCOS following cardiac surgical procedures. The formation of an intermediate- or long-acting metabolite may allow for earlier pharmacologic weaning without fear of losing the beneficial inotropic and hemodynamic effects as a result of drug discontinuation. Moreover, because the mechanism of action is independent of the β-receptor, concomitant administration of β-blocker therapy and levosimendan is not antagonistic.[107] This property allows for earlier reinstitution of β-blocker therapy for prevention or management of postoperative tachyarrhythmias.[108]

The effective perioperative use of levosimendan has been described in cardiac surgical patients with low LVEF.[109–112] In summary, levosimendan improved myocardial performance with an observed increase in SVI and coronary blood flow, as well as a decrease in SVR while minimizing oxygen consumption.[112] Levin and associates[113] demonstrated the superiority of levosimendan versus dobutamine in a randomized trial comprising 137 patients with the LCOS after CABG procedures. The postoperative 30-day mortality rate was lower in the levosimendan group compared with dobutamine (8.7% vs 25%; $P < .05$), as was the need for vasopressors, second or third inotropes, and IABP use.

In another study comparing the combined effects of levosimendan and dobutamine versus milrinone and dobutamine, patients receiving levosimendan and dobutamine demonstrated a sustained increase in SVI several hours after discontinuation of dual drug therapy compared with a dobutamine-milrinone combination.[114] Patients in the dobutamine-levosimendan arm of the trial also required less vasopressor support compared with the dobutamine-milrinone group. In a meta-analysis of clinical trials, Harrison and colleagues[115] evaluated the effects of levosimendan in cardiac surgical patients with and without preoperative systolic dysfunction. These investigators showed that death and other adverse outcomes, such as postoperative renal failure requiring dialysis, postoperative atrial fibrillation, and myocardial injury, were reduced with levosimendan treatment. These benefits were greatest for the patients with diminished LVEF. In the randomized, double-blind study by Eriksson and colleagues, levosimendan facilitated weaning from CPB and reduced the need for additional inotropic or mechanical circulatory support in patients with impaired LVEF (≤50%) who were undergoing CABG.[116] Sixty patients received either levosimendan as a 12 μg/kg bolus followed by 0.2 μg/kg per minute infusion, or placebo, immediately after the induction of anesthesia. Levosimendan significantly facilitated primary weaning from CPB as compared with placebo ($P = .002$). In four patients in the placebo group, the second weaning attempt failed, and these patients had to be supported by IABP, as compared with none in the levosimendan group (P = NS).

Currently, levosimendan is recommended by the European Society of Cardiology for treatment of acute worsening of HF and for acute HF after myocardial infarction.[112,117] It also has been found to enhance contractile function of stunned myocardium in patients with acute coronary syndromes.[118] It is available clinically in Europe and is now undergoing phase III trials in the United States.[112] The use of levosimendan has been reported in cardiac surgical patients with high perioperative risk, compromised LV function, difficulties in weaning from CPB, and severe RV failure after mitral valve replacement.[112,119–124] The drug has been used preoperatively, during emergence from CPB, and in the postoperative period for up to 28 days. The potential for levosimendan to produce increased contractility, decreased resistance, minimal metabolic cost, and minimal arrhythmias makes it a potentially useful addition to the treatments for patients with the LCOS or RV failure.

Vasodilators

The indications for using vasodilators such as NTG, sodium nitroprusside (SNP), nicardipine, and clevidipine in cardiac surgery include management of perioperative systemic or pulmonary hypertension, myocardial ischemia, and ventricular dysfunction complicated by excessive pressure or volume overload (Box 36.6).[125–128] In most conditions, NTG, SNP, or clevidipine may be used because of their shared features such as rapid onset, ultrashort half-lives, and easy titratability. Nevertheless, important pharmacologic differences exist among these vasodilators. In the setting of CAD or ischemia, NTG is preferred because it selectively vasodilates coronary arteries without producing coronary "steal." Similarly, in the management of ventricular volume overload or RV pressure overload, NTG may offer some advantage over SNP. NTG has a predominant influence on the venous bed such that preload can be reduced without significantly compromising systemic arterial pressure. The benefits of NTG are improvement in SV, reduction in wall tension and $M\dot{V}o_2$, increased perfusion to the subendocardium as a result of a lower LVEDP, and maintenance of CPP. SNP is a more potent arterial vasodilator and may potentiate myocardial

BOX 36.6 VASODILATOR MECHANISMS HELPFUL IN DISCONTINUING CARDIOPULMONARY BYPASS

- Decreased right and left ventricular wall stress (afterload)
- Decreased venous return (preload)
- Improved lusitropy
- Improved coronary blood flow

ischemia because of a coronary steal phenomenon or a reduction in CPP. Its greater potency, however, makes SNP a more rational choice for management of perioperative hypertensive disorders and for afterload reduction during or after operations for regurgitant valvular lesions.[125]

Although NTG and SNP have been used for the management of hypertension during cardiac surgical procedures, they both have notable limitations. NTG use as a primary antihypertensive agent is limited by its weak effect on arterial vasodilation. SNP is a potent arterial dilator, but its use is associated with reflex tachycardia, tachyphylaxis, inhibition of hypoxic pulmonary vasoconstriction, increase in intracranial pressure, and reduced renal blood flow.[128] The potential for cyanide toxicity is also an important consideration when administering SNP. This drug also may be difficult to titrate and often causes hypotension related to overshoot. In light of these limitations, the Ca^{2+} channel blocker class of antihypertensive agents such as clevidipine and nicardipine may prove to be valuable alternatives.

Clevidipine is an ultrafast-acting, dihydropyridine L-type Ca^{2+} channel blocker with a direct action on arteriolar resistance vessels and limited effects on venous capacitance vessels.[128–130] The fast onset and offset of approximately 1 minute make clevidipine especially suited for intraoperative management of acute hypertension.[131] Nicardipine is also a dihydropyridine Ca^{2+} channel blocker with a selective arterial vasodilator mode of action.[125,132,133] Nicardipine has a beneficial hemodynamic profile in that the drug reduces systemic and coronary artery resistance while increasing coronary blood flow. However, its use may be limited to the postoperative setting because of its longer half-life and slower offset of action compared with clevidipine.[134,135] In the ECLIPSE (Evaluation of Clevidipine in the Perioperative Treatment of Hypertension Assessing Safety Events) trial, clevidipine was compared with NTG, SNP, and nicardipine in the perioperative treatment of hypertension during cardiac surgical procedures.[128] In an analysis of the individual treatment cohorts, clevidipine was significantly more effective at achieving blood pressure targets within the prespecified range compared with NTG or SNP in the perioperative period. In the postoperative period, the efficacy of clevidipine was similar to that of nicardipine in achieving blood pressure control after cardiac operations. With respect to safety profile, no differences in the incidences of myocardial infarction, stroke, or renal dysfunction were observed among the treatment groups. Mortality rates were similar between the clevidipine-treated versus NTG-treated groups and the clevidipine versus nicardipine-treated groups, whereas mortality rates appeared to be higher in the SNP-treated group compared with the clevidipine-treated group ($P = .04$ in a univariate analysis). The incidence of atrial fibrillation and sinus tachycardia were similar between clevidipine and all comparators.[128]

Despite the benefits of vasodilator therapy in the management of CHF, these drugs can be difficult to use in treatment of perioperative ventricular dysfunction. This is most evident in cases of the LCOS when impaired pump function is complicated by inadequate perfusion pressure. In these situations, multidrug therapy with vasoactive and cardioactive agents is warranted (ie, NTG or SNP in combination with epinephrine or milrinone and norepinephrine). Combination therapy enables greater selectivity of effect. The unwanted side effects of one drug can be avoided while supplementing the desired effects with another agent.[136,137] To maximize the desired effects of any particular combination of agents, frequent assessment of cardiac performance with a pulmonary artery catheter and TEE is needed. This approach allows the Starling curve and the pressure-volume loops to be visualized as they are shifted up and to the left with therapy (see Chapters 6, 13, and 38).

Vasoplegic Syndrome and Cardiopulmonary Bypass

The concept of the vasoplegic syndrome, characterized by hypotension associated with profound vasodilation unresponsive to conventional catecholamines or vasopressors, was introduced in association with CPB in the late 1990s.[138] It has been linked with preoperative use of vasodilators and shown to be a risk factor for increased morbidity and death after cardiac surgical procedures.[139] Two pharmacologic agents have been reported to be used to treat vasoplegic syndrome after CPB: vasopressin and methylene blue (MB).

Vasopressin

Arginine vasopressin (antidiuretic hormone) is a peptide hormone normally produced in the posterior pituitary that plays a crucial role in water homeostasis by controlling water resorption in the renal collecting ducts.[140] Administered as an intravenous infusion, vasopressin was initially used as a potent vasoconstrictor for vasodilatory shock associated with sepsis[141] and ventricular assist device implantation.[142] Because its vasopressor effect is mediated through a different mechanism (VP1 receptors) from that of the catecholamines, vasopressin can be infused at a constant rate as a strategy to decrease high doses of catecholamines such as norepinephrine and has been used in this way to treat vasodilation occurring after CPB.[143] The vasoconstricting effects of vasopressin may spare the pulmonary vasculature, thus making it an attractive choice to treat hypotension associated with RV dysfunction, but this effect has not been clearly demonstrated in intact humans.[144,145] Reported infusion doses vary widely from 0.01 to 0.6 IU/minute.[146] Use of vasopressin has been associated with necrotic lesions of the skin, and this agent should be used with caution and in the lowest possible effective dose.[147]

Methylene Blue

MB, a substance commonly used intravenously during surgical procedures for its ability to dye certain tissues, inhibits guanylate cyclase and hence the production of cyclic guanosine monophosphate, which is known to increase vascular smooth muscle relaxation.[148] MB has been used as a rescue treatment for profound vasodilatory shock in several settings, including cardiac surgery.[149–151] At a dose of 3 mg/kg given during CPB, MB was shown to increase SVR and MAP without adverse effects in a randomized trial of patients taking angiotensin-converting enzyme inhibitors, as well as decrease pressor requirements and serum lactate levels after CPB.[152] In another randomized trial, MB, 2 mg/kg, was given 1 hour preoperatively to patients at risk for CPB-associated vasoplegic syndrome. None of the treatment group developed vasoplegic syndrome, whereas 26% of the control group did.[153] MB causes transient discoloration of the urine and the skin and interferes with pulse oximetry measurements of arterial oxygen saturation. In a retrospective analysis of 57 patients with vasoplegia during cardiac surgical procedures and CPB, use of MB as treatment for vasoplegia was independently associated with poor outcomes.[154] The use of MB has also been implicated in causing serotonin syndrome through its inhibition of monoamine oxidase-A enzyme.[155] In another case report, MB was causally linked to the development of methemoglobinemia during CPB.[156] These reports highlight the need for more studies on the safety and possible poor outcomes associated with MB. Although more studies are warranted, it may be prudent to reserve MB for rescue therapy, as opposed to using it as a preventive agent.[154]

Additional Pharmacologic Therapy

Following the steps outlined in Tables 36.2 and 36.5, most patients can be weaned from CPB. However, a small percentage will be difficult to remove safely from CPB because of their chronic end-stage CHF or an acute insult during cardiac operation that produced cardiogenic shock. These patients probably will require mechanical circulatory support

(eg, IABP, ventricular assist device), as discussed later and in Chapter 28. However, while instituting these further steps, some clinicians may try additional pharmacologic therapy.

Controversial Older Treatments

Some studies suggest that a reduction in plasma thyroid hormone concentration may cause decreased myocardial function after CPB.[157,158] Multiple investigators have documented declines in the circulating triiodothyronine (T_3) concentration during and after CPB, and the most dramatic decreases in T_3 are seen at the end of CPB and during the first few hours after CPB.[157] Thyroid hormone in the form of an intravenous T_3 infusion (2 µg/h to a total dose of 0.5 µg/kg) has been used during cardiac surgical procedures and has resulted in increases in the MAP and HR, as well as reductions in LAP and central venous pressure, in patients who initially could not be weaned from CPB. Moreover, the administration of glucose-insulin-K^+ (GIK) or just glucose and insulin has been found to be useful for metabolic support of the heart after CPB. Insulin therapy may improve glucose use and energy metabolism during cardiac operations, thereby improving myocardial function.[159–163]

Emerging Intravenous Drugs for Heart Failure and Cardiogenic Shock

Natriuretic Peptide

The activation of several neuroendocrine pathways as a result of CPB may contribute to the pathophysiology of postbypass ventricular dysfunction, especially in patients with preoperative LCOS. Release of plasma epinephrine, norepinephrine, and arginine vasopressin has been observed in patients undergoing cardiac surgical procedures with CPB.[164] The overall effects of neuroendocrine activation are the promotion of Na^+ and volume retention and a concomitant increase in SVR, which may contribute to cardiac and renal dysfunction and increased mortality rates.[165,166] The identification of the humoral mediators of neuroendocrine activation has facilitated the development of therapeutic targets aimed at blocking specific neuroendocrine pathways.

The cardiac natriuretic peptides and brain natriuretic peptide (BNP) and their precursors may represent important targets for the modulation or attenuation of the neuroendocrine activation cascade observed in patients with postbypass cardiac dysfunction.[167,168] The recombinant human BNP, nesiritide, possesses both vasodilatory and diuretic effects. This 30–amino acid peptide may also play a role in inhibiting the activation of the renin-angiotensin axis and the release of plasma catecholamines.[169] In patients with HF, intravenous nesiritide acts as a vasodilator and reduces preload and SVR, and CI subsequently increases.[170–172] The drug has no positive inotropic effects. Compared with NTG and dobutamine, nesiritide had a greater effect on decreasing preload than NTG, and it did not cause as many arrhythmias as dobutamine.[173,174] In the Nesiritide Administered Peri-Anesthesia in Patients Undergoing Cardiac Surgery (NAPA) trial, patients with LVEF of less than 40% randomized to receive nesiritide during CABG benefited with improved postoperative renal function and enhanced intermediate survival after 180 days.[175] Chen and colleagues[176] studied the renal effects of low-dose nesiritide in patients with preexisting renal dysfunction undergoing cardiac surgical procedures. These investigators demonstrated that 24 hours of a low-dose infusion of nesiritide at 0.005 µg/kg per minute resulted in the preservation of renal function in the nesiritide-treated group at 48 and 72 hours in patients with preexisting renal insufficiency. The results of these two trials suggest that nesiritide may play a future role in preserving renal function in patients undergoing cardiac operations.

Human atrial natriuretic peptide (ANP) is a 28–amino acid peptide produced primarily by the atria in response to an increased intravascular volume.[177] A low-dose infusion of carperitide (Table 36.8), a recombinant form of ANP, in patients with poor LV function during CABG proved effective in improving renal function marked by lower serum creatinine levels and increased glomerular filtration rate in the treatment group.[178,179] In another randomized controlled study of 303 patients with chronic kidney disease who were undergoing CABG, carperitide infusion conferred a cardioprotective effect, as suggested by reduced rates of cardiac events and cardiac-related deaths in the treatment group compared with placebo.[180] Neurohormonal levels of angiotensin II and aldosterone were also reduced 1 week postoperatively in the treatment group. Sezai and associates[179] later investigated the efficacy of carperitide in patients undergoing CABG in a randomized controlled trial of 367 high-risk patients (European System for Cardiac Operative Risk Evaluation [EuroSCORE] >6). This investigation demonstrated that the rates of major adverse cardiac and cerebrovascular events were significantly lower in the carperitide-treated group compared with placebo ($P < .0001$). The rate of dialysis was also significantly lower in the carperitide-treated group ($P = .0147$) compared with the control group. These investigators concluded that in the early postoperative period, carperitide infusion may confer protection against postoperative major adverse cardiac and cerebrovascular events and hemodialysis in high-risk patients undergoing CABG.

In summary, the administration of low-dose carperitide during CABG improved renal and cardiac outcomes, possibly through a combination of vasodilatory and natriuretic effects and modulation of the neurohormonal response during cardiac surgical procedures with CPB. This drug may provide another option in the management of cardiac and renal dysfunction in patients undergoing cardiac operations with CPB.

TABLE 36.8 Emerging Intravenous Drugs for Heart Failure and Cardiogenic Shock

*Drug**	*Molecular Target and Mechanism of Action*	*Phase of Development*
Istaroxime	Inhibition of Na^+/K^+-ATPase and increased SERCA2a ATPase activity	Phase II
Carperitide	Recombinant atrial natriuretic peptide	Phase II
Levosimendan[a]	Calcium sensitizer-troponin C/K^+-ATP channel	Phase II
Nesiritide	Brain natriuretic peptide	Approved
Omecantiv mecarbil	Cardiac myosin ATPase activator	Phase II

[a]Levosimendan is currently approved in Europe and is undergoing phase III trials in the United States.

ATP, Adenosine triphosphate; *ATPase,* adenosine triphosphatase; *K^+,* potassium; *Na^+,* sodium; *SERCA2a,* sarcoplasmic reticulum calcium adenosine triphosphatase isoform 2a pump.

Modified from George M, Rajaram M, Shanmugam E, et al. Novel drug targets in clinical development for heart failure. *Eur J Clin Pharmacol.* 2014;70:765–774.

Istaroxime

Istaroxime is a first in class intravenous steroid derivative that activates the sarcoplasmic reticulum Ca^{2+} ATPase isoform 2a pump (SERCA2a; see Table 36.8). It also possesses a key inhibitory effect on the membrane Na^+/K^+-ATPase.[169,181] Regulating intracellular Ca^{2+} fluxes is a key mechanism in controlling the relaxation and contractile forces of the myocardium. Diminished activity of SERCA2a contributes to poor contractility and relaxation. Istaroxime has shown great promise in the treatment of HF in clinical trials.[182–184] It exerts its action during both the relaxation and contraction phases of the cardiac cycle.[169,183] This action is accomplished by inhibition of the membrane Na^+/K^+ ATPase, thus leading to an overall increase in cytosolic Ca^{2+} available for contraction.[185,186] During diastole, istaroxime enhances Ca^{2+} sequestration into the sarcoplasmic reticulum by increasing SERCA2a pump activity, which ultimately leads to more effective myocardial relaxation. In the phase II randomized, placebo-controlled, double-blind Hemodynamic Effects of Istaroxime in Patients with Worsening Heart Failure and Reduced LV Systolic Function (HORIZON-HF) trial, istaroxime reduced LVEDP and pulmonary capillary wedge pressures while increasing CI and systolic blood pressures in patients with a history of HF and an LVEF of up to 35%.[184] Escalating doses of 0.5, 1, and 1.5 µg/kg per minute were used to study the efficacy of istaroxime in 3 separate cohorts comprising 40 patients in each respective arm.

The investigators noted an increase in systolic blood pressure without a significant change in diastolic blood pressure. A transient increase in CI with the highest dose and a decrease in HR and diastolic and systolic volumes were observed without a change in ejection fraction. Improvement in diastolic filling parameters was also observed on echocardiography in the istaroxime-treated group.[183,184] Istaroxime has not been investigated in patients undergoing cardiac surgical procedures. Nevertheless, the unique properties of this agent make for a promising candidate for the treatment of the LCOS with separation from CPB.

Omecamtiv Mecarbil

Omecamtiv mecarbil is a first in class intravenous myosin activator (see Table 36.8).[169,187] The tight binding of myosin to actin leads to the contraction mechanism. Increasing the tight binding of myosin to actin proportionally enhances the force and the time of contraction. Omecamtiv mecarbil increases the rate of myosin binding onto actin and leads to both improved contractility and increased systolic ejection time.[169,188] This inotrope is unique in that it improves contractile forces at the level of the sarcomere, downstream from the activation of Ca^{2+}-dependent pathways that may be energetically deleterious.[187] In the phase II double-blind, placebo-controlled Acute Treatment with Omecamtiv Mecarbil to Increase Contractility in Acute Heart Failure (ATOMIC-AHF) study, patients receiving omecamtiv mecarbil exhibited a dose-dependent increase in blood pressure and systolic ejection time and a concomitant decrease in HR.[189] Although the primary end point of improvement in dyspnea was not observed, omecamtiv mecarbil may potentially prove to be a valuable drug because of its lack of chronotropic effects. This new drug is currently in phase II clinical trials and awaits further studies to examine its potential role in cardiac surgery.

Pharmacogenetics and Genotyping: the Rational Basis for Individualized Therapy

Variability in gene expression may play a pivotal role in how an individual patient responds to drug therapy.[190,191] Polymorphisms have been implicated in the differential effects of β-blockers, antiplatelet agents, anticoagulant agents, and antiarrhythmic agents in certain patients.[192–194] Similarly, individual differences in the degree of adrenergic receptor downregulation may mediate variable sensitivity to β-agonists.[192,195] Moreover, genotypic polymorphisms of the mediators of the β-adrenergic signaling pathway may be linked to poor outcome resulting from an increased incidence of major adverse cardiac events after cardiac surgical procedures.[192,196] For instance, specific haplotypes of the downstream effector protein, $G_{\alpha s}$, which is coupled to the adrenergic receptor, may be associated with altered cardiac contractility and hemodynamics.[59,197,198] In addition, inflammatory gene polymorphisms have been associated with increased risk of postoperative myocardial infarction.[199] These examples highlight the importance of molecular genotyping in the clinical management and risk stratification of cardiac surgical patients. The study of pharmacogenetics may lay the foundation for personalizing clinical management based on individual genotyping.[196,200] In the future, it may be conceivable to obtain a molecular "fingerprint" of a patient before a cardiac operation and modify prebypass and postbypass management based on the genotype data (see Chapter 8).

Intraaortic Balloon Pump Counterpulsation

The IABP is a device that is designed to augment myocardial perfusion by increasing coronary blood flow during diastole and unloading the left ventricle during systole (see Chapter 28). This is accomplished by mass displacement of a volume of blood (usually 30–50 mL) by alternately inflating and deflating a balloon positioned in the proximal segment of the descending aorta. The gas used for this purpose is carbon dioxide (because of its great solubility in blood) or helium (because of its inertial properties and rapid diffusion coefficients). Inflation and deflation are synchronized to the cardiac cycle by the electronics of the balloon console by producing counterpulsations. The results of effective use of the IABP are often quite dramatic. Improvements in CO, LVEF, coronary blood flow, and MAP frequently are seen, as well as decreases in aortic and ventricular systolic pressures, LVEDP, pulmonary capillary wedge pressure, LAP, HR, frequency of premature ventricular contractions, and suppression of atrial arrhythmias.

TABLE 36.9 Intraaortic Balloon Pump Counterpulsation Indications and Contraindications

Indications	*Contraindications*
1. Cardiogenic shock a. Myocardial infarction b. Myocarditis c. Cardiomyopathy 2. Failure to separate from CPB 3. Stabilization of preoperative patient a. Ventricular septal defect b. Mitral regurgitation 4. Stabilization of noncardiac surgical patient 5. Procedural support during coronary angiography 6. Bridge to transplantation	1. Aortic valvular insufficiency 2. Aortic disease a. Aortic dissection b. Aortic aneurysm 3. Severe peripheral vascular disease 4. Severe noncardiac systemic disease 5. Massive trauma 6. Patients with "do not resuscitate" instructions 7. Mitral SAM with dynamic outflow tract obstruction

CPB, Cardiopulmonary bypass; *SAM,* systolic anterior motion.

Indications and Contraindications

Since the introduction of the IABP, the indications for its use have grown (Table 36.9). The most common use of the IABP is for treatment of cardiogenic shock. This may occur after CPB or after cardiac operations in patients with preoperative shock, patients with acute postinfarction ventricular septal defects or mitral regurgitation, those who require preoperative stabilization, or patients who decompensate hemodynamically during cardiac catheterization. Patients with myocardial ischemia refractory to coronary vasodilation and afterload reduction are stabilized with an IABP before cardiac catheterization, and some patients with severe CAD prophylactically have an IABP inserted before undergoing CABG or off-pump CABG procedures.[201–205]

Contraindications to IABP use are relatively few (see Table 36.9). The presence of severe aortic regurgitation or aortic dissection is an absolute contraindication for the IABP, although successful reports of its use in patients with aortic insufficiency or acute trauma to the descending thoracic aorta have appeared. Other relative contraindications are listed; use of the IABP in these instances is at the discretion of the physician. Because the hemodynamic changes caused by an IABP theoretically would tend to worsen dynamic outflow tract obstruction caused by systolic anterior motion of the mitral valve, the device should be used with caution, if at all, in these patients.

Insertion Techniques

In the initial development of the IABP, insertion was by surgical access to the femoral vessels. In the late 1970s, refinements in IABP design allowed the development of percutaneous insertion techniques. Now the technique most commonly used, percutaneous IABP insertion, is performed rapidly with commercially available kits.

The femoral artery with the greater pulse is sought by careful palpation. The length of the balloon to be inserted is estimated by laying the balloon tip on the patient's chest at the Louis angle and appropriately marking the distal point corresponding to the femoral artery. Care must be taken when removing the balloon from its package to follow the manufacturer's procedures exactly, to avoid perforating the balloon before insertion. Available balloons come wrapped and need only be appropriately deflated before removal from the package. The femoral artery is entered with the supplied needle, a J-tipped guidewire is inserted to the level of the aortic arch, and the needle is removed.

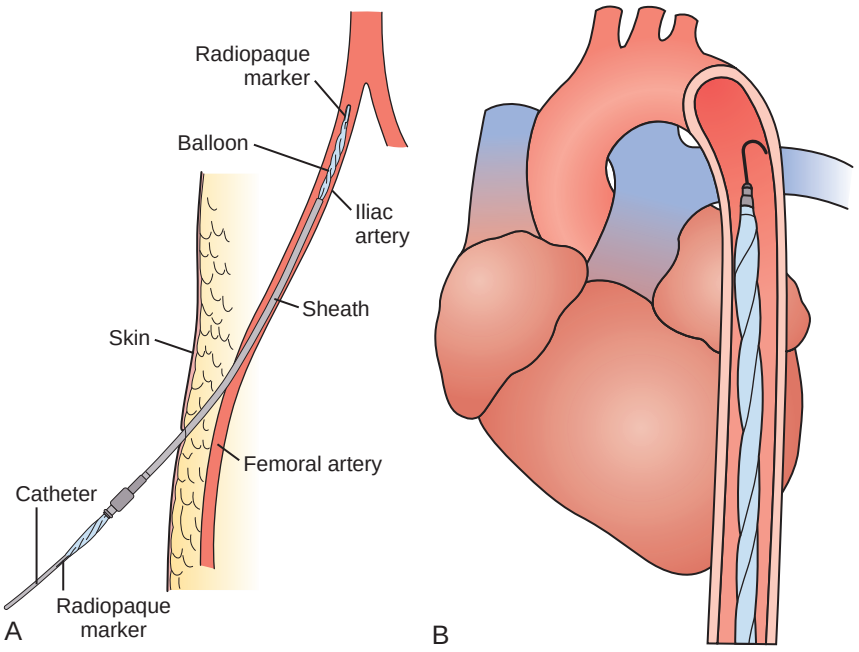

Fig. 36.3 Intraaortic balloon pump insertion. (A) Cannulation and insertion of the balloon through the femoral artery. Notice the tightly wrapped balloon as it traverses the sheath. A guidewire is not visible in this drawing. (B) Correct positioning of balloon in proximal descending aorta. The J-tipped guidewire is seen exiting from the balloon's central lumen. *(A, Courtesy Datascope Corporation, Fairfield, NJ; B, Courtesy Kontron, Inc., Augsburg, Germany.)*

The arterial puncture site is enlarged with the successive placement of an 8-Fr dilator and then a 10.5- or 12-Fr dilator and sheath combination (Fig. 36.3). In the adult-sized (30- to 50-mL) balloons, only the dilator needs to be removed, leaving the sheath and guidewire in the artery. The balloon is threaded over the guidewire into the central aorta and into the previously estimated correct position in the proximal segment of the descending aorta. The sheath is gently pulled back to connect with the leakproof cuff on the balloon hub, ideally so that the entire sheath is out of the arterial lumen to minimize risk for ischemic complications to the distal extremity. Alternatively, the sheath may be stripped off the balloon shaft much like a peel-away pacemaker lead introducer, thereby entirely removing the sheath from the insertion site. At least one manufacturer offers a "sheathless" balloon for insertion.

If fluoroscopy is available during the procedure, correct placement is verified before fixing the balloon securely to the skin. Position also may be checked by radiography or TEE after insertion. If an indwelling left radial arterial catheter is functioning at the time of insertion, a reasonable estimate of position may be made by watching balloon-mediated alteration of the arterial pulse waveform (Fig. 36.4). After appropriate positioning and timing of the balloon, 1:1 counterpulsation may be initiated. The entire external balloon assembly should be covered in sterile dressings.

Removal of a percutaneously inserted IABP may be by the open (surgical removal) or closed technique. If a closed technique is chosen, the artery should be allowed to bleed for several seconds while pressure is maintained on the distal artery after balloon removal to flush any accumulated clot from the central lumen. This maneuver helps prevent distal embolization of clot. Pressure is then applied for 20 to 30 minutes on the puncture site for hemostasis. If surgical removal is chosen, embolectomy catheters may be passed in antegrade and retrograde fashion before suture closure of the artery.

Alternate routes of IABP insertion exist. The balloon may be placed surgically through the femoral artery. This is now performed without the use of an end-to-side vascular conduit, although this placement still requires a second surgical procedure for removal. In patients with extreme peripheral vascular disease or in pediatric patients whose peripheral vasculature is too small, the ascending aorta or aortic arch may be entered for balloon insertion. These approaches necessitate median sternotomy for insertion and usually require reexploration for removal. Other routes of access include the abdominal aorta and the subclavian, axillary, and iliac arteries. The iliac approach may be especially useful for pediatric cases.

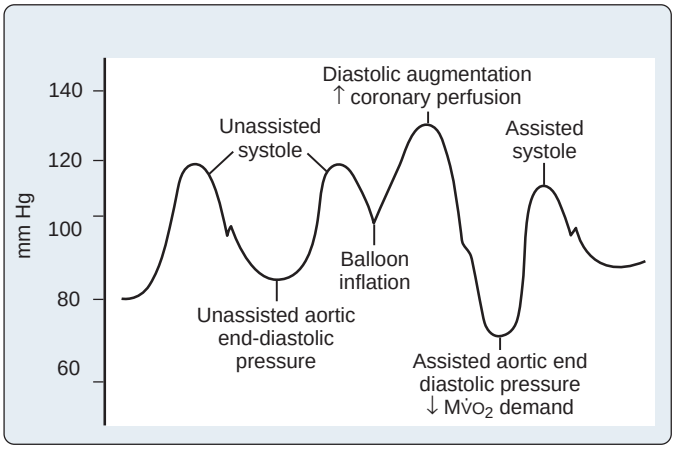

Fig. 36.4 Arterial waveforms seen during intraaortic balloon pump assist. The first two waveforms are unassisted, and the last is assisted. Notice the decreased end-systolic and end-diastolic pressures and augmented diastolic pressures caused by balloon pump augmentation and the (correct) point at which balloon inflation occurs. These are waveforms generated by a correctly positioned and timed balloon. $M\dot{V}O_2$, Myocardial oxygen consumption. *(Courtesy Datascope Corporation, Fairfield, NJ.)*

Timing and Weaning

IABP systems are commercially available from several different manufacturers. The basic console design includes electrocardiographic and

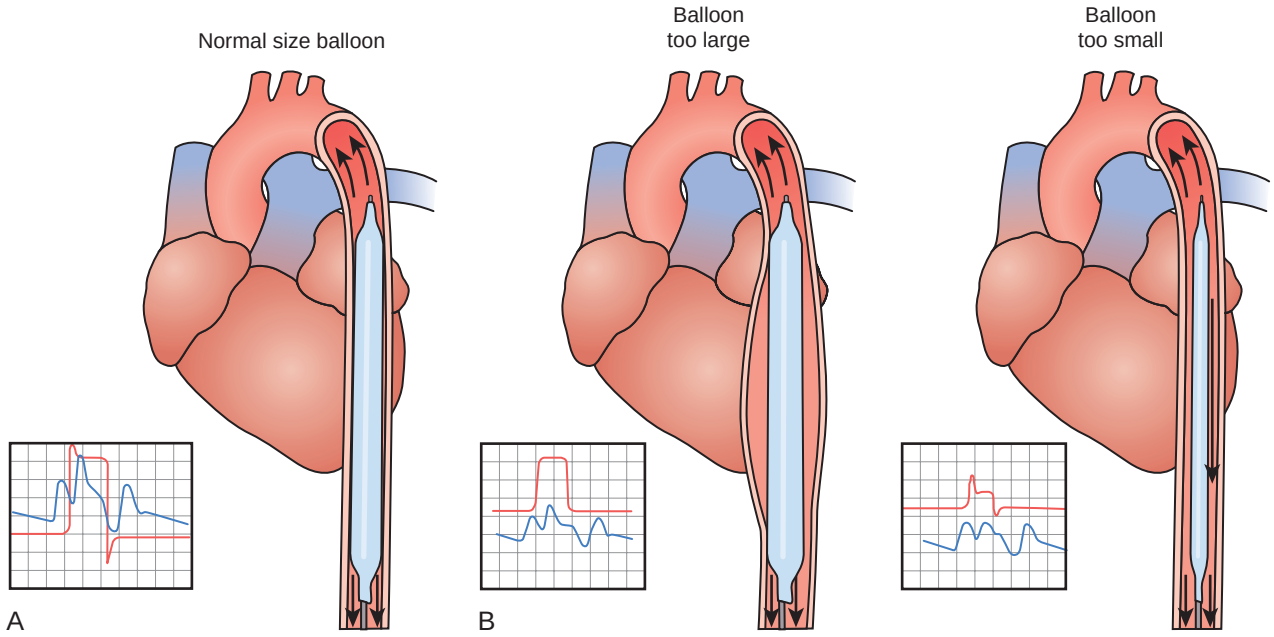

Fig. 36.5 Variations in waveform caused by incorrect balloon size. (A) The balloon is correctly positioned and appropriately sized for the aorta. Notice the arterial waveform diagram in the *lower left corner.* (B) Examples of too large *(left)* or too small *(right)* balloon sizes with their correspondingly altered arterial waveforms. A similar effect can result from overinflation and underinflation of the balloon. Compare the waveforms in B with the ideal waveform in A.

arterial blood pressure waveform monitoring and printing, balloon volume monitoring, triggering selection switches, adjustments for inflation and deflation timing, battery backup power sources, and gas reservoir. Some of these systems have become quite sophisticated, with advanced computer microprocessor circuits allowing triggering based on pacemaker signals or detection of and compensation for aberrant rhythms such as atrial fibrillation. Portable models exist for transportation of patients by ground, helicopter, or air ambulances.

For optimal effect of the IABP, inflation and deflation must be correctly timed to the cardiac cycle. Although certain variables, including positioning of the balloon within the aorta, balloon volume (Fig. 36.5), and the patient's cardiac rhythm, can affect the performance of the IABP, basic principles regarding the function of the balloon must be followed. Balloon inflation should be timed to coincide with aortic valve closure, or aortic insufficiency and LV strain will result. Similarly, late inflation results in a diminished perfusion pressure to the coronary arteries. Early deflation causes inappropriate loss of afterload reduction, and late deflation increases LV work by causing increased afterload, if only transiently. These errors and correct timing diagrams are shown in Figs. 36.4 and 36.6.

As the patient's cardiac performance improves, the IABP support must be removed in stages rather than abruptly. Judicious application and dosing of vasodilator and inotropic medications can assist this procedure. The balloon augmentation may be reduced in steps from 1:1 counterpulsation to 1:2 and then to 1:4, with appropriate intervals at each stage to assess hemodynamic and neurologic stability, CO, and $S\bar{v}O_2$ changes. After appropriate observation at 1:4 or 1:8 counterpulsation, balloon assistance can be safely discontinued, and the device can be removed by one of the methods discussed. If percutaneous removal is chosen, an appropriate interval for reversal of anticoagulation (if used) before removal of the balloon should be allowed.

Complications

Several complications have been associated with IABP use (Table 36.10). The most frequently seen complications are vascular injuries, balloon malfunction, and infection.[201–205] Treatment of these respective problems is straightforward. Flaps, dissections, perforations, embolic events, and pseudoaneurysms should be managed directly by surgical intervention and repair. Steal syndromes or ischemia, if not severe, may be managed with expectantly, but if severe extremity compromise is observed, the balloon should be moved to another site. An alternative means of treatment is a femoral-to-femoral crossover graft placed surgically to help alleviate the affected extremity.

Problems associated with the balloon are managed directly by removal or replacement or, if necessary, repositioning. Gas embolization, although rare, has been successfully treated with hyperbaric oxygen.

Infections usually require removal or replacement of the balloon in an alternate site. Appropriate antibiotic coverage should be instituted and adjusted as culture results become available. Prosthetic materials

TABLE 36.10 Intraaortic Balloon Pump Counterpulsation Complications

Vascular	*Miscellaneous*	*Balloon*
Arterial injury (perforation, dissection)	Hemolysis	Perforation (preinsertion)
Aortic perforation	Thrombocytopenia	Tear (during insertion)
Aortic dissection	Infection	Incorrect positioning

should be removed if present, and débridement of the insertion site should be performed as necessary. Septicemia can occur and have detrimental effects if not aggressively treated.

Fast-Track Postoperative Cardiac Recovery and Outcomes

DANIEL BAINBRIDGE, MD | DAVY C.H. CHENG, MD, MSC

KEY POINTS

1. Cardiac anesthesia has fundamentally shifted from a high-dose narcotic technique to a more balanced approach using moderate-dose narcotics, shorter-acting muscle relaxants, and volatile anesthetic agents.
2. This new paradigm has also led to renewed interest in perioperative pain management involving multimodal techniques that facilitate rapid tracheal extubation such as regional blocks, intrathecal morphine, and supplementary nonsteroidal antiinflammatory drugs.
3. This approach has prompted a change from the classical model of recovering patients in the traditional intensive care unit manner, with weaning protocols and intensive observation, to management more in keeping with the recovery room practice of early extubation and rapid discharge, which has shifted the care of cardiac patients to more specialized post–cardiac surgical recovery units.
4. Fast-track cardiac anesthesia appears to be safe in comparison with conventional high-dose narcotic anesthesia, but if complications occur that would prevent early tracheal extubation, the management strategy should be modified accordingly.
5. The goal of a post–cardiac surgical recovery model is a postoperative unit that allows variable levels of monitoring and care based on patients' needs.
6. The initial management in the postoperative care of fast-track cardiac surgical patients consists of ensuring an efficient transfer of care from operating room staff to cardiac recovery area staff, while at the same time maintaining stable patients' vital signs.
7. It is important to know the risk factors associated with cardiac surgical procedures and to review treatment options for patients with specific reference to outcomes, all within the context of cost and resource use, especially as medicine increasingly involves economic realities.

Cardiac anesthesia itself has fundamentally shifted from a high-dose narcotic technique to a more balanced approach using moderate-dose narcotics, shorter-acting muscle relaxants, and volatile anesthetic agents. This change primarily has been driven by a realization that high-dose narcotics delay extubation and recovery after surgical procedures. This new paradigm also has led to renewed interest in perioperative pain management involving multimodal techniques that facilitate rapid tracheal extubation such as regional blocks, intrathecal morphine, and supplementary nonsteroidal antiinflammatory drugs (NSAIDs). In addition to changes in anesthetic practice, the type of patients presenting for cardiac operations is changing. Patients are now older and have more associated comorbidities (stroke, myocardial infarction [MI], renal failure). Treatment options for coronary artery disease (CAD) have expanded, ranging from medical therapy only to percutaneous coronary interventions (PCIs) and surgical procedures. Surgical options, however, also have expanded and include conventional coronary artery bypass graft surgery (CABG), off-pump coronary artery bypass surgery (OPCAB), minimally invasive direct coronary artery bypass, and robotically assisted coronary artery bypass techniques. Change also has taken place in the recovery of patients undergoing cardiac procedures. Although cardiac surgical procedures often were associated with a high mortality rate and long intensive care unit (ICU) stays, the use of moderate doses of narcotics has allowed for rapid ventilator weaning and discharge from the ICU within 24 hours. This change has prompted a shift from the classical model of recovering patients in the traditional ICU manner, with weaning protocols and intensive observation, to management more in keeping with the recovery room practice of early extubation and rapid discharge. This, in turn, has shifted the care of cardiac patients to more specialized post–cardiac surgical recovery units.

Finally, hard clinical outcomes have driven change in the ongoing management of cardiac patients and are increasingly the focus of research. Intraoperative management now exists within the continuum of preoperative assessment and postoperative care. The outcome for a patient within the hospital setting is only one small aspect of success. Long-term mortality, morbidity, and quality of life indicators are becoming the gold standard in determining benefit or harm for interventions.

This chapter reviews fast-track cardiac anesthesia (FTCA) and its impact on cardiac recovery. The initial perioperative care of routine cardiac surgical cases, including postoperative pain management techniques such as regional blockade and intrathecal morphine, are discussed, followed by specific management issues of commonly occurring problems in the cardiac ICU. Finally, important cardiac outcomes are reviewed, focusing on the different treatment options available to patients with CAD and discussing available evidence for the implementation of these options.

Fast-Track Cardiac Surgical Care

Anesthetic Techniques

Few trials have compared inhalation agents for FTCA. A single trial comparing sevoflurane and isoflurane in patients undergoing valve operations was unable to demonstrate reductions in tracheal extubation times.[1] Several studies examined the effectiveness of propofol versus an inhalation agent; these studies demonstrated reductions in myocardial enzyme release (creatine kinase-MB, troponin I) and preservation of myocardial function in patients receiving inhalation agents.[2–5] Although this end point is a surrogate for myocardial damage

and does not show improved outcome per se, creatine kinase-MB release after CABG may be associated with a poor outcome[6] (Box 37.1).

The choice of muscle relaxant in FTCA is important to reduce the incidence of muscle weakness in the cardiac recovery area (CRA) that may delay tracheal extubation.[7] Several randomized trials compared rocuronium (0.5–1 mg/kg) with pancuronium (0.1 mg/kg) and found significant differences in residual paralysis in the ICU.[8–11] Two studies found statistically significant delays in the time to extubation in the pancuronium-treated group.[9,10] None of the trials used reversal agents, so the use of pancuronium appears acceptable as long as a reversal agent is administered to patients with residual neuromuscular weakness.

Several trials examined the use of different short-acting narcotic agents during FTCA. In these trials, fentanyl, remifentanil, and sufentanil all were found to be efficacious for early tracheal extubation.[12–14] The anesthetic drugs and their suggested dosages are listed in Box 37.2.

BOX 37.1 BENEFITS OF FAST-TRACK CARDIAC ANESTHESIA

- Decreased duration of intubation
- Decreased length of intensive care unit stay
- Decreased cost

BOX 37.2 SUGGESTED DOSAGES FOR FAST-TRACK CARDIAC ANESTHESIA

Induction
Narcotic
Fentanyl 5–10 µg/kg
Sufentanil 1–3 µg/kg
Remifentanil infusions of 0.5–1.0 µg/kg per min

Muscle Relaxant
Rocuronium 0.5–1 mg/kg
Vecuronium 1–1.5 mg/kg

Hypnotic
Midazolam 0.05–0.1 mg/kg
Propofol 0.5–1.5 mg/kg

Maintenance
Narcotic
Fentanyl 1–5 µg/kg
Sufentanil 1–1.5 µg/kg
Remifentanil infusions of 0.5–1.0 µg/kg per min

Hypnotic
Inhalational 0.5–1 MAC
Propofol 50–100 µg/kg per min

Transfer to Cardiac Recovery Area
Narcotic
Morphine 0.1–0.2 mg/kg

Hypnotic
Propofol 25–75 µg/kg per min

MAC, Minimum alveolar concentration.

The efficacy and resource utilization of remifentanil and fentanyl in fast-track coronary artery bypass graft surgery: a prospective randomized, double-blinded controlled, multi-center trial. *Anesth Analg*. 2001;92:1094.

Evidence Supporting Fast-Track Cardiac Recovery

Several randomized trials and one metaanalysis of randomized trials addressed the question of safety of FTCA.[15–21] None of the trials was able to demonstrate differences in outcomes between the fast-track anesthesia group and the conventional anesthesia group (Fig. 37.1). The metaanalysis of randomized trials demonstrated a reduction in the duration of intubation by 8 hours (Fig. 37.2) and in the ICU length of stay (LOS) by 5 hours in favor of the fast-track group. However, the hospital LOS was not statistically different.

One concern with FTCA is the potential for an increase in the incidence of adverse events, notably awareness. Awareness in patients

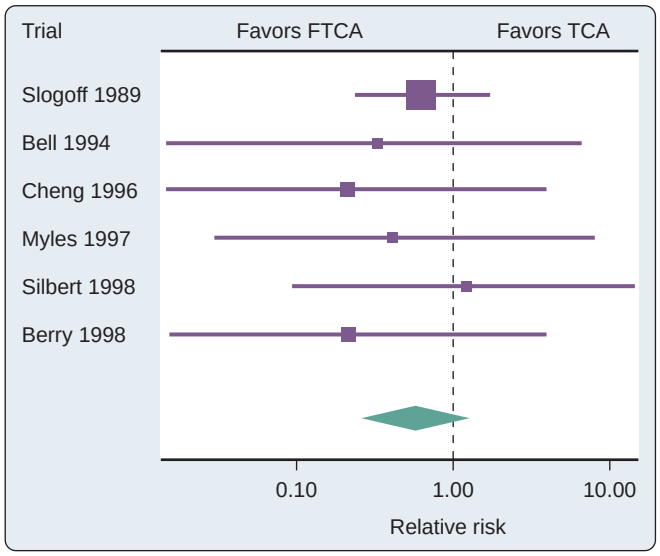

Fig. 37.1 Forrest plot of mortality indicating no difference when fast-track cardiac anesthesia *(FTCA)* was compared with conventional high-dose narcotic anesthesia. *TCA*, Traditional cardiac anesthesia. *(Data from Myles PS, Daly DJ, Djaiani G, et al. A systematic review of the safety and effectiveness of fast-track cardiac anesthesia.* Anesthesiology. *2003;99[4]:982–987.)*

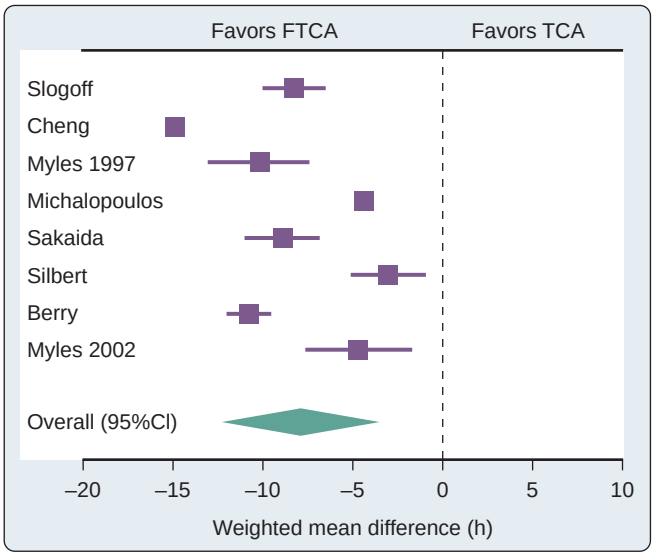

Fig. 37.2 Forrest plot showing the weighted mean difference in extubation times. The overall effect was an 8.1-hour reduction in extubation times. *CI*, Confidence interval; *FTCA*, fast-track cardiac anesthesia; *TCA*, traditional cardiac anesthesia. *(Data from Myles PS, Daly DJ, Djaiani G, et al. A systematic review of the safety and effectiveness of fast-track cardiac anesthesia.* Anesthesiology. *2003;99[4]:982–987.)*

undergoing FTCA was systematically investigated in 2 prospective observational studies with a total of 1131 patients undergoing FTCA. The reported incidence rate of explicit intraoperative awareness was 0.3% (2 of 608) in the first trial and 0.19% (1 of 514) in the second trial.[22,23] This finding is comparable to the reported incidence during conventional cardiac surgical procedures,[24] and it suggests that FTCA does not increase the incidence of awareness compared with conventional cardiac operations.

FTCA appears safe in comparison with conventional high-dose narcotic anesthesia. It reduces the duration of ventilation and ICU LOS considerably without increasing the incidence of awareness or other adverse events.[19–21] FTCA appears effective at reducing costs and resource use.[25,26] As such, it is becoming the standard of care in many cardiac centers. The usual practice at many institutions is to treat all patients as candidates for FTCA with the goal of allowing early tracheal extubation for every patient. However, if complications occur that would prevent early tracheal extubation, the management strategy is modified accordingly. Investigators have demonstrated that the risk factors for delayed tracheal extubation (>10 hours) are increased age, female sex, postoperative use of intraaortic balloon pump (IABP), inotropes, bleeding, and atrial arrhythmia. The risk factors for prolonged ICU LOS (>48 hours) are those of delayed tracheal extubation in addition to preoperative MI and postoperative renal insufficiency.[27] Care should be taken to avoid excessive bleeding (antifibrinolytic agents) and to treat arrhythmias either prophylactically or when they occur (β-blockers, amiodarone).

Post–Cardiac Surgical Recovery Models

The failure of many randomized trials of FTCA to show reductions in resource use likely stems from the traditional ICU models used by these centers during the study period. Even when trials were combined in a metaanalysis, the ICU LOS was reduced by only 5 hours even though patients were extubated a mean of 8 hours earlier.[21] Typically, patients who are extubated within the first 24 hours of ICU admission are transferred to the ward on postoperative day 1 in the morning or early afternoon. This approach allows the following daytime cardiac surgical patients to have available ICU beds, but it prevents patient transfers during nighttime hours. Two models have been proposed to deal with this issue: the parallel model and the integrated model (Fig. 37.3). In the parallel model, patients are admitted directly to a CRA, where they are monitored with 1:1 nursing care until tracheal extubation. The level of care is then reduced to reflect reduced nursing requirements, with ratios of 1:2 or 1:3. Any patients requiring overnight ventilation are transferred to the ICU for continuation of care. The primary drawback of the parallel model is the physical separation of the CRA and ICU, which leads to two separate units and thus does not eliminate the requirement to transfer patients. The integrated model overcomes these limitations because all patients are admitted to the same physical area, but postoperative management such as nurse-to-patient ratio is variable based on patients' requirements.[28–30] Because nursing care accounts for 45% to 50% of ICU costs, reducing the nursing requirements when possible creates the greatest saving. Other cost savings from reductions in arterial blood gas (ABG) measurements, use of sedative drugs, and ventilator maintenance are small. The goal is a postoperative unit that allows variable levels of monitoring and care based on patients' needs.[30] Furthermore, FTCA has been demonstrated to be a safe and cost-effective practice that decreases resource use after patients' discharge from index hospitalizations up to 1-year follow-up.[31]

Initial Management of Patients in Fast-Track Cardiac Anesthesia: The First 24 Hours

On arrival in the CRA, initial management of cardiac patients consists of ensuring an efficient transfer of care from operating room (OR) staff to CRA staff while at the same time maintaining stable patient vital signs. The anesthesiologist should relay important clinical parameters to the CRA team. To accomplish this, many centers have devised handoff sheets to aid in the transfer of care. Initial laboratory studies should be sent (Box 37.3). An electrocardiogram should be ordered, but a chest radiograph is required only in certain circumstances (Box 37.4). The patient's temperature should be recorded, and if low, active rewarming measures should be initiated with the goal of rewarming the patient to 36.5°C. Shivering may be treated with low doses of meperidine (12.5–25 mg, intravenously). Hyperthermia, however, is common later within the first 24 hours after cardiac operations and may be associated with an increase in neurocognitive dysfunction, possibly a result of hyperthermia exacerbating cardiopulmonary bypass (CPB)–induced neurologic injury[25,27] (Box 37.5) (see Chapters 31 and 40).

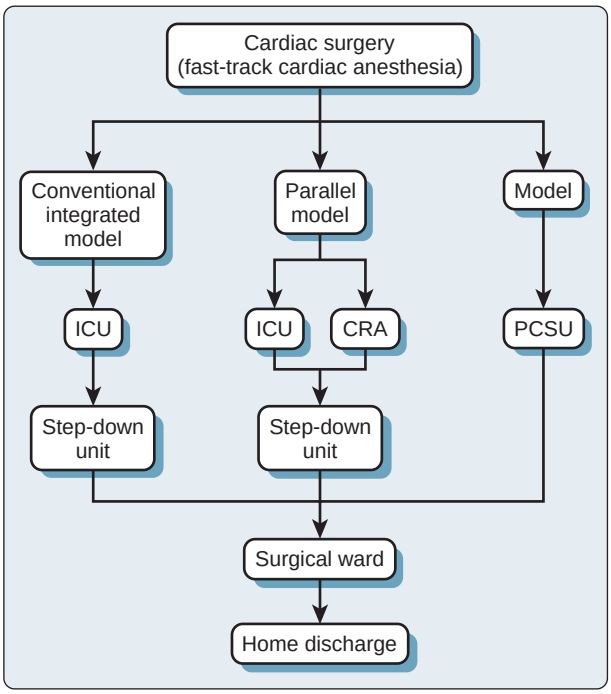

Fig. 37.3 Post–cardiac surgical recovery models. *CRA*, Cardiac recovery area; *ICU*, intensive care unit; *PCSU*, post–cardiac surgical unit.

BOX 37.3 SUGGESTED INITIAL LABORATORY WORK IN ROUTINE CASES, WITH ADDITIONAL LABORATORY WORK TO BE ORDERED AS INDICATED

Routine
Complete blood count
Electrolytes
Blood urea nitrogen/creatinine
aPTT/INR
Arterial blood gases

As Indicated
Fibrinogen
Liver function tests (AST/ALT)
Calcium
Magnesium
Cardiac enzymes (CK-MB, CK, troponin I)

ALT, Alanine aminotransferase; *aPTT*, activated partial thromboplastin time; *AST*, aspartate aminotransferase; *CK*, creatine kinase; *CK-MB*, creatine kinase myocardium band; *INR*, international normalized ratio.

BOX 37.4 SUGGESTED INDICATIONS FOR ORDERING A CHEST RADIOGRAPH

Respiratory
PaO_2/FIO_2 ratio >200
Peak pressure >30 cm H_2O
Asymmetric air entry

Circulatory
Uncertainty of pulmonary artery catheter position (poor trace, inability to wedge catheter)
Hypotension resistant to treatment
Excessive bleeding

Gastrointestinal
Nasogastric or orogastric tube feeding

PaO_2/FIO_2 ratio, Ratio of partial pressure of arterial oxygen to fraction of inspired oxygen.

BOX 37.5 INITIAL MANAGEMENT OF THE FAST-TRACK CARDIAC ANESTHESIA PATIENT

- Normothermia
- Hemoglobin >7 g/dL
- $PaCO_2$ 35–45 mm Hg
- SaO_2 >95%
- Mean blood pressure >50–70 mm Hg
- Potassium: 3.5–5.0 mEq/L
- Blood glucose <10.0 mmol/L (<200 mg/dL)

$PaCO_2$, Partial pressure of arterial carbon dioxide; *SaO_2*, arterial oxygen saturation.

Ventilation Management: Admission to Tracheal Extubation

Ventilatory requirements should be managed with the goal of early tracheal extubation in patients (Box 37.6). ABGs are initially drawn within one-half hour after admission and then repeated as needed. Patients should be awake and cooperative, hemodynamically stable, and have no active bleeding with coagulopathy. Respiratory strength should be assessed by hand grip or head lift to ensure complete reversal of neuromuscular blockade. The patient's temperature should be more than 36°C, preferably normothermic. When these conditions are met and ABG results are within the reference range, tracheal extubation may take place. ABGs should be drawn approximately 30 minutes after tracheal extubation to ensure adequate ventilation with maintenance of partial pressure of arterial oxygen (PaO_2) and partial pressure of arterial carbon dioxide ($PaCO_2$). Inability to extubate patients as a result of respiratory failure, hemodynamic instability, or large amounts of mediastinal drainage necessitates more complex weaning strategies (see Chapter 39). Some patients may arrive after extubation in the OR. Careful attention should be paid to these patients because they may subsequently develop respiratory failure. The patient's respiratory rate should be monitored every 5 minutes during the first several hours. ABGs should be drawn on admission and 30 minutes later to ensure that the patient is not retaining carbon dioxide. If the patient's respirations become compromised, ventilatory support should be provided. Simple measures such as reminders to breathe may be effective in the narcotized or anesthetized patient. Low doses of naloxone (0.04 mg, intravenously) also may be beneficial. Trials of continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or noninvasive ventilation (NIV) may provide enough support to allow adequate ventilation. Reintubation should be avoided because it may delay recovery; however, it may become necessary if the earlier mentioned measures fail, with resulting in hypoxemia, hypercarbia, and a declining level of consciousness.

BOX 37.6 VENTILATION MANAGEMENT GOALS DURING THE INITIAL TRIAL OF WEANING FROM EXTUBATION

Initial Ventilation Parameters
A/C at 10–12 beats/min
Tidal volume 8–10 mL/kg
PEEP 5 cm H_2O

Maintenance of Arterial Blood Gases
pH 7.35–7.45
$PaCO_2$ 35–45 mm Hg
PaO_2 >90 mm Hg
Saturations >95%

Extubation Criteria
Arterial blood gases as above
Awake and alert
Hemodynamically stable
No active bleeding (<400 mL/2 h)
Temperature >36°C
Return of muscle strength (>5 s, head lift/strong hand grip)

A/C, Assist-controlled ventilation; *$PaCO_2$*, partial pressure of arterial carbon dioxide; *PaO_2*, partial pressure of arterial oxygen; *PEEP*, positive end-expiratory pressure.

Optimizing Hemoglobin Concentrations

Anemia is common during and after cardiac surgical procedures, a result of both dilution and blood loss. Although a hemoglobin transfusion threshold of 10 g/dL was once common, a large randomized trial indicated that a lower threshold of 7 g/dL was safe.[32] Many subsequent observational studies and small randomized trials suggested that blood transfusions were harmful and should be avoided. The concerns with most of the existing literature are the age of these studies, their observational design, and the small size of the few existing randomized trials.[33–35] A large randomized trial suggested that a higher target threshold may be of benefit in some patients.[36] In the post-CPB period, patients with incomplete revascularization or with poor target vessels may require a higher transfusion threshold.[32] The ideal hemoglobin level in patients following cardiac operations is unclear. However a minimum hemoglobin level of 7 g/dL. should be maintained. In patients who are acidotic and require high-dose vasopressor or inotropic support, a higher threshold of 8 or 9 g/dL should be targeted. As a result, blood transfusions should be individualized for each patient, but they certainly should be used to maintain a minimal hemoglobin level of 7 g/dL (see Chapters 30 and 35).

Management of Bleeding

Chest tube drainage should be checked every 15 minutes after ICU admission to assess a patient's coagulation status. Although blood loss is commonly divided into two types, surgical or medical, determining the cause of bleeding is often difficult. When bleeding exceeds 400 mL/hour during the first hour, 200 mL/hour for each of the first 2 hours, or 100 mL/hour over the first 4 hours, returning the patient to the OR for chest reexploration should be considered. The clinical situation must be individualized for each patient, however, and in patients with known coagulopathy, more liberal blood loss before chest reexploration may be acceptable. Bleeding after cardiac surgical procedures has numerous medical causes. Platelet dysfunction is common in this setting. The CPB circuit itself leads to contact activation and degranulation of platelets, thus resulting in platelet dysfunction. Residual heparinization is common following cardiac operations and frequently

occurs when either heparinized pump blood is transfused after CPB or insufficient protamine is administered. Fibrinolysis is also common after CPB, predominantly caused by a host of activated inflammatory and coagulation pathways. Coagulation factors may decrease from activation at air-blood interfaces or from dilution with the CPB pump-priming solution. Hypothermia also may aggravate the coagulation cascade and lead to further bleeding.

Conventional coagulation tests are helpful to identify the coagulation abnormality contributing to the bleeding. Common laboratory testing includes activated partial thromboplastin time, international normalized ratio (INR), platelet count, fibrinogen level, and D-dimers. Unfortunately, most conventional measures take 20 to 60 minutes before results are available. This situation has led to the development of new methods to help guide treatment. These bedside point-of-care tests are providing more rapid, clinically relevant results compared with laboratory testing. Point-of-care testing such as thromboelastography has been demonstrated to reduce transfusion requirements without increasing blood loss and is commonly used, especially following difficult cardiac operations[37,38] (see Chapters 19, 29, and 31–35).

Initial medical treatment of excessive blood loss consists of 50 to 100 mg of intravenous protamine to ensure complete heparin reversal. This treatment may need to be repeated if heparinized CPB pump blood has been administered after protamine reversal. Although the reinfusion of chest tube blood was common to avoid exposure to donor packed red blood cells, it is no longer used because this blood is known to contain activated coagulation and inflammatory mediators that may predispose to an increased risk for infection.[39] Tranexamic acid infusions may be used to reduce postoperative blood loss. The dose of tranexamic acid is up to 1 g/hour over a period of 5 hours. DDAVP may also be used and has been shown to be efficacious in patients with uremia or other disorders causing platelet dysfunction.[40] These three agents (protamine, an antifibrinolytic such as tranexamic acid, and DDAVP) represent a pharmaceutic approach to hemostasis and are usually readily available and can be given quickly. This therapy may be followed by the use of blood products as needed to treat ongoing blood loss.[41]

Fresh-frozen plasma usually is given in the setting of an increased INR (>1.5). In patients who have large chest tube drainage (>500 mL/h), fresh-frozen plasma may also be given as part of whole blood reconstitution in a manner similar to trauma resuscitation. This treatment prevents the inevitable coagulopathy caused by rapid blood loss and transfusion. Although approved only for the reversal of warfarin in the setting of an elevated INR, prothrombin complex concentrates are currently being investigated for treatment of bleeding associated with elevated INRs in postoperative cardiac surgical patients.[42]

Platelet levels of less than 100,000/mm^3 may warrant platelet transfusion. However, platelet transfusions carry the greatest risk for transfusion-related complications of any blood component, typically sepsis from bacterial contamination.[43] Platelets should be used only when platelet counts are low, platelet function assays indicate platelet dysfunction, or the patient has a suspected platelet dysfunction, secondary to the use of acetylsalicylic acid, glycoprotein IIb/IIIa inhibitors, or adenosine diphosphate receptor antagonists.

Fibrinogen concentrates are available, and a few studies have looked at the use of this product to prevent or treat bleeding. Few randomized trials exist, and currently the efficacy of these agents to reduce bleeding remains unclear. However, the current trials demonstrate few adverse events with fibrinogen concentrates.[44–46] A correlation between fibrinogen level and bleeding following cardiac surgical procedures was weak, but the potential of fibrinogen concentrates remains promising[47,48] (see Chapters 34 and 35).

Certain physical measures should be instituted, including warming of the hypothermic patient. The effects of positive end-expiratory pressure (PEEP) on postoperative bleeding are equivocal and likely have little benefit in the presence of surgical bleeding or in patients with coagulopathy.[49,50] The use of aprotinin after cardiac operations is likely of little benefit because several randomized trials were unable to demonstrate efficacy[51,52] (Box 37.7).

BOX 37.7 MANAGEMENT OF THE BLEEDING PATIENT

- Review activated coagulation time, prothrombin time, international normalized ratio, and platelet count.
- Administer protamine if bleeding is caused by excess heparin (reinfusion of pump blood).
- Treat the medical cause with platelets, fresh frozen plasma, and cryoprecipitate if bleeding is secondary to decreased fibrinogen.
- Factor VIIa should be considered if bleeding continues despite a normal coagulation profile.
- Treat the surgical cause with reexploration.

Factor VIIa may be used as rescue therapy in patients with uncontrolled bleeding, usually in the presence of normal coagulation test results and no surgical evidence of bleeding.[53] Factor VIIa is usually administered in the OR; however, it may be given in the ICU if bleeding persists despite corrected laboratory results (fibrinogen, INR, partial thromboplastin time). Doses initially were in the range of 75 to 100 μg/kg, but concern over thrombotic complications has led to dosage reductions ranging down to as low as 17 μg/kg.[53–55] Typically, 50 μg/kg total is given in one to two doses with 20 to 30 minutes in between dosing. If the chest tube drainage is reduced, the second dose may be omitted. Concern over a relatively high rate of complications (arterial thromboembolic) and the lack of efficacy (death and reductions in rates of transfusion) resulted in a reduction in the frequency of factor VIIa use postoperatively, and this use of factor VIIa remains an off-label indication.[56]

Electrolyte Management

Hypokalemia is common after cardiac surgical procedures, especially if diuretic agents were given intraoperatively. Hypokalemia contributes to increased automaticity and may lead to ventricular arrhythmias, ventricular tachycardia, or ventricular fibrillation. Treatment consists of potassium infusions (20 mEq potassium in 50 mL of D_5W infused over 1 hour) until the potassium level exceeds 3.5 mEq/mL. In patients with frequent premature ventricular contractions caused by increased automaticity, a serum potassium level of 5.0 mEq/mL may be desirable. Hypomagnesemia contributes to ventricular preexcitation and may contribute to atrial fibrillation (AF). This disorder is common in malnourished and chronically ill patients, a frequent occurrence in the cardiac surgical setting. Management consists of intermittent boluses of magnesium: 1 to 2 g over 15 minutes. Hypocalcemia also is frequent during cardiac operations and may reduce cardiac contractility. Intermittent boluses of calcium chloride or calcium gluconate (1 g) may be required (Box 37.8).

Glucose Management

Diabetes is a common comorbidity (up to 30%) and is a known risk factor for adverse outcomes in patients presenting for cardiac operations.[57–59] Hyperglycemia itself is common during CPB. The risk factors for hyperglycemia include diabetes, administration of steroids before CPB, volume of glucose-containing solutions administered, and use of epinephrine infusions.[60] Poor perioperative glucose control is associated with increases in mortality and morbidity, including an increased risk for infection and prolonged duration of ventilation.[61–65] In a large prospective, randomized, controlled trial of tight glucose control (blood glucose levels of 4.1–6.5 mmol/L) during the postoperative ICU stay, the investigators showed reductions in mortality rates were shown compared with more liberal glucose control (blood glucose levels of 12 mmol/L).[65] This trial enrolled both diabetic and nondiabetic hyperglycemic patients who underwent cardiothoracic

BOX 37.8 COMMON ELECTROLYTE ABNORMALITIES AND POSSIBLE TREATMENT OPTIONS

Hypokalemia (Potassium <3.5 mmol/L)
SSx: muscle weakness, ST-segment depression, "u" wave, T-wave flat, ventricular preexcitation
Rx: IV KCl at 10–20 mEq/h by central catheter

Hyperkalemia (Potassium >5.2 mmol/L)
SSx: muscle weakness, peaked T wave, loss of P wave, prolonged PR/QRS
Rx: $CaCl_2$ 1 g, insulin/glucose, HCO_3^-, diuretics, hyperventilation, dialysis

Hypocalcemia (Ionized Calcium <1.1 mmol/L)
SSx: hypotension, heart failure, prolonged QT interval
Rx: $CaCl_2$ or calcium gluconate

Hypercalcemia (Ionized Calcium >1.3 mmol/L)
SSx: altered mental state, coma, ileus
Rx: dialysis, diuretics, mithramycin, calcitonin

Hypermagnesemia (Magnesium >0.7 mmol/L)
SSx: weakness, absent reflexes
Rx: stop magnesium infusion, diuresis

Hypomagnesemia (Magnesium <0.5 mmol/L)
SSx: arrhythmia, prolonged PR and QT intervals
Rx: magnesium infusion 1 to 2 g

$CaCl_2$, Calcium chloride; *HCO_3^-,* bicarbonate; *IV KCl,* intravenous potassium chloride; *Rx,* treatment; *SSx,* signs and symptoms.

operations, and it demonstrated that tight management of glucose was beneficial in the CRA. However, another multicenter trial, as well as a metaanalysis of tight glucose control in the ICU, suggested an increase in harm, likely related to an increase in episodic hypoglycemia.[66] Therefore, it may be prudent to accept a more liberal blood glucose level (<10.0 mmol/L or <200 mg/dL) to reduce hypoglycemic episodes.

Pain Control

Pain control after cardiac surgical procedures has become a concern as narcotic doses have been reduced to facilitate fast-track protocols. Intravenous morphine or hydromorphone is still the mainstay of treatment in patients after cardiac operations. The most common approach is patient-demanded, nurse-delivered intravenous morphine, and this treatment remains popular because of the 1:1 to 1:2 nursing typically provided during cardiac recovery. However, with a change to more flexible nurse coverage and therefore higher nurse-to-patient ratios, patient-controlled analgesia (PCA) morphine use has become increasingly popular. Several studies examined PCA morphine use in patients after cardiac surgical procedures.[67–70] A metaanalysis looking at PCA morphine for postoperative pain showed small incremental benefits. However, young patients, those who took opioids preoperatively, or patients transferred to a regular ward on the day of the operation may benefit from PCA for pain management[71] (Box 37.9) (see Chapter 42).

Regional Analgesia Techniques

Intrathecal Morphine

Intrathecal morphine was investigated in randomized trials as an adjuvant for pain control in cardiac surgical patients, with doses ranging from 500 µg to 4 mg.[72–75] A metaanalysis of 17 randomized, controlled trials compared intrathecal morphine with standard treatment. No difference was noted in mortality rates, MI, or time to extubation. The investigators reported modest reductions in morphine use and pain scores, whereas the incidence of pruritus was increased.

BOX 37.9 PAIN MANAGEMENT OPTIONS AFTER CARDIAC SURGICAL PROCEDURES

Patient-Controlled Analgesia
Possible benefit in a step-down unit
Reduced 24-hour morphine consumption in 2 of 7 randomized trials

Intrathecal Morphine
Doses studied: 500 µg to 4 mg
Possible benefit in reducing intravenous morphine use
Possible benefit in reducing VAS pain scores
Potential for respiratory depression
Ideal dosing not ascertained; range, 250–400 µg

Thoracic Epidural Regimens
Common dosages from literature:
Ropivacaine 1% with 5 µg/mL fentanyl at 3–5 mL/h
Bupivacaine 0.5% with 25 µg/mL morphine at 3–10 mL/h
Bupivacaine 0.5–0.75% at 2–5 mL/h
Reduced pain scores
Shorter duration of intubation
Risk for epidural hematoma difficult to quantify

Nonsteroidal Antiinflammatory Drugs
Common dosages from literature:
Indomethacin 50–100 mg PR bid
Diclofenac 50–75 mg PO/PR q8h
Ketorolac 10–30 mg IM/IV q8h
Reduces narcotic utilization
Many different drugs studied; difficult to determine superiority of a given agent
Possible increase in serious adverse events (trial using cyclooxygenase-2–specific inhibitors)

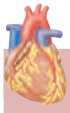
bid, Twice daily; *IM,* intramuscularly; *IV,* intravenously; *PO,* orally; *PR,* rectally; *VAS,* visual analog scale.

Thoracic Epidural Analgesia

Thoracic epidural analgesia has gained some popularity as a method of providing intraoperative and postoperative pain control in cardiac surgery (see Box 37.9). The best evidence for benefit comes from a metaanalysis of 15 randomized, controlled trials.[73] Thoracic epidural analgesia did not significantly affect the incidence of death or MI. It did significantly reduce arrhythmias, pulmonary complications, and time to tracheal extubation. All the randomized trials were performed in patients undergoing CABG. No reported complications resulted from epidural insertion, specifically epidural hematoma; however, all trials were inadequately powered to detect this complication. Attempts have been made to calculate the risk for epidural hematoma by using available published series, with estimates of maximum risk ranging from 1 in 1000 to 1 in 3500, depending on the confidence limits chosen (99% vs 95%).[76] A large retrospective review reported no epidural hematomas in 727 patients undergoing cardiac surgical procedures with CPB and receiving thoracic epidural analgesia on the day of the operation (on entrance into the OR).[77] At least 1 hour elapsed between insertion of the epidural catheter and heparin administration. Nine failed catheter insertions and 4 failed analgesia blocks with 11 bloody taps occurred in this study.[77] Unfortunately, cardiac surgical patients are increasingly likely to be taking antiplatelet medications, such as clopidogrel or prasugrel, which increase the risk for epidural hematoma.[78] The risk for epidural hematoma and the potential delay of surgical procedures following a bloody tap have limited the widespread adoption of thoracic epidural analgesia in cardiac surgery, especially in the United States (see Chapter 42).

Nonsteroidal Antiinflammatory Drugs

The use of NSAIDs has gained popularity in a multimodal approach, by allowing reductions in both pain levels and narcotic side effects



BOX 37.10 MEDICATIONS FOR CARDIAC RISK REDUCTION AFTER CORONARY ARTERY BYPASS GRAFTING

- Aspirin: all patients after bypass grafting
- Clopidogrel: patients who have contraindication to aspirin (may have superior efficacy compared with aspirin)
- β-Blockers: especially with perioperative myocardial infarction
- Lipid-lowering agents: especially statin drugs

(see Box 37.9). The conventional NSAIDs, which nonselectively block the cyclooxygenase-2 (COX-2) isoenzyme, reduce inflammation, fever, and pain, and they also block the COX-1 isoenzyme, thus resulting in the side effects of gastrointestinal toxicity and platelet dysfunction.[79] Numerous randomized trials examined the benefit of NSAID use for postoperative pain control.[80–83] In addition, a metaanalysis looking at the benefit of NSAIDs in the setting of cardiac and thoracic surgery demonstrated reductions in narcotic consumption in patients given NSAIDs.[84] Most patients were younger than 70 years of age and had no coexisting renal dysfunction. The NSAIDs used in this metaanalysis were nonselective COX inhibitors. Several trials suggested increased adverse events, especially in patients with CAD, who receive the COX-2–selective NSAIDs both in the perioperative cardiac setting and while ambulatory. For this reason, COX-2–selective NSAIDs are no longer used in most cardiac centers.[85] Therefore, although NSAIDs have theoretic side effects, the benefit in reduced narcotic consumption and improved visual analog scale pain scores is well demonstrated; many centers continue to use nonselective NSAIDs as analgesia adjuvants in cardiac surgery.[86] However, NSAIDs should be avoided in patients with renal insufficiency, a history of gastritis, or peptic ulcer disease. Adjuvant ranitidine treatment may be considered to prevent gastric irritation.

Medications for Risk Reduction After Coronary Artery Bypass Graft Procedures

CABG surgical procedures reduce the risk of death and angina recurrence, but several medical management issues may help maintain the long-term benefit after CABG operations. Specifically, the use of aspirin, β-blockers, and lipid-lowering agents has been demonstrated to prolong survival or reduce graft restenosis, or both (Box 37.10) (see Chapters 1 and 20).

Aspirin

Many studies demonstrated the efficacy of aspirin (acetylsalicylic acid) use on graft patency and reductions in MI and mortality rates after CABG surgical procedures.[87–91] A large observational study showed a reduction in mortality rate of nearly 3% and a reduction in MI rate of 48% with the early postoperative use of aspirin (within 48 hours).[91] Acetylsalicylic acid dosages have ranged from 100 mg once daily to 325 mg three times daily orally or by suppository up to 48 hours after ICU admission. Typically, an 81-mg oral dose is used (150 mg rectally), with dosing ideally occurring within the first 6 to 8 hours after admission. No additional benefit results from the use of aspirin preoperatively.[92] The beneficial effect on saphenous vein graft patency appears to be lost after 1 year, with prolonged use of aspirin having no further benefit.[93] However, because aspirin, in doses of 75 to 325 mg/day, reduces mortality and morbidity in patients at risk for cardiovascular disease, its continued long-term use is warranted.[94] Clopidogrel, prasugrel, or ticagrelor may be suitable alternatives in patients who are allergic to aspirin. Clopidogrel, through reductions in all-cause mortality, stroke, and MI, may be superior to aspirin in patients who return with recurrent ischemic events after cardiac operations.[95]

β-Blockers

The use of β-blockers in patients after CABG surgical procedures was not shown to improve mortality rates.[96,97] These drugs also failed to reduce rates of perioperative myocardial ischemia in some studies, However, patients who received β-blockers after perioperative MI had reductions in mortality rates at 1 year.[98] Patients with a previous history of MI should continue β-blocker therapy. In addition, withdrawal of β-blockers is associated with increased rates of AF, so patients should be restarted on their β-blocker therapy as soon as it is safe to do so (see Chapter 11).

Statins

Statins should be continued in the postoperative period because clear evidence supports reductions in saphenous vein graft occlusion, AF, and postoperative mortality rates in patients receiving statins postoperatively. Statin use was shown to reduce the progression of atherosclerotic plaque formation within saphenous vein grafts. This resulted in reductions in the need for subsequent revascularization in several trials.[99,100] Statin use that is started in the preoperative period is associated with substantial reductions in the incidence of postoperative AF. An individual metaanalysis of randomized trials involving more than 1000 patients suggested a relative reduction in AF rates of 50% (from an absolute rate of 36% to an absolute rate of 19%).[101]

Anticoagulation for Valve Operations

Anticoagulation should be started in the early postoperative period for patients who have undergone valve replacement with either a mechanical prothesis or bioprosthesis, and it also should be considered when AF complicates the postoperative course.[102] The recommended approach to anticoagulation differs according to the society making the recommendation. The target INR in all cases is based on the valve type (tissue or mechanical), the valve position (mitral or aortic), and the presence of risk factors (AF, previous thromboembolic event, LV dysfunction, or any hypercoagulable state). The use of antiplatelet agents differs between the North American and European guidelines (Table 37.1)[103] The main difference is the routine use in North America of platelet agents (along with warfarin) for all mechanical valves and bioprosthetic valves, as suggested by the American Heart Association and the American College of Cardiology, whereas the European approach is more conservative, suggesting the use of antiplatelet agents in selected patients with mechanical valves and for only the first 3 months following a tissue valve replacement. Newer-generation heart valves are not as thrombogenic as older mechanical valves, and this feature is reflected in the recommendations. In addition, some newer valves may be even less thrombogenic and may require lower INR targets (1.5–2.0 in the aortic position) with the addition of aspirin.[104]

The decision whether to bridge anticoagulation with unfractionated heparin or low-molecular-weight heparin is based on the type of valve, the patient's risk of bleeding, and the patient's health status. Although the North American and European societies favor bridging with heparin, this strategy has no clear benefits over vitamin K antagonists alone. The use of bridging anticoagulants is more frequently seen with mitral valves or in patients with a history of thromboembolic disease. In patients in unstable condition, in whom repeat operations, insertion of chest tubes, or other bedside procedures such as tracheostomy may be performed, the use of heparin (usually low-molecular-weight heparin) is preferred because this agent can be easily discontinued before the procedure and quickly resumed.

Management of Postoperative Complications

Complications are frequent after cardiac surgical procedures. Although many are short-lived, some complications (eg, stroke) are long-term catastrophic events that seriously affect a patient's functional status (see Chapters 40 and 41). The incidence and predisposing risk factors

BOX 37.11 TREATMENT FOR COMPLICATIONS AFTER CARDIAC SURGICAL PROCEDURES

Stroke
- Supportive treatment
- Avoidance of potential aggravating factors (eg, hyperglycemia, hyperthermia, severe anemia)

Delirium
- Usually self-limited
- Close observation required
- Sedatives (midazolam, lorazepam) possibly required

Atrial Fibrillation
- Rate control: calcium channel blockers, β-blockers, digoxin
- Rhythm control: amiodarone, sotalol, procainamide
- Thromboembolic prophylaxis: for atrial fibrillation >48 h

Left Ventricular Dysfunction
- Volume
- Inotropes: epinephrine, milrinone, norepinephrine
- Mechanical support: intraaortic balloon pump

Renal Failure
- Removal of the causative agent (nonsteroidal antiinflammatory drugs, antibiotics)
- Hemodynamic support if necessary
- Supportive care

are well studied for many of these complications (Table 37.2). Many complications have specific management issues that may improve postoperative recovery (Box 37.11).

Stroke

Stroke after cardiac surgical procedures occurs in 2% to 4% of patients and carries a very high 1-year mortality rate of 15% to 30%.[58,105–107] Known risk factors for stroke include age, diabetes, previous history of stroke or transient ischemic attack, peripheral vascular disease, and unstable angina.[58,106] The most common causes are emboli sheared off the aorta during aortic manipulation (proximal anastomosis of the vein grafts, clamping and unclamping of the aorta). However, hemorrhagic and watershed infarcts also occur secondary to the use of large doses of heparin and the frequent occurrence of hypotension during the operation, respectively. AF in the postoperative period also appears to be an important cause of stroke in cardiac surgical patients.[108] Resource use is increased in patients who have a stroke, with prolonged ICU and hospital LOS.[106] Numerous methods of preventing neurologic injury during the intraoperative period have been proposed, including epiaortic scanning, alpha-stat pH management during CABG with CPB, and OPCAB surgery with no-touch surgical techniques.[109–113] Prevention of postoperative neurologic injury may be possible with the aggressive treatment of AF (antiarrhythmic agents, anticoagulants, early cardioversion) to prevent thromboembolism (see the later section on AF). Patients who have an intraoperative stroke should be managed with the goal of preventing further brain injury. Hyperglycemia and hypoglycemia should be avoided because they are associated with poor outcome in brain injured patients.[114–116] Hyperthermia also is known to exacerbate brain injury and should be prevented.[117] Hemoglobin concentrations should be maintained at more than 7 g/dL. Whether maintaining hemoglobin levels greater than 10 g/dL is beneficial is uncertain, but raising the transfusion threshold may be prudent in patients with a perioperative stroke.

Delirium

Delirium is defined generally as an acute transient neurologic condition with impairment of cognitive function, attention abnormalities, and altered psychomotor activity. It often includes a disorder with the sleep/wake cycle. It may manifest as a spectrum from hypoactive delirium, in which the patient presents as listless, uncooperative, and difficult to arouse, to hyperactive delirium, in which the patient is aggressive and agitated. Delirium is fairly common after cardiac operations, with a prevalence rate of 8% to 15%.[118,119] Risk factors associated with delirium include age, previous history of stroke,

duration of the operation, duration of aortic cross-clamp, AF, and blood transfusion.[118–121] Delirium is self-limited and does not adversely affect a patient's outcome or hospital LOS.[120,121]

Prevention and treatment of delirium should focus on reducing or eliminating known predisposing factors. Exposure to benzodiazepines and opioids predisposes patients to delirium. Benzodiazepines should therefore be avoided, and opioids should be limited by adding acetaminophen or other analgesics when appropriate. Sleep/wake cycles are important to prevent delirium. If possible, exposure to sunlight and limits on disturbances at night may improve delirium. Other potentially beneficial interventions include simple measures such as the following: continually reviewing and reinforcing person, time, and place with the patient; removing physical restraints when possible; and encouraging activity and ambulation. Pharmacotherapy for delirium includes the α_2-agonists (dexmedetomidine, clonidine) and the antipsychotic agents (haloperidol, quetiapine, olanzapine, risperidone). The antipsychotic agents are frequently used for delirium, and the prototypical agent is haloperidol. The main concern with the antipsychotic agents is QTc prolongation, which may be additive when other medications such as amiodarone or ciprofloxacin are given. Thus, frequent electrocardiograms are required, especially during initiation of therapy or when a medication known to prolong the QT interval is added. In addition, haloperidol may cause extrapyramidal effects secondary to the blockade of dopamine receptors. All medications must be carefully titrated because delirium by definition has waxing and waning symptoms. Frequently different medications are tried until the patient responds to a particular drug.

Atrial Fibrillation

AF after cardiac surgical procedures is common and occurs in up to 35% of patients.[122] Although the cause of AF is not completely understood, this arrhythmia is associated with increases in death, stroke, and prolonged hospital LOS.[106,108,123] Known risk factors include age, male sex, previous AF, mitral valve operation, and a history of congestive heart failure.[106,124] Prevention and treatment of AF can be achieved effectively with amiodarone, sotalol, magnesium, or β-blockers.[125] Biatrial pacing also may be effective in prophylaxis.[125,126] Management of AF consists of rate control with conversion to sinus rhythm or anticoagulation. Two studies conducted to determine which strategy was superior (Atrial Fibrillation Follow-Up Investigation of Rhythm Management [AFFIRM] and Rate Control Versus Electrical Cardioversion [RACE]) were unable to find a difference between treatment strategies.[127–129]

Rate control may be achieved with a β-blocker or a calcium channel blocker. Digoxin also may be effective, but it is difficult to reach therapeutic levels quickly. An observational review of the AFFIRM trial suggested that β-blockers are superior to either calcium channel blockers or digoxin for rate control in AF.[130] Conversion to sinus rhythm in the patient in stable condition may be achieved with amiodarone, sotalol, or procainamide. Amiodarone is more commonly used in acute management of postoperative AF (150–300 mg, intravenously) than other antiarrhythmic agents, particularly in patients with compromised ventricular function, because it causes little cardiac depression. Finally, persistent AF over 48 to 72 hours requires thromboembolic prophylaxis. Warfarin is recommended for patients at high risk of thromboembolic complications. Patients at high risk are those with a CHA_2DS_2-VASc (congestive heart failure, hypertension, age, diabetes mellitus, previous stroke or transient ischemic attack, history of vascular disease, age, sex category) score greater than 2. One point is given for each of the following: congestive heart failure, hypertension, diabetes mellitus, age 65 to 74 years, vascular disease, and female sex. Two points are given for patients with previous stroke, transient ischemic attack, or thromboembolism, or age greater than 75 years.[131] Recommendations for anticoagulation should be individualized for each patient based on the risks for thromboembolic complications versus bleeding risk. In general, patients with heart valves should be anticoagulated based on the type of valve after the operation, whereas patients with nonvalvular AF should be anticoagulated based on the CHA_2DS_2-VASC score (Table 37.3).[132] Use of the newer oral anticoagulants is effective to prevent thromboembolism, but lack of effective reversal agents limits the use of these drugs in the ICU setting.

TABLE 37.3 Suggested Atrial Fibrillation Thromboembolic Prophylaxis

	CHA_2DS_2-VASc Score

Left Ventricular Dysfunction

Patients with poor left ventricular (LV) function commonly require inotropes or mechanical support after cardiac surgical procedures (see Chapters 11, 28, 36, and 38). Preoperative factors that predict inotrope use in patients undergoing cardiac operations include age, underlying LV dysfunction, and female sex.[133,134] The significance of inotrope use on postoperative outcome is uncertain because some centers routinely use these drugs after CPB.[133] Although pulmonary artery catheters are useful for monitoring trends in cardiac function, transesophageal echocardiography (TEE) provides more detailed information for diagnosing the cause of acute hypotensive episodes and cardiac function. TEE is used commonly in the ICU to assess patients after cardiac operations and has demonstrated efficacy in the diagnosis of cardiac tamponade, cardiac ischemia, and valve dysfunction, thus resulting in improvements in the postoperative course for these patients.[135–138] TEE also provides information on the filling volumes after CPB (see Chapters 13–16).[139–141]

Patients who have an unstable intraoperative course should have filling pressures correlated to TEE findings and the results then passed to the ICU to allow for optimal initial management in the recovery unit. If the patient's condition remains unstable in the ICU, TEE is used and cardiac function is reassessed. When hypovolemia is thought to be the underlying cause of hypotension or low cardiac output, crystalloid may be used to optimize filling. The use of colloids in the critical care setting is controversial given several large trials of starches that showed either little efficacy in volume resuscitation end points and or an increase in adverse events.[142] Therefore intravascular hypovolemia is best treated with the use of intermittent boluses of crystalloid with continuous reassessment of central venous pressure, pulmonary artery pressures, systemic pressures, or LV end-diastolic area.[139] In patients who are actively bleeding or anemic, packed red blood cells may be given to treat the anemia, and fresh-frozen plasma may be used to treat coagulopathy.

If ventricular dysfunction is the main cause of hypotension or a low–cardiac output state, then inotropes and vasopressors should be added (see Chapter 38). Unfortunately, few articles have been published examining the superiority of one inotrope over another. Epinephrine or norepinephrine (0.02–0.04 μg/kg per /min) or dopamine (3–5 μg/kg per min) is commonly used to support patients during removal from CPB and is usually continued into the ICU. If systolic pressure remains low, the epinephrine infusion is usually increased to allow for greater α-receptor action (vasoconstriction). The major disadvantage of epinephrine is the frequent occurrence of lactic acidosis triggered by the agent as a metabolic response, unrelated to hypoperfusion. This response may create confusion about the patient's status if serial arterial lactate determinations are used as a surrogate for adequate perfusion. For patients with low cardiac output

or poor myocardial function noted on TEE, milrinone commonly is used (with or without a full loading dose). Milrinone has the advantage of bypassing β-adrenergic receptors, which are downregulated after cardiac operations.[143] Phosphodiesterase inhibitors appear to improve myocardial performance, especially with the concomitant use of epinephrine.[144] If blood pressure remains low despite this combination therapy, a vasopressin infusion may be started with doses ranging from 1 to 10 U/hour. When volume and medical strategies are insufficient, especially in the presence of ischemic heart disease, mechanical support is added (see Chapters 28 and 36).

IABPs are used in approximately 3% of cardiac surgical patients. The IABP can be placed preoperatively in patients with unstable angina unresponsive to medical treatment, intraoperatively in high-risk patients (redo sternotomy with poor LV function), in patients who fail to wean from CPB, or in patients on maximal inotropic support after CPB. For patients who do not successfully wean from CPB, one retrospective study found 85% success in weaning with the institution of an IABP; however, the overall mortality rate was 35%.[145] Several studies looked at the timing of IABP insertion and found reductions in mortality rates in patients who received the IABP before initiation of CPB.[146–149] Complications from the use of IABP are numerous and include wound site infections, leg ischemia, and renal dysfunction. Several retrospective reviews examined the outcomes after IABP insertion; again, mortality rates were high in patients who received an IABP in the OR or ICU (35%).[150,151]

Right Ventricular Dysfunction

Right ventricular (RV) dysfunction may manifest in patients before cardiac surgical procedures, immediately afterward, or many days after the operation. It is seen commonly in heart transplant recipients, usually secondary to LV failure. It is also seen in patients with pulmonary hypertension, or it may be caused by an RV MI (see Chapters 25 and 26).

RV dysfunction manifests with features of peripheral edema, hypotension, confusion, and abdominal pain or cramping. Liver function test results may be elevated, including INR, aspartate aminotransferase, and alanine aminotransferase. Thus the differential diagnosis frequently includes renal failure, sepsis, bowel ischemia, and liver failure.[152,153]

In patients with invasive monitoring, assessment of RV function may be made indirectly through measurement of central venous pressure, cardiac output, and pulmonary artery pressures. Unless the patient has direct myocardial dysfunction, pulmonary artery pressures are almost always increased. Echocardiography also is useful in assessing patients with suspected RV failure. RV volume overload manifests with an enlarged right ventricle and an associated small and underfilled left ventricle (because of both poor RV output and ventricular interdependence). Tricuspid regurgitation is also frequently present. If the right ventricle also is pressure overloaded, the interventricular septum shifts to the left, and the LV is said to have a D shape. Tricuspid annular-plane systolic excursion (TAPSE) may be helpful in measuring the degree of RV failure.[152–156]

Management of RV failure consists of reducing RV afterload, increasing systemic pressures to prevent RV ischemia, and ensuring adequate RV filling. Volume therapy, although often useful in LV failure and in cases of RV failure associated with normal pulmonary vascular resistance, frequently is detrimental in high-pressure RV failure; caution must be exercised to prevent overloading patients. Inotropes, often in combination with afterload reduction, increase both blood pressure and cardiac output. Norepinephrine, phenylephrine, and vasopressin may all help to increase systemic pressures and thus reduce RV ischemia. Afterload reduction with agents specific to the pulmonary vascular tree also may be beneficial. Nitric oxide and inhaled prostaglandin may be selective for pulmonary vasodilation. Milrinone (0.125–0.5 μg/kg per h) or sildenafil (up to 25 mg orally three times a day) also may be of benefit to reduce pulmonary vascular resistance and improve cardiac output (see Chapters 26, 28, 36, and 38).

In the ICU setting, supportive measures should be instituted, including providing adequate oxygenation, preventing acidosis and atelectasis, and ensuring minimal amounts of ventilatory support to prevent alveolar collapse.

Renal Insufficiency

Renal failure in the postoperative period is rare, occurring in approximately 1% of patients after cardiac surgical procedures (see Chapter 41). Not surprisingly, when it does occur, renal failure prolongs ICU LOS and hospital LOS and increases mortality rates.[59,157] Unfortunately, no clear definition exists for renal impairment or renal failure after CPB. Although the need for dialysis is a straightforward and easily measured outcome, it ignores patients who have reductions in creatinine clearance but do not require dialysis.[59,157] Change in calculated creatinine clearance, which predicts the need for dialysis, prolonged hospital LOS, and death, may be a more suitable outcome measure of renal failure.[158] Several risk factors for postoperative renal failure are recognized, including postoperative low cardiac output, repeat cardiac operation, valve procedures, age older than 65 years, and diabetes.[59,157,159] Management of these patients consists of supportive treatment, determination of the primary cause, and then specific treatment as needed. Supportive treatment consists of ensuring adequate cardiac output, perfusion pressure, and intravascular volume. The cause of renal failure is broadly defined as prerenal, renal, or postrenal. Prerenal causes commonly are related to poor cardiac output or low systemic pressure, and they may be associated with the use of angiotensin-converting enzyme inhibitors and NSAIDs. Renal causes include acute tubular necrosis from an ischemic insult or interstitial nephritis resulting from a host of medications including NSAIDs and antibiotics. Although uncommon in the presence of bladder catheterization, the potential for postrenal obstruction is possible.

Management of renal failure usually requires correction of the underlying problem, which may include improving renal blood flow (volume, inotropes) or discontinuing the offending agent (NSAIDs, antibiotic). To date, no specific treatment exists to prevent acute tubular necrosis. Although dopamine and diuretics were once both thought to be renoprotective, they have not demonstrated efficacy to prevent renal failure.[160] Fenoldopam, a D_1-receptor agonist, may improve renal function in cardiac surgical patients.[161] Investigators suggested that diuretics may be potentially harmful in patients experiencing renal failure.[162] If patients do require dialysis, continuous dialysis may be better than intermittent dialysis.[163] *N*-acetylcysteine has demonstrated efficacy in preventing further renal failure from radiocontrast agents in patients with chronic renal insufficiency.[164] This, however, does not appear to translate to cardiac surgical patients, because several metaanalyses of randomized trials showed little benefit from *N*-acetylcysteine.[164–166]

Postoperative Outcomes

Treatment Options for Coronary Artery Disease

Until the advent of CABG procedures, medical management was the only treatment option for patients with CAD. Today, treatment can be broadly categorized as medical or invasive, with invasive management divided geographically into interventions performed in the cardiac catheterization laboratory or in the OR. Catheterization procedures (percutaneous coronary intervention [PCI]) commonly performed include balloon angioplasty, cardiac stenting, and placement of drug-eluting stents, which release drugs capable of preventing restenosis (see Chapters 3 and 20). Surgical procedures include conventional CABG (with use of CPB) and OPCAB (without use of CPB). OPCAB procedures may be performed through a full sternotomy, a thoracotomy (minimally invasive direct coronary artery bypass), or by using robotically assisted thoracotomy surgery. With the ever-increasing number of available options, it becomes crucial to establish which option is superior with regard to angina recurrence, graft patency, and long-term survival with the least morbidity (MI, stroke, AF) at the lowest

TABLE 37.4 Treatment Options and Outcomes for Coronary Artery Disease

Comparison	*Outcome*	*Revascularization*
Medical vs surgical management	Absolute risk reduction in mortality 5.6% at 5 y 5.9% at 7 y 4.1% at 10 y Benefit of operation greatest in LM, three-vessel disease	37% of medically treated patients converted to surgical treatment
Angioplasty vs surgical management	Absolute risk reduction in mortality 1.9% at 5 y Rates of in-hospital MI and stroke significantly lower in angioplasty group Benefit of operation greatest in diabetes, multivessel revascularization	50% rate of revascularization at 5 y in angioplasty group
Stent vs surgical management	Mortality mixed results, relative reduction ranged from a 50% reduction in favor of CABG to a 75% reduction in favor of stenting MI rates at 1-y equivalent	15–25% rate of revascularization in stent group
OPCAB vs conventional surgical management	No difference in mortality No difference in in-hospital stroke No difference in in-hospital MI	Most OPCAB-treated patients received fewer grafts than CCAB group (0.2 fewer grafts per patient)

CABG, Coronary artery bypass grafting; *CCAB,* conventional coronary artery bypass; *LM,* left main coronary artery disease; *MI,* myocardial infarction; *OPCAB,* off-pump coronary artery bypass.

costs (hospital LOS, ICU LOS, blood transfusions) for each individual patient.

Medical Treatment Versus Surgical Management

Several large randomized trials examined the efficacy of medical versus surgical management in patients with symptomatic CAD (Table 37.4). Most trials were conducted between 1974 and 1984. A metaanalysis published in 1994 incorporated seven trials addressing medical versus surgical management with a 10-year follow-up.[167] Although surgical treatment and medical management have advanced since then (ie, only 9% of patients received internal mammary artery grafts), the findings clearly support the benefits of surgical treatment in high-risk patients. This study reviewed 2600 patients and observed an absolute risk reduction in mortality rates for patients undergoing CABG of 5.6% at 5 years, 5.9% at 7 years, and 4.1% at 10 years. This improvement was most marked in patients with left main CAD, proximal left anterior descending CAD, or triple-vessel CAD. The results tended to underestimate the benefits of surgical treatment because 37.4% of medically treated patients eventually underwent surgical procedures.

CABG procedures reduce mortality significantly compared with medical management alone. This benefit is significantly improved beyond 10 years. In addition, many patients who were initially treated medically eventually require surgical revascularization.

Balloon Angioplasty Versus Conventional Coronary Artery Bypass Graft Procedures

Numerous randomized trials compared percutaneous transluminal coronary angioplasty (PTCA) with CABG (see Chapters 3 and 20). One of the largest trials was the Bypass Angioplasty Revascularization Investigation (BARI), which enrolled 1829 patients who were randomized to undergo either PTCA or CABG.[168] The investigators found no significant differences in survival at both 1 and 5 years, with 5-year survival rates of 89.3% in the CABG group and 86.3% in PTCA group. The rates of in-hospital MI and stroke were greater in the CABG-treated patients compared with the PTCA group (4.6% and 2.1% for Q-wave MI, respectively; $P < 0.01$; 0.8% and 0.2% for stroke, respectively). For patients with diabetes, the 5-year survival rate was 80.6% in the CABG group compared with 65.5% in the PTCA group ($P = 0.003$). The need for repeated revascularization after initial intervention was greater in the PTCA group; at 5 years, only 8% of the patients assigned to CABG had undergone additional revascularization procedures, compared with 54% of those assigned to PTCA (31% of PTCA patients eventually underwent CABG). Several smaller randomized trials found similar results.[169,170]

A metaanalysis of randomized trials was published comparing PTCA with CABG for the management of symptomatic CAD. Thirteen trials involving 7964 patients were included.[171] The investigators reported a 1.9% absolute survival advantage favoring CABG over PTCA at 5 years ($P < 0.02$). No significant difference was noted at 1, 3, or 8 years. In subgroup analysis of patients with multivessel disease, CABG provided a significant survival advantage at both 5 and 8 years. Patients randomized to PTCA had more repeat revascularizations at all time points. This metaanalysis included some coronary stent trials, in which angina recurrence was reduced by 50% at 1 and 3 years, and the stent cohort had a significant decrease in nonfatal MI at 3 years compared with CABG.

These trials focused primarily on patients with multivessel disease. In patients with single-vessel left anterior descending CAD, few randomized trials have been conducted. One trial enrolled 134 patients randomized to PTCA or CABG. After 5 years, 6 patients (9%) had died in the PTCA group versus 2 (3%) in the CABG group (not significant). MI was more frequent after PTCA (15% vs 4%; $P = 0.0001$), but no differences were observed in the rates of Q-wave MI (6% in the PTCA group vs 3% in the CABG group; not significant). Repeat revascularization was required in significantly more patients assigned to the PTCA group (38% vs 9%; $P = 0.0001$).[172]

When compared with coronary angioplasty, CABG procedures reduce mortality rates at 5 years. CABG also reduces the need for additional revascularization procedures. This benefit is greatest in patients with multivessel disease or diabetes.

Stenting Versus Conventional Coronary Artery Bypass Graft Procedures

The SYNTAX trial, first published in 2009, randomized patients with left main CAD or three-vessel CAD to undergo either operation or PCI with a Taxus (Boston Scientific, Natick, Mass) drug-eluting stent. Overall, the study found similar outcomes at 5 years between patients who underwent stenting or surgical treatment, with slightly higher rates of stroke (1.5% vs 4.3%; hazard ratio: 0.33; 95% confidence interval [CI]: 0.12–0.92) in surgical patients. In patients with more complex lesions (as defined by a SYNTAX score >33), however, surgical treatment was clearly superior. The major adverse cardiac and cerebral events (MACCE) rate at 5 years in the cohort with a SYNTAX score greater than 33 was 29.7% for CABG versus 46.5% for PCI-treated patients (hazard ratio: 1.78; 95% CI: 1.21–2.63). This trial changed previously held beliefs in two ways. First, PCI was found to be suitable for patients with left main CAD, which was previously believed to be best managed surgically. Second, patients with three-vessel CAD and complex lesions did much better with surgical treatment than with PCI, for which previous data had been equivocal. For patients with less complex lesions (SYNTAX score <33) the MACCE outcome of death was higher for CABG, whereas revascularization was higher in PCI-treated patients, specifically the need for CABG.[173]

Off-Pump Coronary Artery Bypass Versus Coronary Artery Bypass Graft Procedures

The use of OPCAB techniques has increased in popularity. However, the net effect has been to see the technique become standard of care in some countries, such as India, while waning in popularity in others, such as in North America and Europe, where it has remained at approximately 20% to 30% of cases of CABG.[174] A comprehensive metaanalysis of randomized trials published in 2004 suggested that OPCAB reduces the rate of blood transfusion, AF, infections, and resource use (hospital LOS, ICU LOS, and ventilation time).[175] Unfortunately, the main hope of improvements in neurologic outcome, stroke, and cognitive

dysfunction has proved elusive. In addition, concern was raised over the quality of the anastomosis, especially in trials involving institutions that were low-volume or teaching OPCAB centers.[176,177] Concern has also been raised over the reduction in the number of grafts completed in the OPCAB arm of many randomized trials, a factor that may lead to a reduction in long-term survival.[178,179]

Taken together, the potential benefits of OPCAB procedures may rest with the experience of the center performing the procedure. As with many cardiac surgical procedures, this raises the issue of dedicated care teams to look after patients who require cardiac surgical interventions. Certain surgical approaches (no-touch aortic technique) or medical conditions (calcified ascending aorta) may make an OPCAB approach desirable. However, changing the surgical approach by itself may not reduce mortality or major morbidity rates in most patients.

Postoperative Cardiovascular Management

JERROLD H. LEVY, MD, FAHA, FCCM | KAMROUZ GHADIMI, MD | JAMES M. BAILEY, MD | JAMES G. RAMSAY, MD, PhD

KEY POINTS

1. Maintaining oxygen transport and oxygen delivery appropriately to meet the tissue metabolic needs is the goal of postoperative circulatory control.
2. Cardiac function worsens after cardiac surgical procedures. Therapeutic approaches to reverse this dysfunction are important and often can be discontinued in the first few postoperative days.
3. Myocardial ischemia often occurs postoperatively, and it is associated with adverse cardiac outcomes. Multiple strategies have been studied to reduce this complication.
4. Postoperative biventricular dysfunction is common. It requires interventions to optimize the heart rate and rhythm, provide acceptable preload, and adjust afterload and contractility. In most patients, pharmacologic interventions can be rapidly weaned or stopped within the first 24 hours postoperatively.
5. Supraventricular tachyarrhythmias are common in the first postoperative days, with atrial fibrillation predominating. Preoperative and immediate postoperative pharmacotherapy can reduce the incidence and slow the ventricular response.
6. Postoperative hypertension has been a common complication of cardiac surgical procedures; newer vasodilator drugs are more arterial selective and allow greater circulatory stability than older, nonselective drugs.
7. Catecholamines, phosphodiesterase inhibitors, and the calcium sensitizer levosimendan have been studied for treating biventricular dysfunction.
8. Phosphodiesterase inhibitors and levosimendan are clinically effective inodilators that have important roles in patients with low cardiac output and biventricular dysfunction.
9. Long cardiopulmonary bypass times may cause a refractory vasodilated state ("vasoplegia") requiring combinations of pressors such as norepinephrine and vasopressin.
10. Positive-pressure ventilation has multiple effects on the cardiovascular system, with complex interactions that should be considered in patients after cardiac surgical procedures.
11. Critical care management of patients undergoing transcatheter aortic valve replacement who have experienced intraoperative complications includes understanding and managing the postoperative consequences of iatrogenic vascular injuries, stroke, significant paravalvular leaks, and/or cardiac conduction abnormalities.
12. Hemodynamic management after cardiothoracic operations may benefit from the use of transesophageal echocardiography to determine myocardial function and assess cardiovascular structures. Echocardiography is particularly helpful in the diagnosis of causes of obstructive shock, including pericardial effusions leading to tamponade physiology.
13. Echocardiography during the daily management of both venovenous and venoarterial extracorporeal membrane oxygenation (ECMO) may improve diagnosis of hemodynamic instability, troubleshoot common problems encountered during ECMO management, and aid in weaning the patient from mechanical support.

Postoperative cardiovascular dysfunction is becoming more common as older and increasingly critically ill patients undergo cardiac surgical procedures. Biventricular dysfunction and circulatory changes occur after cardiopulmonary bypass (CPB), but they can also occur in patients undergoing off-pump procedures. Pharmacologic therapy with suitable monitoring and mechanical support may be needed for patients in the postoperative period until ventricular or circulatory dysfunction improves. This chapter reviews management considerations of patients with postoperative circulatory failure.

Oxygen Transport

Maintaining oxygen transport (ie, oxygen delivery [Do_2]) satisfactory to meet the tissue metabolic needs is the goal of postoperative circulatory control. Oxygen transport is the product of cardiac output (CO) times arterial content of oxygen (Cao_2) (ie, hemoglobin concentration × 1.34 mL of oxygen per 1 g of hemoglobin × oxygen saturation [Sao_2]), and it can be affected in many ways by the cardiovascular and respiratory systems, as shown in Fig. 38.1. Low CO, anemia from

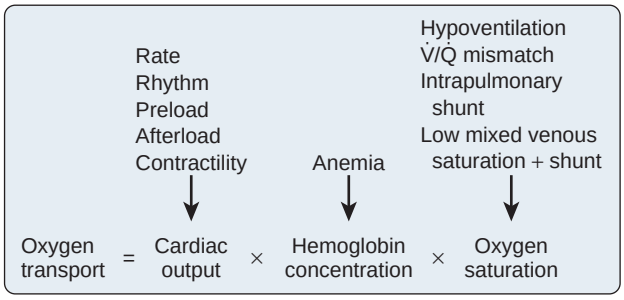

Fig. 38.1 Important factors that contribute to abnormal oxygen transport. $\dot{V}/\dot{Q}$, Ventilation/perfusion.

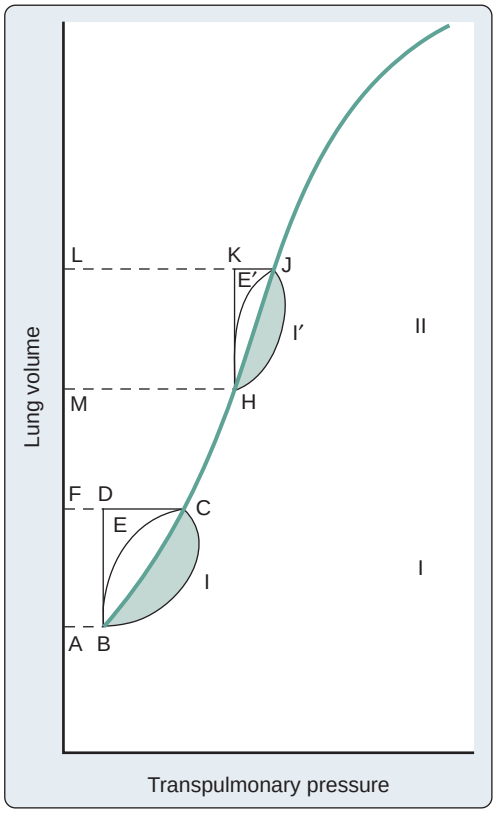

Fig. 38.2 Pressure-volume diagram of elastic and resistive (nonelastic) work done on noncompliant lungs. Breathing at ambient airway pressure and low lung volume (by T tube) *(I)* versus breathing with continuous positive airway pressure (CPAP) at increased lung volume *(II)*. *Solid line, BCHJ* is the elastic pressure-volume curve for the lung, determined by measuring transpulmonary pressures at the instant of zero flow. *Hatched areas* represent nonelastic work (*BIC* and *HI′J*), whereas elastic work is represented by *BCD* and *HJK*. With CPAP, both types of work are reduced. Without CPAP, the area *ABD*F is additional elastic work partly done by the patient and partly by elastic recoil of the chest wall, whereas with CPAP, the additional work represented by *MHKL* is mostly done by the CPAP system. *(From Katz JA, Marks JD. Inspiratory work with and without continuous positive airway pressure in patients with acute respiratory failure.* Anesthesiology. *1985;63:598.)*

blood loss, and pulmonary disease can decrease D_{O_2}. Before altering the determinants of CO, including the inotropic state of the ventricles, an acceptable hemoglobin concentration and adequate Sa_{O_2} should be provided, thus enabling increases in CO to supply the maximum available D_{O_2}. As hemoglobin concentration increases, so does blood viscosity and therefore the work of the heart to eject the blood. In normal hearts (eg, athletes), increasing hemoglobin levels to supranormal increases performance, a finding suggesting that in this setting the increased viscosity is less important than the elevated oxygen-carrying capacity.[1] This issue has not been examined in patients with cardiac disease. Model analysis of data from animal investigations suggested that maintenance of the hematocrit between 30% and 33% provides the best balance between oxygen-carrying capacity and viscosity.[2] This analysis also suggested that in ischemic states a hematocrit in this range may be desirable. Patients needing continued inotropic or mechanical support of ventricular function beyond the first few postoperative hours, especially patients in need of intravascular volume expansion, should probably be transfused to a hematocrit in this range, bearing in mind that blood transfusion has been associated with decreased organ function and increased mortality rates in critically ill patients. Randomized trials suggested that a transfusion threshold of 7 g, rather than 9 g, was associated with at least equivalent outcomes in critically ill patients who did not have acute myocardial infarction (MI) or unstable angina.[3–5] These studies did not identify cohorts of patients who had undergone cardiac surgical procedures. Wu and colleagues[5] found that transfusion for a hematocrit of 30% or lower in older patients with acute MI was associated with a better outcome. This study supports the concept that this is the desirable hematocrit especially in older cardiac surgical patients or in patients experiencing a complicated course.

Hypoxemia from any cause reduces D_{O_2}, and acceptable arterial oxygenation (partial arterial pressure of oxygen [Pa_{O_2}]) may be achieved with the use of an elevated inspired oxygen fraction (F_{IO_2}) or positive end-expiratory pressure (PEEP) in the ventilated patient. Use of PEEP or continuous positive airway pressure (CPAP) in the spontaneously breathing patient may improve Pa_{O_2} by reducing intrapulmonary shunt; however, venous return may be reduced, causing a decrease in CO, with DO_2 decreased despite an increased Pa_{O_2}.[6] It is important to measure CO as PEEP is applied. Intravascular volume expansion may be used to offset this damaging effect of PEEP[7] (see Chapter 39).

In patients with marginal arterial oxygenation, pulmonary function must be closely monitored to allow prompt therapy to be undertaken for abnormalities. Measurements of airway resistance and respiratory system compliance should be made. When resistance is increased, treatment of bronchospasm may improve the Pa_{O_2} and CO because decreases in intrathoracic pressure improve venous return. Treatment of lung overinflation may decrease pulmonary vascular resistance (PVR) and benefit right ventricular (RV) function.[8] If compliance is decreased, application of PEEP or CPAP may help promote reexpansion of atelectatic areas and move the tidal volume to a more compliant section of the pressure-volume relationship of the respiratory system[9] (Fig. 38.2). This approach reduces the work expended by the patient during spontaneous efforts and may reduce PVR.[10]

Unexplained hypoxemia may be caused by right-to-left intracardiac shunting, most commonly by a patent foramen ovale. This situation is most likely to occur when right-sided pressures are abnormally increased; an example is the use of high levels of PEEP.[11] If this condition is suspected, echocardiography should be performed, and therapy to reduce right-sided pressures should be initiated.

Patients with pulmonary disease may experience dramatic worsening of oxygenation when vasodilator therapy is started because of release of hypoxic vasoconstriction in areas of diseased lung.[12] Although CO may be increased, the worsening in Ca_{O_2} results in a decrease in D_{O_2}. Reduced doses of direct-acting vasodilators or trials of different agents may be indicated.

When D_{O_2} cannot be increased to an acceptable level as judged by decreased organ function or development of lactic acidemia, measures to decrease oxygen consumption ($\dot{V}_{O_2}$) may be taken while awaiting improvement in cardiac or pulmonary function. For example, sedation and paralysis may buy time to allow reversible postoperative myocardial dysfunction to improve.

Temperature

Patients are often admitted to the intensive care unit (ICU) after cardiac operations with core temperatures lower than 35°C, especially after off-pump cardiac surgical procedures. The typical pattern of temperature change during and after cardiac operations and the hemodynamic outcomes are illustrated in Fig. 38.3. Decreases in temperature after CPB occur in part because of redistribution of heat within the body and in part because of heat loss. Previous reports found that administration of nitroprusside and the use of high flows (>2.2 L/m^2 per min) during rewarming on CPB could improve the uniformity of rewarming and reduce this afterdrop from 4°C to approximately 2°C.[13] Monitoring of body sites other than the blood and brain (eg, urinary bladder, tympanic membrane temperatures) can help provide more complete rewarming, but the body temperature usually falls after CPB, especially when difficulties are encountered and the chest remains open for an extended period; in such cases, some degree of hypothermia is an almost unavoidable result.[14,15] Intraoperative use of forced-air warming blankets or cutaneous gel pads[16] can help reduce the temperature loss during and after surgical procedures.

The normal thermoregulatory and metabolic responses to hypothermia remain intact after cardiac operations and result in peripheral vasoconstriction that contributes to the hypertension commonly seen early in the ICU.[17] As temperature decreases, CO is decreased because of bradycardia, whereas oxygen consumed per beat is actually increased.[18] Coagulation, platelet, and immune functions are also impaired by hypothermia to potentiate postoperative bleeding and infection.[19–21] Another adverse consequence of postoperative hypothermia is a large increase in ($\dot{V}O_2$ and carbon dioxide production during rewarming.[22] When patients cannot increase CO (ie, DO_2), the effects of this large increase in ($\dot{V}O_2$ include mixed venous desaturation and metabolic acidosis. Unless end-tidal carbon dioxide is monitored or arterial blood gases are analyzed often to show the increased carbon dioxide production and to guide increases in ventilation, hypercarbia will occur, causing catecholamine release, tachycardia, and pulmonary hypertension.[23] The effects of rewarming are most intense when patients shiver.[24] Shivering may be effectively treated with meperidine, which lowers the threshold for shivering. Muscle relaxation may provide more stable hemodynamic conditions than meperidine, but accompanying sedation must be administered to avoid having an awake and paralyzed patient.[25,26]

As the temperature rises, usually to approximately 36°C, vasoconstriction and hypertension are replaced by vasodilation, tachycardia, and hypotension, even without hypercarbia. Often, over minutes, a patient who needs vasodilators for hypertension then requires vasopressors or large volumes of fluid for hypotension. Volume loading during the rewarming period can help to reduce the rapid swings in blood pressure (BP) that may occur. It is important to recognize when these changes result from changes in body temperature, to avoid attributing them to other processes that may call for different therapy.

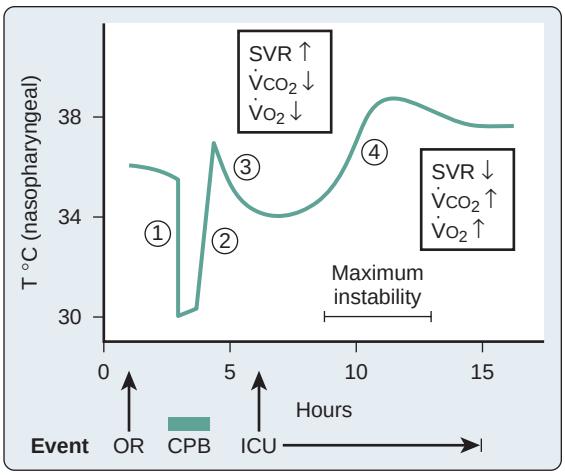

Fig. 38.3 Nasopharyngeal temperature during and after cardiac surgical procedures. *(1)* Core (ie, blood) cooling on cardiopulmonary bypass *(CPB). (2)* Core warming on CPB. *(3)* Afterdrop in temperature *(T)* after separation from CPB. *(4)* Rewarming after admission to the intensive care unit *(ICU).* Systemic vascular resistance *(SVR)* is increased, and carbon dioxide production *($\dot{V}CO_2$)* and oxygen consumption *($\dot{V}O_2$)* are decreased on admission to the ICU because of residual hypothermia. During rapid rewarming, SVR decreases and $\dot{V}CO_2$ and $\dot{V}O_2$ increase; these changes can cause marked cardiac and ventilatory instability. *OR,* Operating room. *(From Sladen RN. Management of the adult cardiac patient in the intensive care unit. In: Ream AK, Fogdall RP, eds.* Acute Cardiovascular Management: Anesthesia and Intensive Care. *Philadelphia: Lippincott; 1982:495.)*

Assessment of the Circulation

Physical Examination

Surgical dressings, chest tubes attached to suction, fluid in the mediastinum and pleural spaces, peripheral edema, and temperature gradients can distort or mask information obtained by the classic techniques of inspection, palpation, and auscultation in the postoperative period. However, the physician should not be deterred from applying these basic techniques in view of their potential benefit. Physical examination may be of great value in diagnosing gross or acute disease, such as pneumothorax, hemothorax, or acute valvular insufficiency, but it is of limited value in diagnosing and managing ventricular failure. For example, in the critical care setting, experienced clinicians (eg, internists) using only physical findings often misjudge cardiac filling pressures by a large margin.[27] Low CO in particular is not consistently recognized by clinical signs, and systemic BP does not correlate with CO after cardiac surgical procedures. Oliguria and metabolic acidosis, classic indicators of a low CO, are not always reliable because of the polyuria induced by hypothermia, oxygen debts induced during CPB that cause acidosis, and medications or fluids given during or immediately after bypass.[28]

Although clinicians are taught that the adequacy of CO can be assessed by the quality of the pulses, capillary refill, and peripheral temperature, no relationship exists between these indicators of peripheral perfusion and CO or calculated systemic vascular resistance (SVR) in the postoperative period.[29] By the first postoperative day, a crude correlation exists between peripheral temperature and cardiac index ($r = -0.60$). Many patients arrive in the ICU in a hypothermic state, and residual anesthetic agents can decrease the threshold for peripheral vasoconstriction in response to this condition.[30] A patient's extremities may therefore remain warm despite a hypothermic core or a decreasing CO. Even after temperature stabilization on the first postoperative day, the relationship between peripheral perfusion and CO is too crude to be used for hemodynamic management.

Invasive Monitoring

Concepts regarding invasive monitoring with a pulmonary artery catheter (PAC) have been modified as a result of several studies in a variety of settings that failed to show a benefit from PAC use. In addition, a poor relationship exists between filling pressures and end-diastolic volume, stroke volume (SV), or volume responsiveness. A review of patients admitted to medical ICUs in the United States demonstrated a reduction of more than 40% in PAC use from 1993–2004.[31] The same trend was evident in surgical patients, including those undergoing cardiac operations. PAC use also has decreased in cardiac surgical patients in many other countries. Greater availability of high-quality bedside echocardiography, often performed by intensivists, has made this modality a technique of choice in the postoperative period and has replaced or decreased PAC use in some centers. Measures of volume responsiveness in mechanically ventilated patients such as pulse pressure or SV variability (from arterial waveform analysis devices) are

widely recognized as more sensitive and specific indicators of the need for intravascular volume expansion than filling pressures.[32]

Despite the lack of a proven benefit with PAC use, many patients continue to have this monitor placed for cardiac surgical procedures. Cardiac anesthesiologists believe that the lack of evidence about the PAC may reflect the lack of a modern, well-designed randomized trial. That no such trials have been conducted in cardiac surgical patients probably attests to the reluctance of cardiac surgeons and anesthesiologists to manage their patients without what they consider to be important information. Postoperatively, many cardiac surgical centers do not have in-house physicians, and surgeons believe that the "objective" PAC data obtained over the telephone is valuable. As less invasive tools such as echocardiography or arterial waveform analysis devices become better known and more readily available, it seems likely that PAC use will diminish further in cardiac surgical patients.

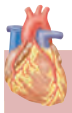
Specialized PACs permit continuous mixed venous oxygen saturation ($S\bar{v}O_2$) monitoring, continuous CO measurement, and calculation of RV volumes and ejection fraction (EF), or they have either imbedded electrodes or channels to pass atrial or ventricular pacing wires. The ability to pace through a PAC is particularly valuable in patients undergoing "minimally invasive" procedures in which the surgeon does not have adequate access to the heart to place epicardial leads. The $S\bar{v}O_2$ catheter helps evaluate the adequacy of DO_2 and allows continuous assessment of the response to therapy, which may affect DO_2 or $\dot{V}O_2$ (eg, PEEP therapy). The trend in the $S\bar{v}O_2$ may function as an early warning signal of worsening in the oxygen supply-demand relationship as DO_2 falls or $\dot{V}O_2$ increases. In the postoperative period, the $S\bar{v}O_2$ does not correlate with CO, because CO is only one of the factors in the oxygen supply-demand relationship.[33]

Echocardiography

Echocardiography is the technique of choice for acute assessment of cardiac function. Just as transesophageal echocardiography (TEE) has become essential for intraoperative management in various conditions, several studies document its utility in the postoperative period in the presence and absence of the PAC.[34–38] It provides information that may lead to urgent surgery or prevent unnecessary surgery, gives important information about cardiac preload, and can detect acute structural and functional abnormalities. Although transthoracic echocardiography (TTE) can be performed more rapidly in this setting, satisfactory images can be obtained only in about 50% of patients in the ICU[39] (see Chapters 14–16). A small lumen single plane disposable echocardiography device, Imacor, has been developed for use up to 72 hours for ICU management (see later).

Postoperative Myocardial Dysfunction

Studies using hemodynamic, nuclear scanning, and metabolic techniques have documented worsening in cardiac function after coronary artery bypass grafting (CABG) procedures.[40–53] Although improvements in myocardial protection, surgical techniques, and operative care have been reported, similar incidences of early biventricular dysfunction (90%) were reported between 1979 and 1990. All these studies showed significant declines in left ventricular (LV) or biventricular (when measured) function in the first postoperative hours, with a gradual return to preoperative values by 8 to 24 hours. In one study, this decline was evident only in one-half of the patients,[44] but in the other studies, more than 90% of patients showed at least a transient decrease in function. Decreased ventricular performance at normal or elevated filling pressures occurs, suggesting decreased contractility. Similarly, "flattening" of the ventricular function curves is usually obvious; this finding suggests that preload expansion greater than 10 mm Hg for central venous pressure (CVP) or 12 mm Hg for pulmonary capillary wedge pressure (PCWP) is of little benefit. In the classic study by Mangano,[45] patients with an LVEF of less than 0.45 or ventricular dyssynergy showed more marked and prolonged dysfunction than did those patients with normal ventricles.



BOX 38.1 RISK FACTORS FOR LOW CARDIAC OUTPUT SYNDROME AFTER CARDIOPULMONARY BYPASS

- Preoperative left ventricular dysfunction
- Valvular heart disease requiring repair or replacement
- Long aortic cross-clamp time and total cardiopulmonary bypass time
- Inadequate cardiac surgical repair
- Myocardial ischemia and reperfusion
- Residual effects of cardioplegia solution
- Poor myocardial preservation
- Reperfusion injury and inflammatory changes

Satisfactory myocardial protection is important to prevent postoperative dysfunction. In off-pump surgical procedures, the idea is to preserve coronary perfusion, but during mechanical manipulation, changes in CO and BP occur. For CABG with CPB, most surgeons use some combination of hypothermia and crystalloid or blood cardioplegia to arrest the heart and reduce its metabolism. Although little consensus exists that any one technique is preferable in all circumstances, cold intermittent crystalloid cardioplegia with systemic hypothermia is the most widely used technique clinically. Salerno and associates[54] recommended continuous, warm, retrograde blood cardioplegia without systemic hypothermia, and Mullen and colleagues[50] suggested that blood cardioplegia had at least a short-term benefit with less myocardial damage and better function; however, other studies of blood cardioplegia have had mixed results[47–52] (see Chapters 31 and 32).

Other proposed factors that contribute to postoperative ventricular dysfunction include myocardial ischemia,[55] residual hypothermia,[46,47] preoperative medications such as β-adrenergic antagonists,[53] and ischemia-reperfusion injury (Box 38.1). Inflammatory cell activation from cytokine generation, upregulation of neutrophil adhesion molecules with neutrophil activation, oxygen free radical formation, and lipoperoxidation after ischemia-reperfusion injury may be important pathways accounting for the dysfunction. Multiple studies showed the importance of limiting myocardial ischemia-reperfusion injury.[56,57] Briesblatt and associates[40] observed the timing of ventricular dysfunction and showed that recovery after CPB for CABG was similar to what had been suggested in animal models of reperfusion injury.[58–60] This nadir at 4 hours corresponds to the peak in cytokine levels. Cytokines can release nitric oxide (NO) from endothelium that produces myocardial depression. Studies evaluating complement inhibition with pexelizumab in improving outcomes described a novel strategy that unfortunately was never approved despite promising results[61] (see Chapter 9).

Postoperative Myocardial Ischemia

Although intraoperative myocardial ischemia has often been a focus, studies showed that ischemia frequently occurs postoperatively and is associated with adverse cardiac outcomes. Leung and colleagues[55] found the electrocardiographic (ECG) and segmental wall motion abnormality (SWMA) evidence of ischemia early postoperatively in up to 40% of patients undergoing CABG procedures. Postbypass SWMAs were significantly associated with adverse outcomes (eg, MI, death) (Fig. 38.4). Surprisingly, these abnormalities most often appeared in the regions of the heart that had been revascularized. Hemodynamic changes rarely preceded ischemia; however, postoperative heart rates (HRs) were, as reported in other studies, significantly higher than intraoperative or preoperative values. Jain and associates[62] found major ECG changes in the 8 hours after cross-clamp release in 58% of CABG-treated patients, and these changes were independent predictors of perioperative MI. Whether such changes occur because of operation and reperfusion or as a result of events after CPB is not known. These

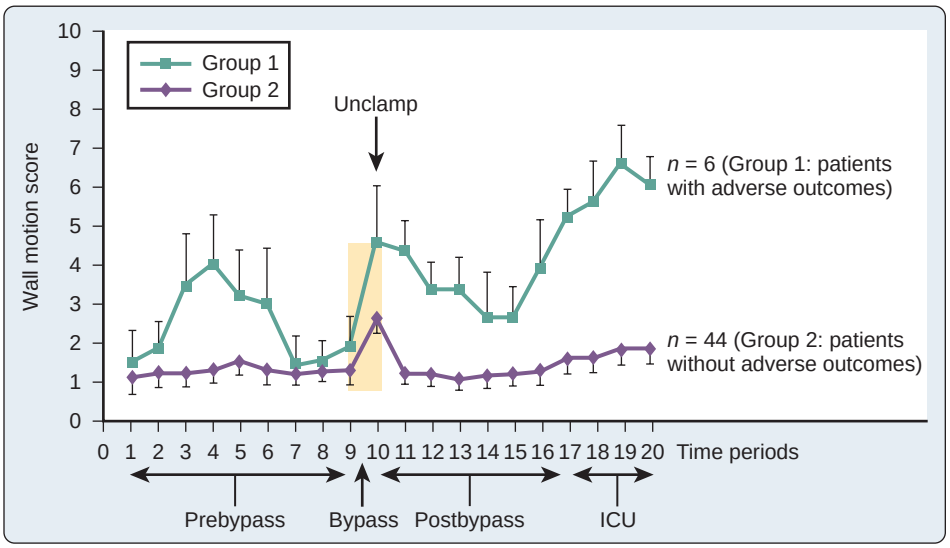


Fig. 38.4 Sequential changes in wall motion score, as measured by transesophageal echocardiography, in patients undergoing elective coronary artery bypass grafting. Score is defined as follows: 0, normal; 1, mild hypokinesis; 2, severe hypokinesis with myocardial thickening; 3, akinesis; and 4, dyskinesis. Adverse outcomes were myocardial infarction, death, or congestive heart failure. The time periods were as follows: 1, after tracheal intubation; 2, before incision; 3, after incision; 4, before sternotomy; 5, after sternotomy; 6 and 7, internal mammary dissection; 8, after pericardiotomy; 9, immediately before bypass; 10, unclamping of aortic side clamp; 11 to14, off bypass; 15, after chest closure; 16, skin closure; 17 to 20, intensive care unit *(ICU)* for the first 4 hours. The *shaded area* indicates the bypass period. *(From Leung JM, O'Kelly B, Browner WS, et al. Prognostic importance of postbypass regional wall motion abnormalities in patients undergoing coronary artery bypass graft surgery.* Anesthesiology. *1989;71:16.)*

findings do suggest that monitoring for ischemia must continue after revascularization. It may be that early recognition and treatment of ischemia or prophylactic medication can help prevent or reduce myocardial ischemia and dysfunction after CABG procedures (see Chapters 7, 11–15, and 20).

Early recovery, or fast-tracking, of the cardiac surgical patient has led to some concern that ischemia will occur as patients awaken early after the operation in pain, especially because Mangano and colleagues[63] showed that sedation with a sufentanil infusion could reduce ischemia in this period. A randomized study by Cheng and associates[64] reduced this concern because awakening and extubation within 6 hours of CABG were not associated with more creatine kinase MB isoenzyme (CK-MB) release or ECG changes than overnight ventilation. Wahr and colleagues[65] showed that even with the use of propofol sedation, hemodynamic episodes (significant changes in HR and BP) are common in the 12 hours after surgical procedures, and ST-segment changes occur in 12% to 13% of patients.

Therapeutic Interventions

Therapeutic interventions for postoperative biventricular dysfunction include the standard concerns of managing low-CO states by controlling the HR and rhythm, providing an acceptable preload, and adjusting afterload and contractility. In most patients, pharmacologic interventions can be rapidly weaned or stopped within the first 24 hours postoperatively.

Postoperative Arrhythmias

Patients with preoperative or newly acquired noncompliant ventricles need a correctly timed atrial contraction to provide satisfactory ventricular filling, especially when they are in sinus rhythm preoperatively. Although atrial contraction provides approximately 20% of ventricular filling, this may be more important in postoperative patients, when ventricular dysfunction and reduced compliance may be present. For example, in medical patients with acute MI, atrial systole contributed 35% of the SV.[66] The SV is often relatively fixed in patients with ventricular dysfunction, and the HR is an important determinant of CO. Rate and rhythm disorders must be corrected when possible, using epicardial pacing wires. Approaches to postoperative rate and rhythm disturbances are shown in Table 38.1. The use of a PAC with atrial or ventricular pacing electrodes or lumina for pacing wires can facilitate

TABLE 38.1 Postoperative Rate and Rhythm Disturbances

Disturbance	*Usual Causes*	*Treatments*
Sinus bradycardia	Preoperative or intraoperative β-blockade	Atrial pacing, β-agonist, anticholinergic
Heart block (first, second, and third degree)	Ischemia Surgical trauma	Atrioventricular sequential pacing Catecholamines
Sinus tachycardia	Agitation or pain Hypovolemia Catecholamines	Sedation or analgesia Volume administration Change or discontinuance of drug
Atrial tachyarrhythmias	Catecholamines Chamber distention Electrolyte disorder (hypokalemia, hypomagnesemia)	Change or discontinuance of drug Treatment of underlying cause (eg, vasodilator, diuresis, potassium or magnesium administration) May require synchronized cardioversion or pharmacotherapy
Ventricular tachycardia or fibrillation	Ischemia Catecholamines	Cardioversion Treat ischemia, may require pharmacotherapy Change or discontinuance of drug

temporary pacing if epicardial wires are not functioning. Failing that, temporary transvenous pacing wires can be placed if needed, and they are often required with the increasing use of minimally invasive cardiac surgical techniques (see Chapters 5 and 21).

Later in the postoperative period (days 1 through 3), supraventricular tachyarrhythmias become a major problem, with atrial fibrillation (AF) predominating. The overall incidence is between 30% and 40%, but with increasing age and valvular surgical procedures, the incidence may be in excess of 60%.[67] Many reasons are recognized for this development, including inadequate intraoperative atrial protection, electrolyte abnormalities, change in atrial size with fluid shifts, epicardial inflammation, stress, irritation, and genetic factors.[68] Randomized trials of off-pump CABG found a similar incidence of postoperative AF compared with on-pump CABG.[69,70]

Advanced age, a history of AF, and valvular heart operations are the most consistently identified risk factors for AF.[68] Because AF is difficult to treat and potentially increases the duration and cost of hospitalization, great interest has been expressed in effective therapy and prophylaxis.[67] Many studies showed that β-blockade significantly reduces the incidence of postoperative AF and that withdrawal of β-blockers in patients receiving them preoperatively is an important risk factor. Guidelines published by the American Heart Association, the American College of Cardiology, and the North American Society of Pacing and Electrophysiology recommended administration of β-blockers to prevent postoperative AF if the patient has no contraindications to this therapy.[71] Sotalol, which has some class III actions, is also effective[72] (see Chapters 4, 5, and 11).

Multiple studies examined the use of amiodarone for prophylaxis or treatment. Intravenous amiodarone is most often used in clinical practice because "acute" loading with oral therapy is often not feasible. Two pivotal studies of amiodarone deserve mention.

In the PAPABEAR (Prophylactic Oral Amiodarone for the Prevention of Arrhythmias That Begin Early After Revascularization, Valve Replacement, or Repair) study, oral amiodarone (10 mg/kg daily) or placebo was given from 6 days before the operation through 6 days postoperatively (13 days).[73] Atrial tachyarrhythmias occurred in fewer amiodarone-treated patients (48 of 299; 16.1%) than in placebo-treated patients (89 of 302; 29.5%) overall; in patients younger than 65 years of age (19 [11.2%] vs 36 [21.1%]; in patients >65 years old (28 [21.7%] vs 54 [41.2%]); in patients who had CABG only (22 [11.3%] vs 46 [23.6%]); in patients who had valve replacement or repair (25 [23.8%] vs 44 [44.1%]); in patients who received preoperative β-blocker therapy (27 [15.3%] vs 42 [25.0%]); and in patients who did not receive preoperative β-blocker therapy (20 [16.3%] vs 48 [35.8%]), respectively. Postoperative sustained ventricular tachyarrhythmias also occurred less frequently in amiodarone-treated patients (1 of 299; 0.3%) than in placebo-treated patients (8 of 302; 2.6%) ($P = .04$).

In another study, Guarnieri and associates[74] evaluated 300 patients randomized in a double-blind fashion to intravenous amiodarone (1 g/day for 2 days) or to placebo immediately after cardiac surgical procedures. The primary end points of the trial were incidence of AF and length of hospital stay. AF occurred in 67 (47%) of 142 patients receiving placebo versus 56 (35%) of 158 patients receiving amiodarone ($P = .01$). Length of hospital stay for the placebo-treated group was 8.2 ± 6.2 days, and it was 7.6 ± 5.9 days for the amiodarone-treated group.

After AF or other supraventricular arrhythmias develop, treatment is often urgently needed for symptomatic relief or hemodynamic benefit. The longer a patient remains in AF, the more difficult it may be to convert the rhythm, and the greater is the risk for thrombus formation and embolization.[68,72] Treatable underlying conditions such as electrolyte disturbances or pain should be corrected while specific pharmacologic therapy is being instituted. Paroxysmal supraventricular tachycardia (uncommon in this setting) can be abolished or converted to sinus rhythm by intravenous adenosine, and atrial flutter can sometimes be converted by overdrive atrial pacing with temporary wires placed at the time of operation. Electrical cardioversion may be needed if hypotension is caused by the rapid HR; however, atrial arrhythmias tend to recur in this setting.[67] Rate control for AF or atrial flutter can be achieved with various atrioventricular nodal blocking drugs, and conversion is facilitated by many of these drugs as well. Table 38.2 summarizes the various treatment modalities for supraventricular arrhythmias. If conversion to sinus rhythm does not

TABLE 38.2 Treatment Modalities for Supraventricular Arrhythmias

Treatment	*Specifics*[a]	*Indications*
Overdrive pacing by atrial wires[b]	Requires rapid pacer (≤800/min); start above arrhythmia rate and slowly decrease	PAT, atrial flutter
Adenosine	Bolus dose of 6–12 mg; may cause 10 s of complete heart block	AV nodal tachycardia, bypass-tract arrhythmia, atrial arrhythmia diagnosis
Amiodarone	150 mg IV over 10 min, followed by infusion	Rate control or conversion to NSR in atrial fibrillation or flutter
β-Blockade	Esmolol, up to 0.5 mg/kg load over 1 min, followed by infusion if tolerated	Rate control or conversion to NSR in atrial fibrillation or flutter
	Metoprolol, 0.5–5 mg, repeat effective dose q4–6h	Rate control or conversion to NSR in atrial fibrillation or /flutter
	Propranolol, 0.25–1 mg; repeat effective dose q4h[c]	
	Labetalol, 2.5–10 mg; repeat effective dose q4h[c]	Conversion of atrial fibrillation or flutter to NSR
	Sotalol, 40–80 mg PO q12h	Conversion of PAT to NSR
Ibutilide	1 mg over 10 min; may repeat after 10 min	Rate control or conversion to NSR in atrial fibrillation or flutter
Verapamil	2.5–5 mg IV, repeated PRN[c]	
Diltiazem	0.2 mg/kg over 2 min, followed by 10–15 mg/h[d]	Rate control or conversion to NSR in atrial fibrillation or flutter
Procainamide	50 mg/min up to 1 g, followed by 1–4 mg/min	Rate control or conversion to NSR in atrial fibrillation or flutter, prevention of recurrence of arrhythmias, treatment of wide-complex tachycardias[e]
Digoxin[f]	Load of 1 mg in divided doses over 4–24 h[g]; may give additional 0.125-mg doses 2 h apart (3–4 doses)	Rate control or conversion to NSR in atrial fibrillation or flutter
Synchronized cardioversion	50–300 J (external); most effective with anterior-posterior patches	Acute tachyarrhythmia with hemodynamic compromise (usually atrial fibrillation or flutter)

[a]See specific drug monographs for full descriptions of indications, contraindications, and dosages. Doses are for intravenous administration; use the lowest dose, and administer slowly in patients with hemodynamic compromise.
[b]Verify that the pacer is not capturing the ventricle.
[c]Infusion may provide better control. This drug is less useful than diltiazem because of myocardial depression.
[d]Limited experience; may cause less hypotension than verapamil.
[e]When diagnosis is unclear (ventricular versus supraventricular) and no acute hemodynamic compromise is present (ie, cardioversion not indicated).
[f]Less useful than other drugs because of its slow onset and modest effect.
[g]Rate of administration depends on the urgency of rate control.
AV, Atrioventricular; *IV,* intravenously; *NSR,* normal sinus rhythm; *PAT,* paroxysmal atrial tachycardia; *PO,* orally; *PRN,* as needed.

occur, electrical cardioversion in the presence of antiarrhythmic drug therapy should be attempted, or anticoagulation should be started.

In summary, AF is a frequent complication of cardiac surgical procedures, but the incidence can be significantly reduced with suitable prophylactic therapy. β-Adrenergic blockers should be administered to patients without contraindication to this treatment, and prophylactic amiodarone can be considered for patients at high risk for postoperative AF. Patients who are poor candidates for β-blockade may not tolerate sotalol, whereas amiodarone does not have this limitation. Further studies need to be performed to assess the role of prophylactic therapy in off-pump cardiac operations more definitively. After AF occurs, the incidence of recurrence is high, so continuing treatment with specific pharmacologic therapy is usually necessary.

Preload

The Frank-Starling law states that myocardial work increases as the resting length of the myocardial fiber increases.[75] In vivo, this implies that SV will increase with increasing end-diastolic volume, although at a certain limit SV reaches a plateau (and possibly decreases), with further increases in end-diastolic volume resulting from excessive muscle stretch. In the normal myocardium, the Frank-Starling mechanism is the most important mechanism for increasing CO, and hypovolemia is a common cause of decreased CO and hypotension in the postoperative period. Assessment of preload is probably the single most important clinical skill for managing hemodynamic instability. Preload rapidly changes in the postoperative period because of bleeding, spontaneous diuresis, vasodilation during warming, the effects of positive-pressure ventilation and PEEP on venous return, capillary leak, and other causes.

Direct assessment of preload is clinically feasible using echocardiography. Several studies have demonstrated a fair-to-good correlation between echocardiographic and radionuclide measures of end-diastolic volume and a good correlation between end-diastolic area measured by TEE and SV.[76–79] Although the use of echocardiography to assess preload must always be tempered by the realization that the clinician is viewing a two-dimensional image of a three-dimensional object, this is the most direct technique clinically available. Greater awareness of the value of TEE in the ICU and increased availability of echocardiography in general have made this modality a first choice for the assessment of preload in the setting of acute unexplained or refractory hypotension. Without echocardiography, pressure measurements are used as surrogates for volume measurements. For example, in the absence of mitral valve disease, left atrial pressure (LAP) is almost equal to LV end-diastolic pressure (LVEDP), and pulmonary artery occlusion pressure (PAOP) is almost equivalent to these two pressures. In patients without LAP catheters, the PAOP or the pulmonary artery diastolic pressure is used (see Chapters 6 and 13).

The use of PAOP as a measure of preload may be misleading in various settings, including after cardiac operations, when changes in pressure may not accurately reflect changes in ventricular end-diastolic volume. Previous studies by Ellis and colleagues[80] and Calvin and associates[81] suggested that fluid therapy in postoperative patients could cause a large increase in LV end-diastolic volume (LVEDV), with minimal or no change in PAOP. Mangano and colleagues[45,82] reported that fluid loading after CPB can uncover LV dysfunction, and these investigators also showed that little benefit is derived from exceeding a PAOP of approximately 12 mm Hg. Whether an elevated PAOP is secondary to an open pericardium, which allows overdistention of the left ventricle, the use of PEEP causing RV distention, or other factors is unclear. Briesblatt and associates[83] evaluated changes in ventricular pressure-volume relationships after CABG procedures while keeping a low-to-normal PAOP (10–15 mm Hg). The increase seen in LVEDV was not significant enough to explain the degree of ventricular dysfunction these investigators noted. Bouchard and colleagues[84] compared ventricular performance assessments from the PAC (ie, LV stroke work index [LVSWI]) with fractional area change and regional wall motion score index from TEE in 60 patients during and after cardiac surgical procedures. These investigators found no correlation between LVSWI and fractional area change and postulated that changes in ventricular compliance, loading conditions, and ventricular function alter the pressure-volume relationship of the left ventricle in a manner that leads to discordant interpretations between the two techniques.

When ventricular compliance is normal and the ventricle is not distended, small changes in end-diastolic volume are usually accompanied by small changes in end-diastolic pressure. In patients with noncompliant ventricles from preexisting congestive heart failure (HF), chronic hypertrophy resulting from hypertension or valvular disease, postoperative MI, or ventricular dysfunction, small increases in ventricular volume may produce rapid increases in end-diastolic pressure that require therapeutic intervention.[83–89] Increased intraventricular pressure elevates myocardial oxygen demand ($M\dot{V}O_2$) and decreases subendocardial coronary artery blood flow.[90] Myocardial ischemia may be the result. Elevations in LVEDP are transmitted to the pulmonary circulation, thus causing congestion and possibly hydrostatic pulmonary edema. Although PAOP or LAP may not always show true preload, good reasons exist to monitor them. The periods when patients are at particular risk for elevations in end-diastolic pressure include awakening, endotracheal suctioning, and rapid-volume resuscitation. If myocardial ischemia or acute HF occurs, sudden increases in the end-diastolic pressure may result.

Many drugs may be used to reduce cardiac preload. Direct-acting vasodilators, especially nitroglycerin, increase venous capacitance and thus decrease end-diastolic volume and pressure.[87–91] Intravenous furosemide, besides its diuretic effect, increases venous capacitance.[92] Diuretics are important to help remove the fluid that is mobilized in the days after surgical procedures. In patients who may not tolerate the acute volume loss that is induced by the loop diuretics, a furosemide infusion allows more gradual diuresis. Such infusions have been shown to be effective in patients with renal dysfunction.[93,94] In a patient who appears refractory to diuresis, it is important to evaluate the circulatory state. Such refractoriness may suggest that a renal insult has occurred, but it may also suggest renal underperfusion. In the latter case, the preload must be kept at the upper range of normal, and CO should be augmented.

A therapeutic agent previously used for acute decompensated left-sided HF was recombinant B-type natriuretic peptide (nesiritide). The mechanism of action occurs at specific cell-surface receptors, stimulation of which increases levels of intracellular cyclic guanosine monophosphate (cGMP). The physiologic effects are mainly vasodilation, natriuresis, and renin inhibition, which result is balanced vasodilation, reducing preload and afterload while simultaneously increasing SV and CO and promoting diuresis.[95] Nesiritide use in high-risk cardiac surgical patients with poor LV function improved renal function and decreased 6 month mortality in the NAPA (Nesiritide Administered Peri-Anesthesia in Patients Undergoing Cardiac Surgery) study.[96] A related drug, human atrial natriuretic peptide, was shown in a small, randomized trial to reduce the need for dialysis and to improve dialysis-free survival after complicated cardiac operations.[97] Further investigations of these drugs are needed in cardiac surgical patients.

Angiotensin-converting enzyme inhibitors can also cause venodilation and reduce preload. Alternatively, opioids or benzodiazepines, or both, used to reduce endogenous catecholamine release, should be considered in the patient who requires mechanical ventilation. Morphine causes histamine release, which directly induces venodilation. In the patient with oliguria and renal failure who has fluid overload, peritoneal dialysis, hemodialysis, or continuous hemofiltration may be needed.[98,99]

Contractility

Contractility is a well-defined concept in vitro, where it can be measured by the velocity of shortening of isolated muscle strips. However, quantifying the contractility of the intact heart has been complicated by the difficulty of finding a variable to measure contractility that is also independent of preload and afterload. The pioneering work of

Sagawa[100] and Suga and colleagues[101] showed that contractility can be measured by the end-systolic elastance of the ventricle, defined as follows:

$$E_{ES} = P_{ES}/(V_{ES} - V_0)$$

in which P_{ES} is the end-systolic pressure, V_{ES} is the end-systolic volume, and V_0 is a dead-space term.

E_{ES} is strictly determined by evaluating ventricular pressure-volume loops for different preloads or afterloads and by defining end-systole as the point in time at which the time-varying elastance is maximal.[102] The slope of the line connecting the points at end-systole is E_{ES}. This parameter varies with changes in inotropic state, but it is *nearly* independent of preload and afterload. Routine measurement of end-systolic elastance is not clinically feasible. However, consideration of the foregoing definition underscores the utility of TEE for the qualitative evaluation of contractility in the clinical setting. A decrease in contractility is manifested as some combination of a decrease in pressure or an increase in V_{ES} (ie, a decrease in SV). End-systolic volume can be estimated using TEE. A large V_{ES} (implying a low EF) with a low or normal BP suggests a low value for E_{ES} and poor contractility. If BP is high, a large value of V_{ES} may be seen even if contractility is normal. By interpreting end-diastolic volume, end-systolic volume, and EF in the context of BP, an assessment of contractility is possible with TEE (see Chapters 6 and 14–16).

An alternative measure of contractility is the preload-recruitable stroke work, which is the slope of the line relating stroke work to preload.[103] In the ICU, it is often estimated by the extent of the increase in CO that accompanies an increase in preload and is not dependent on the availability of TEE. If preload is increased by a change in the patient's position, BP can be a surrogate for CO because it is unlikely that SVR will change in the short time needed for the position change. A change in BP therefore is proportional to the change in CO.

Therapy for decreased contractility should be directed toward correcting any reversible causes, such as myocardial depressants, metabolic abnormalities, or myocardial ischemia. If the cause of depressed myocardial contractility is irreversible, positive inotropic agents may be necessary to keep CO satisfactory to support organ function (see Chapters 6, 11, and 36).

Afterload

Afterload is a concept that is well defined in vitro, where it refers to the added tension imposed on isolated muscle strips with contraction, but it is more difficult to define in vivo. In analogy with in vitro studies, afterload can be equated with ventricular wall stress, expressed as the product of cavity radius times transmural pressure divided by wall thickness, as described by the law of Laplace. However, many investigators find this definition unsatisfactory because it implies that the heart generates its own afterload and because afterload would be viewed as changing during the cardiac cycle.[104] If afterload is viewed as the external forces opposing ejection, possibly the best definition is the aortic input impedance, the complex ratio of pressure to flow, expressed in terms of magnitude, and the phase angle between flow and pressure for any given frequency. However, it has been difficult to analyze the impact of impedance on overall cardiac performance quantitatively (see Chapter 6). Therefore, Sunagawa and associates[105] proposed a simplified theory of ventricular-vascular coupling within the framework of the end-systolic pressure-volume relationship. Using the definition of end-systolic elastance produces the following:

$$E_{ES} = P_{ES}/(V_{ES} - V_0)$$

Equating SV with $V_E - V_{ES}$ (ignoring the difference between end-ejection and end-systole), it is a matter of algebra to show that

$$P_{ES} = E_{ES}(V_{ED} - V_0) - E_{ES} \cdot SV$$

This means that an increase in SV implies a decrease in P_{ES}. The interpretation of this statement from the cardiac perspective is that the work that can be done is finite and that a greater SV can be achieved only by lowering the end-systolic pressure, if contractility (E_{ES}) is fixed. At the same time, it is known that from the perspective of the vasculature, if SV increases, BP increases when vascular tone does not change.

The application of an electrical law describing constant voltages and flows to the circulation, in which pulsatile flow is generated by a pump, resulted in estimates of afterload that are questionable.[104] Although SVR is a component of impedance, it cannot be equated with it. The correct downstream pressure is probably not the CVP.[106] Instead, a critical opening pressure should be used in calculating SVR, and this pressure is not measurable in routine clinical care.[106] Clinical use of such calculated resistances is made complex by the relation of CO to body size; the normal resistance of a small patient is much higher than that of a large patient. A resistance index (ie, using cardiac index instead of CO) partly overcomes this problem, but it is not widely used.

Calculated SVR continues to be used in guiding therapy or drawing conclusions about the state of the circulation. This should be done only cautiously, if at all. SVR is not a complete indicator of afterload. Even if SVR were an accurate measure of impedance, the response to vasoactive agents depends on the coupling of ventricular-vascular function, not on impedance alone. Hemodynamic therapy should be guided based on the primary variables, BP and CO. If preload is appropriate, conditions of both low BP and low CO are treated with an inotropic drug. If BP is acceptable (and preload appropriate) but CO is low, a vasodilator alone or in combination with an inotropic drug is used. If the patient is hypertensive (with low CO), vasodilators are indicated; if the patient is vasodilated (low BP and high CO), vasoconstrictors are employed (Table 38.3).

TABLE 38.3 Hemodynamic Therapy Guidelines

Blood Pressure	*Cardiac Output*	*Treatment*
Low	Low	Inotrope
Normal	Low	Vasodilator with or without inotrope
High	Low	Vasodilator
Low	High	Vasopressor

Postoperative Hypertension

Hypertension has been a common complication of cardiac surgical procedures, and it was reported to occur in 30% to 80% of patients from studies in the 1970s when CABG was common in patients with normal ventricular function.[107–109] The current population of older, sicker patients appears to have fewer problems with hypertension than with low-output syndromes or vasodilation. Although hypertension most commonly occurs in patients with normal preoperative ventricular function, following aortic valve replacement or with a previous history of increased BP, any patient may develop hypertension. Multiple reasons contribute to postoperative hypertension, including preoperative hypertension, preexisting atherosclerotic vascular disease, awakening from general anesthesia, increases in endogenous catecholamines, activation of the plasma renin-angiotensin system, neural reflexes (eg, heart, coronary arteries, great vessels), and hypothermia.[110] Arterial vasoconstriction with various degrees of intravascular hypovolemia is the hallmark of perioperative hypertension.

The hazards of untreated postoperative hypertension include depressed LV performance, increased $M\dot{V}O_2$, cerebrovascular accidents, suture line disruption, MI, rhythm disturbances, and increased bleeding.[108,111,112] Historically, therapy for hypertension in cardiac surgery was sodium nitroprusside because of its rapid onset and short duration of action.[113] With multiple vasodilators available in the current era, sodium nitroprusside is no longer the drug of choice for many reasons. Nitroprusside is a potent venodilator, increasing venous capacitance (decreasing preload), and it can produce precipitous decreases in BP. Nitroprusside also can cause coronary arteriolar dilation with the potential for a steal phenomenon, resulting in

TABLE 38.4 Novel Vasodilators

Drug	*Mechanism of Action*	*Half-Life*
Nicardipine	Calcium channel blocker	Intermediate
Clevidipine	Calcium channel blocker	Ultrashort
Fenoldopam	Dopamine$_1$-agonist	Ultrashort
Nesiritide	Brain natriuretic agonist	Short
Levosimendan	K^+_{ATP} channel modulator	Intermediate

K^+_{ATP}, Adenosine triphosphate–sensitive potassium channel.

myocardial ischemia.[114] In patients with renal failure, the elimination of nitroprusside is reduced, potentially leading to toxic effects of its metabolites cyanide or thiocyanate. This effect also can occur if large doses are given to patients with normal renal function.

Many pharmaceutical alternatives to nitroprusside are available for treating hypertension after cardiac surgical procedures, including nitroglycerin,[115] β-adrenergic blockers,[116] and the mixed α- and β-adrenergic blocker labetalol.[117] Direct-acting vasodilators, dihydropyridine calcium channel blockers (eg, , nicardipine,[118] isradipine,[119] clevidipine[120–123]), angiotensin-converting enzyme inhibitors,[113] and fenoldopam (a dopamine$_1$ [D_1] receptor agonist)[124,125] also have been used. Novel therapeutic approaches are listed in Table 38.4.

Dihydropyridine calcium channel blockers are particularly effective in cardiac surgical patients because these drugs they relax arterial resistance vessels without negative inotropic actions or effects on atrioventricular nodal conduction and provide important therapeutic options. Dihydropyridines are arterial-specific vasodilators of peripheral resistance arteries that cause generalized vasodilation, including the renal, cerebral, intestinal, and coronary vascular beds. In doses that effectively reduce BP, the dihydropyridines have little or no direct negative effect on cardiac contractility or conduction. Although the dihydropyridines are more vasoselective than verapamil and diltiazem, differences exist among dihydropyridines in this respect. Nifedipine is the least vasoselective of the dihydropyridines, isradipine and clevidipine are the most selective, and nicardipine and nimodipine are intermediately selective.[126,127] Nicardipine is an important therapeutic agent to consider because of its lack of effects on vascular capacitance vessels and preload in patients after cardiac operations. The pharmacokinetic profile of nicardipine suggests that effective administration requires variable-rate infusions when trying to treat hypertension because of the half-life of 40 minutes. If even faster control of BP is essential, a dosing strategy consisting of a loading bolus or a rapid infusion dose with a constant-rate infusion may be more efficient. The effect of nicardipine may persist even though the infusion is stopped. Clevidipine, an ultrashort-acting dihydropyridine approved in 2008 in the United States for clinical use, has a half-life of only minutes; this drug represents an important alternative to nitroprusside and has been extensively studied in cardiac surgical patients.[122]

Fenoldopam is a short-acting dopamine agonist that causes arterial-specific vasodilation by stimulation of D_1-receptors. Unlike nitroprusside, D_1-receptor stimulation also increases renal blood flow to produce diuresis and natriuresis. Fenoldopam and nitroprusside were similarly effective in reducing BP in patients who developed hypertension after CABG procedures.[124] Fenoldopam often must be given at higher doses in patients with severe hypertension that may be associated with increases in HR, and this drug is decreasingly used in postoperative settings.

Postoperative Vasodilation

Vasodilation and a need for vasoconstrictor support are relatively frequent complications of cardiac surgical procedures, with and without CPB. The reported incidence is 4% to 44%, but this wide range largely results from the lack of a common definition.[128–130] Vasodilation alone should be associated with a hyperdynamic circulatory state manifesting as systemic hypotension in association with an increased CO (and a low calculated SVR). More commonly after cardiac operations, a combination of vasodilation and myocardial dysfunction occurs, requiring vasoconstrictor and inotropic therapy. Gomez and Biglioli and their colleagues[131–133] coined the term *vasoplegia syndrome* for the condition that requires high doses of vasoconstrictors, and they reported its occurrence after off-pump and on-pump surgical procedures.

Multiple humoral and inflammatory cascades are activated by surgical treatment and CPB, aortic cross-clamping, and reperfusion, with generation of complement anaphylatoxins, kinins, and cytokines, many of which cause vasodilation by direct and indirect vascular mechanisms.[134–136] Another potential cause of systemic vasodilation is splanchnic circulatory insufficiency resulting in endotoxemia, and this, too, has been noted after off-pump procedures.[137,138] The cellular mechanisms and pathogenesis of vasodilatory shock were summarized by Landry and Oliver.[135] Although the most common clinical context of vasodilatory shock is sepsis, the similarity in the cytokine response and the clinical syndrome seen in sepsis with the vasodilated state seen after cardiac surgical procedures is striking. The stimuli of cytokines and increased tissue lactate lead to increased NO synthase and the generation of vasodilating GMP. NO and metabolic acidosis activate potassium channels, which hyperpolarize the cell membrane, thus making it refractory to both calcium entry and norepinephrine and angiotensin II action. At this time, plasma vasopressin levels are low because of central depletion. Reports of marked vasodilatory shock after CPB responsive to vasopressin appeared when this pathophysiologic finding was being actively investigated.[139] The ability of vasopressin to block the potassium channels and interfere with NO signaling makes it an important therapy for this syndrome. Provided the patient has an acceptable CO, vasopressin is a valuable agent for treating vasodilation after cardiac operations, and this agent significantly reduces the dose requirement for norepinephrine. Systemic vasodilation also can result from hyperthermia caused by excessive warming during CPB and during warming in the ICU.

When patients develop acute systemic vasodilation after administration of drugs or blood products, an anaphylactic reaction should be considered. Acute anaphylaxis caused by immunoglobulin E–mediated responses can manifest with systemic vasodilation and increased CO.[140] Alternatively, complement-mediated transfusion reactions to any blood product can manifest with hypotension produced by systemic vasodilation or by thromboxane-mediated acute pulmonary vasoconstriction and RV dysfunction. Antibodies in the donor blood called leukoagglutinins, when directed against recipient white cell antigens, can actively produce white cell aggregation and thromboxane generation. These reactions can produce *transfusion-related acute lung injury,* which can manifest with hypotension, RV failure, and noncardiogenic pulmonary edema.[140] Monitoring of RV function may therefore help to identify these transfusion reactions.

While underlying causes are being sought and treated, the therapeutic approach to systemic vasodilation includes intravascular volume expansion, α-adrenergic agents, and vasopressin. Administration of vasoconstrictors for more than a brief period must be guided by measures of cardiac performance because restoration of BP may camouflage a low-output state. No established guidelines exist for beginning vasoconstrictor therapy; autoregulation in vital organs is lost at arterial mean pressures lower than 60 mm Hg, and it is reasonable to try to achieve this pressure in normotensive patients (possibly higher in hypertensive patients). A study in patients with septic shock was unable to show a benefit from mean arterial pressures (MAPs) greater than 65 mm Hg.[141]

Clinicians are often concerned about the potential for constricting supply vessels or the microcirculation to vital beds (eg, brain, kidney); although not fully evaluated in the postoperative setting, vasoconstrictor administration in septic states does not appear to have such harmful effects.[142] Use of relatively low doses of vasopressin to restore responsiveness to catecholamines makes physiologic sense, but no clear evidence suggests that the use of vasopressin in addition to or instead of norepinephrine is associated with a better outcome.

However, dopamine has been demonstrated to increase mortality rates in cardiogenic shock.[143]

Coronary Artery Spasm

Coronary artery or internal mammary artery vasospasm can occur postoperatively. Mechanical manipulation and underlying atherosclerosis of the native coronary circulation and the internal mammary artery have the potential to produce transient endothelial dysfunction. The endothelium is responsible for releasing endothelium-derived relaxing factor (EDRF), which is NO, a potent endogenous vasodilator substance that preserves normal endogenous vasodilation (see Chapters 7 and 9). Thromboxane can be liberated by heparin-protamine interactions, CPB, platelet activation, or anaphylactic reactions to produce coronary vasoconstriction.[144,145] Calcium administration, increased α-adrenergic tone from vasoconstrictor administration (especially in bolus doses), platelet thromboxane liberation, and calcium channel blocker withdrawal represent added reasons that may put the cardiac surgical patient at risk for spasm of native coronary vessels and arterial grafts. Engelman and associates[145] reported that four patients developed coronary artery spasm after discontinuation of their calcium channel blockers 8 to 18 hours preoperatively. In three of these patients, spasm was identified by the ECG pattern and was documented as the cause of ischemia in the distribution of a nondiseased right coronary artery; in the fourth patient, spasm developed in a bypassed native vessel. In two of the patients, the problem was recognized retrospectively; MIs developed, and one patient died. In the other two patients, spasm was recognized, and intravenous nitroglycerin was given (1–3 μg/kg per min) in combination with nifedipine, 10 mg sublingually every 5 to 6 hours, to reverse the ischemic process. The therapy of choice remains empiric. Nitroglycerin is a first-line drug, but nitrate tolerance can occur. Phosphodiesterase (PDE) inhibitors represent newer approaches to this problem and have been reported to be effective in vascular models of spasm.[146] Intravenous dihydropyridine calcium channel blockers are also important therapeutic considerations.[147]

The radial artery is still used by some surgeons as a bypass conduit for revascularization.[148–150] This conduit was abandoned by some groups because of its propensity to spasm. However, techniques developed in the use of the internal mammary artery have been applied to the radial artery, as well as prophylactic use of calcium channel blocker infusions.[148,150] Which components of this approach are responsible for the reported success are not known, but use of a calcium channel blocking drug is recommended by many surgeons. The arterial selectivity of the dihydropyridine drugs (eg, nicardipine) should be an advantage in this setting.

Decreased Contractility

Drugs that increase contractility all augment calcium mobilization from intracellular sites to and from the contractile proteins or sensitize these proteins to calcium. Although calcium chloride has been used to increase inotropy, evidence suggests that after CPB, its principal action is peripheral vasoconstriction.[151] The same group of investigators showed that exogenously administered calcium chloride attenuates the response to catecholamines in this setting.[152] The administration of calcium salts improves myocardial performance in patients with severe hypocalcemia or hyperkalemia, and it may be indicated during rapid transfusion of citrated blood.[153]

Catecholamines, through β_1-receptor stimulation in the myocardium, increase intracellular cyclic adenosine monophosphate (cAMP). This second messenger increases intracellular calcium and thus improves myocardial contraction.[154] Inhibition of the breakdown of cAMP by PDE inhibitors increases intracellular cAMP independent of the β-receptor.[155] Intracellular calcium availability can be increased by inhibiting sodium/potassium–adenosine triphosphatase (ATPase) with digitalis glycosides, to promote transmembranous sodium-calcium exchange. However, the use of digoxin to increase myocardial contractility for postoperative ventricular dysfunction is limited by its slow onset, low potency, and narrow therapeutic safety margin. The "calcium sensitizers" constitute a newer class of inotropic agents. One drug in this class, levosimendan, is already available in certain countries and is currently being evaluated in a US clinical trial (https://clinicaltrials.gov/ct2/show/NCT02025621?term=levosimendan&rank=12) (Box 38.2).

Prostaglandins (PGI_2, PGE_1, iloprost, and derivatives)

BOX 38.3 DISADVANTAGES OF CATECHOLAMINES

- Increased myocardial oxygen consumption
- Tachycardia
- Arrhythmias
- Excessive peripheral vasoconstriction
- Coronary vasoconstriction
- β-Receptor downregulation and decreased drug efficacy

TABLE 38.5 Catecholamines Used Postoperatively

Drug	*Infusion Dose (μg/kg per min)*
Dopamine[a,b]	2–10
Dobutamine[b]	2–10
Epinephrine[c]	0.03–0.20
Norepinephrine[c]	0.03–0.20
Isoproterenol[c]	0.02–0.10

[a]Less than 2 μg/kg per minute predominantly "dopaminergic" (renal and mesenteric artery dilatation).
[b]If 10 μg/kg per minute is ineffective, change to epinephrine or norepinephrine.
[c]Dose to effect; may require higher dose than indicated.

Catecholamines

The catecholamines used postoperatively include dopamine, dobutamine, epinephrine, norepinephrine, and isoproterenol (Box 38.3). These drugs have various effects on α- and β-receptors and therefore various effects on HR, rhythm, and myocardial metabolism (see Chapters 11 and 36). Dosing recommendations for the catecholamines are provided in Table 38.5.

Isoproterenol

Isoproterenol is a potent β_1-agonist in the heart and β_2-agonist in the periphery. Its positive inotropic effect is accompanied by an increase in HR and a propensity for arrhythmias. In patients with coronary artery disease, tachycardia and associated peripheral vasodilation increase $M\dot{V}O_2$ and decrease coronary perfusion pressure. In patients with bradycardias in whom pacing is not an immediate or practical option or in those in whom increased HR is desirable (eg, cardiac transplant

recipients, patients with regurgitant valvular lesions), isoproterenol has long been used for this purpose, but increasingly dobutamine is used.

Epinephrine

Epinephrine is a potent adrenergic agonist with the desirable feature that, in low doses (<3 μg/min), β_1 and β_2 effects predominate. As the dose is increased, α effects (eg, vasoconstriction) and tachycardia occur. However, in the acutely failing heart postoperatively, only drugs such as epinephrine or norepinephrine provide positive inotropy and perfusion pressure. These features and its low cost make epinephrine a common first-line drug in the postoperative setting. Despite what is often stated in textbooks, epinephrine causes less tachycardia than dopamine[156] or dobutamine[157] at equivalent inotropic doses.[158] Epinephrine is a first-line therapy for anaphylaxis and, when titrated, does not produce ventricular arrhythmias. Because of the metabolic actions of α_2 stimulation, epinephrine infusion can cause hyperglycemia and increased serum lactate levels.[159]

Norepinephrine

Norepinephrine, which has potent β_1- and α-receptor effects, preserves coronary perfusion pressure while not increasing HR, actions that are favorable to the ischemic, reperfused heart. When norepinephrine is used alone without a vasodilator or PDE inhibitor, the potent α_1 effects may have variable effects on CO. Ventricular filling pressures usually increase when this drug is given because of constriction of the capacitance vessels. Administration of a vasodilator, including the PDE inhibitors, with norepinephrine may partially oppose the vasoconstriction. Clinicians may express concern for the renal blood flow when norepinephrine is given for hypotension; however, norepinephrine has long been used as a first-line agent for hypotension and shock in ICU settings and following cardiac operations. Despite perceived concerns, when norepinephrine is infused to increase MAP to greater than 70 mm Hg in sepsis, increases in urine flow and in creatinine clearance rate occurred after 24 hours.[160] Further, the use of norepinephrine in circulatory shock did not increase mortality rates.[161] End-organ ischemia would appear to be unlikely if CO can be preserved at normal levels when norepinephrine is given. PDE inhibitors in combination with norepinephrine attenuate the arterial vasoconstrictive effects.[146]

Dopamine

A precursor of norepinephrine, dopamine probably achieves its therapeutic effects by releasing myocardial norepinephrine or preventing its reuptake, especially in high doses.[162] This indirect action may result in reduced effectiveness when dopamine is given to patients with chronic HF or shock states because the myocardium becomes depleted of norepinephrine stores.[163] In contrast to dobutamine, the α-agonist properties of dopamine cause increases in pulmonary artery pressure (PAP), PVR, and LV filling pressure.[164–166] At low doses (<2 μg/kg per min), dopamine stimulates renal dopaminergic receptors to increase renal perfusion more than can be explained by an increase in CO.[167] Despite this action, a multicenter study demonstrated that use of low-dose dopamine in critically ill patients confers no protection from renal dysfunction.[168] One review suggested that low-dose dopamine use in the ICU had no justification and that it was "bad medicine."[169] At doses higher than 10 μg/kg per minute, tachycardia and vasoconstriction become the predominant actions of this drug. Tachycardia is a consistent side effect, and in patients with cardiogenic shock, dopamine has been shown to increase mortality rates.[143,161]

Dobutamine

In contrast to dopamine, dobutamine shows mainly β_1-agonist properties, with decreases in diastolic BP and sometimes systemic BP observed.[170,171] Dobutamine is functionally similar to isoproterenol, with less tendency to induce tachycardia in the postoperative setting, although it is often infused at doses up to 40 μg/kg per minute to increase HR as part of a dobutamine stress echocardiographic evaluation.[172] However, Romson and colleagues[173] demonstrated that after CPB, the principal effect of dobutamine is a dose-related increase in HR. A very modest effect on SV was observed in patients with poor ventricular function. Salomon and associates[174] showed that dobutamine increased $M\dot{V}O_2$, a change matched by an increase in coronary blood flow, whereas dopamine increased $M\dot{V}O_2$ but failed to increase coronary blood flow. However, the favorable actions of dobutamine may be limited if tachycardia develops, and, as with dopamine, the inotropic potency of dobutamine is modest in comparison with that of epinephrine or norepinephrine.[174]

Phosphodiesterase Inhibitors

The PDE inhibitors are nonglycosidic, nonsympathomimetic drugs that have positive inotropic effects independent of the β_1-adrenergic receptor and unique vasodilatory actions independent of endothelial function or nitrovasodilators.[154,155] Patients with HF have downregulation of the β_1-receptor, with a decrease in receptor density and altered responses to catecholamine administration.[154,175] Milrinone, amrinone, and enoximone bypass the β_1-receptor and increase intracellular cAMP by selective inhibition of PDE fraction III (ie, fraction IV), a cAMP-specific PDE enzyme.[155,176] In vascular smooth muscle, these agents cause vasodilation in the arterial and capacitance beds.[177] PDE inhibitors increase CO, decrease PAOP, and decrease SVR and PVR in patients with biventricular dysfunction, and they are important therapeutic agents in postoperative cardiac surgical patients. Sildenafil and other PDE 5 inhibitors are also increasingly used for pulmonary hypertension.[178] The PDE 5 inhibitor sildenafil (marketed as, eg, Revatio) was approved for the treatment of pulmonary arterial hypertension by the US Food and Drug Administration (FDA) and the European Medicines Agency (EMA) in 2005, and other similar agents are also currently approved[178] (see Chapters 11 and 26).

Effects on Vascular Responses

Any drug that increases cyclic nucleotides (eg, cAMP, cGMP) in vascular smooth muscle produces vasodilation.[176–178] The concentration of cGMP can be increased by the release of nitric oxide produced by nitroglycerin, nitroprusside, and inhaled NO, and cAMP can be increased by prostaglandin E_1 or I_2 (PGE_1 or PGI_2), or by inhibiting its breakdown by PDE inhibition. Increasing cAMP in vascular smooth muscle promotes calcium uptake by the sarcoplasmic reticulum, thus decreasing calcium available for contraction. The net effect of increasing calcium uptake is smooth muscle relaxation. This effect can also occur through stimulation by drugs that inhibit the breakdown of cGMP (eg, nonspecific PDE inhibitor). Sildenafil and its congeners are type V PDE inhibitors that were originally developed for nitrate tolerance but are marketed for erectile dysfunction and pulmonary hypertension.[178]

PDE III inhibitors have a clinical effect as inodilators; they produce dilation of arterial and venous beds and decrease the MAP and central filling pressures. Increases in CO are induced by multiple mechanisms, including afterload reduction and positive inotropy, but not by increasing HR.[179–189] The net effect is a decrease in myocardial wall tension, representing an important contrast to most sympathomimetic agents.[181] Catecholamine administration often needs the simultaneous administration of vasodilators to reduce ventricular wall tension. Milrinone and other PDE inhibitors also have unique mechanisms of vasodilation that may be favorable for coronary artery and internal mammary artery flow[146] (Box 38.4).

Sildenafil inhibits PDE V, an enzyme that metabolizes cGMP, thereby increasing cGMP-mediated relaxation.[178] The current treatment modalities for pulmonary hypertension include conventional supportive therapies and more specific pharmacologic therapies that are targeted at abnormalities of endothelial function. NO and PDE V inhibitors induce pulmonary vasodilation by increasing intracellular cGMP concentrations. Sildenafil is a selective inhibitor of PDE V. Investigations in animal models and clinical reports including some studies in pediatric patients suggest that sildenafil may be a promising agent for treating pulmonary hypertension. The effect of sildenafil on pulmonary vasculature appears to be independent of the underlying cause, thereby providing a role in idiopathic pulmonary arterial

TABLE 38.6 Acute Heart Failure: Therapeutic Goals and Treatment Summary

Goals	*Treatment*
Reduce impedance to ventricular ejection	Vasodilator
Reduce wall stress	Vasodilator
Reduce filling pressures	Diuretics, venodilators
Increase contractility	Inotropic agents, phosphodiesterase inhibitors

BOX 38.4 ADVANTAGES OF PREEMPTIVE PHOSPHODIESTERASE INHIBITOR ADMINISTRATION

- Increased myocardial contractility (left and right ventricles)
- Pulmonary vasodilation
- Resolution and prevention of ischemia
- Minimal drug side effects during cardiopulmonary bypass
- Dilation of internal mammary artery
- Avoidance of mechanical intervention
- Prevention of "failed weaning"

hypertension (PAH), which is associated with congenital heart disease, pulmonary hypertension secondary to lung disease, or persistent pulmonary hypertension of the newborn. It may also be beneficial in postoperative pulmonary hypertension and in patients who are difficult to wean from inhaled NO. Sildenafil is easily administered and effective, and it has minimal systemic adverse effects although drug interactions can occur[182] (see Chapter 26).

Combination Therapy: Catecholamines and Phosphodiesterase Inhibitors

Catecholamine therapy depends on the myocardial cell's capacity to respond to β_1-agonist activity. In patients with preoperative HF, the number of effective β_1-receptors decreases because of downregulation, which refers to reduced density or uncoupling, such that fewer receptors are available for binding with the β_1-agonist.[154,175] When postoperative ventricular dysfunction is treated, a pharmacologic ceiling effect may occur with increasing doses of a single β_1-agonist or even when other catecholamines are added.[176] Combining PDE inhibitors with a catecholamine may significantly increase cAMP levels in patients with β_1-receptor downregulation, such as patients after cardiac surgical procedures.[190] The two forms of therapy may attenuate each other's adverse effects. Catecholamine stimulation of vascular α_1-receptors induces vasoconstriction, which is attenuated by PDE inhibitors.[146] Catecholamines with potent α_1-agonist effects may be needed to prevent hypotension when PDE inhibitors are given postoperatively; or, alternatively, when an α-adrenergic agent is required to obtain acceptable perfusion pressure, PDE inhibitors may be administered to augment CO. The additive improvement in hemodynamic effects of catecholamines in combination with amrinone, milrinone, or enoximone has also been described.[187,191–195] Combined therapy may theoretically avoid dose-related adverse effects of high doses of each individual agent and is useful in RV failure[196] (Table 38.6) (see Chapters 11 and 26).

Dosage and Administration

Suggested dosage regimens are provided in Table 38.7. Available drugs are reviewed in the following sections.

Amrinone

Amrinone, the first bipyridine evaluated for HF and cardiac surgical procedures, has a half-life of approximately 3.5 hours.[197–201] In patients with HF, an intravenous loading dose of 1.5 mg/kg and an infusion of 10 µg/kg per minute resulted in a plasma concentration of 1.7 µg/mL and produced a 30% increase in cardiac index.[197] Recommended dosing includes a bolus dose of 0.75 mg/kg given intravenously over 2 to 3 minutes, followed by a maintenance infusion of 5 to 10 µg/kg per minute. This dose regimen produces subtherapeutic concentrations after 5 to 10 minutes, and it failed to show any hemodynamic effect after it was given 10 minutes before termination of CPB.[201,202] A loading dose of 1.5 to 2.0 mg/kg of this drug during CPB produces therapeutic concentrations for 30 to 60 minutes, after which an infusion is required to keep therapeutic blood levels. With prolonged administration, amrinone produces thrombocytopenia. Amrinone has been replaced with milrinone for clinical use.

TABLE 38.7 Dosing for Phosphodiesterase Inhibitors (Cyclic Adenosine Monophosphate Specific) Used Postoperatively

Drug	*Loading Dose*[a]	*Infusion Rate*
Amrinone	1.5–2.0 mg/kg	5–20 µg/kg per min
Milrinone	50 µg/kg	0.375–0.75 µg/kg per min
Enoximone	0.5–1.0 mg/kg	5–10 µg/kg per min

[a]Loading doses should be administered over 5 to 10 minutes to avoid excessive vasodilation.

Milrinone

Milrinone, an analogue of amrinone, is a bipyridine derivative with inotropic activity that is almost 20 times more potent than that of amrinone and a shorter half-life.[183] Milrinone is an effective inodilator for patients with decompensated HF and low CO after cardiac surgical procedures. Suggested administration of milrinone is a loading dose of 50 µg/kg over 10 minutes, followed by an infusion of 0.5 µg/kg per minute (0.375–0.75 µg/kg per min). By using slower loading doses, high peak concentrations can be prevented, and the vasodilation that is observed with rapid loading can be attenuated.[183] A milrinone loading dose of 50 µg/kg in combination with an infusion of 0.5 µg/kg per minute consistently maintained plasma concentrations more than 100 ng/mL. Clearance was 3.8 ± 1.7 mL/kg per minute, volume of distribution was 465 ± 159 mL/kg, and terminal elimination half-time was 107 ± 77 minutes (values expressed as mean ± standard deviation [SD]).[183] Pharmacokinetic parameters were independent of dose. The relationship between plasma concentration and pharmacodynamic effects produced approximately a 30% improvement in cardiac index with plasma levels of 100 ng/mL, and a curvilinear relationship was noted between plasma levels and improvement in cardiac index. Bailey and colleagues[183] observed that a dose of 50 µg/kg with an infusion rate of 0.5 µg/kg per minute can keep plasma concentrations near the threshold of its therapeutic effects. Compared with amrinone, milrinone has a shorter context-sensitive half-time after administration is stopped without adverse effects on platelet function.[189]

Kikura and associates[194] reported the effects of milrinone on hemodynamics and LV function in cardiac surgical patients who were already treated with catecholamines. After emergence from CPB, patients were randomly assigned to a control group ($n = 10$) or to one of the milrinone dosing groups: intravenous milrinone at 50 µg/kg ($n = 8$), 50 µg/kg and 0.5 µg/kg per minute ($n = 10$), or 75 µg/kg and 0.75 µg/kg per minute ($n = 9$). Hemodynamics and TEE finding were recorded while constant filling pressures were maintained by volume reinfusion. In all three milrinone groups, cardiac index and velocity of circumferential fiber shortening significantly increased from the baseline, and both values were significantly higher at 5 and 10 minutes than those in the control group. The plasma concentration of milrinone with one-half of the maximal increase in velocity of circumferential fiber shortening was 139 ng/mL on the dose-response curve. Milrinone improves hemodynamics and LV function when constant loading conditions are maintained.[194]

TABLE 38.8 Hemodynamic Effect of Milrinone After Cardiac Surgical Procedures[a]

	% Change (Mean ± SEM)			
Parameter	*15 Min*	*60 Min*	*12 H*	*Post*
CI (L/m² per min)				
Low	+40[b] (4.2)	+42[b] (4.9)	+58[b] (8.8)	+44[b] (6.3)

From Feneck RO. Effects of variable dose milrinone in patients with low cardiac output after cardiac surgery. *Am Heart J.* 1919;121(suppl 2):1995.

Feneck[203] studied 99 adult patients with a low CO after elective cardiac surgical procedures. Milrinone was administered as a loading dose of 50 µg/kg over a 10-minute period, followed by a continuous infusion of 0.375, 0.5, or 0.75 µg/kg per minute (low-, middle-, and high-dose groups, respectively) for a minimum of 12 hours. These investigators observed that milrinone therapy was associated with a rapid and well-sustained increase in CO and a decrease in PAOP in all groups. These investigators also found that the increase in cardiac index was associated with elevations in SV and HR (Table 38.8).

Enoximone

Enoximone, an imidazolone derivative, is eliminated mostly by sulfoxidation, is solubilized in propylene glycol and cannot be diluted when administered intravenously. The recommended loading dose is 0.5 to 1.0 mg/kg, followed by an infusion of 5 to 10 µg/kg per minute. Gonzalez and associates[187] reported using enoximone for managing a cardiac index of less than 2.2 L/m² per minute despite a PCWP of 15 mm Hg, catecholamine administration (eg, dobutamine, dopamine), or intraaortic balloon pump counterpulsation after cardiac surgical procedures. Enoximone was administered as a 1 mg/kg loading dose over 10 minutes after a minimum of 4 hours of unsuccessful conventional therapy. An extra dose (0.5 mg/kg) was given if the increase in CO was less than 20%. A continuous infusion of the drug was administered at 3 to 10 µg/kg per minute and was continued for at least 8 hours. In all patients, significant increases in cardiac index and a significant decrease in PCWP occurred. Naeije and colleagues[204] also reported variable effects on BP, HR, and CO of enoximone in a dose of 0.5 mg/kg after cardiac surgical procedures.

Levosimendan

Levosimendan is a calcium-sensitizing drug that exerts positive inotropic effects by sensitization of myofilaments to calcium and vasodilation through opening of ATP-dependent potassium channels on vascular smooth muscle. These effects occur without increasing intracellular cAMP or calcium and without an increase in $M\dot{V}O_2$ at therapeutic doses. As would be expected with an inodilator, the hemodynamic effects include a decrease in PAOP in association with an increase in CO. β-Blockade does not block the hemodynamic effects of this drug. Levosimendan itself has a short elimination half-life, but it has active metabolites with elimination half-lives up to 80 hours. A study in patients with decompensated HF found that hemodynamic improvements at 48 hours were similar whether patients received the drug for 24 hours or 48 hours. Increasing plasma levels of the active metabolite were found for 24 hours after the drug infusion was stopped.[205] Levosimendan is approved in many European countries and is currently undergoing a cardiac surgical trial for use in the United States.

A randomized study enrolling 203 patients with low-output HF found that levosimendan improved hemodynamics more effectively than did dobutamine and was associated with a lower 6-month mortality rate.[206] However, the mortality rate finding may be caused more by adverse effects related to dobutamine than by a positive effect of levosimendan. Another study in 504 patients with LV dysfunction after acute MI demonstrated better 6-month survival with levosimendan, this time compared with placebo.[207] In a small study after cardiac operations, patients were given levosimendan; of 11 patients with severely impaired CO and hemodynamic compromise, 8 patients (73%) showed evidence of hemodynamic improvement within 3 hours after the start of levosimendan infusion. Specifically, cardiac index and SV were significantly increased, whereas MAP, indexed SVR, mean PAP, right atrial pressure (RAP), and PAOP were significantly lowered.[208] Clinical studies continue to evaluate the potential role for this positive inotropic agent in patients with HF.

Right-Sided Heart Failure

HF after cardiac surgical procedures usually results from LV impairment. Although an isolated right-sided MI can occur perioperatively, most perioperative inferior MIs show variable involvement of the right ventricle.[209] The myocardial preservation techniques that are best for the left ventricle may not offer ideal RV protection because the right ventricle is thin walled and more exposed to body and atmospheric temperature. Cardioplegic solution given through the coronary sinus (retrograde) may not reach parts of the right ventricle because of positioning of the cardioplegia cannula in relation to the venous outflow from this chamber and because the thebesian veins do not drain into the coronary sinus.[210] Impairment of RV function postoperatively is more severe and persistent when preoperative right coronary artery stenosis is present.[211] Although depression of the EF is compensated by preload augmentation, RVEF cannot be preserved if coronary perfusion pressure is reduced or impedance to ejection is increased.

Certain aspects of the physiology of the right ventricle make it different from the left ventricle. Normally, the RV free wall receives its blood flow during systole and diastole; however, systemic hypotension or increased RV systolic and diastolic pressures may cause supply-dependent depression of contractility when $M\dot{V}O_2$ is increased while coronary perfusion pressure is decreased.[212] The normal thin-walled right ventricle is at least twice as sensitive to increases in afterload as is the left ventricle[213] (Fig. 38.5). Relatively modest increases in outflow impedance from multiple causes in the postoperative period can exhaust preload reserve and cause a decrease in RVEF with ventricular dilation. RV pressure overload may be complicated by volume overload caused by functional tricuspid regurgitation.[214] Decreases in RV SV reduce LV filling, and dilation of the right ventricle can cause a leftward shift of the interventricular septum that interferes with diastolic filling of the left ventricle (ie, ventricular interaction) (Fig. 38.6). A distended right ventricle limited by the pericardial cavity further decreases LV filling. RV failure has the potential to affect LV performance by decreasing pulmonary venous blood flow, decreasing diastolic distending pressure, and reducing LV diastolic compliance. The resulting decrease in LV output further impairs RV pump function. The mechanical outcomes of RV failure in postoperative cardiac surgical patients are depicted in Fig. 38.7. It can therefore be appreciated how, once established, RV failure is self-propagating, and aggressive treatment interventions may be needed to interrupt the vicious cycle.

Although not consistently proved, PVR has been shown to be reversibly increased immediately after CPB and for several hours into

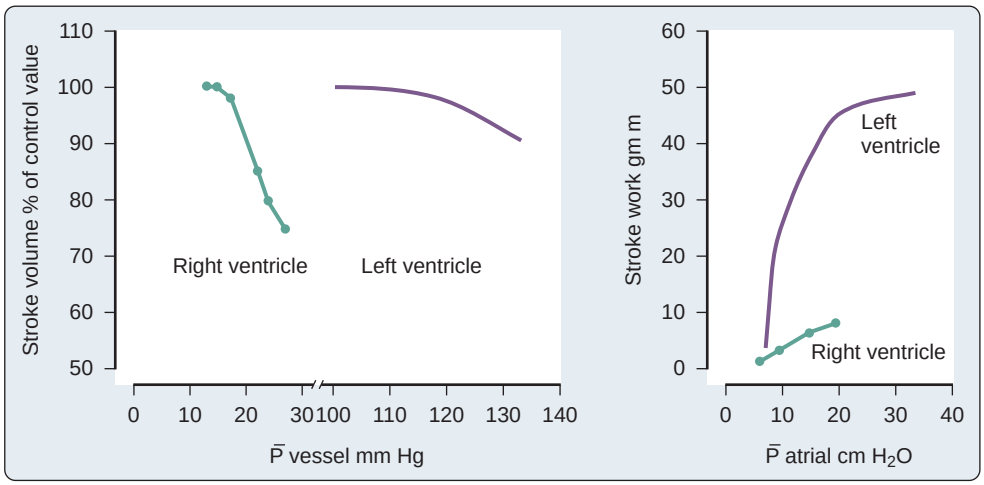

Fig. 38.5 Various effects of afterload and preload seen in ventricular function curves from the right and left ventricles. The right ventricular output is more afterload dependent and less preload dependent than the left ventricular output. $\bar{P}$, Pressure. *(From McFadden ER, Braunwald E. the postoperative period.[215,216] The possible mechanisms include extravascular compression by increased lung water,[216] endocrine-mediated or autonomic nervous system–mediated increases in pulmonary vascular tone,[217] vasoactive substances released from activated platelets and leukocytes,[218] and leukocytes or platelet aggregates obstructing pulmonary vascular beds.[219] Hypoxic pulmonary vasoconstriction may result in increased PVR; more commonly, hypercarbia causes an important increase in PAP.[220,221] The pulmonary vascular bed has been shown to be more sensitive to the vasoconstrictor influences of respiratory acidosis after CPB as compared with the preoperative situation.[222] Moderate respiratory acidosis was shown to cause depression of the RVEF and increased RV end-diastolic volume, and these changes were immediately reversed when normocarbia was reinstituted.[223]

Diagnosis

In the postoperative cardiac surgical patient, a low cardiac index with RAP increased disproportionately compared with changes in left-sided filling pressures is highly suggestive of RV failure. The PAOP may also increase because of ventricular interaction, but the relationship of RAP with PAOP stays close to or higher than 1.0. The absence of a step-up in pressure in going from the right atrium to the pulmonary artery (mean), provided PVR is low, suggests that RV failure is severe and the right side of the heart is acting only as a conduit. This hemodynamic presentation is typical of cardiogenic shock associated with RV infarction. The venous waveforms are accentuated with a prominent Y descent similar to findings in constrictive pericarditis, thus suggesting reduced RV compliance.[224] Large V waves may also be discernible and may relate to tricuspid regurgitation.

The use of a volumetric PAC to calculate right-sided volumes and EF could potentially guide management in the setting of RV failure because increased end-diastolic volume in association with a decreased RVEF indicates decompensation. This catheter-computer system has been validated in comparison with radionuclear and ventriculographic

BOX 38.5 TREATMENT APPROACHES IN POSTOPERATIVE RIGHT-SIDED HEART FAILURE

Preload Augmentation
Volume, vasopressors, or leg elevation (CVP/PCWP <1)
Decrease juxtacardiac pressures (pericardium and/or chest open)
Establishment of atrial kick and treatment of atrial arrhythmias (sinus rhythm, atrial pacing)

Afterload Reduction (Pulmonary Vasodilation)
Nitroglycerin, isosorbide dinitrate nesiritide
cAMP-specific phosphodiesterase inhibitors, α_2-adrenergic agonists
Inhaled nitric oxide
Nebulized PGI_2
Intravenous PGE_1 (and left atrial norepinephrine)

Inotropic Support
cAMP-specific phosphodiesterase inhibitors, isoproterenol, dobutamine
Norepinephrine
Levosimendan

Ventilatory Management
Lower intrathoracic pressures (tidal volume <7 mL/kg, low PEEP)
Attenuation of hypoxic vasoconstriction (high FIO_2)
Avoidance of respiratory acidosis ($PaCO_2$ 30–35 mm Hg, metabolic control with meperidine or relaxants)

Mechanical Support
Intraaortic counterpulsation
Pulmonary artery counterpulsation
Right ventricular assist devices

cAMP, Cyclic adenosine monophosphate; *CVP/PCWP,* central venous pressure/pulmonary capillary wedge pressure; *FIO_2,* fraction of inspired oxygen; *$PaCO_2$,* partial pressure of arterial carbon dioxide; *PEEP,* positive end-expiratory pressure; *PGI_2,* prostaglandin I_2; *PGE_1,* prostaglandin E_1;.

measures, but it may not be accurate in the presence of tricuspid regurgitation.[34,225,226] Unfortunately, tricuspid regurgitation is a common finding in patients with RV dilatation.

Echocardiography allows qualitative interpretation of RV size, contractility, and configuration of the interventricular septum, and it can enable the clinician to provide a definitive diagnosis of RV dysfunction or RV failure. Because of the crescent shape of the right ventricle, volume determination is not easy, but the qualitative examination and assessment for tricuspid regurgitation are very valuable. TEE is also useful to determine whether the increased RAP opens a patent foramen ovale, thus producing a right-to-left shunt. This is important because traditional methods to treat hypoxemia such as PEEP and larger tidal volumes in this setting will only increase the afterload of the right ventricle and potentially increase the shunt and hypoxemia.

Treatment

Treatment approaches in postoperative RV failure may differ from those used in LV failure, and they are affected by the presence of pulmonary hypertension (Box 38.5). In all cases, preload should be increased to the upper range of normal; however, the Frank-Starling relationship is flat in RV failure, and to avoid ventricular dilation, the CO response to an increasing CVP should be determined. Volume loading should be stopped when the CVP exceeds 10 mm Hg and the CO does not increase despite increases in this pressure.[227,228] If a volumetric PAC is in use, an increase in the end-diastolic volume with unchanged or declining RVEF suggests no advantage to further volume loading. The CVP should not be permitted to exceed the PAOP because if these pressures equalize, any increase obtained in pulmonary blood flow will be offset by decreased diastolic filling of the left ventricle by ventricular interdependence.[229] The atrial contribution to RV filling is important when the ventricle is dilated and noncompliant. Maintenance of sinus rhythm and use of atrial pacing are important components of treating postoperative RV failure (see Chapters 6, 11, 16, 22, and 26).

Although vasodilators may lead to cardiovascular collapse in patients with RV infarction (as a result of decreases in RV filling and coronary perfusion), postoperative RV failure is often associated with increased PVR and pulmonary hypertension. In this context, attempts to decrease RV outflow impedance may be worthwhile. Intravenous vasodilators invariably reduce systemic BP and mandate the simultaneous administration of a vasoconstrictor. One way to reduce the pulmonary effects of the needed vasoconstrictor is to administer the vasoconstrictor through a LA catheter and treat RV dysfunction with intravenous prostaglandins and LA norepinephrine.[230] The PDE inhibitors are commonly used for their effect on the pulmonary vasculature and RV function. Interest in and availability of aerosolized pulmonary vasodilators have increased. This route of administration reduces or even abolishes undesirable systemic vasodilation. Delivery of the drug directly to the alveoli improves pulmonary blood flow to these alveoli and potentially improves oxygenation by better matching blood flow to ventilation. Three drugs have been used: NO, PGI_2 (ie, epoprostenol or prostacyclin), and milrinone.[231,232]

NO is an important signaling molecule throughout the body. In the lung, it rapidly diffuses across the alveolar-capillary membrane and activates soluble guanylate cyclase, thereby leading to smooth muscle relaxation by several mechanisms.[231] Inhaled NO is given through a specialized delivery system in a concentration of 5 to 80 parts/million. It is commercially available in the United States, but it is costly. NO has been used successfully to treat RV dysfunction associated with pulmonary hypertension after heart operations,[232] mitral valve replacement,[233] cardiac transplantation,[234] and placement of LV assist devices (LVADs).[235] Although it is widely used to treat the same problems in lung transplantation, a randomized trial of prophylactic inhaled NO in this population failed to show a benefit.[236] This finding should not prevent the use of NO should RV dysfunction occur in the lung transplant recipient. Potential adverse effects of inhaled NO include toxicity from forming nitrogen dioxide (NO_2) and methemoglobin, rebound pulmonary hypertension from abrupt disconnection or withdrawal, and pulmonary vascular congestion from increased pulmonary blood flow in patients with poor LV function. If NO is administered at the recommended dosage, toxicity should not be observed; patients should have the drug gradually withdrawn, and those with poor ventricular function should be closely monitored for increases in left-sided filling pressures.

A less expensive alternative to inhaled NO is aerosolized epoprostenol (ie, prostacyclin or PGI_2). This compound binds to cell-surface prostaglandin receptors, activating adenylate cyclase, which activates protein kinase A to cause a decrease in cytosolic free calcium. It also stimulates endothelial release of NO. It is a profound vasodilator and inhibitor of platelet aggregation. Similar to inhaled NO, delivery of epoprostenol to ventilated alveoli can improve oxygenation by augmenting blood flow to these alveoli. Aerosolized PGI_2 has been successfully used to treat pulmonary hypertension after cardiac surgical procedures[232,237] and pulmonary embolism[238] and to treat hypoxemia in patients with lung injury.[239,240] Use of this agent requires collaboration with pharmacy and respiratory therapy, as well as suitable care and monitoring of the nebulizer device. Adverse effects include the possibility of vagus-mediated bradycardia at low doses and risks similar to those of inhaled NO for abrupt withdrawal or left-sided HF.

Haraldsson and associates[241] studied the use of inhaled (ie, aerosolized) milrinone in patients with mild pulmonary hypertension after CPB. These investigators found that when delivered by this route, milrinone was an effective pulmonary vasodilator without causing systemic hypotension, and the pulmonary vasodilation was additive to that caused by inhaled PGI_2.

Even a moderate increase in arterial carbon dioxide tension ($PaCO_2$) should be avoided in patients with RV failure. Although induced

hypocarbia is of proven benefit in controlling low PVR in neonates, the evidence in adults does not warrant this as a standard therapy because mechanical ventilation–induced changes in intrathoracic pressure have important therapeutic implications[242,243] (see Chapter 39). An intraaortic balloon pump may be of great benefit, even in patients with a right ventricle that is mainly responsible for circulatory decompensation. This beneficial effect is mediated by increased coronary perfusion. Right-sided heart assist devices have a place as temporizing measures in severe intractable right-sided HF. Pulmonary artery counterpulsation is experimental, and its clinical role is uncertain.[244] In cases of severe RV failure it may be necessary to leave the sternum open or to reopen the chest if it has been closed. This approach decreases the tamponade-like compression of the left ventricle by the distended right ventricle, right atrium, and edematous mediastinal tissues.

Effects of Mechanical Ventilation in Heart Failure

HF at the time of a surgical procedure has been identified as a significant predictor of postoperative respiratory complications.[245] Maintenance of gas exchange in these situations usually mandates prolonged ventilatory support. Besides improving Pa_{O_2}, mechanical ventilation can influence D_{O_2} through its effects on CO. Suppression of spontaneous respiratory efforts may substantially decrease the work of breathing and improve the oxygen supply-demand relationship (see Chapter 39). Traditionally, the influence of mechanical ventilation on hemodynamics has been viewed as negative. The unavoidable rise in intrathoracic pressure caused by positive-pressure ventilation or PEEP is associated with decreased CO.[246] However, in the presence of HF or myocardial ischemia, raised intrathoracic pressure has the potential to affect the determinants of global cardiac performance favorably. Understanding these heart-lung interactions is essential for the integrated management of the ventilated patient with HF after cardiac operations. The effects of ventilation on RV and LV failure must receive independent consideration.

Systemic venous return is proportional to the pressure gradient between the systemic veins and the right atrium. Changes in intrathoracic pressure imposed by positive-pressure ventilation or PEEP are transmitted to the compliant right atrium and cause an increase in RAP. This change decreases the driving pressure for venous return, with a reduction in RV preload as the clinically most important mechanism of the decrease in RV SV caused by ventilatory support.[247] The effects of mechanical ventilation on RV preload may be accentuated by hypovolemia or by an increase in venous capacitance caused by vasodilator administration.[248] The effects of raised intrathoracic pressure can be overcome by fluid administration, leg elevation, or even vasopressors to raise the systemic venous pressure. Preload augmentation must be done cautiously if the patient has RV failure.

Two other factors related to raised intrathoracic pressure potentially impede the diastolic filling of the left ventricle. If positive-pressure ventilation or PEEP causes an increase in PVR, RV systolic emptying may be impaired, and the right ventricle will dilate. This change may cause leftward displacement of the interventricular septum and decrease LV compliance.[229] Independent of ventricular interaction, increased lung volume also raises juxtacardiac pressures, thus decreasing the transmural distending pressure.[249]

The end-diastolic volume and the systolic BP are directly proportional to systolic wall stress or ventricular afterload. Because the ventricles and the outflow vessels are surrounded by intrathoracic pressure, increases in this pressure by positive-pressure ventilation decrease the transmural pressure load (aortic or PAP relative to intrathoracic pressure) of each ventricle.[250] On the right side of the heart, the hemodynamic effects of ventilatory support usually result from changes in PVR. To the extent that PEEP increases lung volume above functional residual capacity, PVR may decrease from reduced compression of extraalveolar vessels.[251] Beyond that, large tidal volumes and high levels of PEEP increase PVR.[252] The increase in PVR may be obvious even with normal tidal volumes in airflow-limited diseases. The effects of increased PVR in RV failure are decreased CO and further dilation.

Raised intrathoracic pressure may significantly improve LV performance as a result of the reduced transmural pressure needed to give an acceptable systemic BP.[253] This pressure can be viewed as afterload reduction, a favorable effect separate from the resistance to venous return that may also help such patients. Clinically significant improvements in cardiac function have been documented in patients ventilated for cardiogenic respiratory failure produced by myocardial ischemia and after CABG operations.[254,255] High LV filling pressures may help identify a subgroup benefiting from reduced afterload with increased intrathoracic pressure.[256]

Raised intrathoracic pressure and PEEP have also been suggested to affect the inotropic state of the ventricles. Dilation of the right ventricle in response to an increase in afterload raises the RV distending pressure, which can reduce the pressure gradient for subendocardial coronary blood flow. Decreased RV contractility related to decreased coronary blood flow was described with high levels of PEEP in an animal model with critical right coronary artery obstruction,[212] as well as in patients with significant right coronary artery disease.[256] LV contractility does not seem to be affected by this mechanism.[257] Raised intrathoracic pressure and lung distention may also modulate contractility by stimulating vagal afferents[258] and releasing prostaglandins.[259] The impairment of contractility by these mechanisms appears to be minimal.

The circulatory responses to changes in ventilation should always be assessed in patients with cardiac disease; the goal of improving or maintaining D_{O_2} must be kept in mind. This usually requires measurement of arterial oxygenation and CO. In RV and biventricular failure the increase in the airway pressure caused by ventilatory support should be kept at a minimum compatible with acceptable gas exchange. This means avoidance of high levels of PEEP and trials of decreased inspiratory times, flow rates, and tidal volumes. Breathing modes that emphasize spontaneous efforts such as intermittent mandatory ventilation, pressure support, or CPAP should be considered. Alternatively, if isolated LV failure is the reason for ventilatory therapy, improvements in cardiac performance may be achieved by positive-pressure ventilation with PEEP. In particular, patients with increased LV filling pressures, mitral regurgitation, and reversible ischemic dysfunction may improve from afterload reduction related to increased airway and intrathoracic pressures. Newer modes of ventilatory support that decrease mean airway pressure, such as cardiac cycle–specific, high-frequency jet ventilation[260] and airway pressure release ventilation,[261] and their roles in supporting heart function, are discussed in Chapter 39.

Effects of Ventilatory Weaning on Heart Failure

Traditional criteria for weaning of ventilatory support assess the adequacy of gas exchange and peak respiratory muscle strength.[262] In the patient with HF, the response of global hemodynamics to spontaneous respirations must also be considered. The changes of the loading conditions of the heart brought about by resuming spontaneous ventilation can induce a vicious cycle resulting in hypoxemia and pulmonary edema.

Pulmonary congestion, often present in patients with LV dysfunction, decreases pulmonary compliance. Thus large decreases in inspiratory intrathoracic pressure are needed to cause satisfactory lung inflation. These negative swings of intrathoracic pressure increase venous return.[263] Increased diaphragmatic movements may raise intraabdominal pressure and further increase the pressure gradient for venous return.[264] Decreased intrathoracic pressure also raises the ventricular transmural pressures and the impedance to ventricular emptying. The increased afterload causes further increases in preload, and these changes jeopardize the myocardial oxygen balance. Accordingly, worsening of myocardial ischemia as shown by ST-segment deviations was demonstrated when ventilatory support was removed in patients ventilated after MI.[265] Spontaneous ventilation episodes also precipitated ischemic dysfunction and caused LV dilation and altered thallium-201 uptake in ventilator-dependent patients after lung injury caused by infection or surgical complications.[266]

In the patient with severe ventricular dysfunction, one of the main methods of improving cardiac performance to allow separation from CPB and to maintain function in the postoperative period is to augment preload with fluid therapy. The unavoidable consequences are a positive fluid balance and a weight gain of several kilograms, even after uncomplicated surgical procedures. Diuretic therapy to reduce this hypervolemia and vasodilator therapy to reduce ventricular wall stress should be considered before these patients are exposed to the afterload stress of ventilatory weaning.[263,277]

Cardiac Tamponade

Cardiac tamponade is an important cause of the low-CO state after cardiac operations and occurs when the heart is compressed by an external agent, most commonly blood accumulated in the mediastinum. Hemodynamic compromise, to some degree attributable to the constraining effect of blood accumulating within the chest, is often observed in the 3% to 6% of patients needing multiple blood transfusions for hemorrhage after cardiac surgical procedures.[268] Postoperative cardiac tamponade usually manifests acutely during the first 24 hours postoperatively, but delayed tamponade may develop 10 to 14 days after the operation, and it has been associated with postpericardiotomy syndrome or postoperative anticoagulation.[269–271]

The mechanism of hemodynamic deterioration during cardiac tamponade is discussed in Chapter 24 and mainly is the result of impaired filling of one or more of the cardiac chambers. As the external pressure on the heart increases, the distending or transmural pressure (external intracavitary pressure) is decreased. The intracavitary pressure increases in compensation lead to impaired venous return and elevation of the venous pressure. If the external pressure is high enough to exceed the ventricular pressure during diastole, diastolic ventricular collapse occurs. These changes have been documented in the right and the left sides of the heart after cardiac surgical procedures.[272] As the end-diastolic volume and end-systolic volume decrease, a concomitant reduction in SV occurs. In the most severe form of cardiac tamponade, ventricular filling occurs only during atrial systole. Adrenergic and endocrine mechanisms are activated in an effort to maintain venous return and perfusion pressure.[273,274] Intense sympathoadrenergic activation increases venous return by constricting venous capacitance vessels. Tachycardia helps to maintain CO in the presence of reduced SV. Adrenergic mechanisms may explain decreased urinary output and sodium excretion, but these phenomena may also be caused by reduced CO or a reduction in atrial natriuretic factor from decreased distending pressure of the atria.[237]

The diagnosis of cardiac tamponade depends on a high degree of suspicion. Tamponade after cardiac surgical procedures is a clinical entity distinct from the tamponade typically seen in medical patients in whom the pericardium is intact and the heart is surrounded by a compressing fluid. In the setting of cardiac surgery, the pericardial space is often left open and in communication with one or both of the pleural spaces, and the compressing blood is at least in part in a clotted, nonfluid state and able to cause localized compression of the heart. Serious consideration should be given to the possibility of tamponade after cardiac surgical procedures in any patient with an inadequate or worsening hemodynamic status, as evidenced by hypotension, tachycardia, increased filling pressures, or low CO, especially when chest tube drainage has been excessive. A more subtle presentation of postoperative tamponade is characterized by gradually increasing needs for inotropic and pressor support. Many of the classic signs of cardiac tamponade may not be present in these patients, partly because the patients are usually sedated and ventilated, but also because the pericardium is usually left open, resulting in a more gradual increase in the restraining effects of blood accumulation. Patients may have localized accumulations that affect one chamber more than another.[275] The classic findings of elevated CVP or equalization of CVP, pulmonary artery diastolic pressure, and PAOP may not occur.[276,277] It may therefore be difficult in the presence of declining CO and elevated filling pressures to distinguish tamponade from biventricular failure. A useful clue may be the pronounced respiratory variation in BP with mechanical ventilation in association with high filling pressures and low CO because the additional external pressure applied to the heart by positive-pressure ventilation may further impair the already compromised ventricular filling in the presence of tamponade.

Echocardiography may provide strong evidence for the diagnosis of cardiac tamponade.[277–280] Echolucent crescents between the RV wall and the pericardium or the posterior LV wall and the pericardium are visible with TTE or TEE. Echogenicity of grossly bloody pericardial effusions, especially when clots have been formed, may sometimes make delineation of the borders of the pericardium and the ventricular wall difficult, thus compromising the sensitivity of this technique. A classic echocardiographic sign of tamponade is diastolic collapse of the right atrium or right ventricle, with the duration of collapse bearing a relationship with the severity of the hemodynamic alteration, but such findings are often absent in patients after cardiac surgical procedures.[277,281,282] Often, TTE is difficult because of mechanical ventilation, and TEE is required for satisfactory imagining (see Chapters 15 and 16).

The definitive treatment of cardiac tamponade is surgical exploration with evacuation of hematoma. The chest may have to be opened in the ICU if tamponade proceeds to hemodynamic collapse. For delayed tamponade, pericardiocentesis may be acceptable. Medical palliation in anticipation of reexploration consists of reinforcing the physiologic responses that are already occurring while preparing for definitive treatment. Venous return can be increased by volume administration and leg elevation. The lowest tidal volume and PEEP compatible with adequate gas exchange should be used.[283] Epinephrine in high doses gives the needed chronotropic and inotropic boost to the ventricle and increases systemic venous pressures. Sedatives and opioids should be given cautiously because they may interfere with adrenergic discharge and precipitate abrupt hemodynamic collapse. Occasionally, patients develop significant cardiac tamponade without accumulation of blood in the chest. Edema of the heart, lungs, and other tissues in the chest after CPB may not allow chest closure at the first operation, and staged chest closure may be required after the edema has subsided.[284] Similarly, some patients with an inadequate hemodynamic status after cardiac surgical procedures despite maximum support in the ICU improve with opening of the chest because this tamponade effect is relieved. Reclosure of the chest in the operating room is often possible after a few days of continued cardiovascular support and diuresis.

Transplanted Heart

Postoperative circulatory control in the heart transplant recipient differs in three major respects from that of the patient who has not received a heart transplant: (1) the transplanted heart is noncompliant, with a relatively fixed SV; (2) acute rejection must be considered when cardiac performance is poor or suddenly deteriorates; and (3) these patients are at risk for acute RV failure if pulmonary hypertension develops.[285]

The fixed SV combined with denervation of the donor heart means that maintenance of CO often depends on therapy to maintain an elevated HR (110–120 beats/min). The drug most commonly used is isoproterenol because it is a potent inotropic agent and because it causes a dose-related increase in HR. Its vasodilating β_2-adrenergic effect on the pulmonary vasculature may be of benefit if PVR is greater than normal. Alternatively, atrial pacing may be used to maintain HR if contractility appears normal. Pacing is often used to allow the withdrawal of isoproterenol in the first postoperative days. Parasympatholytic drugs, such as atropine, do not have any effect on the transplanted heart (see Chapter 25).

Major concerns in monitoring and therapy for the transplant recipient are the potential for infection and rejection. Immunosuppressive therapy regimens include cyclosporine and usually steroids or azathioprine, or both. These drugs also suppress the patient's response to infection, and steroid therapy may induce elevations in the white blood

cell count, thus further confusing the issue. Protocols for postoperative care stress strict aseptic technique and frequent careful clinical evaluations for infection.

The adequacy of immunosuppression is monitored by percutaneous myocardial biopsy, usually performed at weekly intervals in the first month. Less invasive techniques, such as echocardiographic evaluation of diastolic function and sophisticated ECG analysis, are being evaluated.[286] Although acute rejection is diagnosed histologically, if it is suspected clinically (ie, acute deterioration in cardiac function), it must be treated with intense immunosuppressive therapy. The agents and doses used vary from institution to institution, but they usually include high-dose steroids and monoclonal antibody to T_3 lymphocytes (OKT3).[287] Pharmacologic management and sometimes mechanical support of biventricular function are required because severe impairment of contractility, ventricular dilation, and even cardiovascular collapse may occur.

Preoperative evaluation helps screen patients with fixed pulmonary hypertension because the normal donor right ventricle may acutely fail if it is presented with an elevated PAP in the recipient.[285] However, patients may have progression of disease between the time of evaluation and operation, or the right ventricle may be inadequately protected during harvest or transport. When separation from CPB is attempted, acute RV dilation and failure occur, and such patients may emerge from the operating room receiving multiple drug therapy, including the inhaled agents NO and prostacyclin, as described earlier, to focus on treating RV dysfunction and/or pulmonary hypertension.[288–292] Gradual withdrawal of these drugs occurs in the first postoperative days, with close monitoring of PAPs and oxygenation.

Concern for fluid balance is heightened in the perioperative period because transplant recipients are often fluid overloaded as a result of chronic biventricular failure and because of the potential for edema in the donor heart and even potentially the lungs. It is not unusual for vigorous diuretic therapy to be initiated within 24 hours of operation, with the goals of negative fluid balance and a PAOP less than 12 mm Hg. Inotropic agents rather than preload augmentation are used to keep CO at an acceptable level during this time. Electrolyte abnormalities induced by this therapy and the use of cyclosporine (which causes potassium and magnesium wasting) are common in this period. In patients with refractory respiratory failure and fluid overload, in whom oxygenation is a critical problem, early intervention with venovenous (VV) extracorporeal membrane oxygenation (ECMO) support is increasingly being considered as a therapeutic option.[293–296] In patients with persistent respiratory failure and/or cardiogenic shock, venoarterial (VA) ECMO also continues to evolve as an important and increasingly used therapeutic option.[297–300]

Advances in Cardiovascular Surgery and Postoperative Management

Advances in cardiothoracic surgery include minimally invasive transcatheter aortic valve replacement (TAVR), the incorporation of echocardiography in the cardiothoracic ICU, and improved biotechnology and durability related to cardiopulmonary support by ECMO. The following section explores these advances and highlights the major postoperative considerations for patients in the cardiothoracic ICU.

Postoperative Management of Complications After Transcatheter Aortic Valve Replacement

TAVR is increasingly used in clinical practice and is also described elsewhere (see Chapters 3, 21, and 27). Although the benefits and indications for TAVR are well established,[301,302] four major clinical challenges have emerged: vascular complications, stroke, paravalvular leak (PVL), and cardiac conduction abnormalities. The mechanisms of these intraoperative complications have immediate postoperative consequences and require appropriate management in the ICU.

Vascular Complications

Major vascular complications are independent predictors of major bleeding, transfusion, end-organ failure, and death.[303] Atherosclerotic disease of the femoral arteries and operator experience are other notable predictors of clinical outcomes. Strategies to minimize vascular injury involve designing smaller and sleeker delivery systems. The Valve Academic Research Consortium (VARC) provided standardized definitions for major and minor vascular injuries to guide clinician practice, communication among services, and comparability across clinical trials.[304,305] Major vascular complications were defined as thoracic aortic dissection, distal extremity or noncerebral vascular embolization requiring surgical intervention, and amputation. In addition, irreversible end-organ injury and iatrogenic access-related vascular injuries resulting in death, unplanned intervention, blood transfusion of 4 units or more, or permanent end-organ injury all meet criteria for major vascular complications related to TAVR.[304,305] Access-related vascular injuries included dissection, stenosis, perforation, pseudoaneurysm formation, arteriovenous fistula, hematoma, compartment syndrome, and irreversible nerve injury.[304,305]

Minor vascular complications were defined by the VARC as distal embolization not requiring surgical intervention or leading to irreversible end-organ damage. Furthermore, the VARC categorized minor vascular injuries as failure of percutaneous access-site closure requiring intervention but not leading to death, blood transfusion of 4 units or more, or permanent end-organ injury.[304,305]

An analysis of vascular complications from the transfemoral TAVR cohorts (n = 419) from the Placement of Aortic Transcatheter Valve (PARTNER) trials demonstrated that the incidence of major and minor vascular complications were 15.3% and 11.9%, respectively, within 30 days of TAVR.[306] Furthermore, the most common major vascular complications were dissection, access-site hematoma, and arteriotomy of the posterior femoral arterial wall. These findings are not surprising considering that the first-generation TAVR delivery systems required introducer sheaths as large as 24 Fr.[306] Moreover, major vascular complications significantly increased the risks of major bleeding (and therefore blood transfusions), renal failure requiring continuous renal replacement therapy, and death at 30 days and again at 1 year.[306] Female sex was the only identified independent predictor of vascular complications (hazard ratio, 2.31; 95% confidence interval [CI], 1.08–4.98; $P = .012$), and baseline renal disease (hazard ratio, 2.26; 95% CI, 1.20–4.43; $P = .002$) independently predicted 1-year mortality rates. Furthermore, the impact of major vascular iatrogenic injuries after TAVR on mortality rates was relatively higher in higher-risk patients.

Even though female sex was identified as the single independent predictor of vascular complications, one study showed that women had better short-term and long-term survival rates after TAVR.[307] One Canadian TAVR observational study found that although women had significantly more VARC-defined major vascular complications ($P = .003$), they had significantly lower 30-day (odds ratio [OR], 0.39; 95% CI, 0.19–0.80; $P = .01$) and 2-year mortality rates (hazard ratio, 0.60; 95% CI, 0.41–0.88; $P = .008$).[307]

Major vascular complications after TAVR remain an important barrier to further outcome improvement and cause much of the morbidity encountered postoperatively in the ICU. Contemporary data from the Mayo Clinic in Rochester, Minnesota showed that the TAVR learning curve reached a plateau after 30 cases of TAVR. For these reasons and the importance of having an experienced TAVR heart team, guidelines have set minimum operator and institutional requirements for these procedures.[308] In addition to operator experience, advances in hardware design with smaller-French introducer sheaths have been ushered into practice to decrease the risk of vascular complications further.[308–311] The delivery systems in second-generation devices are small than 20-Fr caliber,[312] and this change should significantly reduce the frequency of vascular complications.

Postoperative cardiovascular management of the patient who has undergone TAVR complicated by intraoperative vascular injury includes assessment of the degree of vascular injury as dictated by VARC guidelines and subsequent postoperative management in the

ICU. This care includes continuous monitoring of peripheral arterial pulses (focus on access site), adequate perfusion, development and treatment of end-organ dysfunction, and hemodynamic and hemostatic resuscitation.

Stroke

Asymptomatic cerebral embolism is common during TAVR. A detailed series of neuroimaging studies showed that clinically silent cerebral embolism occurs in up to 70% of these patients.[313–315] Major stroke, however, independently predicts prolonged recovery and increased mortality rates. Identified stroke predictors include history of previous stroke, functional disability, transapical approach, and AF. Embolic protection devices are under development to mitigate the risk of embolic stroke after TAVR (personal communication with Howard C. Herrmann, MD, PARTNER trial investigator, University of Pennsylvania, Philadelphia, February 2014).

The clinical stroke rate at 1 year after TAVR was 4.1% in a multicenter French registry ($n = 3195$; 34 centers).[316] The VARC definition of stroke after TAVR includes rapid onset of a neurologic deficit (global or focal), duration longer than 24 hours, absence of another cause of symptoms similar to a cerebrovascular accident, and confirmation of the diagnosis by a neurologist and neuroimaging.[304,305] The stroke was classified as major if the degree of disability was 2 or higher on the modified Rankin scale (ie, any disability that prevents a patient from carrying out his or her normal activities).[304,305] A weighted metaanalysis of TAVR studies (cumulative $n = 3519$; 16 studies from 2001 to 2011) reported a major stroke rate of 3.2% (95% CI, 2.1–4.8), as defined by the VARC criteria.[304,305,317]

Data have shown that the risk of stroke after TAVR is highest within the first week after TAVR while the patient may still be recovering in the hospital or sent home.[318,319] Stroke after TAVR significantly increases mortality rates.[318,319] The long-term effects of asymptomatic cerebral embolism associated with TAVR are unknown. The predictors of stroke early after TAVR include previous stroke, severe arterial atheroma, and a smaller aortic valve area.[318,319] Patients should be admitted to the ICU after undergoing TAVR and postoperatively monitored for immediate evidence of neurocognitive decline or focal neurologic deficit heralding a major stroke. Neurology consultation and activation of a stroke workup protocol native to the home institution should occur, and neuroimaging should be ordered to direct further clinical management. In the event of a stroke in the ICU, multidisciplinary decision making among physicians and patient care teams should be implemented regarding the initiation of permissive hypertension and procedural intervention.

Paravalvular Leak

PVL is common and significantly decreases survival. This undersizing is balanced against oversizing and aortic root trauma or rupture, which typically warrants emergency CPB and immediate repair. The formal grading of PVL severity in TAVR is based on its percentage of the circumferential extent of the aortic valve annulus. Further management strategies for PVL include a repositionable valve prosthesis and transcatheter plugging.

The immediate postoperative importance of PVL after TAVR relates to the presence of aortic regurgitation in an otherwise noncompliant left ventricle with diastolic dysfunction, as commonly seen with severe aortic stenosis. Grading of PVL is important because moderate to severe PVLs may result in symptoms of acute HF and pulmonary edema. The 1-year incidence of PVL of any severity after TAVR in France was 64.5%, with significant PVL independently predicting mortality rates (hazard ratio, 2.49; 95% CI, 1.91–3.25).[316] Two-year data from the PARTNER trial indicated that moderate or severe PVL is more common in TAVR compared with surgical aortic valve replacement (AVR) at 1 year and 2 years (7.0% vs 1.9% at 1 year and 6.9% vs 0.9% at 2 years; $P < .001$ for each comparison).[320] Mild or greater degrees of PVL in this series were associated significantly with mortality rates (hazard ratio, 2.11; 95% CI, 1.43–3.10; $P < .001$).[320] This mortality effect was proportional to the severity of PVL after TAVR. Data from an Italian TAVR registry (n = 663, 14 centers) indicated that although PVL was trace to mild in most cases, moderate or greater PVL (hazard ratio, 3.79; 95% CI, 1.57–9.10; $P = .003$) significantly increased late mortality rates.[321] The German multicenter TAVR registry ($n = 690$) showed that moderate or greater PVL independently predicted in-hospital mortality rates (OR, 2.43; 95% CI, 1.22–4.85; $P = .01$).[322] A single-center TAVR series (n = 145) reported that moderate or greater PVL significantly increased the risks of death (OR, 4.26; 95% CI, 1.59–11.45; $P = .004$) and poor clinical response to TAVR (OR, 10.1; 95% CI, 3.20–31.94; $P < .001$).[323]

The precise grading of PVL by echocardiography remains controversial.[304,305,324,325] The VARC defined the severity of PVL as a percentage of the circumferential extent of the aortic valve annulus as visualized on the midesophageal short-axis view of the aortic valve. The grading system, however, is imprecise, especially when the regurgitant jets may be multiple and eccentric. The diameters of all PVLs can be added together and then expressed as a percentage of the total aortic annular circumference.[326] Mild PVL is defined as having a less than 10% circumferential extent. Moderate PVL is defined as having a 10% to 20% circumferential extent.[304,305,326] In TAVR, it is vital to image the aortic valve in multiple esophageal and gastric views to obtain a comprehensive assessment of the PVL after valve deployment.[304,305,324–326] The cardiothoracic ICU physician should be informed if a post-TAVR patient has moderate or higher degree of PVL because this finding may have consequences for clinical management.

Cardiac Conduction Abnormalities

Cardiac conduction disturbances after TAVR are common and important.[327] Perioperative cardiac conduction disturbances after TAVR have been defined by VARC standardized clinical end-point definitions.[304,305] New-onset AF was defined by the VARC as an arrhythmia within the hospital stay that has the ECG characteristics of AF and lasts longer than 30 seconds.[304,305] The VARC guideline also recommended that the therapeutic approaches to AF are documented, including spontaneous conversion to sinus rhythm, electrical or medical cardioversion, and commencement of oral anticoagulation, as well as the clinical application of rate or rhythm control medications.[304,305] The VARC guidelines also highlighted the risk of atrioventricular (AV) block associated with TAVR.[304,305] The types of heart block may occur anywhere along the cardiac conduction pathway, including first-degree AV block, second-degree AV block (Mobitz I or Mobitz II), third degree AV block, bundle branch block, and AV block requiring pacemaker insertion. High-grade AV block was defined as persistent if it was present every time the underlying native heart rhythm was evaluated.[304,305]

Although AF and heart block are described complications after surgical AVR, these arrhythmias after TAVR currently are being investigated as TAVR enters the mainstream of clinical practice.[328–330] The management of postoperative AF after cardiothoracic procedures is described earlier in this chapter. The management of new-onset AF after TAVR is similar to that after open cardiothoracic surgical procedures, with the exception that pacer wires are not routinely present to facilitate overdrive pacing as they would be in more invasive cardiac operations. On occasion, a transvenous pacer may be present for reasons discussed later in this chapter. For clarity, perioperative pathophysiology and management of AV block after TAVR comprise the focus of this section.

Impact of Transcatheter Aortic Valve Replacement on the Cardiac Conduction System

The native aortic valve lies in close proximity to the AV conduction system, a location that puts the ventricular septal conductive system at risk during aortic valve procedures. A thorough understanding of the surgical anatomy allows the ICU physician to recognize the conductive consequences of aortic valve procedures (Fig. 38.8A). The basal attachments of the three aortic leaflets form an annulus that separates the aortic root from the LV outflow tract (LVOT). The noncoronary cusp lies adjacent to the membranous portion of the interventricular septum (Fig. 38.9A). The superior continuation of the membranous

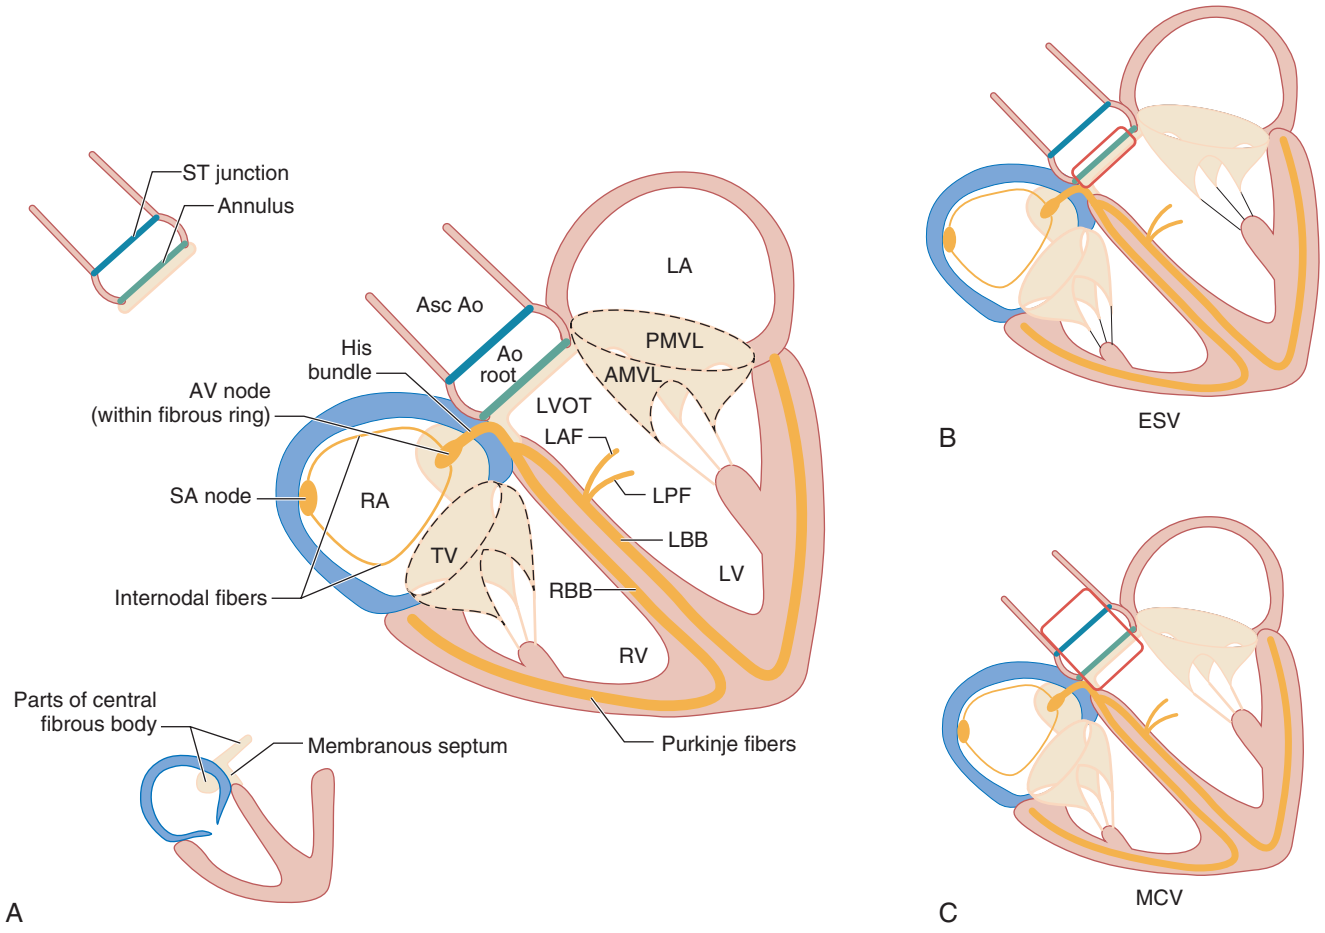

Fig. 38.8 The cardiac conduction system and its relationship with the transcatheter aortic valve replacement bioprostheses. (A) The atrioventricular *(AV)* node within the medial floor of the right atrium *(RA)* gives rise to the bundle of His, which traverses under the membranous septum within the distal left ventricular outflow tract *(LVOT)*. The right bundle branch *(RBB)* travels along the septal aspect of the RV. The left bundle branch *(LBB)* travels superficially along the septal aspect of the left ventricle *(LV)* to branch into the left anterior fascicle *(LAF)* and the left posterior fascicle *(LPF)*. Purkinje fibers mark the distal extent of the conduction system. Perioperative conduction disturbances after transcatheter aortic valve replacement.* J Cardiothorac Vasc Anesth. *2013;27:1414–1420.)*

septum is an interleaflet triangle that separates the noncoronary from the right coronary cusp (see Fig, 38.9A). Both structures, the membranous septum and the interleaflet triangle, are in fibrous continuity and overlie the bundle of His as it extends leftward from the AV node (see Fig. 38.8A). The left bundle branch traverses below the membranous septum and penetrates superficially to traverse along the LV side of the interventricular septum.

The Edwards SAPIEN valve (ESV, Edwards Lifesciences, Irvine, Calif) bioprosthesis is a balloon-expandable trileaflet valve and is deployed through balloon expansion at the level of the annulus (see Figs. 38.8B and 38.9B).[331,332] The Medtronic CoreValve (MCV, Medtronic, Minneapolis, Minn) bioprosthesis is a self-expandable trileaflet valve with an elongated nitinol frame,[331,332] and the final position of the MCV valve covers three levels among the LVOT, aortic valve annulus, and ascending aorta (see Fig. 38.8C). The upper portion is situated within the ascending aorta and supports the position of the valve device in the same direction as blood flow. The middle third contains the leaflets with frame support above the native annulus. The lower third (ventricular) anchors the valve bioprosthesis within the LVOT (see Fig. 38.9B). The circumferential forces of the bioprosthetic valve in TAVR on the adjacent, underlying cardiac conduction system are believed to be a cause of cardiac conduction disturbances after TAVR (see Fig. 38.9B).[333–335]

Conduction disturbances may evolve during the postoperative period while the patient is being cared for in the ICU. In one trial ($n = 67$; MCV and ESV), complete heart block was observed in 22% (29% MCV vs 12% ESV; $P = .09$).[336] Early in the postoperative period, dynamic changes were noted in the patterns of AV block; new left bundle branch block (LBBB) at times resolved completely, and complete heart block developed into bundle branch block or first-degree AV block. Multivariate analysis identified baseline right bundle branch block (RBBB) as an independent predictor of permanent pacemaker

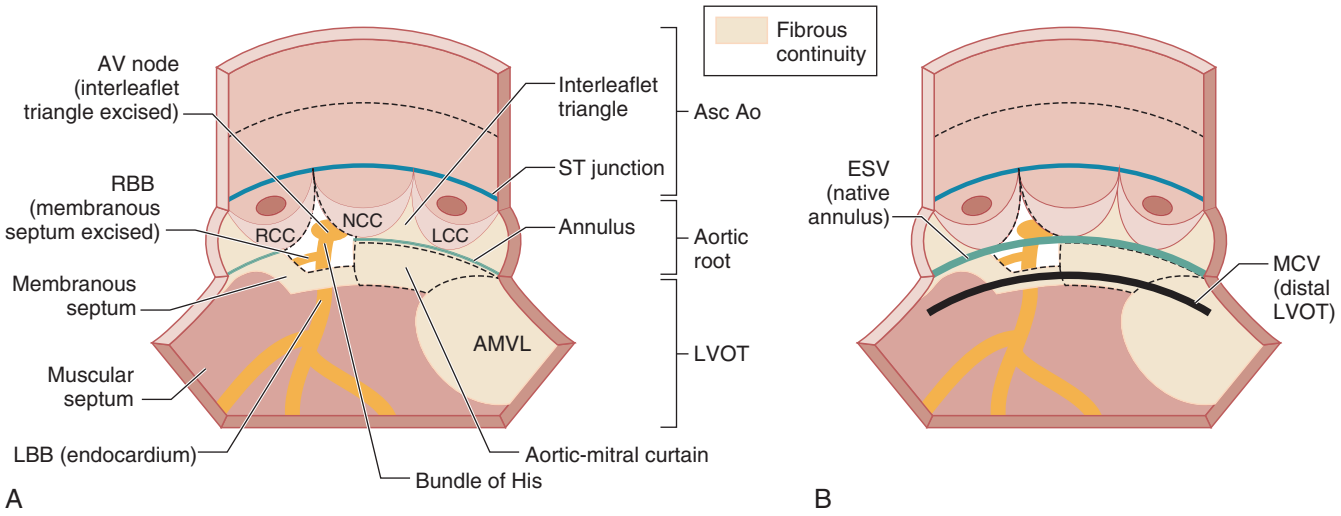

Fig. 38.9 The anatomic relationships of the cardiac conduction system, the aortic valve complex, and the transcatheter aortic valve replacement bioprostheses. (A) The left ventricular outflow tract *(LVOT),* aortic root, and ascending aorta *(Asc Ao)* are depicted to illustrate the proximity of the aortic valve complex to the conduction system. The aortic valve consists of three cusps (*RCC,* right coronary cusp; *LCC,* left coronary cusp; *NCC,* noncoronary cusp). The sinotubular *(ST)* junction represents the superior border of cusp attachment. The interleaflet triangle (between the RCC and the NCC) and relevant membranous septum have been removed to illustrate the underlying conduction tissue. (B) The LVOT, aortic root, and Asc Ao are depicted to illustrate the proximity of the aortic valve complex to the conduction system. The areas marked *MCV* (Medtronic CoreValve, Medtronic, Minneapolis, Minn) and *ESV* (Edwards SAPIEN Valve, Edwards Lifesciences, Irvine, Calif) indicate where the highest radial force is imposed for each bioprosthetic valve device. The maximal compressive effects of the ESV are exerted at the aortic valve annulus, whereas most of the compression from the MCV occurs in the distal LVOT, overlying the conduction system. *AMVL,* Anterior mitral valve leaflet; *LBB,* left bundle branch; *RBB,* right bundle branch. *(From Ghadimi K, Patel PA, Gutsche JT, et al. Perioperative conduction disturbances after transcatheter aortic valve replacement.* J Cardiothorac Vasc Anesth. *2013;27:1414–1420.)*

implantation (PPM) in the postoperative period following TAVR (relative risk [RR] 7.3; 95% CI 2.4–22.2).[336]

In a metaanalysis, the risk of heart block progressing to PPM was fivefold higher with the MCV than with the ESV (25.2% vs 5.0%).[337] The increased risk for complete AV block and PPM in TAVR, compared with surgical AVR, persists even when adjustments are made for age and baseline ECG characteristics.[337] One clinical trial identified baseline RBBB during multivariate analysis as a significant risk factor for pacemaker implantation after TAVR (OR, 8.61; 95% CI 3.14–23.67; $P < .0001$).[338]

It is readily apparent in the literature that the MCV has a significantly higher risk of AV block and pacemaker implantation compared with the ESV.[336–339] This difference is understandable from the anatomy of the AV conduction system and the MCV valve design, as outlined in Figs. 38.8 and 38.9.[340,341] Therefore the intensivist should be alerted if an MCV valve device has been implanted in patient with preoperative RBBB. Baan and colleagues[340] observed that the depth of MCV bioprosthesis implantation within the LVOT was a predictor of persistent new LBBB in 22 of 34 patients (65%). Bioprosthesis depth was assessed with contrast angiography after implantation and was defined as the distance between the ventricular end of the nitinol frame and the level of the native aortic valve annulus. The MCV bioprosthesis depth was 10.2 ± 2.3 mm in patients in whom LBBB had developed ($P = 0.02$).[340] This finding suggests that higher placement may lead to a decreased incidence of clinically significant conduction disturbances. In this same series, predictors of PPM included narrow LVOT diameter ($P = .01$) and mitral annular calcification ($P = .008$).

Risk factors for PPM postoperatively after TAVR have been investigated.[328,329] The following preoperative predictors were identified in a clinical trial with the MCV ($n = 34$; single-center study): (1) LBBB with left-axis deviation, (2) interventricular septal dimension greater than 17 mm, and (3) noncoronary cusp thickness greater than 8 mm.[342] In this trial, the risk of pacemaker implantation in the postoperative period after TAVR with the MCV bioprosthesis could be predicted with 75% sensitivity and 100% specificity if a patient had at least one of the foregoing predictors.[342] Preoperative RBBB has been associated with persistent AV block requiring PPM after TAVR with the MCV device.[343,344] In a larger trial ($n = 181$; all TAVR with MCV at a single Italian university medical center, 2007–2011), LBBB was the most common AV conduction abnormality, with an incidence of 50.3% at the time of discharge.[343] The incidence of PPM in this trial was 32.1%, and RBBB was the single independent predictor of PPM during multivariate analysis (hazard ratio, 16.5; 95% CI 3.3–82.3; $P < .001$).[343] A smaller trial ($n = 80$; 72% MCV and 28% ESV) also documented baseline RBBB ($P = .02$) and the MCV ($P = .01$) as independent predictors of PPM.[344] In a clinical trial ($n = 65$; all TAVR with MCV 2008–2009 at a Spanish university medical center), the only independent predictor of PPM was depth of valve implantation below the aortic valve annulus (OR, 1.9; 95% CI 1.19–3.05; $P < .007$).[345] A distance of 11.1 mm below the level of the annulus in the LVOT predicted the requirement for PPM with a sensitivity of 81% and a specificity of 84.6%.[345]

In a follow-up study ($n = 195$), the same group of investigators evaluated a new delivery system for MCV, which significantly decreased the MCV depth in the LVOT (6.4 ± 3 mm vs 9.6 ± 3.2 mm; $P < .001$) and the risk of PPM (14.3% vs 35.1%; $P = .003$).[346] Multivariate analysis in this larger sample identified the following predictors of PPM after TAVR with MCV: MCV depth in the LVOT (hazard ratio, 1.2; 95% CI 1.08–1.34; $P < .001$), baseline RBBB (hazard ratio, 3.5; 95% CI 1.68–7.29; $P = .001$), and application of the traditional delivery system (hazard ratio, 27; 95% CI 2.81–257; $P = .004$).[346] In a TAVR analysis ($n = 109$; all TAVR with the MCV at a single high-volume German university medical center), the risk factors for PPM also were investigated.[47] Significant predictors of PPM after TAVR in this series included age older than 75 years (OR, 4.6; $P = .02$), baseline HR less than 65 beats/minute

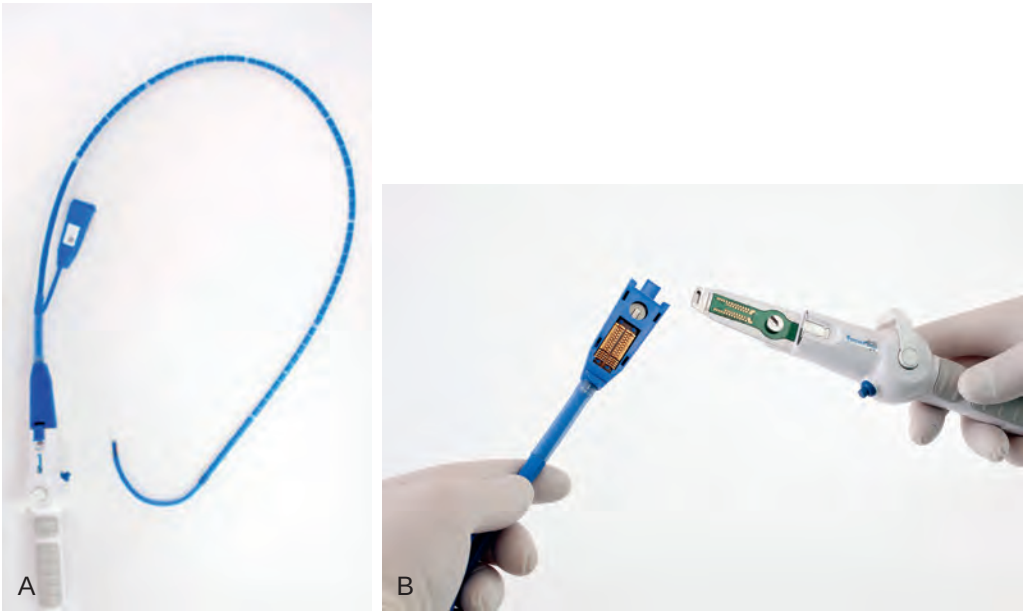

Fig. 38.10 (A) The miniaturized transesophageal echocardiography probe (ClariTEE, Imacor, Garden City, NY), which is 5.5-mm-diameter flexible probe *(blue)* capable of indwelling within the esophagus and providing echocardiographic images for up to 72 hours. The blue probe may be attached to the handle *(white and gray)* for maneuvering and image acquisition. (B) The probe may be detached and reattached from the ultrasound handle, with care taken to align the depicted prongs in the correct position. *(Courtesy Imacor, Garden City, NY.)*

(OR, 2.9; P = .04), MCV oversizing greater than 4 mm (OR, 2.8; P = .03), MCV bioprosthesis larger than 26 mm (OR, 2.2), AF (OR, 5.2; P = .001), and ventricular rate less than 65 beats/minute on postoperative day 1 (OR, 6.0).[347]

Anecdotally, preoperative implantation of a temporary ventricular screw-in lead ("temporary-permanent" pacemaker)[348] or a PAC with pacing capabilities[349] was described in patients meeting institutionally established criteria, to protect against life-threatening conduction abnormalities in the perioperative and postoperative periods. Future studies are under way to evaluate the safety and efficacy of these prophylactic strategies.

In summary, prompt recognition and proper management of AV blockade remain essential in the management of patients undergoing TAVR because hemodynamically significant heart block after TAVR may be common is selected patients and require PPM. It remains to be elucidated how the next generation of TAVR prostheses will affect the incidence, risk factors, and clinical outcomes of associated conduction disturbances. Certainly, in the postoperative ICU setting in the patient who does not have a preoperative pacemaker, new heart block and resulting hemodynamic instability may require swift intervention with transvenous pacing. This temporary measure may be implemented as a bridge to PPM.

Echocardiography in the Cardiothoracic Intensive Care Unit

Guidelines outlining basic TEE examinations have facilitated the adaptation of echocardiography in the ICU by intensivists without previous training in this modality.[350,351] The American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists developed a revised set of basic TEE views,[350,351] and they distinguished this document from the 1999 comprehensive guideline written by Shanewise and colleagues.[352,353] This document outlines 11 TEE views that together comprise the full basic TEE perioperative examination: the midesophageal 4-chamber view, the midesophageal 2-chamber view, the midesophageal long-axis view, the midesophageal ascending aortic long- axis view, the midesophageal ascending aortic short-axis view, the midesophageal aortic valve short-axis view, the midesophageal RV inflow-outflow view, the midesophageal bicaval view, the transgastric midpapillary short-axis view, and the descending aortic long-axis and short-axis views.[350,351] A publication sponsored by the Society of Critical Care Anesthesiologists put forward similar cardiac competencies for procedural TTE training of critical care trainees in the United States with a larger ICU-focused training paradigm.[354] These echocardiographic views may be particularly useful in the ICU when determining the causes of hemodynamic instability after cardiothoracic operations. In the immediate postoperative period, TTE may yield poor visualization as a result of postoperative change and positioning of support devices. For this reason, TEE is advocated during this early point-of-care setting for definitive and accurate diagnoses of hemodynamic aberrancies.

Miniaturized Transesophageal Echocardiography Probe

The use of a miniaturized, monoplane TEE probe (ClariTEE; ImaCor, Uniondale, NY) has been reported to provide benefit in the assessment of hemodynamically unstable patients in the cardiothoracic ICU (Fig. 38.10A).[355,356] This probe is capable of performing monoplane views of midesophageal four-chamber, midesophageal ascending aortic short-axis, and transgastric short-axis views (Fig. 38.11). The probe is 5.5 mm in diameter and is approved by the FDA to remain indwelling for up to 72 hours; it may connect to the portable ultrasound console (see Fig. 38.10A).[357] The probe may be disconnected when required from this portable ultrasound machine to facilitate evaluation of other patients with indwelling probes. The ultrasound machine (computer and monitor screen) is small and can be transported into patients' rooms. The ClariTEE probe uses a relatively high frequency (7 MHz) combined with specialized signal processing software to enhance penetration and contrast resolution. The inability to rotate the ultrasound scan sector, however, makes it difficult to obtain a complete diagnostic ultrasound scan of the cardiovascular structures. Furthermore, care must be taken to fasten the probe onto the ultrasound receiver to avoid damaging the prongs within this blue mini-probe (see Fig. 38.10B). In a retrospective study (n = 21; single academic medical center cardiothoracic ICU in the United States), the miniaturized TEE was used to

identify postoperative hemodynamic instability. In this observational study, discordance between hemodynamic monitoring and episodic TEE was qualitatively observed in 14 patients (66%), a finding suggesting that standard monitoring may be inferior to TEE in defining the clinical situation.[356]

Studies are limited, and caution should be used with any single monitoring device. We find these miniaturized probes satisfactory for hemodynamic management and assessment of gross RV and LV function. At this time, however, standard TEE probes and ultrasound machines are superior in imaging clarity, use of color-flow Doppler or Doppler profiles, and diagnosing causes requiring further procedural or surgical intervention in the setting of hemodynamic instability in the ICU.

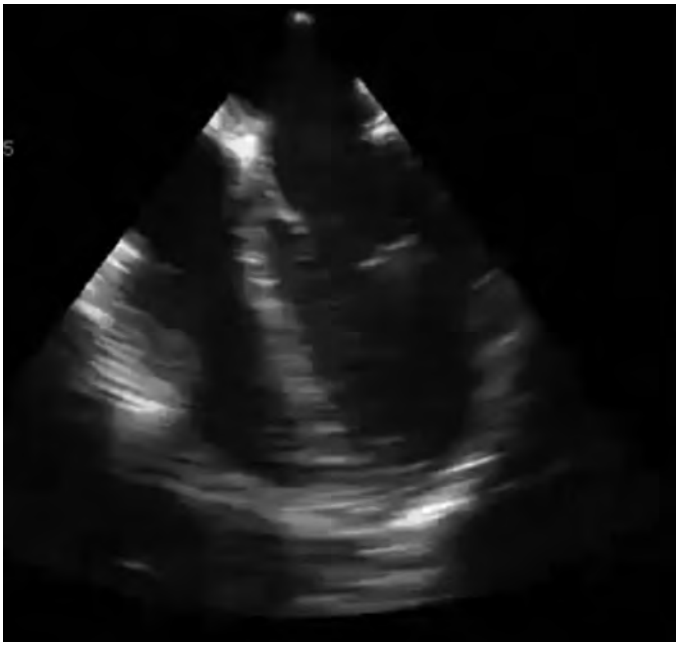

Fig. 38.11 Midesophageal four-chamber view provided by the ClariTEE (Imacor, Inc., Garden City, NY) transesophageal echocardiography probe. The image provides qualitative information (gross function) for hemodynamic management, as well as quantitative data in terms of calculating ejection fraction, but it lacks sufficient Doppler capability. *(Courtesy K. Ghadimi, MD.)*

Echocardiography During Postoperative Intensive Care Unit Management of Left Ventricular Assist Devices

Echocardiography is particularly useful for the postoperative management of patients after LVAD implantation. Assessment of RV function is central to the hemodynamic management of these patients in the immediate postoperative period, and echocardiography may help visualize interventricular septal position, RV systolic function, degree of the tricuspid valve regurgitation, and LV chamber size. TTE typically provides poor visualization of the cardiac chambers postoperatively as a result of inflammation, thoracostomy and mediastinal tubes, and echogenic dropout from the LVAD hardware. For this reason, we advocate TEE during the assessment of hemodynamics in this group of patients.

Right Ventricular Dysfunction After Left Ventricular Assist Device Placement

Classically, the patient may present to the ICU with central venous access, a PAC, and invasive arterial PB monitoring. This hemodynamic data alert the ICU physician to aberrancies that may suggest RV dysfunction, venous hypertension, and inadequate LVAD filling and ejection. The use of echocardiography together with these hemodynamic variables allows the immediate titration of pharmacologic support and LVAD speed to optimize CO, right-sided filling pressures, mixed venous oxygenation, RV systolic function, and LV filling.

Akin to the TEE examination on separation from CPB in the operating room, the TEE examination in the ICU similarly focuses on the position of the interventricular septum. Equal filling and emptying of both the right ventricle and the left ventricle result in a midline position of the septum. When LVAD flows are relatively higher than the ability of the right ventricle to deliver CO to the left ventricle, the interventricular septum tends to bow toward the left ventricle, thus resulting in an LV "suckdown" effect, RV failure, and increased tricuspid regurgitation (Fig. 38.12A).[358] Tricuspid regurgitations occurs as a result of tricuspid valve annular distortion (Fig. 38.12B). This effect may be somewhat offset by increasing SVR, increasing LV chamber size, and tempering the leftward interventricular septal shift. On occasion, titration of pharmacologic and mechanical support (LVAD settings) is ineffective, and a return to the operating room may be warranted for RV assist device (RVAD) placement.

In the event that cardiac filling pressures are low, RV systolic function seems adequate, but markers of systemic perfusion suggest reduced pressure and flow, TEE may be indicated to optimize LVAD speeds while maintaining a midline interventricular septum and determining the degree of mitral regurgitation and LV cavity size. The greatest yield of information through the use of TEE in the ICU comes from the direct visualization of the myocardium and the interplay

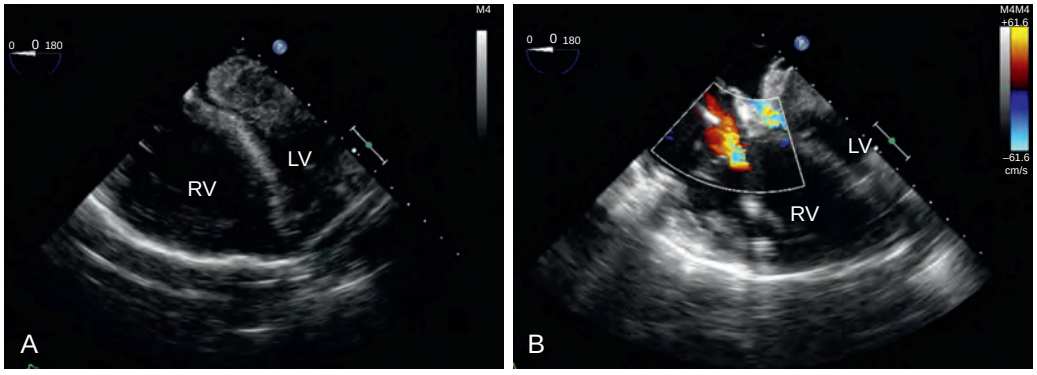

Fig. 38.12 Left ventricular assist device (LVAD) "suckdown" effect seen by transesophageal echocardiography (TEE) in the cardiothoracic intensive care unit. (A) Midesophageal four-chamber view using TEE to illustrate LVAD suckdown as a result of right ventricular failure and relatively increased and mismatched LVAD flows. (B) Midesophageal four-chamber view with color-flow Doppler illustrating severe tricuspid regurgitation during this suckdown event. *LV,* Left ventricle; *RV,* right ventricle. *(Courtesy K. Ghadimi, MD.)*

among the cardiac chambers, as well as the simultaneous assessment of hemodynamic variables (eg, MAP, CVP, PAP, $S\bar{v}O_2$, cardiac index).[359]

Echocardiography to Rule Out Obstructive Shock After Left Ventricular Assist Device Placement

Increasing right-sided filling pressures, reduced cardiac index, and low mixed venous oxygenation saturation may alert the intensivist to problems with intrinsic RV function, but causes of obstructive shock should be excluded. Invasive hemodynamic monitoring cannot always discern among different causes of poor RV function. However, TEE enables the clinician definitively to diagnose new pericardial effusions, large right-sided pleural effusions, or bleeding resulting in mass compression of the atria and/or ventricles. In the setting of cardiac tamponade physiology, immediate return to the operating room is warranted to relieve mass compression of the involved cardiac chambers (Fig. 38.13).

Echocardiography in Patients Requiring Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is mechanical support of the lungs and/or heart for a period of days to weeks by a modified pulmonary or CPB machine; this support is discussed in detail in Chapter 32.[360–362] VV ECMO is primarily used for treating severe but potentially reversible respiratory failure, and VA ECMO is primarily used for treating severe cardiac or cardiorespiratory failure.

Venovenous Extracorporeal Membrane Oxygenation

With VV ECMO, deoxygenated blood is drained from the inflow cannula placed in a large central vein, typically the inferior vena cava (IVC), and oxygenated blood is returned through a cannula whose tip lies in or close to the right atrium. Ideally, all or most of the blood from the outflow cannula passes through the tricuspid valve into the pulmonary circulation. Under the condition that the oxygenated blood does not pass through the tricuspid valve but instead is "recirculated" into the inflow cannula, this blood does not contribute to systemic oxygenation and may result in hypoxemia if the recirculating volume is substantial. Although recirculation may be suspected by nonechocardiographic modalities, echocardiography can verify the diagnosis of clinically important recirculation by directly visualizing flow from the outflow cannula entering the inflow conduit. The relative positions of the inflow and outflow cannulas may be separated under direct echocardiographic guidance with color-flow Doppler imaging to eliminate clinically important recirculation (some degree of recirculation remains and in usually unavoidable). After the direct visual guidance

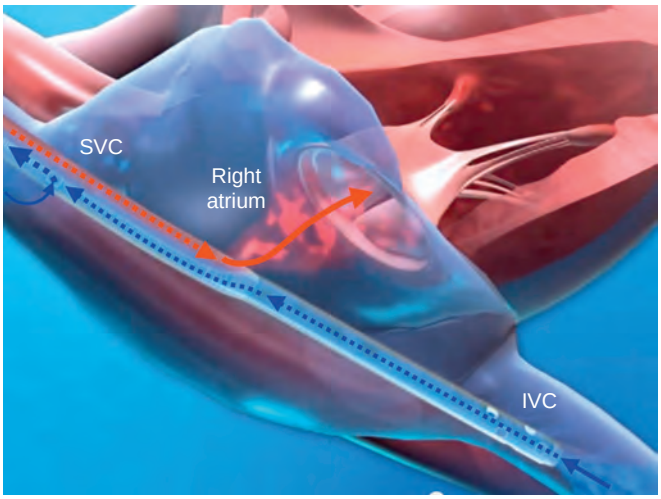

Fig. 38.14 The Avalon Elite Bicaval Dual-Lumen (Avalon Elite Bicaval Dual-Lumen Catheter and Vascular Access Kit, Maquet Cardiopulmonary, Rastatt, Germany) in the correct position. The cannula is inserted through the right internal jugular vein and is positioned through continuous imaging with the distal (inflow) tip in the inferior vena cava *(IVC)* and the proximal (inflow) tip within the superior vena cava (*SVC*) (systemic venous return shown by *blue arrows*). The outflow orifice is positioned medially toward the tricuspid valve and delivers extracorporeal membrane oxygenated blood to the right atrium *(red arrows). (Modified from Maquet, Cardiopulmonary, Rastatt, Germany.)*

of separating the inflow and outflow cannulas, standard assessment for recirculation (eg, preoxygenator PaO_2 < postoxygenator PaO_2) can verify the correction of systemic hypoxemia.

One single-cannula technique uses a double-lumen single cannula (Avalon Elite Bicaval Dual-Lumen Catheter and Vascular Access Kit, Maquet Cardiopulmonary, Rastatt, Germany), and it is designed for placement in the right internal jugular vein.[363] The tip of the (larger) inflow lumen is situated within the IVC, thus taking care to avoid insertion into a hepatic vein (Fig. 38.14). The inflow lumen has an end hole and a side fenestrations at the tip, as well as side holes proximal to the exit site of the inflow lumen that allow drainage from the both the SVC and the IVC (Fig. 38.15, and see Fig. 38.14). The outflow lumen of the single cannula opens 10 cm above the inflow cannula tip and is designed to return blood to the right atrium (see Fig. 38.14).[363] Once inserted, the outflow cannula lumen should be positioned inward and toward the tricuspid valve to direct flow through the valve, although this is more a theoretic than a practical consideration. On occasion, both the openings of the outflow and inflow cannula may be within the IVC because of advancement from the percutaneous insertion site. Certainly, outflow cannula tip position should be a consideration if significant recirculation or low flows are encountered on initiation of VV ECMO flow. TEE may be used to illustrate flow within the inflow and outflow cannula lumina and to illustrate position of each limb within the IVC (Fig. 38.16A) and the right atrium (Fig. 38.16B), respectively. The SVC inflow orifice may be challenging to view by TEE, but it can be assumed to be in correct position if the other two openings are positioned correctly.

Venoarterial Extracorporeal Membrane Oxygenation

During VA ECMO, systemic venous blood drains into the circuit through a cannula placed in the right atrium through either the IVC (femoral approach) or SVC (internal jugular vein approach). This may be visualized by TEE to establish flow through the cannula and correct positioning (Fig. 38.17). If TEE is contraindicated, TTE may provide utility in selected patients who allow adequate echocardiographic visualization through the chest wall (Fig. 38.18). Akin to VV ECMO, blood passes through the inflow cannula of the VA ECMO circuit into the pump and the oxygenator/heat exchanger before returning to the

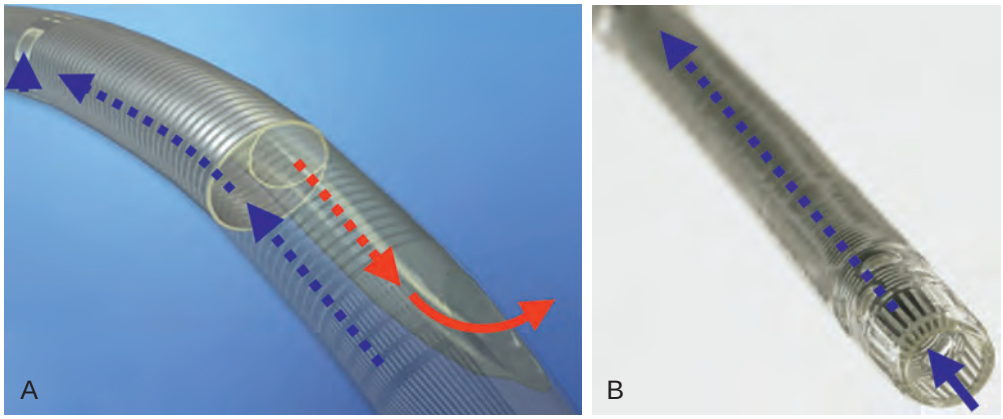

Fig. 38.15 Focused depiction of the Avalon Elite cannula. (A) A flexible membrane separates the oxygenated blood *(red arrows)* from the venous drainage *(blue arrows)*. The superior vena cava *(SVC)* inflow port is visible at *the top left (blue arrowhead)*. (B) The distal inflow tip has a single, fenestrated opening within the inferior vena cava *(IVC)*. *(Modified from Javidfar J, Brodie D, Wang D, et al. Use of bicaval dual-lumen catheter for adult venovenous extracorporeal membrane oxygenation.* Ann Thorac Surg. *2011;91:1763–1768.)*

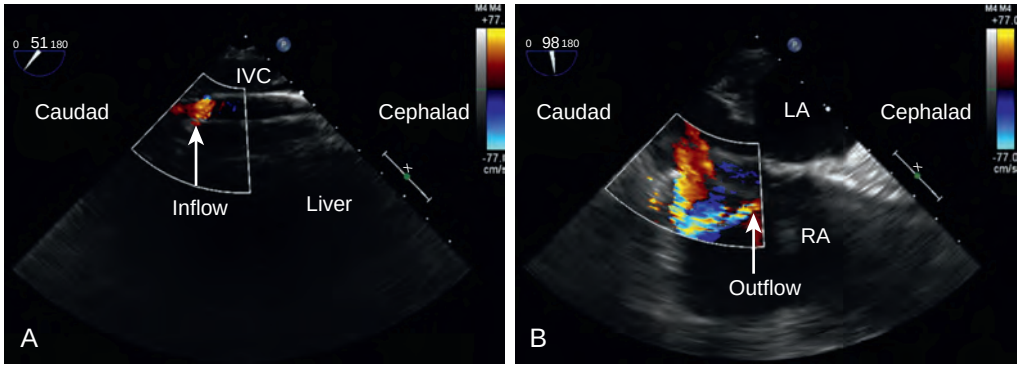

Fig. 38.16 Transesophageal echocardiographic visualization of the Avalon Elite cannula (Maquet Cardiopulmonary, Rastatt, Germany) during venovenous extracorporeal membrane oxygenation. Caudad and cephalad directions are marked on the images for orientation. (A) The inflow lumen of Avalon Elite Bicaval Dual-Lumen Catheter and Vascular Access Kit (is visible within the inferior vena cava *(IVC)* with color-flow Doppler illustrating blood flowing within the inferior intrahepatic IVC toward the inflow tip of the cannula. (B) The outflow cannula of Avalon Elite cannula is visible within the right atrium *(RA)*. Color-flow Doppler imaging illustrates blood flow from the outflow cannula directed medially toward the tricuspid valve (not seen). The color-flow Doppler box encompasses a smaller portion of the cannula outflow and shows a small amount of blood flowing away from the tricuspid valve; this finding is common but is presumably of no clinical significance (in the setting of normal flows and adequate extracorporeal gas exchange). *LA,* Left atrium. *(Courtesy K. Ghadimi, MD.)*

patient through a cannula placed within or grafted to a large artery (femoral, axillary, or aorta, commonly). Systemic arterial blood flow is the sum of the VA ECMO circuit flow and any ejection from the left ventricle. Systemic BP is determined by flow and vascular tone. Because oxygen and carbon dioxide tensions are controlled during extracorporeal support, the patient's systemic arterial oxygen saturation (Sa_{O_2}) is determined entirely by the oxygen saturation of the blood in the ECMO return cannula, which is normally 100%, in the absence of LV ejection. However, if LV ejection is present, Sa_{O_2} depends on the relative flow and oxygen saturation of blood from both the ECMO circuit and blood ejected by the left ventricle.

Using Echocardiography to Troubleshoot Common Complications of Venoarterial Extracorporeal Membrane Oxygenation

- **North-south syndrome:** This syndrome occurs in the specific circumstance of severely impaired lung function in conjunction with femoral placement of the VA ECMO outflow cannula. In this situation, the potential exists for upper body hypoxemia (coronary arteries, cerebral blood vessels, and upper limbs) because proximal branches of the aorta receive predominantly deoxygenated blood ejected from the left heart. This phenomenon of north-south syndrome may be seen on echocardiography as stagnant, "swirling" flow in the descending thoracic aorta as a result of the interface created by blood ejected from the left ventricle and blood returning to the patient from the outflow limb (Fig. 38.19). Even in the presence of significant LV ejection, this situation does not arise if pulmonary function is good or the outflow cannula is transitioned to central placement (proximal aorta or axillary artery). For this reason, institutional practice may dictate transition from peripheral (through the femoral artery) to central (through the aortic or axillary artery) cannulation as soon as the patient is clinically stable enough to handle this transition. Alternatively, after recovery of LV function is confirmed by echocardiography, but lung function continues to suffer, transition to VV ECMO may be initiated.

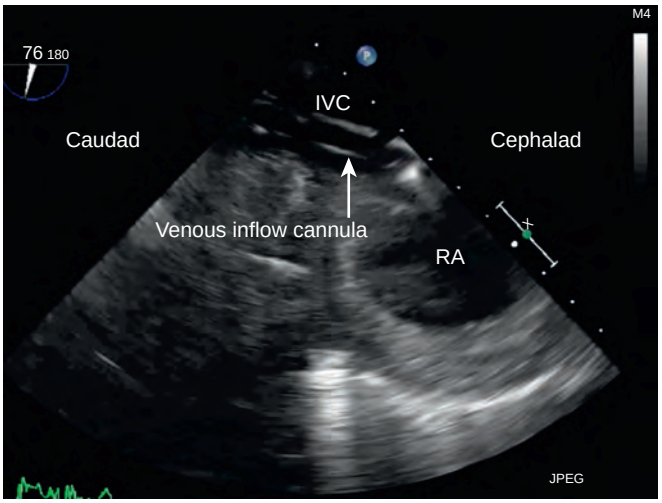

Fig. 38.17 Transesophageal echocardiographic image of the veno-arterial extracorporeal membrane oxygenation inflow cannula within the junction of the inferior vena cava *(IVC)* and the right atrium *(RA)*. Caudad and cephalad directions are marked on the image for orientation. The cannula (which has been inserted percutaneous from the right common femoral vein) tip sits within the RA, and the cannula contains side fenestrations to increase inflow volume. The cannula has been advanced into the superior vena cava (not pictured) under echocardiographic guidance to improve upper body venous drainage. *(Courtesy K. Ghadimi, MD.)*

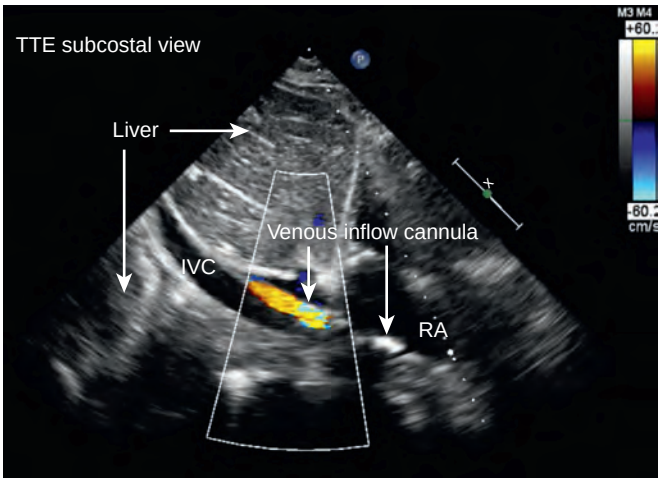

Fig. 38.18 Transthoracic echocardiographic *(TTE)* image of venoarterial (VA) extracorporeal membrane oxygenation (ECMO) inflow cannula within the inferior vena cava *(IVC)* and right atrium *(RA)*. In the subcostal TTE view, the "venous" inflow cannula for a patient undergoing peripheral VA ECMO is visible within the IVC and RA. Fenestrations within the cannula are marked by *white arrows*. In a patient with relative or absolute contraindication(s) to transesophageal echocardiography, TTE is warranted and may provide clear and diagnostic imaging for ECMO cannula placement. *(Courtesy K. Ghadimi, MD.)*

Descending aorta (A) short-axis view and (B) long-axis view illustrate increased spontaneous echogenic contrast *(SEC)* within the descending thoracic aorta signifying stagnant flow. *(Courtesy K. Ghadimi, MD.)*

- **Hemodynamic instability:** Hypotension during "full-flow" VA ECMO and complete circulatory support in the absence of native cardiac function suggests vasodilation or LV distention. LV distention may become particular problematic in patients with aortic and mitral regurgitation. Clinically, the patient may present with pulmonary edema frothing from the endotracheal tube shortly after institution of VA ECMO and/or ventricular arrhythmia requiring defibrillation. The diagnosis may be confirmed by identifying a severely dilated left ventricle with TEE. Increasing pump flows reduce pulmonary blood flow and ameliorate the issue. Failing this, the left side of the heart must be vented. Surgically, the LV vent may be inserted through the right upper pulmonary vein and the cannula advanced across the mitral valve and into the left ventricle. Echocardiographic confirmation of LV vent placement is important to ensure that the left ventricle is decompressed and that the risk of developing LV thrombus has been significantly reduced (Fig. 38.20).

Weaning and Discontinuing Venoarterial Extracorporeal Membrane Oxygenation

An early sign of recovery of myocardial function is the presence of pulsatility on the arterial waveform. Patients are usually weaned from VA ECMO onto moderate doses of inotropic support (eg, epinephrine 0.04–0.1 μg/kg per min). The planned inotropic regimen should be started several hours before weaning. Circuit flows are slowly reduced to 1 to 2 L/minute, cardiac function is assessed with TEE during hemodynamic monitoring. If the patient is hemodynamically stable and TEE imaging demonstrates preserved cardiac function on pharmacologic support, then decannulation and discontinuation of VA ECMO are planned. Patients with an LVEF lower than 30% after 2 days of VA ECMO are significantly less likely to be successfully weaned than those with an EF greater than 30% (8% vs 54%; $P < .001$).[364] The previously described miniaturized TEE probe was used for weaning from VA ECMO in a single-center observational study using a standardized VA ECMO weaning protocol ($n = 21$).[365] The investigators indicated that

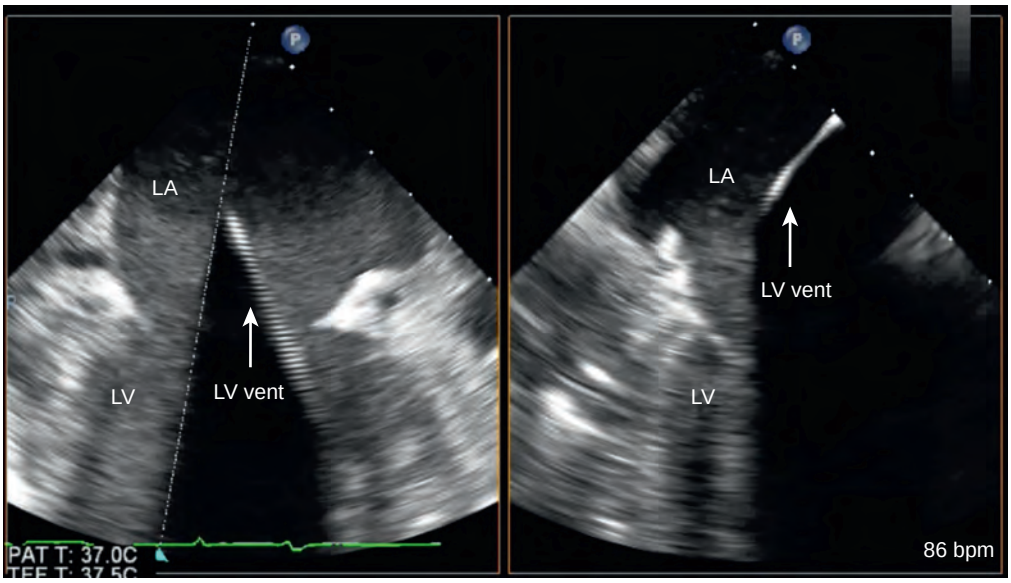

Fig. 38.20 Transesophageal echocardiographic (TEE) image of left ventricular vent *(LV vent)* placement in preparation for deployment of central venoarterial extracorporeal membrane oxygenation. The cross-plane feature of TEE illustrates the LV vent inserted from right upper pulmonary vein (not pictured) and advanced across the mitral valve to provide LV decompression. *LA,* Left atrium; *LV,* left ventricle. *(Courtesy K. Ghadimi, MD.)*

the positive predictive value for ventricular recovery by this mini-TEE probe was 100% using their standardized ECMO weaning protocol (95% CI, 73%–100%).[365]

In conclusion, understanding the process of initiation, management, weaning, and discontinuation from both VV and VA ECMO represents an important skill set for today's cardiothoracic intensivist. In particular, the utility of TEE in the care of these patients with complex conditions provides the intensive care physician with a tool that confirms the diagnosis of common complications or even routine management during VV and VA ECMO.

Postoperative Respiratory Care

THOMAS L. HIGGINS, MD, MBA | DANIEL T. ENGELMAN, MD

KEY POINTS

1. Pulmonary complications following cardiopulmonary bypass are relatively common, with up to 12% of patients experiencing some degree of acute lung injury and approximately 1% requiring tracheostomy for long-term ventilation.
2. Risk factors for respiratory insufficiency include advanced age, presence of diabetes or renal failure, smoking, chronic obstructive lung disease, peripheral vascular disease, previous cardiac operations, and emergency or unstable status.
3. Patients with preexisting chronic obstructive lung disease have higher rates of pulmonary complications, atrial fibrillation, and death.
4. Operating room events that increase risk include reoperation, blood transfusion, prolonged cardiopulmonary bypass time, and low–cardiac output states, particularly if a mechanical support device is required.
5. Transesophageal color Doppler echocardiography is an important tool for real-time bedside monitoring in the postoperative period and has additional applications in assessing ability to wean from long-term ventilatory support.
6. Hospital-acquired infections are important causes of postoperative morbidity. Strategies to reduce the incidence of ventilator-associated pneumonia include early removal of gastric and tracheal tubes, formal infection control programs, hand washing, semirecumbent positioning of the patient, use of disposable heat and moisture exchangers, and scheduled drainage of condensate from ventilator circuits.
7. Patients at risk for acute lung injury and those developing acute respiratory distress syndrome should be switched to a lung-protective ventilation strategy, which involves maintaining peak inspiratory pulmonary pressure less than 35 cm H_2O and restricting tidal volumes to 6 mL/kg of ideal body weight.
8. Permissive hypercapnia may be necessary to implement a lung-protective ventilation strategy. It should be used judiciously in patients with pulmonary hypertension because acidosis can exacerbate pulmonary vasoconstriction and further impair right ventricular function and cardiac output.
9. Impediments to weaning from mechanical ventilation and extubation include delirium, unstable hemodynamic status, respiratory muscle dysfunction, renal failure with fluid overload, and sepsis.
10. Short-term weaning success can be achieved with any variety of ventilation modes. The patient receiving long-term ventilatory support requires an individualized approach that may encompass pressure-support ventilation, synchronized intermittent mandatory ventilation weaning, or T-piece trials. Noninvasive ventilation may assist in the transition from full support to liberation from mechanical ventilation.
11. Although several parameters exist to assess respiratory strength and endurance, the single best parameter is the frequency-to–tidal volume ratio.
12. Long-term administration of neuromuscular blocking agents is associated with persistent muscle weakness. Possible causes included accumulation of drug metabolites, critical illness polyneuropathy, or neurogenic atrophy.
13. A few patients are not able to be weaned from ventilation support. Characteristics of these patients include a persistent low-output state with multisystem organ failure. Echocardiography can be helpful in establishing ventricular filling, contractility, and cardiac output at baseline and during weaning trials. Long-term weaning may be best accomplished in a specialized unit rather than an acute cardiovascular recovery area.

Patients undergoing cardiac surgical procedures experience physiologic stresses from anesthesia, sternotomy or thoracotomy, surgical manipulation, and cardiopulmonary bypass (CPB). Each of these interventions can create transient deleterious effects on pulmonary function even in patients with normal lungs; the effects may be exaggerated in the presence of preexisting pulmonary disease. Important pulmonary changes after cardiac operations include diminished functional residual capacity following general anesthesia and muscle relaxants,[1] transient reduction in vital capacity following median sternotomy and intrathoracic manipulation, atelectasis, and increased intravascular lung water.[2] Acute functional residual capacity reduction creates arterial hypoxemia secondary to a mismatch between ventilation and perfusion and diminishes lung compliance with increased work of breathing. This additional work of breathing, which increases oxygen consumption by up to 20% in spontaneously breathing patients,[3] also increases myocardial work at a time when myocardial reserves may be limited. Changes in spirometric measurements and respiratory muscle strength can last up to 8 weeks postoperatively.[4]

Thus many cardiac surgical patients can be expected to have respiratory complications. Acute lung injury (ALI), sometimes progressing to acute respiratory distress syndrome (ARDS), can occur in up to 12% of postoperative cardiac patients.[5] Approximately 6% of cardiovascular surgical patients require more than 72 hours on the ventilator, and approximately 1% of patients undergo tracheostomy to facilitate recovery and weaning from prolonged support with mechanical ventilation.[6]

Risk Factors for Respiratory Insufficiency

The lung is especially vulnerable because disturbances may affect it directly (atelectasis, effusions, pneumonia) or indirectly (from fluid overload in heart failure; as the result of mediator release from CPB, shock states, or infection; or from changes in respiratory pump function, as with phrenic nerve injury). Postoperative status is determined in part by the patient's preoperative pulmonary reserve, as well as by the level of stress imposed by the procedure. Thus a patient with reduced vital capacity as a result of restrictive lung disease who is undergoing a minimally invasive surgical procedure may have fewer postoperative pulmonary issues than a relatively healthy patient who is undergoing simultaneous coronary artery bypass grafting (CABG) and valve replacement with its longer accompanying operative, anesthetic, and CPB times. Respiratory muscle weakness contributes to postoperative pulmonary dysfunction, and prophylactic inspiratory muscle training has been shown to improve respiratory muscle function, pulmonary function test results, and gas exchange, as well as reducing the incidence of delayed extubation.[7]

Assessing Risk Based on Preoperative Status

Robust models are available to stratify mortality outcome by preoperative risk factors in patients undergoing cardiac surgical procedures.[8–12] The independent (predictive) variables and their weighting vary from model to model. They also vary between models predicting mortality rates and those predicting morbidity or length of stay outcomes,[9] but the commonalities are greater than the differences. The Society of Thoracic Surgeons National Adult Cardiac Surgery Database is widely used in the United States, and it offers, in addition to a mortality prediction, a model customized to predict prolonged ventilation.[10,11] The European System for Cardiac Operative Risk Evaluation (EuroSCORE) is commonly used in Europe.[12] Factors common to outcome risk adjustment models include age, sex, body surface area, presence of diabetes or renal failure, chronic lung disease, peripheral vascular disease, cerebrovascular disease, previous cardiac operation, and emergency or unstable status.[9–11] Chronic obstructive pulmonary disease (COPD) may be an expected major risk for postoperative respiratory morbidity and death, and it appears as a factor in some models. However, hospital mortality rates in patients with mild to moderate COPD are not especially high; the few patients with severe COPD, especially those older than 75 years of age and receiving steroids, are at highest risk.[13] Patients with preexisting COPD have higher rates of pulmonary complications (12%), atrial fibrillation (27%), and death (7%).[13] Obesity, defined by increased body mass index, does not appear to increase the risk of postoperative respiratory failure or death.[14,15] Conversely, even modest elevations of serum creatinine (>1.5 mg/dL) are independently associated with higher morbidity and mortality rates.[9,16]

At least four studies have used multivariate regression techniques to elucidate factors specifically associated with postoperative respiratory failure (Table 39.1). The studies differ in their end points for outcome, and in their choice of preoperative versus operative versus postoperative variables. Spivack and colleagues[17] examined 513 consecutive patients undergoing CAGB and identified reduced left ventricular ejection fraction, preexisting congestive heart failure, angina, current smoking, and diabetes mellitus as predictors of mechanical ventilation support beyond 48 hours. In this study, pulmonary diagnosis, lung mechanics, and blood gas parameters were not independently useful in predicting outcome. Branca and colleagues[18] found that the mortality rate predicted by The Society for Thoracic Surgeons model[10] was the single best predictor of mechanical ventilation support for longer than 72 hours but also identified mitral valvular disease, age, vasopressor and inotrope use, renal failure, operative urgency, type of operation, preoperative ventilation, previous cardiac operation, female sex, myocardial infarction within 30 days, and previous stroke as contributors. Rady and colleagues[19] examined both preoperative and intraoperative factors and noted that transfusion of more than 10 units blood products or total CPB time in excess of 120 minutes was an important operative event in addition to the usual preoperative predictors of extubation failure. Canver and Chandra[20] looked only at operative and postoperative predictors versus the end point of mechanical ventilation for more than 72 hours; these investigators found that prolonged CPB time, sepsis and endocarditis, gastrointestinal bleeding, renal failure, deep sternal wound infection, new stroke, and bleeding requiring reoperation were important predictors of prolonged ventilatory support. None of these models, general or specific to respiratory complications, is sufficiently sensitive or specific to prohibit consideration of surgical treatment for an individual patient, but these models do provide the clinician with an early warning for patients at high risk.

Operating Room Events

Identification of the patient who is difficult to intubate is important for planning extubation for a time when sufficient personnel and equipment are available to implement a potentially difficult reintubation. Opioids and neuromuscular blocking agents with long half-lives may be expected to influence extubation time, but it is the skill of the anesthesiologist in knowing how to use these drugs well and not the specific duration of drug action that influences extubation time. Patients undergoing reoperation are at risk[19–21] partly because of longer CPB times with reoperation, increased use of blood transfusion, and the additional likelihood of bleeding in this population. Length of time on CPB is repeatedly identified as a risk factor,[19–21] and a correlation between CPB time and inflammatory cytokine release has been demonstrated.[22] However, levels of C-reactive protein, an inflammatory marker, do not correlate with outcomes such as time spent on mechanical ventilation.[23] Genetic polymorphisms are associated with respiratory complications,[24] a finding suggesting that risk prediction may require more sophisticated understanding of individual patients' variables. Observations of dose-dependent reductions in adverse events after CABG in patients receiving statins are also intriguing.[25,26] In randomized, double-blind trials, both simvastatin and atorvastatin were shown to have beneficial effects on the systemic inflammatory response after CPB.[27,28]

Cardiovascular collapse occasionally occurs at the time of chest closure secondary to severe distention or edema of the lungs. Physiologically this condition acts much like cardiac tamponade, and the solution is to leave the chest open for 24 to 48 hours. An open chest delays early extubation, and it also has a potential to produce long-term ventilator dependency should infection or sternal osteomyelitis develop.

The prognostic and therapeutic implications of an intraaortic balloon pump (IABP) depend on the reasons for which the device was inserted. Not surprisingly, mortality and ventilation dependency rates are lowest in patients not requiring any mechanical support. In patients whose IABP was placed preoperatively for unstable angina, definitive surgical treatment should correct the problem, and removal of the IABP and extubation need not be delayed. In all other situations, intubation and ventilatory support may be required beyond the time of removal of the IABP because of residual cardiac dysfunction, fluid overload, or associated organ injury. Patients whose IABP was placed for preoperative cardiogenic shock, as an assist to separating from bypass, or for low-output states in the postoperative period have a high mortality risk and frequently need prolonged ventilatory support.

Positive end-expiratory pressure (PEEP) during CPB has been advocated as one method to prevent atelectasis. This approach is impractical in patients with obstructive lung disease because air trapping

interferes with surgical exposure. Recruitment maneuvers following CPB have a variable impact on intubation time; most studies show them to be ineffective in reducing the need for long-term ventilatory support. Alveolar recruitment maneuvers can be performed without deleterious effects, even in morbidly obese patients, as long as intravascular volume is adequate.[29] No compelling data indicate that fluid management choices or the use of steroids before CPB will have substantial effects on intubation time or respiratory failure.

Transcatheter aortic valve replacement (TAVR) has emerged as an option for treating severe aortic valve stenosis.[30] Percutaneous and transcatheter mitral valve replacement procedures have also been described.[31] Initial candidates for these procedures were older patients with comorbidities who were considered to be at high or extreme surgical risk for traditional open valve replacement, but the procedure is rapidly becoming a disruptive technology able to replace traditional open operations as delivery systems become smaller and multidisciplinary teams gain confidence. Randomized trials are under way to assess whether moderate-risk patients will also benefit from this procedure. TAVR is also frequently used as an alternative to reoperative tissue aortic valve replacement. The so-called "valve-in-valve" procedure inserts a new transcatheter valve within a previously placed degenerating tissue valve. TAVR procedures can be performed from multiple access points, including transfemoral, transapical (through a small left thoracotomy), and transaortic (through a small right anterior thoracotomy). In the United States, many centers conduct this procedure using general anesthesia in an operating room or hybrid suite, but increasingly in Canada and Europe, transfemoral TAVR is accomplished in catheterization laboratories, with anesthesia management akin to sedation for angioplasty. A systematic review of seven observational studies totaling 1542 patients suggested that either local or general anesthesia may be used, with similar short-term outcomes.[32]

The acute hemodynamic changes following TAVR are usually well tolerated, but decompensation (shock) may occur, particularly if a dynamic intraventricular pressure gradient develops after the relief of valvular obstruction. In this situation, inotropic (β-adrenergic) support may exacerbate the decompensation; volume expansion and selective α_1 vasopressor support are preferred. The incidence of rescue conversion to sternotomy after TAVR is not well studied (perhaps 1% to 3%[33]), but it carries substantial morbidity, especially in patients deemed too ill for conventional open valve replacement. Major stroke, vascular complications, and hemodynamic changes including new-onset atrial fibrillation can be expected events in the intensive care unit (ICU)[34]; because these events are also seen in patients undergoing CPB and off-bypass procedures, they are discussed later.

Randomized studies are lacking for optimal management of TAVR-treated patients requiring intubation, but extrapolating from the fast-track experience with CABG, even high-risk patients can be managed with early extubation and mobilization.[35] TAVR is a truly collaborative endeavor, requiring close collaboration and cross-training for the heart team, anesthesiology, vascular surgery, cardiac imaging, critical care, and nursing[35] (see Chapters 21 and 27).

Postoperative Events

Historically, patients undergoing CPB were kept intubated and sedated at least overnight to permit stabilization and metabolism of the large doses of opioids then used. This practice began to change in the 1990s with the advent of fast-track recovery, which spread from selected patients to general use.[36,37] The expected ICU course, if the patient is not extubated "on the table,"[38] is a short period of ventilation support while the patient is warmed, allowed to awaken, and observed for bleeding or hemodynamic instability. In low-risk patients, short-stay (8-hour) protocols can deliver clinical results at lower cost comparable to a standard overnight ICU stay.[39] Preoperative risks, issues with difficult intubation, and operating room events should be communicated from the operating room team to the ICU team at the time of ICU admission. Box 39.1 outlines criteria to be met before routine extubation. Laryngeal edema can often be identified by the absence of an air leak when the endotracheal tube cuff is deflated. Intravenous methylprednisolone can reduce the incidence of postextubation stridor.[40] Prophylactic nasal CPAP at 10 cm H_2O for a minimum of 6 hours has been shown to reduce hypoxemia, pneumonia, and reintubation rates after elective cardiac operations.[41]

Before extubation, a quick neurologic examination should be performed to rule out new cerebrovascular events, the presence of excess sedation, or residual neuromuscular blocking agents. Knowing that the work of breathing can consume up to 20% of cardiac output should preclude immediate extubation in the hemodynamically unstable patient. Although patients may be successfully extubated while on the IABP, the need to lie flat after balloon and sheath removal may interfere with their ability to resolve atelectasis and clear secretions. This limitation often dictates continued temporary ventilator support until the patient is able to sit up.

Health care–acquired infections are important causes of postoperative morbidity and increased costs, and include pneumonia, sepsis, and *Clostridium difficile* colitis.[42] Hospital-acquired pneumonia, and specifically ventilator-acquired pneumonia (VAP), may occur in any patient receiving continuous mechanical ventilation. Studies quote rates of hospital-acquired pneumonia of 3% to 8% for cardiac surgical patients, when assessed by criteria used by the Centers for Disease Control and Prevention (CDC), but these rates are lower when assessed by clinicians taking into account alternate explanations for new infiltrates,

BOX 39.1 CRITERIA TO BE MET BEFORE EARLY POSTOPERATIVE EXTUBATION

- *Neurologic*: Awake, neuromuscular blockade fully dissipated (head lift ≥5 s); following instructions, able to cough and protect airway
- *Cardiac*: Stable without mechanical support; cardiac index ≥2.2 L/m^2 per min; MAP ≥70 mm. Hg; no serious arrhythmias
- *Respiratory*: Acceptable CXR and ABGs (pH ≥7.35); minimal secretions, comfortable on CPAP or T-piece with spontaneous respiratory rate ≤20 breaths/min; MIP ≥25 cm H_2O; alternatively, a successful SBT defined as an RSBI <100 and a PaO_2/FIO_2 ≥200
- *Renal*: Undergoing diuresis well; urine output >0.8 mL/kg per h; not markedly fluid overloaded from operative or CPB fluid administration or SIRS
- *Hematologic*: Chest tube drainage minimal
- *Temperature*: Fully rewarmed; not actively shivering

ABG, Arterial blood gas; *CPAP*, continuous positive airway pressure; *CPB*, cardiopulmonary bypass; *CXR*, chest radiograph; *MAP*, mean arterial pressure; *MIP*, maximal inspiratory pressure; *PaO_2/FIO_2*, ratio of arterial partial pressure of oxygen to fraction of inspired oxygen; *RSBI*, rapid shallow breathing index; *SBT*, spontaneous breathing trial; *SIRS*, systemic immune response syndrome.

tachypnea, or hypoxemia.[43] The historical risk of VAP in ICU patients was approximately 1%/day of ventilation when VAP was diagnosed using protected specimen brush and quantitative culture techniques. Strategies believed to be effective at reducing the incidence of VAP include early removal of nasogastric or endotracheal tubes, formal infection control programs, hand washing, semirecumbent positioning of the patient,[44] daily sedation "vacations,"[45] avoidance of unnecessary reintubation, adequate nutritional support, avoidance of gastric overdistention, use of the oral rather than the nasal route for intubation, scheduled drainage of condensate from ventilator circuits,[46] and maintenance of adequate endotracheal tube cuff pressure.[47] Strategies that are not considered effective including routine changes of the ventilator circuit, dedicated use of disposable suction catheters, routine changes of in-line suction catheters, daily replacement of heat and moisture exchangers, and chest physiotherapy.[48] The literature supports both continuous aspiration of subglottic secretions and use of silver-coated endotracheal tubes to reduce the incidence of VAP.[49–51] A Cochrane review found no evidence of benefit from use of incentive spirometry in reducing pulmonary complications after CABG.[52]

Diagnosis of Acute Lung Injury and Acute Respiratory Distress Syndrome

ARDS may develop as a sequela of blood transfusion or CPB, or more commonly in the postoperative patient, it is associated with cardiogenic shock, sepsis, or multisystem organ failure. Components of ARDS include diffuse alveolar damage resulting from endothelial and type I epithelial cell necrosis and noncardiogenic pulmonary edema caused by breakdown of the endothelial barrier with subsequent vascular permeability. The exudative phase of ARDS occurs in the first 3 days after the precipitating event and is thought to be mediated by neutrophil activation and sequestration. Ultimately the alveolar spaces fill up with fluid as a result of increased endothelial permeability.

The clinical presentation is typically an acute onset of severe arterial hypoxemia refractory to oxygen therapy, with a ratio of arterial oxygen partial pressure to fraction of inspired oxygen (PaO_2/FIO_2 or P/F ratio) of less than 200 mm Hg. ARDS is classically diagnosed only in the absence of left ventricular failure, a factor that complicates the diagnosis in the postoperative cardiac patient, who may also be in heart failure. Other findings in ARDS include decreased lung compliance (<80 mL/cm H_2O) and bilateral infiltrates on chest radiographs.[53] Murray and colleagues[54] created a Lung Injury Score that awards points for affected quadrants on chest radiographs, P/F ratio, amount of PEEP applied, and the static compliance of the lung. Scores greater than zero but less than 2.5 are considered to represent ALI, and scores greater than 2.5 meet the threshold for ARDS.

The proliferative phase of ARDS occurs on days 3 to 7 as inflammatory cells accumulate in response to chemoattractants released by the neutrophils. At this stage, the normal repair process removes debris and begin repair, but a disordered repair process may result in exuberant fibrosis, stiff lungs, and inefficient gas exchange. Evidence suggests that careful fluid and ventilator management may affect this process.[55,56] Conventional ventilator support following cardiac operations is to maintain large tidal volumes (typically 10 mL/kg) to reopen atelectatic but potentially functional alveoli. The problem is that the compromised lung is no longer homogeneous, and high pressures can further damage the remaining normal lung. Direct mechanical injury may result from overdistention (volutrauma), high pressures (barotrauma), or shear injury from repetitive opening and closing. "Biotrauma" may also result from inflammatory mediator release and impaired antibacterial barriers.[57] Thus current clinical practice in patients with known or suspected lung injury is to limit inflation pressures. The maximal "safe" inflation pressure is not known, but evidence favors keeping peak inspiratory pressures lower than 35 cm H_2O and restricting tidal volumes to less than 6 mL/kg of ideal body weight in patients at risk for ALI.[58] The landmark Acute Respiratory Distress Syndrome Network (ARDSNet) trial randomized patients to 6 mL/kg versus 12 mL/kg of ideal body weight and demonstrated a significant improvement in 28-day survival rates in the group with a low tidal volume.[59]

Ventilation with lower tidal volumes has been shown to be beneficial in critically ill patients even without ALI, as measured by plasma interleukin-6 levels and progression to lung injury,[60] but this issue has not yet been studied in the cardiac surgical population. A metaanalysis concluded that currently available data cannot confirm or refute any advantage of pressure-controlled over volume-controlled ventilation strategies.[61] A conservative strategy of fluid administration has been shown to improve oxygenation and shorten the duration of mechanical ventilation.[55]

Additional Therapy in Patients With Acute Lung Injury or Acute Respiratory Distress Syndrome

Maintaining a lung-protective ventilatory strategy involves permissive hypercapnia[62] if normal partial pressure of carbon dioxide (PCO_2) levels cannot be achieved with low tidal volumes. The acid-base changes must be monitored carefully, especially in patients with reactive pulmonary vasculature. Prone positioning can help achieve oxygenation.[63] A short daily turn to the prone position does not appear to improve outcome in ARDS, although one post hoc analysis found lower mortality rates in the sickest patients.[64] Lower tidal volumes with increasing amounts of PEEP may promote alveolar recruitment and thus improve oxygenation.[65] Taken to an extreme, patients with ALI may be ventilated with high-frequency oscillation, which is essentially high PEEP with tiny (smaller than dead space), frequently delivered tidal volumes. Other techniques for patients in whom conventional therapy is failing include extracorporeal CO_2 removal,[66] extracorporeal membrane oxygenation (ECMO),[67] inhaled nitric oxide,[68,69] and inhaled prostacyclin.[70] Inhaled nitric oxide has an established role in reducing right ventricular dysfunction when pulmonary hypertension compromises heart transplantation.[71] Although these therapies may be beneficial to other patients in extreme circumstances, prospective controlled trials are lacking. Corticosteroid rescue treatment for ARDS has a long history,[72] but a metaanalysis failed to establish a definitive role, although it did not exclude the possibility of reduced mortality rates or a reduction in ventilator days[73]

Healthy cardiac surgical patients generally do not require much PEEP.[74] Higher levels of PEEP may decrease cardiac output, unless volume loading is used to stabilize preload by maintaining transmural

filling pressures.[75] The effects of PEEP are most marked in the presence of abnormal right ventricular function, particularly if the right coronary artery is compromised.[76] PEEP neither protects against the development of ARDS[77] nor reduces the amount of mediastinal bleeding after cardiac surgical procedures involving CPB.[78] Most clinicians routinely use 5 cm H_2O of PEEP in ventilated patients. However, higher levels of PEEP (often 8–15+ cm H_2O) may be necessary to maintain adequate oxygenation with ALI or developing ARDS; application of PEEP in the postsurgical patient usually involves balancing cardiac and pulmonary goals.

Lung Recruitment

In laboratory and clinical models, an important component of a lung-protective ventilation strategy is recruitment of the lung. This is the closed chest analogy to the open chest recruitment maneuver typically done at the end of CPB to reexpand the collapsed lungs. The goal of opening the lung is to allow ventilation to occur at a point on the pressure-volume curve that avoids repetitive atelectasis (by staying above a critical closing pressure) and at the same time avoiding overinflation.[79] ARDSNet data suggest that the short-term effects of recruitment maneuvers are highly variable and that further study is needed to determine the role of recruitment maneuvers in the management of ALI and ARDS.[80] In many instances, impaired oxygenation results from atelectasis and responds quickly to brief recruitment maneuvers. These maneuvers should be performed cautiously because of the adverse impact of increased airway pressure on venous return and cardiac output if the patient is intravascularly "empty."

In patients who have been extubated, noninvasive ventilation (NIV) is often used to forestall reintubation, particularly in high-risk patients with chronic hypercapnic respiratory disorders or cardiac comorbidity.[81] NIV has been used to treat respiratory failure after extubation in other postsurgical settings, and it is also associated with faster improvement from acute cardiogenic pulmonary edema than with standard oxygen therapy.[82] In a randomized study of 100 patients undergoing CABG or valve operations, noninvasive positive-pressure ventilation with bilevel pressure for 30 minutes after extubation was associated with improved oxygenation.[83] However, a retrospective Spanish study of the use of NIV following extubation failure in the cardiac surgical population found that reintubation was required in one-half of the NIV-treated patients, and NIV was associated with higher hospital mortality rates.[84] Respiratory failure within 24 hours of extubation predicts NIV failure.

Permissive Hypercapnia

Conventional management is to maintain arterial P_{CO_2} (Pa_{CO_2}) within a normal or eucapnic range, classically between 35 and 45 mm Hg. A patient who retains CO_2 on a long-term basis would be considered eucapnic at his or her higher baseline Pa_{CO_2}. The traditional reason for maintaining eucapnia is primarily that acute deviation from a normal or acclimatized Pa_{CO_2} results in alkalemia or acidemia, to which the kidneys respond by retaining or excreting bicarbonate ion. Normal kidneys can compensate for a P_{CO_2}-induced pH change in 12 to 36 hours.[85] If high airway pressures would be required to maintain a normal status, Pa_{CO_2} values up to 60 mm Hg are acceptable as long as cardiovascular stability is present and the pH remains higher than 7.30. Investigators have hypothesized that raised P_{CO_2} levels may even be protective, and that low levels of P_{CO_2} could play a role in organ injury.[86] Permissive hypercapnia should be used judiciously in patients with pulmonary hypertension because acidosis can exacerbate pulmonary vasoconstriction and further impair right ventricular function and cardiac output.[87]

Cardiopulmonary Interactions

An understanding of cardiopulmonary interactions associated with mechanical ventilation is critical to the cardiothoracic intensivist. Hemodynamic changes may occur secondary to changes in lung volume and intrathoracic pressure even when tidal volume remains constant.[88] Pulmonary vascular resistance and mechanical heart-lung interactions play prominent roles in determining the hemodynamic response to mechanical ventilation. Because lung inflation alters pulmonary vascular resistance and right ventricular wall tension, the intrathoracic pressure that a damaged heart will tolerate is limited. High lung volumes may also mechanically limit cardiac volumes. In patients with airflow obstruction, occult PEEP (auto-PEEP) may also contribute to hypotension and low cardiac output.[89] Auto-PEEP can be detected by respiratory waveform monitoring or by pressure monitoring with the ventilator's expiratory port held closed at end-exhalation. Auto-PEEP may respond to bronchodilators and/or increased expiratory time to permit more complete exhalation.

Pulmonary Hypertension

Elevated pulmonary artery pressure results from vasoconstriction, smooth muscle cell proliferation, and endothelial cell proliferation. Collagen vascular diseases, chronic thromboembolic obstruction of the pulmonary arteries, lung diseases such as COPD, congenital heart disease, and left-sided heart failure all may be associated with pulmonary hypertension. These patients can present anesthetic and critical care challenges, especially following CPB, with complement activation, leukocyte activation, and release of inflammatory mediators.[90] Inhaled nitric oxide, prostaglandin E_1, the endothelin-1 antagonist bosentan, and phosphodiesterase inhibitors such as sildenafil and milrinone are among the available therapies.[91–93] A study of 61 high-risk adult cardiac surgical patients with pulmonary hypertension suggested that preemptive treatment, using a combination of milrinone and inhaled prostacyclin before CPB, reduces post-CPB pressures and the need for vasoactive support in the ICU.[94]

Extracorporeal Membrane Oxygenation Support

ECMO provides cardiac and/or pulmonary support for a patient temporarily without enough reserves to be self-sufficient. ECMO has been used for treating severe ARDS,[95] managing pulmonary hypertensive crisis, and as a bridge to lung transplantation.[96] The two types of ECMO are venoarterial (VA) and venovenous (VV). Both provide respiratory support, but only VA ECMO assists cardiac function. Indications for VV ECMO include hypoxemic respiratory failure, generally defined as a P/F ratio less than 100 mm Hg despite optimized ventilator settings (tidal volume, PEEP, inspiratory to expiratory ratio). It is also indicated for hypercapnic respiratory failure with an arterial pH less than 7.20. For patients with respiratory failure, ECMO may not be initiated if the patient has been mechanically ventilated for longer than 7 days because outcomes tend to be poor in this population.[97]

During VV ECMO, blood is extracted from the vena cava, oxygenated externally, and returned to the right atrium (see Chapter 33). VV ECMO provides respiratory support, but the patient is dependent on his or her own hemodynamic function. For VV ECMO, venous cannulas are usually placed in the right common femoral vein (for drainage) and the right internal jugular vein (for infusion). The tip of the femoral cannula should be maintained near the junction of the inferior vena cava and right atrium, and the tip of the internal jugular cannula should be in the right atrium. Alternatively, a double-lumen cannula[98] can be placed in the internal jugular vein, which is large enough to accommodate the necessary 4 to 5 L/minute of blood flow. These cannulas are available in a variety of sizes, with 31 Fr the largest and most appropriate for adult male patients. Ventilator settings are reduced during ECMO to avoid barotraumas and oxygen toxicity. Plateau airway pressures are generally maintained at less than 25 cm H_2O with an F_{IO_2} of less than 0.4.[99] One study suggested that protective strategies are routinely used in high-volume ECMO centers, and that higher PEEP levels during the first 3 days on ECMO support are associated with improved survival.[100]

Improvements in chest radiographic appearance, pulmonary compliance, and arterial oxyhemoglobin saturation indicate that the patient may be ready to be weaned from ECMO. VV ECMO trials are performed by discontinuing all countercurrent "sweep" gas through the oxygenator, so that the patient's native oxygenation can be assessed. Extracorporeal blood flow remains constant, but gas transfer does not occur with the sweep gas eliminated. Patients are observed for several hours, during which time the ventilator settings necessary to maintain adequate oxygenation and ventilation post-ECMO can be determined. Weaning from VA ECMO is beyond the scope of this chapter, but it also involves careful reduction in extracorporeal flow (see Chapter 33).

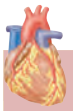
Complications of ECMO include bleeding (30%–40%) as a result of the mandatory anticoagulation, thromboembolism, vascular compromise, and heparin-induced thrombocytopenia. Future technology will include percutaneous low-flow ECMO devices for isolated CO_2 removal.

General Support Issues

Patients requiring long-term ventilation support are prone to numerous complications, including venous thromboembolism, central venous catheter–related bloodstream infections, surgical site infections, VAP, pressure ulcers, nutritional depletion, delirium, and gastrointestinal bleeding. Standard practice in patients receiving long-term ventilation includes prophylaxis against gastrointestinal bleeding with histamine blockers or proton pump inhibitors (unless the patient is receiving continuous gastric feedings), head of bed elevation to 30 degrees or more in hemodynamically stable patients,[44] a brief daily wake-up from sedation,[101] use of in-line suction catheters, glucose control,[102] and appropriate venous thromboembolism prophylaxis. Box 39.2 summarizes these risk reduction efforts. Ensuring that each of these goals is met on each patient every day requires extra work, but it can be accomplished with a daily goals form[103] or with information technology[104] (Fig. 39.1).

Impediments to Weaning and Extubation

Factors limiting the removal of mechanical ventilatory support include delirium, neurologic dysfunction, unstable hemodynamic status, respiratory muscle dysfunction, renal failure with fluid overload, and sepsis. Fig. 39.2 outlines one approach to identifying readiness to wean from ventilation and possible alternative approaches to weaning. Early mobilization including formal exercise programs, such as bedside cycling,[105] can enhance recovery from the catabolic muscle loss with critical illness.



BOX 39.2 SPECIFIC WAYS TO REDUCE INTENSIVE CARE UNIT–ASSOCIATED MORBIDITY

- Earliest possible removal of orogastric and endotracheal tubes with use of oral (not nasal) tubes
- Formal infection control program (hand washing, feedback to staff)
- Head of bed elevation to 30 degrees or more if hemodynamic status permits
- In-line suction catheters to avoid circuit contamination with repeated opening
- Scheduled drainage of condensate
- Adequate endotracheal tube cuff pressure
- Avoidance of the need for reintubation (adequate restraints, sedation)
- Glucose control protocol
- Early nutritional support, preferably by the enteral route
- Stress ulcer prophylaxis
- Deep venous thrombosis prophylaxis
- Brief daily wake-up from sedation
- Early tracheostomy if >14 days of predicted ventilator support
- Use of noninvasive ventilation (CPAP or BiPAP) to avoid reintubation
- Swallowing evaluation before oral feeding if patient is at risk for aspiration

BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure.

Fig. 39.1 A situation awareness monitor can be populated from various sources in the electronic health record. In addition to patient identification data, the display includes current and trended laboratory values, correlation between hemodynamic parameters and infusions, fluid balance, and compliance with elements of the intensive care unit *(ICU)* safety bundle.[104]

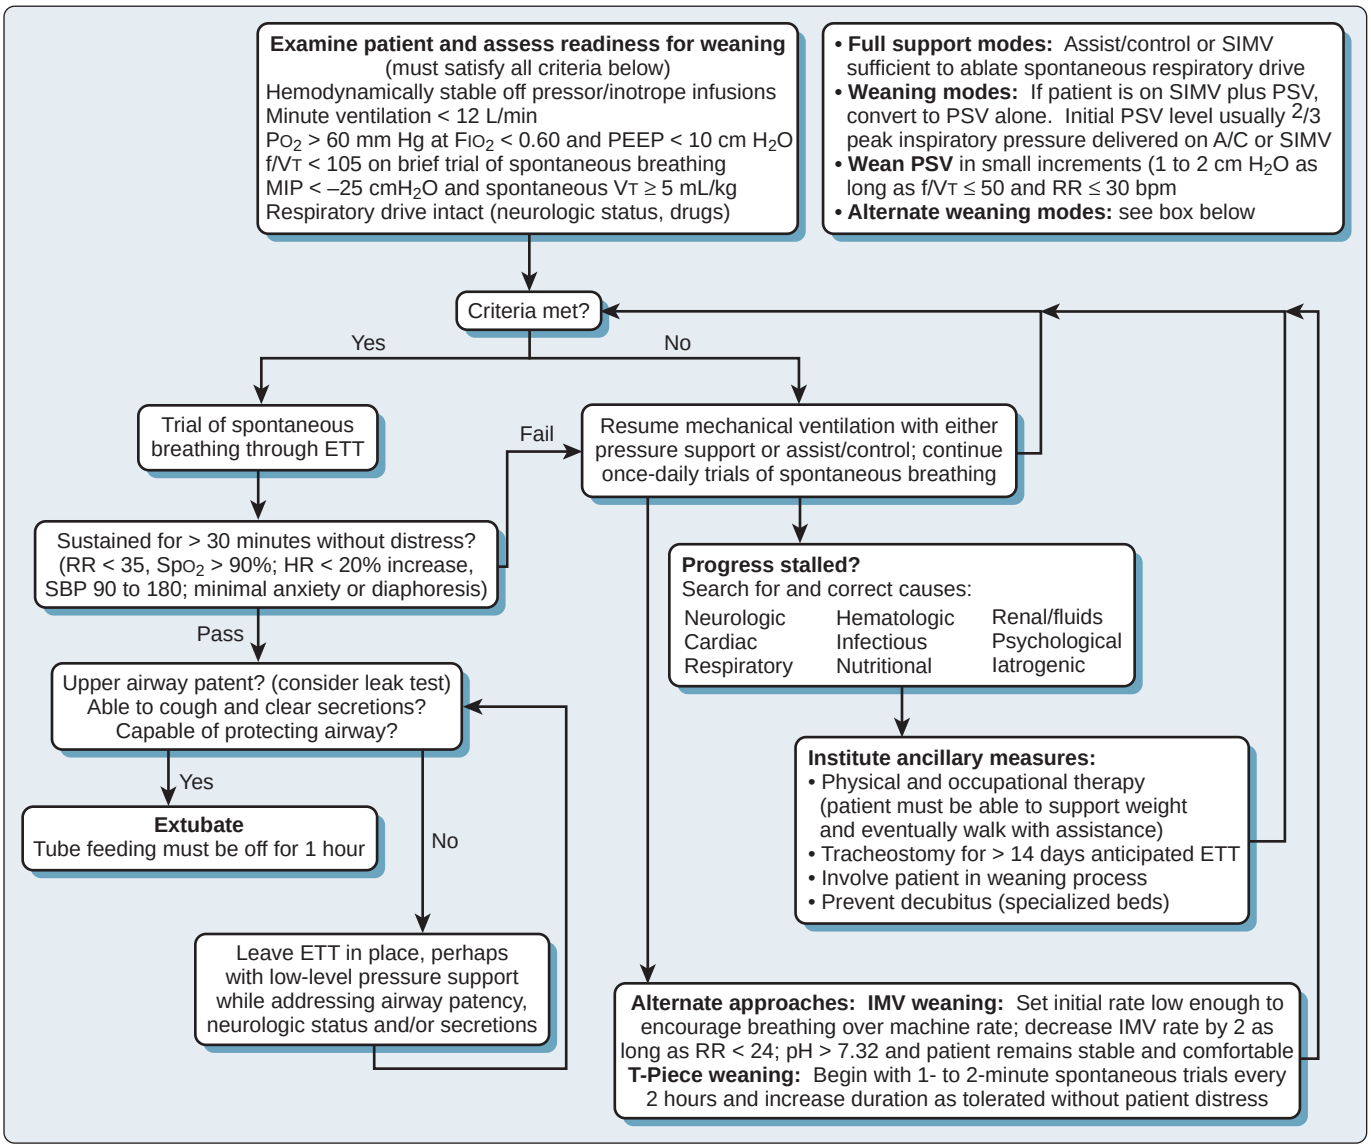


Fig. 39.2 This flow chart addresses care of patients receiving both short-term and long-term ventilatory support in the cardiothoracic intensive care unit. All patients require periodic assessment for readiness for weaning, and if they meet criteria they are eligible for spontaneous trials leading to extubation. Patients who do not meet the criteria should have mechanical ventilation maintained until criteria are met. Pressure-support ventilation *(PSV)* weaning may be possible; if not, alternative approaches include intermittent mandatory ventilation *(IMV)* weaning and T-piece weaning. Patients who stall in their weaning progress should have a comprehensive examination and an assessment of organ systems to search for correctable causes. *A/C,* Assist-control mode; *ETT,* endotracheal tube; *f/VT,* frequency-to-tidal volume ratio; *MIP,* maximal inspiratory pressure; *PEEP,* positive end-expiratory pressure; P_{O_2}, partial pressure of oxygen; *RR,* respiratory rate; *SBP,* systolic blood pressure; *SIMV,* synchronized intermittent mandatory ventilation; Sp_{O_2}, oxygen saturation measured with pulse oximetry.

Neurologic Complications

Delirium after cardiac surgical procedures is common; estimated incidence rates are approximately 30% in the general cardiac surgical population to 83% in mechanically ventilated patients.[106,107] Corticosteroids, as may be used in the treatment of ALI, increase the risk of delirium.[108] Delirium resolves spontaneously or with pharmacologic intervention in almost all patients by postoperative day 6. Evidence from a large trial of mostly medical critical care patients suggests that dexmedetomidine is associated with less delirium than midazolam.[109] Dexmedetomidine has been shown to be safe and effective in patients after CABG.[110] Alcohol or benzodiazepine withdrawal should be considered in the differential diagnosis of delirium. Ketamine may attenuate delirium in CPB-treated patients, possibly because of anti-inflammatory effects,[111] although ketamine itself can cause a dissociative state. Initial postoperative management of agitation consists of reassurance and orientation of the patient and control of pain with opioids and/or acetaminophen. Data suggest that intravenous paracetamol (acetaminophen) with tramadol provides effective pain control after cardiac operations.[112] Intravenous acetaminophen has actually been shown to be more effective than intravenous morphine in patients with acute renal colic.[113] Agitation accompanied by disorientation may be worsened by benzodiazepines, which should be restricted to treatment of oriented but anxious patients or for prophylaxis of alcohol and benzodiazepine withdrawal. If the patient remains agitated

and disoriented, haloperidol may be useful.[114] Newer agents such as risperidone, olanzapine, and quetiapine may also be useful, but they have not been well studied in the cardiothoracic ICU setting. Although some studies supported pharmacologic prophylaxis against delirium, a systematic review and metaanalysis of 13 studies suggested that the evidence is inconclusive in the post–cardiac surgical population.[115]

Diaphragmatic paralysis may complicate any procedure, but it is more common in patients undergoing reoperation, given the difficulty in identifying the phrenic nerve in fibrotic pericardial tissue. Permanent bilateral diaphragmatic paralysis is rare (<0.1% of patients after CPB), but temporary diaphragmatic weakness may occur in 4% or more. The diagnosis of diaphragmatic paralysis should be suspected whenever a patient fails to be weaned from mechanical ventilation; it should be documented by observing paradoxical movement of the diaphragm during inspiration and by comparing vital capacity and tidal volume in the supine and seated positions. Differences in supine and seated vital capacity of more than 10% to 15% should prompt fluoroscopic examination of the diaphragm ("sniff" test). Bilateral paralysis may be missed by this test because comparison of left and right diaphragmatic excursion has lower specificity when both sides of the diaphragm are involved. Transient diaphragmatic paralysis can occur secondary to cold injury to the phrenic nerve.[116] Less often, the phrenic nerve is injured or transected during dissection of the internal mammary arteries or during mobilization of the heart in patients undergoing reoperation.

Patients with respiratory failure and systemic inflammatory response syndrome (SIRS) frequently develop critical illness polyneuropathy, the first sign of which may be failure to be weaned from the ventilator.[117] Disuse atrophy[118] and steroid administration[119] also contribute to muscle weakness. Patients with severe COPD who are dependent on diaphragmatic breathing preoperatively are most likely to manifest diaphragmatic weakness as postoperative ventilator dependency. Full recovery of diaphragmatic function may take 4 months to more than 2 years, and partial recovery is apparent when the patient can lie flat without dyspnea.[120] Adjuncts to improving diaphragmatic strength include inspiratory muscle training,[7] normalizing calcium and phosphate levels, and possibly the use of aminophylline.[121]

Cardiac Complications

Acute myocardial dysfunction occurs in almost all post-CPB patients, and it reaches a nadir approximately 4 hours (range, 2–6 hours) after CPB. Patients with persistent low-output syndrome have an increased risk of cardiac death, as well as complications such as renal failure, respiratory failure, gastrointestinal bleeding, and neurologic sequelae. Regional differences in blood flow can also occur even in the presence of an adequate overall cardiac output, so a normal whole-body cardiac index does not guarantee adequate perfusion of individual organs. Multiorgan failure may be precipitated by a period of gut ischemia or hyperpermeability followed by translocation of gut bacteria and release of endotoxin and other vasoactive substances leading to generalized inflammation and organ injury.[122]

Patients maintained on long-term amiodarone therapy are prone to postoperative respiratory failure, longer intubation times, and longer ICU stays, even with only subclinical evidence of pulmonary amiodarone toxicity.[123] Rarely, patients taking amiodarone develop life-threatening pulmonary complications, including ARDS. Histologic lung examination of these patients demonstrates marked interstitial fibrosis with enlarged air spaces ("honeycomb" appearance) and hyperplasia of type II pneumocytes.[124]

Acute left ventricular dysfunction may occur in patients with COPD during the shift from mechanical to spontaneous ventilation.[125] Attention to fluid balance and aggressive diuresis or use of ultrafiltration helps with weaning. Although it is useful to compare the patient's current and preoperative body weights, catabolic states arising postoperatively, and especially during sepsis, reduce lean body weight. Patients may be "unweanable" until fluid removal reduces body weight to several kilograms lower than the preoperative value.

Patients with valvular disease have significantly higher respiratory system and lung elastances and resistances than those undergoing operations for ischemic heart disease, but these values may correct with successful surgical procedures.[126] Thus patients undergoing valve operations have less work of breathing and improved respiratory function after correction of the valvular disease, but patients undergoing CABG are less likely to show dramatic improvement postoperatively.

Utility of Echocardiography in the Intensive Care Unit Setting

Transesophageal color Doppler echocardiography (TEE), transthoracic echocardiography (TTE), and three-dimensional echocardiography[127] are commonly used preoperatively, in the operating room, and in the ICU to assess ventricular function and valvular disease.[128,129] High-quality images from TEE or TTE can be valuable diagnostic tools in the management of critically ill patients, as well as in the diagnosis and treatment of respiratory disease related to cardiopulmonary dysfunction.[130]

Pleural Effusion

Accumulation of fluid in the pleural space from bleeding or transudate can compress the lung parenchyma and cause basal atelectasis resulting in impaired gas exchange. An undetected pleural effusion may also act as a potential source of postoperative infection. The TTE probe can be used to assess the size of a pleural effusion, help mark the skin at the site that is optimal for needle insertion to drain the effusion, and verify that no lung tissue is present in the area where the operator plans to insert the needle (Fig. 39.3). TEE can also identify the pleural fluid.[131] When the patient is supine, fluid pools in the dorsal and caudal portions of the pleural space. From the four-chamber view the TEE probe is rotated counterclockwise to obtain the short-axis view of the descending aorta. In the presence of a left-sided pleural effusion a "crescent-shape linked to a tiger's claw" may be noted. To examine for a right-sided pleural effusion, the probe is rotated clockwise from the four-chamber view position. A crescent-shaped, echo-free space adjacent to the transducer is noted.

Treatment of pleural effusion is with thoracentesis or placement of a tube thoracostomy. Drainage of pleural fluid results in a significant improvement in oxygenation in acute respiratory failure patients who were refractory to treatment with mechanical ventilation and PEEP.[132]

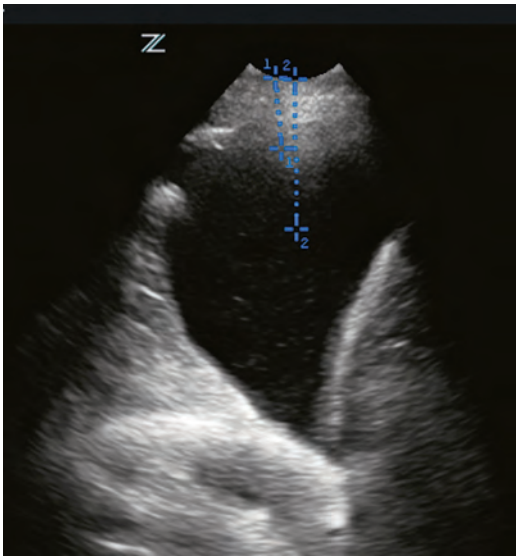

Fig. 39.3 Pleural effusion, left hemithorax: With the patient seated erect, the transducer is oriented perpendicular to the left chest wall at the skin mark. The following measurements were obtained: depth to enter the fluid collection, 1.7 cm; depth to midfluid collection, 3.7 cm.

Patent Foramen Ovale

When a mechanically ventilated patient becomes more hypoxemic despite efforts to improve ventilation, shunt-induced hypoxemia caused by a patent foramen ovale should be considered, along with other causes such as pulmonary embolism. Echocardiography can identify specific abnormalities in mechanically ventilated patients when weaning is difficult or refractory hypoxemia is not explained by pulmonary disease alone.[133] The diagnostic accuracy of TEE is superior to that of TTE in identifying cardiac causes of shock, especially in ventilated patients.[134]

Septic Shock

The treatment of critically ill patients frequently requires comprehensive evaluation of hemodynamic status. Pulmonary artery catheters have not been shown to improve survival,[135] and their use appears to be declining, although less so in surgical units than in medical units.[136] Echocardiography is increasingly used for intermittent assessment of patients with circulatory failure in the ICU and allows rapid assessment and differentiation of the cause of shock. Preliminary evidence suggests that a transoral miniaturized hemodynamic echocardiographic device (hTEE, ImaCor, Garden City, NY) can be used to guide therapy with continuous data.[137]

Assessing Preload for Fluid Management

Inadequate fluid administration can be detrimental, but avoiding inefficient and potentially deleterious volume expansion is equally important. Bedside echocardiography is one of several options for goal-directed therapy,[138] along with mixed venous O_2 saturation,[139] stroke volume variation,[140] and pulse pressure variation.[141] Passive leg-raising using esophageal Doppler imaging and respiratory variation in pulse pressure predicts fluid responsiveness.[142] However, both stroke volume and pulse pressure variability lose discrimination with an irregular rhythm such as atrial fibrillation, which is common in postoperative cardiac patients. Vieillard-Baron and Charon[143] showed that the collapsibility index (maximal diameter on expiration—minimal diameter on inspiration / maximal diameter on expiration expressed as a percentage) of the superior vena cava greater than 36% using TEE accurately distinguishes responders to a fluid challenge from nonresponders.

Pericardial Effusion

The classic Beck triad of jugular venous distention, muffled heart sounds, and hypotension manifests in less than 40% of patients with cardiac tamponade. When these signs are present, they may not appear until late in the clinical course. Echocardiography is an essential tool in making the accurate diagnosis of pericardial effusion especially in a hypotensive patient who does not respond to volume expansion or inotropic support. Findings of pericardial effusion with systolic collapse of the right atrium, diastolic collapse of the right ventricle, and mitral valve inflow decrease by 25% during inspiration (in spontaneously breathing patients), or the tricuspid valve in ventilated patients, are all consistent with cardiac tamponade. Computed tomography–guided pericardiocentesis can be highly successful in avoiding complications such as pneumothorax.[144]

Renal Failure and Fluid Overload

Significant oliguria or anuric renal failure occurs after 1% to 4% of cardiac surgical procedures, and lesser degrees of renal dysfunction, marked by elevated serum creatinine, occur in up to 30%. Univariate predictors of serious acute renal failure include low cardiac output at the end of CPB, advanced age, preoperative cardiac failure, need for postoperative circulatory support, blood transfusions, and prolonged time on CPB.[145] In patients with developing acute kidney injury, infusions of dopamine or fenoldopam do not reduce the need for renal replacement therapy or alter 30-day mortality rates.[146] Contrast-induced nephropathy is always a concern; risk factors for postoperative acute kidney injury include diabetes mellitus and cerebrovascular disease.[147] The incidence of acute kidney injury is significantly higher when the operation occurs within 24 hours of contrast injection and in patients undergoing valve surgery in addition to CABG (but not CABG alone); delaying cardiac operations beyond 24 hours of exposure to contrast agents is justified.[148] When renal failure occurs, it often follows one of three well-defined patterns.[149] Abbreviated acute renal failure occurs after an isolated insult, results in a peak in serum creatinine level around the fourth postevent day, and generally resolves if no other events occur. The second pattern initially resembles the first, except the acute insult is accompanied by prolonged circulatory failure. This pattern runs a longer course, with recovery typically occurring in the second or third week after injury, in tandem with improvements in cardiac output. In the third pattern, recovery is complicated by a second insult such as sepsis, massive gastrointestinal bleeding, or myocardial infarction, and permanent renal failure may result. Because fluid overload with renal failure may precipitate respiratory and cardiac failure, early application of continuous arteriovenous hemofiltration and related techniques to remove excess fluid can facilitate separation from ventilator support.[150]

Infectious Complications

A median sternotomy approach to cardiac surgery entails sawing through the sternum. Although rigid plate fixation has been shown to accelerate bone healing after cardiac operations,[151] most patients still have the split sternum approximated with wire closure. Mediastinitis, sternal dehiscence, or both, are complications of coronary revascularization, with an incidence of approximately 1% and a mortality rate of approximately 13% and a tendency to prolong ventilator dependency. Predisposing factors for wound complications after cardiac operations include diabetes, low cardiac output, use of bilateral internal mammary artery grafts, and reoperation for control of bleeding.[152] Keeping blood glucose lower than 200 mg/dL in the perioperative period reduces the sternal wound infection rate from 2.4% to 1.5%.[153] Tight glucose control, however, increases the risk of hypoglycemia,[154] and many clinicians have abandoned the very tight limits (keeping glucose <110 mg/dL) previously advocated. Mediastinal infection manifests as unexplained fever, an unstable sternum, and sometimes, failure to be weaned from ventilation. In addition to selective antibiotic therapy, surgical débridement and drainage of the wound are usually necessary. Polymicrobial isolates are associated with poor outcome. Additional management of mediastinitis may include primary or delayed sternal closure using pectoralis or omental flaps.

Pneumonia, tracheobronchitis, central line catheter sepsis, and urinary tract infections are frequent in the ventilator-dependent patient. Continuous lateral rotational therapy reduces the prevalence of pneumonia, but it may not affect mortality rates or the duration of mechanical support.[155] The diagnosis of VAP[156] can be difficult to confirm because upper airway organisms can contaminate the sputum specimen. Special suction catheters with a protected tip may be used for a "mini"-bronchoalveolar lavage to improve the yield of sputum cultures. Because typical perioperative antibiotic prophylaxis consists of an antistaphylococcal penicillin or cephalosporin, nosocomial pneumonia is likely to occur with organisms such as *Pseudomonas, Klebsiella, Serratia, Acinetobacter*, or methicillin-resistant *Staphylococcus aureus* (MRSA). Treatment of the secondary infection may be followed by a tertiary infection with organisms that are more difficult to eliminate, such as *Candida, Torulopsis,* or other fungal species.

Gastrointestinal Complications

Gastrointestinal complications requiring intervention occur in 1% to 3% of patients.[157] Postoperative ileus can affect diaphragmatic excursion and increase the work of breathing. Upper gastrointestinal bleeding is common. Pancreatitis, mesenteric ischemia, perforation, and bleeding elsewhere in the gastrointestinal tract are problems seen with critically ill patients, especially those with multisystem failure. Mesenteric ischemia can be the result of low perfusion or embolic atheroma from large-vessel manipulation. Gut ischemia is a potential source of bacteremia, especially problematic for patients with artificial valves. The risk

of gastrointestinal bleeding can be minimized with antacid therapy, histamine blockers, or barrier protection agents. Enteral nutritional support also appears to protect the gastric mucosa.[158]

Diarrhea can occur as the result of mesenteric ischemia, but it is also frequently caused by *C. difficile* overgrowth in patients treated with antibiotics, especially later-generation cephalosporins. Administration of proton pump inhibitors versus histamine blockers or sucralfate is associated with a higher risk for developing *C. difficile*.[159] Patients undergoing prolonged acute mechanical ventilation have a significantly higher risk of concurrent *C. difficile*–associated diarrhea, with attendant increases in hospital length of stay and costs.[160] The rapid assay for *C. difficile* can miss certain strains; culture of stool is not as rapid, but it is more reliable. Treatment of *C. difficile* colitis can be accompanied by oral or intravenous metronidazole or enteral (not intravenous) vancomycin. Toxic megacolon is a surgical emergency requiring immediate attention. Nutrition depletion is common in patients receiving long-term ventilation, and early enteral feeding should be implemented in high-risk patients unless specific contraindications such as ongoing bowel ischemia exist.

Nutritional Support and Weaning

Respiratory failure can be precipitated by high carbohydrate loads delivered during attempts to provide nutritional support, so the goals should be to institute support early before serious depletion occurs and to use an appropriate mix of fat and carbohydrate to maintain a respiratory quotient less than 1.0. Weekly monitoring of transferrin or prealbumin levels screens for changes in nutritional status; more sophisticated analysis including metabolic monitoring and nitrogen balance can identify reasons for poor response to therapy.

The adequacy of nutritional support has a strong influence on the patient's ability to be weaned from ventilation. Preoperative albumin levels lower than 2.5 g/dL are associated with increased risk of reoperation for bleeding, postoperative renal failure, and prolonged ventilatory support, ICU, and hospital length of stay.[14] Weaning success occurs in approximately 93% of patients with adequate nutritional support, but in only 50% of those with inadequate nutrition.[161] Increases in albumin and transferrin level with parenteral nutrition predict eventual ability to be weaned from ventilation.[162] Enteral and parenteral routes appear to be similar in caloric delivery, infectious complications, and mortality rates, although hypoglycemia and vomiting are more likely with enteral delivery.[163]

Modes of Ventilator Support

Positive-pressure ventilators used outside the operating room have a non-rebreathing circuit, may be volume or pressure limited, and may be triggered by changes in flow or changes in pressure. All modern ventilators contain multiple modes of ventilation support that accommodate both mandatory and patient-triggered breaths. The most common modes of positive-pressure ventilation are assist-control (A/C), synchronized intermittent mandatory ventilation (SIMV), and pressure-support ventilation (PSV). With volume modes, the inspiratory flow rate, targeted volume, and inspiratory time are set by the clinician, and inspiratory peak pressure varies depending on the patient's lung compliance and synchrony with the ventilator. Volume cycling ensures consistent delivery of a set tidal volume as long as the pressure limit is not exceeded. With nonhomogeneous lung disorders, however, delivered volume tends to flow to areas of low resistance; this may result in overdistention of healthy segments of lung and underinflation of atelectatic segments with consequent ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching. Fig. 39.4 demonstrates pressure and flow tracings with volume ventilation. Volume breaths may be triggered by a timer (control mode ventilation) or by the patient's effort between the control-mode breaths (A/C ventilation). In either case, the tidal volume delivered is determined by the ventilator settings. This situation can present a problem in a patient with tachypnea as a response to neurologic injury. If the patient breathes inappropriately in response to normal arterial levels of CO_2, significant respiratory alkalosis will result. A/C mode is most appropriate for the patient whose respiratory drive is normal but whose muscles are weak, or when neuromuscular blockade is employed, in which case A/C mode essentially becomes control-mode ventilation.

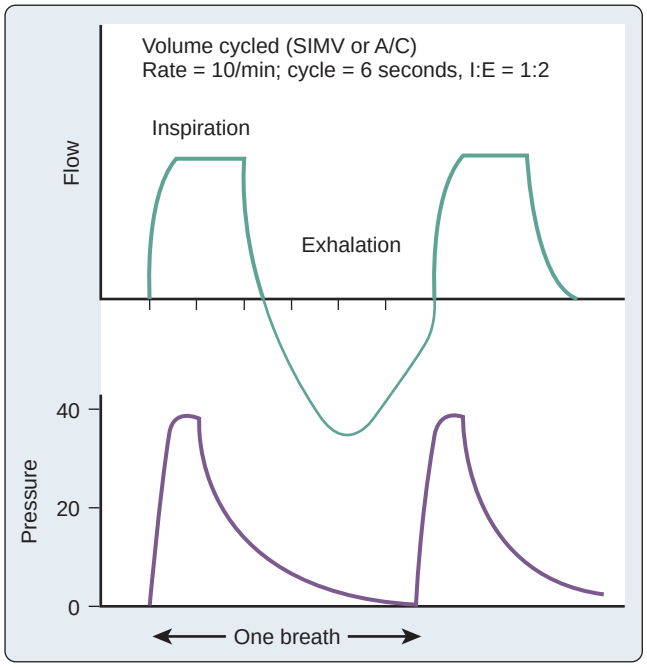

Fig. 39.4 The *top tracing* shows the inspiratory flow, which is close to a square wave. Originally this flow pattern was dictated by the function of mechanical valves, but it may now be duplicated electronically. Note that the flow waveform becomes negative (opposite direction) during the exhalation phase. The typical volume cycled breath with a square waveform results in a rapid rise to peak inspiratory pressure followed by a gradual decline. If the safety pressure limit is exceeded, the peak of the pressure waveform may be truncated. *A/C,* Assist-control mode; *I:E,* inspiration-to-expiration ratio; *SIMV,* synchronized intermittent mandatory ventilation.

Intermittent mandatory ventilation (IMV) and later SIMV were developed to facilitate weaning from mechanical ventilatory support. With either IMV modality, a basal respiratory rate is set by the clinician that may be supplemented by patient-initiated breaths. In contrast to A/C ventilation, however, the tidal volume of the patient's spontaneous breaths is determined by the patient's own respiratory strength and lung compliance rather than delivered as a preset volume. SIMV mode is appropriate for patients with normal lungs who are recovering from opioid anesthesia. Weaning is accomplished by reducing the mandatory IMV rate and allowing the patient to assume more and more of the respiratory effort over time. SIMV mode has been used for weaning in patients with complex cases, but the weaning effort may stall at very low IMV rates if the patient cannot achieve spontaneous volumes sufficient to activate the pulmonary stretch receptors. Under these circumstances, the patient is likely to become tachypneic, and weaning attempts will fail. Thus other methods of weaning support may be needed.

Pressure-Controlled Ventilation

Pressure-controlled ventilation (PCV) is available on most ventilators, and allows the clinician to specify a target inspiratory pressure; the ventilator then calculates and delivers the optimal flow rate to achieve the desired tidal volume and inspiratory-to-expiratory ratio (I:E ratio). Fig. 39.5 demonstrates the difference between PCV and volume-controlled ventilation with regard to inspiratory flow. Pressure-controlled inverse-ratio ventilation (PC-IRV) is PCV with an inspiratory time that exceeds expiratory time (I:E ratio >1.0). Consider that opening alveoli with damaged lungs sometimes requires exceeding a

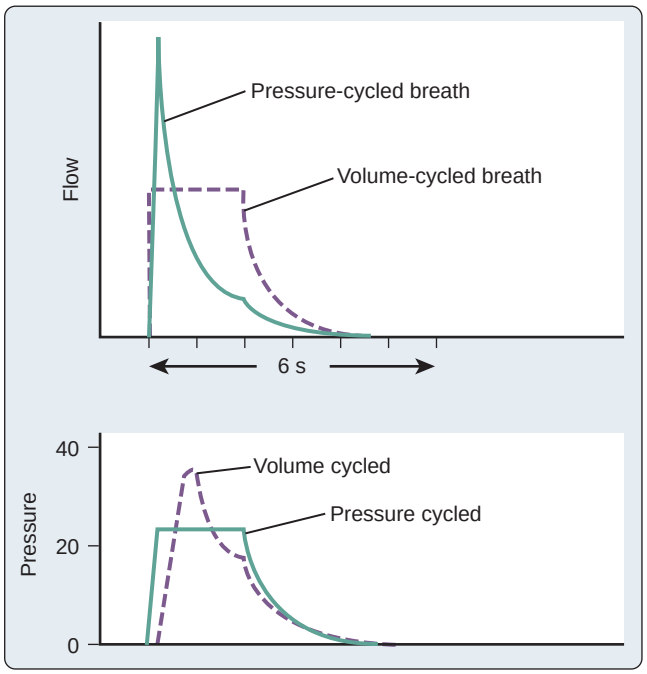

Fig. 39.5 The difference between pressure-cycled breaths and volume-cycled breaths is demonstrated. With a pressure cycle breath, the flow is titrated by a feedback mechanism to maintain a set inspiratory pressure. Thus flow is very rapid at the beginning of the inspiratory cycle and rapidly tapers, in contrast to a volume-cycled breath in which the waveform is more or less consistent throughout the inspiratory cycle. The *bottom section* shows the difference in pressure tracings. As noted before, volume-cycled ventilation reaches a peak and then falls back. In contrast, pressure-cycled ventilation reaches a lower but sustained pressure limit and holds at that level for the inspiratory time. In the absence of significant pulmonary disease, either mode of ventilation results in a rapid decrease of pressure once exhalation occurs.

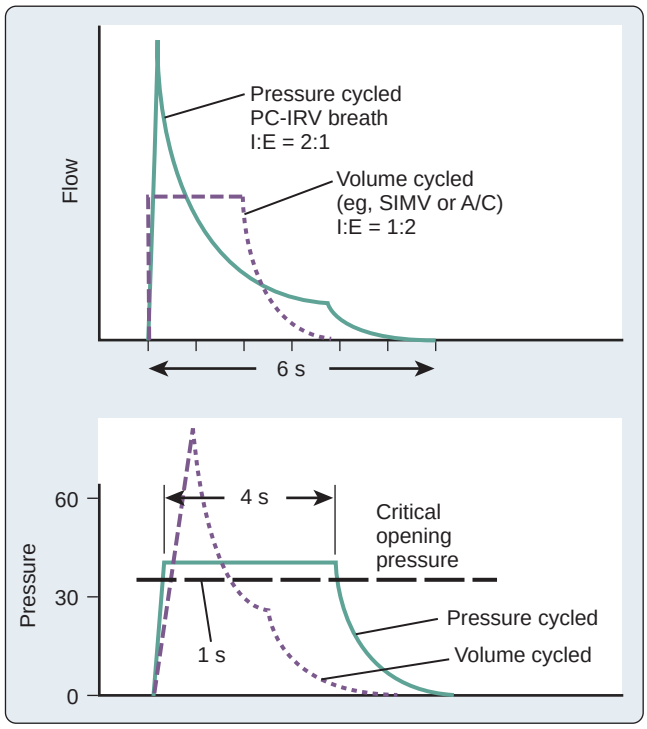

Fig. 39.6 Volume-cycled and pressure-cycled modes are compared as in Fig. 39.5. If a critical opening pressure is present to recruit atelectatic lung segments, a pressure-controlled ventilation mode, particularly if the inspiration-to-expiration ratio (I:E ratio) is inverted, is far more successful at maintaining an inspiratory pressure above the critical opening pressure for a greater length of time. Attempting to increase the volume-cycled flow would result in unacceptably high peak inspiratory pressures in an attempt to achieve more time above the critical opening pressure. Even in volume control, however, inspiratory pauses or changes to the flow rate in I:E ratio may be able to achieve longer sustained inspiratory pressures. *A/C,* Assist-control mode; PC-IRV, pressure-controlled inverse-ratio ventilation; *SIMV,* synchronized intermittent mandatory ventilation.

critical opening pressure for an adequate amount of time (Fig. 39.6). With standard ventilation, this time above the critical pressure can be lengthened only by increasing the peak inspiratory pressure, which is generally undesirable with a damaged lung. With PC-IRV, the pressure waveform is optimized to allow a long inspiratory time above the critical opening pressure while avoiding high peak pressures. The disadvantage of PC-IRV is that the increased inspiratory time necessarily reduces exhalation time, which may lead to stacking of breaths or auto-PEEP in patients with abnormal lungs. Tharratt and colleagues[164] demonstrated that PC-IRV allowed a reduction in minute ventilation and reduced peak pressures while increasing mean airway pressures in patients with ARDS. At a given plateau pressure (similar end-inspiratory distention), lower tidal volume and increased PEEP are associated with better recruitment and oxygenation.[165]

Changing a patient from convention volume-controlled ventilation to PC-IRV can be accomplished by noting the existing tidal volume, inspiratory pressures, and I:E ratio and switching to PCV mode with similar inspiratory peak pressure, rate, and inspiratory time. The level of inspiratory pressure is then titrated to deliver a tidal volume similar to what the patient was receiving with volume control ventilation. Then the inspiratory time can be lengthened to achieve better oxygenation or decreased to allow sufficient exhalation time if auto-PEEP is evident. In any patient with abnormal lungs, but particularly if an IRV mode is used, the patient must be monitored for the development of auto-PEEP, identified either by monitoring failure of the pressure waveform to return to baseline between breaths or by instituting an expiratory hold and noting the difference in pressure between the ventilator's pressure gauge and the level of PEEP that was specified. Sedation and often neuromuscular blockade are necessary if the I:E ratio is inverted. Adjusting the ventilator settings in pressure-control mode is not always intuitive. Increased rates may paradoxically decrease CO_2 elimination if tidal volumes decrease. Improvements in oxygenation may not occur until the patient is stabilized and given sufficient time (≥30 minutes) to recruit atelectatic segments. Recruitment maneuvers when initiating PCV may help to open up atelectatic segments that may remain open once recruited. Airway pressure-release ventilation is functionally similar to PC-IRV in terms of recruitment, but it can often be accomplished in spontaneously breathing patients.[166] Adaptive-support ventilation, a microprocessor-controlled mode that maintains preset minute ventilation, has also been used in cardiothoracic surgical patients.[167]

Pressure-Support Ventilation

PSV, which is primarily a weaning tool, must be distinguished from pressure-control ventilation, which is generally used during the maintenance phase of ventilation. PSV may be used in conjunction with CPAP or SIMV modes. Pressure support augments the patient's spontaneous inspiratory effort with a clinician selected level of pressure. Putative advantages include improved comfort for the patient, reduced ventilatory work, and faster weaning. The volume delivered with each PSV breath depends on the pressure set for inspiratory assist, as well as the patient's lung compliance. The utility of PSV in weaning from long-term ventilation support is that it allows the patient's ventilatory muscles to assume part of the workload while augmenting tidal volume, thus preventing atelectasis, sufficiently stretching lung receptors, and keeping the patient's spontaneous respiratory rate within

a reasonable physiologic range. With some older (and now mostly obsolete) ventilators, the inspiratory phase of PSV is terminated when flow falls to less than 25% of the initial value. In the presence of a cuff leak around the endotracheal tube, the flow rate may not fall to sufficiently low levels to terminate the breath, and the patient will struggle while trying to exhale against the inspiratory flow. This problem is rare or nonexistent with newer ventilators. Tidal volume varies markedly with the patient's lung compliance, so close clinical observation is needed with the initiation of PSV. Monitoring end-tidal CO_2 as well as pulse oximetry readings during the PSV weaning phase helps limit phlebotomy for arterial blood gas measurements.

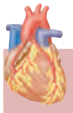
Liberation From Mechanical Support (Weaning)

An important concept to consider is that weaning from ventilator support is not synonymous with extubation. In certain conditions weaning is possible, but extubation is not (eg, upper airway edema or compression, glottic dysfunction with aspiration, neurologic dysfunction, or any other inability to protect the airway). As noted earlier, extubation to CPAP may be an option when chronic respiratory disorders or cardiac morbidity are affecting oxygenation.[81] A second important concept is that a formal weaning process is not essential in a normal postoperative patient, although SIMV or PSV weaning may be most convenient. The adaptive-support ventilation mode has been demonstrated to reduce ventilation time by more than 2 hours versus physician-directed weaning in patients undergoing fast-track cardiac valvular operations.[168] In the absence of significant cardiopulmonary dysfunction, extubation depends more on a stable clinical condition, adequate warming, elimination, and metabolism of anesthetic agents and reversal of neuromuscular blockade. Weaning strategies, however, are almost always required after more than 3 days of ventilation support.

When terminating mechanical ventilation, two phases of decision making are involved. First, resolution of the initial process for which mechanical ventilation was begun should occur. The patient cannot have sepsis, be hemodynamically unstable, or be burdened with excessive respiratory secretions. If these general criteria are met, then specific weaning criteria can be examined. These include oxygenation (typically a PaO2 >60 mm Hg on 35% inspired oxygen and low levels of PEEP), adequate oxygen transport (measurable by oxygen extraction ratio or assumed if the cardiac index is adequate and lactic acidosis is not present), adequate respiratory mechanics (tidal volume, maximal inspiratory pressure) and adequate respiratory reserve (minute ventilation at rest of <10 L/min), and a low frequency-to–tidal volume ratio (f/VT <100; see next section) indicating adequate volume at a sustainable respiratory rate.

Objective Measures of Patients' Strength and Endurance

Although clinicians may use a variety of parameters to determine readiness for extubation, few parameters have been examined carefully. Vital capacity, defined as the volume of gas exhaled after maximal inspiration, is normally greater than 70 mL/kg. A clinical readiness threshold of 10 to 15 mg/kg has been proposed, but this is neither sensitive nor specific. For patients receiving short-term ventilatory support, vital capacity is less reliable than the ability to maintain a pH value greater than 7.35 while the IMV rate is decreased to CPAP.[169] Maximal inspiratory pressure is often referred to as inspiratory force, negative inspiratory force, or peak negative pressure and quantifies inspiratory effort as a marker of respiratory muscle strength. The proper technique involves airway occlusion for up to 20 seconds starting at full exhalation by using a one-way valve that allows the patient to exhale after attempted inspiration. Normal values of maximal inspiratory pressure should exceed 100 cm H_2O in male patients and 80 cm H_2O in female patients. Values are usually expressed as an absolute to avoid confusion with "less than" or "greater than" when referring to a negative number.



BOX 39.3 NONRESPIRATORY FACTORS AFFECTING WEANING FROM MECHANICAL VENTILATION

- Cardiac function
- Nutritional status
- Renal function
- Fluid balance
- Sepsis or infection
- Hematologic status or anemia
- Metabolic disturbance
- Pharmacologic therapy and metabolites
- Neurologic compromise
- Neuropsychiatric issues or delirium
- Sleep deprivation
- Endotracheal tube size
- Patient's self-perception of breathing

The classic cutoff value of 20 to 30 cm H_2O is associated with a 26% false-positive and 100% false-negative rate in predicting extubation success. Maximal inspiratory pressure is best used for serial evaluation of patients and is more a measure of strength than endurance.

Attempts have been made to predict endurance by using the resting minute ventilation rate, but using the common value of 10 L/minute as the threshold results in a false-positive rate of 11% and a false-negative rate of 75% in predicting successful extubation. Similarly, the ability to sustain maximum voluntary ventilation twice the minute ventilation is correctly predictive in only approximately 75% of the patients. More sophisticated measurement of endurance can be accomplished using a diaphragmatic or intercostal electromyographic power spectrum, but these techniques are not practical for routine clinical use. Yang and Tobin[170] developed an index using the ratio of respiratory rate (frequency [f], measured in breaths/min) to tidal volume (VT, measured in liters). An f/VT ratio greater than 105 has a predictive value of 89% for weaning failure.[170] An issue with all measured respiratory parameters or scoring systems is that they rarely include nonrespiratory parameters affecting weaning (Box 39.3).

Weaning: The Process

The actual process of weaning from mechanical ventilatory support must be individualized. No "one size fits all" method exists. While gradually lowering the SIMV rate in increments of two breaths/minute generally works for short-term ventilatory support, patients receiving long-term ventilatory support often have difficulty making the transition from SIMV rates of two breaths/minute to CPAP. The time-honored method of weaning by maintaining a patient on full ventilatory support and alternating with increasingly longer periods of spontaneous ventilation on a T-piece is effective, but it is time consuming because it requires setting up additional equipment and also requires a nurse or respiratory therapist to be immediately available at the bedside during each weaning attempt. Diaphragmatic effort is significantly lower during a T-piece trial with a deflated tracheostomy tube cuff than with the cuff inflated.[171] Weaning trials with the cuff deflated may thus be more physiologic when attempting weaning from the ventilator in a patient for whom this process is difficult. Breath-to-breath monitoring, display of tidal volumes, and ventilator alarms are not available during a T-piece trial. More commonly, pressure support is used as an adjunct to weaning either with IMV or CPAP while the patient is still connected to the ventilator and its alarm system.

Our preference is to conduct CPAP weaning with pressure support alone (ie, no additional IMV rate) because mechanical ventilation introduces one more variables into the evaluation of a patient's progress. Sufficient CPAP is applied to maintain open alveoli (generally 5–8 cm H_2O, but often higher when recovering from ALI or ARDS), and then the pressure-support level is titrated to provide the patient

with sufficient tidal volume to achieve a respiratory rate lower than 24 breaths/minute. Rapid rates are detrimental to weaning, because diaphragmatic blood flow is limited during contraction. As the patient's exercise tolerance improves, the pressure-support level can be lowered in increments of 2 to 3 cm H_2O. It is usually necessary to address fluid overload, nutritional support, and other nonpulmonary factors to achieve the pressure-support reduction.

Regardless of which weaning method is chosen, it is important to end each weaning trial with success rather than to stress the patient to the point of fatigue. Cohen and colleagues[172] identified the clinical sequence of inspiratory muscle fatigue. The earliest sign of inspiratory muscle fatigue is a spectrum shift in the electromyographic power spectrum, which is impractical to measure in the clinical setting. However, the next most sensitive sign is an increase in respiratory rate, which occurs before respiratory alternans, abdominal paradox, increase in the $PaCO_2$ level, or acidemia. Thus respiratory rate can serve as a sensitive marker of weaning progress.

Specific Impediments to Weaning

Weaning from ventilator support affects cardiac output in response to changes in pulmonary vascular resistance. Increased pulmonary vascular resistance can lead to septal shifts and consequent changes in the efficiency of right ventricular and left ventricular function. Thus it makes little sense to attempt weaning in the hemodynamically unstable patient. Our approach has been to keep these patients on full ventilator support with sedation and neuromuscular blockade if necessary until the acute cardiac problem is resolved.

Older ventilators with demand-valve systems impose an additional work of breathing, although it would be rare to see such ventilators in clinical use today. Current ventilators use computer-assisted demand valve technology to supply a variable flow rate, unlike older ventilators, in which a fixed low gas flow rate occasionally resulted in the inability to supply peak flow on demand. Nonetheless, if the patient is demonstrating apparent air hunger during the weaning process, a quick check of the inspiratory flow rates can often solve the problem. Pulmonary effusions and pneumothorax can develop in patients in otherwise stable condition and may also manifest as stalled weaning. Stacking of breaths or auto-PEEP can occur if the expiratory time is too short for patients, particularly patients with obstructive disease, to exhale fully before the next breath is delivered.

Ventilator Dyssynchrony

Increases in intercostal muscle tone and increases in abdominal muscle tone, pressure, or contents decrease chest cage compliance. During volume-cycled ventilation, a decrease in chest cage compliance results in elevated intrathoracic pressure that may reduce venous return to the right side of the heart.[88] A patient may also actively attempt to impede flow during the inspiratory cycle, a process referred to as "fighting," being "out of phase," or "breathing against" the ventilator.

The most common reason for "fighting" the ventilator is a mismatch between ventilator support and patient demand. During the triggering phase, insensitive systems or intrinsic PEEP may cause delayed or missing triggers. During flow delivery, either inadequate flow or excessive flow can be responsible. Cycling may also be mismatched if the patient's effort continues despite termination of the machine breath or if the patient is exhaling to terminate a prolonged machine breath. These phenomena and appropriate remedies were discussed in a comprehensive review with accompanying pressure, flow, and volume tracings.[173] With sudden onset of distress, inadequate ventilation (hypercarbia), acidemia, inadequate oxygenation, central nervous system dysfunction, pain, and/or anxiety must be excluded. Endotracheal cuff leak, misplacement of the endotracheal tube, inadequate inspiratory flow rates, pneumothorax, abdominal distention, sepsis, pain, and anxiety should all be considered in the differential diagnosis.

Assisting the patient with manual ventilation or switching to assist modes for a short time with or without additional sedation often allows the patient to settle down and return to synchrony with the ventilator. Pressure and flow tracings displayed on the ventilator can narrow the differential diagnosis and confirm whether adjustments to the inspiratory flow rate are helpful. Neurally adjusted ventilator assist is emerging as a method to match ventilator assistance more closely to patients' needs by assessing diaphragmatic electrical activity through an esophageal probe.[174] As diaphragmatic activity occurs before airway flow or pressure changes, synchrony between the patient and the ventilator may be improved using neurally adjusted ventilator assist, although more clinical studies are needed.

Muscle Weakness and Critical Illness Polyneuropathy

Long-term administration of neuromuscular blocking agents, particularly drugs such as vecuronium with a steroid structure; have been associated with persistent paralysis.[175] One explanation may be the accumulation of the metabolite 3-desacetylvecuronium, which is rarely seen in patients with normal renal function but is quite common in patients with delayed recovery.[175] However, prolonged paralysis can also be seen after treatment with other drugs such as pancuronium, metocurine, and *cis*-atracurium, which do not necessarily share the same structure or have persistent metabolism. The suspicion is that neurogenic atrophy occurs with prolonged paralysis resulting in low-grade flaccid quadriplegia or more localized weakness of respiratory muscles.

Prolonged ICU stay may also precipitate psychiatric problems even in psychologically normal patients, although these problems occur more commonly in patients with an underlying psychiatric history. Light, noise, and lack of sleep can change a patient's perception of reality. Psychological dependency on the ventilator may also develop, although this is rare. Careful attention to maintaining a normal day/night sleep cycle, ensuring adequate sleep, creating a quiet ICU environment, judicious use of pharmacologic agents such as haloperidol or quetiapine,[176] and involvement of the patient and family as participants in the weaning process may be helpful when psychological impediments to weaning exist.

Tracheostomy

Prolonged endotracheal intubation results in damage to the respiratory epithelium and cilia and may lead to vocal cord damage and airway stenosis.[177,178] If mechanical ventilation is anticipated for longer than 14 days, consideration should be given to early tracheostomy.[179] Other indications for tracheostomy include copious or tenacious secretions in debilitated patients who are unable to clear secretions spontaneously. Tracheostomy is relatively contraindicated in patients with ongoing mediastinitis or local infection at the tracheostomy site because of the potential for mediastinal contamination with respiratory secretions. Tracheostomy is not a risk-free procedure, and complications include pneumothorax, pneumomediastinum, subcutaneous emphysema, incisional hemorrhage, late tracheal stenosis or tracheomalacia, stomal infections, and rarely tracheoinnominate fistula. Early tracheostomy can be accomplished at the bedside with commercially available kits.[180] Swallowing dysfunction may occur following tracheostomy or after prolonged endotracheal intubation introducing the risk of aspiration pneumonia or respiratory failure. A swallowing evaluation is indicated before allowing a patients with a tracheostomy to attempt oral feeding. This evaluation is usually accomplished with a formal speech pathology consultation, but swallowing difficulty may also be noted by the nurses during attempted feedings.

Inability to Wean

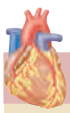
A few patients are not able to be weaned from ventilator support despite all efforts. Predictive models, however, are rarely useful for deciding which patients will not benefit from further intensive care.[5,9,17,21,181]

It is rarely a single problem, but rather the interactions among multiple morbidities that create a situation in which the patient may never be able to achieve the "escape velocity" needed to separate from the

ventilator. At this point, a discussion with the patient (if he or she has decisional capacity) or the health care proxy can be helpful in defining the benefits and burdens of further therapy and the patient's desires. Consultation with the hospital's ethics team may be very helpful. A frank assessment of which problems can be "fixed" versus those that are irreversible will define care options. Patients who remain in low–cardiac output states cannot resolve their multiple organ failure and thus their dependence on high-technology support including ventilation and hemodialysis. Unless patients are candidates for long-term ventricular assist devices or heart transplantation, they are facing a slow, technology-assisted decline that will end in an untreatable infection. Conversely, malnutrition and deconditioning in the absence of ongoing sepsis and organ system failure sometimes respond to prolonged rehabilitation, which may be better handled by a long-term ventilation facility than an acute care hospital. The critical issue is the patient's reserve because unless the patient has adequate cardiac and pulmonary reserve to tolerate stress once all remediable problems have been addressed, indefinite technologic support (ventilation, dialysis) will be required.

Conclusions

Successful postoperative respiratory care, including weaning from long-term mechanical ventilation and multisystem organ failure, requires an individualized and holistic approach to the patient. Weaning should be the first priority for the day, and all other demands should be minimized if possible. If trips to the computed tomography scanner or therapeutic interventions such as wound débridement are anticipated, weaning may not be possible for part of the day. Thus we try to minimize interruptions and to group them so as not to interrupt the weaning process. With that goal in mind, it is also essential to avoid disrupting the patient's nighttime sleep, so that the patient can be well rested and ready to participate in the weaning process. Detailed and full instructions must be given to the patient, and it is frequently helpful to include family members in the discussion so that they can serve as adjunct respiratory coaches. We try to avoid pushing the patient to the point of exhaustion or panic and use a planned, conservative approach such that weaning always ends in a sense of accomplishment for the patient rather than failure. Windows of opportunity for weaning from mechanical support are few and must often be created. Box 39.4 summarizes recommendations for the cardiac surgical patient who is difficult to wean from mechanical ventilation.



BOX 39.4 SUMMARY

1. Recognize patients at risk based on preoperative and intraoperative events (see Table 39.1).
2. Where possible, minimize the risk of adverse events (see Box 39.2).
3. Prioritize organ system support: without adequate perfusion, all other systems will fail.
4. Maintain full ventilator support during the acute phase of respiratory insufficiency or circulatory failure to avoid unnecessary fatigue.
5. Adopt a lung-protective ventilation strategy for patients with acute lung injury or acute respiratory distress syndrome.
6. Expect and defend against common problems (see Box 39.3).
7. Pay attention to general support measures and safety issues including sedation holidays and infection control.
8. Prepare the patient and family for involvement in the rehabilitation phase.
9. Have a clear weaning plan or protocol, and follow it.
10. Recognize when the burdens of treatment are disproportionate, and initiate appropriate discussions with the patient or health care proxy.

Central Nervous System Dysfunction After Cardiopulmonary Bypass

SUZANNE FLIER, MD, MSc | JOHN M. MURKIN, MD, FRCPC

KEY POINTS

1. Despite a progressive decrease in cardiac surgical mortality, the incidence of postoperative neurologic complications has remained relatively unchanged over the decades. During this same interval, the age, acuity, and extent of comorbidities in cardiac surgical patients have increased.
2. The risk for stroke in patients undergoing coronary artery surgery increases progressively with increasing age, ranging from 0.5% for patients younger than 55 years to 2.3% for those older than 75 years.
3. Age-associated increased risk of stroke and adverse central nervous system (CNS) outcome appear to be powered primarily by comorbidities, particularly ascending and aortic arch atherosclerosis.
4. Neurologic events in cardiac surgical patients are associated with increased postoperative mortality, prolonged intensive care unit stay, longer hospital stay, decreased quality of life, and decreased long-term survival.
5. Neurologic complications range from coma, stroke, and visual field deficits to impairments of cognitive processes (eg, delirium, impaired memory and attention, mood alterations).
6. Mechanisms for neurologic injury in cardiac surgery include some combination of cerebral embolism, hypoperfusion, and inflammation, associated vascular disease, and altered cerebral autoregulation, rendering the brain more susceptible to injury.
7. Progression of underlying disease is a confounder in assessing late postoperative CNS complications.
8. While occlusive carotid disease is associated with increased risk of perioperative stroke, such stroke is not infrequently contralateral, and concomitant perioperative carotid endarterectomy may increase risk of stroke and other major adverse events.
9. Perioperative risk factors for neurologic complications include renal dysfunction, diabetes mellitus, hypertension, prior cerebrovascular disease, aortic atheromatosis, manipulation of ascending aorta, complex surgical procedures, bypass time longer than 2 hours, hypothermic circulatory arrest, hemodynamic instability during and after bypass, new-onset atrial fibrillation, hyperglycemia, hyperthermia, and hypoxemia.
10. Routine epiaortic scanning before instrumentation of the ascending aorta is a sensitive and specific technique used to detect nonpalpable aortic atheromatosis.
11. In patients with significant ascending aorta atheromatosis, avoidance of aortic manipulation ("no-touch technique") is associated with decreased perioperative stroke.
12. Strategies to decrease the impact of cardiopulmonary bypass (CPB) on embolization, inflammation, and coagulation will decrease neurologic complications.
13. Cerebrovascular disease renders patients who experience wide hemodynamic perturbations during CPB at greater risk for perioperative stroke.
14. Modular minimally invasive extracorporeal circulation (MiECC) is a new approach to physiologically integrated CPB and is associated with a variety of improved outcomes.
15. Minimal access (minimally invasive) surgery can produce greater physiologic derangements and risk of adverse outcomes compared with conventional CPB.
16. Cerebral near-infrared spectroscopy (cerebral oximetry) can detect cerebral ischemia and is associated with decreased incidence of stroke and improved outcomes after cardiac surgery.
17. There is a greater incidence of early postoperative cognitive dysfunction in patients exposed to conventional CPB compared with off-pump and noncardiac surgical patients.
18. The incidence of late cognitive dysfunction and stroke appears to be similar between groups undergoing conventional CPB, percutaneous coronary intervention, or medical management, implying progression of underlying disease and atrial arrhythmias as primary mechanisms of late stroke.
19. Pharmacologic management should be directed primarily toward intraoperative usage of volatile anesthetics, continuance of perioperative aspirin and statin medications, minimization of hyperglycemia, and vigilant therapy for postoperative atrial arrhythmia.

From 2001 to 2011, coronary artery bypass graft (CABG) procedures decreased by nearly 50% to 213,700 procedures, whereas percutaneous coronary intervention (PCI) decreased by more than 25% to 560,500 procedures in 2011.[1] Although these trends may reflect a variety of environmental, lifestyle, and therapeutic factors, overt and subclinical perioperative cerebral injury remains a compelling problem and continues to influence the debate over optimal strategy for coronary revascularization.

In a retrospective review of 86,244 CABG and 103,549 PCI patients undergoing revascularization for stable multivessel coronary disease from 2004 through 2008, who were identified from national registries, the 4-year composite event rate of death, myocardial infarction, and stroke favored CABG, whereas the risk of stroke alone favored PCI. This difference was primarily due to the higher 30-day stroke rate for CABG of 1.55% versus 0.37% for PCI.[2] Although a meta-analysis and a large prospective study appeared to demonstrate that the early excess risk of stroke in CABG was compensated for by a slow but progressive catch-up phenomenon in patients undergoing PCI, it has been argued that these analyses were all underpowered for stroke.[3,4] In contrast, a subsequent metaanalysis of 57 studies involving 80,314 patient records determined a significantly lower risk of stroke within 30 days and a lower cumulative stroke with PCI as compared with CABG up to year 5.[5] Importantly, in this meta-analysis the incidence of late stroke (>30 days) was similar between the two groups.[5]

As such, these and similar studies strongly affirm that it is primarily intraoperative factors associated with CABG that give rise to the increased stroke risk. Accordingly, the risk factors, causes, and potential for mitigation of perioperative stroke and neurobehavioral outcomes associated with cardiac surgery and cardiopulmonary bypass (CPB) are the topic of this chapter.

Categorization of Central Nervous System Injury

In a seminal study, Roach and colleagues[6] classified central nervous system (CNS) injury into two broad categories: type I (focal injury, stupor, or coma at discharge) and type II (deterioration in intellectual function, memory deficit, or seizures). Cerebral injury can also be broadly classified as stroke, delirium (encephalopathy), or postoperative cognitive dysfunction as outlined in the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) guidelines for CABG.[7] Perioperative cognitive performance is assessed through the administration of a series of standardized psychometric tests, ideally administered before and after surgery.

Stroke is defined clinically as any new focalized sensorimotor deficit persisting longer than 24 hours, identified either on clinical grounds only or, ideally, as confirmed by magnetic resonance imaging (MRI), computed tomography, or other form of brain imaging.

Transient ischemic attack (TIA) is defined as brief neurologic dysfunction persisting for less than 24 hours. Neurologic dysfunction lasting longer than 24 hours but less than 72 hours is termed a *reversible ischemic neurologic deficit.*

Delirium is described as a transient global impairment of cognitive function, reduced level of consciousness, profound changes in sleep pattern, and attention abnormalities.

Cognitive dysfunction is defined as a decrease in score falling below some predetermined threshold, such as a decrease in postoperative score of magnitude 1 standard deviation or more derived from the preoperative performance of the study group as a whole.

Seizure is categorized as either convulsive or nonconvulsive and may be related to overt CNS injury or alternatively may reflect transient biochemical or pharmacologically mediated neuroexcitation.

The incidence of stroke or type I injury after closed-chamber cardiac procedures is generally considered to be approximately 1%.[8] For isolated single valve surgical repair or replacement, most recent data from the Society of Thoracic Surgeons (STS) database encompassing 109,759 procedures report a stroke rate of 1.6%,[9] increasing to 2.9% for combined CABG and valve surgery based on reports of 101,661 patients.[10] It is interesting that, whereas STS database is predicated upon self-reporting of outcomes incidences, a meta-analysis of 40 observational studies reporting on 8975 patients aged 80 years or older undergoing combined conventional aortic valve replacement (AVR) and CABG reported a postoperative stroke rate of 3.7% (95% confidence interval [CI], 2.8–4.8; 12 studies, 2770 patients) not inconsistent with STS database results.[11]

The incidence of cognitive dysfunction (type II) is reported as ranging in rate from 30% to 80% in the early postoperative period.[7,12–19] The difference in the incidence of cerebral injury after cardiac surgery is related to the type and complexity of the procedure, whether it is off-pump coronary artery bypass (OPCAB), CABG, open chamber, combined CABG and valvular surgery, or aortic arch and related procedures.[15,20–22] The increasing usage of minimally invasive valvular and coronary revascularization techniques, as well as the expanding role for catheter-based valve replacement, have independently impacted the risk of CNS injury and are discussed separately in this chapter.

Overall, the increased length of stay and increased mortality rates associated with any form of cerebral complication in cardiac surgical patients are striking.[7,12,19,23] Despite the relatively greater impact on mortality of stroke as opposed to cognitive dysfunction, type II injury is still associated with a fivefold increase in mortality. In their study based on data from mid-1990s, Roach and colleagues evaluated 2108 patients undergoing CABG at 24 U.S. institutions and recorded adverse cerebral outcomes in 6.1% of patients overall.[6] Of these, 3.1% experienced type I focal injury, stupor, or coma and had an associated in-hospital mortality rate of 21%, whereas 3.0% of patients experienced deterioration of intellectual function or seizures and had a mortality rate of 10%. In contrast, a significantly lower overall mortality rate of 2% was seen in those patients without adverse cerebral outcomes. In addition, patients with neurologic complications had, on average, a twofold increase in hospital length of stay and a sixfold likelihood of discharge to a nursing home. Independent risk factors were identified for both types I and II cerebral injury. Predictors of both types of cerebral complications included advanced age of older than 70 years and a history or the presence of significant hypertension. Predictors of type I deficits include the presence of proximal aortic atherosclerosis as defined by the surgeon at the time of surgery, a history of prior neurologic disease, use of the intraaortic balloon pump, diabetes, a history of hypertension, a history of unstable angina, and increasing age. Perioperative hypotension and the use of ventricular venting were also weakly associated with this type of outcome.[6]

An important caveat that must be borne in mind when interpreting Roach and colleagues' results is that type II injury as identified in their study is not necessarily equivalent to perioperative cognitive dysfunction as demonstrated in other studies. Type II injury was detected on clinical grounds alone rather than on the basis of deterioration in performance on a predefined series of specific cognitive tests. The latter are a much more sensitive measure of performance and thus detect cognitive dysfunction with a considerably greater frequency; as such, they potentially have a much different, although not necessarily benign, implication from the increased mortality rates associated with type II injury demonstrated by Roach and colleagues.[6,24]

Early, Delayed, and Late Stroke

In considering the incidence of perioperative stroke it is apparent that distinguishing stroke as early (ie, neurologic deficit apparent on emergence from anesthesia), delayed (ie, neurologic deficit developing more than 24 hours postoperatively), or late (ie, stroke developing more than 30 days postoperatively), is important in order to better discriminate causative factors and potential risk reduction strategies. Such an analysis facilitates identification of potentially causal intraoperative events (eg, hypotension, atherosclerotic aorta), from perioperative occurrences (eg, atrial fibrillation) and later progression of underlying disease (eg, cerebrovascular atherosclerosis).[25]

In an analysis of 2516 consecutive patients who underwent either CABG (n = 1399) or OPCAB (n = 1117), more than half of strokes (29 of 46; 63%) were delayed strokes.[25] Patients undergoing OPCAB had significantly lower risk of early stroke (0.1% vs 1.1%; P = .0009), whereas the incidence of delayed strokes was not different significantly (0.9% vs 1.4%; P = .3484) between patients undergoing CABG and OPCAB.[25] Similarly, in a review of more than 7839 CABG, 297 OPCAB, and 986 combined CABG and valve surgeries, an overall early stroke incidence of 1.6% and delayed stroke incidence of 1.1% was reported.[26] Univariate analysis indicated higher early stroke risk for CABG versus OPCAB (1.4% vs 0.3%; P = .011). Multivariate analysis indicated that risk factors for early stroke were advanced age, high preoperative creatinine level, extent of aortic atherosclerosis, and duration of CPB. Factors associated with delayed stroke were female gender, unstable angina, previous cerebrovascular disease, inotropic support requirement, and postoperative atrial fibrillation. Early stroke was associated with increased mortality mainly in the acute perioperative period, whereas delayed stroke was associated with increased long-term mortality.[26]

These studies strongly indicate that patient comorbidities, particularly aortic atherosclerosis, in concert with intraoperative factors, whether associated with CABG, OPCAB, or PCI, fundamentally impact the incidence of early stroke and are thus potentially modifiable, whereas late stroke reflects progression of comorbid disease and atrial arrhythmias.

Age-Associated Risk for Central Nervous System Injury

In a review of 67,764 cardiac surgical patients, of whom 4743 were octogenarians, and who underwent cardiac surgery at 22 centers in the National Cardiovascular Network, Alexander and coworkers reported that the incidence of type I cerebral injury (defined by Roach et al as stroke, TIA, or coma)[6] was 10.2% in patients older than 80 years versus 4.2% in patients younger than 80.[27] Although global mortality for cardiac surgery in octogenarians was greater than in younger patients, the researchers reported that when octogenarians without significant comorbidities were considered, their mortality rates were similar to those of younger patients.[27]

This observation has been confirmed in a recent single-center study of 418 consecutive patients older than 80 years who underwent cardiac surgery between 2000 and 2012 and who were matched according to gender, surgical procedure, and comorbidities with 426 younger patients.[28] This study identified postoperative stroke in 4.1% of octogenarian patients and in 3.5% of matched controls (P = .65). In younger patients, peripheral vascular disease and cardiac rhythm disturbances were significant risk factors, whereas factors related to intraoperative brain oxygenation (ie, preoperative anemia) were the most critical determinant of stroke in the older patients. In a recent review from the STS National Adult Cardiac Surgery Database of 774,881 patients undergoing isolated CABG between January 2002 and December 2006, the overall incidence rate of stroke was 1.4%, increasing to 2.3% in patients aged 75 years and older.[8] Stroke rate was inversely related to body surface area; this may again reflect a decrease in red cell mass and greater degree of hemodilution during CPB and was directly proportional to serum creatinine concentration, as well as presence of valvular heart disease and other comorbidities.[8]

In this respect, in addition to the age-related factor, reports from Europe and North America consistently describe previous cerebrovascular disease, diabetes mellitus, hypertension, peripheral vascular disease (including carotid disease), aortic atherosclerosis, renal dysfunction, infarction or unstable angina within 24 hours before surgery, and intraoperative and postoperative complications as being additional factors increasing the incidence of cerebral injury in cardiac surgical patients (Box 40.1) Determining the impact of age-associated cerebral injury in cardiac surgery is becoming more relevant because of the progressive increase in the average age of the general population and, in particular, of the cardiac surgical population.[6,8,20,23,29,30]

BOX 40.1 FACTORS RELATED TO CEREBRAL INJURY IN CARDIAC SURGERY

- Age[8,27,28]
- Aorta atheromatosis[160,161,163,164,166,168,391–393]
- Carotid disease[30,394]
- Diabetes mellitus[6,8,21,131,174,218,395]
- Hypertension[6,8,395,396]
- Peripheral vascular disease[6,68,165,218,395,397]
- Renal dysfunction[8,398]
- Stroke or cerebrovascular disease[6,21,30,131,399]
- Recent unstable angina or acute myocardial infarction[6,218,398,400]
- Preoperative low output/low ejection fraction[397,398]
- Combined/complex procedures[15,395]
- Redo surgery[218,395]
- Prolonged cardiopulmonary bypass time[22,68,395]
- Intraoperative hemodynamic instability[15,22,149,395]
- Postoperative atrial fibrillation[149,168,398,399]

Risk factors consistently reported for perioperative cerebral injury in cardiac surgery patients; see reference numbers and discussion in the text.

The presence of preoperative comorbidities is increasingly recognized as the primary determinant of the age-associated risk for CNS complications. As overall survival and quality of life after cardiac surgery continue to improve in older patients, advanced age alone is no longer considered a deterrent when evaluating a patient for cardiac surgery, with some centers reporting similar incidences of stroke in octogenarians independent of whether CABG or OPCAB was employed.[11,20,27,29,31] The presence and extent of comorbidities should be considered as being of equal or greater importance than age itself as a risk factor for cerebral injury in cardiac surgical patients.

Retrospective Versus Prospective Neurologic Assessment

The detection of CNS injury depends critically on the methodology used, and retrospective studies have been demonstrated as insensitive in various studies.[14,18,32,33] As Sotaniemi and colleagues demonstrated, a retrospective chart review is inadequate as an assessment of the overall incidence of postoperative neurologic dysfunction.[33] In their study of 100 patients in whom a 37% incidence rate of neurologic dysfunction had been diagnosed by careful neurologic examination, the prevalence rate of cerebral abnormalities detected by retrospective analysis of the same patient pool was only 4%. The reasons for the inability of retrospective chart audit to detect the majority of patients with neurologic dysfunction are readily apparent and include incompleteness of records, a reluctance to document apparently minor complications, and, most important, an insensitivity to subtle neurologic dysfunction. The timing, thoroughness, and reproducibility (single examiner) of the neurologic examinations, as well as the incorporation of a preoperative assessment for comparison, all determine the sensitivity and accuracy with which postoperative CNS injury can be detected.[14,18,32,34,35] Many of the types of neurologic impairment now being documented are subclinical and not readily detectable by a standard "foot-of-the-bed" assessment and have currently unknown implications for longer term patient outcomes.[36,37]

This is most clearly illustrated by a recent prospective study by Messé and colleagues in which 196 patients (mean age, 75.8 ± 6.2 years) undergoing AVR for calcific aortic stenosis were evaluated by neurologists preoperatively and postoperatively and underwent postoperative MRI.[36] Over a 4-year period, clinical strokes were detected in 17%, whereas the frequency of stroke in the STS database in a comparable cohort was less than 5%.[9] Moderate or severe stroke (National Institutes of Health Stroke Scale ≥10) occurred in 8 patients (4%)

and was strongly associated with in-hospital mortality (38% vs 4%; $P = .005$), while silent infarct was identified on postoperative MRI in 59 (54%) of the 109 stroke-free subjects but was not associated with in-hospital mortality or increased length of stay.[36]

Delirium

In a study by Bucerius and coworkers [15] assessing CNS outcomes from 16,184 patients undergoing cardiac operations with CPB ($n = 14,342$) or without CPB ($n = 1847$), the overall prevalence rate of postoperative delirium was 8.4%. Stepwise logistic regression revealed history of cerebrovascular disease, peripheral vascular disease, atrial fibrillation, diabetes mellitus, left ventricular ejection fraction of 30% or less, preoperative cardiogenic shock, urgent operation, intraoperative hemofiltration, operation time of 3 hours or more, and a high perioperative transfusion requirement as being independent predictors of delirium, whereas beating-heart surgery and younger patient age were identified as having a significant protective effect.[15] In a prospective follow-up study of 112 cardiac surgical patients, the incidence rate of postoperative delirium was 21% and was associated with significantly increased mortality and readmission to hospital, as well as significantly greater incidences of cognitive and sleep disturbances.[38] Similarly, in a prospective study of 221 patients, 31% developed delirium of whom older age, higher Charlson's comorbidity index, lower Mini-Mental State Examination (MMSE) score, length of CPB, and systemic inflammatory response syndrome in the intensive care unit (ICU) were independently associated with delirium.[39] Other studies have also identified heightened inflammatory response characterized by increased levels of interleukin (IL)-2 and tumor necrosis factor-α (TNF-α) as associated with postoperative delirium.[40] Alternatively, Hori and associates detected a lower incidence of delirium of 9.2% (42/491 patients) that was associated with high mean arterial pressures (MAPs) above the near-infrared spectroscopy (NIRS)–detected upper limit of cerebral autoregulation during CPB, as well as age, prior stroke, and mechanical ventilation more than 48 hours as causative factors.[41]

Seizures

In a recent prospective study of 101 post–cardiac surgical patients, the incidence of electroencephalographically detected seizures was 3% (2 focal and convulsive, 1 generalized and electrographic) in which all 3 patients with seizures were 65 years or older, had open-chamber procedures, and underwent CPB for a duration longer than 120 minutes.[42] Risk factors recently associated with seizures after cardiac surgery include open-chamber cardiac surgery,[43–45] deep hypothermic circulatory arrest,[43] aortic calcification or atheroma,[43] critical preoperative state[43] or high APACHE II score,[45] tranexamic acid exposure,[44–47] preoperative cardiac arrest,[45] long CPB time,[45] previous cardiac surgery,[45] poor renal function,[45,48] age 75 years or older,[44] and peripheral vascular disease.[44]

Independent of CNS injury, recent evidence has focused on seizures associated with high dosage of tranexamic acid (>30 mg/kg), an antifibrinolytic administered to decrease blood loss and transfusion requirements.[47] Studies have generally implicated open-chamber procedures associated with prolonged duration CPB and renal failure as contributory and thought to be due to increased cerebral spinal fluid concentrations of tranexamic acid–producing enhanced neuronal excitation by impairing neuronal inhibition due to direct postsynaptic receptor blockade by tranexamic acid of the inhibitory neurotransmitter γ-aminobutyric acid (GABA).[49]

Neuropsychologic Dysfunction

Compared with stroke, cognitive dysfunction (neurocognitive dysfunction) is a considerably more frequent sequela of cardiac surgery and has been demonstrated in up to 80% of patients early after surgery.[18,50,51] The pathogenesis of cognitive dysfunction after cardiac surgery is still uncertain. Variables that have been postulated to explain the development of postoperative neurocognitive decline include advanced age, concomitant cerebrovascular disease, and severity of cardiovascular disease, as well as progression of underlying disease. Various intraoperative factors such as cerebral emboli, hypoperfusion or hypoxia, activation of inflammatory processes, aortic cross-clamp or CPB time, low MAP and cerebral venous hypertension have all been implicated. In many instances, subtle signs of neuropsychological dysfunction are detectable only with sophisticated cognitive testing strategies, although depression and personality changes may be noted by family members. It should be recognized that formalized cognitive testing is reproducible and quantifiable and represents an objective outcome measure; as such, it can act as a benchmark to assess various therapeutic interventions (eg, the efficacy of putative cerebroprotectants, equipment modifications, pH management strategies). In addition, a number of studies have made correlations between early postoperative cognitive dysfunction and intraoperative cerebral oxygen desaturation, as well as new ischemic lesions on MRI.[52,53] Assessment of early cognitive dysfunction can be used to discriminate between various intraoperative treatment modalities (eg, pH management, use of cell saver, epiaortic scanning [EAS]). However, whether early postoperative cognitive dysfunction represents permanent neurologic damage remains controversial.[54]

Newman and colleagues sought to determine the course of cognitive change 5 years after CABG, reporting an incidence rate of cognitive decline of 53% at discharge, 36% at 6 weeks, 24% at 6 months, and 42% at 5 years.[55] Cognitive function at discharge was a significant predictor of long-term function. Their results confirmed the relatively high prevalence and persistence of cognitive decline after CABG and suggested a pattern of early improvement followed by a later decline that is predicted by the presence of early postoperative cognitive decline.[55] What is interesting is the apparent lack of association between cognitive dysfunction and aortic atherosclerosis. At least in one study of 162 CABG patients who had a perioperative neurocognitive evaluation and evaluable intraoperative transesophageal echocardiography (TEE) images, no significant relation was found between cognitive dysfunction and atheroma burden in the ascending arch or descending aorta, suggesting that aortic atherosclerosis may not be the primary factor in the pathogenesis of post-CABG cognitive changes.[56]

In the systematic review and meta-analysis in CABG patients by Van Dijk and colleagues, data from six highly comparable studies were pooled and demonstrated an incidence of cognitive deficit (defined as a decrease of at least 1 standard deviation in at least 2 of 9 or 10 neuropsychological tests) of 22.5% (95% CI, 18.7–26.4) at 2 months after surgery.[18] In a prospective study of 316 CABG patients, Murkin and colleagues reported a perioperative stroke rate of 2.8% and demonstrated that 33% of 239 patients assessed 2 months after surgery evidenced cognitive dysfunction, and that 45% experienced either neurologic or cognitive dysfunction, in comparison with their preoperative performance.[57]

One important confounder in many of the earlier studies is the absence of a nonsurgical control cohort with similar comorbidities also followed longitudinally with cognitive testing. Several more recent studies have demonstrated similar incidences of later cognitive dysfunction whether patients underwent CABG, off-pump surgery, PCIs, or were managed medically.[54,58] These results strongly imply that underlying comorbidities and progression of cerebrovascular disease are the most relevant factors in late postoperative cognitive dysfunction rather than cardiac surgery per se.

The mid- and long-term impact of neurocognitive dysfunction on quality of life after cardiac surgery has been addressed by different studies.[24,59,60] Ahlgren and investigators prospectively evaluated neurocognitive function and driving performance after CABG in 27 patients who underwent neuropsychological examination involving 12 cognitive tests, including a standardized on-road driving test and a test in an advanced driving simulator before and 4 to 6 weeks after surgery.[59] Twenty patients who underwent PCIs under local anesthesia served as a control group. After surgery, 48% of patients in the CABG group showed cognitive decline, whereas significantly fewer patients in

the PCI group, only 10%, showed cognitive decline after intervention. Of particular relevance to functional quality of life, patients demonstrating cognitive decline also tended to drop in the on-road driving scores to a larger extent than did patients without a cognitive decline.[59] Di Carlo and colleagues administered a series of cognitive tests before and 6 months after the operation to 110 patients (mean age, 64.1 years; 70.9% male sex) undergoing cardiac surgery.[60] The degree of the impairment was determined by two independent neuropsychologists in relation to its impact on everyday life activities. At 6-month assessment, 10 patients (9.1%) were ranked as having severe deterioration, 22 (20%) as having mild or moderate deterioration, and 78 (70.9%) as unchanged or improved.[60] At 5-year follow-up, Newman and coworkers also found a significant correlation between cognitive function and quality of life in patients after cardiac surgery.[24] Lower overall cognitive function scores at 5 years were associated with lower general health and a less productive working status.

Overall, it appears that underlying patient comorbidities rather than use of CPB or even surgery or PCI or medical management are most important in the genesis of long-term cognitive outcome. Although cognitive testing can be used to discriminate and optimize among various perioperative treatment modalities, the incidence of neurocognitive dysfunction between studies is potentially unreliable as an index of the absolute incidence of neurocognitive dysfunction, because of the high variability in methodologies among studies (ie, differing definitions of neurocognitive dysfunction, choice of tests, employment of relevant comparator groups), associated with a given procedure (eg, CABG surgery). Cognitive testing is best used as a comparator tool to discriminate between treatment modalities.

Neuropsychological Testing

As noted in the studies discussed, neuropsychological testing has been used increasingly in an attempt to discriminate the efficacy of various treatment modalities or as an index of cognitive functioning after CPB. In large measure, the sensitivity of this type of testing is such that very small decrements in performance can be assessed and quantified. It appears that a patient may have a consistent decrease in cognitive performance, with or without evidence of subtle neurologic abnormalities, yet may be apparently oblivious to it, whether because of denial or an absence of awareness. Commonly, such a patient's family may have noted some nonspecific alteration in mood or behavior, likely a manifestation of the same dysfunction detected on cognitive testing.

Preoperative Cognitive Function

One of the earliest prospective reports of neurobehavioral sequelae of cardiac surgery appeared in 1954, and it focused on the acute and chronic stress responses manifested as psychobehavioral syndromes in patients undergoing valvular surgery.[61] More recently, Rankin and associates used a 1-hour neuropsychological battery administered before surgery to 43 patients before prospective randomization to either CABG or OPCAB and again to 34 of those patients 2 to 3 months after surgery by an examiner blind to surgical condition.[62] Neuropsychological status did not change 2.5 months after surgery between OPCAB or CABG groups. However, both groups showed dramatic presurgical cognitive deficits in multiple domains, particularly verbal memory and psychomotor speed. This corroborates previous research suggesting that patients requiring CABG may evidence significant presurgical cognitive deficits as a result of existing vascular disease.

Neuropsychological Test Selection

Research examining cognitive functioning in patients undergoing CPB has frequently focused on the assessment of cognitive functioning within the domains of attention/concentration, psychomotor speed, motor dexterity, and verbal learning. Under the best case scenario, it might be desirable to use a complete battery of neuropsychological tests assessing the entire spectrum of cognitive functions. However, the cost of such a procedure and the time demands make such an approach unrealistic.

In perioperative cardiac surgical patients, the evaluation is necessarily limited by constraints of time and fatigue; thus, tests used should have good sensitivity to dysfunction, even if at the expense of specificity. Tests that can be administered quickly and reliably and are highly sensitive, particularly to dysfunction within cognitive domains localized to brain regions vulnerable to effects of microemboli or transient hypoxia, should be selected.

Research suggests that among the tests most appropriate under these circumstances are tests of attention/concentration, psychomotor speed, motor dexterity, and verbal learning. Research as to the behavioral consequences of hypoxia (and other conditions associated with more diffuse brain damage) suggests these domains are likely to be compromised.[63] This presumption has also been supported by research to date examining behavioral consequences of CPB. Frequently, the Grooved Pegboard Test (motor dexterity), various subtests of the Wechsler Adult Intelligence Scale-Revised (Digit Symbol [psychomotor speed]), some of the seven subtests of the Wechsler Memory Scale (Mental Control [attention], Digit Span [concentration], Paired Associates Verbal Learning [verbal learning]), as well as the Halstead Reitan Trail Making Test (Trails A and B), have been used in whole or in part for the assessment of cognitive impairment after CPB.[24,50,55,57,59,60,64–73]

Methodologic Issues in Neurobehavioral Assessment

The Statement of Consensus on Assessment of Neurobehavioral Outcomes after Cardiac Surgery encouraged a more standardized and comparable methodology in assessment of cognitive injury, identifying several key issues of concern in perioperative cognitive testing.[34]

1. A spectrum of postoperative CNS dysfunction, both acute and persistent, occurs in a proportion of patients after cardiac surgery, including brain death, stroke, subtle neurologic signs, and neuropsychological impairment.
2. A number of patients who will undergo cardiac surgery have preexisting CNS abnormalities. Patients' neurologic and neuropsychological states need to be assessed before surgery to provide accurate baseline information.
3. The individual change in performance from baseline to a time after surgery is essential to any evaluation of the impact of surgery or any intervention associated with it.
4. When indicated, designs should incorporate the use of a control or comparison group. This is arguably one of the most important recommendations that was made, but, as noted earlier, until recently it has not been consistently applied, resulting in discordant results in the literature.
5. Because of the time constraints and physical limitations of the patient in performing a neuropsychological assessment in the context of cardiac surgery, care must be taken to select appropriate tests. Selection of tests should take the following issues into consideration:
   - Cognitive domain of the test
   - Sensitivity and reliability of the test
   - Time taken to perform the test
   - Degree to which learning may occur in the test
   - Availability of parallel forms of the test
   - Physical effort required to perform the test
   - Overall balance of the cognitive domains assessed in the battery
6. Tests should be free from sex, race, and ethnic bias and be structured to avoid floor and ceiling effects.
7. Because of the multifocal nature of the potential lesion locations, no single test will always detect postoperative neurobehavioral dysfunction.
8. Care must be taken in performing the assessments because neurobehavioral performance can be influenced by environmental, psychiatric, physiologic, and pharmacologic factors.
9. Because the performance of neuropsychological tests may be influenced by mood state and mood state variations, it is important

that mood state assessments be performed concurrently with the neuropsychological assessments.
10. To ensure objectivity and reliability of the assessment, for each patient, the testing should be performed by the same suitably qualified and trained individual, and tests should minimize subjectivity and be performed in a standardized manner. The examiner should be blinded to any treatment.
11. A comprehensive and concise neurologic examination should be performed by a suitably qualified and trained individual.
12. Because the incidence of postoperative neurobehavioral dysfunction is greatest in the immediate postoperative period and then declines, care must be taken to perform at least one assessment when performance is more stable. Ideally, this should be at least 3 months after surgery.
13. Investigators should be aware that new events may occur in the days after surgery.
14. Cognitive testing may be associated with improvement in performance on repeated testing, recognized as "practice effect." This improvement needs to be taken into consideration in any analyses of the data. In addition, study design incorporating procedures to minimize practice effects (ie, providing sufficient practice trials on each test at each assessment period) is encouraged.[21]

Based on the proceedings of these consensus conferences,[34] the following cognitive tests were recommended as necessary but not sufficient components of any neuropsychological test battery based on their availability in multiple languages and availability of paper-and-pencil versions for use with cardiac surgical patients:

- Rey Auditory Verbal Learning Test
- Trail Making A
- Trail Making B
- Grooved Pegboard

Furthermore, in 1997 an additional statement was published in which consensus was reached that (1) individual change scores rather than group means should be used, (2) there should be consistency of setting for testing, and (3) practice effect in neurocognitive testing should be corrected for.[35]

Mechanisms of Brain Injury

Determining which factor or, more likely, which combination of factors is responsible for postoperative neurologic or behavioral dysfunction in patients undergoing cardiac surgery using CPB is problematic (Box 40.2). From the few studies in which a surgical control group has been used, it appears that elements inherent to CPB are causative, particularly in dysfunction occurring in the immediate postoperative period.[57,72] How much of this dysfunction is as a direct result of exposure to CABG and CPB or occurs as a result of underlying comorbid disease is an area of active ongoing investigation. Underlying disease such as aortic and cerebrovascular atherosclerosis, hypertension, and diabetes, which predispose such patients to CNS dysfunction as a result of nonspecific stress associated with major surgery independent of CABG clearly plays a role. Based on postmortem studies, as well as correlative analyses of intraoperative events with neurologic outcomes, two primary mechanisms appear to be responsible for brain injury in otherwise uncomplicated cardiac operations: cerebral hypoperfusion and cerebral emboli.

Intraoperative cerebral embolization of particulate and microgaseous elements has a significant role in the genesis of cerebral events in postoperative cardiac surgical patients.[51,74–83] Increasing attention is also being paid to the role of perioperative hypoperfusion, particularly in patients with intracranial and extracranial atherosclerosis, and to the effect of inflammatory processes triggered during exposure to surgery and CPB.[22,84,85]

In a prospective study of 151 consecutive Japanese patients (115 men and 36 women ranging in age from 41 to 82 years) scheduled for CABG, carotid and intracranial arteries were examined for occlusive lesions with magnetic resonance angiography.[86] Cervical carotid artery stenoses of more than 50% narrowing were detected in 16.6% of the patients, and intracranial artery stenoses of more than 50% narrowing were detected in 21.2% of the patients. In a similar study of 201 Korean patients presenting for CABG, more than 50% had evidence of either extracranial or intracranial atherosclerotic disease, whereas 13% of patients had evidence of both.[87] In this series, 25.4% of patients had single or multiple postoperative CNS complications, and intracranial atherosclerotic disease was found to have a strong independent association with the development of CNS complications. The presence of both extracranial and intracranial atherosclerotic disease was even more strongly associated with adverse perioperative CNS outcomes than was intracranial atherosclerotic disease alone.[87]

In those studies in which a control group (subjected to a noncardiac procedure) was used, the incidence of both new neurologic signs and cognitive dysfunction was significantly greater in the patients undergoing CABG in the first several postoperative days compared with the surgical cohort.[57,88]

There is also evidence of a greater stroke rate in cardiac surgery from the recently published SYNTAX trial in which 1800 patients with three-vessel or left mainstem coronary artery disease were randomized to PCI or conventional CABG surgery.[89] This study demonstrated no difference in mortality at 1 year but a significantly ($P = .002$) lower incidence of primary composite end point of major adverse cardiac or cerebrovascular event in CABG (12.4%) versus PCI (17.8%) patients. However, although the overall outcome should argue strongly in favor of CABG surgery, the stroke rate was significantly greater in CABG (2.2%) than PCI (0.6%) patients.

More recent evidence is also focusing on new-onset postoperative atrial fibrillation (POAF) as being associated with increased long-term mortality and stroke.[90,91] Formerly, POAF was thought to be relatively benign and self-limited, whereas a recent meta-analysis involving records of 69,518 patients identified new-onset POAF following CABG as associated with significantly higher risk of mortality in short- and long-term follow-up and higher rates of stroke and other complications.[90] As discussed later, such evidence is giving new impetus to surgical and pharmacologic strategies to decrease risk of POAF and attendant complications.

BOX 40.2 RISK FACTORS FOR NEUROLOGIC COMPLICATIONS IN CARDIAC SURGERY

- Hemodynamic instability
- Diabetes mellitus
- Advanced age
- Combined/complex procedures
- Prolonged cardiopulmonary bypass time
- Prior stroke/cerebrovascular disease
- Aortic atheromatosis
- Renal dysfunction
- Peripheral vascular disease

Neuropathologic Studies

In an early series from 1962 to 1970 that examined 206 patients dying after cardiac surgery or CABG and a group of 110 patients dying after non-CPB vascular surgery, Aguilar and investigators reported that there was a high correlation between the use of CPB and the incidence of brain lesions.[92] They reported that the most significant abnormalities found, in both severity and frequency of occurrence, were emboli in small cerebral vessels; acute petechial, perivascular, and focal subarachnoid hemorrhages; and acute ischemic neuronal damage (Box 40.3). They noted the virtual disappearance from the brain of nonfat emboli such as fibrin, platelet aggregates, polarizable crystalline material, xanthomatous debris, striated muscle, and calcium in cases examined after the introduction of arterial line filtration, whereas they reported that cerebral embolization of such debris was commonly

BOX 40.3 MECHANISMS AND FACTORS FOR NEUROLOGIC LESIONS

- Embolization
- Hypoperfusion
- Inflammation
- Influencing factors
- Aortic atheroma plaque
- Cerebrovascular disease
- Altered cerebral autoregulation
- Hypotension
- Intracardiac debris
- Air
- Cerebral venous obstruction on bypass
- Cardiopulmonary bypass circuit surface
- Reinfusion of unprocessed shed blood
- Cerebral hyperthermia
- Hypoxia

observed in patients dying after CPB before the introduction of arterial line filtration.[92] Other early studies showed that measures taken to decrease the duration of CPB, as well as the introduction of arterial line filtration and filtration of the cardiotomy suction return, decreased overt neurologic dysfunction.[76,79,93]

A review of autopsy findings from 221 patients dying after CABG or valve surgery between 1982 and 1989 reported a direct correlation among age, severe atherosclerosis of the ascending aorta, and presence of atheroemboli.[94] Atheroemboli were significantly more common in patients who underwent CABG versus valvular surgery, and there was a high correlation of atheroemboli with severe atherosclerosis of the ascending aorta, being present in 37.4% of patients with severe disease of the aorta versus only 2% of those without. Of all patients who had evidence of atheroemboli, 95.8% had severe atherosclerosis of the ascending aorta.[94] Doty and colleagues reviewed the records of 49,377 autopsy cases and surgical specimens from the Johns Hopkins Hospital between 1973 and 1995.[77] Three hundred twenty-seven patients (0.7%) had an identifiable atheroembolism on histologic examination. Of these patients, 29 (0.2%) had undergone a cardiac surgical procedure within 30 days of autopsy or surgical resection. Six of the 29 patients (21%) had atheroembolism to the heart, 7 patients (24%) had embolism to the CNS, 19 patients (66%) had embolism to the gastrointestinal tract, 14 patients (48%) had embolism to one or both kidneys, and 5 patients (17%) had embolism to a lower extremity. Sixteen patients (55%) had atheroembolism in two or more areas. In six patients (21%), death was directly attributable to atheroembolism, including intraoperative cardiac failure from coronary embolism (three), massive stroke (two), and extensive gastrointestinal embolization (one).[77]

In a neuropathologic study of brains from 262 patients dying after having undergone CABG, valve replacement, or heart transplantation surgery, 49% of cases demonstrated evidence of circulatory disturbances identified as macrohemorrhages and microhemorrhages, infarcts, subarachnoid hemorrhages, or hypoxemic brain damage.[95] The infarcts were caused by local arteriosclerosis of cerebral arteries, fat emboli, arterial emboli from operative sites, or foreign body emboli. These investigators concluded that histologically overt microemboli did not play a major role in their findings and that nonfatal white matter microhemorrhages were found with varying frequency, especially after valve operations.[95] These observations are not inconsistent with the apparent lack of correlation seen in several beating-heart surgery studies between differing incidences of transcranial Doppler (TCD)–detected cerebral emboli and cognitive dysfunction.[74,96]

In a postmortem study of brain histology, four of five patients dying after CPB, two patients dying after proximal aortography, and six dogs placed on CPB were all found to have small capillary and arteriolar dilations (SCADs) distributed throughout brain parenchyma, consistent with sites of gas bubbles or fat emboli (Fig. 40.1).[81] These microvascular anomalies were only found in conjunction with use of CPB or proximal aortic instrumentation. In a subsequent series of

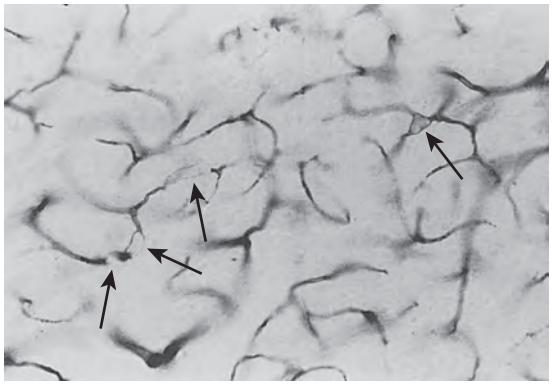

Fig. 40.1 Microemboli or small capillary and arteriolar dilatations (SCADs) in arterioles of human brain 1 day after cardiopulmonary bypass. The afferent microvessels are black. The SCADs are dilated clear areas *(arrows)*; the largest one here measures 25 μm in diameter. It is believed these represent the "footprints" of emboli that were almost completely removed by the reagents used in this histochemical staining method. Alkaline phosphatase–stained 100-μm-thick celloidin section; magnification ×300 before 50% reduction. *(Reprinted from Moody DM, Brown WR, Challa VR, et al. Brain microemboli associated with cardiopulmonary bypass: a histologic and magnetic resonance imaging study.* Ann Thorac Surg. *1995;59:1304–1307.)*

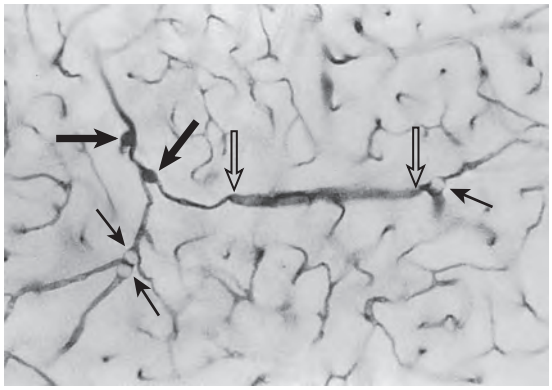

Fig. 40.2 Microemboli *(white arrows)* "bracketed in time" by sequentially injected microspheres of different colors. Clear microspheres *(small black arrows)* and black microspheres *(large black arrows)* can be seen distal to proximal order in a single arteriolar complex. In this experiment, clear spheres were injected into the carotid artery of a dog, followed in succession by injection of corn oil and then black spheres. Direction of blood flow in the arteriole is from top to bottom. Alkaline phosphatase–stained 100-μm-thick celloidin section; microspheres = 15 μm. *(Reprinted from Moody DM, Brown WR, Challa VR, et al. Brain microemboli associated with cardiopulmonary bypass: a histologic and magnetic resonance imaging study.* Ann Thorac Surg. *1995;59:1304–1307.)*

canine CPB studies by this same group of researchers, use of colored microspheres was able to "time-lock" the development of SCADs to the period associated with CPB (Fig. 40.2).[97]

Watershed Infarctions

Watershed, or boundary zone, infarcts are ischemic lesions that are situated along border zones between the territories of two major cerebral arteries (eg, the middle and posterior, or the anterior and middle cerebral arteries) where terminal arteriolar anastomoses exist (Fig. 40.3).[98–101] In a series reported by Malone and colleagues, a correlation was made between the presence of intraoperative electroencephalographic (EEG) abnormalities (virtual or complete electrical silence), usually seen in conjunction with sustained hypotensive episodes, and neuropathologic lesions found at necropsy.[99] In all nine

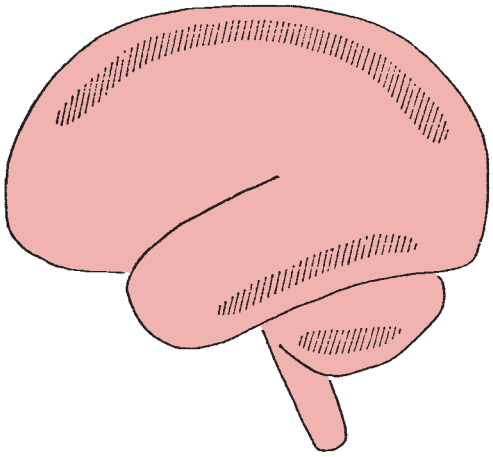

Fig. 40.3 Hatched areas showing the most frequent locations of boundary area, or watershed zone infarcts in the brain, situated between the territories of major cerebral or cerebellar arteries. *(From Torvik A. The pathogenesis of watershed infarcts in the brain.* Stroke. *1984;2:221–223.)*

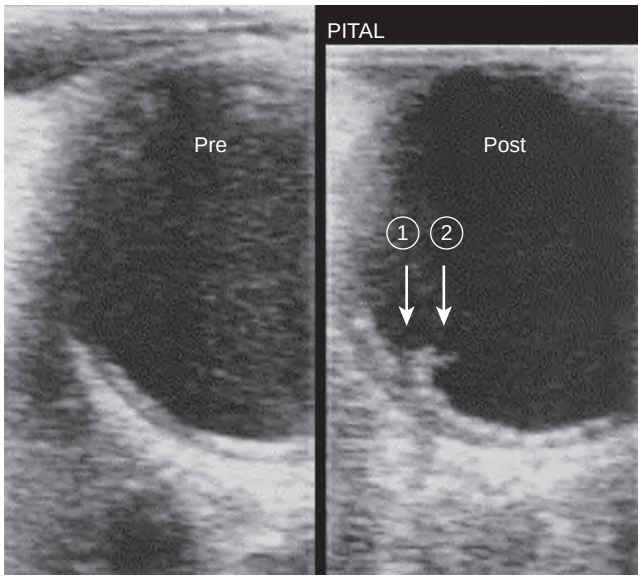

Fig. 40.4 New intimal tear *(arrow 1)* and new mobile lesions *(arrow 2)* likely to have been caused by aortic clamping. *(From Ura M, Sakata R, Nakayama Y, Goto T. Ultrasonographic demonstration of manipulation-related aortic injuries after cardiac surgery.* J Am Coll Cardiol. *2000;35:1303–1310.)*

patients with clinical evidence of brain damage, cortical boundary zone (watershed) lesions were observed in the parieto-occipital areas. Malone and colleagues suggest that this location is the most sensitive area for placement of recording EEG electrodes because it is where minimal boundary zone ischemic lesions occurred in the absence of other lesions, and it is also where ischemic lesions were found in their maximal severity and extent.[99]

A profound reduction in systemic blood pressure is the most frequent cause of watershed infarcts. These areas are thought to be more susceptible to ischemia resulting from hypotension because of their critical dependence on a single blood supply. Wityk and coworkers studied the pattern of ischemic changes on diffusion- and perfusion-weighted MRI in a case series of 14 patients and 4 patients, respectively, with neurologic complications after cardiac surgery.[102] Acute ischemic lesions were classified as having a territorial, watershed, or lacunar pattern of infarction. Patients with multiple territorial infarcts in differing vascular distributions that were not explained by occlusive vascular lesions were classified as having multiple emboli. Diffusion-weighted MRI revealed acute infarcts in 10 of 14 patients, of whom 4 had combined watershed and multiple embolic patterns of ischemia. Findings of perfusion-weighted MRI were abnormal in two of four patients, showing diffusion-perfusion mismatch. Both patients had either fluctuating deficits or TIAs, and their conditions improved with blood pressure increase.[102]

By the same rationale, however, these areas are also highly susceptible to ischemia because of end-artery embolization, and it is also recognized that although severe hypotension is the most common cause, showers of microemboli may lodge preferentially in these areas and cause infarcts in the underlying brain.[102–105] As such, although they commonly arise from profoundly hypotensive episodes, watershed lesions are not pathognomonic of a hypotensive episode and may be the result of cerebral emboli. Embolization and hypoperfusion acting together play a synergistic role and either cause or magnify the brain damage of cardiac surgical patients. The negative influence of hemodynamic instability and hypoxia has been demonstrated by several researchers, showing improved outcomes by an early and aggressive recognition and correction of hypoperfusion.[15,22,68,98,106,107]

Cerebral Emboli and Outcome

Cerebral emboli during CPB can be arbitrarily differentiated into macroemboli (eg, calcific or atherosclerotic debris) and microemboli (eg, microgaseous bubbles, microparticulate matter). Overt and focal neurologic damage likely reflects the occurrence of cerebral macroemboli (eg, calcific and atheromatous debris generated during valve tissue removal or instrumentation of an atheromatous aorta), whereas less focal neurologic dysfunction has been ascribed to cerebral microemboli.[6] Microemboli are primarily detected based on characteristic TCD signature being transient (<300 ms), high intensity (>3 decibels above spectrum), high frequency ("chirpy"), and unidirectional and appear to have some role in diffuse, subtle neurologic and cognitive disturbances, whereas macroemboli likely produce clinically apparent catastrophic strokes. Whatever the nature of the cerebral insult, however, it seems that coexistent inflammatory processes can exacerbate the magnitude of injury.

In a perioperative study of 127 patients undergoing OPCAB (n = 61) or CABG (n = 66), 35 (27.6%) showed new brain infarcts on postoperative diffusion-weighted MRI.[108] Most lesions were clinically silent, located in the cortical territory (80%), small (<1.5 cm) in diameter (89%), and not related to the underlying cerebral arterial abnormality (80%). Older age, use of CPB, a moderate to severe aortic plaque, and high levels of high-sensitivity C-reactive protein were independent predictors of new brain infarction, suggesting that a systemic inflammatory response may also contribute to the pathogenesis of post-CABG new infarcts.[108]

In a study to assess the impact of surgical manipulation of the aorta and correlations with postoperative stroke, Ura and colleagues performed EAS before aortic cannulation and after decannulation in 472 patients undergoing cardiac surgery with CPB and followed them for new type I neurologic complications.[109] Grade 2 aortic atherosclerosis was present in 73 patients (15%) and grade 3 in 28 patients (6%). Based on these results, in 63 of 472 patients the operative procedure was modified to change the cannulation site (52 patients) or avoid cross-clamping (23 patients). After aortic decannulation, a new lesion in the ascending aortal intima was identified in 16 patients (3.4%), of which 10 were severe (mobility or disruption of intima) (Fig. 40.4). Twelve were attributable to aortic clamping and four (all severe) to cannulation or decannulation. A total of 10 patients sustained neurologic complications, of whom 3 were diagnosed with severe new lesions (P < .001). The incidence rate of new lesions was directly related to extent of aortic atheroma, being 11.8% if the atheroma was approximately 3 to 4 mm thick and as high as 33.3% if the atheroma was greater than 4 mm, but only 0.8% when it was less than 3 mm.[109] Again, this underscores the need to reliably detect and ultimately avoid disruption of aortic atherosclerotic plaque.

Sylivris and investigators studied 41 consecutive patients undergoing CABG with TCD monitoring and preoperative and postoperative MRI brain scans.[110] A subgroup of 32 patients underwent neuropsychological testing the day before and 5 to 6 days after the operation, of whom 27 had TCD data. Among the subgroup of patients with reliable TCD data and neuropsychological studies, early neuropsychological deficit after CABG was found in 17 (63%) of the 27 patients. On univariate analysis, the time duration on CPB, total microembolic load during bypass, and microembolic rates during bypass were all significantly greater in the group with neuropsychological decline. Actual rates of emboli detected per minute were greatest during release of the aortic cross-clamp. Five patients had strokes, of which four had a significant decline in neuropsychological functioning. Unlike the association between microembolic signals during bypass and neuropsychological deficits, there was no relation between these factors and radiologic evidence of cerebral infarction. Not inconsistent with the findings of Ura and colleagues described earlier, there was a significantly greater microembolic load during aortic instrumentation in patients with cerebral infarction, temporally suggestive of particulate emboli, which was not apparent in comparison with patients with neuropsychological deficits alone.[109,110]

A study with a newer generation of TCD, which uses two different frequencies of insonation and purportedly discriminates between gaseous and particulate emboli, compared the number and nature of intraoperative microemboli in patients undergoing on-pump and off-pump cardiac surgical procedures in 45 patients (15 OPCAB, 15 on-pump CABG, and 15 open cardiac procedures).[74] The investigators demonstrated significantly fewer emboli in the OPCAB versus on-pump CABG and open procedure groups, averaging 40 (range, 28–80), 275 (range, 199–472), and 860 (range, 393–1321) emboli, respectively ($P < .01$). Twelve percent of microemboli in the OPCAB group were defined as solid compared with 28% and 22% in the on-pump CABG and open procedure groups, respectively. In the on-pump groups, 24% of microemboli occurred during CPB, and 56% occurred during aortic manipulation for cannulation, decannulation, application, and removal of cross-clamp or side clamp, again underscoring the importance of minimizing aortic instrumentation.[74]

Gaseous emboli are not innocuous, however. In various studies in nonheparinized animals it has been demonstrated that the effects of air emboli on the cerebral vasculature not only are due to bubble entrapment with direct blockage of cerebral vessels but also represent the effects that such bubbles have on vascular endothelial cells.[111] Ultrastructural examinations of pial vessels in rats exposed to cerebral air emboli demonstrated severe injury to endothelial plasmalemma, leading to loss of cellular integrity and endothelial cell swelling.[112] Such endothelial damage produces disruptions of vasoreactivity, as has been observed in cat pial vessels exposed to air emboli. In these capillary beds, the endothelial layer demonstrated ultrastructural abnormalities that included degradation of intercellular junctions, flattening of nuclei, and crenation of the plasmalemma. Air embolism also produces changes in blood elements leading to formation of a proteinaceous capsule around the bubbles, marked dilation of pial vessels, platelet sequestration, and damage to endothelial cells.[113–115] Air-induced mechanical trauma to the endothelium causes basement membrane disruption, thrombin production, release of P-selectin from intracellular vesicles, synthesis of platelet-activating factor, and a reperfusion-like injury with perturbations in inflammation and thrombotic processes. These phenomena likely impair nitric oxide production, causing alterations in cerebral microvascular regulation.[116,117] Whether heparin anticoagulation during CPB mitigates the impact of cerebral gas embolization as demonstrated during cerebral angiography remains speculative.[118]

Kincaid and coworkers used a cell saver to process the cardiotomy blood in dogs that underwent hypothermic CPB.[119] The brain tissue from two groups of dogs (group I, cardiotomy suction blood reinfused through arterial line filter; group II, cardiotomy suction blood collected and processed in a cell saver) was examined for the presence of SCADs. Mean SCAD density in the cell-saver group was less than that in the arterial filter group (11 ± 3 vs 24 ± 5; $P = .02$). The researchers concluded that using a cell saver to scavenge shed blood during CPB decreases cerebral lipid microembolization.[119]

This hypothesis was investigated in two separate randomized, prospective studies in cardiac surgical patients to assess the impact of cell-saver usage on cognitive dysfunction after cardiac surgery.[120,121] A series of 226 patients older than 60 years undergoing CABG surgery were randomly allocated to either processing of shed blood by cell-saver or control groups.[120] Anesthesia and surgical management were standardized. EAS of the proximal thoracic aorta was performed in all patients, and TCD was used to measure cerebral embolic rates. Cognitive dysfunction was present in 6% of patients in the cell-saver group and 15% of patients in the control group 6 weeks after surgery ($P = .038$). However, significantly ($P = .018$) more patients in the cell-saver group required transfusion of fresh frozen plasma (25%) versus the control group (12%). In a remarkably similar study from Rubens and coworkers, patients undergoing coronary and/or aortic valve surgery using CPB were randomized to receive unprocessed blood (control, $n = 134$) or cardiotomy blood that had been processed by centrifugal washing and lipid filtration (treatment, $n = 132$).[121] The treatment group received more intraoperative red blood cell transfusions (0.23 ± 0.69 vs 0.08 ± 0.34 units; $P = .004$), and both red blood cell and non–red blood cell blood product use was greater in the treatment group. Postoperative bleeding was greater in the treatment group. Patients also underwent neuropsychometric testing before surgery and at 5 days and 3 months after surgery. No difference was found in the incidence of postoperative cognitive dysfunction in the two groups. Similarly, there was no difference in the quality of life, nor was there a difference in the number of emboli detected in the two groups. These researchers concluded that processing of cardiotomy blood before reinfusion results in greater blood product use with greater postoperative bleeding in patients undergoing cardiac surgical procedures and that there was no clinical evidence of any neurologic benefit with this approach in terms of postoperative cognitive function. In summary, both of these studies showed an increase in use of allogeneic blood products and perioperative blood loss as a consequence of routine cell-saver usage, with either no or minor improvements in incidence of postoperative cognitive decline. In view of the variable impact on neurocognitive dysfunction demonstrated in these studies and the detrimental impact of perioperative allogeneic transfusion, routine usage of cell saver for processing of cardiotomy suction blood for removal of SCADs is unwarranted because of increased risk of bleeding and transfusion.[122]

An alternate approach to emboli elimination employs a modified aortic cannula incorporating a separate suction lumen for which a recent study randomized 66 patients undergoing elective AVR surgery with or without CABG surgery to the use of the emboli protection cannula or a standard aortic cannula.[123] The primary end point was the volume of new brain lesions measured by diffusion-weighted MRI performed preoperatively and postoperatively. The volume of new brain lesion assessed by diffusion-weighted MRI for the modified cannula group was 44.00 ± 64.00 versus 126.56 ± 28.74 mm^3 in the control group, and 41% of the modified cannula group demonstrated new postoperative lesions versus 66% in the control group. The incidence of clinical complications was similar in both.[123] Whether these results will be confirmed in larger trials, and, if confirmed, what the longer term impact of such a decrease in subclinical cerebral emboli and diffusion-weighted MRI–detected lesions will be on later cognitive performance and quality of life remain to be seen. However, it is a promising development and further evidence that emboli reduction is feasible and can decrease the magnitude and incidence of postoperative brain lesions.

Neurocognitive Dysfunction Unrelated to Cerebral Microgaseous Emboli

Just as calcific or atheromatous macroembolic debris from the ascending aorta or aortic arch is a prime factor in the production of clinical stroke syndromes, microembolic elements, either gaseous or

particulate, were thought to produce cognitive dysfunction. However, studies from beating-heart surgery in which CPB is avoided, appear to have a relatively similar incidence of cognitive dysfunction to CABG using conventional CPB, despite a much lower incidence of embolic events.[74,96,124] This suggests that there may be different factors operative in the production of gross neurologic damage than in the genesis of cognitive dysfunction.

A series of longitudinal studies by Selnes and others in patients undergoing off-pump cardiac surgery, as well as those treated medically, have suggested that long-term changes in cognitive function are not specific to CABG or use of CPB and may rather reflect progression of underlying disease.[54,58,125,126] Other longitudinal studies have, however, demonstrated a greater incidence of cognitive dysfunction in CABG patients in comparison with various nonsurgical control groups, though the comparability of underlying disease processes between groups remains a significant confounder in many such studies.[55,127]

However, as there is general agreement that the incidence of early postoperative cognitive dysfunction is greater in CABG patients compared with other, noncardiac surgical groups, and because correlations have been made between such early postoperative cognitive dysfunction and new ischemic lesions on MRI studies in valve surgery patients,[52] and between cerebral oxygen desaturation and early postoperative cognitive dysfunction in CABG patients,[53] it does appear as though early postoperative cognitive dysfunction is, in part, reflective of subclinical brain injury; as such, efforts to mitigate against early postoperative cognitive dysfunction are warranted.

Cerebrovascular Disease

Relatively few studies have examined the cerebrovascular responses to CPB in patients with known cerebrovascular disease. Because of the vasodilatory effects of increased carbon dioxide in patients with cerebrovascular disease, pH-stat management could theoretically induce redistribution of regional cerebral blood flow (CBF) from marginally perfused to well-perfused regions (ie, an intracerebral steal). Gravlee and associates investigated patients with cerebrovascular disease undergoing CABG and assessed the CBF responses to varying pH management, between alpha-stat and pH-stat.[128] They confirmed the responsiveness of the cerebral vasculature to changes in arterial partial pressure of carbon dioxide ($PaCO_2$) during hypothermic CPB but did not demonstrate evidence of intracerebral steal at greater $PaCO_2$ levels in any of these patients. In all patients, however, arterial perfusion pressure was greater than 65 mm Hg during CBF measurements, which may have offset any tendency for regional CBF inhomogeneities.

Using TCD monitoring of CBF velocity, 18 patients with severe carotid stenosis and 37 with no or mild stenosis were monitored during CPB.[129] Although not specified, it appears as though pH-stat management was used, because flow velocities correlated with $PaCO_2$ and arterial pressure. There were no significant differences detectable in flow velocity between patients with or without significant carotid stenosis. In a case report of a single patient with bilateral carotid stenoses, alpha-stat pH management was used and arterial pressure was varied from 35 to 85 mm Hg, whereas CBF was measured during hypothermic CPB.[130] The CBF values obtained from contralateral hemispheres were essentially equal and remained so throughout the range of different perfusion pressures used. These studies suggest that the cerebrovascular responses to CPB in patients with cerebrovascular disease do not differ significantly from those of normal patients with respect to gross measures of cerebrovascular responsiveness. Other factors, including associated aortic atherosclerosis, may be more important.

Hogue and investigators examined demographic and perioperative data prospectively collected from 2972 patients undergoing cardiac surgery.[131] Carotid artery ultrasound examination was performed before surgery for patients aged 65 years or older and in patients with a history of TIAs or prior stroke. Epiaortic ultrasound was performed at the time of surgery in all patients to assess for atherosclerosis of the ascending aorta. Strokes occurred after surgery in 30 women and 18 men ($P < .0001$). A history of stroke was the strongest predictor of new stroke for both women and men. A previous cerebrovascular event was a more important predictor of stroke for men than women.[131]

A small study of 32 patients undergoing cardiac surgical procedures with asymptomatic preoperative silent infarctions detected by diffusion-weighted MRI was unable to demonstrate any increase in risk of adverse postoperative CNS complications, although the sample size limits the generalizability of these results.[132] In a larger study of 514 consecutive patients who underwent cardiac surgery with CPB ($n = 484$) or OPCAB ($n = 30$), preoperative studies diagnosed 17% of patients as having obstructive cerebrovascular disease ($n = 88$), detected by carotid ultrasonography and/or magnetic resonance angiography. Of these 88 patients, impaired cerebral perfusion reserve was identified in 1 (1.1%) through the use of brain perfusion single-photon emission computed tomography (SPECT) and reactivity to acetazolamide.[133] Of this group no patients experienced perioperative hemodynamic ischemic stroke, suggesting it is unusual for obstructive cerebrovascular disease to affect the incidence of hemodynamic ischemic stroke during cardiac surgery.

Cerebral Perfusion Pressure

Despite the previously described findings, intraoperative hypotension during cardiac surgery has been related to postoperative neurologic dysfunction.[13,22,78] Ridderstolpe and colleagues published a retrospective study of 3282 patients of mean age of 65.6 years who underwent cardiac surgery in the period from July 1996 through June 2000.[22] Cerebral complications occurred in 107 patients (3.3%). Of these, 60 (1.8%) were early, 33 (1.0%) were delayed, and in 14 (0.4%) patients the onset was unknown. Predictors of early cerebral complications were older age, preoperative hypertension, aortic aneurysm surgery, prolonged CPB time, hypotension at CPB completion and soon after CPB, and postoperative arrhythmia and supraventricular tachyarrhythmia. Predictors of delayed cerebral complications were female sex, diabetes, previous cerebrovascular disease, combined valve surgery and CABG, postoperative supraventricular tachyarrhythmia, and prolonged ventilator support. Early cerebral complications seemed to be more serious, with more permanent deficits and a greater overall mortality rate (35.0% vs 18.2%). The results of this study suggest that aggressive antiarrhythmic treatment and blood pressure control may improve the cerebral outcome after cardiac surgery.[22]

EEG patterns consistent with ischemia—increased slow wave activity, diffuse slowing of EEG activity—have been reported to occur during CPB episodes thought to be associated with cerebral hypoperfusion.[134–136] Episodes of flow reduction during normothermia frequently produced ischemic changes, whereas similar decreases during stable hypothermia were not associated with EEG changes.[134] Indeed, ischemic EEG changes are frequently seen in association with reductions in perfusion flow rate during the initiation of CPB (see Chapters 18, 31, and 32).[134–136] Using computerized electroencephalography to quantitate episodes of low-frequency power as an index of cerebrocortical ischemia in 96 patients undergoing CABG, a correlation was made among episodes of hypotension, focal increases in low-frequency EEG power, and the occurrence of postoperative disorientation.[137]

During the transition to CPB, the brain is particularly vulnerable to ischemia, inasmuch as cerebral metabolic rate for oxygen ($CMRO_2$) is apparently unchanged, yet the brain is initially perfused with an asanguineous prime, and even after equilibration during established CPB, hematocrit is generally maintained at a range between 20% and 30%. As a result, any further decreases in cerebral perfusion, in the absence of concomitant decreases in $CMRO_2$, are poorly tolerated. During hypothermic conditions, there is a profound decrease in $CMRO_2$, exceeding 50% for a 10°C reduction in temperature.[138] Without need to postulate an extension of the lower limit of cerebral autoregulation, it is clear that under anesthesia, and particularly during hypothermic CPB, CBF is maintained at very low levels of cerebral

perfusion pressure. As discussed later, this was initially reported by Govier and coworkers and further explored by Murkin and colleagues and Prough and colleagues.[138–140]

Using radioisotope techniques for measurement of CBF, and incorporating a jugular venous catheter for calculation of $CMRO_2$, it was determined that there is a profound reduction in $CMRO_2$ during hypothermic CPB and that CBF is decreased proportionately and will autoregulate down to a cerebral perfusion pressure of 20 mm Hg, in the presence of alpha-stat pH management.[138] Low arterial pressure during the hypothermic phase of CPB is thus unlikely to result in cerebral ischemia in the absence of cerebrovascular disease. In a study of high versus low arterial pressure management during CPB in 248 patients undergoing CABG, however, an apparently lower rate of postoperative complications was reported by Gold and colleagues for those patients in the high-pressure group.[141] Although specific CNS morbidity, cognitive and functional status outcomes, and mortality rate did not differ significantly between groups, the overall complication rate for combined cardiac and neurologic complications was significantly lower in the high-pressure group, advocating for a less liberal blood pressure management during CPB. Moreover, as the average age and extent of disease in patients presenting for CABG continue to increase, the number of patients with concomitant cerebrovascular disease, and thus potentially deranged cerebral autoregulation, presents an increasingly important group. This is not inconsistent with data demonstrating a high incidence of cerebrovascular disease in coronary revascularization patients.[56,59]

Using NIRS to detect cerebral autoregulation in 450 patients undergoing CABG and/or valve surgery, the area under the curve of the product of the duration and magnitude of blood pressure below the limits of cerebral autoregulation was compared between patients with and without major postoperative morbidity or mortality (eg, stroke, renal failure, mechanical lung ventilation >48 hours, inotrope use >24 hours, or intraaortic balloon pump insertion). Eighty-three out of 450 experienced major morbidity or operative mortality, and the study demonstrated that the area under the curve below the limits of cerebral autoregulation was independently associated with major morbidity or operative mortality after cardiac surgery.[142] This is directionally similar to what had been previously reported by Murkin and coworkers in a prospective study of NIRS that demonstrated a similar association between cerebral desaturation and major morbidity or operative mortality.[143]

Cerebral Venous Obstruction

It should also be appreciated that during CPB, cerebral venous hypertension can result from partial obstruction of the superior vena cava (Fig. 40.5), particularly in the presence of a single two-stage venous cannula, and may cause cerebral edema and produce a disproportionate decline in cerebral perfusion pressure relative to arterial pressure.[144] In a study by Avraamides, surgical dislocation of the heart during CPB produced increases in proximal superior vena cava pressure and resulted in significant decreases in CBF velocity as measured with TCD,

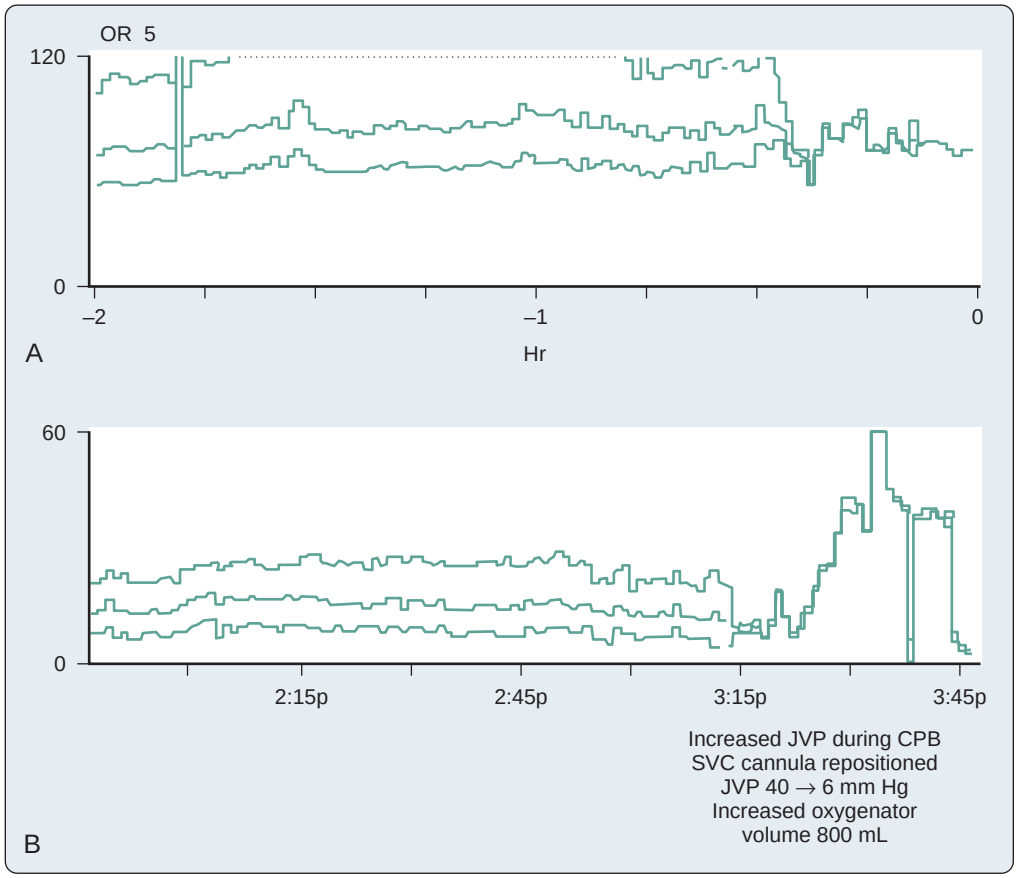

Fig. 40.5 (A) Systolic, mean, and diastolic arterial blood pressures, with commencement of cardiopulmonary bypass *(CPB)* indicated at 3:15 pm, after which mean arterial pressure (MAP) is shown. (B) Pulmonary artery systolic, mean, and diastolic pressures with proximal jugular venous pressure *(JVP)* recorded at 3:15 pm, with commencement of CPB. A single two-stage venous cannula was used for CPB. With rotation of the heart, venous return to the oxygenator decreased and JVP approached MAP values. *SVC,* Superior vena cava. *(Modified from Murkin JM. Intraoperative management. In: Estaphanous FG, Barash PG, Reves JG, eds.* Cardiac Anesthesia Principles and Clinical Practice. *Philadelphia: Lippincott; 1994:326.)*

despite stable arterial pressure and pump flow rates.[145] This strongly suggests that cerebral venous hypertension, as can occur during CPB with myocardial dislocation and impaired drainage of superior vena cava, may result in cerebral ischemia if unrecognized and untreated. It is feasible that such unrecognized cerebral venous hypertension has resulted in some of the postoperative neurologic syndromes that have been reported.[146]

In a study of 92 patients undergoing CABG, the effect of changes in jugular venous bulb pressure (JVBP) on plasma blood-brain barrier was detected by retrograde cannulation of jugular bulb to measure concentrations of plasma S-100β protein, matrix metalloproteinase 9, creatine kinase isoenzyme BB (CK-BB), and arteriovenous total and ionized magnesium as biomarkers of blood-brain barrier dysfunction. CPB increased JVBP, and that JVBP elevated above 12 mm Hg increased biomarkers of blood-brain barrier disruption.[147]

Although the association between arterial hypotension during CPB and cerebral dysfunction remains contentious, there is some evidence that certain subsets of patients may be at particular risk. Newman and associates used preoperative and postoperative cognitive testing to assess the effects of MAP and rate of rewarming on cognitive decline in 237 patients.[148] They demonstrated significant interactions between cognitive decline and MAP less than 50 mm Hg on one measure of cognitive performance and between rate of rewarming and age on another. They concluded that although MAP and rewarming were not primary determinants of cognitive decline, hypotension and rapid rewarming contributed significantly to cognitive dysfunction in older patients. Again, because older patients comprise an increasing segment of the population undergoing cardiac surgical procedures, these aspects are becoming increasingly important clinical management issues.

Hemodynamic Instability During Cardiopulmonary Bypass

Hemodynamic complications, either before, during, or after surgery, have been found to increase cerebral injury in cardiac surgical patients. In a study by Bucerius and colleagues, ejection fraction less than 30%, urgent operations, and preoperative cardiogenic shock were related to increased postoperative delirium.[15] Ridderstolpe and investigators found that hypotension and postoperative arrhythmias were related to cerebral complications, whereas Stanley and colleagues reported that POAF was related to increased cognitive decline.[22,149] Ganushchak and coworkers reported in a retrospective analysis of 1395 patients that the frequency of neurologic complications was 3.9% in the group of patients who experienced large fluctuations in hemodynamic parameters while on CPB, whereas in the group of patients with more stable values on CPB, the incidence rate of neurologic complications was 0.3%.[150] These studies indicate an increased susceptibility of the brain in cardiac surgical patients to apparently "benign" hemodynamic alterations that either produce or enhance cerebral injury, probably through hypoperfusion of the brain tissue. This is of particular importance since it has been estimated that more than 50% of CABG patients have coexisting cerebrovascular disease.[86,87]

The interaction of emboli, perfusion pressure, and the particular conditions of the regional cerebral circulation (eg, preexisting cerebral intravascular lesions) determine the final expression of brain damage in the cardiac surgical patient. In a retrospective study, Ganushchak and associates tested the hypothesis that combinations of hemodynamic events from apparently normal CPB procedures are related to the development of postoperative neurologic complications and affect the impact of common clinical risk factors.[150] A multivariate statistical procedure (cluster analysis) was applied to a data set of automatically recorded perfusions from 1395 patients who underwent CABG. The following five parameters emerged for cluster analysis: MAP, dispersion of MAP, dispersion of systemic vascular resistance, dispersion of arterial pulse pressure, and the maximum value of mixed venous saturation. Using these parameters, they found four clusters that were significantly different by CPB performance (first cluster, 389 patients; second cluster, 431 patients; third cluster and fourth cluster, 229 patients each). The researchers found that patients in cluster 4 represented procedures with high alterations of hemodynamic parameters during CPB, as compared to stable procedures in cluster 1. For example, the range of on-pump hemodynamic variables such as MAP, arterial pulse pressure, systemic vascular resistance, and rectal temperature was doubled in cluster 4 compared with cluster 1, indicating more hemodynamic instability. The frequency of postoperative neurologic complications was 0.3% in the first cluster and increased to 3.9% in the fourth cluster. Importantly, the impact of common clinical risk factors for postoperative neurologic complications was affected by the performance of the CPB procedure. For example, the frequency of neurologic complications among patients with cerebrovascular disease in their medical history was 22% in the fourth cluster, whereas it was zero in the second cluster. Patients with cerebrovascular disease who undergo CPB procedures with large fluctuations in hemodynamic parameters are at particularly increased risk for the development of postoperative neurologic complications.[150]

Aortic Atherosclerosis

Atheroembolism from an atheromatous ascending aorta and aortic arch is recognized as a major risk factor in the patient undergoing cardiac surgical procedures and is a widespread problem.[88,151–156] In a study of 298 asymptomatic members from the Framingham cohort aged 60 ± 9 years and of whom 51% were women, subjects underwent thoracoabdominal aortic cardiovascular MRI, which demonstrated aortic plaque of 1-mm radial thickness was present in 38% of the women and 41% of the men.[151] The Stroke Prevention: Assessment of Risk in the Community (SPARC) study used TEE in 581 people older than 44 years.[152] Atheroma was identified in 51.3% of patients, of whom 7.6% had severe atheroma (>4 mm thick, ulcerated or mobile). The prevalence rate of aortic arch atheroma increased with age, such that severe atheroma was seen in more than 20% of patients older than 74 years—a primary factor in the age-associated increase in risk of perioperative stroke.[88]

Atheroembolism in cardiac surgery has a broad spectrum of clinical presentations, including devastating injuries and death, yet its true incidence is probably underestimated.[77,94,157,158] Thoracic aorta atheromatosis is associated with coronary artery disease and stroke in the general population.[88,153–156] A review by Macleod and investigators concluded that the risk for stroke is four times greater in patients with severe arch atheroma.[154] Yahia and colleagues prospectively studied patients with diagnoses of TIA or stroke using TEE to assess aortic atheromatosis.[156] Thoracic aortic atheromas were present in 141 of 237 patients (59%); mild plaque (<2 mm) was present in 5%, moderate plaque (2–4 mm) in 21%, severe plaque (≥4 mm) in 33%, and complex plaque in 27%. Plaques were more frequently present in the descending aorta and the arch of the aorta than in the ascending aorta.[156] Watanabe and coworkers investigated whether thoracic aorta calcification on computed tomography and coronary risk factors had any correlation with obstructive coronary artery disease on angiography.[155] Two hundred twenty-five consecutive patients underwent both thoracic conventional helical computed tomography and coronary angiography. Thoracic aorta calcification was detected in 185 patients; 141 of 225 patients had significant obstructive coronary artery disease. All of the 13 patients without thoracic aorta calcification and no coronary risk factors had no coronary artery disease. In a recent small (N = 124) single-center study, the severity of TEE-diagnosed aortic atherosclerosis increased significantly between 2002 and 2009.[159] Significant atherosclerosis of the ascending aorta is present in 20% to 40% of cardiac surgical patients, the percentage increases with age (Fig. 40.6), and it is an independent risk factor for stroke (type I cerebral injury).[131,160–168]

Diabetes Mellitus and Hyperglycemia

The presence of diabetes is recognized as a factor related to increased morbidity and mortality in cardiac surgical patients.[169–173] The incidence

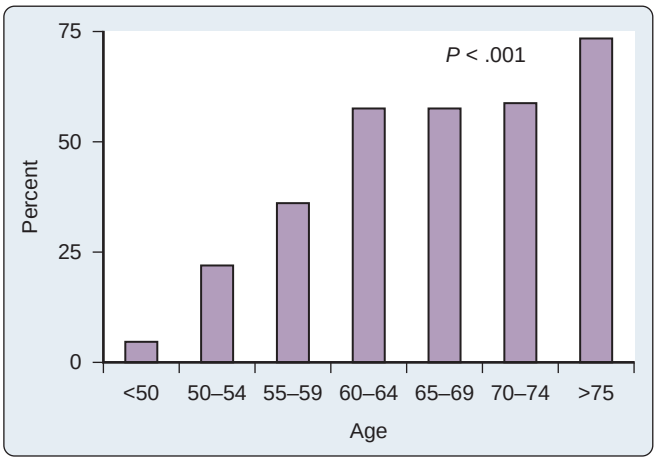

Fig. 40.6 Prevalence of severe atherosclerosis of the ascending aorta at autopsy after operations for coronary and valvular heart disease, 1982–1989. *(From Blauth CI, Cosgrove DM, Webb BW, et al. Atheroembolism from the ascending aorta. An emerging problem in cardiac surgery.* J Thorac Cardiovasc Surg. *1993;103:1104–1111.)*

of diabetes mellitus increases with age, and its presence is known to accelerate the damage caused by atherosclerosis; thus, an increasingly greater percentage of patients coming for CABG have concomitant diabetes, currently estimated as a comorbidity in approximately 30% to 40% of CABG patients. Bucerius and associates found diabetes to be associated with increased incidence of stroke and delirium and prolonged ICU and hospital stays.[174] Mortasawi and investigators[175] and Nussmeier[21] describe diabetes mellitus as associated with increased incidences of stroke and mortality. In a large study, McKhann and colleagues prospectively collected data on 2711 CABG patients and identified diabetes mellitus as an independent risk factor for both stroke and encephalopathy.[17] Part of the risk may involve cerebral hypoperfusion because increased extent and duration of cerebral oxygen desaturation during CPB has been documented in diabetic patients, with patients with insulin-dependent diabetes demonstrating the lowest values (as measured via jugular oximetry) and the poorest response to increases in MAP.[176]

Studies identify normoglycemia as a desirable perioperative goal in cardiac surgical patients regardless of whether they are diabetic.[170,172] Experimental and clinical evidence shows that hyperglycemia is associated with exacerbation of neurologic injury.[177] Approaches to maintain serum glucose values less than 150 mg/dL have shown favorable results. Furnary and coworkers reported on 3554 patients who underwent CABG from 1987 through 2001, demonstrating that the observed mortality in the group managed with tighter glucose values was lower and concluded that continuous intravenous insulin infusion added a protective effect against death.[171] Carvalho and associates used an aggressive approach to maintain serum glucose values between 80 and 110 mg/dL and reported that this is a safely attainable goal.[169] One study positively correlated average blood glucose on the first postoperative day with a variety of adverse outcomes (stroke, myocardial infarction, septic complication, or death). For each 1-mmol/L increase greater than 6.1 mmol/L (1 mmol = 18 mg/dL), risk increased by 17%.[178] The ideal value of serum glucose in cardiac surgical patients remains unknown, but the evidence available suggests that maintenance of euglycemia is related to a better prognosis.

In accordance with these data, STS guidelines for glucose control in patients undergoing cardiac surgery recommend that in both diabetic and nondiabetic patients, blood glucose levels should be maintained at less than or equal to 180 mg/dL with intravenous insulin as required.[179] However, there are concerns regarding potential adverse effects associated with hypoglycemia, including increased risk for mortality associated with even a single episode of severe hypoglycemia as seen in medical/surgical intensive care patients.[180] Furthermore, in a randomized, prospective study of 400 cardiac surgical patients managed either with tight glucose control (intravenous insulin to maintain intraoperative glucose between 80 and 100 mg/dL) or conventional management (glucose level < 200 mg/dL), a significantly greater incidence of stroke was found in the treatment group.[181] Hence, avoidance of hypoglycemia should be paramount. Accordingly, an important caveat recommending preservation of lower limit of glucose level greater than 100 mg/dL should be appended to the guidelines.[182] Overall, it would appear that maintenance of perioperative serum glucose between 100 and 180 mg/dL in both diabetic and nondiabetic patients is desirable.

Cerebral Blood Flow

In the mid-1960s, Wollman and investigators used changes in the arterial and jugular venous oxygen content differences ($A\text{-}Vd_{O_2}$) to estimate changes in CBF during alterations of MAP and arterial carbon dioxide tensions (Pa_{CO_2}) in patients undergoing CPB.[183] They observed a direct correlation between Pa_{CO_2} and $A\text{-}Vd_{O_2}$ (CBF), but no relation between $A\text{-}Vd_{O_2}$ and MAP. Although the concepts of alpha-stat and pH-stat pH management had not been formulated at that time, these authors recommended maintaining temperature-corrected Pa_{CO_2} between 30 and 40 mm Hg during hypothermic CPB (see Chapter 31).

In 1968, a Japanese investigator, using the recently developed technique of radioisotope clearance, measured CBF and CMR_{O_2} during CPB.[184] In a series of 40 patients, krypton-85 clearance, with concomitant cannulation of the superior jugular bulb, was used to measure CBF and calculate CMR_{O_2} during CPB. The influence of nonpulsatile CPB on the cerebral vasculature was also directly observed using retinal photomicrography. Although critical data such as esophageal temperatures and hematocrits were not reported, the observed 35% decrease in CBF with institution of CPB, 63% decrease in CMR_{O_2} during hypothermia, 23% decrease in CMR_{O_2} during rewarming, and retinal venous engorgement during rewarming are consistent with subsequent research findings. This report apparently also marked the first observations in humans of retinal microembolism occurring during CPB, consistent with but markedly preceding the reports of Blauth and colleagues.[75]

Few subsequent radioisotope CBF studies during CPB in humans were reported for the next 15 years. Other investigators used indirect estimates of CBF (eg, $A\text{-}Vd_{O_2}$, TCD CBF velocities, or thermodilution techniques) to estimate CBF.[185]

pH Management and Cerebral Blood Flow

Relatively little new information regarding the cerebral circulation in human beings during CPB appeared until 1983, when Henriksen and colleagues reported evidence of cerebral hyperemia occurring during CPB.[186] This report was followed in 1984 by a seminal paper from Govier and coworkers, who not only incited controversy with their observations of ischemic threshold levels of CBF during CPB, in direct contrast with the hyperperfusion reported by Henriksen, but also made preliminary observations on many of the other critical variables thought to influence CBF during CPB.[140]

Without the measurement of concomitant cerebral metabolism, these apparently discordant observations of CBF could not be reconciled. Murkin and coworkers subsequently reported their observations of both CBF and CMR_{O_2} during hypothermic CPB in humans, using a xenon-133 clearance technique for measurement of CBF, similar to techniques used by Kubota, Govier and coworkers, and Henriksen and colleagues, but with the addition of a jugular bulb catheter for sampling effluent cerebral venous blood for measurement of cerebral metabolic activity.[138] It was hypothesized that differences in pH management accounted for the divergent values previously reported for CBF during hypothermic CPB. Accordingly, patients were managed with either alpha-stat or pH-stat pH management during hypothermic CPB. A similar and pronounced reduction in CMR_{O_2} was observed in both groups during hypothermia (Fig. 40.7), and in the alpha-stat group,

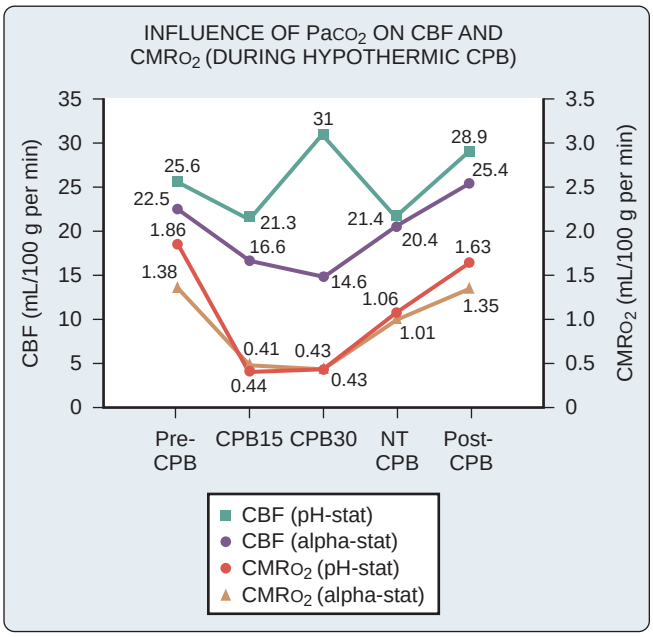

Fig. 40.7 Cerebral blood flow *(CBF)* and cerebral metabolic rate for oxygen *($CMRO_2$)* in the alpha-stat (non–temperature-corrected) and pH-stat (temperature-corrected) groups. Note the convergence of $CMRO_2$ and divergence of CBF between groups during the hypothermic phase of cardiopulmonary bypass *(CPB). (From Murkin JM. Cerebral hyperperfusion during cardiopulmonary bypass: the influence of $PaCO_2$. In: Hilberman M, ed.* Brain Injury and Protection During Heart Surgery. *Boston: Martinus Nijhoff; 1988:57.)*

global cerebral flow/metabolism coupling was preserved in comparison with the group managed with pH-stat (Fig. 40.8). Decreases in CBF and $CMRO_2$, significantly lower than similar measures before and after CPB, were still evident after rewarming during normothermic nonpulsatile CPB. These low values for CBF and $CMRO_2$ were restored to control levels shortly after separation from CPB. Alpha-stat management preserved autoregulation and the relation between CBF and metabolism and has become the standard of care for adult patients undergoing CPB with mild and moderate hypothermia.[138]

Cerebral Hyperthermia

Cerebral hyperthermia during the rewarming phase of CPB can exacerbate a preexisting injury before rewarming and may be detrimental itself. Hyperthermia can have a strong impact on cerebral oxygen transfer and neurologic outcome. Glutamate levels can increase during cerebral hyperthermia, leading to eventual cell death. Rapid rewarming decreases jugular venous hemoglobin saturation, creating a mismatch between cerebral oxygen consumption and delivery.[187,188] Okano and associates assessed the effects of normothermia and mild hypothermia (32°C) during CPB on jugular venous oxygen saturation ($SjvO_2$) in 20 patients scheduled for elective CABG.[189] The $SjvO_2$ in the normothermic group was decreased significantly at 20 and 40 minutes after the onset of CPB compared with pre-CPB, whereas there was no change in $SjvO_2$ in the mild hypothermic group during the study. The investigators concluded that cerebral oxygenation, as assessed by $SjvO_2$, was increased during mild hypothermic CPB compared with normothermic CPB. Kawahara and colleagues examined the effect of rewarming rates on $SjvO_2$ in 100 patients scheduled for elective CABG and randomly divided into two groups: a control group and a slow rewarming group.[187] Cerebral desaturation (defined as an $SjvO_2$ value < 50%) during rewarming was more frequent in the control group than in the slow group. The ratio of the cerebral desaturation time to the total CPB time in the control group differed significantly from those in the slow group (control group: 17 ± 11 minutes, 12% ± 4%; slow group: 10 ± 8 minutes, 7% ± 4%, respectively; $P < .05$).[187] Consistent with this, in a study of the impact of rate of rewarming on cognitive outcomes in 165 CABG patients randomized to two differing rewarming strategies, Grigore and colleagues demonstrated a significant association between change in cognitive function and rate of rewarming.[66]

Grocott and colleagues recorded hourly postoperative temperatures in 300 patients undergoing CABG on CPB and determined the degree of postoperative hyperthermia using peak temperature within 24 hours, as well as area under the curve for temperatures higher than 37°C.[190] Patients underwent a battery of cognitive testing both before surgery and 6 weeks after surgery. The maximum temperature within 24 hours after CABG ranged from 37.2°C to 39.3°C. Findings showed that the maximum postoperative temperature was independently associated with cognitive dysfunction at 6 weeks.[190] Accordingly, slower rewarming rate with lower peak temperatures during CPB may be an important factor in the prevention of neurocognitive decline after hypothermic CPB, and interventions to avoid postoperative hyperthermia may be warranted to improve cerebral outcome after cardiac surgery.

Cardiopulmonary Bypass Equipment

Early studies demonstrated increased microemboli in patients undergoing CPB using bubble oxygenators, with a reduction in cerebral embolization with the use of membrane oxygenators and arterial line filtration (Box 40.4).[75,76,191–193] Using intraoperative fluorescein retinal angiography, Blauth and coworkers reported retinal microembolizations occurring during CPB with much greater frequency in patients in whom bubble versus membrane oxygenators were used.[76] Using TCD for detection of cerebral emboli, Padayachee and associates demonstrated continuous generation of cerebral emboli in all patients managed using bubble oxygenators and none in patients in whom a membrane oxygenator was used.[192] They also demonstrated the efficacy of arterial line filtration to significantly decrease cerebral embolic load.[193] It is apparent that emboli may be generated continuously during CPB and that equipment modification (eg, arterial line microfiltration and preferential usage of membrane oxygenators) can decrease the generation of such emboli.[194] Membrane oxygenators are currently recommended for CPB[80] (see Chapters 31 and 32).

It is equally evident that equipment modifications, although decreasing the embolic load, cannot completely eliminate it.[192,195] Georgiadis and investigators used Doppler ultrasound and evaluated the percentage of microembolic signal (MES) reduction caused by the arterial filter and the proportion of MESs actually reaching the brain by comparing the MES counts detected before the arterial filter, after the arterial filter, and in both middle cerebral arteries.[196] Eleven patients underwent surgery using normothermic CPB, alpha-stat, a membrane oxygenator, and a 40-μm arterial filter. Evaluation of MESs was only performed during extracorporeal circulation, was initiated after cannulation and clamping of the ascending aorta, and was terminated shortly before the aortic clamp was removed. The arterial filter resulted in a 58.9% reduction of MESs, with only 4.4% (2624/59,132) of the MESs detected after the arterial filter. The proportion of MESs detected in the middle cerebral artery corresponded to the total cerebral perfusion under CPB, estimated as 5% to 10% of the total perfusion volume.[196]

Schoenburg and colleagues used a dynamic bubble trap, incorporated in the arterial line after a 40-μm filter, to reduce the number of gaseous microemboli in 50 patients undergoing CABG.[197] In 26 patients, a dynamic bubble trap was placed between the arterial filter and the aortic cannula (group 1), and in 24 patients, a placebo dynamic bubble trap was used (group 2) with TCD continuously measured on both sides during bypass, which was separated into four periods: phase 1, start of bypass until aortic clamping; phase 2, aortic clamping until rewarming; phase 3, rewarming until clamp removal; and phase 4, clamp removal until end of bypass. The bubble elimination rate during bypass was 77% in group 1 and 28% in group 2. The number of TCD-detected high-intensity signals was lower in group 1

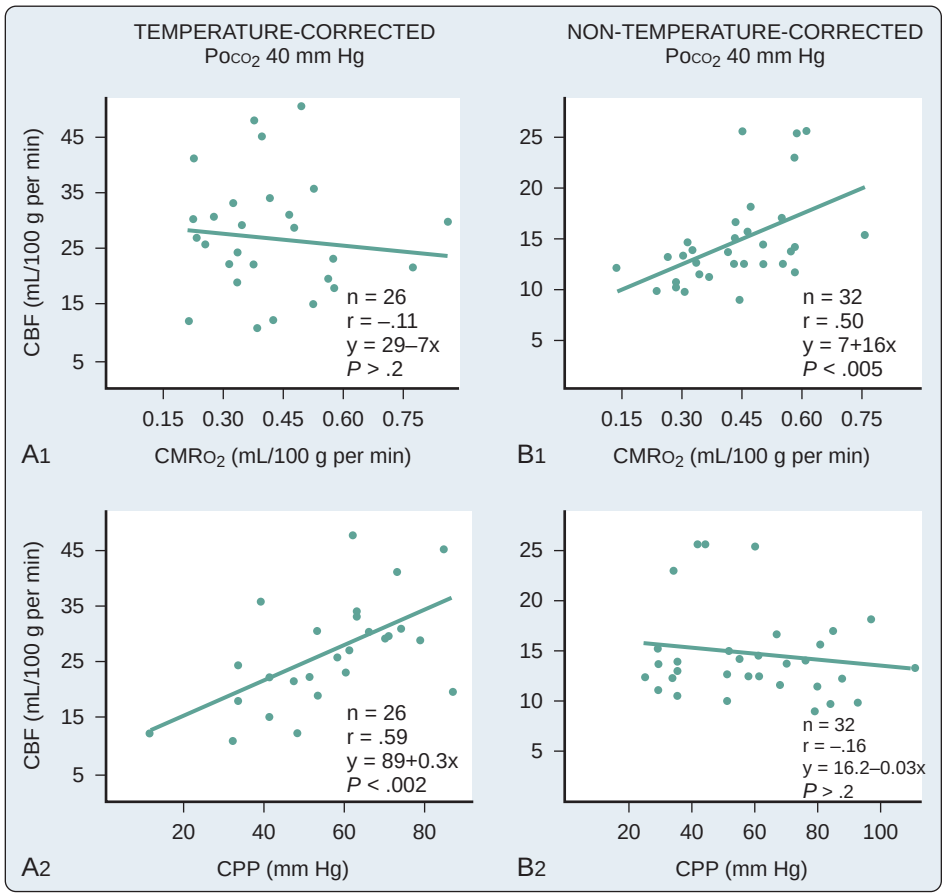

Fig. 40.8 Simple linear regression of cerebral blood flow *(CBF)* versus cerebral perfusion pressure or cerebral oxygen consumption for temperature-corrected and non–temperature-corrected groups. There is no significant correlation between CBF and cerebral metabolic rate for oxygen *($CMRO_2$)* in the temperature-corrected group *(A1)*, whereas CBF significantly correlates with $CMRO_2$ in the non–temperature-corrected group *(B1)*. CBF is significantly correlated with cerebral perfusion pressure *(CPP)* in the temperature-corrected group *(A2)*, whereas CBF is independent of CPP in the non–temperature-corrected group *(B2)*. *(From Murkin JM, Farrar JK, Tweed A, et al. Cerebral autoregulation and flow/metabolism coupling during cardiopulmonary bypass: the influence of $PaCO_2$. Anesth Analg. 1987;66:825–832.)*

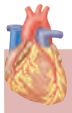

BOX 40.4 CLINICAL STRATEGIES THAT MAY DECREASE NEUROLOGIC COMPLICATIONS IN CARDIAC SURGERY

- Early and aggressive control of hemodynamic instability
- Perioperative euglycemia between 100 and 180 mg/dL
- Routine epiaortic scanning before manipulation of ascending aorta
- Avoidance of manipulation of ascending aorta in severe atheromatosis
- Maintenance of adequate cerebral perfusion pressure (neuromonitoring/cerebral oximetry)
- Monitoring of cerebral venous pressure via a proximal central venous pressure catheter or the introducer port of a pulmonary artery catheter
- Alpha-stat pH management during moderate hypothermic cardiopulmonary bypass (CPB)
- Avoidance of arterial inflow temperature greater than 37°C
- Use of CPB circuitry incorporating membrane oxygenator and 40-μm arterial line filter
- Use of surface-modified and reduced-area CPB circuitry
- Use of cerebral oximetry

during phase 1 (5.8 ± 7.3 vs 16 ± 15.4; $P < .05$ vs group 2) and phase 2 (6.9 ± 7.3 vs 24.2 ± 27.3; $P < .05$ vs group 2) but not during phases 3 and 4. The researchers determined that the dynamic bubble trap can remove gaseous microemboli.[197] Unfortunately, no psychometric studies were performed on either group of patients, but future research in this area might yield positive influence on neurologic outcome by decreasing gas microemboli. Other investigators have demonstrated that air within the venous line of the CPB circuit, resulting from air entrainment at the venous cannulation site, injection of drugs into the venous line, or use of cardiotomy suction can pass through the oxygenator and appear as microemboli within the arterial line, even in the presence of a venous line defoamer and with use of a membrane oxygenator. Georgiadis and coworkers used tubing systems that included an arterial line 40-μm filter.[196] They demonstrated that the arterial filter resulted in a 58.9% reduction of microemboli signals with only 4.4% of the MESs detected after the arterial filter was detected in the middle cerebral artery.

Modification of the inflammatory response to the CPB using modified surface CPB circuits and leukocyte-depleting filters has also been explored. Hamada and associates examined the combined use of heparin coating of the CPB circuit and a leukocyte-depleting arterial line filter.[198] Thirty patients were randomly allocated to equal groups with a conventional circuit and arterial line filter, a heparin-coated

circuit with a conventional filter, or a heparin-coated circuit with a leukocyte-depleting arterial line filter. Plasma IL-6 and IL-8 concentrations in the heparin bonded with leukocyte-depleting filter group were lower than in the conventional circuit group. Although a decrease in inflammatory mediator release has been observed by using leukocyte-depleting filters, the impact of these types of filters on neurologic outcome is less clear. In a meta-analysis of 28 relevant clinical studies, Whitaker and investigators concluded that conventional arterial line filtration had a definite effect in reducing post-CPB neuropsychological deficit.[199] The results of studies using the leucocyte-depleting filter were less clear-cut.

In an attempt to decrease emboli originating from the surgical field, cell savers have been used for processing cardiotomy suction blood before returning it to the CPB circuit. Jewell and colleagues reported on 20 patients prospectively randomized to either cell saver or cardiotomy suction.[200] They found that compared with cardiotomy suction, cell saver removed significantly more fat from shed blood, such that the percentage reduction in fat weight achieved by cell saver or cardiotomy suction was 87% compared with 45%. De Vries and coworkers published a study on patients randomly assigned to have a fat removal filter for the cardiotomy suction.[201] The fat filter removed 40% more fat, leukocytes, and platelets from cardiotomy suction blood during cardiac surgery compared with the control group without the filter.

In addition, various intraoperative manipulations, particularly instrumentation of the atherosclerotic aorta, are independent risks for the generation of cerebral emboli and likely produce particulate and microparticulate emboli, rather than oxygenator-generated microgaseous and microaggregate emboli.[94,160,202,203] Avoidance of manipulation of a diseased aorta seems to decrease embolization and cerebral injury.[71,204,205] An alternative approach, emboli reduction by capture using an intraaortic filter inserted through a side chamber of a modified aortic cannula, has also been assessed (Fig. 40.9).[109]

In a nonrandomized study, Schmitz and associates examined the impact of intraaortic filtration during CPB.[206] Patients undergoing cardiac surgical procedures ($n = 304$) had intraaortic filtration using a 150-μm net deployed through the aortic cannula, whereas a further 278 patients formed the control group. Patients in the filter group experienced a lower incidence of adverse neurologic outcomes than patients in the control group (4.3% vs 11.9%), with significantly fewer TIAs (0% vs 1.4%), less delirium (3.0% vs 6.5%), and less memory deficit (1.3% vs 6.2%). There were also fewer strokes in the filter group compared with the control group (0.7% vs 2.2%). Although the sample size was relatively small and the patients were not randomly assigned, the study findings suggest a protective effect of intraaortic filters on CNS injury.[206] In a large, multiinstitutional, prospective, randomized trial of 1289 patients in whom intraaortic filtration or conventional CPB cannula was used, emboli were identified in 598 (96.8%) of 618 filters successfully deployed, and their post hoc analysis indicated a reduction in postoperative renal complications.[207] In other studies, intraaortic emboli trapping devices have been used with varied results.[196,204] In a small study by Eifert and investigators in 24 patients, the use of the intraaortic filter device did not show any difference in neurologic, neuroradiographic, or neuropsychological outcomes, yet the intraaortic filter was effective in capturing particulate material.[195] Similar efficacy in capturing intraoperative material using intraaortic filters during CPB was reported by Reichenspurner and colleagues.[208] It appears as though intraaortic filters can be safely deployed and that they capture particulate emboli, the predominant origin of which is atheromatous.

In a recent study of 150 CABG patients randomized to either intraaortic filtration, dynamic bubble trap, or conventional management, no difference was found in the overall incidence of postoperative MRI-detected small ischemic brain lesions (17/143) between groups, whereas dynamic bubble trap was associated with significantly fewer TCD-detected cerebral emboli and improved cognitive performance at 3 months after surgery in comparison with control and intraaortic filtration groups.[209]

Minimally Invasive Extracorporeal Circulation

A recent development in the drive for more physiologic CPB has been the advent of minimally invasive extracorporeal circulation (MiECC).[210] This system consists of a modular biocompatible closed circuit of minimal priming volume, incorporating a centrifugal pump and membrane oxygenator, and has been shown to result in significantly decreased inflammatory markers.[211] A metaanalysis of 24 studies involving 2770 patients showed an association with a significant decrease in mortality (0.5% vs 1.7%; $P = .02$), postoperative myocardial infarction (1.0% vs 3.8%; $P = .03$), and neurologic events (2.3% vs 4.0%; $P = .08$).[212] Again, MiECC was also associated with reduced systemic inflammatory response as measured by polymorphonuclear elastase, hemodilution as calculated by hematocrit drop after procedure, need for red blood cell transfusion, reduced levels of peak troponin release, incidence of low cardiac output syndrome, need for inotropic support, peak creatinine level, occurrence of POAF, duration of mechanical ventilation, and ICU stay.[212]

Because the technique of modular MiECC (Fig. 40.10) has been employed for combined CABG and valve surgery,[213] as well as in high-risk patients,[214] and shown to result in less cerebral microembolization and improved cerebral tissue oxygenation,[215] as well as improved neurocognitive outcomes,[216] there is significant potential that such an approach to CPB may well become the standard of care in the near future.[217]

Cerebroprotective Strategies

Risk Assessment

Using a risk-stratification analysis of the same database as Roach and colleagues, Newman and colleagues developed a preoperative index predicting major perioperative neurologic events of which key predictors were age, history of neurologic disease, diabetes, previous CABG, unstable angina, and history of pulmonary disease (Fig. 40.11).[6,218] The Stroke Risk Index allows neurologic risk to be estimated for each patient, thus enabling the most appropriate perioperative therapy to be used, whether surgical modification, change in perfusion management, applied neuromonitoring, or administration of putative pharmacologic cerebroprotectants. It is also useful as a scale to compare risk

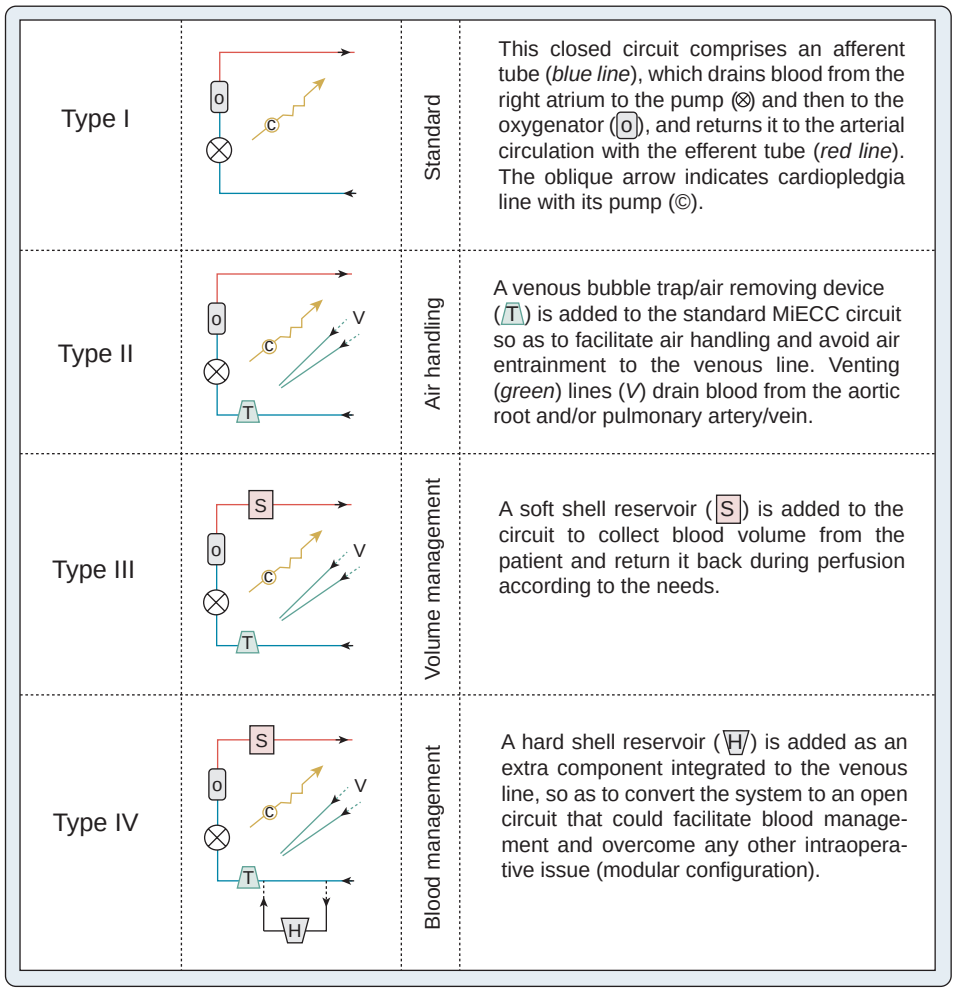

Fig. 40.10 Classification of minimally invasive extracorporeal circulation *(MiECC)* circuits. The modular type IV circuit is literally type III with a standing-by component, used only when necessary. *(From Anastasiadis K, Antonitsis P, Argiriadou H, et al. Modular minimally invasive extracorporeal circulation systems; can they become the standard practice for performing cardiac surgery?* Perfusion *2015;30:195–200.)*

indices and thus the efficacy of different interventions across clinical outcome studies.[12,162]

In a recent analysis of the incidence of the rate and predictors of long-term stroke and death up to 2 years postoperatively in a cohort of 108,711 patients who underwent cardiac surgery, 1.8% had a stroke perioperatively, and 3.6% had a stroke within the ensuing 2 years.[219] The strongest predictors of both early and late stroke were advanced age (65 years or older), combined CABG and valve surgery, a history of stroke or TIA, and peripheral vascular disease–again likely markers of aortic atherosclerosis, and valve surgery alone, whereas preoperative need for dialysis and again, new-onset POAF, were predictors of only early stroke. A CHADS2 (C, congestive heart failure; H, hypertension > 140/90; A, age >75; D, diabetes mellitus; S, prior stroke or TIA) score of 2 or higher was associated with an increased risk of stroke or death compared with a score of 0 or 1 (19.9% v. 9.3%) among patients with a history of atrial fibrillation, 16.8% versus 7.8% among those with new-onset POAF, and 14.8% versus 5.8% among those without this condition. Among other factors, this study again highlights both the acute and long-term stroke risk associated with perioperative atrial fibrillation.[219]

Reporting a negative multicenter study assessing acadesine (adenosine regulating agent) for efficacy in decreasing death, stroke, or need for mechanical cardiovascular support in 3080 patients undergoing CABG, four independent preoperative risk factors were predictive of the composite end point of major morbidity or operative mortality; these risk factors are a history of heart failure, increasing age, peripheral vascular disease, and receiving aspirin before CABG (which was protective).[220] Of note, the duration of CPB was the only intraoperative variable that contributed to adverse outcomes and suggests once again that there are intraoperative factors that contribute to adverse outcomes and may be remediable.

The role of perioperative inflammation and the importance of intraoperative hemodynamic factors was further highlighted in a retrospective study of 1046 patients who underwent OPCAB and in whom postoperative C-reactive protein elevation was shown to be associated with long-term postoperative major adverse cardiac and stroke events (which was mitigated by postoperative statin medication) and in which postoperative C-reactive protein elevation was associated with intraoperative parameters, reflecting hypoperfusion and inflammation.[221] As discussed later, this study suggests that statins may have a salutary effect on stroke incidence as well as further indicating that hemodynamic instability is associated with a heightened inflammatory response and greater stroke risk.

Carotid Endarterectomy

In the current cardiac surgical population, 17% to 22% of patients have a moderate carotid artery stenosis of 50% or more, and 6% to

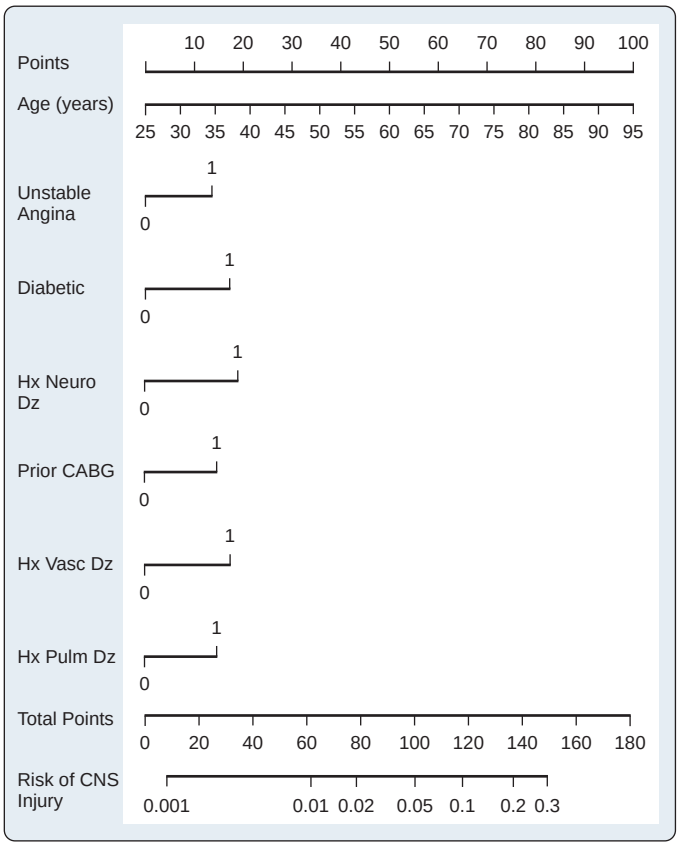

Fig. 40.11 Nomogram for computing risk of central nervous system *(CNS)* injury. Neurologic risk is determined by assigning points for age and positive history of the predictors listed. Total points for each variable are read from the points line at the top of the nomogram. After the total points for an individual patient are computed, the risk for CNS injury can be determined by plotting the total points received against the risk score at the bottom of the nomogram. For example, 100 total points predict a risk for CNS injury of 5%. *CABG,* Coronary artery bypass graft; *Hx Neuro Dz,* history of symptomatic neurologic disease; *Hx Pulm Dz,* history of emphysema, chronic bronchitis, asthma, or restrictive lung disease; *Hx Vasc Dz,* history of atherosclerotic vascular disease or previous vascular surgery. *(From Newman MF, Wolman R, Kanchuger M, et al. Multicenter preoperative stroke risk index for patients undergoing coronary artery bypass graft surgery. Multicenter Study of Perioperative Ischemia [McSPI] Research Group.* Circulation. *1996;94[Suppl 9]:II74–II80.)*

12% have a severe stenosis of 80% or more.[12] The risk for postoperative stroke is 10% in patients with moderate and 11% to 19% in patients with severe stenosis, whereas it remains 2% or less in patients with a stenosis of less than 50%. Although in patients presenting for cardiac surgery, severe bilateral carotid artery disease is rare, the risk for perioperative stroke is as high as 20%.[12,222–224] However, it is not clear that carotid endarterectomy decreases this rate, because in a meta-analysis, pooled data for stroke or death did not support carotid endarterectomy for risk reduction from asymptomatic carotid stenosis during CABG (relative risk, 0.9; $P = .5$).[225] In a review, it was estimated that only about 40% of perioperative strokes (at most) could be directly attributable to ipsilateral carotid artery disease.[226] Accordingly, in a patient with asymptomatic carotid stenosis, combined surgery should not be undertaken unless the surgical team is very experienced in combined carotid endarterectomy/CABG procedures. Concomitant carotid endarterectomy is unlikely to decrease a patient's stroke risk. Rather, carotid stenosis should be regarded as indicating a high likelihood of aortic and/or concomitant intracerebral disease, and that use of EAS with appropriate modification of surgical approach and applied neuromonitoring can be of particular benefit in this high-risk group.

Transesophageal Echocardiography Versus Epiaortic Scanning

The detection of ascending aorta atheromatosis is a cornerstone of strategies to decrease the incidence of stroke during and after cardiac surgical procedures. Manual palpation of the aorta, despite its widespread utilization, has a very low sensitivity for this purpose.[71,227] The association between severe thoracic aortic plaques (defined as 5-mm-thick focal hyperechogenic zones of the aortic intima and/or lumen irregularities with mobile structures or ulcerations) and coronary artery disease is well established.[166] Identifying severe aortic disease has important clinical implications because surgical technique, including surgical procedure and siting of cannulation and anastomotic sites for proximal grafts, can be altered to avoid producing emboli and stroke. Intraoperative EAS is a helpful tool for the diagnosis of ascending aortic atherosclerosis and has revealed major insights into the nature and distribution of this disease.

Djaiani and coworkers performed TEE and EAS to assess the severity of aortic atherosclerosis in the ascending aorta and the aortic arch.[161] Patients were allocated to either low- or high-risk groups according to aorta intimal thickness. TCD was used to monitor the middle cerebral artery. Diffusion-weighted MRI was performed 3 to 7 days after surgery. The NEECHAM Confusion Scale was used to assess cognitive function and monitor patient consciousness level. In the high-risk group (intimal thickness > 2 mm), confusion was present in six (16%) patients versus five (7%) patients in the low-risk group, and there was a threefold increase in median embolic count (223.5 vs 70.0). Diffusion-weighted MRI–detected brain lesions were present only in patients from the high-risk group (61.5% vs 0%). There was significant correlation between the NEECHAM scores and embolic count in the high-risk group.[167] Multiple studies have documented that most of the significant atherosclerotic lesions in the ascending aorta are missed by intraoperative palpation by the surgeon, and intraoperative echocardiographic studies of the aorta have been recommended (Fig. 40.12).[13,71,161,164,168,195,227–230] However, the ability of TEE to reliably detect ascending aorta and aortic arch lesions is limited.

The high acoustic reflectance attributable to the air-tissue interface resulting from overlying right main bronchus and trachea limits TEE assessment of the upper ascending aorta, where cannulation is generally undertaken.[71,204,227,229] Intraoperative EAS is a helpful tool for the diagnosis of ascending aortic atherosclerosis and has revealed major insights into the nature and distribution of this disease. Konstadt and associates investigated 81 patients (57 male and 24 female, aged 32–88 years; mean age, 64 years) scheduled for elective cardiac surgical procedures.[204,230] A comprehensive examination of the entire thoracic aorta in both the longitudinal and transverse planes was performed with the aid of biplane TEE. In both echocardiographic examinations, the presence and location of protruding plaques and intimal thickening greater than 3 mm were recorded. Fourteen (17%) of the 81 patients had significant atherosclerotic disease of the ascending aorta as diagnosed by EAS echocardiography. The sensitivity of TEE was 100%, the specificity was 60%, the positive predictive value was 34%, and the negative predictive value was 100%. According to the examiners, if the complete biplane TEE examination is negative for plaque, it is highly unlikely that there is significant plaque in the ascending aorta. If the TEE examination is positive for plaque, there is a 34% chance that there is significant disease of the ascending aorta, and EAS should be considered. TEE is a sensitive but only mildly specific method of determining whether ascending aortic atherosclerosis is present.[195,204,228–230]

The standard for aortic assessment before instrumentation continues to be visual inspection and palpation by the surgeon, despite the fact that this has been shown to identify atheromatous disease in only 25% to 50% of patients and, even when identified, to significantly underestimate its severity.[71,84,227,231,232] Identification of ascending aorta atheromatous disease would prompt the surgical team for strategies to modify, decrease, or avoid aortic manipulation. Management strategies for the diseased ascending aorta range from minimally invasive aortic "no-touch" techniques (NTTs) to maximally invasive procedures,

including ascending aorta replacement or extensive aortic debridement under deep hypothermic circulatory arrest (HCA).[233] Royce and colleagues outlined specific techniques for EAS, as well as steps to be used by the surgical team to mitigate aortic atheroemboli.[234] Operative modifications in CABG include avoidance of aortic cross-clamping, alternative sites of aortic cross-clamping, and avoidance of proximal anastomoses by usage of all arterial conduit or Y-grafts. A decreased incidence of stroke and CNS dysfunction has been associated with this approach (Fig. 40.13).[235]

In a large retrospective cohort of 2292 patients who underwent isolated OPCAB, patients were subdivided into two groups: the non-EAS group (n = 1019), who underwent OPCAB under only intraoperative TEE, and the EAS group (n = 1273), who underwent OPCAB under EAS and demonstrated an incidence of early stroke trending to favor EAS versus non-EAS groups (0.8% [10/1273] vs non-EAS 1.7% [17/1019]; P = .052) for which in the subgroups of patients with partial aorta clamping, the incidence of the early stroke was significantly lower in the EAS group (2.8% [9/317] vs 0.7% [2/301]; P = .041).[236] This study is again compelling evidence that a primary factor in early postoperative stroke is instrumentation of an atherosclerotic aorta, even during OPCAB,[237]and whether due to direct plaque fracture or secondary embolization due to intimal disruption,[109] this again underscores the necessity for EAS and/or NTTs to avoid what is a potentially remedial but otherwise devastating perioperative complication.

"No-Touch" Technique

Avoidance of instrumentation of the ascending aorta in patients with severe aortic atheromatosis has been advocated. Leacche and colleagues retrospectively reviewed data from 640 OPCAB patients and identified 84 patients in whom they adopted an NTT.[163] In these patients, revascularization was performed with single or bilateral internal thoracic arteries and by connecting additional coronary grafts (saphenous vein, radial artery) in a T or Y configuration. In the NTT group, the frequencies were greater for severe atherosclerosis of the aorta (13% vs 0%), carotid disease (25% vs 16%), and history of previous cerebrovascular accidents (17% vs 8%). In the NTT group, weak trends toward a lower incidence of postoperative delirium (8% vs 15%; P = .12), a lower incidence rate of stroke (0% vs 1%; P = .85), and a shorter ICU stay (P = .07) were observed.[163] In a review of 1993 beating-heart surgery patients, Calafiore and colleagues[104] observed that in patients with evidence of peripheral vascular disease, use of aortic partial occlusion clamp was associated with a similar stroke rate as in patients in whom conventional CPB was used.[237] They concluded that in patients with extracoronary vasculopathy, aortic manipulation must be avoided to reduce the incidence of stroke. Gaspar and coworkers used EAS and TEE in 22 patients considered to be at high risk for stroke in whom severe aortic atheroma (maximum aortic wall thickness > 5 mm or mobile plaque) was detected, and with the use of aortic NTT and beating-heart surgery, no strokes occurred.[229]

Royse and colleagues performed screening of the aorta for atheroma before aortic manipulation and used an exclusive Y-graft revascularization technique, which involves no aortic coronary anastomoses.[71] Aortic atheroma was detected using EAS and TEE. In the control group, aortic atheroma was assessed by manual palpation, whereas TCD of the right middle cerebral artery was used to detect cerebral microemboli. Neuropsychological dysfunction was assessed using a battery of 10 psychometric tests, and they demonstrated that at 60 days after surgery, dysfunction in the control group was 38.1%, whereas in the TEE/Y-graft group, it was reduced to 3.8%. Microemboli detected by TCD during periods of aortic manipulation were greater for those with late dysfunction (5.2 ± 3.0 compared with 0.5 ± 0.2), suggesting an embolic cause for cognitive dysfunction.[71]

Powerful evidence implicating aortic instrumentation comes from a 12,079-patient study of isolated coronary artery bypass surgery in which aortic manipulation was completely avoided by using in situ internal thoracic arteries for inflow in 1552 patients (no-touch), a clampless facilitating device for proximal anastomoses in 1548 patients, and aortic clamping in 8979 patients.[238] The study demonstrated an overall incidence of postoperative stroke of 1.4% (n = 165), with an

unadjusted incidence of 0.6% ($n = 10$) in the no-touch group, 1.2% ($n = 18$) in the clampless facilitating device group, and 1.5% ($n = 137$) in the clamp group ($P < .01$ for no-touch vs clamp). The ratio of observed to expected stroke rate increased as the degree of aortic manipulation increased from 0.48 in the no-touch group, to 0.61 in the clampless facilitating device group, and to 0.95 in the clamp group, demonstrating that aortic clamping was independently associated with an increase in postoperative stroke compared with a no-touch technique. Even after correcting for use of CPB, aortic clamping was an independent risk factor for postoperative stroke, since both the OPCAB partial clamp and the on-pump cross-clamp techniques increased the risk of postoperative stroke compared to no-touch.[238]

CO_2 Insufflation During Open-Chamber Procedures

A primary determinant of the number and duration of microgaseous emboli during open-chamber procedures relates to methodologies for removal of intracavitary air. Although needle aspiration and/or aortic root venting are standard techniques for air removal, use of CO_2 insufflation, either continuously or immediately before closure of ventriculotomy, has been shown to significantly increase the efficacy of de-airing, resulting in decreased systemic gaseous emboli.[85,239] However, although there has been a general expectation of improvements in neurologic and cognitive outcomes resulting from such CO_2 insufflation, it has been surprisingly difficult to demonstrate. In a recent prospective study of 80 patients undergoing valve surgery and randomized to CO_2 insufflation versus conventional de-airing, although postoperative auditory-evoked potential monitoring demonstrated shorter P-300 latency in the CO_2-insufflated group, there was no detectable difference in clinical outcomes or in the incidence of cognitive dysfunction between groups.[240] In a recent review on the role of CO_2 insufflation, the reviewers concluded that although the use of CO_2 field flooding has been observed to be associated with a significantly lower count of intracardiac air bubbles and improved survival in two small studies, so far there is no evidence of a sustained reduction of cerebrovascular complications.[241]

Temperature and Coronary Artery Bypass Grafting

How much does cerebral hyperthermia superimposed on a brain suffused with focal ischemic lesions contribute to postoperative CNS dysfunction? It is known that the vulnerability of the normothermic brain to focal ischemic insult demonstrates a surprising variability in the presence of small gradations in temperature. Busto and associates demonstrated that at 33°C, expression of cerebral ischemia was virtually eliminated compared with controls maintained at 36°C.[242] In fact, a large measure of the apparent cerebroprotective efficacy of the glutamate-receptor antagonist MK-801 in global ischemia was demonstrated by Buchan and Pulsinelli to be mediated by just such a small secondary decrease in brain temperature.[243] Conversely, small increases in brain temperature, such as to 39°C increments as may occur during CABG (Fig. 40.14), have been shown to profoundly enhance the susceptibility of the brain to focal ischemic insult and result in ischemic lesions of much greater extent in comparison with controls at 37°C.[244]

Normothermic Cardiopulmonary Bypass

The demonstration of apparently improved myocardial performance and shorter CPB and operating room times after normothermic CPB has prompted several outcome studies to assess the efficacy of this therapy, with particular focus now centered on CNS outcomes. Hypothermia reduces cerebral metabolic rate; thus, mild hypothermia might protect the brain by preferentially suppressing energy utilization to maintain cellular integrity.[245] In support of this are results from a subset of 138 patients randomized to normothermic or hypothermic CPB, in whom a detailed prospective neurologic examination and a series of cognitive tests were performed before surgery, at postoperative days 1 to 3 and 7 to 10, and again at 1 month after surgery.[246] Seven of 68 patients in the normothermic group were found to have a central

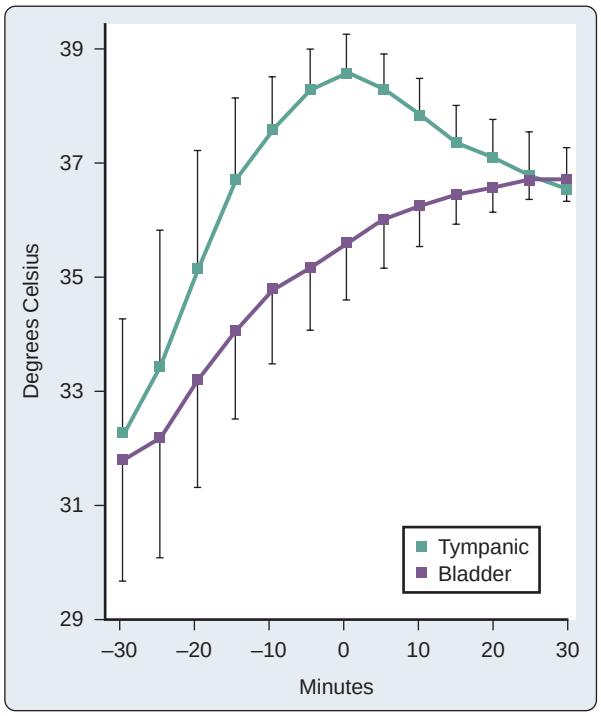

Fig. 40.14 Tympanic and bladder temperatures during rewarming. Time 0 is the maximal temperature achieved. Mean ± standard deviation values are shown. *(From Nathan JH, Lavallée G. The management of temperature during hypothermic cardiopulmonary bypass: I. Canadian survey.* Can J Anaesth. *1995;42:669–671.)*

neurologic deficit compared with none of the patients in the hypothermic group, a significantly greater incidence. In a separate study of 96 patients undergoing CABG and randomized to CPB at either 28°C, 32°C, or 37°C, patients managed at 37°C had a significantly greater incidence of deterioration on cognitive test scores than did those managed at either 28°C or 32°C.[247] No additional benefit in terms of cognitive function was conferred by cooling to 28°C versus 32°C.[199] Nathan and investigators reported on CABG patients operated under hypothermic (32°C) CPB and then randomly assigned to rewarming to 37°C (control) or 34°C (hypothermic), with no further intraoperative warming.[248] Neurocognitive testing was performed 1 week and 3 months after surgery. Eleven tests were combined into three cognitive domains: memory, attention, and psychomotor speed and dexterity. The incidence of cognitive deficits 1 week after surgery was 62% in the control group and 48% in the hypothermic group (relative risk, 0.77; $P = .048$). In the hypothermic group, the magnitude of deterioration in attention and in speed and dexterity was reduced by 55.6% ($P = .038$) and 41.3% ($P = .042$), respectively. At 3 months, the hypothermic group still performed better on one test of speed and dexterity.[248]

Other studies have demonstrated apparently different results, however. Engelman and colleagues randomized a series of 291 patients undergoing coronary revascularization to either hypothermic or tepid/normothermic perfusion.[249] Twelve intraoperative ischemic strokes occurred; six of these were in the group receiving hypothermic perfusion, and six were in the group receiving the tepid/normothermic perfusion. Measurements of the infarct volume showed that three of the strokes in each group resulted in minor or small infarcts and that three in each group were significant, major strokes. The volume of infarction, whether including all six patients in each group or only those with major strokes, was no different between the hypothermic and the tepid/normothermic groups. The researchers observed no relation between the size of a cerebral ischemic infarct and the perfusate temperature during coronary revascularization.[249] Similarly, Dworschak and coworkers found no difference in brain isoenzyme

S-100β release pattern or in clinical neurologic complications between two groups of CABG patients randomly assigned to normothermic or hypothermic (32°C) CPB.[250] In a large, prospective study, Grigore and associates randomly assigned 300 patients undergoing elective CABG to tepid/normothermic (35.5–36.5°C) or hypothermic (28–30°C) CPB and used a battery of neurocognitive tests evaluating four distinct cognitive domains administered before surgery and at 6 weeks after surgery.[66] Again, there were no differences in neurologic or neurocognitive outcomes between normothermic and hypothermic groups in multivariable models. In a separate study, Grimm and investigators found subclinical impairment of cognitive brain function to be more pronounced in CABG patients undergoing mildly hypothermic CPB compared with normothermic CPB.[251] Accordingly, a protective effect of hypothermia on neurologic outcome in CABG has not been verified in most clinical trials, possibly because of too fast and/or excessive rewarming of patients or, more likely, because the impact of only transient cooling during CPB does not extend into the postoperative interval when cerebral hyperthermia has also been demonstrated and correlated with impaired cognitive performance at 6 weeks after surgery.[12,190,252–255]

Procedural Risk

Valve Surgery Versus Coronary Artery Bypass Graft Surgery

In a large retrospective review by Alexander and colleagues of 64,467 patients who underwent CABG alone and 3297 patients who underwent CABG in conjunction with AVR or CABG in conjunction with mitral valve repair or replacement, the incidence rate of type I cerebral injury in patients younger than 80 years was 4.2% for CABG, 9.1% for CABG with AVR, and 11.2% for CABG with mitral valve repair or replacement.[27] Notably, the total CPB time was 96 minutes for CABG, 148 minutes for CABG in conjunction with AVR, and 161 minutes for CABG with mitral valve repair or replacement. It thus remains unclear whether it is the procedure itself or the prolonged duration of CPB, either acting directly or as a marker of a greater surgical difficulty and thus perioperative hemodynamic instability, that is fundamentally causative.[256]

Wolman and colleagues prospectively studied 273 patients from 24 U.S. medical centers who underwent combined intracardiac surgery and CABG.[19] Adverse cerebral outcomes occurred in 16% of patients (43/273), being nearly equally divided between type I cerebral injury (8.4%; 5 cerebral deaths, 16 nonfatal strokes, and 2 new TIAs) and type II cerebral injury (7.3%; 17 new intellectual deteriorations persisting at hospital discharge and 3 newly diagnosed seizures), rates of injury twofold to threefold greater than demonstrated after CABG alone by this same group of investigators.[19] Associated resource utilization was significantly increased according to type of CNS injury: prolonging median ICU stay from 3 days (no adverse cerebral outcome) to 8 days associated with type I injury and from 3 to 6 days in those patients with type II injury. Significant risk factors for type I cerebral injury related primarily to embolic phenomena, including proximal aortic atherosclerosis, intracardiac thrombus, and intermittent clamping of the aorta during surgery. Risk factors for type II cerebral injury included proximal aortic atherosclerosis; a preoperative history of endocarditis, alcohol abuse, perioperative arrhythmia, or poorly controlled hypertension; and the development of a low-output state after CPB.[19]

In a recent prospective cohort study, 196 patients of mean age 75.8 ± 6.2 years who underwent AVR were evaluated by neurologists preoperatively and postoperatively and underwent postoperative MRI. Clinical strokes were detected in 17%, TIAs occurred in 2%, and the in-hospital mortality rate was 5%.[36] In comparison, the frequency of stroke in the STS database is 1.4% after isolated AVR.[9] Clinical stroke was associated with increased length of stay and moderate or severe stroke (National Institutes of Health Stroke Scale score ≥10) occurred in 8 (4%) and was strongly associated with in-hospital mortality (38% vs 4%; $P = .005$). Of the 109 stroke-free patients who underwent postoperative MRI, silent infarct was identified in 59 (54%) but was not associated with in-hospital mortality or increased length of stay.

Circulatory Arrest

Retrograde and Selective Anterograde Cerebral Perfusion

During complex aortic arch repair, surgical access may require interruption of systemic perfusion for relatively protracted periods. Although moderate (25–30°C) and deep (<25°C) hypothermia remain a mainstay for cerebral and systemic protection, the duration of safe cerebral ischemia time and the nature and techniques for provision of cerebral perfusion during times of HCA have been an area of active interest.

In a nonrandomized study, Reich and colleagues performed preoperative and postoperative cognitive testing on 56 patients undergoing HCA, of whom 12 patients underwent retrograde cerebral perfusion (RCP).[257] Memory dysfunction and the overall incidence of cognitive dysfunction had strong associations with RCP even when controlling separately for age and cerebral ischemia time, suggesting worsened outcome with RCP. Okita and colleagues separately evaluated 60 patients who were nonrandomized but were sequentially stratified to receive either RCP or selective antegrade cerebral perfusion (ACP) using serial brain imaging, brain isoenzyme measurement, and limited cognitive testing.[258] They also demonstrated that the prevalence of clinically defined transient brain dysfunction was significantly greater in patients with RCP. Svensson and colleagues used cognitive testing in a subset of 30 of 139 patients undergoing HCA and prospectively randomized three groups to receive either HCA alone, HCA and RCP, or HCA and selective ACP.[259] Comparison of postoperative mean cognitive test scores showed that the HCA alone group did significantly better than either the RCP or ACP group patients.

Despite its conceptual attractiveness and relative ease of application, RCP has not been demonstrated to result in clinically significant CBF, even under conditions of hypothermia-induced decreased cerebral metabolism. In a primate study comparing HCA alone with HCA combined with RCP, less than 1% of the RCP inflow returned to the aortic arch, and histologic analysis revealed slightly more glial edema in the RCP group.[260] Similarly, during HCA in 14 pigs, use of RCP or RCP with inferior vena cava occlusion also resulted in negligible CBFs, and it was similarly observed that less than 13% of retrograde superior vena caval inflow blood returned to the aortic arch with either technique.[261]

It appears as though modified RCP may be effective in flushing emboli from the cerebral circulation, but at the cost of some mild cerebral ischemic damage. Juvonen and coworkers studied the impact on histologic and behavioral outcome of an interval of RCP with and without inferior vena cava occlusion, versus ACP control, after cerebral arterial embolization in a chronic porcine model.[262] Microsphere recovery from the brain revealed significantly fewer emboli after RCP with inferior vena cava occlusion but demonstrated that significant mild ischemic damage occurred after RCP even in nonembolized animals but not in the other groups. Behavioral scores by day 7 were considerably lower in all groups after embolization, with no significant differences between groups.

Another interesting study of Okita and colleagues is a retrospective review of 8169 patients who underwent total arch replacement between 2009 and 2012 and of whom 7038 patients had ACP and 1141 patients had HCA/ RCP, in whom the duration of CPB and cardiac ischemia was longer in the ACP group. The investigators found no significant differences between the ACP and RCP groups with regard to 30-day mortality (3.2% vs 4.0%), hospital mortality (6.0% vs 7.1%), incidence of stroke (6.7% vs 8.6%), or transient neurologic disorder (4.1% vs 4.4%). In addition, there were no significant differences between the groups in a composite outcome of hospital death, bleeding, prolonged ventilation, need for dialysis, stroke, and infection (ACP 28.4% vs HCA 30.1%).[263] However, HCA/RCP resulted in a significantly higher rate of prolonged stay in the ICU (>8 days: 24.2% vs 15.6%). The investigators concluded that ACP might be preferred as the brain protection method for complicated aortic arch procedures.

pH Management During Hypothermic Circulatory Arrest

The milieu in which HCA is conducted may well also have an important impact on CNS outcomes, but this has not yet been systematically investigated in adult patients. Clinical studies and experimental evidence point to a benefit of pH-stat management in infants and children undergoing HCA.[264] However, it should be noted that neither the clinical studies in pediatric patients nor the experimental models using nonatheromatous animals are necessarily relevant to the adult patient who invariably has substantial atheromatous disease within the ascending aorta, often with concomitant extracranial and intracranial involvement. For adults undergoing moderate hypothermic CPB at least, the weight of evidence from CNS outcomes of at least three separate, prospective, randomized, clinical trials supports alpha-stat pH management over pH-stat.[57,265,266] In this context, alpha-stat has also been associated with decreased cerebral embolization[267] and preservation of cerebral autoregulation,[138,265] factors likely of paramount importance in perioperative CNS injury in adult patients undergoing HCA.

In none of these studies were stroke rate, mortality, or other measures of morbidity influenced by treatment mode, although all were underpowered to detect such outcomes. However, Hagl and associates retrospectively analyzed outcomes in 717 survivors of ascending aortic and aortic arch surgery.[268] They determined that the method of cerebral protection did not influence the occurrence of stroke but that ACP resulted in a significant reduction in the incidence of temporary neurologic dysfunction, a result not seen after RCP. Directionally similar results demonstrating that antegrade perfusion was associated with significantly lower incidences of temporary neurologic complications, earlier extubation, shorter ICU stay, and shorter hospitalization in comparison with patients managed with RCP have been shown by Apostolakis and colleagues.[269] Halkos and investigators demonstrated that during proximal aortic surgery, selective ACP was associated with lower mortality, as well as improved resource utilization and fewer pulmonary and renal complications.[270]

It is unlikely that pH management will substantially change the results of RCP versus ACP discussed earlier; however, the study conducted by Harrington and colleagues used alpha-stat management, whereas the study done by Reich and colleagues used pH-stat management, both with similar directional results relatively unfavorable to RCP.[67,257] Whether pH management will influence the overall incidence of CNS dysfunction after HCA is unknown. A recent metaanalysis has concluded that in the absence of randomized trials, pH-stat management for infants and alpha-stat management for adults would appear to be the most appropriate strategies for patients undergoing HCA.[271] Based on the impact of pH management on CBF, a strong argument could be made to use pH-stat during the cooling phase before circulatory arrest followed by alpha-stat during rewarming, as practiced in some institutions.[272]

During HCA, meticulous clinical management with systemic hypothermia combined with topical cooling of the head, avoidance of cerebral hyperthermia during rewarming and in the immediate postoperative interval, maintenance of normal perioperative blood glucose concentrations, careful de-airing of graft and arteries, ideally with carbon dioxide flushing before reperfusion, all coupled with an expeditious surgical repair designed to minimize the duration of HCA, should be the goal.

Minimal Access Surgery and Circulatory Support

Development of Minimal Access Surgical Techniques

In the mid-1990s, efforts occurred to decrease the invasiveness of CABG in order to reduce postoperative morbidity and mortality. Research focused on trying to avoid instrumentation of the aorta (neurologic complications), avoid sternotomy (infectious complications), and avoid use of CPB (inflammation, bleeding, neurologic complications). First, the port-access endovascular technique was developed, avoiding sternotomy, right atrial manipulation (POAF), and external aortic cross-clamping.[273] Retrograde CPB was established through femoral arterial and venous cannulation. In lieu of aortic clamping, a transfemoral endoaortic balloon catheter was used for aortic occlusion, aortic-root venting, root pressure monitoring, and anterograde cardioplegia administration. The left internal mammary artery graft was placed on the left anterior descending coronary artery (LAD) through a limited left anterior thoracotomy incision. However, there were issues of balloon migration and occlusion of arch vessels, as well as intraoperative aortic dissection or iliac artery dissection. It was therefore recommended to include preoperative screening for peripheral vascular disease (a contraindication for endovascular CPB), as well as intraoperative monitoring of both right and left radial artery pressures.[274] After 1166 cases (614 CABG, 412 mitral valve procedures, and 140 other procedures), the reported 30-day stroke rate after CABG was 1.2% and after mitral valve surgery was 4.0%.[274] This was equivalent to the stroke rate of 1.4% after isolated conventional CABG of the STS database.[8] Furthermore, the STS stroke rate after mitral valve surgery is considerably lower (mitral valve replacement 2.1%, mitral valve repair 1.4%), demonstrating that minimal access surgery is not necessarily minimally invasive.[9] The main culprits are thought to be the deployment of an intravascular balloon in the ascending aorta and difficulty of retrograde de-airing leading to cerebral air embolism. Moreover, retrograde femoral arterial perfusion is thought to increase stroke risk, especially in patients with severe (grade IV or V) atherosclerosis of arch and/or ascending aorta.[275] The collaborators themselves decided to stop using port-access and performed minimally invasive direct coronary artery bypass grafting (MIDCAB) instead.[274]

The MIDCAB procedure was developed as an off-pump LAD bypass through a limited left thoracotomy, with transient occlusion of the LAD.[276] Avoiding both CPB and aortic manipulation, it could potentially protect patients from neurologic adverse events. In a series of 199 patients, 14 (7%) were converted to conventional sternotomy; all but 1 of these was due to technical difficulties. From the 185 remaining MIDCAB patients, only 1 had an undefined neurologic complication. However, since this technique is technically difficult for right coronary lesions and effectively impossible for circumflex arterial lesions, it is now used only in a hybrid approach, which incorporates percutaneous catheter–based interventions for multivessel disease.

A third approach, OPCAB, uses a full sternotomy, without CPB and aortic cross-clamping, but still makes use of aortic side clamps. This procedure is used for approximately 25% of all CABG in the United States and is associated with less perioperative morbidity.[277] The true reduction in postoperative neurologic adverse events, however, remains to be elucidated. The body of evidence on postoperative stroke is confounded by procedural differences related to use of EAS and partial aortic clamping in different study groups. For example, use of EAS in the conventional CABG study population will minimize a beneficial effect in the OPCAB group. Likewise, use of aortic side clamps in the OPCAB group in the presence of markers of vascular disease will also preclude major reduction in postoperative neurologic outcomes. Robotic surgery was introduced to further minimize the route of access to the mediastinum and was combined with OPCAB to avoid use of CPB. Robotic surgery was used initially for bypass grafting. Centers now report robot-assisted atrial septal defect and patent foramen ovale closure, as well as robot-assisted mitral valve surgery.[278,279]

Similar to CABG surgery, valvular surgery has also embraced minimal access. Aortic valve surgery is now performed via right anterior thoracotomy and right upper partial sternotomy incisions in order to reduce wound infections. More recently, percutaneous transcatheter (transfemoral or transapical) aortic valve implantation (TAVI) approaches have been introduced to avoid CPB and hence CPB-induced morbidity.[280] However, there is still concern of atherosclerotic emboli released during deployment of the valve or during transfemoral catheterization. Because the latter techniques are relatively new, there is still uncertainty regarding long-term durability and clinical results compared with open heart surgery. Potential TAVI candidates

are therefore mainly high-risk and older symptomatic patients with severe aortic stenosis.

Transcatheter mitral valve interventions or mitral clip procedures for mitral regurgitation are yet another chapter in the development of minimally invasive cardiac surgery and were first introduced in 2005. These procedures eliminate use of CPB, sternotomy, and manipulation of the aorta and are expected to reduce postoperative neurologic morbidity. Nevertheless, outcome data from these new techniques mainly focus on surgical results, and data on neurologic outcomes are currently limited.

Off-Pump Coronary Artery Bypass

In 2012, the CORONARY investigators published the 30-day outcome of 4752 patients that were randomized to compare OPCAB to conventional CABG. The reported incidence of stroke was similar in both groups (1.0% vs 1.1%).[281] At 1 year, the incidence of stroke had marginally increased, but the increase was similar between the two groups (1.5% vs 1.7%).[282] This was surprising since avoidance of aortic cannulation and cross-clamping were thought to reduce the embolic risk. This may have been because 102 patients assigned to conventional CABG crossed over to have OPCAB because of a calcified aorta, or it may have been due to lack of power.

Previously, in 2004, a meta-analysis on OPCAB versus conventional CABG also found no difference in the incidence of stroke at 30 days from 21 randomized clinical trials ([RCT]; $n = 2859$; OPCAB 0.4 vs CABG 1.0%; odds ratio [OR], 0.68; 95% CI, 0.33–1.40).[277,283] One year after surgery the stroke rate increased to OPCAB 1.1% compared with CABG 2.3% ($n = 864$, 4 RCTs; OR, 0.50; 95% CI, 0.17–1.50). As the researchers point out, the study population consisted only of patients with lesions amenable to OPCAB, with exclusions of circumflex lesions beyond the first obtuse margin, affecting generalizability. Moreover, crossover rates were higher in OPCAB versus CABG patients (8.0 vs 1.7%), introducing room for possible bias. In comparison, a large body of nonrandomized studies showed reduced stroke risk with OPCAB versus conventional CABG (40% to 45% risk reduction, respectively), possibly because of patient selection or a lack of power among RCTs.[277]

Results on early cognitive outcome or cognitive function in patients already experiencing decline preoperatively are conflicting. Two studies report that OPCAB was associated with a significant reduction in decline,[284,285] whereas another trial did not find a difference.[124] Mid-term cognitive outcome at 2 and 6 months also differs across studies from a reduction in number of patients with cognitive dysfunction after OPCAB to no difference between groups.[124,285,286] One year after surgery the number of patients experiencing cognitive decline is the same between OPCAB versus CABG.[124,284,286,287] More recently the CORONARY trial investigators studied neurocognitive outcome at discharge, 30 days and 1 year after surgery and found the same direction of effect. At discharge they found less neurocognitive decline from baseline in the OPCAB group, assessed with use of the Digit Symbol Substitution Test, but no significant between-group difference at 30 days or 1 year.[282] No differences between groups was found in change in scores on two more tests. This is in accordance with an observational study comparing 89 OPCAB with 129 conventional CABG patients that also found decreased early neuropsychological dysfunction 1 week after surgery in the OPCAB group.[288] OPCAB surgery in comparison to CABG therefore seems to impact early but not late neurocognitive outcome, probably reflecting the progression of underlying disease.

Endoscopic, Robot-Assisted Coronary Artery Bypass Graft Procedures

A systematic review of 14 studies on endoscopic, robot-assisted CABG procedures included 880 OPCAB and 360 CABG surgeries.[289] Weighted mean incidence of stroke within 1 year after endoscopic, robot-assisted OPCAB was 0.7% versus 0.8% robot-assisted CABG. However, because seven of the eight studies reporting on postoperative stroke were nonrandomized cohorts, these low incidence figures probably reflect the selection of low-risk patients for endoscopic, robot-assisted OPCAB and robot-assisted CABG.[289]

Transcatheter Aortic Valve Implantation

Only three RCTs evaluating TAVI have been conducted so far, comprising 1564 patients; of these three trials, two report on postoperative stroke (769 patients).[290–292] In the multicenter trial of Kodali and colleagues (PARTNER trial), 699 high-risk patients were assigned to surgical AVR or TAVI (transapical).[292] Patients at 25 sites were included if they had severe aortic stenosis with an aortic valve area of less than 0.8 cm^2 and were determined to be at high surgical risk because of comorbidities that were associated with an estimated 30-day mortality risk of at least 15%. The total number of strokes over the follow-up period of 36 months was the same (24 TAVI and 20 AVR; hazard ratio [HR], 1.22; 95% CI, 0.67–2.23). However, in the first 30 days, the hazard of stroke was increased in the TAVI group (4.6% with TAVI vs 2.4% with surgery).[292] This raised concern that TAVI is responsible for early strokes, possibly owing to increased liberation of atherothrombotic debris (from valve or aorta), causing embolic ischemic strokes. Nielsen and colleagues conducted a multicenter trial in patients over 75 years aiming to include 200 patients and follow them for a composite end point of 30-day all-cause mortality, major stroke, and renal failure requiring dialysis.[291] Unfortunately, the study was prematurely terminated after inclusion of 70 patients, when the primary end point was met in 5 patients in the transapical TAVI (2 deaths, 2 strokes, 1 renal failure) versus 1 patient in the surgical group (stroke).[291] In their discussion, the authors touch upon the increased early stroke risk after TAVI, emphasizing the importance of early dual anticoagulation. Furthermore they recommend preoperative computed tomography imaging improving valve sizing, possibly preventing the adverse events of paravalvular leak caused by undersizing and occlusion of LAD after TAVI.

Schymik and coworkers published results of 1000 consecutive patients undergoing transapical or transfemoral TAVI in their institution between 2008 and 2012.[293] Selection criteria for TAVI were EuroSCORE (European System for Cardiac Operation Risk Evaluation) of more than 15, irrespective of age; age older than 75 years with predisposing risk factors such as prior heart surgery, comorbidities, or frailty; and patients with known porcelain aorta. In this high-risk patient cohort with mean age of 81, female gender greater than 50%, and EuroSCORE higher than 20, the researchers found a 30-day incidence of stroke or TIA of only 1.7% after 413 transapical procedures and 2.3% after 587 transfemoral procedures. After propensity score matching, the incidences were similar: 2.0% versus 2.3%. This is in contradiction with the belief that transfemoral catheterization increases the risk of disrupting calcific plaques, especially in patient with severe (grades IV and V) aortic arch or ascending aortic atherosclerosis.[275]

Knipp and associates reported a single-center nonrandomized study on cognitive function 3 months after surgical AVR and TAVI.[294] Sixty-four patients with severe aortic stenosis were subjected to neurologic and neuropsychological testing before and after surgery, at discharge, and at 3-month follow-up. Diffusion-weighted MRI was performed before surgery and before discharge. Of the 64 patients, 27 underwent transapical TAVI and 37 had surgical AVR. Patients undergoing TAVI were significantly older, had more comorbidities, and had a higher estimated operative risk for mortality. In TAVI patients there was no statistically significant decrease in any of the six cognitive domains tested. However, the composite cognitive score suggested a clinically relevant deficit in 18% of patients at discharge and in 28% patients at 3 months. From the available MRI studies, 7 out of 12 TAVI patients had areas of new focal ischemia, all clinically silent, not unlike the results of Messé and investigators in which a 54% incidence of new lesions on MRI was noted after surgical AVR.[36] The presence of these lesions was unrelated to cognitive dysfunction.[294]

Taken together, these studies indicate the following: (1) Extensive preoperative assessment is necessary to correctly size the aortic annulus and identify severe atherosclerotic lesions in ascending aorta and arch. (2) TAVI is associated with an increased risk of early stroke, emphasizing the need for coagulation after TAVI.[295] Early studies with new cerebral filters suggest frequent capture of atherothrombotic material after TAVI; however, clinical studies are yet to be published.[296] (3) TAVI

procedures should only be performed by experienced, high-volume centers.[297] This is once more demonstrated by the high number of procedures (1000 in 4 years), yet low number of adverse neurologic outcomes (2–2.3%) presented by Schymik and colleagues.[293] (4) It is still unknown if transfemoral catheterization increases the risk of postoperative neurologic events compared with transapical TAVI.[275]

The SANITY study, a prospective, multicenter study comparing the incidence of neurologic injury associated with transapical, transaortic, or transfemoral TAVI and surgical AVR, has hypothesized that surgical AVR is associated with less neurologic injury than transcatheter valve insertion, and transapical/transaortic with less neurologic damage than transfemoral.[298] This study aims to include 150 high-risk patients with severe aortic stenosis, who are planned for either surgical or transcutaneous treatment, and who have an STS score higher than 8%, EuroSCORE higher than 20%, or EuroSCORE II higher than 10%. It is hoped that extensive preoperative evaluation of patient demographics, calcification of aorta, neurocognitive function, and functional capacity; intraoperative assessment of hemodynamics and cerebral oximetry; and postoperative follow-up for adverse events, neurocognitive change, and serologic markers; and MRI, diffusion-weighted MRI, and susceptibility-weighted MRI until 6 months after surgery will enhance the existing body of knowledge in this area once the results have been analyzed and published.

MitraClip

The MitraClip procedure is used to treat patients with moderate-to-severe and severe mitral regurgitation (MR). During this procedure a device is advanced via the femoral vein into the right atrium and then via a transseptal route antegradely into the left atrium and further into the left ventricle under two- and three-dimensional TEE and fluoroscopic guidance. In most patients general anesthesia is used, whereas use of CPB and aortic clamping or cannulation is avoided. With the clip arms opened at 160 to 180 degrees, the device is retracted against the mitral valve to grasp the anterior and posterior leaflet at the site of the maximum regurgitation jet. The clip arms are then closed to approximate the leaflets (called *edge-to-edge repair*). If reduction in MR is acceptable and appropriate leaflet insertion is ascertained, the clip device is released from the delivery system. Additional MitraClip implantations are performed if residual lateral/medial MR is present. The first study on mitral clips implantation (EVEREST I) enrolled 27 patients with moderate-to-severe or severe MR.[299] Of 24 patients receiving a clip, 1 suffered from a stroke after the procedure. The EVEREST II trial, wherein 279 patients with moderate-to-severe or severe MR were randomized to percutaneous repair or conventional surgery, found less efficacy after percutaneous repair (55% vs 73%) but also less incidence of major adverse events (15% vs 48%), mainly attributed to bleeding.[300] Major stroke occurred in two patients in each group.

Recently, Eggebrecht and colleagues published data from the multicenter German registry on MitraClip procedures,[301] which was established to assess safety and efficacy and is open to all German sites performing percutaneous mitral valve interventions. Their analysis of 828 high-risk patients (median age, 76; median EuroSCORE, 20.0%) from 15 centers demonstrated an in-hospital stroke rate of 0.9%, an in-hospital TIA rate of 1.0%, and an overall in-hospital death rate of 2.2%. The ACCESS-EU study prospectively enrolled 567 patients of (mean age, 73.7; mean EuroSCORE, 23.0%) from 15 different European sites between April 2009 and April 2011.[302] The patients were followed for 1 year for adverse events, quality of life, and 6-minute walking test and demonstrated a 30-day stroke incidence of 0.7% and a 1-year stroke rate of 1.1%.

The incidence rates of stroke from both studies are considerably lower than those reported in the STS database, in which the frequency of cerebrovascular accident after isolated surgical mitral valve replacement is 2.1%, and after surgical mitral valve repair 1.4%.[9] However, since long-term efficacy is still questioned, it is useful to look at their 12-month outcomes. The investigators reported that 78.9% were free of MR 2+ severity, 6.3% underwent mitral surgery, and 3.4% underwent a second MitraClip procedure. The Kaplan-Meier estimate of freedom from all-cause mortality at 12 months was 81.8% (95% CI, 78.1–84.8%).[302] A recent systematic review by Philip and colleagues of 21 studies in patients with a high risk of surgical mortality (EuroSCORE > 18 or STS score > 10) reports a 30-day success rate of 96.3% for MitraClip vs 98.1% for mitral valve surgery, with an urgent mitral valve surgery rate of 2.7% versus 0.6%.[303] However, with a mean death rate of 3.3% for MitraClip vs 16.2% for mitral valve surgery and a stroke rate of 1.1% and 4.5%, respectively, it seems that in high-risk patients MitraClip may be associated with significantly lower risk for neurologic morbidity and mortality.

Extracorporeal Membrane Oxygenation and Ventricular Assist Device Procedures and Cerebral Dysfunction

Venoarterial extracorporeal membrane oxygenation (ECMO) has been used successfully for cardiogenic shock and cardiac arrest refractory to usual resuscitative techniques as a form of mechanical support. Therefore, all patients on ECMO represent a very high-risk patient group who would otherwise probably die. In the absence of large clinical trials, performance of pooled analysis represents the best method for ascertaining complication rates associated with ECMO in patients who experience cardiogenic shock and cardiac arrest. However, there is an abundance of insertion techniques, with a heterogeneous risk profile. The first and major defining characteristic is site of cannulation, peripheral versus central. Central cannulation is most often used in patients who cannot be weaned from bypass. This patient group therefore has a high a priori chance of cerebral complication resulting from long CPB time and low cardiac output syndrome. Peripheral cannulation can be started intraoperatively in the same patient group to allow primary chest closure. However, most peripheral cannulation will be performed without use of CPB and aortic cross-clamping, for example in ICUs, thereby lowering the predisposing factors for adverse neurologic outcome. Still, it entails aortic manipulation by advancing the arterial cannula via the femoral or axillary artery. A recent meta-analysis on venoarterial ECMO, including all studies with more than 10 patients published after 2000, retrieved 20 studies encompassing 1866 patients.[304] The reported pooled estimate stroke rate from three studies (630 patients) was 5.9% (95% CI, 4.2–8.3%), and overall neurologic complications rate from nine studies (1019 patients) was 13.3% (95% CI, 9.9–17.7%), encompassing hemorrhage, ischemic stroke, coma, anoxic brain injury, brain death, or brain injury.[304] In summary, ECMO insertion is performed only in very high-risk patients and involves considerable risk for adverse neurologic events.

Patients receiving ventricular assist devices (VADs) represent a slightly different group. They have been screened to see that no contraindications exist for this complex surgery. Most patients receive VAD as bridge to therapy (56%) or destination therapy (43%) for heart failure. A small percentage of patients receive VAD as rescue therapy (0.3%) or bridge to recovery (1.0%).[305] The ultimate clinical goals of VAD therapy are to restore adequate blood flow, preserve end organ function, and provide effective decompression of failing ventricles. VAD insertion involves a long procedure with CPB and aortic cross-clamping. The reported rates of stroke after VAD implantation are variable and reflect differences in follow-up and patient population. Neurologic events seem to be relatively common and are associated with bad patient outcome. Consistent evidence shows that pulsatile pumps tend to lead to more complications (especially malfunction and infection) compared with continuous pumps. The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) Fifth Annual Report shows a twofold increase of postoperative neurologic dysfunction associated with pulsatile versus continuous flow (3.81 vs 1.83%; $P < .0001$).[306] Thus it comes as no surprise that currently less than 5% of implanted VADs are pulsatile pumps.[305] Moreover, it seems that the total burden of adverse events is slightly decreasing with greater experience using continuous-flow devices.[305]

However, although the early stroke risk after VAD insertion is low, it increases steadily over time. Outcomes in a group of 5366 adult primary continuous-flow left ventricular assist devices indicated the risk of stroke at 1 month was 3%, increasing to 11% at 12 months, 17% at 24 months, and 19% at 36 months after implantation, presumably due to the constant thrombogenic threat of artificial hardware in the main vasculature.[306] This further emphasizes the need for adherence to long-term anticoagulation regimes.

Applied Neuromonitoring

Intraoperative neurophysiologic monitoring may be of benefit to decrease CNS injury.[307] Intraoperative TCD has been demonstrated to detect embolic events in real time and allows modification of perfusion and surgical techniques. It has been shown that the numbers of emboli generated by perfusionist interventions (eg, drug injection, blood return), as well as episodes of entrainment of air from the surgical field, are rapidly identified and corrected by TCD detection of intraoperative emboli (see Chapter 18).[308]

Brain oximetry studies using noninvasive NIRS have shown promising results.[143,309–314] In Goldman and colleagues' large, nonrandomized cohort study, NIRS was used to monitor cerebral oxygen saturation in 1034 cardiac surgical patients and was compared with outcomes in 1245 patients who underwent cardiac surgery immediately before cerebral oximetry was incorporated.[313] The study group had significantly more patients in New York Heart Association (NYHA) classes III and IV than the control group, but the study group overall had fewer permanent strokes (10 [0.97%] vs 25 [2.5%]; $P = .044$) and the proportion of patients requiring prolonged ventilation was significantly smaller in the study group, as was the length of hospital stay. Murkin and coworkers reported a prospective, blinded, randomized study of NIRS cerebral oximetry in 200 cardiac surgical patients and demonstrated significantly fewer adverse clinical outcomes in NIRS versus control groups ($P = .027$).[143]

Even during beating-heart procedures, compromised cerebral perfusion can occur relatively frequently, and if unrecognized, may account for the relative lack of difference in CNS outcomes between CABG and OPCAB surgery.[315] Combined electroencephalography and cerebral oximetry identified episodes of cerebral ischemia in 15% of a series of 550 beating-heart patients; all were treated successfully by a combination of pharmacologically improved cardiac output, increased perfusion pressure, and cardiac repositioning.[315]

In a study utilizing cerebral oximetry in 265 patients undergoing primary coronary artery bypass surgery and randomized to active monitoring and a series of interventions designed to improve regional hemoglobin oxygen saturation (rSO_2) or to a control group in which blinded monitoring was used, a significant association was found between prolonged cerebral desaturation and early cognitive decline, as well as a threefold increased risk for prolonged hospital stay.[53] However, cerebral desaturation rates were similar between groups and ascribed to poor compliance with the treatment protocol, resulting in no difference in the incidence of cognitive dysfunction between groups. In a study of 103 patients undergoing valvular heart surgery in whom blinded cerebral NIRS monitoring was used, cerebral oxygen desaturation was again found to be associated with significantly longer duration of postoperative hospitalization.[316]

In a prospective, randomized, blinded study in 200 patients undergoing coronary artery grafting, Murkin and colleagues demonstrated that active treatment of declining rSO_2 values prevented prolonged cerebral desaturations and was associated with a shorter ICU length of stay and a significantly reduced incidence of major organ morbidity or mortality in comparison with a similar control group.[143] In this study, the intervention protocol undertaken to return rSO_2 to baseline resulted in a rapid improvement in rSO_2 in 84% of cases and did not add undue risk to the patient, including no increase in allogeneic blood transfusions.[317] There were also numerically fewer clinical cerebrovascular accidents in the monitored patients directionally consistent with previous studies.[313] More recently, use of an active treatment algorithm to minimize cerebral desaturation has been shown to be associated with decreased neurocognitive dysfunction and decreased markers of brain dysfunction.[318,319] As such, a physiologically derived treatment algorithm for management of perioperative cerebral oxygen desaturation has been proposed and is shown in Fig. 40.15.[320] An important aspect in using cerebral NIRS devices is the efficacious use of a treatment algorithm for management of cerebral desaturation.

Another recent development in cerebral oximetry monitoring has been the recognition that it can be used to determine the lower limit of cerebral autoregulation (LLA) and that perfusion pressures below this limit are associated with a variety of adverse outcomes, including major organ morbidity and mortality, analogous to the findings of Murkin and colleagues, as well as stroke and acute kidney injury.[142,321,322]

Some of the concerns associated with cerebral oximetry, including extracerebral signal contamination, and change in arterial/venous partitioning, have been addressed in a new generation device.[323] The incorporation of a Doppler ultrasound to focus NIRS photons has permitted the direct measurement of changes in microcirculatory CBF using ultrasound-tagged photons, and a series of preliminary studies have demonstrated the utility of this approach to assess the integrity of cerebral autoregulation and LLA.[324]

Neuromonitoring During Deep Hypothermic Circulatory Arrest

Moderate (25–30°C) and deep (<25°C) hypothermia remain a mainstay for cerebral and systemic protection during complex aortic arch repair because surgical access may require interruption of systemic perfusion for relatively protracted periods. As there is relatively little ability to monitor cerebral well-bring during such times because electroencephalography becomes progressively attenuated at less than 25°C, cerebral NIRS has been advocated as a means of monitoring and detecting onset of cerebral ischemia during deep HCA.[325,326] Although some groups monitor jugular venous oxygen saturation (SjO_2) using retrograde cannulation of the internal jugular vein as an index of cerebral metabolic suppression during cooling, correlation has not been demonstrated between SjO_2 and cerebral NIRS during deep HCA.[327] A possible explanation could be that NIRS is a highly regional measure of cerebral cortical oxygen tissue saturation, whereas SjO_2 is a measure of cerebral mixed venous oxygen saturation and thus reflective of global changes in venous oxygenation and, as such, potentially less sensitive to regional perfusion inhomogeneities.

In addition to deep HCA, some centers use RCP via the superior vena cava or, increasingly, selective anterograde cerebral perfusion (SACP) via the innominate or subclavian artery. There have been a variety of case reports of the ability of cerebral NIRS to detect onset of cerebral ischemia during aortic arch surgeries, and there is growing interest in the role of cerebral NIRS as a measure of adequacy of perfusion in this setting.[328–332] It is increasingly recognized that RCP does not provide sufficient nutritive flow to sustain cerebral integrity for an extended interval, as has been reflected in lower rSO_2 values seen during NIRS monitoring in RCP versus SACP.[328,330,333]

In a study investigating the role of NIRS monitoring during SACP, a study was undertaken in 46 consecutive patients in whom SACP was established by separate concomitant perfusion of the innominate and the left carotid arteries or by perfusion of the right subclavian artery (with or without left carotid artery perfusion) and during which bilateral regional cerebral tissue oxygen saturation index was monitored.[334] Stroke was the primary clinical end point, together with indices of diagnostic performance of the NIRS device. In this series, six patients died in the hospital and six patients (13%) in whom regional cerebral tissue oxygen saturation values were significantly lower during SACP experienced a perioperative stroke. Regional cerebral tissue oxygen saturation decreasing to 76% to 86% of baseline during SACP had a sensitivity of up to 83% and a specificity of up to 94% in identifying individuals with stroke. It was concluded that using NIRS monitoring of regional cerebral tissue oxygen saturation during SACP allows detection of clinically important cerebral desaturations and can help

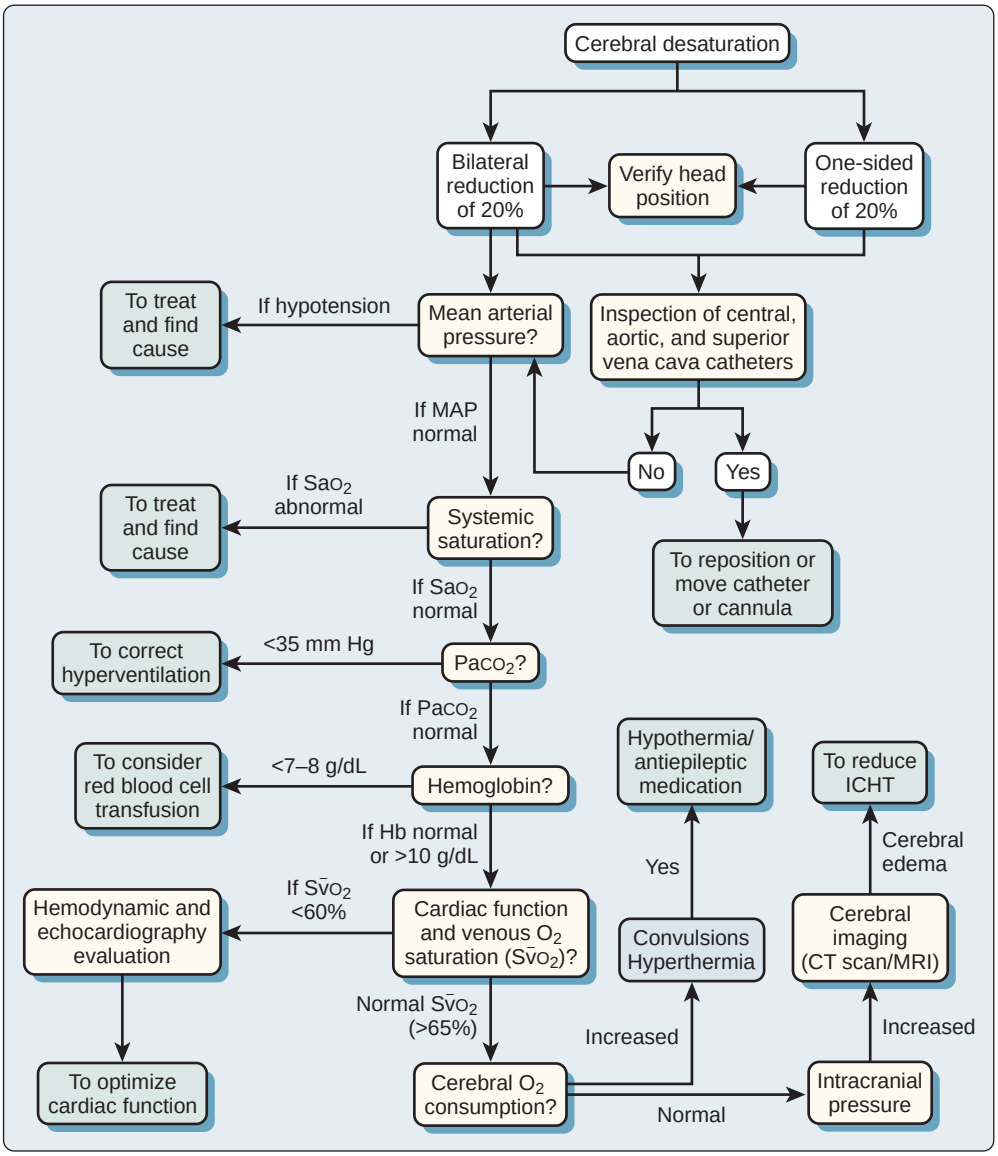

Fig. 40.15 Algorithm for the use of brain oximetry. *CT,* Computed tomography; *ICHT,* intracranial hypertension; *MAP,* mean arterial pressure; *MRI,* magnetic resonance imaging; *$Paco_2$,* arterial partial pressure of carbon dioxide; *Sa_{O_2},* arterial oxygen saturation; *$S\bar{v}o_2$,* mixed venous oxygen saturation. *(Reprinted from Denault A, Deschamps A, Murkin JM. predict perioperative neurologic sequelae, supporting its use as a non-invasive trend monitor of cerebral oxygenation.[334]

In adult patients, cerebral malperfusion can occur either as a consequence of ascending aortic dissection with occlusion of carotid lumen, kinking or obstruction of perfusion cannula during selective cerebral perfusion for circulatory arrest procedures, or migration of aortic endoclamp cannula during minimal-access cardiac surgery with potential compromise of cerebral perfusion.[335–337] Reports are increasing that bilateral rSo_2 monitoring can detect contralateral desaturation during unilateral selective cerebral perfusion. This can result from an incomplete circle of Willis, which, in some series, has a prevalence rate of up to 50% and has been estimated to be a factor in cerebral malperfusion in approximately 15% of patients.[338,339] In a more recent case report, cerebral rSo_2 monitoring was used during selective cerebral perfusion in the absence of systemic CPB during repair of traumatic aortic arch rupture and detected both episodes of cerebral malperfusion and, most critically, acute thrombosis of carotid artery graft leading to thrombectomy and restoration of flow.[340] In addition, a number of cases of aortic arch surgery have been reported in which cerebral oximetry has detected cerebral hypoperfusion caused by various factors, including diminished Blalock-Taussig shunt flow after pediatric cardiac surgery.[341]

Pharmacologic Cerebral Protection

Whereas multiple advances toward understanding the basic mechanisms of brain injury have led to the development of multiple pharmacologic strategies for neuroprotection, in general, pharmacologic protection from cerebral ischemia remains an elusive goal. Based on sound experimental evidence, including data from animal studies, a number of putative neuroprotective agents have been examined in cardiac surgical patients, but the results have been mostly negative.[342] Agents tested have included those that reduce brain oxygen consumption to increase tolerance to ischemia (thiopental and propofol) and

those that target established neuroprotective pathways, including the *N*-methyl-D-aspartate (NMDA) receptor, calcium channels, oxidant stress, the GABA receptor, and others. Post hoc analyses of several trials have suggested encouraging neuroprotective effects from remacemide and complement-inhibiting agents.[342] However, for the most part, there are no widely accepted pharmacologic agents with proven efficacy to reduce the extent of brain injury associated with cardiac surgery.

Although there had been one clinical study in which a significant reduction in persistent neurologic defects after open-chamber cardiac surgery was reported after administration of high-dose thiopental, this was not confirmed in closed-chamber CABG procedures.[343,344] Other data have suggested that if there is any such thiopental-derived cerebroprotective effect, the mechanism may be caused by lower cerebral metabolic rate and lower CBF due to cerebral vasoconstriction, with a concomitant reduction in the delivery of emboli into the brain, rather than occurring primarily as a result of a decrease in $CMRO_2$.[345] However, a three-center study including 225 patients undergoing mitral or aortic valve surgery and randomized to high-dose propofol with induction of burst-suppression on electroencephalography or a sufentanil control group was unable to detect any significant differences in neurologic or neuropsychological outcomes between groups.[346] These investigators concluded that neither cerebral metabolic suppression nor reduction in CBF reliably provides neuroprotection in open-chamber cardiac surgery.

Another interesting association existed between β-blocker and lowered incidences of stroke and adverse CNS events. In 2002, Amory and associates reported a retrospective review of 2575 CABG patients in which patients who had received perioperative β-blockers had a significantly lower incidence of severe neurologic outcomes versus those who did not, demonstrating a 1.9% incidence of stroke and coma versus 4.3%, and an incidence of any postoperative neurologic complication of 3.9% versus 8.2%, respectively.[347] However, concerns regarding perioperative β-blocker therapy have been raised by the results of the PeriOperative ISchemic Evaluation (POISE) trial in which 8351 patients with, or at risk for, atherosclerotic disease who were undergoing noncardiac surgery were randomized to receive extended-release metoprolol ($n = 4174$) or placebo ($n = 4177$).[348] Although significantly fewer patients in the metoprolol group than in the placebo group had a myocardial infarction, there were more deaths in the metoprolol group than in the placebo group (3.1% vs 2.3%; HR, 1.3%), more patients in the metoprolol group than in the placebo group had a stroke (1.0% vs 0.5%; HR, 2.2), and more patients died from fatal stroke (11% vs 5% of all deaths).[348] This new finding is consistent with data on increased stroke risk in patients with hypertension treated with β-blockers.[349] One explanation might be found in the nonselective β-blocking properties of metoprolol, inhibiting the β_2-induced cerebral vasodilation. A retrospective propensity matched cohort indeed found evidence for less incidence of postoperative strokes in patients on bisoprolol, as compared to those given metoprolol or atenolol.[350] In conclusion, initiating new β-blocker therapy in the preoperative setting could be unsafe and should be avoided, as should withdrawal before surgery, and if used, perhaps β_1 selective agents should be preferred over nonselective agents.

As a broad-spectrum antiinflammatory agent, the serine protease inhibitor aprotinin has been shown to positively impact coagulation and inflammatory alterations triggered by CPB and has also been associated with decreased incidences of stroke and major CNS injury in cardiac surgical patients.[351–353] However, because the clinical usage of aprotinin has been suspended indefinitely because of several reports of increased mortality and adverse events associated with aprotinin therapy in cardiac surgical patients,[354–356] the future of this drug remains controversial.[357,358]

There are some other interesting associations between certain drug therapies having antiinflammatory and antiplatelet properties and lowered incidences of stroke and adverse CNS events. In a prospective study of 5065 patients undergoing CABG conducted at 70 centers in 17 countries, the relation between early aspirin use and fatal and nonfatal outcomes was investigated.[359] Among patients who received aspirin within 48 hours after revascularization, subsequent mortality rate was 1.3% compared with 4% ($P < .001$) among those who did not receive aspirin, and aspirin therapy was also associated with a 48% reduction in the incidence of myocardial infarction (2.8% vs 5.4%; $P < .001$), a 50% reduction in the incidence of stroke (1.3% vs 2.6%; $P = .01$), a 74% reduction in the incidence of renal failure (0.9% vs 3.4%; $P < .001$), and a 62% reduction in the incidence of bowel infarction (0.3% vs 0.8%; $P = .01$). These findings are strongly supportive of perioperative aspirin therapy and suggest that platelets have a fundamental role in orchestrating the ischemic response to reperfusion injury of multiple organ systems in patients undergoing cardiac surgery.

Another promising line of investigation for cerebral protection is the role for 3-hydroxy-3-methyl-glutaryl coenzyme–A (HMG CoA) reductase inhibitors (eg, statins).With evidence accruing that statins not only have a lowering effect on LDL cholesterol but also present pleiotropic and neuroprotective effects, evidence for stroke reduction is accumulating. Currently statins are thought to possess antiatherosclerotic properties, increase plaque stability, and exert favorable effects on inflammation, vasomotor function, local fibrinolysis, and platelet activity.[360–363] A prospective single-center study to determine predictive factors for postoperative stroke in 810 CABG patients found that preoperative statins were cerebroprotective (OR, 0.24; 95% CI, 0.07–0.78).[364] A small trial combining high-dose statins with high-dose angiotensin-converting enzyme inhibitors compared with standard dosing found an intraoperative reduction in proinflammatory mediators and normalization of postoperative myocardial scintigraphic ischemia scores in comparison with preoperative scores.[365] However, a single-center retrospective cohort study of 5121 CABG patients compared incidences of stroke, diagnosed by neurologists, and encephalopathy, defined as seizures, decreased level of arousal, delirium, or mental state change after 24 hours after CABG until hospital discharge. They could not reproduce these results and found no difference in stroke/encephalopathy between statin users and nonusers (propensity adjusted OR, 0.96; 95% CI, 0.78–1.17).[366] Perhaps, there is a strong dose-effect relationship that needs further elucidation.

Another plausible mechanism for statin-induced neuroprotection could be the prevention of POAF, possibly inflammation induced, leading to less postoperative stroke. A best evidence–based report reviewed 445 papers of which 12 represented best evidence,[367] and among which was a systematic review including 91,491 patients.[368] The reviewers found that preoperative statin therapy in patients undergoing elective cardiac surgery is associated with (1) lower incidence and risk of developing POAF, (2) reduced stroke rate, (3) shorter hospital stay, and (4) reduced levels of inflammatory markers postoperatively. However, again, the optimal duration, dose, and type of statin could not be concluded from this review.[367] Another recent study performed a post hoc analysis of 1509 patients with mild to moderate aortic stenosis randomized to receive simvastatin and ezetimibe versus placebo. These researchers found that the combined statin therapy did not lower the risk of stroke before or after AVR (429 patients).[369] However, it is likely that the mechanism for perioperative stroke in AVR is different from that of CABG-induced stroke. Taken together, these studies seem to indicate that therapies associated with decreased platelet functionality and lowered inflammatory and sympathetic responses appear to be associated with decreased incidence of stroke and adverse CNS events.

A large multicenter trial on the intraoperative use of dexamethasone in 4494 cardiac surgical patients found no difference in the incidence of postoperative stroke (dexamethasone 1.3% vs placebo 1.4%).[370] A preplanned substudy of this trial followed 291 patients for postoperative cognitive decline. A 1-month POCD incidence of 13.6% in the dexamethasone group versus 7.2% in the placebo group was reported. At 12 months the incidence had declined to 7.0% versus 3.5%.[371] Another substudy on the incidence and duration of delirium in the first 4 days after surgery did not demonstrate a difference

between dexamethasone (14.2%) and placebo (14.7%).[372] Therefore, blunt systemic inhibition of inflammation does not seem to provide protection of the brain in cardiac surgery.

Several preliminary studies had suggested that intraoperative administration of lidocaine infusion during cardiac surgery was associated with a decreased incidence of postoperative cognitive dysfunction.[73,373] However, in prospective randomized trials this was not demonstrated.[374,375] In view of these divergent results, whether lidocaine infusion will have any further role as a cerebroprotectant remains uncertain.[376] Recently, Mathew and colleagues reported on the effects of magnesium infusion on postoperative neurocognitive decline in a RCT of 389 patients undergoing cardiac surgery and found no difference between intraoperative magnesium versus placebo at 6 weeks after surgery.[377]

A large trial of perioperative nimodipine in valve replacement surgery had to be terminated prematurely after enrollment of only 150 of 400 patients because of a significant increase in major bleeding and an increased mortality in the 6-month follow-up period.[378] Also, there was no beneficial effect on the incidence of new neurologic deficits. A Cochrane review on calcium antagonists in ischemic stroke also failed to find a beneficial effect.[379]

More promising is the evidence on NMDA receptor antagonists. Since focal cerebral ischemia causes release of excitatory amino acid neurotransmitters, especially glutamate, this results in overstimulation of receptors and downstream pathways, leading to irreversible ischemic damage. A prospective trial on remacemide versus placebo given 4 days prior to surgery until 5 days after surgery resulted in less neurocognitive decline and better learning ability at 8 weeks after surgery.[380] A Cochrane review studied the effect of excitatory amino acid antagonist on patients with acute stroke but failed to find a difference between treatment and control groups and even found a trend toward increased mortality with certain NMDA receptor antagonists.[381] Therefore, it seems too early to draw any firm conclusions.

Piracetam, a nootropic compound that modulates cerebral functions by directly enhancing cognitive processes, has also been subjected to three small trials in cardiac surgery. Although end points were different, they all found a beneficial effect of piracetam infusions (short-term neuroprotective effect, less neurocognitive dysfunction at 6 weeks, less early neurocognitive decline).[382] Perhaps this could be one of few medications actually improving neurologic outcome, although larger trials are needed for confirmation.

Theoretically, volatile anesthetics and nonvolatile xenon possess neuroprotective effects as well. There is experimental evidence for increased perfusion of ischemic areas, decreased cerebral metabolism, inhibition of glutamate receptor activity and neurotransmitter activity, inhibition of ion channels thereby preventing pathologic calcium or sodium influx, reduction of injurious oxidative stress, maintenance of mitochondrial function, and inhibition of apoptosis.[383] However, apart from an abundance of animal data, clinical evidence is still scarce.[384] In cardiac surgery there is some evidence for better neurocognitive outcome or organ dysfunction (sevoflurane, desflurane, isoflurane, xenon),[385–388] but other studies failed to find such differences.[389] According to clinicaltrials.gov, more trials are currently investigating the neuroprotective effects of anesthetics, and it is hoped they will provide more insight in the coming years.

Although these results suggest that there is as yet no pharmacologic magic bullet that can be used to reduce neurologic injury in patients undergoing cardiac surgery, a combination of technical and pharmacologic measures is currently available that might positively affect the CNS outcomes of these patients.[390] In patients identified as being at risk for perioperative cerebral injury, preventive measures (as outlined in Box 40.4) should be instituted with organ-targeted management to guide the whole intraoperative and postoperative period. A multidisciplinary group of physicians, epidemiologists, and perfusionists set out to develop an evidence-based review of practice of CPB in adults, focusing on neurologic injury, glycemic control, hemodilution, and inflammatory response.[390] They summarized these measures as neurologic protection by means of:

- the use of alpha-stat pH management during moderate hypothermic CPB,
- avoidance of cerebral hyperthermia by limiting arterial line temperature to 37°C,
- avoidance of direct reinfusion of unprocessed cardiotomy suction blood by use of blood cell processing and secondary filtration,
- intraoperative TEE or epiaortic ultrasonographic EAS in all patients,
- use of arterial line filters to minimize embolic load,
- maintenance of euglycemia,
- reduction of CPB circuit area and use of biocompatible surface-modified circuits, and
- reduced hemodilution to avoid subsequent allogeneic blood transfusion.

Further recommendations would include monitoring cerebral venous outflow pressure via proximal jugular venous pressure, avoidance of hypotension, and the use of tepid rather than normothermic perfusion during CPB. As the age and incidence of comorbid disease in the cardiac surgical population continue to increase, the importance of these issues becomes ever more acute. In summary, primary prevention continues to be the only effective measure to decrease the incidence of cerebral injury in patients undergoing cardiac surgical procedures.

Long-Term Complications and Management

MARTIN BIRCH, MD | MONICA I. LUPEI, MD | MICHAEL WALL, MD, FCCM | JULIA WEINKAUF, MD

KEY POINTS

1. After undergoing cardiac surgical procedures, patients usually follow a fairly predictable postoperative course: the hemodynamic sequelae of cardiopulmonary bypass abate; the patient is weaned from mechanical ventilation and extubated; and within 24 hours, most patients are discharged from the intensive care unit (ICU).
2. After undergoing cardiac operations, a small percentage of patients have complicated courses and prolonged stays in the ICU.
3. Patients with extended stays in the ICU have a higher-than-average mortality rate because of noncardiac organ dysfunction.
4. Anesthesiologists and intensivists caring for patients who have prolonged stays in the ICU and who have complex medical issues must take into account all organ systems when determining the correct diagnosis and prescribing appropriate treatment.
5. Meticulous attention to detail and the application of recent evidence-based treatments will result in improved survival in patients who have extended stays in the ICU.

This chapter focuses on the long-term complications and management of patients after cardiac surgery in the intensive care unit (ICU) and includes a discussion of specific infections observed in patients after surgery, the management of acute renal failure, and the role of nutritional support in the critically ill. The chapter also covers complications after newer surgical procedures such as transcatheter aortic valve replacement (TAVR), other minimally, invasive hybrid procedures, and long-term complications of ventricular assist devices (VADs) and extracorporeal membrane oxygenation (ECMO). Finally, this chapter concludes with an overview of the numerous ethical dilemmas that this technology has created for patients, families, and clinicians.

Infections After Cardiac Surgery

Device-Related Infections

Cardiac-Implanted Electronic Devices

As the number of cardiac-implanted electronic devices (CIEDs; eg, pacemakers, cardioverter defibrillators, cardiac resynchronization therapy) is gradually increasing, their complications, such as infections, are also increasing. CIED-related infections can be difficult to diagnose since echocardiography is less accurate and blood cultures are less sensitive than in endocarditis. Most of the patients exhibit nonspecific symptoms, and fewer than 10% of the patients develop septic shock.[1]

The incidence of CIED-related infections varies among studies from between 0.5% and 2.2%, with a twofold to fivefold increase in incidence after a revision.[1] One large National Hospital Discharge Survey conducted in the United States reported that CIED-related infections increased out of proportion to the number of implanted devices, probably because of the preponderance of patients with organ dysfunction and diabetes mellitus receiving CIEDs in recent years.[2] One high-volume center in the United States reported a CIED-related infection incidence of 1%; the risk factors for infection were device replacement, prior lead dislodgment, and more complex devices.[3] A large national database from Taiwan, which included more than 40,000 patients who were followed over 14 years, revealed that the incidence of CIED-related infections was 2.45 per 1000 CEID years.[4] This large study reported that CIED-related infections were more common in young men and in patients requiring replacement of the device, with the caveat that high-volume centers had a lower incidence of infection.[4] The increased number of prior complex procedures and the lack of antibiotic prophylaxis were the most consistent reported risk factors in other studies.[1] The most common pathogens identified across different studies were staphylococci and other gram-positive bacteria (68%–93%). All-cause mortality associated with CIED-related infection varied between 0% and 35%.[1]

The management of suspected CIED-related infections, including the number and sequence of blood cultures and antibiotic therapy, should be guided by the clinical severity (Table 41.1). The treatment recommendations for definite CIED-related infections include early removal of the entire system (ie, all leads and generator) along with appropriate antibiotic therapy.[1]

Ventricular Assist Devices

Left ventricular assist device (LVAD) driveline-related infections occur with an incidence up to 20% and commonly develop more than 30 days after implantation.[5] Infections in patients with LVADs are associated with increased hospitalization, frequent need for re-operation, increased risk of stroke, and delay in heart transplantation.[6] Some authors report a trend toward decreased survival in patients with an LVAD who develop infections.[7]

A multicenter study that included patients who received HeartWare VADs in the ADVANCE Bridge-to-Transplant Trial and the Continuous Access Protocol reported that driveline exit site infections occurred in 16.9% of patients and sepsis occurred in 17.2% of patients, commonly more than 30 days after implantation.[8] Patients with LVAD infections had a larger body mass index and frequently had a history of diabetes mellitus.[8] *Staphylococcus aureus* was the most common organism identified in patients with an LVAD and with sepsis complications.[8] A large multicenter study conducted in the United States revealed that risk factors for postcardiac surgery infection included postoperative red blood cell units transfused, longer duration of surgery, and

TABLE 41.1 Management of Cardiac-Implanted Electronic Devices–Related Infection With Lead or Endocarditis Involvement

Evidence of Severe Sepsis	*NO Evidence of Severe Sepsis*
Initial actions: 1. Conduct blood cultures testing twice within 1 hour. 2. Start empirical intravenous antimicrobial therapy within 1 hour, after blood cultures are tested. 3. Obtain an urgent echocardiographic scan within 24 hours.	*Initial actions:* 1. Blood cultures testing three different times (more than 6 hours apart) 2. Obtain an echocardiographic scan. 3. Follow blood culture and echocardiographic results.
Positive blood cultures and/or echocardiographic evidence of vegetations: 1. Remove system, and repeat echocardiographic scan. 2. If native cardiac structures are involved, then conduct 4 weeks of empirical antimicrobial therapy. 3. Extracardiac focus is a 6-week course of antibiotic therapy. 4. If it is a lead only infection, then consider a short course (2 weeks) of antibiotic therapy.	*NO positive blood cultures and/or echocardiographic evidence of vegetations:* 1. Review diagnosis, and repeat echocardiographic scan and blood cultures as clinically indicated. 2. If generator pocket infection signs are present, then consider 10–14 days of antibiotic treatment after the removal of the system.

Adapted from Sandoe JA, Barlow G, Chambers JB, et al. Guidelines for the diagnosis, prevention and management of implantable cardiac electronic device infection. Report of a joint Working Party project on behalf of the British Society for Antimicrobial Chemotherapy (BSAC, hot organization) British Heart Rhythm Society (BHRS), British Cardiovascular Society (BCS), British Heart Valve Society (BHVS) and British Society for Echocardiography (BSE). *J Antimicrob Chemother.* 2015;70(2):325–359.

transplant or VAD implantation.[9] The management of LVAD driveline-related infections potentially require driveline repositioning or LVAD exchange with antibiotic bead implantation and systemic antibiotic treatment.[5]

Intravascular Devices

Intravascular devices such as arterial, central venous, or pulmonary artery catheters are universally used in patients after cardiac surgery. Patients who have intravascular catheters often acquire bloodstream infections (BSIs), which are associated with prolonged hospitalization and increased risk of mortality.[10,11] Central line–associated BSI (CLABSI) is defined by the Centers for Disease Control and Prevention (CDC) as bacteremia not related to an infection at another site or two or more positive blood cultures with a common skin contaminant associated with signs and symptoms of infection. CLABSIs are prevalent worldwide, and the rate is almost fourfold higher internationally (7.6 per 1000 central-line days) than the national rate in the United States (2 per 1000 central-line days).[11,12] The CDC reported a significant reduction of CLASBI incidence in ICUs in the United States in the recent years: a 58% reduction from 2001 to 2009.[11] The risk of a BSI for arterial catheters is lower than the risk associated with noncoated, uncuffed, nontunneled short-term central vascular catheters (1.7 vs 2.7 per 1000 catheter days).[13] If arterial catheters are inserted using maximum barrier precautions, then a very low risk of BSIs (0.41 per 1000 catheter days) can be achieved.[14]

The recognized risks factors for the development of CLABSIs were prolonged hospitalization before catheter insertion, femoral and internal jugular catheterization, longer catheterization duration, neutropenia, use of total parenteral nutrition, extensive catheter manipulation, and reduced nurse-to-patient ratio.[15] A summary report by the National Healthcare Safety Network revealed that the majority of CLABSI cases were caused by gram-positive organisms (60%), including coagulase-negative staphylococci (34%), the *Enterococcus* species (16%), and *Staphylococcus aureus* (10%); approximately 18% of the reported CLABSI cases were attributable to gram-negative organisms (18%) and to the *Candida* species (12%).[16]

The prominent reduction of the CLASBI rate with the implementation of various prevention initiatives has prompted the development of many quality improvement initiatives with the goal to achieve a minimum-to-none CLABSI incidence.[11] The CDC published guidelines for the prevention of catheter-related infections (CRIs) in 2011.[17] The summary of the guidelines is presented in Box 41.1.

BOX 41.1 PREVENTION OF INTRAVASCULAR CATHETER–RELATED INFECTIONS

Central Venous Catheter Infection Prevention

- Use the subclavian site if possible, and avoid using the femoral site.
- Use ultrasound, if available, to reduce the number of imaging attempts.
- Use the catheter with the minimum number of lumens necessary.
- Use strict hand hygiene, skin preparation with an antiseptic, and full barrier precaution for insertion.
- Maintain aseptic technique through the insertion and care of the catheter.
- Regularly monitor the catheter insertion site for signs of infection.
- Use 2% chlorhexidine for daily skin cleansing.
- Do not routinely replace the catheter to prevent infection.
- Do not use guidewire to exchange the catheter in case of suspected infection.
- Remove the catheter when it is no longer necessary.

Arterial Catheters Infection Prevention

- In adults, radial, brachial, and dorsalis pedis are preferred over axillary and femoral sites.
- Use a minimum of cap, mask sterile gloves for arterial catheter insertion, and full barrier precautions for the femoral site.
- Replace the arterial catheter only when clinically indicated.
- Remove the arterial catheter when no longer necessary.

Adapted from O'Grady NP, Alexander M, Burns LA, et al. Guidelines for the prevention of intravascular catheter-related infections. *Am J Infect Control.* 2011;39(4 Suppl 1):S1–S34.

Sternal Wound Infections

The CDC classifies this surgical site infection as superficial or deep. Based on the CDC definition of a deep sternal wound infection (DSWI), this surgical site infection occurs within 30 to 90 days after a surgical procedure. The incision is dehiscent or deliberately opened, an association exists with fever or localized pain and tenderness, or an abscess has formed. The DSWI is an uncommon but serious complication after cardiac surgery that is associated with unfavorable morbidity and increased mortality.[18,19]

A large retrospective study from a single institution in Canada that included more than 30,000 patients after cardiac surgery reported an incidence of DSWI of 0.77%.[19] The mortality of the patients with DSWI (6.9%) was significantly higher than the mortality of the patients without DSWI (2.8%). The researchers identified old age, diabetes, previous stroke and transient ischemic attacks, congestive heart failure, and bilateral internal mammary artery grafts for the coronary artery bypass graft (CABG) procedure as risk factors for DSWI after cardiac surgery. Mechanical ventilation duration and ICU and hospital lengths of stay were longer in patients diagnosed with DSWI as compared with patients without DSWI. *Staphylococcus aureus* and gram-positive bacteria were the most common pathogens. A large multicenter study conducted in the United States revealed an incidence of 0.56% of DSWI.[9] Another prospective study revealed a DSWI incidence of 0.47% after CABG surgery with an associated in-hospital mortality rate of 9.1%.[20] The risk factors for DSWI after CABG surgery were female gender, hypertension, and reexploration for bleeding. A study conducted in Japan that included more than 73,000 patients revealed an incidence of DSWI of 1.8% after cardiac surgery, with an

TABLE 41.2 Modified Duke Criteria for Diagnosing Infective Endocarditis

Major Criteria	*Minor Criteria*
1. Two positive blood cultures with typical microorganisms collected at least 12 hours apart (or one positive blood culture for *Coxiella burnetii*)	1. Fever >38°C 2. Vascular phenomena (systemic emboli, Janeway lesions) 3. Immunologic phenomena (Osler nodes, Roth spots)
2. Evidence of endocardial involvement (new murmur, echocardiographic evidence of a cardiac mass, abscess, valve dehiscence)	4. Predisposition to infective endocarditis (previous infective endocarditis or intravenous drug abuse) 5. Microbiologic evidence that does not meet major criteria

Adapted from Thanavaro KL, Nixon JV. Endocarditis 2014: an update. *Heart Lung.* 2014;43(4): 334–337.

incidence of 2.8% after combined valve and CABG surgery and 3.4% after combined CABG and thoracic aortic surgery.[21] Diabetes mellitus was found to be a significant risk factor for DSWI, and the diagnosis was associated with increased mortality, especially when it coincided with reexploration and bleeding.

Another study reported that the incidence of surgical site infection after cardiac surgery decreased from over 8% to less than 2% after routine implementation of nasal mupirocin and preoperative chlorhexidine showering.[22] The recommended treatment for DSWI is adequate systemic antibiotic therapy, along with either surgical débridement with antibiotic irrigation and primary closure or sternotomy with flap reconstruction.[18]

Prosthetic Valve Endocarditis

The diagnosis of endocarditis requires a high level of clinical suspicion, considering that the clinical presentation is frequently nonspecific with fever, chills, fatigue, or weight loss. The modified Duke criteria are the gold standard for the infective endocarditis (IE) diagnosis: two major, one major and three minor, or five minor clinical criteria are required (Table 41.2).[23] Prosthetic valve IE can occur early (less than 1 year after valve replacement) or late (more than 1 year after surgery). The risk of IE was found to be 1% to 4% early after surgery, and 0.5% to 1% per patient year of prosthetic valve later after surgery.[24,25] The prosthetic valve and CIED-associated IE incidences has increased in recent years.[26,27] The reported risk was similar for mitral or aortic valve replacement (AVR), regardless of the type of prosthesis; however, it was higher if more than one valve was replaced (de Gevigney, Pop, and Delahaye, 1995).[28] *Staphylococcus aureus* was reported to be the most common pathogen in prosthetic valve IE (34%), followed by the *Streptococcus* species (23%), the *Enterococcus* species (19%), and coagulase-negative *Staphylococcus* (18%).[27] The gram-negative bacilli HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* species) accounted for 5% to 10% of cases of IE, and *Candida* species represented less than 1%.

Despite the low level of evidence regarding the benefit of antibiotic prophylaxis in the prevention of IE, the current recommendation remains that all patients with prosthetic valves receive antibiotic prophylaxis before dental or surgical procedures.[23] Because echocardiography can be inconclusive in cases of prosthetic endocarditis, new evidence has revealed that a positron emission tomography/computed tomography (PET/CT) scan might be a better option for prosthetic- and CIED-related endocarditis diagnoses.[29] Evidence also suggests that antibiotic treatment decreases the risk of stroke after IE.[30] Based upon current guidelines of the American College of Cardiology and the American Heart Association (ACC/AHA), surgery is indicated in prosthetic valve–related IE, resulting in hemodynamic instability, heart failure, or valvular complications such as dysfunction or dehiscence, obstruction or regurgitation, and abscess or fistula formation, but it is not indicated in uncomplicated cases.[31] A review of 17 studies showed that surgery improves survival and is the treatment of choice for prosthetic valve–related IE, especially if caused by *Staphylococcus aureus*.[32] The authors of the review also suggested performing surgery for prosthetic valve–related IE treatment before the development of cerebral complications (Box 41.2).[27,31]

BOX 41.2 INDICATIONS FOR SURGERY IN PROSTHETIC VALVE INFECTIVE ENDOCARDITIS

- Surgery is indicated for aortic or mitral valve infective endocarditis (IE) complicated with severe regurgitation or obstruction or heart failure or hemodynamic instability.
- Surgery is also indicated for locally uncontrolled infection (eg, abscess, false aneurysm, fistula, enlarging vegetation).
- Surgery should be considered for persistent fever and positive blood cultures for longer than 7 to 10 days or infection caused by fungi or multiresistant organisms (*Serratia marcescens, Pseudomonas* species).
- Surgery is possibly indicated for IE with large vegetation (>10 mm) after one or more embolic episodes, despite appropriate antibiotic therapy or associated with complicated clinical course (eg, heart failure, persistent infection, abscess); or for IE with very large vegetation (>15 mm).
- Surgery is commonly indicated for IE caused by *Staphylococcus* species because the clinical course might be particularly severe with perivalvular abscess and valve dehiscence formation.

Systemic Inflammatory Response Syndrome and Sepsis

Systemic inflammatory response syndrome (SIRS) and sepsis are clinical entities initially defined at the American College of Chest Physicians and the Society of Critical Care Medicine Consensus Conference in 1992,[33] and the definitions were updated in 2001 at the International Sepsis Definition Conference.[34] Box 41.3 summarizes the diagnostic criteria for sepsis as described in the International Guidelines for Management of Severe Sepsis and Septic Shock published in 2013.[35]

The number of sepsis cases reported in the United States exceeds 750,000 per year, of which 50% were treated in ICUs.[36] Up to 15 and 19 million new sepsis cases per year were estimated to develop worldwide each year.[37] Most studies have reported that sepsis mortality remained high over time, and septic shock accounted for the highest mortality approaching 50%.[38–40] Recent epidemiologic evidence showed improvement in outcomes with a 57% reduction in sepsis mortality from 1988 and 1989 to 2010 through 2012.[41] Although some studies conducted in the early 2000s revealed the preponderance of gram-positive bacteria in sepsis, the most recent European Prevalence of Infection in Intensive Care (EPIC II) study reported gram-negative organisms were isolated in 62%, gram-positive bacteria in 47%, and fungi in 19% of cases.[39,42]

Some authors report that infections are the most common noncardiac complication after cardiac surgery.[43,44] Sepsis accounted for 20% of the infection cases in a large multicenter study.[44] Hospital costs, lengths of stay, and readmissions were significantly associated with hospital-acquired infections after cardiac surgery. Another large prospective study revealed that nearly 5% of the patients were diagnosed with major infections (eg, DSWI, mediastinitis, infectious myocarditis or pericarditis, endocarditis, cardiac device infection, pneumonia, empyema, *Clostridium difficile* colitis, BSI) after cardiac surgery.[43] The risk factors associated with increased infections were chronic lung disease, heart failure, long surgery, emergent surgery, prolonged mechanical ventilation, and postoperative antibiotic administration for longer than 48 hours.[43] Major infections significantly increased the mortality rate after cardiac surgery.

Considering the high mortality and morbidity risk of sepsis, a group of experts representing numerous international organizations

BOX 41.3 DIAGNOSTIC CRITERIA FOR SEPSIS

Infection Documented or Suspected With Some of the Following Criteria

General Variables
Fever
Hypothermia
Tachycardia
Tachypnea
Altered mental status
Positive fluid balance
Hyperglycemia in the absence of diabetes

Inflammatory Variables
Leukocytosis
Leucopenia
Greater than 10% immature leucocytes
Increased plasma C-reactive protein
Increase plasma procalcitonin

Hemodynamic Variables
Arterial hypotension

Organ Dysfunction Variables
Hypoxemia
Oliguria
Creatinine increase
Coagulation abnormalities
Ileus
Hyperbilirubinemia

Tissue Perfusion Variables
Increased lactic acid
Decreased capillary refill

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving Sepsis Campaign Guidelines Committee including the Pediatric Subgroup. *Crit Care Med.* 2013;41(2):580–637.

BOX 41.4 SUMMARY OF THE SURVIVING SEPSIS CAMPAIGN GUIDELINES

- Routine screening of patients who are potentially infected and seriously ill is recommended for severe sepsis.
- Protocolized resuscitation of patients with hypoperfusion should be initiated during the first 6 hours of recognizing septic shock.
- Effective intravenous antimicrobials should be administrated within the first hour of recognizing severe sepsis or septic shock, ideally after culture collection.
- Crystalloids should be the initial fluid of choice in the resuscitation of severe sepsis and septic shock. Albumin may be added when substantial amount of crystalloids are needed.
- Norepinephrine should be the first vasopressor of choice. Epinephrine may be added when an additional agent is needed.
- Hydrocortisone is not indicated if fluid therapy and vasopressor restores hemodynamic stability. If hemodynamic stability is not achievable, then 200 mg daily hydrocortisone might be beneficial.
- Empiric antibiotic combination therapy should not be administered for more than 3 to 5 days. De-escalation to the appropriate single therapy should be performed when available.
- The typical antibiotic therapy duration should be 7 to 10 days.
- Glucose management in the ICU to maintain glycemia <180 mg/dL is indicated.
- Transfusion is indicated only for hemoglobin levels less than 7 g/dL (with a goal range of 7–9 g/dL) unless severe hypoxemia, myocardial ischemia, coronary artery disease, or acute hemorrhage is present.

Adapted from Dellinger RP, Levy MM, Rhodes A, et al. Surviving Sepsis Campaign Guidelines Committee including the Pediatric Subgroup. *Crit Care Med.* 2013;41(2):580–637.

launched the Surviving Sepsis Campaign (SSC) and published guidelines in 2003, which were updated in 2012.[35] Emerging evidence regarding sepsis management and some of the SSC guidelines have been continually challenged since their publication in 2012. A large multicenter study comparing the protocol-based early septic shock therapy with the standard of care revealed no difference in mortality.[45] Of note, the mortality in all arms ranged from 18% to 21%, substantially lower than historically reported and probably related to the overall improvement of sepsis care.[46] A recent multicenter open-label trial readdressed the question of crystalloid versus albumin use in the treatment of severe sepsis and found no difference in mortality.[47] The SSC guidelines are outlined in Box 41.4.

Pneumonia

Pneumonia is a difficult diagnosis to make in patients after cardiac surgery because the typical radiographic signs might be confused with postsurgical changes. A study that evaluated autopsy-proven pneumonia in patients who were mechanically ventilated concluded that no single radiographic sign with diagnostic accuracy greater than 68% was recognized.[48] The clinical pulmonary infections score (CPIS) is based on six clinical signs, each worth between 0 and 2 points (Table 41.3).[49] A CPIS greater than or equal to 6 was the threshold that accurately identified the patients with pneumonia in one study,[49] but other authors challenged CPIS specificity.[50] The National Nosocomial Infection Surveillance (NNIS) system was developed in the 1970s by the CDC to provide definitions suitable for interhospital comparison.[51] The NNIS system's definition of pneumonia comprises physiologic, radiologic, and laboratory data including quantitative bronchoalveolar lavage (>10^4 colony-forming units per milliliter [CFU/mL]) and protective specimen brushing (>10^3 CFU/mL). A systematic review of 159

articles concluded that the bacteriologic criteria did not improve the accuracy of the diagnosis of ventilator-associated pneumonia (VAP), as compared with the clinical assessment.[52]

Pneumonia is an important complication after cardiac surgery. A multicenter study revealed that pneumonia represented 48% of hospital-acquired infections in patients who underwent cardiac surgery.[44] Another large study reported an incidence of 2.38% among patients who underwent cardiac surgery.[43] A large European study revealed that the history of chronic obstructive lung disease was significantly

associated with respiratory infection after cardiac surgery.[53] One study reported that pneumonia was the most common infection in patients who required blood transfusions after cardiac surgery.[9]

Approximately 5.5% of patients require prolonged mechanical ventilation after cardiac surgery.[54] Considering the increased mortality and health care costs related to VAP, the Institute for Healthcare Improvement (IHI) recommends the use of a five-component ventilator bundle, which has been associated with a lower incidence of VAP: (1) head of the bed elevation, (2) daily sedation interruption and spontaneous breathing trials, (3) peptic ulcer disease prophylaxis, (4) deep vein thrombosis (DVT) prophylaxis, and (5) daily oral care with chlorhexidine. A single-center study revealed that the implementation of four preventative measures (some of the IHI recommended bundle along with subglottic secretion aspiration) was associated with a decreased incidence of VAP in patients after cardiac surgery.[55] A systematic review concluded that no evidence supports the contention that quantitative cultures of respiratory secretions improved outcomes when compared with qualitative cultures in patients with hospital-acquired pneumonia.[56] Another systematic review of eight studies that included 1703 patients concluded that a short course (7 or 8 days) of antibiotic treatment might be more appropriate than a prolonged course for VAP treatment not attributable to nonfermenting gram-negative bacilli.[57]

Urinary Tract Infection

Urinary tract infection (UTI) is one of the most common hospital-acquired infections and accounts for 4.4% of infections after cardiac surgery.[53,57] Diabetes mellitus and advanced age are associated with increased incidences of UTI in patients after cardiac surgery. Bacteriuria rapidly develops in patients with a urinary catheter, with an average of 3% to 10% per day of catheterization.[58] The incidence of UTI diagnosed in ICUs in a large single-center study was 9%, out of which only 0.4% developed UTI-associated bacteremia or fungemia.[57] Bacteriuria is frequently asymptomatic (approximately 90% of the cases), and therefore the diagnosis of UTI is primarily clinical.[58,59] Traditional diagnostic criteria for UTI include the presence of pyuria and great than 10^5 CFU/mL urine. UTI treatment is not indicated unless laboratory data are associated with clinical signs and symptoms of infection (eg, temperature >38°C, urgency, frequency, dysuria, suprapubic tenderness). Because 80% of UTIs are attributable to the presence of an indwelling catheter, the removal of unnecessary catheters is recommended (Nicolle, 2008).[60]

Clostridium difficile Colitis

Clostridium difficile is a gram-positive, spore-forming, anaerobic rod rarely found in healthy adults (5%–15%). Colonization with *Clostridium difficile* can occur after treatment with any antibiotic and is due to alteration of normal flora. The spread is via the fecal oral route.[61,62] The spectrum of *Clostridium difficile* infection is wide: from antibiotic-associated diarrhea to antibiotic-associated colitis or antibiotic-associated pseudomembranous colitis.[63] The clinical presentation varies from low-grade fever, leukocytosis, and watery diarrhea (10 to 15 bowel movements per day) to toxic megacolon.

The risk factors associated with *Clostridium difficile* infection are prolonged antibiotic treatment, the use of proton pump inhibitors, older age, severe underlying disease, immunosuppression, or inflammatory bowel disease.[64,65] A hypervirulent *Clostridium difficile* strain that produces high levels of toxins has been associated with very severe disease outbreaks in several hospitals in North America and Europe.[66] A large, multicenter, observational study revealed that *Clostridium difficile* infection accounted for 18% of the hospital-acquired infections after cardiac surgery.[44]

The diagnosis of *Clostridium difficile* colitis is suggested by the presence of fecal leukocytes, signs of SIRS, and persistent diarrhea, despite a discontinuation of enteral feeding with carbohydrates that might cause watery diarrhea. The enzyme immunoassay tests for toxins A and B were widely used in the past but have relatively poor sensitivity and specificity.[65] The most sensitive and specific tests for *Clostridium difficile* are nucleic acid amplification tests; for instance, the polymerase chain reaction (PCR) test detects the toxins genes, but even this test might give false-negative results.[65,67]

The treatment of *Clostridium difficile* colitis is based on its severity. For mild-to-moderate disease, metronidazole, 500 mg, taken daily three times orally for 10 days is recommended, whereas for severe disease, vancomycin, 125 mg, administered daily four times orally for 10 days is recommended.[65,68] Vancomycin orally plus metronidazole intravenously is recommended for severe and complicated disease. Vancomycin enema might be a useful alternative or an additional treatment, especially in patients with ileus or toxic megacolon. Surgical treatment should be considered in severe and complicated *Clostridium difficile* colitis with septic shock and severe sepsis.[68] For recurrent *Clostridium difficile* infection, fecal microbiota transplant might be considered as an alternative for a pulsed, prolonged vancomycin regimen.[65,68] Health care personnel and visitors entering the room of any patient with known or suspected *Clostridium difficile* infection should use hand hygiene and barrier precautions.

Acute Kidney Injury

Acute kidney injury (AKI) is a frequent and potentially devastating complication after cardiac surgery. When severe, dialysis may be necessary. Risk factors are multiple, and the etiology and pathogenesis is complex and only incompletely understood. Multiple preventative strategies have been tried. Unfortunately, the benefit is unclear, especially pharmacologic prevention. After the onset of AKI, multiple therapeutic interventions also have been tried, and these, too, have been mostly unsuccessful. The purpose of this section is to describe briefly the incidence of and risk factors for the development of AKI, as well as the pathophysiologic mechanisms underlying this complication. Additionally, preventative strategies and potential treatments of AKI and the decision-making process concerning dialysis initiation are reviewed.

Incidence of and Risk Factors for Cardiac Surgery–Associated Acute Kidney Injury

The incidence of cardiac surgery–associated AKI (CSA-AKI) is difficult to delineate, because it changes with the definition of AKI and differs for different surgical procedures. The consequences of CSA-AKI are severe. Mortality after routine CABG surgery can increase from less than 1% to 20% when moderate AKI develops. If dialysis is required, then mortality can exceed 50%. Additionally, costs dramatically increase.[69,70] Over the past several years, attempts have been made to standardize the definition of AKI, starting with the introduction of the Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Renal Disease (RIFLE) criteria in 2004.[71] The RIFLE criteria scored acute renal dysfunction according to increases in creatinine (Cr) concentration, decreases in glomerular filtration rate (GFR), or oliguria over the course of 7 days or less. Loss and failure were defined, based on the required length of renal replacement therapy (RRT) (Tables 41.4 through 41.6 compare various criteria.) Three years later the Acute Kidney Injury Network (AKIN) refined the RIFLE criteria by removing the loss of kidney function, the end-stage renal disease criteria, and the GFR criteria, and then adding the initiation of RRT to the definition of stage 3 AKI.[72] In 2012, the Kidney Disease Improving Global Outcomes (KDIGO) criteria were published, which are similar to the AKIN criteria.[73] The incidence of CSA-AKI can vary from approximately 9% to 40%, depending on the definition used and the procedure performed. Although more carefully defining AKI is an enormous advance, Cr-based criteria are problematic. Cr typically rises approximately 48 hours after the inciting injury, cardiopulmonary bypass (CPB) prime dilution may falsely lower Cr levels, and urine output criteria can be unreliable (Gaffney and Sladen, 2015).[74] Novel biomarkers (see the following text under "Biomarkers") may help with an earlier diagnosis.

TABLE 41.4 RIFLE Criteria

	Glomerular Filtration Rate Criteria	*Urine Output Criteria*
Risk	1.5 × increase in baseline Cr or GFR decrease by 25%	UO <0.5 cc/kg/hr × 6 hours
Injury	2 × increase in baseline Cr or GFR decrease by 50%	UO <0.5 cc/kg/hr × 12 hours
Failure	3 × increase in baseline Cr or Cr >4 or GFR decrease by 75%	UO <0.3 cc/kg/hr × 24 hours or anuria
Loss	Persistent ARF: Complete loss of renal function >4 weeks	
ESRD	End-stage renal disease

From http://kdigo.org/home/guidelines/acute-kidney-injury/

Patient risk factors are well studied. They include advanced age, female gender, chronic obstructive pulmonary disease (COPD), diabetes, peripheral vascular disease, congestive heart failure (CHF), baseline renal insufficiency, cardiogenic shock, need for emergent surgery, and left main coronary artery disease. Procedural risk factors include CPB time, aortic cross-clamp time, transfusion requirements, valvular surgery, combined procedures, and on-pump versus off-pump procedures.[69,75,76]

Biomarkers

The search for early biomarkers of CSA-AKI is intense because of the problems associated with traditional clinical criteria. Multiple biomarkers have been studied and show promise. The most frequently studied are neutrophil gelatinase–associated lipocalin (NGAL) and plasma cystatin C levels. NGAL is derived from tubular epithelial cells, and gene expression is upregulated early in the course of AKI.[74] The utility of NGAL as an early biomarker for CSA-AKI has been confirmed in multiple studies. A systematic review performed by Haase-Fielitz and associates[77] confirmed quite good receiver-operating characteristics, with an area under the curve of >0.8.

Plasma cystatin C levels quickly increase after a decrease in GFR, and these levels are potentially a useful biomarker of CSA-AKI. Additionally, an elevated preoperative cystatin C level plus preoperative proteinuria are associated with multiple risk factors and the development of CSA-AKI.[74]

Etiology and Pathogenesis

Multiple perioperative insults lead to the development of CSA-AKI, and it is unlikely that one particular insult is the primary causative factor. Preoperative hemodynamic instability coupled with the administration of nephrotoxins, such as intravenous contrast dye, is an early insult. During CPB, blood loss and transfusion, atheroembolism, and further hemodynamic instability add further injury. After CPB, hemodynamic instability is not uncommon, and insults can continue if complications such as infections and sepsis occur. The renal medulla is exceptionally prone to hypoxemia and, even under normal conditions, has a very low tissue oxygen tension. The oxygen tension becomes virtually undetectable during CPB.[70] Additionally, CPB aggravates systemic inflammation, leading to cytokine-mediated renal injury.[69]

Prevention

Unfortunately, many of the risk factors for and injuries that cause CSA-AKI are not modifiable. Although some are, they are generally surgical in nature. Careful and timely surgery, with shorter CPB and cross clamp times, will lead to lower rates of renal injury. Less bleeding with fewer transfusions will also be renoprotective. The ACC/AHA Guidelines recommend potentially delaying surgery in patients with preexisting renal dysfunction until the effects of contrast can be assessed.[78]

Multiple pharmacologic agents have been studied. Some show promise, whereas others demonstrate futility. A metaanalysis of six small randomized controlled trials demonstrated some potential efficacy for fenoldopam, a selective dopamine$_1$–receptor agonist. Although the risk of AKI was lower, there was more hypotension and a greater need for a vasoactive medication was observed. The need for RRT, mortality, and length of stay were all unchanged.[79]

Natriuretic peptides show promise for potential pharmacologic renoprotection. Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) create a favorable physiologic environment by decreasing renin-angiotensin-aldosterone system activation, which increases renal vasodilation, improves diuresis, and helps avoid or reduce the use of loop diuretic agents.[69] Two trials have shown efficacy for ANP infusions during cardiac surgery.[80,81]

Sodium bicarbonate has failed to show a renoprotective benefit. Two recent randomized controlled trials failed to show efficacy.[82,83] Turner and colleagues[83] randomized 120 patients to receive either a sodium chloride infusion or a sodium bicarbonate infusion starting before CPB and ending the day after surgery. The trial was stopped early after the first interim analysis showed no efficacy. A similar study was conducted by Haase and associates,[82] although the sample size was larger (350 patients). Not only did sodium bicarbonate provide no benefit, but mortality in the group that received sodium bicarbonate was significantly higher (6.3% vs 1.7%). Based on these data, bicarbonate cannot be recommended.

N-Acetylcysteine has been studied multiple times. The results are conflicting, but two metaanalyses failed to demonstrate efficacy.[84,85]

Treatment

Unfortunately, there is no treatment for CSA-AKI once it occurs. The best practice is to optimize hemodynamics, avoid nephrotoxins, and hope that renal function recovers. If renal function does not recover or if it worsens, then the patient may require dialysis. Standard indications for dialysis initiation are presented in Box 41.5.

Determining when renal replacement should be initiated is not always clear. Additionally, it is not precisely clear what determines *early* or *late* initiation, as the periods defining these terms greatly vary from study to study. Although the evidence is difficult to sort through and

BOX 41.5 INDICATIONS FOR RENAL REPLACEMENT THERAPY

Uremia
Hyperkalemia that cannot be medically managed
Significant volume overload unresponsive to diuretics
Severe metabolic acidosis
Removal of dialyzable toxins

Adapted from Liu Y, Davari-Farid S, Arora P, et al. Early versus late initiation of renal replacement therapy in critically ill patients with acute kidney injury after cardiac surgery: a systematic review and meta-analysis. *J Cardiothorac Vasc Anesth.* 2014;28(3):557–563.

remains an area of great controversy and ongoing research, it appears that initiating RRT *early* in the course of oliguric AKI not responsive to diuretic medications improves outcomes.[86]

RRT can be prescribed in two basic ways, continuous or intermittent. Each has its own advantages and disadvantages. Continuous therapy provides greater hemodynamic stability and the ability for more controlled and well-tolerated fluid removal, whereas intermittent treatment has the ability to clear blood of harmful electrolytes or toxins more quickly. No data are available that clearly demonstrates the superiority of one technique over the other. Continuous RRT can usually be changed to intermittent therapy after a period of relative hemodynamic stability and when the ability to manage volume status improves.

No evidence-based criteria exist for the cessation of RRT. Cessation depends on multiple criteria, such as the return of renal function and increased urine output, the ability to manage volume status without RRT, the risk outweighs the benefit, or potential medical futility in the moribund patient.[87]

Nutritional Support

Nutritional support is an increasingly important part of intensive care. To care for patients' nutritional needs appropriately, several questions must be answered. Who should receive nutritional support? What is their baseline nutritional status? When should nutrition start? What should be fed to them, and via which route should they be fed? How much should be fed to them, and how should that amount be determined? The questions are straightforward, as are some of the answers. However, some answers are complicated, and the literature is large and not always consistent. The purpose of this section is to briefly answer these questions and to provide information how best to provide nutritional care.

Who Should Receive Nutritional Support?

Which patient should receive nutritional support is intimately tied to his or her baseline nutritional status and illness severity, which is discussed more thoroughly in the text that follows. Both the American Society of Parenteral and Enteral Nutrition (ASPEN) and the European Society for Clinical Nutrition and Metabolism (ESPEN) recommend enteral nutritional support for all critically ill patients who cannot meet metabolic requirements on their own, although the level of evidence is not strong. The rationale is multifactorial (the level of recommendation is grade C in both guidelines).[88,89] Enteral nutrition maintains gut integrity and may help prevent the increased permeability associated with bacterial translocation and the potential development of multiorgan dysfunction syndrome.[90] The immune response is also modulated, decreasing the inflammatory response, and oxidative stress and insulin resistance are decreased.[91] Additionally, a nutritional deficit develops early in the course of critical illness and may be attenuated by early initiation of enteral support.[92,93]

Nutritional Assessment

Not all critically ill patients benefit to the same degree from nutritional support. Patients who are sicker with prior malnutrition and those expected to spend considerable time in the ICU will more likely benefit from early support than patients who are less sick with normal or mild nutritional derangements and who are expected to have a relatively short length of stay in the ICU.[91] Both the ASPEN and the ESPEN recommend a nutrition assessment for all patients who are hospitalized. Although the level of evidence is low (level E in the ASPEN Clinical Guidelines), the rationale is that malnutrition is frequently found and that patients who are malnourished have more complications, more infections, longer lengths of stay, and higher mortality.[88,94] Additionally, nutritional status rapidly declines in critically ill patients. Losses of body protein can be as high as 1 to 2 kg in 10 days.[92] Multiple nutritional assessment tools have been published, although many look only at nutritional status, and not disease severity, and have not been validated in the ICU.[95]

In contradistinction to many tools, the Nutrition Risk Screening (NRS) 2002 was developed to account for both baseline nutritional status and illness severity. The NRS 2002 was developed by an ESPEN working group. By analyzing data from multiple retrospective studies, they developed an assessment tool based on a relationship between clinical outcome and nutritional intervention, finding who benefitted from nutritional intervention. The tool was then validated against 128 controlled trials that demonstrated clinical benefit from nutritional intervention.[95] ESPEN now recommends nutritional assessment with the NRS 2002.[96] The score is determined by three components. First, baseline nutritional status is determined, and then, disease severity is ascertained. Both are scored from 0 to 3. The two scores are added together, and an extra point is added for age older than 70 years. If the total score is greater than 3, then the patient is at high nutritional risk, and an intervention should be developed (Table 41.7 demonstrates NRS 2002 scoring.)

Heyland and colleagues[97] developed the Nutrition Risk in the Critically Ill (NUTRIC) score specifically for patients in the ICU. They prospectively collected data about variables that measured the degree of malnutrition, illness severity, and markers of inflammation such as C-reactive protein. The addition of inflammatory markers was important. Critically ill patients are exceptionally stressed and catabolic. This state likely arises from the cytokine and hormonal milieu characteristic of critically ill patients.[98] A complex multivariable regression determined which variables were most important and developed a score based on those variables. The total score can be as high as 10; the higher the score, the greater the risk of 28 day mortality. Variables include age, Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) II score, baseline Sequential Organ Failure Assessment (SOFA) score, number of comorbidities, the number of days in the hospital before ICU admission, and interleukin 6 (IL-6) levels.[97] The NUTRIC score was internally well validated but may have limited use, as some its components (IL-6 level) are not routinely measured.

When Should Nutrition Be Initiated?

ASPEN, ESPEN, and the Canadian Critical Care Nutrition Guidelines all recommend that enteral nutrition should start within 24 hours of ICU admission. The recommendations were based on multiple clinical trials, during which the preponderance of evidence clearly suggested that overall nutrition was improved, ventilator-free days were increased, infection rate was lower, and the trend toward mortality was reduced. There were no differences in ICU lengths of stay.[89,96]

Although the reasons for initiating early enteral nutrition are well known, physicians have considered hemodynamic instability, which requires vasopressor support, a potential contraindication to early enteral nutrition because enteral nutrition increases the metabolic demand of the small intestine. An increase in splanchnic blood flow is required to meet this demand, and the demand may be greater than can be supplied by an unstable patient, causing bowel ischemia.

TABLE 41.7 Nutritional Risk Screening 2002 (ESPEN Guidelines)

Impaired Nutritional Status		*Severity of Disease (Approximate Increase in Requirements)*	
Mild Score 1	Weight loss >5% in 3 months or Food intake <50%–75% of normal requirement during the preceding week	Mild Score 1	Hip fracture Chronic illness, in particular, with acute complications, such as cirrhosis, COPD Chronic hemodialysis, diabetes, cancer
Moderate Score 2	Weight loss >5% in 2 months or BMI 18.5–20.5 + impaired general condition or Food intake 25%–50% of normal requirement during the preceding week	Moderate Score 2	Major abdominal surgery Stroke Severe pneumonia, hematologic malignancy
Severe Score 3	Weight loss >5% in 1 month (approximately >5% in 3 months) or BMI <18.5 + impaired general condition or Food intake 0%–25% of normal requirement during the preceding week	Severe Score 3	Head injury Bone marrow transplantation In intensive care unit (APACHE410)
Score: +		Score: = Total Score

Additionally, even if splanchnic flow can increase, it may be at the expense of blood flow to other organs.[99,100] Khalid and associates[101] conducted an analysis of prospectively collected data from 1174 patients who were hemodynamically unstable and mechanically ventilated for longer than 2 days to test the alternate hypothesis that early enteral nutrition may improve outcome. Patients who received enteral nutrition within 48 hours had a lower ICU (22.5% vs 28%) and hospital (34% and 44%) mortality rate. The sickest patients appeared to benefit the most. Although uncontrolled, the analysis provided evidence that early enteral nutrition in patients who are hemodynamically unstable is safe and probably beneficial. The Canadian Critical Care Nutrition Guidelines noted this potential benefit in the sickest patients. The ASPEN guidelines, which recommended withholding enteral nutrition from patients who were hemodynamically unstable, were published in 2009, before the publication of the Khalid study in 2010. Until the updated ASPEN guidelines are published, it remains unknown whether the recommendation will change.

Via Which Route Should Nutritional Support Be Given?

ASPEN, ESPEN, and the Canadian Critical Care Nutrition Guidelines all state that the enteral route is the preferred course. Parenteral nutrition should be given to patients who will likely be unable to receive enteral nutrition for a considerable period.[91] Parenteral nutrition is disadvantageous; morbidity and mortality associated with parenteral nutrition is increased. The studies are problematic in that differences in the amount of energy delivered to the parenteral and enteral groups are significant.[102] Increased energy delivery may be harmful early in the course of critical illness (see the following text). Randomized prospective data are most useful, and three studies have been recently published. The Early Parenteral Nutrition Completing Enteral Nutrition in Adult Critically Ill Patients (EPaNIC) study is the largest and demonstrated harm caused by the addition of early parenteral nutrition started on day 3, compared with late initiation on day 7.[103] Over 4000 patients were randomized. Patients in the early initiation group spent more time in the ICU, developed more new infections, spent more time on the ventilator, and had a longer duration of RRT if it was needed. Two other smaller randomized controlled trials by Heideggar and colleagues[104] and Doig and associates[105] did not show harm caused by the early use of parenteral nutrition; however, the net benefit was weak.

Gastrointestinal motility is compromised in critically ill patients, with up to 50% of patients displaying delayed gastric emptying.[106] Controversy exists as to whether the placement of a gastric or postpyloric feeding tube is superior. There are data that support the use of postpyloric feeding tubes, especially in relation to the ability to achieve nutritional goals and pneumonia rates.[107] However, postpyloric tube placement can be difficult to achieve. For these reasons, the Canadian Critical Care Nutrition Guidelines recommend placement of a postpyloric feeding tube for patients considered to be at high-risk for enteral nutrition intolerance, such as patients receiving vasoactive medications, continuous sedative medications, or neuromuscular blocking drugs, and patients with high gastric residual volumes.

What Should Nutritional Support Consist Of?

Multiple enteral formulas are available and are considered to be medical foods by the US Food and Drug Administration (FDA). As such, they are not as tightly regulated as pharmaceutical agents and are designed to meet the micronutrient and macronutrient requirements of patients.[108] The formulas may be subdivided in myriad ways, based on the macronutrient content (polymeric vs elemental or semielemental), caloric concentration, protein and electrolyte concentration, and fat content, among other factors. Choosing which formula to use depends on the patient and what is available at particular institutions.

Standard polymeric formulas are most common. They contain nonhydrolyzed carbohydrate, protein, and fat. They also contain the recommended dietary allowance (RDA) of most vitamins and minerals. Their concentration varies between 1 and 2 kcal/mL. Higher concentration formulas tend to be used when fluid restriction is important.[108] Renal formulas are similar to standard formulas but tend to contain less protein, potassium, and phosphorus. Renal formulas also are more concentrated, usually 1.5 to 2 kcal/mL. Critically ill patients requiring dialysis, especially continuous RRT, will need protein supplementation.

Fiber is frequently added to formulas, especially to prevent or treat diarrhea. The type of fiber can vary (soluble or insoluble), and the amount contained in commercial products is significantly less than the RDA for those with normal gut function. To meet the RDA, supplemental fiber needs to be added. The ASPEN guidelines make several specific recommendations regarding fiber. The guidelines recommend using soluble fiber in fully resuscitated critically ill patients with diarrhea, never using insoluble fiber in critically ill patients, and not using fiber in patients at risk for bowel ischemia.[89] The Canadian recommendations significantly differ. They concluded that available data are insufficient to make any recommendations regarding the use of fiber and specifically state that the effect of fiber on diarrhea is negligible.

Pulmonary formulas were developed with two thoughts in mind. First, having a high fat-to-carbohydrate ratio would lower the respiratory quotient (RQ) and thereby decrease carbon dioxide (CO_2) production. Second, an immunomodularity effect created by the use of fish oil–derived omega-3 fatty acids and alpha-linolenic acid, instead of the omega-6 fatty acids used in standard formulas, could theoretically

reduce the production of arachidonic metabolites. The reduction in arachidonic metabolites would then reduce the damaging inflammatory milieu observed in patients with acute respiratory distress syndrome (ARDS). The data concerning the maximum volume of oxygen (V_{O_2}), CO_2 production, and RQ are mixed. Early reports demonstrated benefit. Later reports seem to show that the improvements in these parameters were more likely related to the prevention of overfeeding.[108]

Using fish oil–derived omega-3 fatty acids and alpha-linolenic acid deserves special attention. Based on three studies, the ASPEN guidelines made a grade A recommendation that patients with ARDS should receive formulas characterized by "[A]n anti-inflammatory lipid profile."[89,109–111] The 2009 Canadian Guidelines made similar recommendations. In 2011, two studies were published that considerably changed things. The Omega trial was designed to test the hypothesis that antiinflammatory nutrition would be beneficial for patients suffering from acute lung injury (ALI) or ARDS.[112] A total of 272 patients were randomized; 143 patients received omega-3 supplementation, whereas 129 patients received an isocaloric control supplement. Ventilator-free days were the primary endpoint. After the first interim analysis, the data safety monitoring board stopped the study for futility. The patients receiving omega-3 supplementation did worse than the control patients. They had fewer ventilator-free days, ICU-free days, and nonpulmonary organ–free days, and the trend toward mortality increased. Grau-Carmona and associates[113] published a similar study, although the primary endpoint was new organ dysfunction. Secondary outcomes were mortality, nosocomial infections, ventilator-free days, and ICU lengths of stay. A total of 160 patients were randomized, and 132 were studied. No differences in any outcome variable were observed, except for ICU lengths of stay, which were slightly shorter in the antiinflammatory group (16 vs 18 days). Because of these findings, the Canadian Clinical Practice Guidelines downgraded their recommendation from recommend to should be considered.[114]

Other immunomodulatory additives have been tested, the most important of which is glutamine. Glutamine is a glutathione precursor and is potentially involved in decreasing oxidative stress. It is also potentially and relatively depleted in critically ill patients, and low plasma glutamine levels are associated with increased mortality rate.[115] The Reducing Deaths Due to Oxidative Stress (REDOXS) Study was designed to test the hypothesis that glutamine and antioxidant supplementation would decrease mortality in critically ill patients.[116] The study had a 2×2 randomized factorial design. A total of 1223 patients were randomized, 302 were assigned to the placebo group, 303 were assigned to receive glutamine, 308 were to receive antioxidants, and 310 were to receive glutamine plus antioxidants; 28-day mortality was the primary endpoint. Mortality was higher in patients who received glutamine. This study had methodologic problems involving randomization, as well as the large doses of glutamine given, which led to an unbalanced amino acid profile.[104] However, the results of the MetaPlus Study corroborate the findings of REDOXS Study.[117] The MetaPlus Study was a randomized, double-blinded, multicenter trial comparing the efficacy of high protein enteral nutrition with high protein enteral nutrition plus glutamine, omega-3 fatty acid, and antioxidants. The primary endpoint was the incidence of new infections. No differences were observed in the primary endpoint. Of note, however, medical patients receiving supplementation had a higher 6-month mortality rate (54% vs 35%). Subgroup analysis is hypothesis generating at best, but the possibility of considerable harm makes the results worrisome. The 2013 Canadian guidelines strongly recommended that glutamine not be used in critically ill patients with shock and multiorgan failure.[114]

How Much Should Patients Be Fed, and How Is This Determined?

Resting energy expenditure is difficult to estimate in critically ill patients. Equations, such as the Harris-Benedict equation, are frequently used. Alternatively, clinicians can provide approximately 20 to 30 kcal/kg/day, and protein delivery should be between 1.5 and 2 g/kg/day. However, these estimations do not agree with measurements of energy expenditure, such as those made by indirect calorimetry, and tend to underestimate energy expenditure.[118,119] Whether these differences are problematic is not clear. No available data describes outcome differences. However, avoiding overfeeding patients, especially early in the course of their illnesses, is very important, as illustrated by the EPaNIC trial and a study by Arabi and associates,[120] which demonstrated that patients who were underfed and who received approximately 60% of their caloric requirements had a lower in-hospital mortality rate than those who received near target caloric intake.[103,120]

Complications of Transcatheter Aortic Valve Replacement

TAVR has been used in many high-risk patients and, to some extent, in intermediate-risk patients with severe aortic stenosis (AS) since its introduction in Europe in 2001 (see Chapters 21 and 27). This procedure was developed to offer an alternative treatment for patients with severe AS classified as at too high risk for open surgical aortic valve replacement (SAVR). In 2011, the FDA granted the approval of this procedure for the replacement of severely stenosed aortic valves.[121]

Mortality After Transcatheter Aortic Valve Replacement

The first large, multicenter, prospectively randomized trial, the Placement of Aortic Transcatheter Valve (PARTNER) Trial, was conducted in 25 centers in the United States and comprised two cohorts: PARTNER A compared the outcomes of the high-risk patients treated with TAVR versus SAVR, and PARTNER B compared the outcomes of the inoperable patients treated with TAVR versus standard therapy.[122–124] Cohort A enrolled 699 high-risk patients and revealed that the 30-day mortality rate was 3.4% for TAVR and 6.5% for SAVR, the 1-year mortality rate was 24.2% and 26.8%, respectively, and the 2-year mortality rate remained similar between TAVR and SAVR.[122–124] Of the 348 patients treated with TAVR, 244 underwent transfemoral TAVR (TF-TAVR) and 104 underwent transapical TAVR (TA-TAVR). In high-risk patients, TA-TAVR and SAVR were associated with higher periprocedural risk of death as compared with TF-TAVR. In Cohort B, 358 inoperable patients were enrolled. The 30-day mortality rate was 5% for TF-TAVR and 2.8% for standard therapy; the 1-year mortality rate was 30.7% and 50.7%, respectively; and the 2-year mortality rate was 43.3% and 68%, respectively.[123,125,126] A Nonrandomized Continuous Access (NRCA) registry was created after the completion of the randomization of the PARTNER trial.[127] The 1-year mortality rate was significantly lower in the NRCA cohort (19%), as compared with TF-TAVR in the PARTNER trial (25.3%), with the caveat that many baseline characteristics were significantly different. Results from a multicenter registry in Europe of 697 patients revealed an in-hospital mortality rate of 7.5% post-TAVR versus 22.6% post-SAVR.[128] For reasons not yet elucidated in the PARTNER trial, the 2-year mortality among female patients tended to be lower with TAVR, especially TF-TAVR (28.2%) versus SAVR (38.2%).[123,129,130]

Stroke After Transcatheter Aortic Valve Replacement

At 30 days, the incidence of stroke in the PARTNER trial cohort A was significantly higher after TAVR (4.6%) versus SAVR (2.4%), and stroke increased the hazard of death.[122] This stroke hazard peaked early after TAVR and remained constant thereafter in relation to SAVR.[123] The overall rate of stroke was significantly higher after TAVR (13.8%), as compared with medical treatment (5.5%) in inoperable patients.[125] The rate of procedural stroke was significantly higher with TAVR (5.4%) versus SAVR (0.7%) in women, and it was similar with TAVR (4.5%) versus SAVR (4%) in men.[130] A systematic review and metaanalysis of 25 multicenter studies and 33 single-center studies

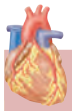
published in 2013 revealed that the risk of stroke within 30 days after TAVR is similar between TF-TAVR and TA-TAVR and the different valve types.[126]

Paravalvular Leak After Transcatheter Aortic Valve Replacement

A paravalvular leak post-TAVR could be the result of incomplete prosthesis apposition to the annulus, annular eccentricity, undersized prosthetic valve, or malposition of the implanted device (see Chapters 15, 22, and 27). Moderate-to-severe paravalvular aortic regurgitation (AR) was more frequent after TAVR at 1 and 2 years (7% and 6.9%), as compared with SAVR (1.9% and 0.9%) in the PARTNER trial cohort A and was associated with increased late mortality.[122] The effect of AR on mortality was proportional to the severity of regurgitation. In the PARTNER trial cohort B, the TAVR group and standard therapy group had similar degrees of AR at both 1 year and 2 years. The trend toward a higher mortality rate at 1 year associated with paravalvular regurgitation dissipated at 2 years follow-up in the PARTNER trial cohort B.[125] Based on the current literature, the causal relationship between mild paravalvular leak and mortality remains unclear.[127]

Vascular and Bleeding Complications After Transcatheter Aortic Valve Replacement

Major vascular complications were more frequent 1 year after TAVR (11.3%), as compared with SAVR (3.8%), whereas major bleeding was less frequent 1 year after TAVR (15.7%) than after SAVR (26.7%) in the PARTNER trial cohort A, and the differences were maintained at 2 years.[122] Major bleeding was also more common after TAVR, as compared with standard therapy in the PARTNER trial cohort B.[125] The results of a large study that included 2401 patients who underwent TAVR from a randomized and nonrandomized continuous access registry revealed that the incidence of the late major bleeding complication was 5.9%.[129] The common major bleeding complications after TAVR were gastrointestinal (40.8%), neurologic (15.5%), trauma or fall (7.8%), and genitourinary (6.3%). The occurrence of a major late bleeding complication was a strong independent predictor of mortality, and it was associated with a fourfold increase in late mortality. The association between moderate-to-severe paravalvular leak and the incidence of late major bleeding might be explained by high shear stress and flow turbulence leading to cleavage of proaggregation proteins and, subsequently, causing increased bleeding susceptibility (Box 41.6).[129,131]



BOX 41.6 SUMMARY OF COMPLICATIONS RELATED TO TRANSCATHETER AORTIC VALVE REPLACEMENT

- TAVR remains a noninferior alternative to SAVR in high-risk patients and a superior alternative to standard treatment in inoperable patients with severe aortic stenosis with regards to mortality.
- The increased early stroke incidence and the increased paravalvular leak, along with their association with mortality, portend significant concerns.
- A high-level suspicion for stroke should ensure that prompt diagnostic testing and treatment are part of the post-TAVR plan.
- Paravalvular regurgitation requires special consideration and follow-up, considering its association with worse later outcomes.

TAVR, Transcatheter aortic valve replacement; *SAVR*, surgical aortic valve replacement.

Complications of Minimally Invasive Cardiac Surgery

Minimally invasive cardiac surgery has been gradually used since early 1990 with the intention of decreasing morbidity, inflammatory response, and organ dysfunction derived from surgical access, CPB, and the manipulation of the large vessels.

Minimally Invasive Coronary Artery Bypass Graft

Most of the studies comparing minimally invasive CABG surgery with on-pump standard sternotomy CABG surgery are small, and many of the studies are nonrandomized (see Chapter 20). One small study revealed that a ministernotomy offered no advantage over the standard procedure with regards to postoperative pulmonary function recovery.[132] A few nonrandomized studies reported the benefit of a minithoracotomy for respiratory function recovery in patients with chronic respiratory disease, but more postoperative pain was reported, as compared with a standard sternotomy.[133] The Sternotomy Versus Thoracotomy (STET) trial revealed that a left anterolateral thoracotomy off-pump CABG (OPCAB) surgery was associated with shorter intubation times and fewer arrhythmias, but the OPCAB surgery was also associated with longer operative time, a greater need for postoperative pain relief, and worse lung function at discharge as compared with the standard OPCAB procedure with a median sternotomy.[134] Mortality and long-term morbidity outcomes were similar after the OPCAB and on-pump revascularization; however, recurrent angina was more frequent after the OPCAB.[135] A large metaanalysis including over 13,000 patients revealed that the OPCAB was associated with a decreased incidence of stroke but with similar mortality and myocardial infarction rates, as compared with on-pump CABG surgery.[136] Importantly, patients older than 80 years of age had a lower incidence of stroke and a trend toward better survival with the use of off-pump revascularization.[137] A major concern with the OPCAB is the need for an emergent conversion to the on-pump CABG surgery, which leads to increased perioperative mortality and morbidity (Polomsky and Puskas, 2012).[137] Another controversial area with the OPCAB procedure is the ability to complete the revascularization, possibly leading to fewer grafts as compared with the on-pump CABG surgery.[136] Therefore a hybrid approach for revascularization has been advocated and has been associated with shorter lengths of stay and intubation times, less pain and blood loss, and fewer transfusions as compared with the OPCAB.[137,138] Robotic-assisted CABG surgery was also associated with lower mortality and a lower incidence of complications when a single graft was performed; however, the benefits were reduced when multiple grafts were required.[139]

Minimally Invasive Aortic Valve Replacement

Since the first report of the right thoracotomy approach for AVR in 1993, the minimally invasive AVR has been performed via right anterior thoracotomy or upper hemisternotomy.[140] A propensity-matched single-center study revealed that the minimally invasive AVR is associated with shorter mechanical ventilation duration, lower incidence of postoperative atrial fibrillation, and fewer transfusions.[141] A pooled analysis of propensity-matched data of 18 studies showed that ischemic time and CPB time were significantly longer, whereas mechanical ventilation time, and ICU and hospital lengths of stay were shorter with minimally invasive AVR, as compared with conventional AVR.[142] The pain scores, the transfusion requirements, and the incidences of stroke and atrial fibrillation were comparable between minimally invasive and conventional AVR. A single-center study also revealed that minimally invasive AVR was associated with increased survival in octogenarians requiring redo surgery, as compared with conventional AVR.[143] Another review of 13 articles concluded that minimally invasive reoperative AVR can be at least as safe as conventional full sternotomy and is associated with shorter hospital lengths of stay, less blood products, shorter mechanical

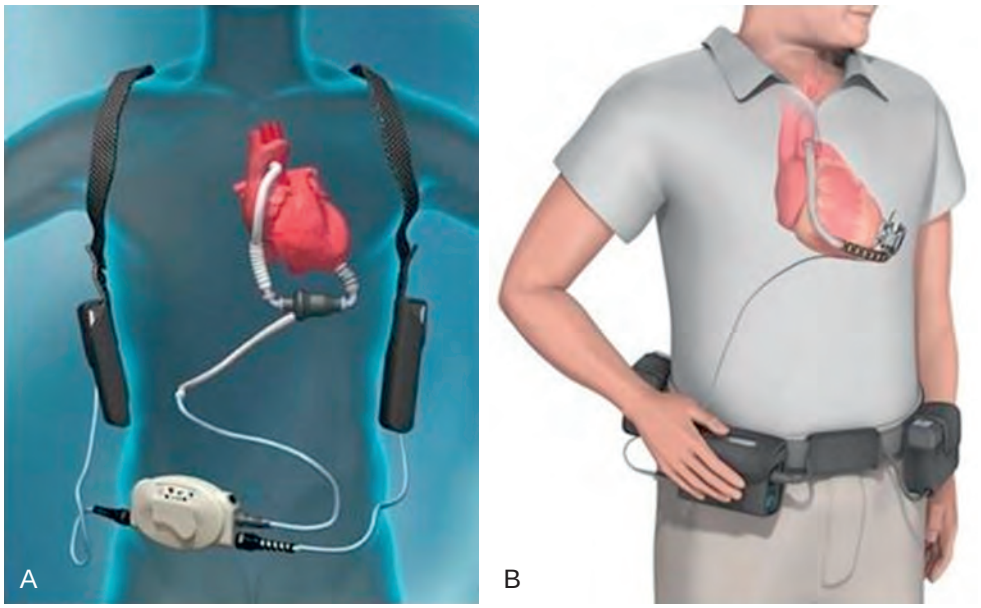

Fig. 41.1 (A) The Heartmate II ventricular assist device. *(From www.thoratec.com.)* (B) The HeartWare ventricular assist device. *(From www.heartware.com.)*

ventilation duration, and fewer sternal wound infections (see Chapters 21 and 29).[144]

Minimally Invasive Mitral Valve Surgery

To minimize surgical trauma and potentially positively affect surgical pain, length of recovery, and cosmesis, minimally invasive mitral valve surgery has been increasingly used since early 1990.[145] An observational study conducted at one institution revealed that patients who underwent cardiac reoperation via minithoracotomy for mitral or aortic valve surgery had significantly lower hospital mortality (5.6%), as compared with median sternotomy (11.3%), fewer blood transfusions, and shorter hospital lengths of stay.[146] A single-center reported their immediate and long-term results after minimally invasive mitral valve repair surgery in a large series of patients: 1.3% operative mortality, and 95% freedom from reoperation or severe recurrent mitral regurgitation.[147] At present, no randomized controlled trial has compared the safety and efficacy of these minimally invasive procedures with open surgeries for mitral valve disease, but the historical cohorts and the case series suggest that the minimally invasive approach is a feasible alternative.[148]

Complications of Mechanical Assist Devices

Long-Term Complications of Ventricular Assist Device Implantation

The landmark Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial of 2001 demonstrated that implanting LVAD improved survival and the quality of life for patients with heart failure over medical management (see Chapter 28).[149] This trial paved the way for a new paradigm in heart failure management, during which VADs are not only solely used in patients who are failing medical management as a bridge-to-transplant, but they are also used as destination therapy (DT) for patients in end-stage heart failure who are not candidates for heart transplantation.[150] Furthermore, as devices have improved, survival rates in patients who have a nonemergent VAD implant have started to approach that of heart transplant patients, with a 2-year survival for heart transplantation unchanged at approximately 80% over the last 10 years.[151] Thus VADs are increasingly chosen as DT in lieu of transplantation, even in patients who are transplant eligible.[150,152] This development could lead to a future in which a heart for transplant may not be quite in such short supply when compared with the demand.

The adverse event burden that patients with a implanted VAD experience is key to the long-term success of their implant and is increasingly critical in this new era of DT VADs. The original pulsatile-flow VADs (eg, HeartMate XVE) have been replaced by continuous-flow devices (eg, HeartMate II, HeartWare HVAD, DuraHeart II) (Fig. 41.1) for DT, as they generally show improved outcomes.[153,154] Many long-term complications of VAD use still remain, however, which are discussed in the following text.

Device Infection

Stating definitive infection rates is difficult, because they greatly vary, depending on the device, definitions used, reporting, and severity of infection.[155] Additionally, many studies that report definitive infection rates are small, single-center studies from the time when pulsatile VADs were still being used. Since rates of infection and other complications have dropped with the use of continuous-flow devices, these data are increasingly irrelevant.

Recently reported rates of all infections in patients with a VAD range up to 49%, with a range of serious infections, such as interior pump infections, occurring in less than 1%, to less serious infections such as percutaneous site infections ranging from 12% to 32%. The latest Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) report states an infection rate of 9.96 per 100 patient months.[150] Overall sepsis rates are relatively high at 11% to 36%.[155–161] One recent, single-center trial reported an overall driveline infection rate of 12%.[162] The only independent characteristic predictive of infection was increased duration of support. *Staphylococcus* and *Pseudomonas* species were the most commonly cultured organisms, as in previous studies, likely attributable to these organisms' ability to create a biofilm.[163]

Although most VAD-related infections are superficial and can be treated with antibiotics and local débridement, serious infectious complications lead to 11% of device failures.[164] More aggressive treatment strategies that have been reported include vacuum-assisted wound closure and antibiotic-impregnated beads.[165,166] Curbing an infection as soon as possible is particularly important to prevent the need for

device exchange, which carries significantly lower survival rates with each exchange.[150]

Device Thrombosis

Mechanical propulsion of blood within the VAD has several consequences, including stasis and contact with the nonbiologic material, which can lead to thrombosis. Hematologic effects differ, depending on the type of device. Continuous axial flow pumps, such as the HeartMate II, spin at higher revolutions per minute and have more surface-area contact with blood, whereas centrifugal flow pumps such as the HeartWare have fewer and slower moving parts that contact the blood, resulting in less shear stress, less hemostasis, and less blood component activation. Because of this, axial flow pumps have higher rates of hemolysis than centrifugal flow models.[167] Centrifugal flow pumps may ultimately prove to have fewer hemocompatibility issues such as thrombosis as well.[158]

Device-related thrombosis is a feared complication of long-term VAD use; it requires device exchange or transplant. Furthermore, device-related thrombosis is the most common cause of device failure at 50%.[164] Rates of device-related thrombosis in the HeartMate II original studies were 2% to 4% of patients.[161] A recent increase in the incidence to approximately 8% has been blamed on changes in practice regarding anticoagulation, although this is speculative.[121,168]

Thrombosis is diagnosed by elevated lactate dehydrogenase levels, reflecting associated hemolysis attributable to increased turbulence near the thrombus, echocardiographic findings, CT angiography, and increasing pump power use.[167] Conservative treatment strategies that have been reported with success include glycoprotein IIb/IIIa inhibitors and thrombolytic therapy. If these fail or if hemodynamic compromise occurs, then the device must be exchanged.[155]

Gastrointestinal Bleeding

Many factors predispose the patient with a VAD to bleeding events. First, patients require chronic anticoagulation therapy to avoid thrombotic complications. Typical regimens include full-dose aspirin and warfarin with an international normalized ratio (INR) of 2 to 2.5.[155] Another factor predisposing patients to bleeding events is a consequence of the mechanical propulsion of blood, which causes shear stress on the blood components. This leads to acquired von Willebrand (vWB) disease attributable to cleavage of the vWB factor multimers, leading to increased rates of bleeding events.[169] The levels of the vWB factor have been shown to be preserved in centrifugal-flow devices, as compared with axial-flow devices, but this did not appear to translate into different bleeding risks.[170] One recent study with the HeartWare centrifugal-flow device showed a relatively low rate of gastrointestinal bleeding (GIB) of 5%, but it was not clear whether the low rate of GIB was associated with preserved levels of the vWB factor.[171]

GIB is the most frequently experienced bleeding event in patients with a VAD, with reported rates ranging from 10% to 40%.[156,157,172–174] Patients with continuous-flow VADS tend to form arteriovenous malformations (AVMs) in the intestines, which are thought to be the result of the low pulse-pressure state, and further increase the risk for GIB.[172] Pulsatile-flow VADS have lower rates of GIB, independent of anticoagulation status, likely attributable to the absence of AVMs.[174,175]

Management of the patient with a VAD and GIB is similar to a patient without a VAD, primarily consisting of transfusion, anticoagulation cessation, and endoscopic evaluation. Bleeding of a large number of AVMs in the small intestine may result in more capsule endoscopic studies. Aspirin should be restarted after the cessation of the bleeding and warfarin after individual patient consideration.[176]

Neurovascular Events

Between 2% and 14% of patients with a VAD will experience a stroke, and 4% to 11% will have a stroke leading to disability or death.[155–157,159–161,177] Disabling stroke is a dreaded event with possibly the greatest impact on the quality of life and the potential to complicate the course of a patient with an otherwise perfectly functioning VAD. Rates of neurologic events are less in continuous-flow devices, as compared with pulsatile-flow devices.[154] The rates of neurologic events have also declined over time in continuous-flow devices, but the explanation remains unclear. One trial found a reduction in stroke rate from 19% in the original HeartMate II DT trial to 12% in the post-FDA approval period.[177]

An important patient factor in stroke is anticoagulation status. Multiple studies have found that patients with laboratory values favoring coagulation (high platelet count, low INR and prothrombin time [PT]) correlate with ischemic stroke, and patients with values reflecting anticoagulation (high INR and PT) correlate with hemorrhagic stroke.[173,178,179] Careful monitoring of chronic anticoagulation therapy is, no doubt, critical to balance the risk of thrombotic events with hemorrhage.

Device Failure

One-year survival after nonemergent implant of a continuous-flow device is now 80%; 1-year survival drops to 65% after a second implant and 50% after a third.[150] Whether this decrease is due to underlying conditions that may have predisposed to a problem with the pump or to the device exchange itself remains unclear, but exchange is still avoided until deemed absolutely necessary. One recent review focused on device failure in original retrospective observational studies. Device failure occurred at rates of approximately 4%, with a median duration of support of around 500 days. Pump thrombosis was the most common cause of failure at 50%. Lead or cable damage was the next cause at 22%, followed by mechanical failure at 12%, and infection at 11%.[164]

Bend-relief disconnect is a recently described cause of device failure observed in the HeartMate II.[180] The purpose of the bend relief is to prevent kinking in the outflow from the pump to the aorta. A detachable ring seals the relief closed, with the purpose of being able to detach the ring should the graft need to be visualized in the future. The ring can become spontaneously detached in vivo, potentially leading to thrombosis, increased hemolysis, worsened heart failure, or severe hemorrhage.

Long-Term Complications of Extracorporeal Membrane Oxygenation

The use of ECMO outside of the surgical unit was first reported in 28 cases by Bartlett and associates[181] in 1972 (see Chapters 32 and 33). Since then, extracorporeal life support (ECLS) has been used in thousands of patients with respiratory or cardiovascular failure that have not responded to medical management. However, indications and guidelines for the use of ECLS/ECMO remain controversial.[182,183] The mortality rate in patients undergoing ECMO remains high. Mortality rates range from 21% to 50% in patients undergoing ECMO for respiratory failure, whereas in patients with heart failure, the mortality rate is in the 40% range.[184]

Complications are extremely common in patients undergoing ECMO. Combes and colleagues[185] reported that 57% of all patients undergoing ECMO for cardiac failure had at least one major complication. In an excellent review article, Esper and associates[186] divided complications into two general categories: device-related and patient-related. The ECMO circuit, itself, is complex, and failures from each component (eg, cannula, tubing, pump, oxygenator, heat exchanger, tubing and return cannula [arterial or venous]) have been reported. Fortunately, with modern cannulas, centrifugal pumps, heparin-coated circuits, and hollow-filter oxygenators, the incidence of circuit-related failures seems to be decreasing.[187] Problems with venous drainage cannulas may include partial obstruction that will increase venous pressure in the patient (an increase in venous pressure may also decrease organ perfusion pressure) and decrease flow rates

that will affect oxygenation, ventilation, and blood pressure if using venoarterial (VA) ECMO. Venous drainage may also be decreased if the pump flows are too high, which results in "suck down" where the cannula is occluded because the vein collapses around it, preventing venous drainage. When vein collapse happens, the circuit tubing often "shakes" or "chatters." The collapse can usually be treated by transiently decreasing flows, a fluid bolus, or both. Echocardiography is useful to confirm cannula position. Another cannula problem with venovenous (VV) ECMO can occur when the venous drainage cannula is too close to the venous return cannula from the oxygenator and the oxygenated blood is drained back into the ECMO circuit, which results in inadequate tissue oxygenation. This problem is usually treated by adjusting the position of the cannulas.

A newer bicaval Avalon Elite dual lumen cannula (Avalon Laboratories, Rancho Dominguez, CA) is now being used for VV-ECMO that drains blood from both the superior vena cava and the inferior vena cava and returns it to the right atrium. When properly positioned by echocardiography or fluoroscopy, femoral cannulation is avoided. However, a high rate (up to 80%) of upper extremity DVT is associated with the use of this cannula.[188] Complete or partial resolution of the DVT occurred in all patients after the cannula was removed, and no patient had a documented pulmonary embolism.

Hemolysis is also a common complication that has been reported in 10% to 67% of neonates treated with ECMO.[189] Hemolysis can lead to anemia, hyperbilirubinemia, AKI, and neurologic complications. Risk factors for hemolysis include the type of oxygenator used, mean venous inlet pressure, and mean pump speed. Hemolysis can be limited by using the largest cannula and the lowest pump speeds possible.

Thrombosis of the pump and/or oxygenator is another dreaded complication of ECMO that must be balanced against over-anticoagulation and bleeding.[186] Unfortunately, no standardized, universally accepted guidelines are available for anticoagulation or for the monitoring of adequate anticoagulation in patients on ECMO.

Cheng and colleagues[190] recently published an excellent review and metaanalysis of complications in 1866 patients undergoing ECMO for cardiac failure. They reported an overall survival rate of 35%, with a range of 21% to 65%. The complication rates are shown in Table 41.8 and are similar to complication rates reported by Ventetuolo and associates.[184]

ECMO is also incredibly expensive, costing $65,519 more in the patients randomized to the conventional ventilation or ECMO for Severe Adult Respiratory failure (CESAR) trial.[191] In this study, ECMO showed a favorable lifetime predicted cost utility of $131,000 per life year.

Finally, ECMO has created numerous ethical problems for patients, families, and clinicians. The most stressful for everyone is the so-called "bridge to nowhere" in which patients on ECMO have no long-term alternative for life support. This and other common ethical dilemmas are reviewed in detail in an excellent review article by Abrams and colleagues.[192]

In conclusion, ECMO is an expensive intervention that has a mortality rate of 20% to 50% and a morbidity rate of approximately 50%. Further studies are underway to continue to define the indications and management of ECMO to improve outcomes.

TABLE 41.8 Complications for Extracorporeal Membrane Oxygenation for Cardiac Failure

	Rate	*95% Confidence Interval*
Lower extremity ischemia	16.5	12.5–22.6
Compartment syndrome or fasciotomy	10.3	7.3–14.5
Lower extremity amputation	4.7	2.3–9.3
Stroke	5.9	4.2–8.3
Other neurologic injury	13.3	9.9–17.7
Acute kidney injury	55.6	35.5–74
Renal replacement therapy	46	36.7–55.5
Major bleeding	40.6	26.8–56.6
Reoperation for bleeding or tamponade	41.6	24.3–61.8
Infection	30.4	15.5–44

Patient and Family Support, Palliative Care, and End-of-Life Issues

Twenty percent of Americans who die each year do so during or shortly after a stay in the ICU.[193] This fact places ICU providers in a key position of helping families and patients begin to navigate a difficult process that has the potential to end in an unforeseen and undesirable way. Certainly, helping patients live with a good quality of life for as long as possible is preferable, but when the end inevitably comes, helping patients and their families experience a "good death" can also be invaluable.

Patient care in the cardiothoracic ICU is extremely technology heavy and becoming more so with time. Supporting organ vital functions is almost indefinitely possible, moving the interventions and care from what used to be "can we" questions to "should we" questions, which result in far more difficult decisions for practitioners, patients, and families.

One complexity particular to surgical ICUs is that the ongoing goals of care may differ among practitioners. A covenant of care often exists between surgeons and their patients. This covenant is described by medical anthropologist Joan Cassell, in which the surgeon's commitment to the patient is characterized as not "giving up" and defeating death at all costs. This commitment can lead to conflicts with intensivists, who more often emphasize the quality of life[194] and can create confusion for the patient and their families, who may be hearing mixed messages.

Patients in the cardiac surgical ICU tend to be older and have chronic medical conditions. These patients have often been prompted to create an advanced directive or living will. Patients and families can feel forearmed when this has already been discussed and is in place. Unfortunately, when unforeseen circumstances and questions of whether to continue curative treatment arise, the wording is often unhelpful when it comes to making practical decisions in the ICU. Typical standardized documents say something to the effect that the patient would not want to continue to receive medical intervention or "heroic procedures" if no "realistic" hope of recovery exists. Unfortunately, having no hope or no chance is extremely rare, and physicians do not know how to predict whether or when a patient will die.[195]

Prognosticating

Patients coming through the ICU are having major surgery and have underlying medical comorbidities; their chance of a poor outcome is not insignificant. A patient having CABG surgery has an overall 3.2% chance of death by 30 days. If a patient has a left ventricle ejection fraction of less than 20%, then that risk increases to 8% by 30 days.[196,197] In patients 80 years of age and older, the 30-day mortality rate for an AVR is 6.6%. Often, these patients are also approaching the end of their lives, with a 2-year mortality rate of 35%.[122] At the extreme end of the morbidity spectrum is the patient who receives VA-ECMO for a cardiac arrest, severe cardiogenic shock, or failure to wean from CPB; hospital survival is a mere 35% to 43%.[185,198,199] This scenario is not infrequently encountered in the cardiac surgical ICU.

Scoring systems can be helpful in getting a sense of a patient's likelihood of doing poorly. Several scoring systems for patients undergoing cardiac surgery have been validated.[200,201] Another system that predicts morbidity and mortality is the cardiac anesthesia risk evaluation (CARE) score (Box 41.7).[202] The CARE model incorporates severity of

cardiac disease, comorbidities, nature of the surgery, and urgency into a scale of 1 to 5 with an E that designates emergency. For example, a 4E patient would be a patient with an uncontrolled medical problem having a complex surgery that is also an emergency; the risk of hospital mortality is 17% (Table 41.9).

The troubling population in the ICU is made up of patients who become chronically critically ill, with physical and cognitive impairments. These are the patients who linger in the ICU, often malnourished and frail, and are unable to be liberated from respiratory support. Hospital mortality for these patients is between 20% and 49%. Even when these patients are able to be eventually discharged from the hospital, the 1-year mortality rate is approximately 50%.[203]

BOX 41.7 CARDIAC ANESTHESIA RISK EVALUATION SCORE

1. Patient with stable cardiac disease and no other medical problem: a noncomplex surgery is undertaken.
2. Patient with stable cardiac disease and one or more controlled medical problems[a]: a noncomplex surgery is undertaken.
3. Patient with any uncontrolled medical problem[b] *or* patient in whom a complex surgery is undertaken.[c]
4. Patient with any uncontrolled medical problem *and* in whom a complex surgery is undertaken.
5. Patient with chronic or advanced cardiac disease for whom cardiac surgery is undertaken as a last hope to save or improve life.
6. Emergency: surgery is performed as soon as the diagnosis is made and the surgical unit is available.

[a]Examples: Controlled hypertension, diabetes mellitus, peripheral vascular disease, chronic obstructive pulmonary disease, controlled systemic diseases, and others as judged by clinicians.
[b]Examples: Unstable angina treated with intravenous heparin or nitroglycerin, preoperative intraaortic balloon pump, heart failure with pulmonary or peripheral edema, uncontrolled hypertension, renal insufficiency (creatinine level >140 µmol/L), debilitating systemic diseases, and others as judged by clinicians.
[c]Examples: Reoperation, combined valve and coronary artery surgery, multiple valve surgery, left ventricular aneurysmectomy, repair of ventricular septal defect after myocardial infarction, coronary artery bypass of diffuse or heavily calcified vessels, and other as judged by clinicians.

Palliative Care

Recognizing that palliative care does not exclude curative treatment is important. Palliative care is a concept that incorporates symptom management into medical and surgical disease therapy. It recognizes that the patient has a chronic disease that must be managed and is designed to relieve suffering and to improve the quality of life, which can enhance disease-specific therapies but need not replace them. Almost without exception, the cardiac surgery patient almost without exception has a chronic disease that must be indefinitely managed. Thus palliative care, with the goals of managing symptoms and improving the quality of life, is often appropriate to incorporate into the care plan, even if stopping therapy is not expected in the near future.[204]

Palliative care consults have been shown to increase lifespan, decrease costs, and improve patient satisfaction.[205–208] Thus early integration of a palliative care approach to a patient's care plan has no apparent drawbacks. If disease-specific therapies become ineffective or exhausted or if the goals of care change to sole palliation, then palliative therapies can be ramped up accordingly (Fig. 41.2).

Recommendations for Patient and Family Support

Some ICUs have instituted a set schedule for family meetings starting from admission, or a set time for "family rounds" when families can be

TABLE 41.9 Probabilities of Mortality, Morbidity, and Prolonged Postoperative Length of Stay in Hospital, as Predicted by the CARE Score

CARE Score	*Mortality (%)*	*Morbidity (%)*	*Prolonged LOS (days)*
1	0.5 (0.3–0.9)	5.4 (4.3–6.8)	2.9 (2.2–3.9)
2	1.1 (0.7–1.7)	10.3 (8.9–12.1)	5.1 (4.2–6.3)
3	2.2 (1.6–3.1)	19.0 (17.2–20.9)	8.8 (7.6–10.2)
3E	4.5 (3.5–5.7)	32.1 (29.3–35.0)	14.7 (12.8–16.8)
4	8.8 (6.9–11.3)	48.8 (44.1–53.6)	23.5 (20.1–27.3)
4E	16.7 (12.4–22.1)	65.8 (59.5–71.6)	35.4 (29.3–42.0)
5	29.3 (20.8–39.6)	79.6 (73.2–84.7)	49.4 (40.4–58.5)
5E	46.2 (32.4–60.5)	88.7 (83.5–92.5)	63.6 (52.5–73.4)

Values obtained from the logistic regression analysis performed in the reference population (n=2000). Numbers in parentheses are 95% confidence intervals.

BOX 41.8 BUNDLE OF MINIMAL PALLIATIVE CARE QUALITY MEASURES IN THE INTENSIVE CARE UNIT

ICU Day 1 Goals
- Identify the medical decision maker.
- Determine whether there is an advance directive.
- Determine resuscitation (DNR/DNI) status.
- Give institutional ICU information, if applicable.
- Perform regular pain assessments, strive for optimal pain management.

ICU Day 3 Goals
- Involve social work support if not already done.
- Involve spiritual support if not already done.

ICU Day 5 Goals
- Conduct an interdisciplinary family meeting in a dedicated space.

ICU, Intensive care unit; *DNR,* do not resuscitate; *DNI,* do not intubate.
Adapted from Nelson JE, Mulkerin CM, Adams LL, Pronovost PJ. Improving comfort and communication in the ICU: a practical new tool for palliative care performance measurement and feedback. *Qual Saf Health Care.* 2006;15(4):264–271. Copyright ©2015 by Elsevier. Adapted with permission.

at the bedside and expect care providers to visit. This practice has many potential benefits. It allows family members and patients to become familiar with the care providers before a potential complication or urgent situation arises, and it can improve patient and family satisfaction, in that they believe they are more regularly informed. Family meetings also provide opportunities to discuss a patient's goals of care in a nonurgent manner, while eliminating some of the anxiety that can be provoked by a hastily scheduled meeting should the patient's status unexpectedly decline. Nelson and associates[209] developed a bundle of palliative care quality measures to be used in the ICU with a recommended standard timeline of actions (Box 41.8). Patients with a statistically poor prognosis or an unexpected ICU admission should have a family meeting earlier, ideally on ICU day 1.

Facilitating a family meeting is a skill that requires practice. Extensive literature is available to provide guidance. Meetings should include members of all disciplines as appropriate, and introductions of all participants should be made. The family's understanding of the patient's condition should be assessed. A clear, coherent message should be delivered to the family about the patient's condition, including clear prognosticating as much as possible.

If decisions need to be made about further treatment, then the goal is to discover what the patient's goals of care would be in this situation. It is the surrogates' role to help interpret those wishes, based on their knowledge of the patient, not to express their own wishes for care plans. It can then be appropriate for providers to make recommendations to the decision maker about further care, taking into consideration the patient's perceived wishes and the clinical situation. As Pelligrino wrote, "The efficacy of a treatment is for clinicians to assess and comment on, but the burdens and benefits of a treatment (in terms of its quantitative or qualitative goals) [are] in the purview of the patient."[210] Thus decisions to limit or change the goals of care are a joint decision between practitioners and family members, based on the patient's perceived wishes within the clinical context.

Withdrawal of Life-Sustaining Treatments and Palliative Sedation

If the decision is made that curative treatment has been exhausted and that the goals of care are changed to palliative only, then disease-specific treatment and life-sustaining therapies can be stopped or not escalated, according to the surrogates' and providers' judgment. Excellent resources exist that can guide the mechanics of this process.[211,212]

Postoperative Pain Management for the Cardiac Patient

MARK A. CHANEY, MD

KEY POINTS

1. Inadequate postoperative analgesia and/or an uninhibited perioperative surgical stress response has the potential to initiate pathophysiologic changes in all major organ systems, including the cardiovascular, pulmonary, gastrointestinal, renal, endocrine, immunologic, and/or central nervous systems, all of which may lead to substantial postoperative morbidity. Adequate postoperative analgesia prevents unnecessary patient discomfort, may decrease morbidity, may decrease postoperative hospital lengths of stay, and thus may decrease costs.
2. Pain after cardiac surgery may be intense and originates from many sources, including the incision (sternotomy or thoracotomy), intraoperative tissue retraction and dissection, vascular cannulation sites, vein-harvesting sites, and chest tubes, among other sources. Achieving optimal pain relief after cardiac surgery is often difficult, yet it may be attained through a wide variety of techniques, including local anesthetic infiltration, nerve blocks, intravenous agents, intrathecal techniques, and epidural techniques.
3. Traditionally, analgesia after cardiac surgery has been obtained with intravenous opioids (specifically morphine). However, intravenous opioid use is associated with definite detrimental side effects (nausea and vomiting, pruritus, urinary retention, respiratory depression), and longer-acting opioids such as morphine may delay tracheal extubation during the immediate postoperative period via excessive sedation and/or respiratory depression. Thus in the current era of early extubation (eg, fast-tracking), cardiac anesthesiologists are exploring unique options other than traditional intravenous opioids for the control of postoperative pain in patients after cardiac surgery.
4. Although patient-controlled analgesia is a well-established technique (used for more than 2 decades) and offers potential unique benefits (eg, reliable analgesic effect, improved patient autonomy, flexible adjustment to individual needs), whether it truly offers significant clinical advantages (compared with traditional nurse-administered analgesic techniques) to patients immediately after cardiac surgery remains to be determined.
5. Cyclooxygenase-2 (COX-2) inhibitors possess analgesic (opioid-sparing) effects and lack deleterious effects on coagulation, in contrast with nonselective nonsteroidal antiinflammatory drugs (NSAIDs). However, current evidence does not suggest that COX-2 inhibitors provide major advantages over traditional NSAIDs. Furthermore, potential links between this class of drugs and cardiovascular complications, sternal wound infections, and thromboembolic complications need to be fully evaluated.
6. Administration of intrathecal morphine to patients initiates reliable postoperative analgesia after cardiac surgery, yet its effect on respiratory depression remains unpredictable, potentially delaying tracheal extubation. Intrathecal opioids or local anesthetics cannot reliably attenuate the perioperative stress response associated with cardiac surgery that persists during the immediate postoperative period. Although intrathecal local anesthetics (not opioids) may induce perioperative thoracic cardiac sympathectomy, the hemodynamic changes associated with total spinal anesthesia make the technique unpalatable in patients with cardiac disease.
7. Administration of thoracic epidural opioids or local anesthetics to patients initiates reliable postoperative analgesia after cardiac surgery. The quality of analgesia obtained with thoracic epidural anesthetic techniques is sufficient to allow cardiac surgery to be performed in "awake" patients (ie, without general endotracheal anesthesia). The administration of thoracic epidural local anesthetics (not opioids) can both reliably attenuate the perioperative stress response associated with cardiac surgery that persists during the immediate postoperative period and induce perioperative thoracic cardiac sympathectomy.
8. Use of intrathecal and epidural techniques in patients undergoing cardiac surgery remains extremely controversial. Concerns regarding the risk of hematoma formation and the fact that numerous clinical investigations regarding this topic are suboptimally designed and use a wide array of disparate techniques have prevented clinically useful conclusions.
9. For a wide variety of reasons, including the increased use of small incisions, the last decade has seen a resurgence of nerve blocks (including catheter-based techniques) in patients undergoing cardiac surgery. Recent clinical studies using intercostal, intrapleural, and paravertebral blocks indicate that these techniques may have unique clinical advantages, even when compared with traditional intrathecal and epidural techniques. The emergence of liposomal bupivacaine, which has the potential to provide clinical analgesia for 96 hours after a single injection, may revolutionize the use of single-shot nerve blocks for patients undergoing cardiac surgery.
10. As a general rule, avoiding intense, single-modality therapy for the treatment of acute postoperative

pain is best. The administration of two analgesic agents that act by different mechanisms (multimodal or balanced analgesia) provides superior analgesic efficacy with equivalent or reduced adverse effects. Analgesic therapies should be used only after thoughtful consideration is given to the risks and benefits for each individual patient. The therapy or therapies selected should reflect the individual anesthesiologist's expertise, as well as the capacity for safe application of the chosen modality in each practice setting. The choice of medication, dose, route, and duration of therapy should always be individualized.

Adequate postoperative analgesia prevents unnecessary patient discomfort, may decrease morbidity, may decrease postoperative hospital lengths of stay, and thus may decrease costs. Because postoperative pain management has been deemed important, the American Society of Anesthesiologists has published practice guidelines regarding this topic.[1] Furthermore, in recognition of the need for improved pain management, The Joint Commission has developed standards for the assessment and management of pain in accredited hospitals and other health care settings.[2] Patient satisfaction (no doubt linked to adequacy of postoperative analgesia) has become an essential element that influences clinical activity of not only anesthesiologists but all health care professionals.

Achieving optimal pain relief after cardiac surgery is often difficult. Pain may be associated with many interventions, including sternotomy, thoracotomy, leg-vein harvesting, pericardiotomy, and/or chest tube insertion, among other interventions. Inadequate analgesia and/or an uninhibited stress response during the postoperative period may increase morbidity by causing adverse hemodynamic, metabolic, immunologic, and hemostatic alterations.[3–5] Aggressive control of postoperative pain, associated with an attenuated stress response, may decrease morbidity and mortality in high-risk patients after noncardiac surgery[6,7] and may also decrease morbidity and mortality in patients after cardiac surgery.[8,9] Adequate postoperative analgesia may be attained via a wide variety of techniques (Box 42.1). Traditionally, analgesia after cardiac surgery has been obtained with intravenous opioids (specifically morphine). However, intravenous opioid use is associated with definite detrimental side effects (eg, nausea and vomiting, pruritus, urinary retention, respiratory depression), and longer-acting opioids such as morphine may delay tracheal extubation during the immediate postoperative period via excessive sedation and/or respiratory depression. Thus in the current era of early extubation (fast-tracking), cardiac anesthesiologists are exploring unique options other than traditional intravenous opioids for the control of postoperative pain in patients after cardiac surgery.[10–12] The last decade has witnessed increased use of smaller incisions by cardiac surgeons, prompting clinical investigations into the use of intercostal, intrapleural, and paravertebral blocks (with and without catheters), and the emergence of long-acting liposomal bupivacaine may revolutionize the use of these techniques. No single technique is clearly superior; each possesses distinct advantages and disadvantages. It is becoming increasingly clear that a multimodal approach and/or a combined analgesic regimen (using a variety of techniques) is the best way to approach postoperative pain in all patients after surgery to maximize analgesia and minimize side effects. When addressing postoperative analgesia in cardiac surgical patients, the choice of technique (or techniques) should be made only after a thorough analysis of the risk-benefit ratio of each technique in the specific patient in whom analgesia is desired.

BOX 42.1 TECHNIQUES AVAILABLE FOR POSTOPERATIVE ANALGESIA

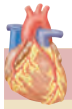
- Local anesthetic infiltration
- Nerve blocks
- Opioids
- Nonsteroidal antiinflammatory agents
- α-Adrenergic agents
- Intrathecal techniques
- Epidural techniques
- Multimodal analgesia

Pain and Cardiac Surgery

Surgical or traumatic injury initiates changes in the peripheral and central nervous systems that must be addressed therapeutically to promote postoperative analgesia and, it is hoped, positively influence clinical outcomes (Box 42.2). The physical processes of incision, traction, and cutting of tissues stimulate free nerve endings and a wide variety of specific nociceptors. Receptor activation and activity are further modified by the local release of chemical mediators of inflammation and sympathetic amines released via the perioperative surgical stress response. The perioperative surgical stress response peaks during the immediate postoperative period and exerts major effects on many physiologic processes. The potential clinical benefits of attenuating the perioperative surgical stress response (above and beyond simply attaining adequate clinical analgesia) have received significant attention during the 2000s and remain fairly controversial.[13] However, inadequate postoperative analgesia and/or an uninhibited perioperative surgical stress response clearly has the potential to initiate pathophysiologic changes in all major organ systems, including the cardiovascular, pulmonary, gastrointestinal, renal, endocrine, immunologic, and/or central nervous systems, all of which may lead to substantial postoperative morbidity.

Pain after cardiac surgery may be intense, and it originates from many sources, including the incision (eg, sternotomy, thoracotomy), intraoperative tissue retraction and dissection, vascular cannulation sites, vein-harvesting sites, and chest tubes, among other sources.[14,15] Patients in whom an internal mammary artery is surgically exposed and used as a bypass graft may have substantially more postoperative pain.[16]

A prospective clinical investigation involving 200 consecutive patients undergoing cardiac surgery via median sternotomy assessed the location, distribution, and intensity of postoperative pain.[14] All patients received 25 to 50 μg/kg of intraoperative intravenous fentanyl, were subjected to routine cardiopulmonary bypass (CPB), had their arms positioned along their body on the surgical table, had their sternum closed with five peristernal wires, and received mediastinal and thoracic drains passed through the rectus abdominis muscle just below the xiphoid. A subgroup (127 patients) also underwent long saphenous vein harvesting from either the calf (men) or thigh (women). All patients were extubated before the first postoperative



BOX 42.2 PAIN AND CARDIAC SURGERY

- Originates from many sources.
- Most commonly originates from the chest wall.
- Preoperative expectations influence postoperative satisfaction.
- Quality of postoperative analgesia may influence morbidity.

morning. Postoperative analgesic management was standardized and included intravenous morphine, oral paracetamol, oral tramadol, and subcutaneous morphine. Pain location, distribution, and intensity were documented in the morning on the first, second, third, and seventh postoperative days using a standardized picture dividing the body into 32 anatomic areas. A numerical rating scale of 0 to 10 (with 0 representing no pain and 10 representing the worst possible pain) was used to assess maximal pain intensity. These investigators found that maximal pain intensity was highest on postoperative day 1 and lowest on postoperative day 3. However, maximal pain intensity was only graded as moderate (mean pain score was approximately 3.8) and did not diminish during the first 2 postoperative days and yet started to decline between postoperative days 2 and 3. Pain distribution did not appear to vary throughout the postoperative period, yet its location did (more shoulder pain was observed on postoperative day 7). As time after surgery increased, the pain usually moved primarily from the incisional and epigastric regions to osteoarticular areas.

Another source of postoperative pain in patients after cardiac surgery is thoracic cage rib fractures, which may be common.[17,18] Furthermore, sternal retraction, causing posterior rib fracture, may lead to brachial plexus injury. In these patients, routine chest radiographs may appear normal despite the presence of fracture. Thus bone scans (better at detecting rib fractures than chest radiographic images) are recommended whenever unexplained postoperative nonincisional pain is present in a patient who has undergone sternal retraction.[18] Other studies have indicated that the most common source of pain in patients after cardiac surgery is the chest wall. Age also appears to affect pain intensity; patients younger than 60 years of age often have greater pain intensity than patients older than 60 years of age. Although maximal pain intensity after cardiac surgery is usually only moderate, ample room for clinical improvement in analgesic control to minimize pain intensity remains, especially during the first few postoperative days.

Persistent pain after cardiac surgery, although rare, can be problematic.[19–21] The cause of persistent pain after sternotomy is multifactorial, yet tissue destruction, intercostal nerve trauma, scar formation, rib fractures, sternal infection, stainless-steel wire sutures, and/or costochondral separation may all play roles.[22] Such chronic pain is often localized to the arms, shoulders, or legs. Postoperative brachial plexus neuropathies also may occur and have been attributed to rib fracture fragments, internal mammary artery dissection, suboptimal positioning of the patient during surgery, and/or central venous catheter placement. Postoperative neuralgia of the saphenous nerve has also been reported after harvesting of saphenous veins for coronary artery bypass grafting (CABG). Younger patients appear to be at greater risk for the development of chronic, long-lasting pain. The correlation of severity of acute postoperative pain and the development of chronic pain syndromes has been suggested (patients requiring more postoperative analgesics may be more likely to develop chronic pain), yet this link is still vague.

Ho and associates[19] assessed 244 patients after cardiac surgery and median sternotomy and found that persistent pain (defined as pain still present 2 or more months after surgery) was reported in almost 30% of patients. The incidence rate of persistent pain at any site was 29% (71 patients) and for sternotomy was 25% (61 patients). Other common locations of persistent pain reported to these investigators were the shoulders (17%), back (16%), and neck (6%). However, such persistent pain was usually reported as mild, with only 7% of patients reporting interference with daily living. The most common words used to describe the persistent pain were "annoying" (57%), "nagging" (33%), "dull" (30%), "sharp" (25%), "tiring" (22%), "tender" (22%), and "tight" (22%). The temporal nature of this pain was mostly reported as being transient and intermittent. Twenty patients (8%) also described symptoms of numbness, burning pain, and tenderness over the internal mammary artery–harvesting site, symptoms suggestive of internal mammary artery syndrome. Thus it was concluded that mild persistent pain after cardiac surgery and median sternotomy is common yet only infrequently substantially interferes with daily life.

Although the most common source of pain in patients after cardiac surgery remains the chest wall, leg pain from vein-graft harvesting can be problematic as well. Such pain may not become apparent until the late postoperative period, which may be related to the progression of patient mobilization and the decreasing impact of sternotomy pain (unmasking leg incisional pain). Using minimally invasive vein-graft harvesting techniques (endoscopic vein-graft harvesting) decreases the intensity and duration of postoperative leg pain, compared with conventional open techniques.[23] Although initial harvest times may be prolonged, harvest times become equivalent between the two techniques (endoscopic vs conventional) once a short learning curve is overcome. Furthermore, leg morbidity (eg, infection, dehiscence) may be less in patients undergoing endoscopic vein-graft harvesting, compared with patients undergoing conventional open techniques because of different incisional lengths.

Patient satisfaction with quality of postoperative analgesia is as much related to the comparison between anticipated and experienced pain as it is to the actual level of pain experienced. Satisfaction is related to a situation that is better than predicted, dissatisfaction to one that is worse than expected. Patients undergoing cardiac surgery remain concerned regarding the adequacy of postoperative pain relief and preoperatively tend to expect a greater amount of postoperative pain than that which is actually experienced.[15] Because of these unique preoperative expectations, patients after cardiac surgery who postoperatively receive only moderate analgesia will likely still be satisfied with their pain control. Thus patients may experience pain of moderate intensity after cardiac surgery yet still express very high satisfaction levels.[15,16]

Scientific advances have allowed a better understanding of how and why pain occurs, leading to unique and possibly clinically beneficial pain management strategies. Noxious input from an acute injury may trigger a state of central nervous system sensitization, called *wind-up.* In essence, dorsal horn neurotransmitter release via nociceptive input conditions the central nervous system in such a way that responsiveness (secondary hyperalgesia) is enhanced. Although experimental evidence indicates that enhanced responsiveness outlasts the initial provocative insult (induced sensitivity outlasts the stimulus), the exact clinical relevance remains to be determined. Advances regarding spinal cord neuropharmacology have led to research aimed at modifying or blocking *N*-methyl-D-aspartate receptors to influence pain control and the concept of preemptive analgesia, which is predicated on addressing pain before it initiates peripheral and central sensitization. However, given the redundancy in neurotransmitter receptor systems in the central nervous system, it is unlikely that blocking only one component will result in clear clinical benefits. Although the use of *N*-methyl-D-aspartate receptor antagonists and the concept of preemptive analgesia are intriguing and certain clinical investigations appear to support their utility, clear and definite clinical benefits in humans remain to be determined. Debate continues over the potential benefits of *N*-methyl-D-aspartate receptor antagonists and the utility of preemptive analgesic treatment, as well as the direction in which research and conceptual development in this exciting field needs to proceed.

Potential Clinical Benefits of Adequate Postoperative Analgesia

Inadequate analgesia (coupled with an uninhibited stress response) during the postoperative period may lead to many adverse hemodynamic (tachycardia, hypertension, vasoconstriction), metabolic (increased catabolism), immunologic (impaired immune response), and hemostatic (platelet activation) alterations (Box 42.3). In patients undergoing cardiac surgery, perioperative myocardial ischemia (diagnosed by electrocardiography and/or transesophageal echocardiography) is most commonly observed during the immediate postoperative period and appears to be related to outcome.[24,25] Intraoperatively, initiation of CPB causes substantial increases in stress response hormones (eg, norepinephrine, epinephrine) that persist into the

- Decreased morbidity

immediate postoperative period and may contribute to myocardial ischemia observed during this time.[26–28] Furthermore, postoperative myocardial ischemia may be aggravated by cardiac sympathetic nerve activation, which disrupts the balance between coronary blood flow and myocardial oxygen demand.[29] Thus during the pivotal immediate postoperative period after cardiac surgery, adequate analgesia coupled with stress-response attenuation may potentially decrease morbidity and enhance health-related quality of life.[29,30]

Existing evidence indicates that aggressive control of postoperative pain in patients after noncardiac surgery may beneficially affect outcome.[6,7] In 1987, Yeager and colleagues[7] in a small ($n = 53$ patients), randomized, controlled clinical trial involving patients undergoing major thoracic vascular surgery revealed that patients who were managed with more intense perioperative anesthesia and analgesia demonstrated decreased postoperative morbidity and improved operative outcome. In 1991, Tuman and associates[6] in another small ($n = 80$ patients), randomized, controlled clinical trial involving patients undergoing lower extremity revascularization revealed that patients who were managed with more intense perioperative anesthesia and analgesia demonstrated improved outcome compared with patients receiving routine on-demand narcotic analgesia.

Existing evidence also indicates that aggressive control of postoperative pain in patients after cardiac surgery may beneficially affect outcome. Two intriguing clinical investigations published in 1992 hint at such possibilities.[8,9] Mangano and associates[8] prospectively randomized 106 adult patients undergoing elective CABG to receive either standard postoperative analgesia or intensive analgesia during the immediate postoperative period. Standard-care patients received low-dose intermittent intravenous morphine for the first 18 postoperative hours, whereas intensive-analgesia patients received a continuous intravenous sufentanil infusion during the same time period. Patients receiving sufentanil demonstrated lesser severity of myocardial ischemia episodes (detected by continuous electrocardiographic monitoring) during the immediate postoperative period. The authors postulated that the administration of intensive analgesia during the immediate postoperative period may have more completely suppressed sympathetic nervous system activation, thereby having numerous beneficial clinical effects, including alterations in the sensitivity of platelets to epinephrine, alterations in fibrinolysis, enhanced regional left ventricular function, and decreased coronary artery vasoconstriction, all potentially leading to a reduced incidence and reduced severity of myocardial ischemia. Anand and Hickey[9] prospectively randomized 45 neonates undergoing elective cardiac surgery (mixed procedures) to receive either standard perioperative care or deep opioid anesthesia. Standard-care patients received a halothane-ketamine-morphine anesthetic with intermittent intravenous morphine for the first 24 postoperative hours, whereas deep-opioid patients received an intravenous sufentanil anesthetic with a continuous infusion of either intravenous fentanyl or intravenous sufentanil during the same postoperative period. Neonates receiving continuous postoperative opioid infusions demonstrated a reduced perioperative stress response (assessed via multiple blood mediators), less perioperative morbidity (hyperglycemia, lactic acidemia, sepsis, metabolic acidosis, disseminated intravascular coagulation), and significantly fewer deaths than the control group (0/30 vs 4/15, respectively; $p < 0.01$). The accompanying editorial accurately summarizes this clinical investigation: "What Anand and Hickey have shown is that this reluctance to treat pain adequately is not a necessary evil. It markedly contributes to a bad outcome."[31] Unfortunately, aggressive control of postoperative pain in patients after cardiac surgery with relatively large amounts of intravenous opioids in this manner does not allow tracheal extubation in the immediate postoperative period (a goal of current practice).

Techniques Available for Postoperative Analgesia

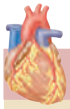
Although the mechanisms of postoperative pain and the pharmacologic actions of analgesic drugs are relatively well understood, the delivery of effective postoperative analgesia remains far from universal. Many techniques are available (see Box 42.1). In general, the American Society of Anesthesiologists Task Force on Acute Pain Management in the Perioperative Setting reports that the existing literature supports the efficacy and safety of three techniques used by anesthesiologists for perioperative pain control: (1) regional analgesic techniques, including but not limited to intercostal blocks, plexus blocks, and local anesthetic infiltration of incisions; (2) patient-controlled analgesia (PCA) with systemic opioids; and (3) intrathecal and epidural opioid analgesia.[1] Regarding regional analgesic techniques, the existing literature supports the analgesic efficacy of peripheral nerve blocks and postincisional infiltration with local anesthetics for postoperative analgesia, and yet it is equivocal regarding the analgesic benefits of preincisional infiltration. Regarding PCA with systemic opioids, the existing literature supports its efficacy compared with intramuscular techniques for postoperative pain management, yet the existing literature is equivocal regarding the efficacy of PCA techniques compared with nurse- or staff-administered intravenous analgesia. In addition, the existing literature is equivocal regarding the comparative efficacy of epidural PCA versus intravenous PCA techniques.

When background opioid infusions are included with PCA techniques, patients report better analgesia and greater morphine consumption without increased incidence of nausea, vomiting, pruritus, or sedation. Although greater morphine consumption during PCA with continuous background infusion might predispose patients to respiratory depression, the existing literature is insufficient to reveal this potential adverse effect. Finally, regarding intrathecal and epidural opioid analgesia, the existing literature supports the efficacy of epidural morphine and fentanyl for perioperative analgesia but is insufficient to characterize the spectrum of risks and benefits associated with the use of other specific opioids administered by these routes. Pruritus and urinary retention more frequently occur when morphine is given intrathecally or epidurally compared with systemic (intravenous or intramuscular) administration. Furthermore, epidural morphine provides more effective pain relief than intramuscular morphine. Similarly, epidural fentanyl provides more effective postoperative analgesia than intravenous fentanyl. The existing literature is insufficient to evaluate the effects of epidural techniques administered at different times (eg, preincisional, postincisional, postoperative).

Local Anesthetic Infiltration

Pain after cardiac surgery is often related to median sternotomy, peaking during the first 2 postoperative days. Because of problems associated with traditional intravenous opioid analgesia (nausea and vomiting, pruritus, urinary retention, respiratory depression) and with the more recently introduced nonsteroidal antiinflammatory drugs and cyclooxygenase (COX) inhibitors (gastrointestinal bleeding, renal dysfunction), alternative methods of achieving postoperative analgesia in cardiac surgical patients have been sought. One such alternative method that may hold promise is the continuous infusion of a local anesthetic (Box 42.4).

In a prospective, randomized, placebo-controlled, double-blind clinical trial, White and colleagues[32] studied 36 patients undergoing



BOX 42.4 LOCAL ANESTHETIC INFILTRATION

- Advantage: Simple, reliable analgesia
- Disadvantage: Tissue necrosis?

cardiac surgery. Intraoperative management was standardized. All patients had two indwelling infusion catheters placed at the median sternotomy incision site at the end of surgery; one was placed in the subfascial plane above the sternum and the other one was placed above the fascia in the subcutaneous tissue. Patients received 0.25% bupivacaine ($n = 12$), 0.5% bupivacaine ($n = 12$), or normal saline ($n = 12$) via a constant-rate infusion through the catheter (4 mL/hr) for 48 hours after surgery. Average times to tracheal extubation were similar in the three groups (approximately 5 to 6 hours). Compared with the control group (normal saline), a statistically significant reduction in verbal rating scale pain scores and intravenous PCA morphine use was observed in the 0.5% bupivacaine group. Patient satisfaction with pain management was also improved in the 0.5% bupivacaine group versus the control group. However, no significant differences were observed in PCA morphine use between the 0.25% bupivacaine and control groups. Although tracheal extubation time and the duration of the intensive care unit (ICU) stay (30 versus 34 hours, respectively) were not significantly altered, time to ambulation (1 vs 2 days, respectively) and the duration of hospital stay (4.2 vs 5.7 days, respectively) were lower in the 0.5% bupivacaine group than in the control group. Serum bupivacaine concentrations in patients were reasonable, yet one complication related to the local anesthetic delivery system was encountered when a catheter tip was inadvertently broken off during its removal from the incision site, which required surgical reexploration of the wound under local anesthesia. The authors conclude that continuous infusion of 0.5% bupivacaine at 4 mL/hr is effective for decreasing postoperative pain and the need for postoperative supplemental opioid analgesic medication and for improving patient satisfaction (earlier ambulation, reduced length of hospital stay) with pain management after cardiac surgery.

Another clinical investigation revealed the potential benefits of using a continuous infusion of a local anesthetic in patients after cardiac surgery. In this prospective, randomized, placebo-controlled, double-blind clinical trial, Dowling and associates[33] studied 35 healthy patients undergoing cardiac surgery. Patients undergoing elective CABG via median sternotomy were randomized to either ropivacaine or placebo groups. At the end of the surgery but before wound closure, bilateral intercostal nerve injections from T1 to T12 were performed using 20 mL of either 0.2% ropivacaine or normal saline. After sternal reapproximation with wires, two catheters with multiple side openings were placed anterior to the sternum (Fig. 42.1). These catheters were connected to a pressurized elastomeric pump containing a flow regulator, which allowed for the delivery of 0.2% ropivacaine or normal saline at approximately 4 mL/hr. The intraoperative anesthetic technique was standardized (short-acting anesthetics were used to minimize the presence of residual anesthetic agents in the postoperative period) as was postoperative pain management via intravenous PCA morphine (for 72 hours). Both groups exhibited similar postoperative extubation times (approximately 8 hours). The sternal catheters were removed in both groups after 48 hours. Total mean PCA morphine consumption during the immediate postoperative period (72 hours) was significantly decreased in the ropivacaine group compared with the placebo group (47.3 vs 78.7 mg, respectively; $p = 0.038$). Mean overall pain scores (scale ranging from 0 for no pain to 10 for maximum pain imaginable) were also significantly decreased in the ropivacaine group compared with the placebo group (1.6 vs 2.6, respectively; $p = 0.005$). Most interestingly, patients receiving ropivacaine had a mean hospital length of stay of 5.2 ± 1.3 days compared with 8.2 ± 7.9 days for patients receiving normal saline, a

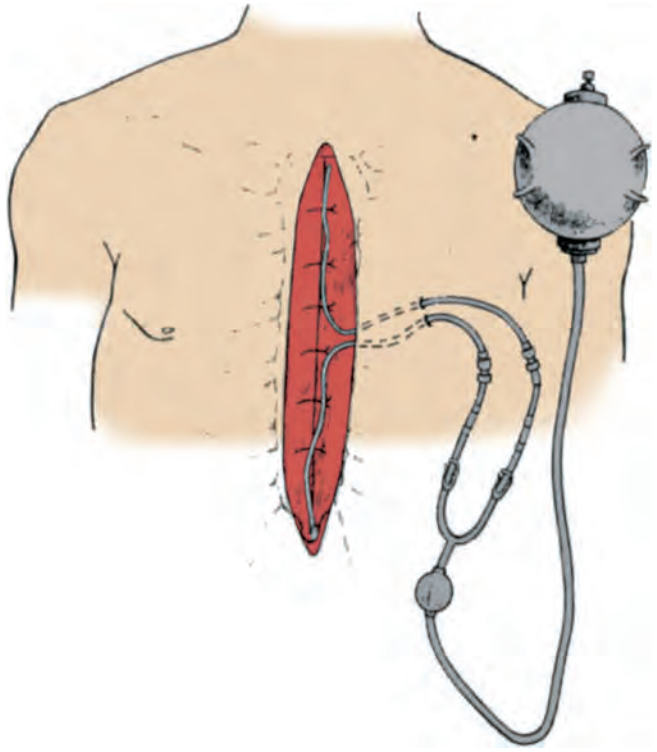


Fig. 42.1 Intraoperative placement of the pressurized elastomeric pump and catheters. *(Dowling R, Thielmeier K, Ghaly A, et al. Improved pain control after cardiac surgery: results of a randomized, double-blind, clinical trial.* J Thorac Cardiovasc Surg. *2003;126:1271–1278.)*

difference that was statistically significant ($p = 0.001$). One patient in the placebo group had an extremely long postoperative hospitalization (39 days). However, the difference between the two groups regarding the lengths of hospital stay remained statistically significant even when this outlier was removed (5.2 ± 1.3 days vs 6.3 ± 2.8 days, respectively; $p < 0.01$). Despite the differences in postoperative analgesia, postoperative pulmonary function (assessed via forced expiratory volume in 1 second and peak expiratory flow) was similar between the two groups. No difference was observed in wound infections or wound healing between the two groups during hospitalization or after hospital discharge. No complications related to placement of the sternal wound catheters or performance of the intercostal nerve blocks were encountered. The authors concluded that their analgesic technique significantly improves postoperative pain control while decreasing the amount of opioid analgesia required in patients subjected to standard median sternotomy. The significant decrease in hospital lengths of stay observed by the investigators is intriguing, may result in substantial cost reductions, and deserves further study.

The management of postoperative pain with continuous direct infusion of a local anesthetic into the surgical wound has been described after a wide variety of surgeries other than cardiac (eg, inguinal hernia repair, upper abdominal surgery, laparoscopic nephrectomy, cholecystectomy, knee arthroplasty, shoulder surgery, gynecologic operative laparoscopy).[34] The infusion pump systems used for anesthetic wound infusion are regulated by the US Food and Drug Administration (FDA) as medical devices. Thus adverse events involving these infusion pump systems during direct local anesthetic infusion into surgical wounds are reported to this organization. Complications encountered with these infusion pump systems reported to the FDA include tissue necrosis, surgical wound infection, and cellulitis after orthopedic, gastrointestinal, podiatric, and other surgeries. None of these reported adverse events involved patients undergoing cardiac surgery. The most commonly reported complication was tissue necrosis, an adverse event rarely seen after normal surgical procedures. Furthermore, the consequences of

these reported adverse events were typically severe and required intervention and additional medical and/or surgical treatment. Although these initial reports may be isolated incidents, they may also represent an early warning sign and provide a potentially important signal, suggesting the need for further investigation into the relationship between the use of these pumps for direct continuous infusion of local anesthetics and other drugs into surgical wounds and the adverse events of tissue necrosis, serious infections, or cellulitis. Neither of the two clinical investigations involving local anesthetic infusion in patients after cardiac surgery with median sternotomy reported such wound complications.[32,33] Regardless, these safety issues merit careful consideration because of the importance of sternal wound complications in this setting.

The anterior and posterior branches of the intercostal nerves innervate the sternum. Parasternal infiltration of a local anesthetic therefore is a possible means of improving postoperative analgesia. Although the use of parasternal blocks has not been extensively investigated, one small, prospective, randomized, placebo-controlled, double-blind clinical study indicated that parasternal block and local anesthetic infiltration of the sternotomy wound and mediastinal tube sites with local anesthetic may be a useful analgesic adjunct for patients who are expected to undergo early tracheal extubation after cardiac surgery.[35]

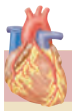
Nerve Blocks

With the increasing popularity of minimally invasive cardiac surgery, which uses nonsternotomy incisions (minithoracotomy), the use of nerve blocks for the management of postoperative pain has increased[36–43] (Box 42.5). Thoracotomy incisions (transverse anterolateral minithoracotomy, vertical anterolateral minithoracotomy), because of costal cartilage tissue trauma to ribs, muscles, or peripheral nerves, may induce more intense postoperative pain than that resulting from median sternotomy. Adequate analgesia after thoracotomy incisions is important because pain is a key component in the alteration of lung function after this type of incision. Uncontrolled pain causes a reduction in respiratory mechanics, reduced mobility, and increases in hormonal and metabolic activity. Perioperative deterioration in respiratory mechanics may lead to pulmonary complications and hypoxemia, which may in turn lead to myocardial ischemia or infarction, cerebrovascular accidents, thromboembolism, delayed wound healing, increased morbidity, and prolonged hospital stay. Various analgesic techniques have been developed to treat postoperative thoracotomy pain. The most commonly used techniques include intercostal nerve block, intrapleural administration of a local anesthetic, and thoracic paravertebral block. Intrathecal techniques and epidural techniques are also effective in controlling postthoracotomy pain and are covered in greater detail later in this chapter.

Intercostal nerve block has been extensively used for analgesia after thoracic surgery[36,38] and can be performed either intraoperatively or postoperatively. It usually provides sufficient analgesia lasting approximately 6 to 12 hours (depending on the amount and type of local anesthetic used) and may need to be repeated if additional analgesia is required. Local anesthetics may be administered as a single injection under direct vision before chest closure, as a single preoperative percutaneous injection, as multiple percutaneous serial injections, or via an indwelling intercostal catheter. Blockade of intercostal nerves interrupts C-fiber afferent transmission of impulses to the spinal cord. A single intercostal injection of a long-acting local anesthetic can provide pain relief and improve pulmonary function in patients after thoracic surgery for up to 6 hours. A continuous extrapleural intercostal nerve block technique may be used, during which a catheter is placed percutaneously into an extrapleural pocket by the surgeon to achieve longer duration of analgesia. A continuous intercostal catheter allows frequent dosing or infusions of local anesthetic agents and avoids multiple needle injections. Various clinical studies have confirmed the analgesic efficacy of this technique, and the technique compares favorably with thoracic epidural analgesic techniques.[36,38] A major concern associated with intercostal nerve block is the potentially high amount of local anesthetic systemic absorption. However, multiple clinical studies involving patients undergoing thoracic surgery have documented safe blood levels with standard techniques. Clinical investigations involving patients undergoing thoracic surgery indicate that intercostal nerve blockade by intermittent or continuous infusion of bupivacaine (0.25% to 0.5%) or ropivacaine (0.5% to 0.75%) through indwelling intercostal catheters is an effective method for supplementing systemic intravenous opioid analgesia for postthoracotomy pain.[36,38,44,45] The value of single preclosure injections remains doubtful.

Intrapleural administration of local anesthetics initiates analgesia via mechanisms that remain incompletely understood. However, the mechanism of action of extrapleural analgesia seems to depend primarily on diffusion of the local anesthetic into the paravertebral region. Local anesthetics then affect not only the ventral nerve root but also afferent fibers of the posterior primary ramus. Posterior ligaments of the posterior primary ramus innervate posterior spinal muscles and skin and are traumatized during posterolateral thoracotomy. Intrapleural administration of a local anesthetic to this region through a catheter inserted in the extrapleural space creates an analgesic region in the skin. The depth and width of this region depend on the diffusion of the local anesthetic in the extrapleural space. With this technique, local anesthetics may be administered by intermittent or continuous infusion regimens via an indwelling intrapleural catheter placed between the parietal and visceral pleura. Concerns regarding systemic absorption of a local anesthetic and toxicity are always present with this technique yet have not been substantiated in clinical studies that assayed plasma levels. A handful of clinical investigations involving patients undergoing thoracic surgery via thoracotomy incision suggests that 0.25% to 0.5% bupivacaine may improve analgesia in patients after thoracic surgery, yet its true efficacy as a postoperative analgesic in this patient population remains somewhat controversial.[39] The analgesic benefits are short in duration, and a significant overall opioid-sparing effect does not appear to occur. Furthermore, the optimal concentration and duration regimen remains undefined. However, a prospective, randomized, clinical study involving 50 patients undergoing minimally invasive direct CABG via minithoracotomy indicates that an intrapleural analgesic technique with 0.25% bupivacaine is safe, effective, and compares favorably (ie, provides superior postoperative analgesia) with a conventional thoracic epidural technique.[40] These investigators noted, however, that careful catheter positioning, chest tube clamping, and anchoring of the catheter are mandatory for postoperative intrapleural analgesia to be effective. A major factor implicated in the lack of efficacy regarding intrapleural techniques is loss of the local anesthetic solution through intercostal chest drainage tubes. Although clamping the chest tubes during the postoperative period will increase analgesic efficacy, it may not be safe to clamp chest tubes for extended periods because they provide important drainage of blood and air and allow for enhanced lung patency and expansion. Apart from proper catheter positioning (inserting the catheter under direct vision and anchoring the catheter to skin are both essential), effective analgesia with this technique also appears to depend on whether lung surgery is performed or whether the anatomic and physiologic structure of the pleura is relatively intact.

Thoracic paravertebral block involves the injection of a local anesthetic adjacent to the thoracic vertebrae close to where the spinal nerves emerge from the intervertebral foramina (Fig. 42.2). Thoracic paravertebral block, compared with thoracic epidural analgesic techniques, appears to provide equivalent analgesia, is technically easier, and may harbor less risk. Several different techniques exist for successful thoracic paravertebral block and have been extensively reviewed.[37,46]



BOX 42.5 NERVE BLOCKS

- Advantage: Simple, long-lasting analgesia
- Disadvantage: Unreliable?

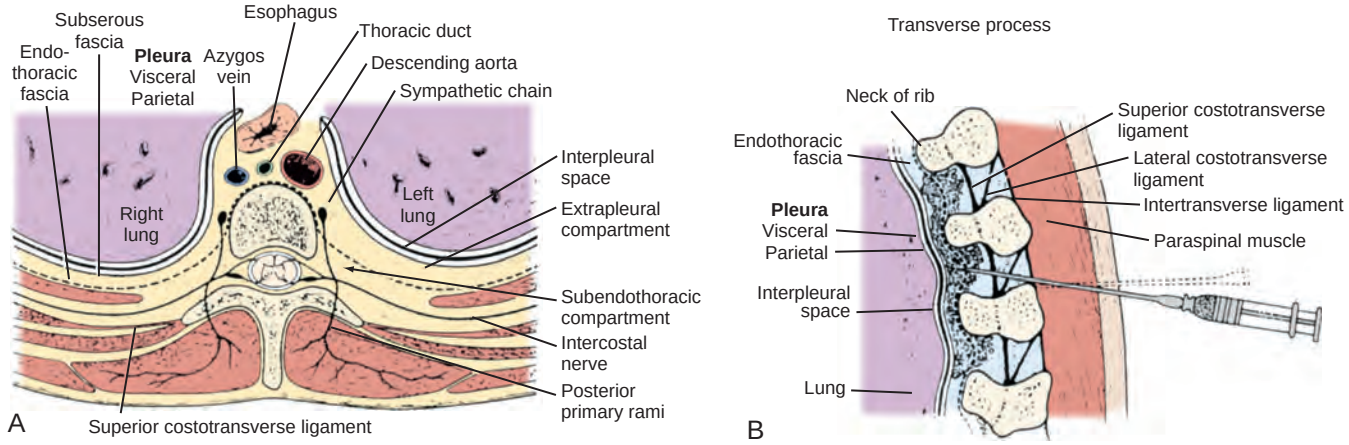


Fig. 42.2 Anatomy of the thoracic paravertebral space (A) and sagittal section through the thoracic paravertebral space showing a needle that has been advanced above the transverse process (B). *(From Karmakar MK. Thoracic paravertebral block.* Anesthesiology. *2001;95:771–780.)*

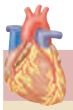
The classic technique, most commonly used, involves eliciting loss of resistance. Injection of a local anesthetic results in ipsilateral somatic and sympathetic nerve blockade in multiple contiguous thoracic dermatomes above and below the site of injection, together with the possible suppression of the neuroendocrine stress response to surgery. These blocks may be effective in alleviating acute and chronic pain of unilateral origin from the chest, abdomen, or both. Bilateral use of thoracic paravertebral block has also been described. Continuous thoracic paravertebral infusion of a local anesthetic via a catheter placed under direct vision at thoracotomy is also a safe, simple, and an effective method of providing analgesia after thoracotomy. It is usually used in conjunction with adjunct intravenous opioid or other analgesics to provide optimal relief after thoracotomy. Although supplemental intravenous analgesics are usually required, opioid requirements are substantially reduced.

Unilateral paravertebral block is useful for attaining postthoracotomy analgesia because pain after lateral thoracotomy is essentially always unilateral. The role of bilateral thoracic paravertebral block remains to be defined. The benefits of unilateral paravertebral blockade are a reduced incidence of adverse events (hypotension, urinary retention) and a decreased risk for systemic local anesthetic toxicity because less local anesthetic is used. Continuous thoracic paravertebral block as part of a balanced analgesic regimen may provide effective pain relief with few adverse effects after thoracotomy and appears to be comparable with thoracic epidural analgesia (TEA).[37,46–49]

Intercostal nerve block, intrapleural administration of local anesthetic, and thoracic paravertebral block offer the advantages of simplicity and efficacy in controlling postoperative pain in patients after thoracic surgery. However, although analgesic efficacy of these techniques may be comparable with intrathecal and epidural techniques, these methods appear to work best as part of a multimodal analgesic regimen (ie, supplementing other analgesic techniques). Complications associated with the infiltration of large quantities of local anesthetics, which is often required, is always a concern when using these analgesic techniques.

For a wide variety of reasons, including the increased use of small thoracic incisions by cardiac surgeons, the last decade has seen a resurgence of nerve blocks (usually catheter-based techniques) in patients undergoing cardiac surgery. Specifically, recent clinical studies using intercostal catheters,[50] intrapleural catheters,[51–53] and paravertebral blockade[46,54–56] indicate that these techniques may have unique advantages, even when compared with traditional intrathecal and epidural techniques.[57–63] Lastly, the emergence of liposomal bupivacaine, which has the potential to provide clinical analgesia for 96 hours after a single injection, may revolutionize the use of single-shot nerve blocks for thoracic and cardiac surgeries.[64–66]



BOX 42.6 OPIOIDS

- Advantages
  - Time-tested analgesia
  - Reliable
- Disadvantages
  - Pruritus
  - Nausea and vomiting
  - Urinary retention
  - Respiratory depression

Opioids

Beginning in the 1960s and continuing for essentially 30 years, large doses of intravenous opioids (starting with morphine) have been administered to patients undergoing cardiac surgery[67,68] (Box 42.6). Because even very large amounts of intravenous opioids do not initiate "complete" anesthesia (eg, amnesia, analgesia, muscle relaxation), other intravenous and inhalation agents must be administered during the intraoperative period.[69] Analgesia is the best known and most extensively investigated opioid effect, yet opioids are also involved in a diverse array of other physiologic functions including the control of pituitary and adrenal medulla hormone release and activity, the control of cardiovascular and gastrointestinal function, and the regulation of respiration, mood, appetite, thirst, cell growth, and the immune system.[70] A number of well-known and potential side effects of opioids (eg, nausea and vomiting, pruritus, urinary retention, respiratory depression) may limit postoperative recovery when they are used for postoperative analgesia.

Opioids interact with specific receptors that are widely distributed within the central nervous system to produce a variety of pharmacologic effects. Currently, three major distinct opioid-receptor types are recognized: μ, κ, and δ. The μ receptor has two subtypes: a high-affinity μ_1 receptor and a low-affinity μ_2 receptor. The supraspinal mechanisms of analgesia are thought to involve μ_1 receptors, whereas spinal analgesia, respiratory depression, and gastrointestinal effects are associated with the μ_2 receptor. Other subtypes of the μ receptor have been isolated, yet their clinical relevance remains to be elucidated. Likewise, subtypes of the κ and δ receptors have also been isolated. Selective κ agonists may have therapeutic potential as analgesics, lacking the adverse side effects produced by the current μ-receptor agonists. δ_1 Receptors appear to mediate spinal analgesia, whereas δ_2 receptors appear to mediate supraspinal analgesia. Unfortunately, despite

extensive pharmacologic and functional studies of the wide variety of opioid receptors, understanding the structural basis of their actions remains quite limited.

The classic pharmacologic effect of opioids is analgesia, and these drugs have traditionally been the initial choice when a potent postoperative analgesic is required. Two anatomically distinct sites exist for opioid receptor–mediated analgesia: supraspinal and spinal. Systemically administered opioids produce analgesia at both sites. Supraspinally, the μ_1 receptor is primarily involved in analgesia, whereas the μ_2 receptor is the receptor predominantly involved in the spinal modulation of nociceptive processing. κ Receptors are important in mediating spinal and supraspinal analgesia as well. δ Ligands may have a modulatory rather than a primary analgesic role. All three types of opioid receptors (μ, κ, and δ) have been demonstrated in peripheral terminals of sensory nerves. Activation of these receptors seems to require an inflammatory reaction because locally applied opioids do not produce analgesia in healthy tissue. The inflammatory process also may activate previously inactive opioid receptors.

Although nausea and vomiting, pruritus, and urinary retention are more commonly encountered, respiratory depression remains the most feared complication associated with use of opioids.[71] All μ receptor agonist opioids produce dose-related respiratory depression that appears to be mediated via μ_2 receptors. Pure κ agonists have little effect on respiration, and the role of δ receptors in respiratory control remains to be elucidated. The primary respiratory effect of opioids is a reduction in the sensitivity of the respiratory center to carbon dioxide (together with depression of both medullary and peripheral chemoreceptors). Initially, respiratory rate is affected more than tidal volume, which may actually increase. With increasing doses of opioids, respiratory rhythmicity is disturbed, resulting in the irregular gasping breathing characteristic of opioid overdose. In addition to the retention of carbon dioxide, respiratory depression may also result in hypoxia (the hypoxic drive to ventilation is depressed by the opioids as well). Older adult patients seem to be more sensitive to the respiratory depressant effects of opioids than younger patients, and the dose used needs to be adjusted accordingly. The realization that all other central nervous system depressants, such as benzodiazepines, barbiturates, and/or inhalation anesthetics, will potentiate the respiratory depressant effects of the opioids is also important to keep in mind. Furthermore, in addition to the parent opioid drug, metabolites may contribute to respiratory depression in some circumstances. For instance, metabolites of morphine (morphine-6-β-glucuronide) may occur in substantial quantities after intravenous administration and may be responsible for a considerable proportion of the clinical effects of intravenous morphine.

Morphine is the prototype opioid agonist with which all opioids are compared and is perhaps the most popular analgesic used in patients after cardiac surgery. Many semisynthetic derivatives are made by simple modifications of the morphine molecule. Morphine is a poorly lipid soluble and binds approximately 35% to plasma proteins, particularly albumin. Morphine is primarily metabolized in the liver, principally by conjugation to water-soluble glucuronides. The liver is the predominant site for morphine biotransformation, although extrahepatic metabolism also occurs in the kidney, brain, and possibly the gut. Extrahepatic clearance accounts for approximately 30% of the total body clearance. The terminal elimination half-life of morphine is 2 to 3 hours. In patients with liver cirrhosis, morphine pharmacokinetic actions are variable, probably reflecting the variability of liver disease in patients. Morphine's terminal elimination half-life in patients with renal disease is comparable with that of patients without renal disease. Although morphine is perhaps the most popular intravenous analgesic used in patients after cardiac surgery, other synthetically derived opioids have been developed and may be used as well. These include fentanyl, alfentanil, sufentanil, and remifentanil.

Fentanyl is considerably more potent (60 to 80 times) than morphine. However, at the opioid receptor, the intrinsic affinities of fentanyl and morphine differ by only a factor of 2 to 3. The differences between receptor affinities and clinical potency ratios arise from differing physiochemical and pharmacokinetic properties of the drugs, in particular the differences in lipid solubility. Fentanyl is highly lipid soluble, which influences the rate of entry and exit to and from organs and tissues, especially the central nervous system, which has a high lipid content.

Fentanyl is rapidly transferred across the blood-brain barrier, resulting in a rapid onset of action after intravenous injection. The relative potential for entering the central nervous system is approximately 150 times greater for fentanyl than for morphine. However, the large quantities of fentanyl taken up by adipose tissues may act as a reservoir (depending on dosage amounts) that slowly releases fentanyl back into the systemic circulation when plasma concentrations decline to less than that in fat. This slow reentry may serve to maintain the plasma concentration and is one factor in the relatively long plasma terminal elimination half-life of fentanyl. The drug is rapidly and extensively metabolized by the liver to inactive metabolites. After a bolus intravenous injection, plasma fentanyl concentrations decrease rapidly because of the distribution from the plasma to tissues; consequently, fentanyl has a short duration of action after moderate (10 μg/kg) doses (see Chapter 10).

Larger doses convert fentanyl from a short-acting to a long-acting drug. With increased doses, the distribution phase is completed before the fentanyl concentration declines to threshold levels; therefore duration of action becomes dependent on the decrease in concentration during the much slower elimination phase. Thus to avoid an accumulation of fentanyl, successive doses at regular intervals should be progressively reduced in amount or the interval between doses of the same size should be progressively lengthened. When fentanyl is administered by continuous intravenous infusion, the rate of decline of fentanyl plasma concentration is significantly dependent on the duration of the infusion. Fentanyl undergoes substantial first-pass uptake in the lungs (approximately 80% of the injected dose). Hepatic extraction of fentanyl is also high, making its clearance dependent on liver blood flow. Thus factors that reduce liver blood flow also will decrease fentanyl clearance. Fentanyl metabolites will likely accumulate in patients with impaired renal function, yet this accumulation is unlikely to have clinical consequences because the metabolites are pharmacologically inactive. Because the liver is the principal organ for fentanyl biotransformation, decreases in hepatic function caused by liver disease will be expected to alter fentanyl pharmacokinetics.

The popularity of fentanyl as an intraoperative analgesic agent relates directly to the cardiovascular stability it provides, even in critically ill patients. Additionally, its analgesic efficacy relative to the intensity of side effects has prompted much interest in its use as an analgesic after surgery and/or in critically ill patients.[72] Fentanyl, as well as any opioid, can be administered intravenously for postoperative analgesia in many ways: using a loading dose with a continuous fixed or variable infusion, a fixed background infusion with PCA, or PCA alone. An intravenous bolus of 1 to 2 μg/kg is usually administered before initiating an infusion. If variable, the infusion rate is usually 1 to 2 μg/kg/hr and may be adjusted upward or downward as required by fluctuations in analgesic requirements or the appearance of side effects. Before the infusion rate is increased, small intravenous bolus doses of fentanyl may be administered. Infusion rates of 1.5 to 2.5 μg/kg/hr usually provide good-to-excellent postoperative analgesia. At rest, the quality of analgesia remains stable; however, with movement, analgesia may not be sufficient, even with greater infusion rates.

A background low-dose intravenous infusion of fentanyl may be combined with PCA to provide satisfactory analgesia with potentially fewer adverse effects. PCA bolus doses typically range from 5 to 50 μg, and background infusion rates may be fixed (ranging from 5 to 50 μg/hr) or variable (adjusted up and down according to clinical criteria). Generally, the larger the background infusion rate, the smaller the PCA bolus dose. Lockout intervals (ie, minimum time between doses) range from "on demand" (no lockout interval) to 15 minutes with the most common lockout interval being 1 to 5 minutes. The technique of using a background infusion plus PCA produces excellent postoperative analgesia. Fentanyl is rarely used alone for PCA because of

its brief duration of action. Morphine remains the most commonly administered opioid used alone in PCA.

Transdermal delivery of fentanyl has also been investigated extensively. This modality is simple, noninvasive, and allows continuous release of fentanyl into the systemic circulation. However, the steady release of fentanyl in such a manner does not allow flexibility in dose adjustment, which may result in inadequate treatment of postoperative pain during rapidly changing intensity. Thus intravenous opioids are often necessary to supplement analgesia when transdermal fentanyl is used to manage acute postoperative pain.

Alfentanil is approximately 5 to 10 times less potent than fentanyl. The drug acts rapidly; its peak effect is reached within minutes after intravenous administration. Its duration of action after bolus administration is also shorter than fentanyl. Alfentanil is highly lipid soluble (approximately 100 times more lipid soluble than morphine) and rapidly crosses the blood-brain barrier. Alfentanil pharmacokinetics is minimally affected by renal disease, and hepatic extraction is more a function of intrinsic hepatic enzyme capacity and protein binding than liver blood flow.

The performance of a patient-demand, target-controlled alfentanil infusion system has compared favorably with traditional morphine PCA in patients after cardiac surgery. Checketts and associates[73] prospectively randomized 120 patients undergoing elective cardiac surgery to receive either morphine PCA or alfentanil PCA for postoperative analgesia (nonblinded study). All patients received a similar standardized intraoperative anesthetic technique and were extubated during the immediate postoperative period. Overall median visual analogue pain scores were significantly lower in patients receiving alfentanil, yet both alfentanil and morphine delivered high-quality postoperative analgesia (Fig. 42.3). Although the clinical impression of these investigators was that alfentanil patients were less sedated in the immediate postoperative period, this clinical observation was not substantiated after statistical analysis of sedation scores. The two groups did not differ with respect to overall sedation scores, frequency of nausea and vomiting, hemodynamic instability, myocardial ischemia, or hypoxemia during the immediate postoperative period.

Sufentanil is approximately 10 times more potent than fentanyl. The drug is extremely lipid soluble and highly bound to plasma proteins. Because of its high potency, conventional clinical doses of sufentanil result in plasma concentrations that rapidly decline to less than the sensitivity of most assayed methods, making it difficult to determine accurate pharmacokinetic parameters. However, sufentanil pharmacokinetic actions appear not to be altered in patients with renal disease. Because hepatic sufentanil clearance approaches liver blood flow, the drug's pharmacokinetic properties are expected to change with hepatic disease yet the clinical relevance remains undetermined. Sufentanil undergoes substantial (approximately 60%) first-pass uptake in the lungs.

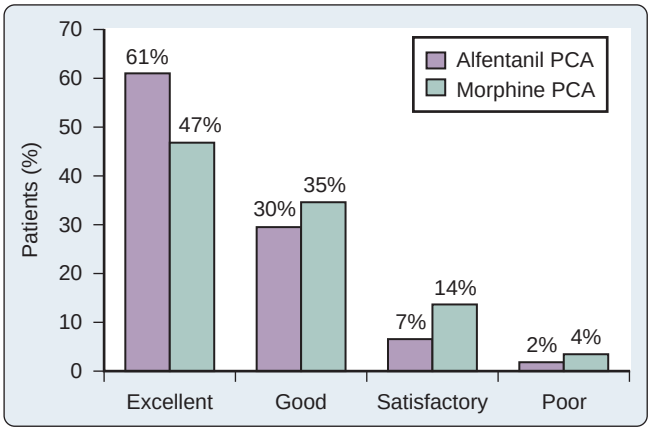


Fig. 42.3 Overall patient satisfaction with postoperative analgesia. Ninety-one percent of patients using alfentanil rated their postoperative analgesia as excellent or good, whereas 82% of patients using morphine rated their postoperative analgesia similarly (differences not statistically significant). *PCA,* Patient-controlled analgesia. *(From Checketts MR, Gilhooly CJ, Kenny GN. Patient-maintained analgesia with target-controlled alfentanil infusion after cardiac surgery: a comparison with morphine PCA.* Br J Anaesth. *1998;80:748–751.)*

Remifentanil has a very fast onset and an ultrashort duration of action; it is unique in that it is readily susceptible to rapid hydrolysis by nonspecific esterases in the blood and tissues. The drug is moderately lipophilic and is half as potent as fentanyl when blood concentrations causing equivalent analgesia are compared. Remifentanil has an elimination half-life of 10 to 20 minutes, and the time required for a 50% reduction in blood concentration after discontinuation of an infusion that has attained a steady state is approximately 3 minutes and does not increase with the duration of infusion. Available evidence suggests that neither the pharmacokinetics nor the pharmacodynamics of remifentanil is significantly altered in patients with severe hepatic or renal disease. These properties should confer ease of titration to changing analgesic conditions. However, the quick offset of action, although desirable, may result in inadequate postoperative analgesia. Because of the rapid offset of analgesic effect of remifentanil, the continued requirement for postoperative analgesia needs to be considered before the remifentanil is discontinued. A transition must be made from remifentanil to some other longer-acting analgesic agent for the initiation of substantial postoperative analgesia. Although the transition to postoperative pain management can be made using a remifentanil infusion alone, this appears to be associated with a high incidence of adverse respiratory effects.

Bowdle and colleagues[74] evaluated the use of a remifentanil infusion to provide postoperative analgesia during recovery from total intravenous anesthesia with remifentanil and propofol from a wide variety of noncardiac surgeries (eg, abdominal, spine, joint replacement, thoracic). This multiinstitutional study involving 157 patients had a detailed protocol that specified doses and method of administration of all anesthetic drugs. Total intraoperative intravenous anesthesia consisted of midazolam (premedication only), remifentanil, propofol, and vecuronium. Propofol was stopped immediately before intraoperative extubation, and the remifentanil infusion was continued for postoperative analgesia. During the immediate postoperative period, intravenous morphine was administered during tapering of remifentanil infusion. Adverse respiratory events that included oxygen saturation via pulse oximetry less than 90%, respiratory rate less than 12 per minute, and apnea, affected 45 patients (29%; 2 required naloxone). Apnea occurred in 11 patients (7% treated with mask ventilation and downward titration of remifentanil infusion; 1 required naloxone). The administration of a bolus of remifentanil preceded the onset of adverse respiratory events in 19 of 45 cases and in 9 of 11 cases of apnea.

These data suggest that remifentanil boluses plus an infusion are particularly likely to produce clinically significant adverse respiratory events. The authors of this open, dose-ranging study concluded that although remifentanil certainly initiates analgesia, its use in the immediate postoperative period may pose dangers.[74] Additional studies are needed to investigate the transition from remifentanil to longer-lasting analgesics and to refine strategies that minimize respiratory depression while optimizing pain control. The administration of a potent, rapid-acting opioid such as remifentanil by continuous infusion for postoperative analgesia must be performed with meticulous attention to detail and constant vigilance. Extreme caution should be exercised in the postoperative administration of bolus doses of remifentanil because substantial respiratory depression (including apnea) may develop. Furthermore, the remifentanil infusion should be inserted into the intravenous line as close as possible to the patient to minimize dead space, and the rate of the main intravenous infusion should be controlled at a rate that is high enough to continuously flush remifentanil from the tubing. A more dilute remifentanil solution that runs at greater rates (on a volume-per-time basis) helps minimize the effect of variations in flow rate of the main intravenous tubing on

delivery of remifentanil to the patient. Remifentanil also may possess detrimental cardiovascular effects via bradycardia and decreases in systemic vascular resistance, leading to decreased cardiac output and hypotension.[75] Such changes may occur during clinically used doses for cardiac surgery (0.1 to 1.0 µg/kg/min), inducing significant cardiovascular disturbances that are potentially deleterious to patients with cardiac disease.[75]

Patient-Controlled Analgesia

When intravenous opioids are used for controlling postoperative pain (most commonly morphine and fentanyl), PCA technology is generally used. Essentials in the successful use of PCA technology include loading the patient with intravenous opioids to the point of patient comfort before initiating PCA, ensuring that the patient wants to control analgesic treatment, using an appropriate PCA dose and lockout interval, and considering the use of a basal rate infusion. Focused guidance of PCA dosing by a dedicated acute pain service, compared with surgeon-directed PCA, may result in more effective analgesia with fewer adverse effects. Patient-controlled epidural analgesic techniques with opioids and/or local anesthetic agents also have been proved reliable, effective, and safe.[76,77]

Although PCA is a well-established technique that has been used for more than 2 decades and offers potential unique benefits (eg, reliable analgesic effect, improved patient autonomy, flexible adjustment to individual needs), whether it truly offers significant clinical advantages compared with traditional nurse-administrated analgesic techniques to patients immediately after cardiac surgery remains to be determined.[78–83] A clinical investigation by Gust and associates[79] indicates that PCA techniques provide a higher quality of postoperative analgesia, which may lead to a reduction in postoperative respiratory complications. In this prospective, randomized, clinical investigation involving 120 healthy patients, following extubation after elective CABG, patients received intravenous PCA piritramide, intravenous PCA piritramide plus rectal indomethacin, or conventional nurse-controlled analgesia with intravenous piritramide and/or rectal indomethacin for 3 days. Postoperative assessment included daily visual analog pain scores and chest radiographs graded for the extent of atelectasis by a radiologist blinded to treatment. Perioperative management (surgical treatment, intraoperative anesthetic management) was standardized. Although chest radiography atelectasis scores and visual analog pain score values were similar among the three groups on the first and second postoperative days, chest radiography atelectasis scores and visual analog pain score values were significantly better on the third postoperative day in the two PCA groups compared with the control (nurse-controlled analgesia) group. At the end of the study, all patients retrospectively graded their postoperative pain management on average as good but significantly more patients in the two PCA groups assessed their pain management as excellent compared with the control group. These investigators concluded that treatment with PCA may reduce respiratory complications in patients after CABG. However, no difference was observed regarding perioperative oxygenation values among the three groups during the entire study period, and not a single patient in any group prospectively met the defined criteria for a diagnosis of pneumonia. Other clinical investigations also have indicated that PCA techniques, compared with standard nurse-based pain therapy, may provide higher quality analgesia leading to reduced cardiopulmonary morbidity after cardiac surgery.[80,83]

Despite the popularity of PCA techniques and the results of the previously quoted studies, other clinical investigations have demonstrated no major benefits offered.[78,81,82] Tsang and Brush[78] prospectively evaluated 69 patients after cardiac surgery via median sternotomy. Thirty-nine patients were randomized to receive PCA morphine after surgery, whereas 30 were randomized to receive nurse-administered morphine after surgery. Perioperative care was standardized, visual analog pain scores were used for pain assessment, and pulmonary function tests were performed before surgery and every 6 hours after surgery until discharge from the ICU. These clinical investigators found

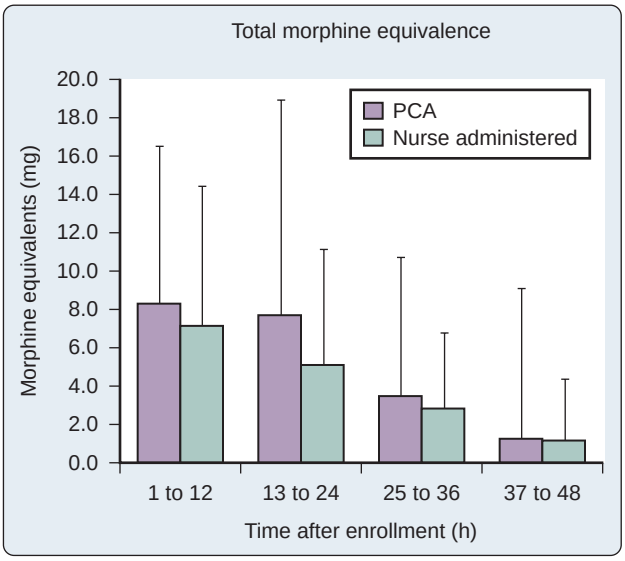

Fig. 42.4 Total Morphine Equivalents. Dosages of morphine equivalents in the patient-controlled analgesia *(PCA)* and nurse-administered groups during each observation period. No differences existed between the two groups at any observation period. *(From Tsang J, Brush B. Patient-controlled analgesia in postoperative cardiac surgery.* Anaesth Intensive Care. *1999;27:464–470.)*

no differences between the two groups regarding postoperative morphine consumption (Fig. 42.4), postoperative visual analog pain scores, postoperative sedation scores, and postoperative pulmonary function (Fig. 42.5). These investigators concluded that no significant advantages were achieved when routinely using PCA in patients after cardiac surgery. Interestingly, in this study, opinions expressed by the nursing staff on the use of PCA were not as positive as expected. Repeating the instructions to patients on PCA was often required during the study period. Potential reasons for the need to repeat instructions on PCA included poor retention of preoperative learning because of anxiety after hospital admission, incomplete recovery of higher cognitive function after prolonged general anesthesia and CPB, and/or ICU-induced disorientation.

These results suggested that additional patient limitations to the effective use of PCA may exist immediately after cardiac surgery, even though patients can obey simple commands and acknowledge discomfort. Munro and colleagues,[81] when comparing intravenous PCA morphine and nurse-administered subcutaneous morphine, detail similar findings. They prospectively randomized 92 patients undergoing elective cardiac surgery to receive either intravenous PCA morphine or nurse-administered subcutaneous morphine during the postoperative period. They found no differences between the two groups regarding many postoperative variables, including total postoperative morphine requirements, postoperative visual analog pain scores at rest and with movement, daily verbal pain relief scores, side effect profiles, and physiotherapists' evaluation of effectiveness of analgesia for chest physiotherapic treatments. Subcutaneous techniques are attractive because they have low equipment and disposable costs, eliminate the need for bulky pumps in ambulating patients, and may be more effective for older adults or the postoperative patient who is mildly confused.

Myles and associates[82] were also unable to find any specific clinical benefits during the use of PCA techniques in patients after cardiac surgery. In their prospective clinical investigation, 72 patients undergoing elective cardiac surgery were randomized to receive either intravenous PCA morphine or intravenous nurse-titrated morphine during the immediate postoperative period. The investigators of this study found no differences between the two groups regarding many postoperative variables, including postoperative morphine consumption, pain scores, nausea scores, and serum cortisol levels (Fig. 42.6). Similar to Munro and associates,[81] they noted that patients also had variable

ability and understanding of the requirements of PCA, particularly in the early postoperative period when they were either confused or too weak to operate the demand button. These investigators also noted that the patients who received experienced one-to-one nursing care reported improved overall pain management. Other studies evaluating PCA have also found that nurse-administered techniques may provide the highest quality analgesia. It could therefore be argued that these studies support increased staff education and involvement to optimize postoperative analgesia. The nurses in these clinical investigations all raised concerns regarding the time required for PCA setup and the inability of patients to cope with the demands of PCA in the early stages of their recovery, particularly if the patients were older adults, confused, or both. However, PCA was well received later in the recovery process and was found to be less demanding on nursing time.

Nonsteroidal Antiinflammatory Agents

Nonsteroidal antiinflammatory drugs (NSAIDs), in contrast with the opioids' central nervous system mechanism of action, primarily exert their analgesic, antipyretic, and antiinflammatory effects peripherally by interfering with prostaglandin synthesis after tissue injury[84,85] (Box 42.7). NSAIDs inhibit COX, the enzyme responsible for the conversion of arachidonic acid to prostaglandin (Fig. 42.7). Combining NSAIDs with traditional intravenous opioids may allow a patient to achieve an adequate level of analgesia with fewer side effects than if a similar level of analgesia was obtained with intravenous opioids alone. Numerous clinical investigations reveal the potential value (opioid-sparing effects) of NSAIDs when combined with traditional intravenous opioids during the postoperative period after noncardiac surgery. In fact, the administration of NSAIDs is one of the most common nonopioid analgesic techniques currently used for postoperative pain management. The efficacy of NSAIDs for the management of postoperative pain has been repeatedly demonstrated in many analgesic

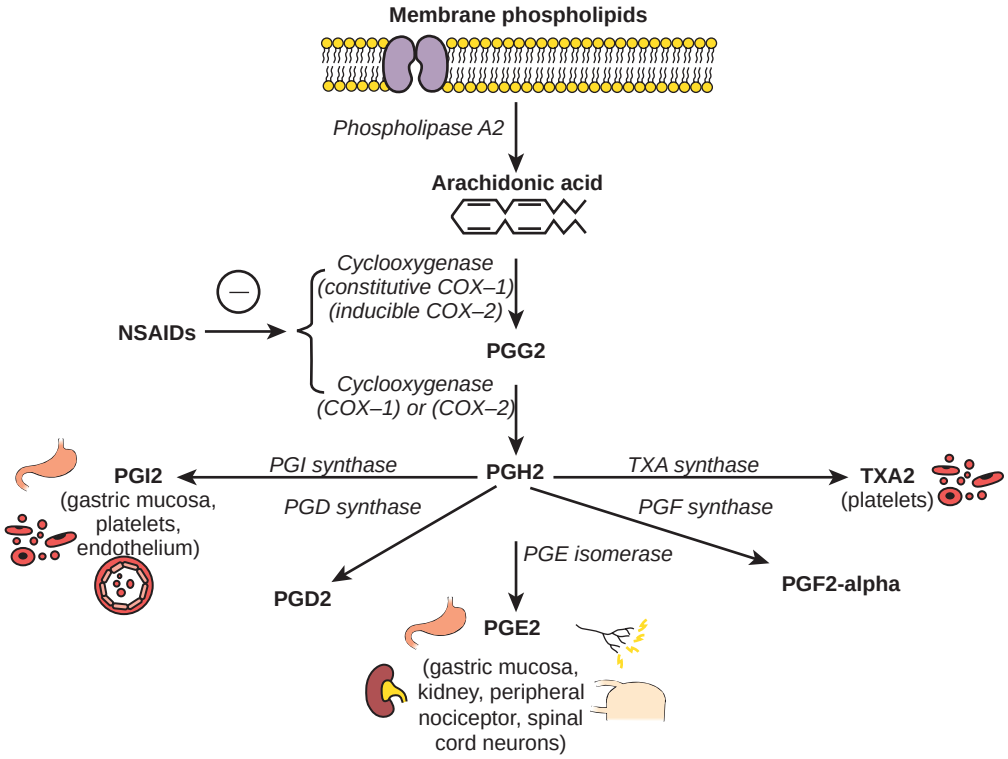

Fig. 42.7 The Role of Cyclooxygenase in Prostaglandin Synthesis. Prostaglandin *(PG)* and thromboxanes *(TX)*, which are important in inflammation and homeostasis, are products of a biochemical cascade during which membrane phospholipids are converted to arachidonic acid, then to intermediate prostaglandins by cyclooxygenase, and to their final products by a series of synthases. *COX,* Cyclooxygenase; *NSAIDs,* nonsteroidal antiinflammatory drugs. *(From Gilron I, Milne B, Hong M. Cyclooxygenase-2 inhibitors in postoperative pain management: current evidence and future directions.* Anesthesiology. *2003;99:1198–1208.)*

clinical trials. Unlike opioids, which preferentially reduce spontaneous postoperative pain, NSAIDs have comparable efficacy for both spontaneous and movement-evoked pain, the latter of which may be more important in causing postoperative physiologic impairment. Certainly, NSAIDs reduce postoperative opioid consumption, accelerate postoperative recovery, and represent an integral component of balanced postoperative analgesic regimens after noncardiac surgery. However, little is known regarding NSAID use in the management of pain after cardiac surgery. Concerns regarding NSAID side effects, including alterations in the gastric mucosal barrier, renal tubular function, and inhibition of platelet aggregation, have likely made clinicians reluctant to use NSAIDs in patients undergoing cardiac surgery. Other rare adverse effects of NSAIDs (from COX inhibition) include hepatocellular injury, asthma exacerbation, anaphylactoid reactions, tinnitus, and urticaria. Despite these fears, a small number of clinical investigations seem to indicate that NSAIDs may provide analgesia in patients after cardiac surgery without untoward effects (eg, gastrointestinal ulceration, renal dysfunction, excessive bleeding). Although NSAIDs have been associated with reports of increased postoperative blood loss, other studies have failed to corroborate this blood loss.

NSAIDs are not a homogenous group and vary considerably in analgesic efficacy as a result of differences in pharmacodynamic and pharmacokinetic parameters. NSAIDs are nonspecific inhibitors of COX, which is the rate-limiting enzyme involved in the synthesis of prostaglandins. COX exists in multiple forms. Most importantly, a constitutive form, cyclooxygenase-1 (COX-1), is present in normal conditions in healthy cells, and an inducible form (COX-2) exists, which is the major isozyme induced by and associated with inflammation. Simplistically, COX-1 is ubiquitously and constitutively expressed and has a homeostatic role in platelet aggregation, gastrointestinal mucosal integrity, and renal function, whereas COX-2 is inducible and primarily expressed at the sites of injury (and in the kidney and brain) and mediates pain and inflammation. NSAIDs are nonspecific inhibitors of both forms of COX yet vary in their ratio of COX-1 to COX-2 inhibition. Molecular studies distinguishing between constitutive COX-1 and inflammation-inducible COX-2 enzymes have led to the exciting hypothesis that the therapeutic and adverse effects of NSAIDs could be uncoupled[86–91] (Fig. 42.8). Subsequently, clinicians have witnessed an exponential increase in publications and the growing use of COX-2 inhibitors in the perioperative period after noncardiac surgery. A compelling body of evidence now exists that COX-2 inhibitors, similar to their predecessors, the nonselective NSAIDs, generally provide postoperative analgesia, decrease intravenous opioid requirements, and greater patient satisfaction compared with placebo. Some evidence also suggests that opioid-sparing by COX-2 inhibitors also spares opioid side effects. The primary advantage of COX-2 inhibitors, compared with NSAIDs, is their lack of effect on platelet function and bleeding, hence the opportunity for perioperative administration.

Only a handful of clinical studies have investigated the potential of NSAIDs in the management of pain after cardiac surgery.[92–95] One well-designed clinical investigation revealed that a combination of NSAIDs and intravenous opioids may provide superior analgesia after cardiac surgery without untoward effects. Rapanos and colleagues[94] prospectively randomized 57 patients to receive either indomethacin suppositories or placebo suppositories in a double-blinded fashion during the immediate postoperative period after elective CABG. Patients receiving indomethacin suppositories demonstrated significantly less ($p = 0.019$) morphine consumption (assessed via PCA morphine) and significantly lower ($p = 0.006$) pain scores (assessed via visual analog pain scores) during the immediate postoperative period compared with those in the control placebo group. Postoperative morphine use during the first 24 postoperative hours was 22 ± 13 mg in the indomethacin group

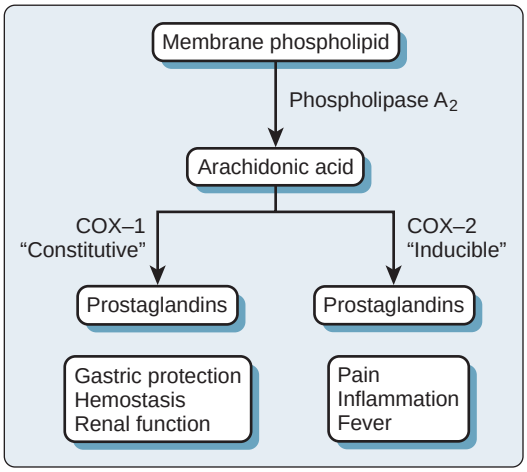

Fig. 42.8 Cyclooxygenase *(COX)* Pathways. Molecular studies distinguishing between COX-1 and COX-2 enzymes have led to the exciting hypothesis that the therapeutic and adverse effects of the nonspecific inhibitors (nonsteroidal antiinflammatory drugs) could be uncoupled. *(From Gajraj NM. Cyclooxygenase-2 inhibitors.* Anesth Analg. *2003;96: 1720–1738.)*

and 36 ± 26 mg in the placebo group. No differences were observed between groups regarding tracheal extubation time or postoperative blood loss (assessed via chest tube output). None of the study subjects in either group developed postoperative renal dysfunction. In fact, a moderate reduction in serum creatinine concentration was observed in both groups. These investigators concluded that the combination of indomethacin suppositories with morphine after cardiac surgery results in reduced postoperative pain scores and opioid consumption without an increase in side effects.

However, two well-designed clinical investigations demonstrate that the use of NSAIDs or NSAID-like drugs (acetaminophen) in patients after cardiac surgery may not offer any substantial clinical benefits.[92,95] Hynninen and associates[92] in a prospective, double-blind, placebo-controlled study, randomized patients to receive diclofenac ($n = 28$ patients), ketoprofen ($n = 28$ patients), indomethacin ($n = 27$ patients), or placebo ($n = 31$ patients) for postoperative analgesia after elective CABG via a median sternotomy. All patients received standardized fast-track cardiac anesthesia and standardized postoperative analgesia treatment. Mean morphine consumption in the immediate postoperative period was significantly reduced in only the diclofenac group when compared with the placebo group (12 mg vs 19 mg, respectively; $p < 0.05$). Total analgesic consumption calculated as morphine equivalents was also significantly lower in only the diclofenac group compared with the placebo group (18 mg vs 27 mg, respectively; $p < 0.05$). No additional important differences were observed when doses of other analgesics were compared. The visual analogue pain scores at rest were comparable among the four groups at all times. Additionally, no postoperative differences were observed among the four groups regarding creatinine concentration, percentage of patients with 20% or greater increases in the creatinine level after surgery, and 24-hour blood loss. Although some NSAIDs may offer opioid-sparing effects, these findings indicated that others may not.

Lahtinen and colleagues[95] in a prospective, double-blind, placebo-controlled study, patients were randomized to receive either propacetamol, a prodrug of acetaminophen ($n = 40$ patients), or placebo ($n = 39$ patients) for postoperative analgesia after elective CABG via a median sternotomy. Acetaminophen (not an NSAID) might be a safer nonopioid analgesic in cardiac surgery because it does not depress platelet function or renal function as much as traditional NSAIDs. The mechanism behind the analgesic action of acetaminophen remains unclear. Acetaminophen has only a weak inhibitory influence on peripheral COX pathways and has no substantial antiinflammatory activity. Acetaminophen-induced analgesia may be partially centrally mediated, and the peak cerebrospinal fluid concentrations may reflect analgesic action. Intravenous propacetamol is quickly hydrolyzed to acetaminophen in the bloodstream. In the clinical investigation by Lahtinen and colleagues,[95] a standardized intraoperative anesthetic technique was used for all patients, and extubation times were identical between the two groups (approximately 5 hours). From the time of extubation, all patients had access to PCA oxycodone using a standardized protocol. The variation of oxycodone consumption was large in both groups. Although postoperative cumulative oxycodone consumption (combined amount administered via PCA and given as rescue doses) was less in the propacetamol group compared with the placebo group, the difference was not statistically significant (124 ± 51 mg vs 142 ± 58 mg, respectively; $p = 0.15$). Postoperative visual analog pain scores obtained at rest and during a deep breath were similar, as well as patients' satisfaction with analgesia between the two groups. Furthermore, no differences existed between the two groups regarding postoperative pulmonary function tests (eg, forced expiratory volume in 1 second, peak expiratory volume, forced vital capacity), blood gas analysis, bleeding, renal function tests, and liver function tests. Postoperative nausea and vomiting were the most common adverse events, which occurred with identical frequency in both groups. These investigators conclude that propacetamol neither enhances postoperative opioid-based analgesia in patients after CABG nor does it decrease cumulative opioid consumption or reduce adverse effects.

One prospective, randomized clinical study investigated the potential advantages and disadvantages of using COX inhibitors in patients after cardiac surgery. Immer and associates[96] prospectively randomized 69 patients scheduled for elective CABG with conventional sternotomy to receive either a COX-2 inhibitor (etodolac), a nonselective COX inhibitor (diclofenac), or a weak opioid (tramadol) for postoperative analgesia. Postoperative pain was assessed via a visual analogue scale, perioperative blood samples were obtained for serum creatinine and urea levels, and creatinine clearance was determined on postoperative day 1 (before starting the study medication) and on postoperative day 4 (after receiving the study medication). In patients with insufficient postoperative analgesia (defined via predetermined visual analog scale score), supplemental subcutaneous morphine was administered. Total morphine consumption and occurrence of nausea were recorded daily. At the doses analyzed by these investigators, etodolac and diclofenac produced slightly better postoperative analgesia (assessed via visual analog scale scores and morphine consumption) with fewer adverse effects (assessed via antiemetic therapy) than tramadol. However, a short-lasting impairment of renal function was found in patients treated with etodolac and diclofenac (assessed via serum creatinine and urea levels; Figs. 42.9 and 42.10). However, at hospital discharge, no significant differences existed among the three groups regarding serum creatinine and urea levels (see Figs. 42.9 and 42.10). Lastly, all three groups experienced similar decreases in postoperative creatinine clearance.

Another clinical investigation of patients after CABG suggested a proportionately, but not significantly, greater incidence of serious cardiac and cerebrovascular adverse events in patients taking COX-2 inhibitors. In this multicenter (58 institutions), prospective, randomized, double-blind, parallel-group trial performed by Ott and associates,[97] 462 patients undergoing CABG were allocated at a ratio of 2:1 to parecoxib (prodrug of valdecoxib) group (311 patients) or standard care control group (151 patients;). Patients in the parecoxib/valdecoxib group required significantly less morphine or morphine equivalents than patients in the control group during the postoperative period (up to 6 days). Both patients and physicians evaluated the study medication (parecoxib/valdecoxib) as significantly better than control therapy. Pain questionnaires detected significant improvements in the parecoxib/valdecoxib group beginning on day 4 and continuing for at least 4 days. However, although no differences were observed between the groups in overall adverse events, serious adverse events occurred twice as frequently in parecoxib/valdecoxib–treated patients than in control patients (19% vs 10%, respectively; $p = 0.015$). Regarding individual serious adverse events, a greater incidence rate in sternal

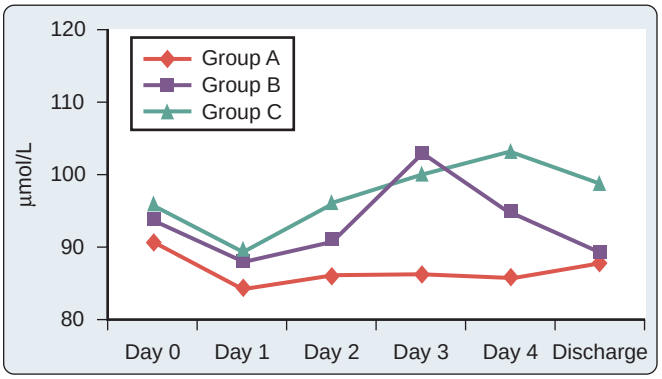

Fig. 42.9 Serum Creatinine Values. Serum creatinine values for groups A (tramadol), B (diclofenac), and C (etodolac) on postoperative days 1 to 4 and at discharge. Results are displayed as mean values. Serum creatinine levels were significantly greater on postoperative days 3 and 4 in groups B and C compared with group A ($p < 0.05$). However, at discharge, no significant differences were found among the three groups. *(From Immer FF, Immer-Bansi AS, Trachsel N, et al. Pain treatment with a COX-2 inhibitor after coronary artery bypass operation: a randomized trial.* Ann Thorac Surg. *2003;75:490–495.)*

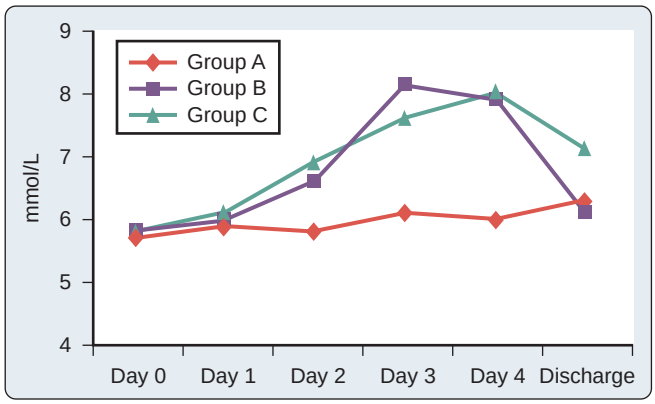

Fig. 42.10 Serum Urea Values. Serum urea values for groups A (tramadol), B (diclofenac), and C (etodolac) on postoperative days 1 to 4 and at discharge. Results are displayed as mean values. Serum urea levels were significantly greater on postoperative days 3 and 4 in groups B and C compared with group A ($p < 0.05$). However, at discharge, no significant differences were found among the three groups. *(From Immer FF, Immer-Bansi AS, Trachsel N, et al. wound infection was found in the parecoxib/valdecoxib patients (3%) versus control patients (0%) ($p = 0.035$). The effects of NSAIDs on sternal wound complications had not been previously reported. The COX-2 enzyme enables prostaglandin release and the inflammatory response. Inhibition of this enzyme by nonspecific COX inhibitors (NSAIDs), as well as specific COX-2 inhibitors, might impede reparative inflammatory responses and increase susceptibility to sternal wound infections. An alternative hypothesis is that reduced fever and tachycardia in NSAID/COX-2 inhibitor–treated patients may delay detection of infection, resulting in further progression and greater consequence. Regardless of the mechanism, these safety issues merit careful consideration because of the importance of sternal wound complications in this setting. The incidence of other individual serious adverse events, including cerebrovascular complications, myocardial infarction, and renal dysfunction, were proportionally greater in the parecoxib/valdecoxib group but not significantly different between the two groups. Specifically, when the groups were compared, more patients in the treatment group (parecoxib/valdecoxib) experienced cerebrovascular disorders (3% vs 1%; $p = 0.177$), myocardial infarction (2% vs 1%; $p = 0.669$), and renal dysfunction (2% vs 0%; $p = 0.184$) when compared with control patients.

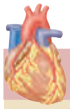
Such thrombosis-mediated complications merit careful consideration. In cardiac surgery patients who are exposed to CPB, the delicate balance among platelets, endothelial cells, and serum clotting factors is disturbed, with consequent thrombosis and clot lysis disparately and unpredictably occurring throughout the vascular system. Given that COX-2 inhibitors are platelet sparing, these drugs might tip the balance toward thrombosis during periods of platelet activation. In addition, because COX-1 is unaffected, consequent release of thromboxane A_2 may further promote platelet activation and thrombosis. Of note, some analyses addressing these issues in chronically treated patients with arthritis indicate a potential association between COX-2 inhibition and thrombogenic events (eg, myocardial infarction, stroke, vascular death).[98] Ott and associates[97] concluded that in patients undergoing CABG, the COX-2 inhibitor combination of parecoxib/valdecoxib is effective in controlling postoperative analgesia, yet the treatment regimen may be associated with an increased incidence of serious adverse events overall and sternal wound infections in particular. Their study therefore raised important concerns requiring a comprehensive evaluation of the potential link between this class of drugs and perioperative complications in a large-scale clinical trial before the COX-2 inhibitors are routinely used in patients undergoing cardiac surgery.

Over time, significantly more will be learned about COX-2 inhibitors. Their analgesic (opioid-sparing) effects and lack of deleterious effects on coagulation (in contrast with nonselective NSAIDs) are certainly desirable. The evidence to date does not suggest that COX-2 inhibitors provide major advantages over traditional NSAIDs. Their continued development will possibly lead to specific drugs with a superior therapeutic profile. Many important questions regarding their safety remain unanswered, such as effects on central nervous system sensitization, perioperative renal function, preemptive analgesia, clinically significant blood loss, the gastrointestinal system, the cardiovascular system, chronic postsurgical pain, bone and wound healing, blood pressure, and peripheral edema, among others. Specifically regarding patients undergoing cardiac surgery, the potential links between this class of drugs and sternal wound infections and thromboembolic complications need to be fully evaluated. Lastly, the recent and unprecedented retraction of numerous peer-reviewed articles and abstracts (spanning 15 years) published by a leading investigator in the perioperative use of NSAIDs and COX-2 inhibitors raises important questions as to the potential adverse impact of this investigator's fraudulent work on the practice of acute postoperative pain management.[99] Simply put, such unprecedented retraction forces clinicians to question all that was previously known (and assumed true) of the advantages and disadvantages of using NSAIDs and COX-2 inhibitors, prompting the need for future clinical analysis studies to address these important issues.

Alpha$_2$-Adrenergic Agonists

The α_2-adrenergic agonists provide analgesia, sedation, and sympatholysis (Box 42.8).[100] The initial impetus for the use of α_2 agonists in anesthesia resulted from astute clinical observations made in patients during intraoperative anesthesia who were receiving clonidine therapy. Soon thereafter, investigators revealed that clonidine substantially reduced anesthetic requirements (minimal alveolar concentration). More recently, dexmedetomidine has undergone extensive clinical evaluation for perioperative use. Dexmedetomidine exerts profound effects on cardiovascular parameters and thus appears to affect its own pharmacokinetics. At high doses, there is significant vasoconstriction, which probably reduces the drug's volume of distribution. The elimination half-life of dexmedetomidine is 2 to 3 hours.

α_2-Adrenergic agonists produce clinically sedative effects via stimulation of α_2 receptors in the locus ceruleus and clinically analgesic effects via stimulation of α_2 receptors within the locus ceruleus and spinal cord.[101] Existing evidence indicates that α_2 agonists enhance the



BOX 42.8 ALPHA$_2$-ADRENERGIC AGONISTS

  - Hypotension

analgesic effects of the opioids via an unknown mechanism of action. Several mechanisms of action have been postulated for the analgesia noted with α_2-adrenergic agonists including supraspinal, ganglionic, spinal, and peripheral mechanisms. Clinically, systemic administration of these agents produces antinociception and sedation, whereas intrathecal administration usually produces only antinociception. Similar to other adrenergic receptors, the α_2-adrenergic agonists demonstrate tolerance after prolonged administration.

As with all clinically used analgesics, the α_2-adrenergic agonists possess clinically important side effects that may limit their usefulness. The effects of dexmedetomidine on the respiratory system include a decrease in tidal volume, minimal changes in respiratory rate, and a rightward shift and depression of slope of the carbon dioxide response curve, all of which may cause hypercarbia. However, respiratory depression associated with the drug is usually clinically unimportant, even during profound levels of sedation. The effects of dexmedetomidine on the cardiovascular system are many and, in contrast with the respiratory effects, may become clinically important. Physiologic changes include decreased heart rate, decreased systemic vascular resistance, and possibly indirectly decreased myocardial contractility, all potentially leading to decreased cardiac output and decreased blood pressure in susceptible patients. By developing more highly selective α_2-adrenergic agonists, it is hoped that these detrimental cardiovascular effects will be minimized while maximizing the desired analgesic and sedative properties. Currently, the clinical role of these drugs includes preoperative sedation, an intraoperative adjuvant during anesthesia to reduce sedative and analgesic requirements, and postoperative sedation and analgesia. The potential ability of the α_2-adrenergic agonists to reduce and/or prevent perioperative myocardial ischemia, although intriguing, remains to be determined.[102]

The potential perioperative analgesic benefits of α_2 agonists when administered to patients undergoing cardiac surgery were demonstrated 30 years ago. In 1987, Flacke and associates[103] in prospective, nonblinded fashion, randomized patients undergoing elective CABG to receive either perioperative oral clonidine supplementation (10 patients) or serve as control patients (10 patients). Outside of oral clonidine supplementation, management of the two study groups was identical. Patients receiving oral clonidine required significantly less preinduction diazepam and significantly less intraoperative sufentanil (Fig. 42.11) and isoflurane to maintain intraoperative normotension (clearly establishing clonidine's sedative and analgesic properties). Furthermore, patients receiving oral clonidine were extubated earlier during the postoperative period, compared with control patients (approximately 11 vs 16 hours, respectively; $p < 0.05$). However, 4 of 10 patients receiving oral clonidine required atropine for treatment of intraoperative bradycardia. Unfortunately, postoperative analgesia was not assessed in this clinical investigation.

Although the analgesic properties of α_2-adrenergic agonists are undisputed, most of the clinical investigations regarding perioperative use of this class of drugs remain focused on exploiting the sedative effects and beneficial cardiovascular effects (decreasing hypertension and tachycardia) associated with their use.[104–107] α_2-Adrenergic agonists have been used perioperatively in patients undergoing cardiac surgery. However, the focus of such clinical investigations has been on the intraoperative period and the potential for enhanced postoperative hemodynamic stability, potentially leading to reduced postoperative myocardial ischemia (but not specifically to enhance postoperative analgesia).[108–111] Taken together, these clinical investigations indicate that perioperative administration of α_2-adrenergic agonists to patients undergoing cardiac surgery decreases intraoperative anesthetic requirements, may enhance perioperative hemodynamic stability, and may decrease perioperative myocardial ischemia. α_2-Adrenergic agonists may also cause excessive postoperative sedation and initiate postoperative hemodynamic instability via bradycardia and/or decreased systemic vascular resistance, leading to hypotension and increased pacing requirements in susceptible patients. The potential ability of this class of drugs to initiate reliable postoperative analgesia awaits definitive investigation.

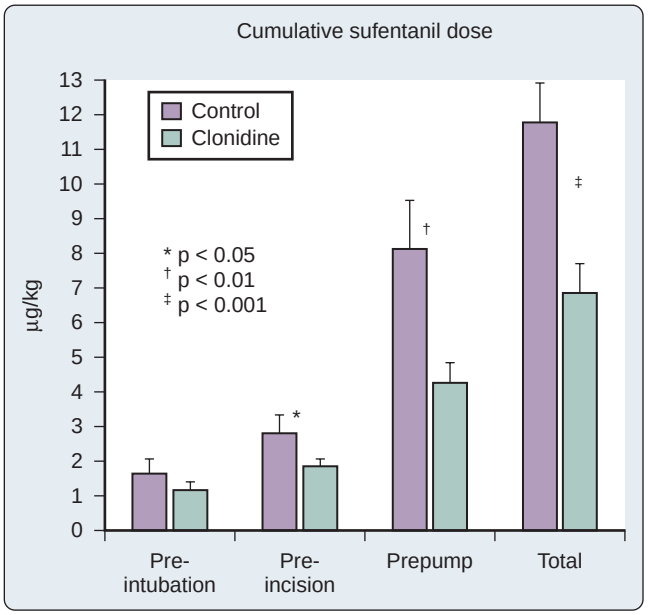

Fig. 42.11 Cumulative Sufentanil Dose. Mean cumulative sufentanil doses are shown for the periods before intubation, before incision, before cardiopulmonary bypass (CPB) surgery, and for the entire anesthetic period. *(From Flacke JW, Bloor BC, Flacke WE, et al. Reduced narcotic requirement by clonidine with improved hemodynamic and adrenergic stability in patients undergoing coronary bypass surgery.* Anesthesiology. *1987;67:11–19.)*

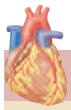
Intrathecal and Epidural Techniques

Numerous clinical investigations clearly indicate that intrathecal and/or epidural techniques (using opioids and/or local anesthetics) initiate reliable postoperative analgesia in patients after cardiac surgery[112] (Boxes 42.9 and 42.10). Traditional additional potential advantages of using intrathecal and/or epidural techniques in patients undergoing cardiac surgery include stress-response attenuation and thoracic cardiac sympathectomy. Recent animal investigations seem to indicate that intrathecal morphine may also confer protection against myocardial ischemia and reperfusion injury through the activation of spinal cord opioid receptors.[113–115] Although the signaling pathway of this form of remote cardioprotection has not yet been elucidated, it does not seem to require peripheral opioid–receptor involvement.

An uninhibited stress response during the postoperative period may lead to many adverse hemodynamic (tachycardia, hypertension, vasoconstriction), metabolic (increased catabolism), immunologic (impaired immune response), and hemostatic (platelet activation) alterations. Intrathecal or epidural anesthesia and analgesia (with local anesthetics or opioids) can effectively inhibit the stress response associated with surgical procedures.[29] Local anesthetics appear to possess greater efficacy than opioids in perioperative stress-response attenuation, perhaps because of their unique mechanism of action. Although still a matter of some debate, perioperative stress-response attenuation

BOX 42.9 INTRATHECAL TECHNIQUES

- Advantages
  - Simple, reliable analgesia
  - Stress-response attenuation
  - Less hematoma risk than epidural techniques
- Disadvantages
  - No cardiac sympathectomy
  - Hematoma risk increased
  - Side effects of intrathecal opioids



BOX 42.10 EPIDURAL TECHNIQUES

- Advantages
  - Reliable analgesia
  - Stress-response attenuation
  - Cardiac sympathectomy
- Disadvantages
  - Labor intensive
  - Hematoma formation risk increased
  - Side effects of epidural opioids

with epidural local anesthetics and/or opioids in high-risk patients after major noncardiac surgery may decrease morbidity and mortality.[6,7,29] In patients undergoing cardiac surgery, initiation of CPB causes significant increases in stress-response hormones that persist into the immediate postoperative period.[26–28] Attenuation of this component of the perioperative stress response with intravenous opioids also may decrease morbidity and mortality in these patients.[8,9] Unfortunately, perioperative stress-response attenuation in patients undergoing cardiac surgery with intravenous opioids in this manner does not allow tracheal extubation to occur in the immediate postoperative period. Intrathecal or epidural anesthesia and analgesia techniques (particularly with local anesthetics) are attractive alternatives to intravenous opioids in this setting because of their potential to attenuate the perioperative stress response yet still allow tracheal extubation to occur in the immediate postoperative period.

The myocardium and coronary vasculature are densely innervated by sympathetic nerve fibers that arise from T1 to T5 and profoundly influence total coronary blood flow and distribution.[116] Cardiac sympathetic nerve activation initiates coronary artery vasoconstriction[117] and paradoxic coronary vasoconstriction in response to intrinsic vasodilators.[118] In patients with coronary artery disease, cardiac sympathetic nerve activation disrupts the normal matching of coronary blood flow and myocardial oxygen demand.[119,120] Animal models have revealed an intense poststenotic coronary vasoconstrictive mechanism mediated by cardiac sympathetic nerve activation that attenuates local metabolic coronary vasodilation in response to myocardial ischemia.[121,122] Furthermore, myocardial ischemia initiates a cardiocardiac reflex mediated by sympathetic nerve fibers, which augments the ischemic process.[123] Cardiac sympathetic nerve activation likely plays a central role in initiating postoperative myocardial ischemia by decreasing myocardial oxygen supply via the mechanisms previously listed.[29,124]

Thoracic epidural anesthesia (TEA) with local anesthetics effectively blocks cardiac sympathetic nerve afferent and efferent fibers.[29] Opioids, similarly administered, are unable to effectively block such cardiac sympathetic nerve activity.[29] Patients with symptomatic coronary artery disease benefit clinically from cardiac sympathectomy, and the application of thoracic sympathetic blockade in the management of angina pectoris was described as early as 1965.[125] TEA with local anesthetics increases the diameter of stenotic epicardial coronary artery segments without causing dilation of coronary arterioles,[119] decreases determinants of myocardial oxygen demand,[120] improves left ventricular function,[126] and decreases anginal symptoms.[120,127] Furthermore, cardiac sympathectomy increases the endocardial-to-epicardial blood flow ratio,[128,129] beneficially affects collateral blood flow during myocardial ischemia,[120] decreases poststenotic coronary vasoconstriction,[122] and attenuates the myocardial ischemia-induced cardiocardiac reflex.[122] In an animal model, TEA with local anesthetics actually decreased the size of the myocardial infarction after coronary artery occlusion.[128] Of note, systemic absorption of the local anesthetic does not cause these beneficial effects.[128] In short, TEA with local anesthetics may benefit patients undergoing cardiac surgery by effectively blocking cardiac sympathetic nerve activity and improving the balance of the myocardial oxygen supply and demand.

Intrathecal Techniques

The application of intrathecal analgesia to patients undergoing cardiac surgery was initially reported by Mathews and Abrams in 1980[130] who described the administration of intrathecal morphine (1.5 to 4.0 mg) to 40 adults after the induction of general anesthesia for cardiac surgery. Somewhat remarkably, all 40 patients awakened free from pain at the end of surgery (before leaving the surgical unit), and 36 patients were tracheally extubated before being transferred to the ICU. All 40 patients were entirely pain free for the first 28 postoperative hours, and 17 did not require any supplemental analgesics before being discharged from the hospital. Of the 17 patients who received 4 mg intrathecal morphine, 11 did not require any postoperative analgesic drugs. Mathews and Abrams[130] summarized, "The benefits of recovering from surgery free from pain have been impressive. This has been particularly appreciated by patients who have had previous operations with conventional anesthesia and postoperative analgesic drugs. The patients have been remarkably comfortable, able to move more easily in bed, and more cooperative, thus greatly helping their nursing care." After this impressive clinical display, other investigators have subsequently applied intrathecal anesthesia and analgesia techniques to patients undergoing cardiac surgery.[131–171]

Most clinical investigators have used intrathecal morphine in hopes of providing prolonged postoperative analgesia. Some clinical investigators have used intrathecal fentanyl, sufentanil, and/or local anesthetics for intraoperative anesthesia and analgesia (with stress-response attenuation) and/or thoracic cardiac sympathectomy. An anonymous survey of members of the Society of Cardiovascular Anesthesiologists published in 2001 indicated that almost 8% of practicing anesthesiologists incorporate intrathecal techniques into their anesthetic management of adults undergoing cardiac surgery.[172] Of these anesthesiologists, 75% practice in the United States, 72% perform the intrathecal injection before the induction of anesthesia, 97% use morphine, 13% use fentanyl, 2% use sufentanil, 10% use lidocaine, and 3% use tetracaine.[172]

Two randomized, blinded, placebo-controlled clinical studies reveal the ability of intrathecal morphine to induce significant postoperative analgesia after cardiac surgery.[143,150] In 1988, Vanstrum and colleagues[150] prospectively randomized 30 patients to receive either intrathecal morphine (0.5 mg) or intrathecal placebo before the induction of anesthesia. Intraoperative anesthetic management was standardized; after surgery, all patients received only intravenous morphine administered by a nurse who attempted to keep the linear analog pain score at less than 4 (a score of 1 represented no pain, 10 represented the worst pain imaginable; the scale was 25 cm long). Although pain scores between groups were not significantly different at any postoperative time interval tested, patients who received intrathecal morphine required significantly less intravenous morphine than placebo controls (2 vs 8 mg, respectively; $p < 0.02$) during the initial 30 hours after intrathecal injection (Fig. 42.12). Associated with this enhanced analgesia in patients receiving intrathecal morphine was a substantially decreased need for antihypertensive medications (eg, sodium nitroprusside, nitroglycerin, hydralazine) during the immediate postoperative period. The use of

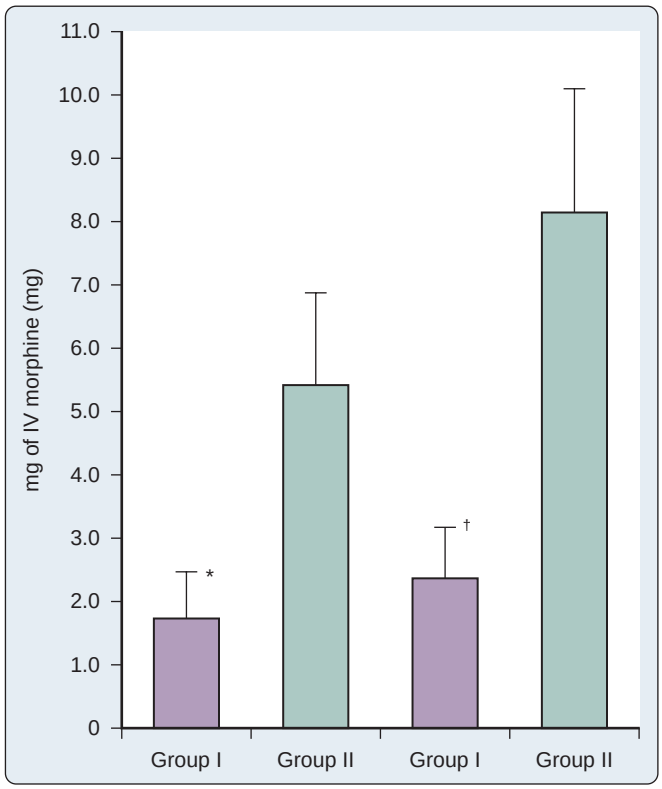


Fig. 42.12 Postoperative Supplemental Intravenous (IV) Morphine Requirements. Patients receiving intrathecal morphine (Group I) required significantly less supplemental intravenous morphine during the initial 24 postoperative hours (*, $p < 0.048$) and during the initial 30 postoperative hours (†, $p < 0.02$) compared with patients receiving intrathecal placebo (Group II). *(From Vanstrum GS, Bjornson KM, Ilko R. Postoperative effects of intrathecal morphine in coronary artery bypass surgery.* Anesth Analg. *1988;67:261–267.)*

intrathecal morphine did not significantly affect the time to tracheal extubation (approximately 20 hours) and postoperative arterial blood gas tensions after anesthesia. In 1996, Chaney and associates[143] prospectively randomized 60 patients to receive either intrathecal morphine (4 mg) or intrathecal placebo before the induction of anesthesia for elective CABG. Intraoperative anesthetic management was standardized, and all patients received intravenous morphine via PCA after tracheal extubation exclusively. The mean time from ICU arrival to tracheal extubation was similar in all patients (approximately 20 hours). However, patients who received intrathecal morphine required significantly less intravenous morphine than placebo controls (33 mg vs 51 mg, respectively; $p < 0.05$) during the initial postoperative period (Table 42.1). Despite enhanced analgesia, no clinical differences were observed between the groups regarding postoperative morbidity (eg, pruritus, nausea, vomiting, urinary retention, prolonged somnolence, atrial fibrillation, ventricular tachycardia, myocardial infarction, stroke), mortality, or duration of postoperative hospital stay (approximately 9 days in each group).

The mid-1990s saw the emergence of fast-track cardiac surgery, with the goal being tracheal extubation in the immediate postoperative period. Chaney and colleagues[142] in 1997 were the first to study the potential clinical benefits of intrathecal morphine when used in patients undergoing cardiac surgery and early tracheal extubation. They prospectively randomized 40 patients to receive either intrathecal morphine (10 μg/kg) or intrathecal placebo before the induction of anesthesia for elective CABG. Intraoperative anesthetic management was standardized (intravenous fentanyl, 20 μg/kg; intravenous midazolam, 10 mg); after surgery, all patients received intravenous morphine via PCA exclusively. Of the patients who were

TABLE 42.1 Postoperative Supplemental Intravenous Midazolam and Morphine Requirements

	Group MS (n = 27)	*Group NS (n = 29)*
Midazolam use from ICU arrival to extubation, mg (range)	8.7 ± 15.8 (0–80)	8.3 ± 15.4 (0–66)
Morphine use from ICU arrival to 8:00 AM POD 2, mg (range)	33.2 ± 15.8 (4–74)	51.1 ± 45.7 (4–254)
Morphine use from 8:00 AM POD 2 to 8:00 AM POD 3, mg (range)	14.2 ± 16.4 (0–68)	12.1 ± 12.6 (0–42)

Patients receiving intrathecal morphine (group MS) required significantly less supplemental intravenous morphine during the immediate postoperative period compared with patients receiving intrathecal placebo (group NS; 33.2 vs 51.1 mg, respectively; $p < 0.05$).

ICU, Intensive care unit; *POD,* postoperative day.

tracheally extubated during the immediate postoperative period, the mean time from ICU arrival to tracheal extubation was significantly ($p = 0.02$) prolonged in patients who received intrathecal morphine (11 ± 4 hours) compared with placebo controls (8 ± 3 hours). Three patients who received intrathecal morphine had tracheal extubation substantially delayed (12 to 24 hours) because of prolonged ventilatory depression (likely secondary to intrathecal morphine). Although the mean postoperative intravenous morphine use for 48 hours was less in patients who received intrathecal morphine (43 mg) compared with patients who received intrathecal placebo (55 mg), the difference between groups was not statistically significant. No clinical differences existed between groups regarding postoperative morbidity, mortality, or duration of postoperative hospital stay (approximately 9 days in each group).

These somewhat discouraging findings (eg, absence of enhanced analgesia, prolongation of tracheal extubation time) stimulated the same group of investigators in 1999 to try again, this time decreasing the amount of intraoperative intravenous fentanyl that the patients received in hopes of decreasing the effect of fentanyl on augmenting postoperative respiratory depression associated with intrathecal morphine.[140] Forty patients were prospectively randomized to receive either intrathecal morphine (10 μg/kg) or intrathecal placebo before the induction of anesthesia for elective CABG. Intraoperative anesthetic management was standardized (intravenous fentanyl, 10 μg/kg; intravenous midazolam, 200 μg/kg); after surgery, all patients received intravenous morphine exclusively via PCA. Of the patients tracheally extubated during the immediate postoperative period, mean time to tracheal extubation was similar in patients who received intrathecal morphine (7 ± 3 hours) compared with intrathecal placebo patients (6 ± 3 hours). However, once again, four patients who received intrathecal morphine had tracheal extubation substantially delayed (14, 14, 18, and 19 hours) because of prolonged respiratory depression (likely secondary to intrathecal morphine). The mean postoperative use of intravenous morphine during the immediate postoperative period was actually greater in patients receiving intrathecal morphine (50 mg) compared with patients receiving intrathecal placebo (36 mg), yet the difference between groups was not statistically significant. No clinical differences existed between groups regarding postoperative morbidity, mortality, or duration of postoperative hospital stay (approximately 6 days in each group). Thus Chaney and associates,[140,142,143] from their three prospective, randomized, double-blind, placebo-controlled, clinical investigations in the late 1990s involving 140 healthy adults undergoing elective CABG, concluded that although intrathecal morphine can certainly initiate reliable postoperative analgesia, its use in the setting of fast-track cardiac surgery and early tracheal extubation may be detrimental by potentially delaying tracheal extubation in the immediate postoperative period.

Since this time, however, other clinical investigators have revealed that certain combinations of intraoperative anesthetic techniques

TABLE 42.2 Analysis of Outcome Measures After Elective Cardiopulmonary Bypass Surgery[a]

	Placebo (n = 19)	*250 µg (n = 16)*	*500 µg (n = 15)*	P
Ventilatory time (min)	441 ± 207	325 ± 187	409 ± 245	0.270
Morphine (mg)	21.3 ± 6.2	13.6 ± 7.8	11.7 ± 7.4	0.001

[a]Adult patients received placebo, intrathecal morphine (250 µg), or intrathecal morphine (500 µg) during the postoperative period.

From Alhashemi JA, Sharpe MD, Harris CL, et al. Effect of subarachnoid morphine administration on extubation time after coronary artery bypass graft surgery. *J Cardiothorac Vasc Anesth.* 2000;14:639–644.

coupled with appropriate doses of intrathecal morphine will allow tracheal extubation after cardiac surgery within the immediate postoperative period to co-exist with enhanced analgesia. Alhashemi and colleagues[132] prospectively randomized 50 adults undergoing elective CABG to receive either one of two doses of intrathecal morphine (250 µg or 500 µg) or intrathecal placebo. Intraoperative anesthetic management was standardized (fentanyl, midazolam), and all patients received intermittent morphine by a blinded practitioner during the postoperative period. Tracheal extubation times were similar in the placebo group, 250 µg intrathecal morphine group, and 500 µg intrathecal morphine group (7, 5, and 7 hours, respectively; $p = 0.270$). However, postoperative morphine requirements in the placebo group (21 ± 6 mg), 250 µg intrathecal morphine group (14 ± 8 mg), and the 500 µg intrathecal morphine group (12 ± 7 mg) were substantially different. At least a 36% reduction in postoperative intravenous morphine requirements was observed among those patients who received intrathecal morphine. Although no differences in postoperative intravenous morphine requirements were observed among patients randomized to receive either 250 or 500 µg intrathecal morphine, both groups required significantly less intravenous morphine during the immediate postoperative period compared with control patients ($p = 0.001$). However, despite enhanced analgesia, no differences existed among the study groups with regards to midazolam, nitroglycerin, and sodium nitroprusside requirements in the postoperative period (Table 42.2). Furthermore, postextubation blood gas analysis, use of supplemental inspired oxygen, and ICU lengths of stay (approximately 22 hours in all groups) were comparable among the three groups.

These investigators, as well as others, reveal that the use of intrathecal morphine in patients undergoing fast-track cardiac surgery and early tracheal extubation may, if used appropriately, provide enhanced postoperative analgesia without delaying tracheal extubation. The authors also interestingly postulated that limiting the amounts of intraoperative intravenous opioids and intravenous sedatives and applying a postoperative tracheal extubation protocol may be more important in achieving the goal of early tracheal extubation after cardiac surgery than adequate pain control during the immediate postoperative period.

Many other suboptimally designed clinical investigations (eg, retrospective, observational) attest to the ability of intrathecal morphine to induce substantial postoperative analgesia in patients after cardiac surgery (Table 42.3). Intrathecal doses of 0.5 mg to 10.0 mg administered before CPB initiates reliable postoperative analgesia, the quality of which depends not only on the intrathecal dose administered but also on the type and amount of intravenous analgesics and sedatives used for the intraoperative baseline anesthetic. The optimal dose of intrathecal morphine for achieving maximum postoperative analgesia with minimum undesirable drug effects is uncertain. Naturally, when larger doses of intrathecal morphine are used, more intense and prolonged postoperative analgesia is obtained at the expense of more undesirable drug effects (nausea and vomiting, pruritus, urinary retention, respiratory depression).

Because of morphine's low lipid solubility, analgesic effects after intrathecal injection are delayed. Consequently, even large doses of intrathecal morphine administered to patients before cardiac surgery will not initiate reliable intraoperative analgesia[150–152,155] and therefore would not be expected to potentially attenuate the intraoperative stress response associated with CPB. Only an extremely large dose of intrathecal morphine (10 mg) may initiate reliable intraoperative analgesia in this setting.[154] One clinical investigation has examined the ability of intrathecal morphine to potentially attenuate the intraoperative stress response associated with CPB as measured by blood catecholamine levels.[143] In Chaney and associates'[143] clinical investigation, patients were prospectively randomized to receive either intrathecal morphine (4 mg) or intrathecal placebo before the induction of anesthesia for elective CABG with CPB. Intraoperative anesthetic management was standardized and multiple arterial blood samples were perioperatively obtained to ascertain norepinephrine and epinephrine levels. Patients who were administered intrathecal morphine experienced similar perioperative increases in blood catecholamine levels when compared with placebo controls. Thus intrathecal morphine (even in relatively large doses) appeared to be unable to reliably attenuate the perioperative stress response associated with cardiac surgery and CPB.

Although intrathecal morphine cannot reliably prevent the perioperative stress response associated with CPB, it may potentially attenuate the stress response during the immediate postoperative period by initiating postoperative analgesia. Vanstrum and colleagues[150] revealed that patients who were administered 0.5 mg intrathecal morphine before the induction of anesthesia not only required significantly less intravenous morphine after surgery compared with placebo control patients, but they also required significantly less intravenous nitroprusside (58 vs 89 mg, respectively; $p < 0.05$) during the initial 24 postoperative hours to control hypertension, which suggests partial postoperative stress-response attenuation.

Some clinical investigators have used intrathecal fentanyl, sufentanil, and/or local anesthetics for patients undergoing cardiac surgery, hoping to provide intraoperative anesthesia and analgesia (and stress-response attenuation), with mixed results (see Table 42.3). The administration of intrathecal local anesthetics to patients after the induction of anesthesia for cardiac surgery may help promote intraoperative hemodynamic stability,[144,146] whereas intrathecal sufentanil (50 µg) administered before the induction of anesthesia for cardiac surgery can reduce volatile anesthetic requirements during mediastinal dissection but is unable to reliably block intraoperative hemodynamic responses to laryngoscopy and intubation.[147] The addition of intrathecal clonidine in various amounts (100 µg, 1 µg/kg) may potentiate intrathecal morphine-induced postoperative analagesia.[157,159,163,170]

Most clinical attempts at inducing thoracic cardiac sympathectomy in patients undergoing cardiac surgery have used TEA with local anesthetics. However, a small number of clinical investigators have attempted cardiac sympathectomy in this setting with an intrathecal injection of local anesthetic. In 1994, as retrospectively reviewed, 18 adult patients were administered lumbar intrathecal hyperbaric bupivacaine (23 mg to 30 mg) and/or hyperbaric lidocaine (150 mg) mixed with morphine (0.5 mg to 1.0 mg) after the induction of anesthesia.[146] In an attempt to produce total spinal anesthesia and thus thoracic cardiac sympathectomy, the Trendelenburg position was maintained for at least 10 minutes after intrathecal injection. Heart rate decreased significantly (baseline mean 67 beats per minute [bpm] to postinjection mean 52 bpm) after intrathecal injection, indicating cardiac sympathectomy was obtained. Not a single patient exhibited electrocardiographic evidence of myocardial ischemia before CPB. Although these authors reported that the technique provided stable perioperative hemodynamics, 17 of 18 patients intraoperatively required intravenous phenylephrine to increase blood pressure. In 1996, the same group of investigators reported similar hemodynamic changes in a case report involving a 10-year-old child with Kawasaki disease who underwent CABG and received intrathecal hyperbaric bupivacaine mixed with morphine via a lumbar puncture after the induction of anesthesia.[144] Although Kowalewski's group reported that these patients experienced enhanced postoperative analgesia, definite conclusions cannot

TABLE 42.3 Reports of Intrathecal Anesthesia and Analgesia for Cardiac Surgery

First Author	Year	Study Design	Total Patients	Drugs: Dose	Intraoperative Management	Remarks

Peterson[137]	2000	Retrospective	18	Morphine: 5–10 µg/kg Tetracaine: 1–2 mg/kg	Not standardized	No benefit
Hammer[138]	2000	Retrospective	25	Morphine: 7–20 µg/kg Tetracaine: 0.5–2 mg/kg	Not standardized	No benefit
Chaney[140]	1999	Prospective, randomized, blind, placebo-controlled	40	Morphine: 10 µg/kg	Standardized	No benefit
Shroff[141]	1997	Prospective, randomized	21	Morphine: 10 µg/kg	Not standardized	Reliable postoperative analgesia Facilitated early extubation
Chaney[142]	1997	Prospective, randomized, blind, placebo-controlled	40	Morphine: 10 µg/kg	Standardized	Hindered early extubation
Chaney[143]	1996	Prospective, randomized, blind, placebo-controlled	60	Morphine: 4.0 mg	Standardized	Significant postoperative analgesia No stress-response attenuation
Taylor[145]	1996	Retrospective	152	Morphine: 30 µg/kg	Not standardized	Reliable postoperative analgesia
Kowalewski[146]	1994	Retrospective	18	Morphine: 0.5–1.0 mg Bupivacaine: 23–30 mg Lidocaine: 150 mg	Not standardized	Reliable postoperative analgesia Possible thoracic cardiac sympathectomy
Swenson[147]	1994	Retrospective	10	Morphine: 0.5 mg	Not standardized	Reliable postoperative analgesia Facilitated early extubation
Fitzpatrick[149]	1988	Prospective, randomized	44	Morphine: 1.0–2.0 mg	Not standardized	Significant postoperative analgesia
Vanstrum[150]	1988	Prospective, randomized, blind, placebo-controlled	30	Morphine: 0.5 mg	Standardized	Significant postoperative analgesia Possible stress-response attenuation
Casey[151]	1987	Prospective, randomized, blind, placebo-controlled	40	Morphine: 20 µg/kg	Standardized	No benefit
Cheun[152]	1987	Prospective, observational	180	Morphine: 0.1 mg/kg	Not standardized	Reliable postoperative analgesia
Aun[153]	1985	Prospective, randomized	60	Meperidine: 1.5 mg/kg Morphine: 2.0–4.0 mg	Not standardized	Significant postoperative analgesia
Jones[155]	1984	Prospective, observational	56	Morphine: 20–30 µg/kg	Not standardized	Reliable postoperative analgesia
Mathews[130]	1980	Retrospective	40	Morphine: 1.5–4.0 mg	Not standardized	Reliable postoperative analgesia

be reached regarding this technique because of study design formats (retrospective review, case report).

A small ($n = 38$ patients), prospective, randomized, blinded clinical investigation showed that large doses of intrathecal bupivacaine (37.5 mg) administered to patients immediately before the induction of general anesthesia (19 patients received intrathecal bupivacaine, 19 patients served as controls) for elective CABG may potentially initiate intraoperative stress-response attenuation (assessed via serum mediator levels, hemodynamics, and qualitative and quantitative alterations in myocardial β receptors).[173] However, no effect on clinical outcome parameters (eg, tracheal extubation times, respiratory function, perioperative spirometry) was observed. Mean tracheal extubation time measured from the time of sternotomy dressing application was extremely short in both groups (11 to 19 minutes). Specifically regarding postoperative analgesia, postoperative pain scores, and morphine use via PCA did not differ between the two groups. Not surprisingly, phenylephrine use was more common in patients who received intrathecal bupivacaine compared with control patients.

Many clinical investigations involving the use of intrathecal analgesic techniques in patients undergoing cardiac surgery indicate that the administration of intrathecal morphine to patients before CPB initiates reliable postoperative analgesia after cardiac surgery. Intrathecal opioids or local anesthetics cannot reliably attenuate the perioperative stress response associated with CPB that persists during the immediate postoperative period. Although intrathecal local anesthetics (not opioids) may induce perioperative thoracic cardiac sympathectomy, the hemodynamic changes associated with total spinal anesthesia make the technique unpalatable in patients with cardiac disease. A recently published metaanalysis of randomized, controlled trials (25 randomized trials, 1106 patients) concluded that spinal analgesia does not improve clinically relevant outcomes in patients undergoing cardiac surgery.[174] Additional large reviews came to the same conclusion.[175,176] Meylan and associates[176] concluded that "this analgesic intervention that reduces postoperative morphine consumption but not morphine-related adverse effects, that only slightly improves postoperative pain intensity, that significantly increases the risk of pruritus, and that is associated with a finite risk of respiratory depression should be abandoned." The most recently published clinical investigation involving intrathecal morphine for cardiac surgery dates back to 2009,[157] indicating perhaps that intrathecal morphine has become "The Forgotten Child" (see Table 42.3)[177]

Epidural Techniques

The initial description of TEA applied to a cardiac surgical patient occurred in 1954, during the formative years of CPB. Clowes and colleagues[178] described their presurgical anesthetic technique in a 55-year-old man with severe cardiac failure: "An endotracheal tube was passed with topical anesthesia. Under extradural block of the upper thorax, hypotension developed but responded to the administration of a vasopressor drug. At this time the patient became comatose" (Fig. 42.13). The patient eventually died. The application of TEA to patients undergoing cardiac surgery during the modern surgical era was initially reported by Hoar and associates[179] in 1976. They described the intraoperative insertion of thoracic epidural catheters in 12 patients after CABG and intravenous protamine but before transfer to ICU. The epidural catheters were injected with lidocaine and bupivacaine during the immediate postoperative period to promote analgesia and control hypertension effectively. The administration of epidural local anesthetics to these patients significantly decreased postoperative blood pressure in hypertensive and normotensive patients, and not a single patient required cardiac or peripheral vascular stimulants during the immediate postoperative study period. The 1987 report by El-Baz and Goldin[180] was the first to describe the insertion of thoracic

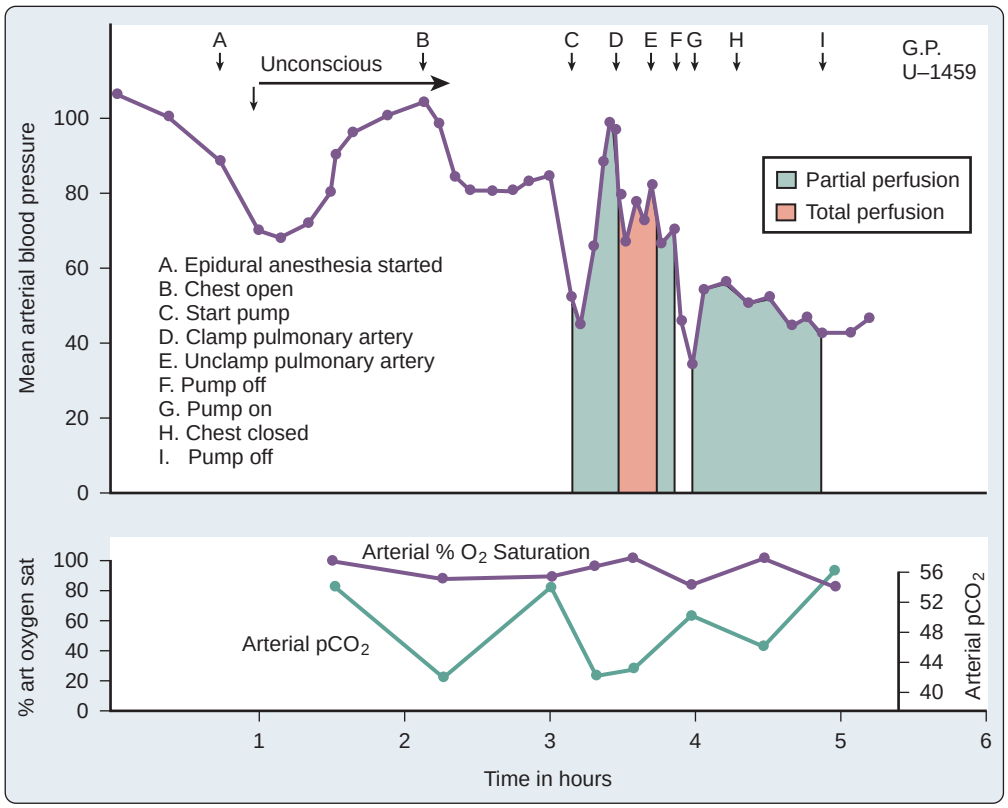

Fig. 42.13 Graph of clinical course of a patient is severe cardiac failure receiving presurgical epidural anesthesia in 1954. pCO_2, Carbon dioxide partial pressure. *(From Clowes GH Jr, Neville WE, Hopkins A, et al. Factors contributing to success or failure in the use of a pump oxygenator for complete by-pass of the heart and lung, experimental and clinical.* Surgery. *1954;36:557–579.)*

epidural catheters in patients before performing cardiac surgery. In prospective, randomized fashion, patients undergoing elective CABG received either routine treatment for postoperative pain (n = 30 patients, intravenous morphine) or a continuous infusion of morphine (0.1 mg/hr) via a thoracic epidural catheter (n = 30 patients). Thoracic epidural catheters were inserted at T3 to T4 immediately before the induction of anesthesia on the day of surgery. The intraoperative anesthetic technique was standardized, and the mean postoperative tracheal extubation time was significantly shorter in patients receiving TEA compared with control patients (9 ± 3 hours vs 18 ± 5 hours, respectively; $p < 0.01$). Continuous thoracic epidural infusion of morphine also achieved more effective postoperative pain relief than intravenous morphine (significantly better pain scores and significantly less supplemental intravenous morphine). Furthermore, in a subgroup of 20 patients (10 per group), postoperative stress was assessed via serum cortisol and β-endorphin levels. Patients receiving TEA had significantly lower postoperative levels of these mediators compared with control patients, indicating potential postoperative stress-response attenuation. Continuous thoracic epidural infusion of morphine (compared with control patients) was also associated with a lower incidence of opioid-related side effects during the immediate postoperative period. The insertion of the thoracic epidural catheter immediately before administering systemic heparin was not associated with any neurologic problems.

Since this initial impressive display of potential benefits (eg, reliable postoperative analgesia, stress-response attenuation, facilitation of early tracheal extubation), other clinical investigators have subsequently applied TEA to patients undergoing cardiac surgery.[181–216] Most clinical investigators have used thoracic epidural local anesthetics in hopes of providing perioperative stress-response attenuation and/or perioperative thoracic cardiac sympathectomy. Some clinical investigators have used thoracic epidural opioids to provide intraoperative and/or postoperative analgesia. An anonymous survey of members of the Society of Cardiovascular Anesthesiologists published in 2001 indicated that 7% of practicing anesthesiologists incorporate thoracic epidural techniques into their anesthetic management of adults undergoing cardiac surgery.[172] Of these anesthesiologists, 58% practice in the United States. Regarding the timing of epidural instrumentation, 40% perform instrumentation before the induction of general anesthesia, 12% perform instrumentation after the induction of general anesthesia, 33% perform instrumentation at the end of surgery, and 15% perform instrumentation on postoperative day 1.[172]

TEA with local anesthetics and/or opioids induces significant postoperative analgesia in patients after cardiac surgery. Patients randomized to receive a continuous thoracic epidural morphine infusion (0.1 mg/hr) after cardiac surgery required significantly less postoperative supplemental intravenous morphine compared with patients without thoracic epidural catheters (5 vs 18 mg/day per patient, respectively; $p < 0.05$) during the initial 3 postoperative days.[180] Children (aged 2 to 12 years) randomized to receive caudal epidural morphine (75 μg/kg) intraoperatively after cardiac surgery required significantly less postoperative supplemental intravenous morphine compared with patients who did not receive epidural morphine (0.3 vs 0.7 mg/kg, respectively; $p < 0.01$) during the initial 24 postoperative hours.[200] Numerous additional clinical studies further attest to the ability of TEA with local anesthetics and/or opioids to induce substantial postoperative analgesia in patients after cardiac surgery (Table 42.4).

One unique clinical investigation directly compared TEA and intravenous clonidine in patients undergoing cardiac surgery. Loick and colleagues[184] prospectively randomized 70 patients undergoing elective CABG to receive TEA supplementation (bupivacaine, sufentanil continuous infusion) perioperatively to general anesthesia (n = 25 patients), to receive intravenous clonidine supplementation (continuous infusion) perioperatively to general anesthesia (n = 24 patients), or to receive only general anesthesia (n = 21 control patients). Hemodynamics, plasma epinephrine and norepinephrine levels, plasma cortisol levels, the myocardium-specific contractile protein troponin T levels, and other plasma cardiac enzymes were perioperatively assessed. Both the TEA and intravenous clonidine groups experienced postoperative decreases in heart rate compared with the control group (without jeopardizing cardiac output or perfusion pressure). The effects on stress-response mediators were unpredictable and variable. Electrocardiographic evidence of ischemia (ST-segment elevation, ST-segment depression) occurred in 70% of control patients, 50% of TEA patients, and 40% of intravenous clonidine patients. The release of troponin T was attenuated (compared with control patients) in the TEA group only (no effect in the intravenous clonidine group). Interestingly enough, the highest quality of postoperative analgesia was found in the patients receiving intravenous clonidine. In the intravenous clonidine group, visual analogue pain scores were nearly halved when compared with the other two groups. Sedation scores were similar among the three groups with the exception of the 24-hour value in the intravenous clonidine group, which was greater than that in the TEA group. The postoperative comfort scores (rated between excellent and good) did not differ among the three groups.

Many clinical investigations have proved that TEA with local anesthetics also significantly attenuates the perioperative stress response in patients undergoing cardiac surgery. Patients randomized to receive intermittent boluses of thoracic epidural bupivacaine intraoperatively, followed by continuous infusion postoperatively, exhibited significantly decreased blood levels of norepinephrine and epinephrine perioperatively when compared with patients similarly managed without thoracic epidural catheters.[194] Furthermore, increased blood catecholamine levels in these patients were associated with increased systemic vascular resistance.[194] Patients randomized to receive continuous thoracic epidural bupivacaine infusion perioperatively exhibited significantly decreased blood levels of norepinephrine and cortisol perioperatively when compared with patients similarly managed without thoracic epidural catheters.[191] Patients randomized to receive a continuous thoracic epidural bupivacaine and sufentanil infusion perioperatively exhibited significantly decreased blood levels of norepinephrine after sternotomy when compared with patients similarly managed without thoracic epidural catheters.[197]

Other clinical studies further attest to the ability of TEA with local anesthetics to promote perioperative hemodynamic stability in patients undergoing cardiac surgery, which suggests perioperative stress-response attenuation.[179,193,194,197] Although most clinical attempts at stress-response attenuation involve thoracic epidural administration of local anesthetics, one investigation indicated that TEA with opioids may significantly attenuate the perioperative stress response in patients undergoing cardiac surgery. In this clinical investigation, patients who were randomized to receive a continuous thoracic epidural morphine infusion after surgery exhibited significantly decreased blood levels of cortisol and β-endorphin postoperatively when compared with patients similarly managed without thoracic epidural catheters.[180]

Two provocative clinical studies demonstrated the ability of TEA to induce significant thoracic cardiac sympathectomy in patients undergoing cardiac surgery.[192,193] In the first study, patients undergoing CABG were evaluated with reverse thermodilution catheters that had been inserted into the midcoronary sinus under fluoroscopic guidance before the induction of anesthesia.[192] Intraoperative anesthetic management was standardized. Coronary sinus blood flow was measured by a constant-infusion technique, and coronary vascular resistance was calculated using coronary perfusion pressure (arterial diastolic pressure minus pulmonary capillary wedge pressure) and coronary sinus blood flow. Patients who had been randomized to receive intermittent boluses of thoracic epidural bupivacaine intraoperatively, followed by a continuous infusion after surgery, exhibited significant decreases in coronary vascular resistance after CPB when compared with pre-CPB values. Patients similarly managed but without thoracic epidural catheters exhibited significant increases in coronary vascular resistance after CPB. In the second study, patients undergoing CABG were evaluated with catheters that had been inserted into the coronary sinus under fluoroscopic guidance and continuous pressure monitoring before the induction of anesthesia.[193] Intraoperative anesthetic management was standardized, and all patients received a continuous

intravenous infusion of tritiated norepinephrine, which allowed the assessment of cardiac norepinephrine spillover to plasma via isotope dilution technique. Blood samples were obtained from the coronary sinus and radial artery, and the rate of norepinephrine spillover from the heart was calculated according to the Fick principle to assess cardiac sympathetic activity. Patients who were randomized to receive a single bolus of thoracic epidural mepivacaine immediately after the induction of anesthesia exhibited significantly decreased cardiac norepinephrine spillover after sternotomy when compared with patients similarly managed without thoracic epidural catheters. Furthermore, 20% of patients managed without thoracic epidural catheters exhibited electrocardiographic evidence of myocardial ischemia after sternotomy, whereas no patient managed with a thoracic epidural catheter exhibited myocardial ischemia during this time.

Perioperative cardiac sympathectomy induced via TEA with local anesthetics may clinically benefit patients undergoing cardiac surgery by increasing myocardial oxygen supply.[119,128,129] However, such a cardiac sympathectomy may offer additional benefits to patients undergoing cardiac surgery. Multiple clinical studies have demonstrated that TEA with local anesthetics significantly decreases heart rate before[197] and after[191,197] the initiation of CPB and significantly decreases the need to administer β-blockers after CPB.[194] Multiple clinical studies have also demonstrated that TEA with local anesthetics significantly decreases systemic vascular resistance before[193,194] and after[197,201] the initiation of CPB. Furthermore, patients undergoing cardiac surgery who receive TEA with local anesthetics not only exhibit significant decreases in postoperative heart rate and systemic vascular resistance, but they also exhibit significant decreases in postoperative electrocardiographic evidence of myocardial ischemia when compared with patients similarly managed without thoracic epidural catheters.[197]

A relatively large clinical investigation highlighted the potential clinical benefits of TEA in cardiac surgical patients. Scott and associates[182]

TABLE 42.5 Various Outcomes of Patients

Outcome	*TEA (n = 206),* n *(%)*	*GA (n = 202),* n *(%)*
Supraventricular arrhythmia	21 (10.2)	45 (22.3)
Lower respiratory tract infection	31 (15.3)	59 (29.2)
Renal failure	4 (2.0)	14 (6.9)
Cerebrovascular accident	2 (1.0)	6 (3.0)
Acute confusion	3 (1.5)	1 (5.5)
Significant bleeding	35	23
Any complications	84	108

Significant (unadjusted) differences existed among groups regarding supraventricular arrhythmia ($p = 0.0012$), lower respiratory tract infection ($p = 0.0007$), renal failure ($p = 0.016$), acute confusion ($p = 0.031$), and any complications ($p = 0.011$).
GA, General anesthesia; *TEA*, thoracic epidural analgesia.

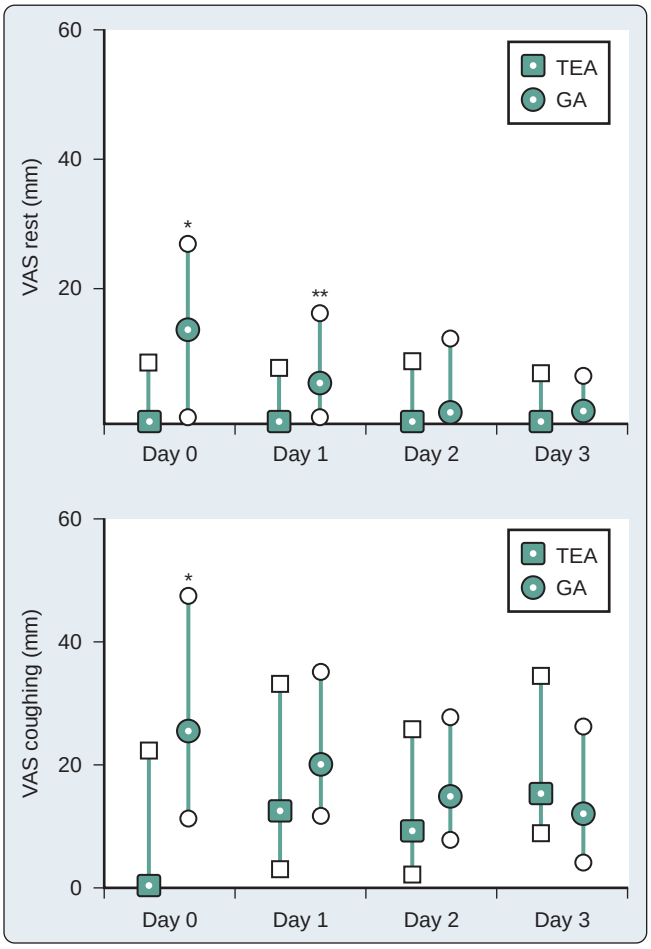

Fig. 42.14 Visual Analogue Scale (VAS) Scores. VAS scores for pain at rest (*top*) and with coughing (*bottom*) on the day of surgery and the first 3 postoperative days. Significant differences ($p < 0.03$) existed between the two groups only on postoperative day 0 (rest and coughing) and on postoperative day 1 (rest only). *GA*, General anesthesia; *TEA*, thoracic epidural analgesia. *(From Priestley MC, Cope L, Halliwell R, et al. Thoracic epidural anesthesia for cardiac surgery: the effects on tracheal intubation time and length of hospital stay.* Anesth Analg. *2002;94:275–282.)*

prospectively randomized (nonblinded) 420 patients undergoing elective CABG to receive either TEA (bupivacaine/clonidine) and general anesthesia or general anesthesia alone (control group). The two groups received similar intraoperative anesthetic techniques. In TEA patients, the thoracic epidural infusion was continued for 96 hours after surgery (titrated according to need). In control patients, target-controlled infusion of alfentanil was used for the first 24 postoperative hours, followed by PCA morphine for the next 48 hours. After surgery, striking clinical differences were observed between the two groups (Table 42.5). Postoperative incidence of supraventricular arrhythmia, lower respiratory tract infection, renal failure, and acute confusion all were significantly lower in patients receiving TEA compared with control patients. However, data from this clinical investigation must be viewed with caution. The clinical protocol dictated that β-adrenergic blocker therapy could not be intraoperatively or postoperatively used for the 5 days of the study period (except in those patients who developed a new arrhythmia requiring additional therapy). Because approximately 90% of this study's patients were taking β-adrenergic blockers before surgery, this unique perioperative management clouds the interpretation of postoperative supraventricular arrhythmia data. Despite prospective randomization, substantially fewer patients receiving TEA were current active smokers before surgery compared with control patients (6% vs 13%, respectively), which clouds the interpretation of postoperative lower respiratory tract infection data. These investigators also found that postoperative preextubation maximal expiratory lung volumes were increased in TEA patients (compared with control patients) and postoperative tracheal extubation was facilitated via TEA as well, yet TEA patients and control patients were managed somewhat differently during the immediate postoperative period. Although postoperative analgesia was not definitively assessed in this clinical investigation, 12% of control patients were converted to TEA during the first 24 postoperative hours because of suboptimal postoperative analgesia, whereas only 3% of TEA patients were converted to target-controlled infusion alfentanil or PCA morphine because of suboptimal postoperative analgesia. The results of this clinical investigation are certainly intriguing, yet definitive conclusions regarding the use of TEA techniques in patients undergoing cardiac surgery cannot be drawn because of the study's substantial limitations, highlighted by an accompanying editorial[217] and three subsequent letters to the editor.[218–220]

In contrast with the encouraging findings of Scott and associates'[182] clinical investigation, two prospective, randomized, nonblinded clinical investigations revealed that using TEA techniques in patients undergoing cardiac surgery may not offer substantial clinical benefits.[221,222] In 2002, Priestley and associates[222] prospectively randomized 100 patients undergoing elective CABG to receive either TEA (ropivacaine/fentanyl) and general anesthesia or general anesthesia alone (control group). The two groups received significantly different intraoperative anesthetic techniques. Before surgery, TEA patients received epidural ropivacaine/fentanyl for 48 hours (supplemental analgesics were available if needed), whereas control patients received nurse-administered intravenous morphine followed by PCA morphine. Patients receiving TEA were extubated sooner than control patients (3 vs 7 hours, respectively; $p < 0.001$), yet this difference may have been secondary to the different amounts of intraoperative intravenous opioid administered to the two groups (intraoperative intravenous anesthetic technique not standardized). Postoperative pain scores at rest were significantly lower in patients receiving TEA only on postoperative days 0 and 1 (equivalent on days 2 and 3). Postoperative pain scores during coughing were significantly lower in patients receiving TEA only on postoperative day 0 (equivalent on days 1, 2, and 3; Fig. 42.14). No significant differences were observed between the two groups in postoperative oxygen saturation on room air, chest radiograph changes, or spirometry (Table 42.6). Furthermore, no clinical differences were detected between the two groups regarding postoperative mobilization goals, atrial fibrillation, postoperative hospital discharge eligibility, or actual postoperative hospital discharge. In short, this clinical investigation revealed that TEA may provide enhanced postoperative analgesia (although brief) and enhance early postoperative tracheal extubation, yet it has no effect on important clinical parameters such as morbidity and hospital length of stay.

TABLE 42.6 Spirometry Results

	Mean FEV_1 (SD)		Mean FVC (SD)	
Variable	TEA (L)	GA (L)	TEA (L)	GA (L)
Predicted	2.9 (0.4)	2.9 (0.5)	3.9 (0.5)	3.9 (0.6)
Preoperative	2.5 (0.4)	2.6 (0.8)	3.3 (0.8)	3.4 (0.9)
Postoperative day 1	1.0 (0.3)	1.0 (0.4)	1.2 (0.4)	1.4 (0.5)
Postoperative day 2	1.1 (0.3)	1.1 (0.4)	1.4 (0.4)	1.5 (0.5)
Postoperative day 4	1.4 (0.4)	1.3 (0.5)	1.8 (0.6)	1.7 (0.6)

No significant differences existed between patients receiving thoracic epidural analgesia (TEA) and control patients receiving general anesthesia (GA).

TABLE 42.7 Visual Analog Scale Scores

Pain Score	High Thoracic Epidural Analgesia (mean ± SD)	Control (mean ± SD)
Rest day 1	0.02 ± 0.2	0.8 ± 1.8
Cough day 1	1.2 ± 1.7	4.4 ± 3.1
Rest day 2	0.1 ± 0.4	1.2 ± 2.7
Cough day 2	1.5 ± 2.0	3.6 ± 3.1
Rest day 3	0.2 ± 1.0	0.3 ± 1.1
Cough day 3	1.7 ± 2.3	2.7 ± 3.0

Mean pain scores at rest and with cough for postoperative days 1, 2, and 3. Significant differences ($p < 0.05$) existed between groups on postoperative days 1 and 2 (at rest and with cough) yet not on day 3.

SD, Standard deviation.

From Royse C, Royse A, Soeding P, et al. Prospective randomized trial of high thoracic epidural analgesia for coronary artery bypass surgery. *Ann Thorac Surg.* 2003;75:93–100.

In 2003, Royse and associates[221] prospectively randomized 80 patients undergoing elective CABG to receive either TEA (ropivacaine/fentanyl) and general anesthesia or general anesthesia alone (control group). The two groups received very different intraoperative anesthetic techniques. After surgery, TEA patients received epidural ropivacaine/fentanyl until postoperative day 3, whereas control patients received nurse-administered intravenous morphine followed by PCA morphine. Patients receiving TEA were tracheally extubated sooner during the immediate postoperative period than control subjects (3 vs 5 hours, respectively; $p < 0.001$), yet this difference may have been secondary to the administration of different amounts of intraoperative intravenous anesthetics (intraoperative anesthetic technique was not standardized). Postoperative pain scores at rest and with cough were significantly lower in patients receiving TEA on postoperative days 1 and 2 only (equivalent on postoperative day 3; Table 42.7). Similar to the investigation conducted by Priestley and associates,[222], no substantial differences were observed between the two groups regarding important postoperative clinical parameters such as respiratory function, renal function, atrial fibrillation, ICU length of stay, and hospital length of stay.

In 2006, Hansdottir and associates[223] provided additional evidence that TEA techniques offer no real clinical benefits to patients undergoing cardiac surgery. This relatively large (113 patients) prospective trial randomized patients undergoing elective cardiac surgery to receive either patient-controlled TEA (catheter inserted the day before surgery; using bupivacaine, fentanyl, and epinephrine) or patient-controlled intravenous morphine analgesia during the immediate postoperative period. Perioperative care was standardized (all patients underwent general anesthesia and received a median sternotomy). When the two groups were compared, the only difference was a shorter time to postoperative tracheal extubation in patients receiving TEA (2 vs 7 hours). No differences were observed regarding postoperative analgesia (at rest and during cough), degree of sedation, lung volumes (forced vital capacity, forced expiratory volume in 1 second, peak expiratory flow), degree of ambulation, global quality of recovery score (including all five domains studied), cardiac morbidity (myocardial infarction, atrial fibrillation), renal morbidity (peak serum creatinine), neurologic outcome (stroke, confusion), ICU stay, or hospital length of stay. Furthermore, this group of experienced investigators reported a very high failure rate (17%) for the use of thoracic epidural catheters in these patients.

Numerous other clinical investigations have demonstrated varying degrees of mild clinical benefits (see Table 42.4).[224–250] For instance, Lagunilla and colleagues[241] found that high thoracic epidural blockade with ropivacaine increased myocardial oxygen availability in patients before surgical revascularization without deleterious hemodynamic disturbances, and Tenenbein and associates[236] found that high TEA decreased postoperative pain and atelectasis and improved pulmonary function in patients undergoing myocardial revascularization. Lastly, Bakhtiary and colleagues[238] revealed that high TEA in combination with general anesthesia significantly reduced the incidence of perioperative arrhythmias such as atrial fibrillation and significantly reduced serum epinephrine levels. However, the vast amount of clinical investigations continues to reveal no clinical benefits above and beyond the initiation of reliable postoperative analgesia (see Table 42.4).

The February 2011 issue of *Anesthesiology* highlights the controversial nature of this topic as two clinical studies with opposite conclusions were published. Caputo and associates[232] randomized 226 patients undergoing off-pump CABG to receive general anesthesia plus epidural ($n = 109$) or general anesthesia alone ($n = 117$). The primary outcome was the length of postoperative stay, and secondary outcomes were arrhythmia, inotropic support, intubation time, perioperative myocardial infarction, neurologic events, intensive care stay, pain scores, and analgesia requirement. They found that the addition of TEA to general anesthesia significantly reduced the incidence of postoperative arrhythmias and improved pain control and overall quality of recovery, allowing earlier extubation and hospital discharge. In contrast, Svircevic and colleagues[233] randomized 654 patients undergoing elective on-pump and off-pump cardiac surgery to combined general anesthesia and TEA ($n = 325$) versus general anesthesia alone ($n = 329$). Follow-up was at 30 days and 1 year after surgery. The primary endpoint was 30-day survival free from myocardial infarction, pulmonary complications, renal failure, and stroke. They were unable to demonstrate a clinically relevant benefit of TEA on the frequency of major complications. These authors concluded, "Given the potentially devastating complications of epidural hematoma after insertion of an epidural catheter, it is questionable whether this procedure should be applied routinely in cardiac surgical patients who require full heparinization." These two clinical studies were accompanied by an editorial that stated that "… we continue to try and show that regional anesthesia and analgesia can substantially alter surgical outcomes without success … perhaps it is time to move away from trying to prove that anesthetic interventions will reduce morbidity or mortality and to focus on tangible benefits to patients or their families."[251]

Despite enhanced postoperative analgesia offered via TEA techniques, such analgesia does not appear to decrease the incidence of persistent pain after cardiac surgery. Ho and associates[19] assessed 244 patients after cardiac surgery with median sternotomy. One hundred and fifty patients received perioperative supplementation of general anesthesia with TEA (ropivacaine-fentanyl infusion initiated before the induction of anesthesia and continued after surgery for 2 to 3 days). Ninety four patients received general anesthesia and routine postoperative nurse-controlled intravenous morphine infusion for analgesia, together with intraoperative wound infiltration with ropivacaine at chest wall closure. Persistent pain, defined as pain still present 2 or more months after surgery, was similar in the two cohorts (reported in almost 30% of patients). However, persistent pain reported by these patients was mild in most cases, infrequently interfering with daily life.

The quality of analgesia obtained with TEA techniques is sufficient to allow cardiac surgery to be performed in awake patients without general endotracheal anesthesia. The initial report of awake cardiac

surgery was published in the *Annals of Thoracic Surgery* in 2000. Karagoz and associates[252] described the perioperative course of five patients who underwent elective off-pump single-vessel CABG via minithoracotomy with only TEA (spontaneous ventilation throughout). All five patients did well, and none had to be converted to general endotracheal anesthesia. Soon thereafter, Aybek and colleagues[253] described the perioperative course of 12 patients who underwent elective off-pump multivessel CABG via complete sternotomy with only TEA. All patients did well, yet two patients required conversion to general endotracheal anesthesia (one for incomplete analgesia, one for pneumothorax). Also in 2002, Souto and associates[254] revealed that "outpatient" CABG (discharge to home within 24 hours of hospital admission) was possible in a small ($n = 20$) group of patients undergoing cardiac surgery solely via TEA. Since these initial small clinical reports appeared, larger series of patients have been published, demonstrating that awake cardiac surgery is feasible and safe.[255–265] In 2003, the first case report of awake cardiac surgery requiring CPB was published.[266] In this astonishing case report from Austria, a 70-year-old man with aortic stenosis underwent aortic valve replacement with the assistance of normothermic CPB (total time: 123 minutes; cross-clamp time: 82 minutes) solely via TEA. Verbal communication with the patient was possible on demand throughout the CPB surgery. The patient did well and experienced an unremarkable postoperative course.

The many clinical investigations involving the use of TEA techniques in patients undergoing cardiac surgery indicate that the administration of thoracic epidural opioids or local anesthetics before and/or after CPB initiates reliable postoperative analgesia. The administration of TEAs (not opioids) can both reliably attenuate the perioperative stress response associated with CPB (that persists during the immediate postoperative period) and induce perioperative thoracic cardiac sympathectomy. Enhanced postoperative analgesia likely facilitates early tracheal extubation after cardiac surgery, yet patients may be extubated after cardiac surgery (with or without CPB) in the surgical unit without the assistance of TEA techniques.[267]

All clinical reports involving the use of intrathecal anesthesia and TEA and analgesia techniques for cardiac surgery involve small numbers of patients, and few (if any) are well designed (see Tables 42.2 and 42.3). Only a handful of clinical studies involving intrathecal analgesia are prospective, randomized, blinded, and placebo-controlled (see Table 42.3). No blinded, placebo-controlled clinical studies involving epidural techniques (see Table 42.4) have been reported. Furthermore, very few of the existing clinical studies involving intrathecal anesthesia and TEA techniques for cardiac surgery use the clinical outcome as a primary endpoint. Thus clear deficiencies in the literature prohibit a definitive analysis of the risk-benefit ratio of intrathecal anesthesia and TEA techniques as applied to patients undergoing cardiac surgery.

A 2004 metaanalysis by Liu and colleagues[268] assessed the effects of perioperative central neuraxial analgesia on outcome after CABG. These authors, via MEDLINE and other databases, searched for randomized, controlled trials in patients undergoing CABG with CPB. Fifteen trials enrolling 1178 patients were included for TEA analysis, and 17 trials enrolling 668 patients were included for intrathecal analysis. Although TEA techniques did not affect the incidences of mortality or myocardial infarction, they reduced the risk for arrhythmias (atrial fibrillation and tachycardia) and pulmonary complications (pneumonia and atelectasis), reduced the time to tracheal extubation, and reduced analog pain scores. Intrathecal techniques did not affect incidences of mortality, myocardial infarction, arrhythmias, or time to tracheal extubation and only modestly decreased systemic morphine use and pain scores, while increasing the incidence of pruritus. These authors concluded that central neuraxial analgesia does not affect rates of mortality or myocardial infarction after CABG, yet its use is associated with improvements in faster time to tracheal extubation, decreased pulmonary complications and cardiac arrhythmias, and reduced pain scores. However, the authors also noted that the majority of potential clinical benefits offered by central neuraxial analgesia (earlier extubation, decreased arrhythmias, enhanced analgesia) may be reduced and/or eliminated with changing cardiac anesthesia practice using fast-track techniques, using β-adrenergic blockers or amiodarone, and/or using NSAIDs or COX-2 inhibitors. These authors also noted that the risk for spinal hematoma (addressed later in this chapter) associated with regional techniques in patients undergoing full anticoagulation for CPB remains uncertain. Subsequent metaanalyses by Bignami and associates[269] in 2010 (33 randomized trials, 2366 patients) and Svircevic and associates[270] in 2011 (28 randomized trials, 2731 patients) reached somewhat different conclusions. The Bignami study[269] suggested that epidural techniques may decrease renal failure, time on mechanical ventilation, and composite endpoint of mortality and myocardial infarction, whereas the Svircevic[270] study suggested that epidural techniques may decrease the incidence of supraventricular arrhythmias and respiratory complications, yet have no beneficial effects on myocardial infarction, stroke, or mortality.

The use of intrathecal and/or epidural techniques in patients undergoing full thoracotomy incisions (rare during cardiac surgery, yet sometimes used in certain circumstances) deserves brief mention.[271] Many factors are involved in the occurrence of pulmonary dysfunction after full thoracotomy. Postoperative changes in pulmonary function result from lung resection, atelectasis, and/or volume loss caused by pneumothorax and inspiratory muscle dysfunction. Pain after full thoracotomy can be intense, which may produce pulmonary complications after surgery. Somewhat surprisingly, patients undergoing a "clamshell" incision (transverse thoracosternotomy) for bilateral lung transplantation do not experience more postoperative pain than patients undergoing a standard full thoracotomy for single-lung transplantation, and lung transplant recipients undergoing full thoracotomy have a lower incidence of adequate pain relief than patients undergoing full thoracotomy for other indications.[272] These clinical observations emphasize that the condition of the patient may play a major role (together with the type of incision) regarding the adequacy of postoperative pain control. Clearly, compared with full thoracotomy incisions, patients receiving minithoracotomy incisions experience less postoperative pain and consume fewer supplemental analgesics during the immediate postoperative period. Furthermore, up to one half of all patients undergoing full thoracotomy incision will experience chronic pain related to the surgical site.

Adequate postoperative pain control after full thoracotomy may help prevent the development of chronic postoperative thoracotomy pain. Therefore an effective postoperative analgesic plan must be developed for these patients. In contrast with median sternotomy incisions and minithoracotomy incisions, some clinical evidence indicates that the use of regional anesthetic techniques may decrease postoperative complications after full thoracotomy incisions. Specifically, Ballantyne and colleagues[273] and Licker and associates[274] provided evidence that postoperative pain control with epidural techniques after full thoracotomy incision may reduce pulmonary morbidity and overall patient mortality. However, although existing evidence suggests that TEA offers superior postoperative analgesia (superiority of thoracic over lumbar routes has recently been called into question), not all clinical studies have shown that such techniques truly improve postoperative pulmonary function and reduce postoperative pulmonary complications.

Side Effects of Intrathecal and Epidural Local Anesthetics

Hypotension is the most troubling and undesirable drug effect of intrathecal and epidural local anesthetics. Spinal anesthesia to upper thoracic dermatomes produces a decrease in mean arterial blood pressure that is accompanied by a parallel decrease in coronary blood flow.[275,276] Exactly what percentage of blood pressure decrease is acceptable remains speculative, especially in patients with coronary artery disease. Disturbances in myocardial oxygenation appear to occur in patients with coronary artery disease if coronary perfusion pressure is allowed to decrease by more than 50% during the induction of TEA with local anesthetics.[277] Furthermore, if α-adrenergic agonists are used to increase blood pressure during this time, then there may be detrimental effects (vasoconstriction) on the native coronary arteries

and bypass grafts.[278,279] Of the 19 patients who received intrathecal local anesthetics to produce total spinal anesthesia for cardiac surgery, 18 required intravenous phenylephrine intraoperatively to increase blood pressure, indicating that hypotension is a substantial problem with this technique.[144,146] Hypotension also appears to be relatively common when TEA with local anesthetics are used in this setting. Volume replacement, β-adrenergic agonists, and/or α-adrenergic agonists are required in a fair proportion of patients, and coronary perfusion pressure may decrease in susceptible patients after CPB.

After epidural administration, local anesthetics can produce blood concentrations of drug that may initiate detrimental cardiac electrophysiologic effects and myocardial depression.[280] In fact, myocardial depression has been detected in patients receiving TEA with bupivacaine, a clinical effect that is at least partially caused by increased blood concentrations of the drug.[281] Concomitant use of β-adrenergic blockers may further decrease myocardial contractility in this setting.[282,283] Patients undergoing cardiac surgery who were randomized to receive intermittent boluses of thoracic epidural bupivacaine intraoperatively, followed by continuous infusion after surgery, exhibited significantly increased pulmonary capillary wedge pressures after CPB when compared with patients similarly managed without epidural catheters (11 vs 6 mm Hg, respectively; $p < 0.001$), which suggests myocardial depression.[194]

Two case reports also indicated that the use of epidural anesthesia and analgesia may either mask myocardial ischemia or initiate myocardial ischemia.[284,285] Oden and Karagianes[285] described the perioperative course of an older patient who had a history of exertional angina and underwent uneventful cholecystectomy. After surgery, analgesia was achieved with continuous lumbar epidural fentanyl. On postoperative day 2, with continuous lumbar epidural fentanyl being administered, ST-segment depression was noted on the electrocardiogram. The patient was awake, alert, and did not experience angina. Initiation of intravenous nitroglycerin at this time resulted in normalization of ischemic electrocardiographic changes. The authors of this report thought that epidural fentanyl-induced analgesia masked the patient's typical anginal pain. Easley and colleagues[284] describe the perioperative course of a middle-aged patient without cardiovascular symptoms (borderline hypertension) who was scheduled for exploratory laparotomy. Before surgery, a low thoracic epidural catheter was inserted and local anesthetic was administered (sensory level peaked by pinprick at T2). The patient at this time began complaining of left-sided jaw pain, and substantial ST-segment depression was noted on the electrocardiogram. Surgery was canceled, and the patient was treated with aspirin and nitroglycerin. The electrocardiogram normalized; yet, based on electrocardiographic changes, troponin levels, and creatine kinase-MB fractions, the patient was diagnosed with a non–Q-wave myocardial infarction. Coronary angiography on the following day was unremarkable, and a presumptive diagnosis of coronary artery spasm was made. These authors thought that low thoracic epidural-induced sympathectomy led to alterations in the sympathetic-parasympathetic balance (vasoconstriction above the level of block) leading to coronary artery spasm.

Side Effects of Intrathecal and Epidural Opioids

Although many have been described, the four clinically relevant undesirable drug effects of intrathecal and epidural opioids are pruritus, nausea and vomiting, urinary retention, and respiratory depression.[286] After the administration of intrathecal or epidural opioids, the most common side effect is pruritus. The incidence rate varies widely (from 0% to 100%) and is often identified only after direct questioning of the patient. Severe pruritus is rare, occurring in only approximately 1% of patients. The incidence of nausea and vomiting is approximately 30%. The incidence of urinary retention also varies widely (from 0% to 80%) and occurs most frequently in young male patients. When intrathecal or epidural opioids are used in patients undergoing cardiac surgery, the incidences of pruritus, nausea and vomiting, and urinary retention are similar to that described earlier. Of note, if a large dose (4 mg) of intrathecal morphine is administered, then prolonged postoperative urinary retention may occur.[143]

The most important undesirable drug effect of intrathecal and epidural opioids is respiratory depression. Only 4 months after the initial use of intrathecal[287] and epidural[288] opioids in humans, life-threatening respiratory depression was reported.[289–291] The incidence of respiratory depression that requires intervention after conventional doses of intrathecal and epidural opioids is approximately 1%, the same as that after conventional doses of intramuscular and intravenous opioids. Early respiratory depression occurs within minutes of opioid injection and is associated with the administration of intrathecal or epidural fentanyl or sufentanil. Delayed respiratory depression occurs hours after opioid injection and is associated with the administration of intrathecal or epidural morphine. Delayed respiratory depression results from cephalad migration of morphine in the cerebrospinal fluid and the subsequent stimulation of opioid receptors located in the ventral medulla.[292] Factors that increase the risk for respiratory depression include large and/or repeated doses of opioids, intrathecal use, advanced age, and concomitant use of intravenous sedatives.[286] The magnitude of postoperative respiratory depression is profoundly influenced by the dose of intrathecal or epidural morphine administered and the type and amount of intravenous analgesics and amnestics used for the intraoperative baseline anesthetic. Prolonged postoperative respiratory depression may delay tracheal extubation, and naloxone may be required in some patients. Children may be more susceptible to developing postoperative respiratory depression when intrathecal morphine is used. Of 56 children (aged 1 to 17 years) administered either 20 or 30 μg/kg intrathecal morphine before surgical incision for cardiac surgery, 3 of 29 who received 20 μg/kg and 6 of 27 who received 30 μg/kg required naloxone after surgery for respiratory depression.[155]

One clinical study indicates that the administration of intrathecal morphine to patients undergoing cardiac surgery may be contraindicated if early extubation is planned.[142] Patients were randomized to receive either intrathecal morphine (10 μg/kg) or intrathecal placebo before the induction of anesthesia. Intraoperative anesthetic management was standardized and consisted of intravenous fentanyl (20 μg/kg) and intravenous midazolam (10 mg total) together with inhaled isoflurane and/or intravenous nitroglycerin, if required. Regarding patients extubated during the immediate postoperative period, the mean time from ICU arrival to extubation was significantly increased in those who received intrathecal morphine compared with those who received intrathecal placebo (11 vs 8 hours, respectively; $p = 0.02$). However, other clinical studies indicate that intrathecal or epidural morphine may yet prove to be a useful adjunct for cardiac surgery and early extubation. The optimal dose of intrathecal or epidural morphine in this setting, together with the optimal intraoperative baseline anesthetic that will provide significant postoperative analgesia yet not delay tracheal extubation in the immediate postoperative period, remains to be elucidated. In contrast with intrathecal and epidural opioids, epidural local anesthetics, which initiate no respiratory depression, should not delay tracheal extubation in the immediate postoperative period.

Risk for Hematoma Formation

Intrathecal or epidural instrumentation entails risk, the most feared complication being epidural hematoma formation. The estimated incidence of hematoma formation is approximately 1:220,000 after intrathecal instrumentation.[293] Hematoma formation is more common (approximately 1:150,000) after epidural instrumentation because larger needles are used, catheters are inserted, and the venous plexus in the epidural space is prominent.[293] Furthermore, hematoma formation does not exclusively occur during epidural catheter insertion; almost one half of all cases develop after catheter removal.[293]

Although spontaneous hematoma can occur in the absence of intrathecal or epidural instrumentation,[294] most occur when instrumentation is performed in a patient with a coagulopathy (from any cause) or when instrumentation is difficult or traumatic.[293] Paradoxically, intrathecal or epidural instrumentation has been safely performed in

patients with known clinical coagulopathy.[295,296] Of 1000 epidural catheterizations performed in 950 patients receiving oral anticoagulants at the time of catheter insertion, none experienced signs or symptoms of hematoma formation.[296] Of 336 epidural injections performed in 36 patients with chronic cancer pain either fully anticoagulated (oral anticoagulants or intravenous heparin) or profoundly thrombocytopenic (platelet count < 50,000/mm^3) at the time of instrumentation, none had signs or symptoms of hematoma formation.[295]

Risk is increased when intrathecal or epidural instrumentation is performed before systemic heparinization, and hematoma formation has occurred in patients when diagnostic or therapeutic lumbar puncture has been followed by systemic heparinization.[297–300] When lumbar puncture is followed by systemic heparinization, concurrent use of aspirin, difficult or traumatic instrumentation, and the administration of intravenous heparin within 1 hour of instrumentation increase the risk for hematoma formation.[299] However, by observing certain precautions, intrathecal or epidural instrumentation can be safely performed in patients who will subsequently receive intravenous heparin.[301,302] By delaying surgery 24 hours in the event of a traumatic tap, by delaying heparinization 60 minutes after catheter insertion, and by maintaining tight perioperative control of anticoagulation, more than 4000 intrathecal or epidural catheterizations were safely performed in patients undergoing peripheral vascular surgery who received intravenous heparin after catheter insertion.[302] A retrospective review involving 912 patients further indicates that epidural catheterization before systemic heparinization for peripheral vascular surgery is safe.[301] However, the magnitude of anticoagulation in these two studies (activated partial thromboplastin time of approximately 100 seconds[301] and activated coagulation time approximately twice the baseline value[302]) involving patients undergoing peripheral vascular surgery was substantially less than the degree of anticoagulation required in patients subjected to CPB.

Most clinical studies investigating the use of intrathecal or epidural anesthesia and analgesia techniques in patients undergoing cardiac surgery include precautions to decrease the risk for hematoma formation. Some used the technique only after the demonstration of laboratory evidence of normal coagulation parameters, delayed surgery 24 hours in the event of traumatic tap, or required that the time from instrumentation to systemic heparinization exceed 60 minutes. Although most clinicians investigating the use of epidural anesthesia and analgesia techniques in patients undergoing cardiac surgery insert the catheters the day before scheduled surgery, investigators have performed instrumentation on the same day of surgery. Institutional practice (same-day admit surgery) may eliminate the option of epidural catheter insertion on the day before scheduled surgery. An alternative is to perform epidural instrumentation postoperatively (before or after tracheal extubation) after laboratory evidence demonstrates normal coagulation parameters.

Although most investigators agree that the risk for hematoma formation is likely increased when intrathecal or epidural instrumentation is performed in patients before systemic heparinization required for CPB, the absolute degree of increased risk is somewhat controversial; some believe the risk rate may be as high as 0.35%.[297] An extensive mathematical analysis by Ho and associates[303] of the approximately 10,840 intrathecal injections in patients subjected to systemic heparinization required for CPB (without a single episode of hematoma formation) reported in the literature as of 2000, the minimum risk was estimated at 1:220,000 and the maximum risk for hematoma formation was 1:3600; however, the maximum risk may be as high as 1:2400. Similarly, of approximately 4583 epidural instrumentations in patients subjected to systemic heparinization required for CPB (without a single episode of hematoma formation) reported in the literature as of 2000, the minimum risk for hematoma formation was 1:150,000 and the maximum risk for hematoma formation was 1:1500; however, the maximum risk may be as high as 1:1000.[303]

Certain precautions, however, may decrease risk.[293,297] The technique should not be used in a patient with known coagulopathy from any cause. Surgery should be delayed 24 hours in the event of a traumatic tap, and time from instrumentation to systemic heparinization should exceed 60 minutes. In addition, systemic heparin effect and reversal should be tightly controlled (smallest amount of heparin used for the shortest duration compatible with therapeutic objectives), and patients should be closely monitored after surgery for signs and symptoms of hematoma formation. An obvious economic disadvantage of intrathecal or epidural instrumentation in patients before cardiac surgery is the possible delay in surgery in the event of a traumatic tap. However, one study involving more than 4000 intrathecal or epidural catheterizations via a 17-gauge Tuohy needle indicated that the incidence of traumatic tap (blood freely aspirated) is quite rare (< 0.1%).[302]

In 2004, the first case report of an epidural hematoma associated with a thoracic epidural catheter inserted in a patient before cardiac surgery was published.[304] This 18-year-old man had a thoracic (T9 to T10) epidural catheter uneventfully inserted after induction of general anesthesia (the patient had intense fear of needles) immediately before the initiation of CPB for aortic valve replacement surgery. Three hours elapsed from instrumentation to systemic heparinization. The entire intraoperative course and immediate postoperative course were uneventful (tracheally extubated soon after surgery, ambulating without difficulty on postoperative day 1). At 49 hours after surgery, intravenous heparin therapy was initiated (prosthetic valve thromboprophylaxis). At 53 hours after surgery, alteplase (thrombolytic drug) was used to flush a dysfunctional intravenous catheter. Within 2 hours of intravenous alteplase administration, the patient reported intense back pain while ambulating. At this point, the epidural catheter was removed. The activated partial thromboplastin time assessed at this time (during catheter removal) was 87 seconds (reference range, 25 to 37 seconds). The patient also was thrombocytopenic at this time. On catheter removal, the patient experienced sudden onset of numbness and weakness distal to T9. Intravenous heparin was discontinued, a computed tomographic scan was inconclusive, requiring a magnetic resonance imaging scan, which revealed an epidural hematoma. Within 5 hours from the onset of neurologic symptoms, the patient underwent surgical evacuation of the hematoma, which extended from the T8 to T11 levels. Intraoperatively, intravenous methylprednisolone (30 mg/kg) was administered, followed by an infusion (5.4 mg/kg/hr) that was continued for 72 hours. Twenty-four hours after laminectomy, the patient demonstrated mild residual lower extremity motor and sensory deficits. Six weeks later, his neurologic examination returned to normal. The authors noted the factors (eg, heparin, alteplase, thrombocytopenia) affecting coagulation in this patient that likely led to hematoma formation and theorized that removing the catheter may have increased bleeding, further compounding the problem.

Since 2004, additional such accounts reporting catastrophic consequences such as permanent paralysis have appeared in the literature.[305–307] In addition, thromboembolic complications (neurologic stroke) may occur during the postoperative period when normalization of coagulation parameters (in a patient requiring anticoagulation) is achieved to safely remove the epidural catheter.[308] Thus bleeding and/or thromboembolic complications associated with these techniques in this setting are very real and potentially catastrophic.

The use of regional anesthetic techniques in patients undergoing cardiac surgery remains extremely controversial, prompting numerous editorials by recognized experts in the field of cardiac anesthesia.[309–313] One of the primary reasons such controversy exists (and likely will continue for some time) is that the numerous clinical investigations regarding this topic are suboptimally designed and use a wide array of disparate techniques, preventing clinically useful conclusions on which all can agree.[314–318]

Multimodal Analgesia

The possibility of synergism among analgesic drugs is a concept that is nearly a century old.[319,320] Although subsequent research has demonstrated the difference between additivity and synergy, the fundamental strategy behind such combinations (multimodal or balanced analgesia) remains unchanged—enhanced analgesia with the minimization

of adverse physiologic effects. The use of analgesic combinations during the postoperative period, specifically the combination of traditional intravenous opioids with other analgesics (eg, NSAIDs, COX-2 inhibitors, ketamine), has been proven clinically effective in noncardiac patients for decades. Early clinical investigations simply reported analgesic efficacy, whereas more recent clinical investigations have additionally evaluated and described specific opioid-sparing effects, which should lead to a reduction in side effects. For example, in the late 1980s, initial clinical studies involving ketorolac (the first parenteral NSAID available in the United States) revealed significant opioid-sparing effects (analgesia) together with a reduction in respiratory depression. Subsequently, substantial clinical research has clearly established the perioperative analgesic efficacy and opioid-sparing effects of NSAIDs (together with a reduction of side effects).

The American Society of Anesthesiologists Task Force on Acute Pain Management in the Perioperative Setting reports that the literature supports the administration of two analgesic agents that act by different mechanisms via a single route for providing superior analgesic efficacy with equivalent or reduced adverse effects.[1] Potential examples include epidural opioids administered in combination with epidural local anesthetics or clonidine and intravenous opioids in combination with ketorolac or ketamine. Dose-dependent adverse effects reported with the administration of a medication occur whether it is given alone or in combination with other medications (opioids may cause nausea, vomiting, pruritus, or urinary retention, and local anesthetics may produce motor block). The literature is insufficient to evaluate the postoperative analgesic effects of oral opioids combined with NSAIDs, COX-2 inhibitors, or acetaminophen compared with oral opioids alone. The Task Force believes that NSAIDs, COX-2 inhibitors, or acetaminophen administration has a dose-sparing effect for systemically administered opioids. The literature also suggests that two routes of administration when compared with a single route may be more effective in providing perioperative analgesia. Examples include intrathecal or epidural opioids combined with intravenous, intramuscular, oral, transdermal, or subcutaneous analgesics versus intrathecal or epidural opioids alone. Another example is intravenous opioids combined with oral NSAIDs, COX-2 inhibitors, or acetaminophen versus intravenous opioids alone. The literature is insufficient to evaluate the efficacy of pharmacologic pain management combined with nonpharmacologic, alternative, or complementary pain management compared with pharmacologic pain management alone.

How Important Is Postoperative Pain After Cardiac Surgery?

Cardiac surgery is unique; because of this, it involves unique risks not routinely associated with noncardiac surgery.[321] Furthermore, as all are aware, for a wide variety of reasons, patients who are undergoing cardiac surgery continue to get older and sicker (more comorbidities: neurologic dysfunction, myocardial dysfunction, renal dysfunction). Multiple factors interact in a complicated manner during the perioperative period that affect the outcome and quality of life after cardiac surgery including the type and quality of surgical intervention, extent of postoperative neurologic dysfunction, extent of postoperative myocardial dysfunction, extent of postoperative pulmonary dysfunction, extent of postoperative renal dysfunction, extent of postoperative coagulation abnormalities, extent of systemic inflammatory response, and quality of postoperative analgesia. Obviously, depending on specific clinical situations, certain factors are more important than others. The potential clinical value of preventive (preemptive) analgesia remains extremely controversial.[322,323] Determining, exactly, how important attaining adequate or high-quality postoperative analgesia truly is in relation to all these important clinical factors surrounding a patient undergoing cardiac surgery is extremely difficult (if not impossible). For example, how important is it to obtain high-quality postoperative analgesia in an 80-year-old patient with preoperative myocardial dysfunction, renal dysfunction, and a heavily calcified aorta after double-valve replacement? It could be argued that factors other than quality of postoperative analgesia will determine the clinical outcome in this patient. On the other hand, how important is it to obtain high-quality postoperative analgesia in an otherwise healthy 50-year-old patient after routine CABG? It is likely that this patient's clinical outcome will be satisfactory even if postoperative analgesia is suboptimal. In essence, for cardiac and noncardiac surgery patients alike, evidence is insufficient to confirm or deny the ability of postoperative analgesic techniques to truly affect postoperative morbidity or mortality.[324–332]

BOX 42.11 FACTORS AFFECTING OUTCOME AFTER CARDIAC SURGERY

- Type and quality of surgical intervention
- Extent of postoperative neurologic dysfunction
- Extent of postoperative myocardial dysfunction
- Extent of postoperative pulmonary dysfunction
- Extent of postoperative renal dysfunction
- Extent of postoperative coagulation abnormalities
- Extent of systemic inflammatory response
- Quality of postoperative analgesia

Conclusions

Multiple factors are important during the perioperative period that potentially affect outcome and quality of life after cardiac surgery; these factors include the type and quality of surgical intervention; the extent of postoperative neurologic dysfunction, myocardial dysfunction, pulmonary dysfunction, renal dysfunction, coagulation abnormalities, and extent of systemic inflammatory response; and/or the quality of postoperative analgesia, among other factors[333] (Box 42.11). This list is presented in no particular order. Obviously, depending on specific clinical situations, such as the surgical procedure and patient comorbidity, among others, certain factors will be more important than others. Determining exactly how important attaining adequate postoperative analgesia truly is in relation to all of these clinical factors surrounding a patient undergoing cardiac surgery is extremely difficult (if not impossible). A clear link between adequate or high-quality postoperative analgesia and clinical outcome in patients after cardiac surgery has yet to be established.[333–336]

However, despite the absence of substantiating scientific evidence, most clinicians intuitively believe that attaining high-quality postoperative analgesia is important because it may prevent adverse hemodynamic, metabolic, immunologic, and hemostatic alterations, all of which may potentially increase postoperative morbidity. Although many analgesic techniques are available, intravenous systemic opioids form the cornerstone of postcardiac surgery analgesia. Opioids have been used with good results for many years in the treatment of postoperative pain in patients after cardiac surgery. Although NSAIDs (specifically COX-2 inhibitors) have recently received considerable attention, important clinical issues regarding their safety (eg, gastrointestinal effects, renal effects, hemostatic effects, immunologic effects) need to be resolved. Although PCA techniques are commonly used, their clear superiority over traditional nurse-controlled analgesic techniques remains unproven. The use of intrathecal and epidural techniques in patients undergoing cardiac surgery will likely remain extremely controversial. With the increased use of smaller incisions by cardiac surgeons, increased use of nerve blocks (intercostal, intrapleural, paravertebral) deserves further clinical study, and the emergence of liposomal bupivacaine may revolutionize these techniques in this setting. As a general rule, avoiding intense, single-modality therapy for the treatment of acute postoperative pain is best. Clinicians should strive for an approach that uses a number of different therapies (multimodal therapy), each counteracting pain through different

mechanisms. Preemptive analgesia, although intriguing, needs further study to determine its role in affecting postoperative analgesia and outcome.[337–340]

Finally, the American Society of Anesthesiologists Task Force on Acute Pain Management in the Perioperative Setting offers sound advice.[1] It recommends that anesthesiologists who manage perioperative pain use analgesic therapeutic options only after thoughtfully considering the risks and benefits for the individual patient. The therapy or therapies selected should reflect the individual anesthesiologist's expertise, as well as the capacity for safe application of the chosen modality in each practice setting. This expertise includes the ability to recognize and treat adverse effects that emerge after the initiation of therapy. Whenever possible, anesthesiologists should use multimodal pain management therapy. Dosing regimens should be administered to optimize efficacy while minimizing the risk for adverse events. The choice of medication, dose, route, and duration of therapy should always be individualized.

Perioperative Cardiovascular Evaluation and Management for Noncardiac Surgery

KAMROUZ GHADIMI, MD | ANNEMARIE THOMPSON, MD | LEE A. FLEISHER, MD

KEY POINTS

1. Preoperative assessment of the cardiac patient undergoing noncardiac surgery includes categorizing the risk of a major adverse cardiac event (MACE) in order to optimize perioperative care.
2. The risk of MACE depends on patient risk factors including the noncardiac procedure, age of the patient, emergent status of the procedure, preexisting organ dysfunction, and independence in daily activities.
3. Cardiac risk model calculators such as the Revised Cardiac Risk Index (RCRI), the American College of Surgeons' National Surgical Quality Improvement Program (ACS-NSQIP), and the Gupta model used to estimate the risk of perioperative myocardial infarction or cardiac arrest (MICA) exist to facilitate quantification of risk and to aid the perioperative physician in optimizing patient care.
4. The 2014 American College of Cardiology (ACC) and American Heart Association (AHA) guideline document, *Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery*, discusses new and updated recommendations in a stepwise approach to care of the patient with cardiovascular disease presenting for noncardiac surgery.
5. The applicability of the various recommendations within the 2014 ACC/AHA guideline document is determined by the patient's risk for development of MACE.
6. Within the 2014 ACC/AHA guideline document are important updates related to the perioperative administration of various cardiac-related medications, including β-blockers, angiotensin-converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARBs), α_2-adrenergic agents (eg, clonidine), aspirin, and dual-antiplatelet therapy with thienopyridines, vitamin K antagonists, and novel oral anticoagulants.
7. A clear understanding of antiplatelet therapy and the temporal relationship between percutaneous coronary interventions and scheduled surgery are important in determining the timing and perioperative management of noncardiac surgery.
8. Transfusion is an important part of perioperative management in the setting of hemodynamic instability, evidence of MACE, or surgical hemorrhage. In the case of hemodynamic stability with MACE, no specific recommendations are available; the decision to transfuse and the hemoglobin goal for transfusion are decided by the perioperative team.
9. Pulmonary arterial hypertension and subsequent right ventricular (RV) dysfunction are a major cause of poor perioperative outcomes in this patient population. Every effort should be made to optimize ventilation/perfusion matching and to reduce pulmonary vascular resistance preoperatively in order to avoid hemodynamic collapse due to RV failure.

Patients undergoing surgery experience a well-described stress response of sympathetic nervous system activation, insulin resistance, cytokine production, leukocyte proliferation, and pituitary hormone secretion.[1,2] These physiologic changes in the setting of preexisting patient comorbidities, surgical complexity including breaches of visceral and vascular containment, and postoperative complications and recovery may contribute to the occurrence of perioperative cardiovascular events in patients undergoing noncardiac surgery. As part of a perioperative team approach, every patient should undergo an individualized risk assessment to delineate the risks, benefits, and alternatives of surgical intervention. Interventions for optimizing cardiovascular health should be performed or alternative approaches considered to ensure the maximal benefit with minimal risk to the patient. This chapter reviews the initial preoperative cardiac evaluation, including a discussion of common risk calculators, to assist the clinician with risk assessment and surgical planning.

The 2014 American College of Cardiology (ACC) and American Heart Association (AHA) clinical practice guideline, *Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery,* is also reviewed.[3,4] The European Society of Cardiology (ESC), in collaboration with the European Society of Anaesthesiology (ESA), also published guidelines on the cardiovascular assessment and management of patients undergoing noncardiac surgery in 2014.[5] The ACC/AHA and the ESC/ESA coordinated to ensure that their recommendations were consistent and to provide rationales in clinical areas where their recommendations diverged.

The recommendations of these professional societies regarding specific and frequently encountered perioperative challenges are discussed in this chapter, including significant updates since the previous guidelines were published in 2007.[6,7] Medical therapy with β-blockers, angiotensin-converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARBs), α_2-agonists, aspirin (including dual-antiplatelet therapy [DAPT]), vitamin K antagonists (VKAs), and novel oral anticoagulants (NOACs) are also addressed. Perioperative management of anemia, pulmonary vascular disease, and right ventricular (RV) dysfunction is also discussed.

Preoperative Cardiac Assessment: Categorizing Risk

Patients with underlying cardiovascular disease have an increased risk of perioperative cardiac complications compared with their healthier counterparts.[3–5] This results in part from the presence of coronary artery disease (CAD) leading to impaired left ventricular ejection fraction (LVEF) and in part from the aforementioned physiologic factors associated with surgery that predispose patients to myocardial ischemia.[1,2] Hemodynamic instability, including acute blood loss, results in reduction of oxygen delivery to metabolically active tissue. Increased myocardial oxygen demand secondary to tachycardia or acute hypertension may occur related to anesthetic administration and surgical stimulation. Perioperative disturbance of the balance between myocardial oxygen supply and demand can result in significant mismatch and can precipitate myocardial ischemia when demand critically exceeds supply.

Validated algorithms have been developed to determine the cardiovascular risk of mortality and morbidity encountered by a patient for each noncardiac operation. Stratification is performed to objectively determine and categorize patients as being at low, intermediate, or high risk. High-risk patients include those with recent myocardial infarction (MI) or unstable angina, decompensated heart failure (HF), high-grade arrhythmias, or hemodynamically important valvular heart disease (eg, aortic stenosis).[3–5] These patients are at increased risk for perioperative cardiovascular events including MI, HF, cardiac arrest, conduction abnormalities, and death.[3–5] Certainly, the emergent or urgent status of the surgery significantly influences perioperative cardiovascular risk because of summation of the effects of the acute illness, the nature of the emergent operation, and the lost opportunities for risk assessment and elective modification.[3–5] However, patients with the conditions listed are at increased risk for a perioperative cardiovascular event compared with normal, age-matched controls. In most emergent cases, the benefit of proceeding with surgery outweighs the risk of waiting to perform additional testing.[3–5] The physician-anesthesiologist should be prepared to manage cardiovascular events encountered during the intraoperative period related to the emergent status of the surgery.[3–5]

The initial preoperative evaluation and risk assessment are typically performed by either a primary care physician or an anesthesiologist. Referral to a cardiologist is warranted if specialized procedures are indicated for life-threatening conditions. Intermediate- and high-risk patients may have overt evidence of cardiovascular disease such as angina, dyspnea, syncope, and palpitations during evaluation or a history positive for heart disease, hypertension, diabetes, chronic kidney disease, cerebrovascular events, or peripheral arterial disease.[3,4] Cardiac functional status (peak work capacity) may be expressed in metabolic equivalents (METs), as initially determined by the Duke Activity Status Index (Table 43.1).[8,9] One MET is equivalent to oxygen utilization by an adult at rest.[8] One important indicator for major adverse cardiac events (MACE) after major noncardiac surgery is preoperative inability to climb two flights of stairs or walk four city blocks.[10,11] However, ambulatory limitations due to orthopedic or pulmonary conditions may confound the true assessment of cardiac functional status, and alternative testing may be required for at-risk patients.[3–5] The decision to pursue cardiovascular or pulmonary testing should be considered only if the results would affect surgical decision making (eg, pursuing a less invasive route, opting for no treatment intervention) or would likely identify an immediately life-threatening condition requiring treatment.[3,4]

TABLE 43.1 Duke Activity Status Index

Activity	*Energy Expenditure (in METs)*
Can You…	
1. Take care of yourself—that is, eating, dressing, bathing, or using the toilet?	2.75
2. Walk indoors, such as around your house?	1.75
3. Walk a block or two on level ground?	2.75
4. Climb a flight of stairs or walk up a hill?	5.50
5. Run a short distance?	8.00
6. Do light work around the house such as dusting or washing dishes?	2.70
7. Do moderate work around the house such as vacuuming, sweeping floors, or carrying groceries?	3.50
8. Do heavy work around the house such as scrubbing floors or lifting or moving heavy furniture?	8.00
9. Do yardwork such as raking leaves, weeding, or pushing a power mower?	4.50
10. Have sexual relations?	5.25
11. Participate in moderate recreational activities such as golf, bowling, dancing, doubles tennis, or throwing a baseball or football?	6.00

METs, Metabolic equivalents (1 MET is the equivalent of resting oxygen consumption).

Preoperative Cardiac Assessment: Risk Model Calculators

Risk model calculators estimate the probability of a perioperative event based on information obtained from the history, physical examination, and type of surgery. These risk models are more applicable for patients at intermediate to high perioperative cardiac risk during noncardiac surgery. Patients at low risk for MACE should proceed to surgery without further evaluation.

In order to appropriately identify individualized risk using a risk calculator, specific information pertaining to both the patient and the surgery must be provided. Information is entered into one or both of two commonly used perioperative risk indices: the Revised Cardiac Risk Index (RCRI)[12] and the American College of Surgeons' National Surgical Quality Improvement Program (ACS-NSQIP) surgical risk calculator (www.facs.org).[13] The RCRI determines preoperative risk based on the following criteria: type of surgery, history of ischemic heart disease, congestive HF, cerebrovascular disease, preoperative treatment with insulin, and creatinine level greater than 2.0 mg/dL (Fig. 43.1). The RCRI for an individual patient can be quantified readily with an online calculator (www.mdcalc.com). The ACS-NSQIP calculator incorporates 20 patient risk factors in addition to the surgical procedure (Fig. 43.2). The surgery-specific estimates from the RCRI and ACS-NSQIP calculators report the risk of myocardial infarction or cardiac arrest (MICA), typically categorized as less than 5% in high-risk procedures, 1% to 5% in intermediate-risk procedures, and less than 1% in low-risk procedures.[14] As a rule, emergency surgery is associated with 2 to 5 times the risk of MACE compared with elective procedures.[15]

The results of risk calculation can be applied in several ways. Once patient risk is estimated, perioperative physicians and the patient can proceed with the planned operation, modify the treatment plan, or postpone the procedure. On the day of surgery, the options for consideration include proceeding directly with the operative plan, delaying surgery to allow further diagnostic evaluation (eg, myocardial stress testing, echocardiography, 24-hour ambulatory monitoring), and changing the planned surgery. This last option may involve performing a surgical procedure with less risk, selecting a nonsurgical alternative such as palliation, or cancelling the operation so that cardiac interventions such as coronary revascularization or heart valve intervention can be performed. In addition to risk-assessment models such as the RCRI[12] and the ACS-NSQIP calculator, the Gupta Perioperative Risk Calculator, which is used to estimate the risk of MICA, also includes high-risk patients who have been managed with current medical practices and surgical techniques.[16] The Gupta index was derived and validated from large data sets within the ACS-NSQIP database (2007

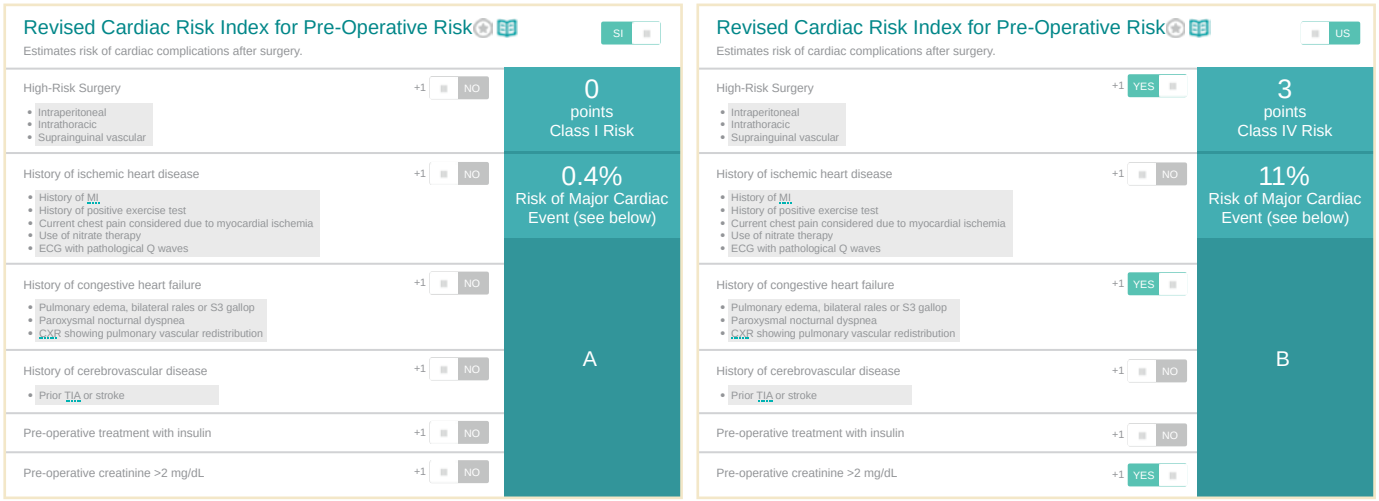

Fig. 43.1 Revised Cardiac Risk Index calculator results are depicted for two patients. (A) Patient A has no risk factors and a calculated risk for major adverse cardiac events equal to 0.4%. (B) Patient B has several risk factors and a calculated risk for major adverse cardiac events equal to 11%. *(From* http://www.mdcalc.com/revised-cardiac-risk-index-for-pre-operative-risk/*.)*

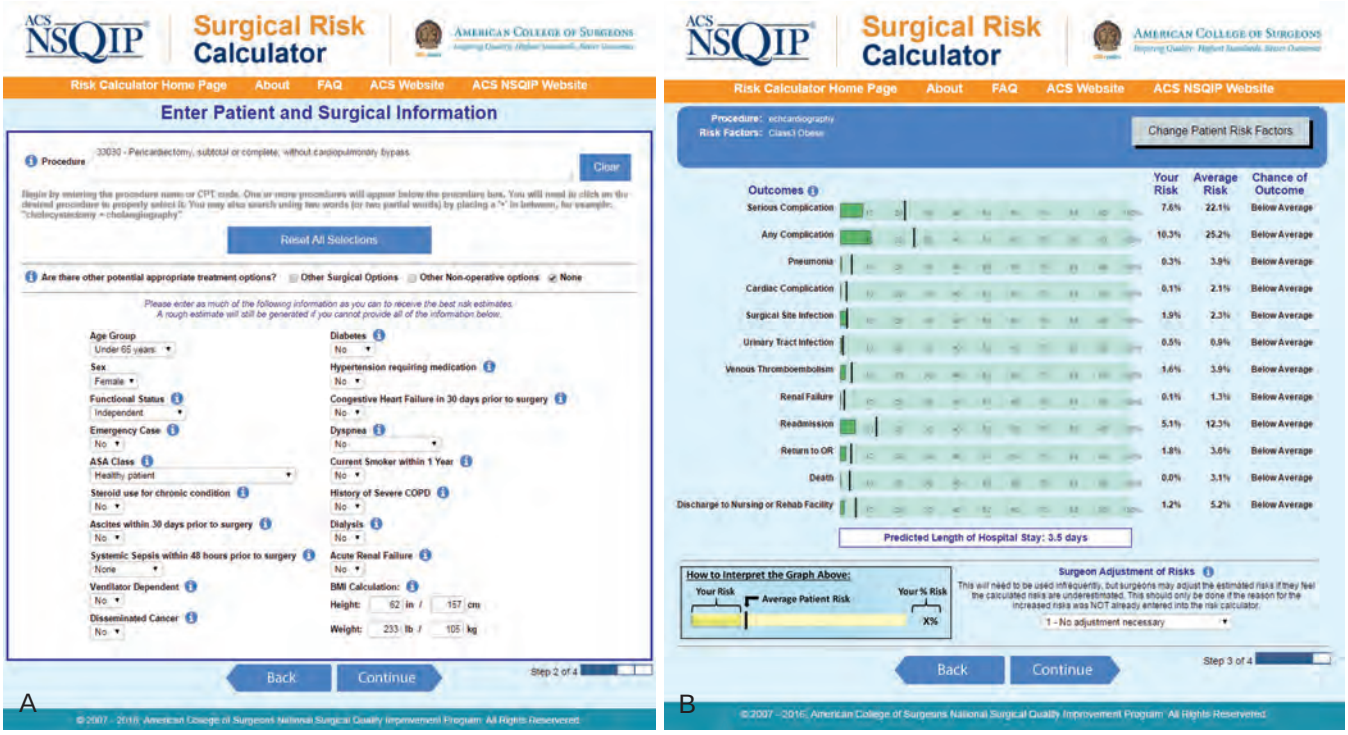

Fig. 43.2 National Surgical Quality Improvement Program (NSQIP) risk calculator. (A) The online site display where patient and surgical features may be put into the data calculator. (B) As an example, the surgical risk calculation has been performed for a patient undergoing a pneumonectomy with specific risk factors. The resulting surgical risk calculation, including negative outcomes, estimated risk of each outcome, and the chance of the outcome (eg, average, above average) are displayed. Notice in the lower right corner that the surgeon may adjust the risk calculation; in this example, no adjustment has been made. *(From* http://riskcalculator.facs.org/RiskCalculator/*.)*

derivation cohort, $N = 211{,}410$; 2008 validation cohort, $N = 257{,}385$).[16] The Gupta index has the same discriminative ability and predictive accuracy as the larger ACS-NSQUIP variable model and outperforms the RCRI, likely due in part to the evolution of surgical procedures that have tended to lower operative risk in the almost 20 years since the RCRI was formulated.[10] Because the ACS-NSQIP and Gupta surgical risk calculators are more comprehensive and procedure specific, they have largely replaced older models for risk stratification.[17–22] The risk calculation models are discussed individually in the following sections.

Revised Cardiac Risk Index

The RCRI is sometimes referred to as the Lee index, after the primary author of the original 1999 article.[12] In the derivation of the index, 2893 patients undergoing elective major noncardiac operations were monitored for major cardiac complications (ie, death, acute MI, pulmonary edema, ventricular fibrillation/cardiac arrest, and complete heart block). The index was validated in a cohort of 1422 similar individuals. The Lee index is based on six independent predictors for perioperative complications (see Fig. 43.1). The predictive value was significant in all types of major noncardiac surgery except for abdominal aortic aneurysm surgery. A systematic review evaluated the ability of the RCRI to predict cardiac complications and mortality after major noncardiac surgery in various populations and settings.[23] The RCRI performed well in distinguishing patients at low risk versus high risk for all types of noncardiac surgery, the area under the receiver operating characteristic curve (AUC), also called the C statistic, being 0.75 and the 95% confidence interval (CI) being 0.72–0.79. However, it was somewhat less accurate in patients undergoing vascular noncardiac surgery (AUC, 0.64; 95% CI, 0.61–0.66).[23] In addition, the RCRI did not predict all-cause mortality well—a flaw that is inherent to a risk predictor that does not capture risk factors for noncardiac causes of perioperative mortality. Moreover, only one third of the perioperative deaths were from cardiac causes.[23]

ACS-NSQIP Universal Surgical Risk Calculator

A universal surgical risk calculator model was developed from the ACS-NSQUIP database using a Web-based tool consisting of 20 patient factors plus the surgical procedure (see Fig. 43.2). This model has excellent performance in regard to mortality (C statistic, 0.944) and morbidity (C statistic, 0.816).[24] Although it is more comprehensive than the other risk calculators, it has not been validated through external studies, and it may be more cumbersome, limiting its use.

Gupta MICA ACS-NSQIP Database Risk Model

The NSQIP database was used by Gupta and colleagues[16] to determine risk factors associated with perioperative MICA. A simplified online calculator using only the greatest risk variables was developed, as outlined in Fig. 43.3 (www.qxmd.com). Among the more than 200,000 patients who underwent surgery in 2007, 0.65% developed perioperative MICA. On multivariate logistic regression analysis, five factors were identified as predictors: (1) type of surgery, (2) dependent functional status, (3) elevated creatinine, (4) American Society of Anesthesiologists' physical status score, and (5) increased age (see Fig. 43.3). The risk model was developed using these five factors and subsequently validated on a 2008 data set (n = 257,385). The risk model had a relatively high predictive accuracy (C statistic, 0.874) and outperformed the RCRI (C statistic, 0.747).[16]

In summary, risk calculators are important tools that are used to quantify the perioperative risk of a cardiac event. Once a patient is deemed to be at intermediate or high risk, the 2014 ACC/AHA guideline may be used to guide further perioperative optimization and management.

Perioperative Cardiac Assessment: Algorithmic Approach

The 2014 ACC/AHA perioperative guideline proposed a stepwise approach to perioperative cardiac assessment, incorporating both the physician's role in managing risk and providing informed consent and the patient's perspective in weighing risks, benefits, and alternatives to invasive testing or preventive therapies.[3,4] The emphasis placed on sharing information contextually with other perioperative physicians and with the patient highlights the importance of providing patient-centered care while minimizing risk for each intervention. The algorithmic flow chart begins with determination of surgical urgency, followed by assessment of the presence or absence of a preoperative acute coronary event, and concludes with a perioperative risk calculation for MACE (Fig. 43.4)[3,4] (see Chapter 1). For patients at low risk of MACE, no further testing is needed, and the patient may proceed to surgery without further evaluation. For patients at significant risk for MACE, an objective determination of the functional capacity of the patient is recommended. If a patient at elevated risk for MACE has 4 METs or greater functional capacity, no further evaluation is required

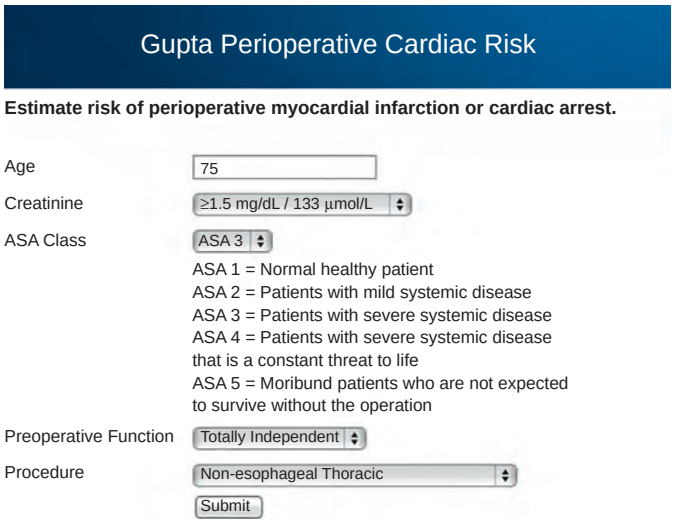

Fig. 43.3 Gupta Perioperative Risk Calculator for estimating the risk of MICA is designed to receive input on the patient's age, creatinine level, ASA score, preoperative ability to manage ADLs, and procedure category. As an example, information and risk factors have been entered for a patient undergoing a nonesophageal thoracic procedure. The resulting Gupta perioperative cardiac risk score is calculated at the bottom. *ASA*, American Society of Anesthesiologists, *ADLs*, activities of daily living, *MICA*, myocardial infarction or cardiac arrest. *(From* https://www.qxmd.com/calculate/calculator_245/gupta-perioperative-cardiac-risk.*)*

Patient scheduled for surgery with known or risk factors for CAD (Step 1)
Emergency
Yes
Clinical risk stratification and proceed to surgery
No
ACS (Step 2)
Yes
Evaluate and treat according to GDMT
No
Estimated perioperative risk of MACE based on combined clinical/surgical risk (Step 3)
Low risk (<1%) (Step 4)
Elevated risk (Step 5)
Moderate or greater (4 METs) functional capacity
Excellent (>10 METs)
No further testing (Class IIa)
Moderate/good (4–10 METs)
No further testing (Class IIb)
Proceed to surgery
No further testing (Class III:NB)
Proceed to surgery
No or unknown
Poor OR unknown functional capacity (<4 METs): Will further testing impact decision making OR perioperative care? (Step 6)
Yes
Pharmacologic stress testing (Class IIa)
If normal
If abnormal
Coronary revascularization according to existing CPGs (Class I)
No
Proceed to surgery according to GDMT OR alternate strategies (noninvasive treatment, palliation) (Step 7)

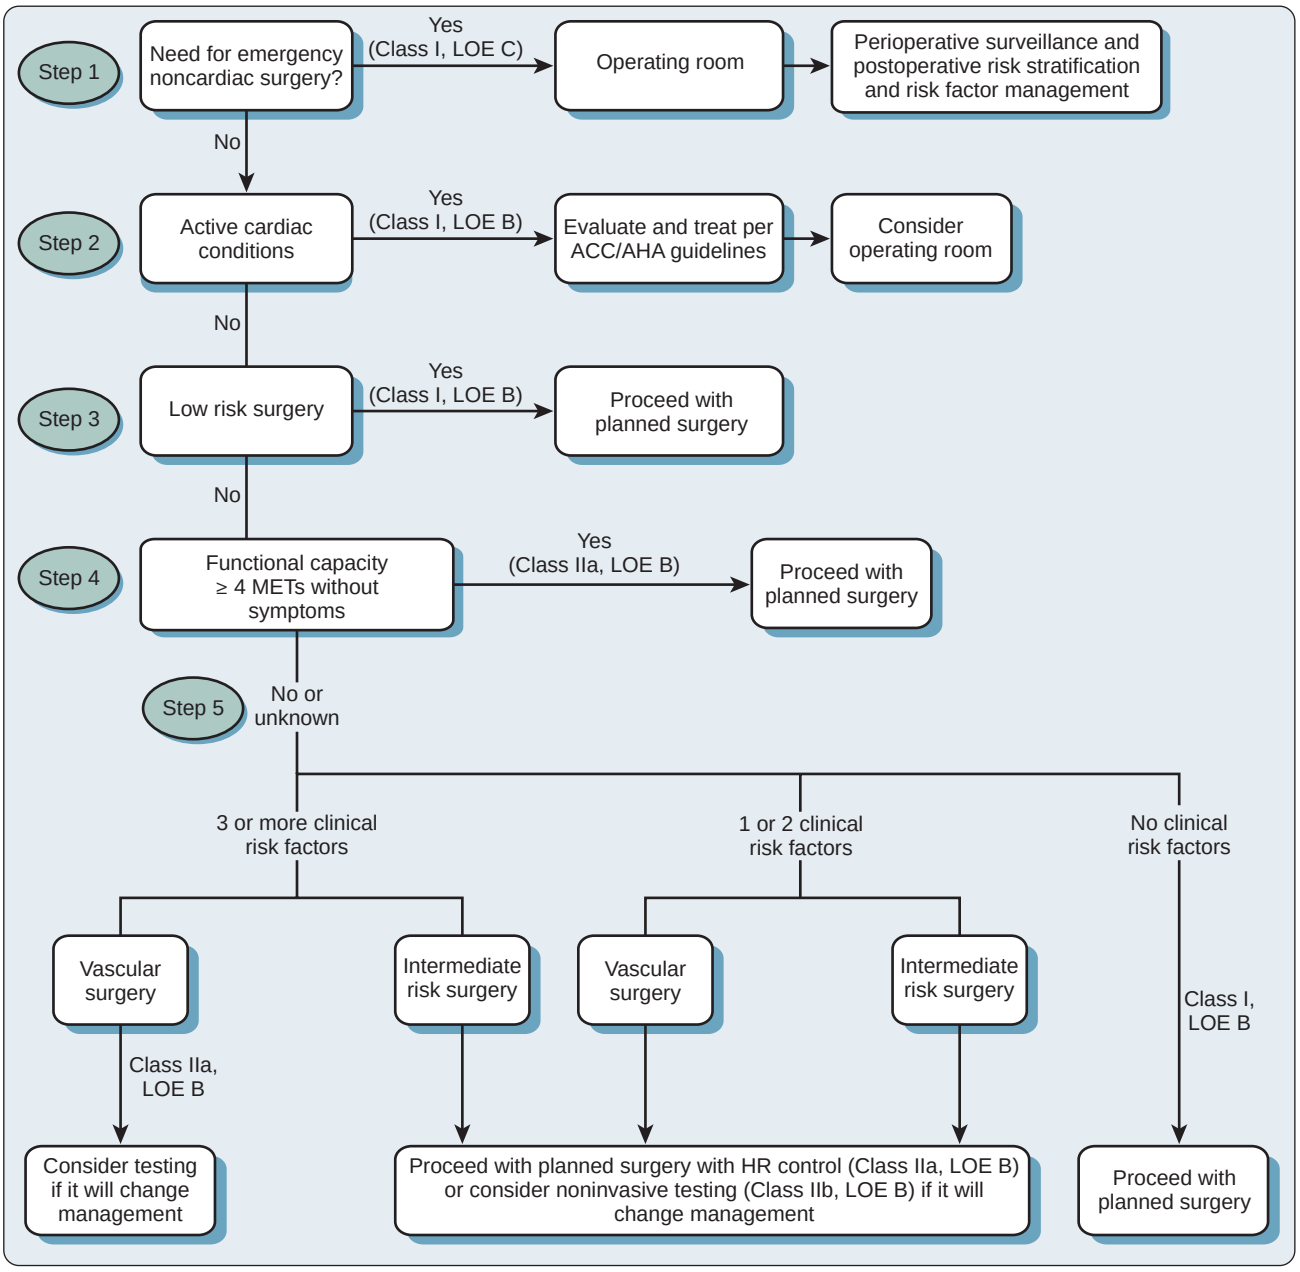

Fig. 43.5 The 2007 ACC/AHA guideline algorithm depicting the stepwise approach to perioperative cardiac assessment for coronary artery disease. *HR*, heart rate; *LOE*, level of evidence; *METs*, metabolic equivalents. *(From Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Developed in collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery.* Circulation. *2007;116:e418–e499.)*

(see Table 43.1).[8] For elevated risk with poor (<4 METs) or indeterminate functional capacity, further testing is advised only if it will affect the decision making for surgical timing and cardiac intervention (eg, pharmacologic stress testing, coronary revascularization).

The management options should be discussed not only among the perioperative physicians but also with the patient. The patient's informed opinion and the clinical impact of further perioperative testing have been incorporated into the 2014 ACC/AHA algorithm (see Fig. 43.4).[3,4] This algorithm differs from the 2007 version (Fig. 43.5) in that it incorporates a clinical "pause" when patients with poor to indeterminate functional capacity are identified.[6,7] As a result, high-risk patients with limited functional capacity do not automatically undergo further testing; instead, the perioperative team and patient can discuss whether the test results will affect either surgical

or perioperative management. If further testing will not impact the surgical plan or perioperative care, then the high-risk patient should either proceed directly to surgery or consider noninvasive treatment and palliation strategies.

The 2014 ACC/AHA guideline features important information extracted from the critical analysis of almost 500 referenced articles that are summarized and appended to the document.[3,4] Important perioperative updates in the evaluation of myocardial ischemia, management of medical therapy in patients with cardiovascular disease, and options for patients after percutaneous coronary interventions are discussed in remaining sections of this chapter. Perioperative recommendations for medical therapy, including β-blockers, ACEI, and α_2-agonists (e.g., clonidine), are also discussed. The perioperative management of antiplatelet therapy in patients with and without coronary stents is highlighted because it is commonly used and important (see Chapter 44).

Classification of Recommendations

The 2014 ACC/AHA guideline includes a comprehensive evaluation of the best available evidence. For specific topics requiring intensive review of data, a formalized systematic review by a separate Evidence Review Committee was undertaken to summarize findings pertaining to the improvement of perioperative care in patients with cardiovascular disease undergoing noncardiac surgery.[25] The guideline provides an organized framework of generalized perioperative management by applying scientific evidence to clinical practice. The recommendations were developed from an evidence base that included randomized controlled trials (RCTs), registries, metaanalyses, nonrandomized studies, case series, and expert opinion (Fig. 43.6). Each recommendation was assigned a class and a level of evidence (LOE) determined by the guideline writing committee to provide information to the clinician regarding the likelihood that the recommendations are well supported by the evidence (see Fig. 43.6).[3,4] Understanding the class and evidence level for a particular recommendation is important when one is considering either implementing or forgoing a particular treatment intervention.

The 2014 ACC/AHA perioperative guideline includes classes of recommendation (I through III) and levels of evidence (A through C) (see Fig. 43.6). A class I recommendation suggests that the benefits clearly outweigh the risks of a particular intervention and that the procedure or treatment *should* be performed or administered. Class IIa suggests that it is reasonable to perform a particular intervention; class IIb indicates that an intervention may be considered; and class

III indicates that the intervention will be of no benefit and may even be harmful. The evidence level encompasses the extent to which the population of interest has been evaluated regarding the measure of interest. For example, evidence level A implies that multiple populations have been evaluated in RCTs. On the other hand, evidence level C suggests that a very limited population of patients has been evaluated in case series, case reports, and expert opinion.

The ACC/AHA guideline writing committee also incorporated clinical practice guidelines produced after 2007 as a further evidence update. The 2014 recommendations aim to convey to perioperative practitioners the significance of each intervention as it pertains to the reduction of MACE.

Screening for Myocardial Ischemia: The Electrocardiogram and Troponins

The 2014 ACC/AHA guideline on perioperative evaluation and management of the cardiac patient undergoing noncardiac surgery recommended a 12-lead electrocardiogram (ECG) for patients with CAD, arrhythmias, structural cardiac disease, cerebrovascular disease, or peripheral arterial disease, unless they are undergoing low-risk surgery (class IIa, LOE B).[3,4] This recommendation underscores the idea that even high-risk patients undergoing low-risk surgeries do not require a routine ECG before surgery. A routine preoperative ECG is not helpful in managing patients undergoing low-risk surgery regardless of cardiovascular disease burden or risk factors. However, a postoperative ECG is recommended if there is a clinical suspicion for postoperative myocardial ischemia, infarction, or arrhythmia after noncardiac surgery. A routine postoperative ECG in asymptomatic patients is not useful regardless of risk factors. The decision to perform a postoperative ECG should be guided by patient symptoms and clinical evaluation.

The measurement of laboratory markers of myocardial injury (eg, troponins) is recommended for patients at high risk of MACE who may benefit from an intervention (class II, LOE B).[3,4] Routine measurement of troponins is not recommended without patient selection (class II, LOE B). The clinical utility of screening with troponin for perioperative MI in at-risk patients who may be asymptomatic remains uncertain in the absence of a defined management strategy. Although perioperative screening with troponin does assess risk, this approach still lacks specificity. RCTs are in progress to evaluate whether interventions based on troponin surveillance reduce the risk of MACE in the perioperative period.[3,4]

Management of Cardiac Medications

β-Receptor Antagonists

The 2014 ACC/AHA guideline provides recommendations for perioperative β-blockade based on multiple trials, including a metaanalysis by Wijeysundera and associates.[25] The key findings of this metaanalysis were not affected by the exclusion of trials with questionable scientific integrity.[26,27] Although this comprehensive report was incorporated into the 2014 ACC/AHA perioperative guideline, two recommendations are of particular interest. First, β-blockade should be continued in patients undergoing noncardiac surgery who have been prescribed these medications chronically (class I, LOE B). This recommendation emphasizes the importance of continuing chronic β-blockade, not only for the continued clinical benefit but also to prevent the negative cardiovascular consequences of acute withdrawal.[3,4] Second, it is recommended that β-blockers not be initiated within 1 day of noncardiac surgery. Although β-blockers given immediately before surgery may prevent nonfatal MI, the benefit of MI prevention is offset by increases in hypotension, stroke, and death (class III, LOE B)[2,4,28] (see Chapter 11).

Angiotensin Blockers

ACEI and ARBs are among the most commonly prescribed antihypertensives.[29,30] Both have cardiovascular and metabolic effects beyond their antihypertensive properties. Their prescription frequency partially relates to their demonstrated outcome and mortality benefit in patients with MI who have residual left ventricular dysfunction, in patients with HF, and in diabetics with kidney disease. In diabetics with renal dysfunction, these agents may delay progression to end-stage renal disease.[31–33] A very large retrospective study of 79,000 patients undergoing noncardiac surgery compared patients taking ACEI with patients not taking ACEI.[34] An analysis of a matched, nested cohort of the study demonstrated increased transient intraoperative hypotension among patients taking ACEI but failed to show any difference in other outcomes. Of note, current clinical practice guidelines recommend continuing ACEI in the setting of acute HF or hypertension.[35,36] A recent metaanalysis (18 trials, $N = 54,528$) demonstrated that in cardiac surgery, ACEI and ARBs did not reduce MACE overall but did significantly reduce mortality in diabetics ($P = .03$).[37] Based on the available data, it is reasonable to continue ACEI or ARBs perioperatively (class IIa, LOE B).[3,4] However, if ACEI or ARBs are withheld before surgery, it is recommended that they be restarted as soon as clinically feasible in the postoperative period (class IIa, LOE C). These agents are associated with intraoperative hypotension.[38,39] This hypotension can be ameliorated by withholding these agents for about 24 hours before surgery and/or using titrated vasopressor therapy during the intraoperative period, including vasopressin in refractory cases.[30,38]

Risk of MACE and α_2-Agonists

α_2-Agonists, such as clonidine, should be avoided when attempting to prevent MACE in patients undergoing noncardiac surgery (class III, LOE B). A prospective RCT (135 centers, $N = 10,010$) evaluated clonidine (0.2 mg/day) in patients with cardiovascular disease after they had undergone noncardiac surgery.[40] Clonidine was initiated preoperatively and continued postoperatively for 72 hours. Clonidine failed to reduce the 30-day incidence of death or nonfatal MI after surgery (hazard ratio [HR], 1.08; 95% CI, 0.03–1.26; $P = .29$). Clonidine administration did, however, increase the risks of nonfatal cardiac arrest (HR, 3.20; 95% CI, 1.17–8.73; $P = 0.02$) and clinically significant hypotension (HR, 1.32; 95% CI, 1.24–1.40; $P < .001$).[40] Further analysis from this large RCT demonstrated that acute perioperative clonidine exposure did not reduce the risk of acute renal injury (relative risk [RR], 1.03; 95% CI, 0.90–1.18).[41] Furthermore, the increased risk of clinically important hypotension associated with clonidine significantly increased the risk of acute renal injury (HR, 1.34; 95% CI, 1.14–1.58). Despite earlier promising evidence that clonidine may reduce perioperative mortality, its perioperative role for myocardial protection in noncardiac surgery has largely been suspended in response to the findings of this landmark trial.[42] However, the role of acute clonidine for reduction of perioperative cardiac risk in patients on chronic β-blockade was explored in a pilot RCT that confirmed its feasibility, safety, and tolerability.[43] Adequately powered RCTs are needed to evaluate perioperative clonidine for this indication in this perioperative population.

Aspirin Therapy in Patients Without Coronary Stent Implantation

The effects of aspirin were evaluated by the Perioperative Ischemia Evaluation (POISE-2) investigators in patients undergoing noncardiac surgery who were without a recent history of coronary stent placement.[44] Patients at risk for MACE were separated into those taking and not taking preoperative aspirin. Patients who were not previously on aspirin ($N = 5628$) were randomized to receive aspirin (initial dose, 200 mg; followed by 100 mg daily) or placebo on the day of surgery and for 30 days after surgery. Patients previously on aspirin ($N = 4382$) were randomized to receive aspirin (with similar dosing) or placebo beginning on the day of surgery and for 7 days postoperatively, after which they resumed their preoperative dosing regimen. Aspirin administration did not decrease the incidence of death or nonfatal MI at 30 days after surgery (HR, 0.99; 95% CI, 0.86–1.15; $P = .92$).[44] Aspirin exposure did, however, increase the risk of clinically significant bleeding (HR, 1.23; 95% CI, 1.01–1.49; $P = .04$). Based on

these recent high-quality data, the 2014 ACC/AHA guideline strongly recommended against routine aspirin therapy without previous coronary stent implantation (class III, LOE B) unless the risks of myocardial ischemia exceed the risks of surgical bleeding (class III, LOE C). It recommended only that consideration be given to the administration of aspirin for elective noncardiac surgery in the absence of recent percutaneous coronary intervention and stenting (class IIb, LOE B).[45]

Dual-Antiplatelet Therapy After Coronary Stent Implantation

Patients with a history of coronary stent implantation require special attention to maximize the chance of maintaining stent patency and minimize the risk of perioperative stent thrombosis.[46,47] DAPT with aspirin and a P2Y12 platelet inhibitor (eg, clopidogrel, prasugrel, ticagrelor) should be continued for urgent noncardiac surgery occurring within 6 weeks after percutaneous coronary intervention regardless of stent type (ie, bare metal stent [BMS] or drug-eluting stent [DES]) (class I, LOE C)[3,4] (see Chapter 44). Elective noncardiac surgery after DES placement may be considered after 180 days (approximately 6 months) if the health risk of delaying the surgery exceeds the risks of ischemia from stent thrombosis due to cessation of antiplatelet agents (class IIb, LOE B).[3,4] This recommendation is based in part on a large, retrospective, cohort study of noncardiac surgical patients ($N = 41,989$; 1980 with MACE and 40,009 with no MACE).[48] The time from stent placement to surgery was related to MACE within the first 6 months after stent implantation, but not if it exceeded 6 months (odds ratio [OR], 0.92; 95% CI, 0.82–1.05). These findings were supported in further large cohort studies (cumulative $N > 65,000$).[49,50]

Most importantly, the 2014 guideline recommends that *elective* noncardiac surgery should *not* be performed within 6 weeks after BMS or 12 months after DES placement if discontinuation of DAPT will be required before surgery, because the chance of harm outweighs the benefits of cessation (class III, LOE B).[3,4] Aspirin should be continued in the postoperative period, and the P2Y12 platelet inhibitor should be restarted as soon as is reasonable after surgery in patients undergoing procedures that require preoperative discontinuation of DAPT (class I, LOE C).[3,4] Discussion among the clinicians caring for a patient with coronary stents should address the balance between the risk of perioperative coagulopathy due to continuation of antiplatelet agents and the risk of stent thrombosis as a result of discontinuation (class I, LOE C). A summary of the recommendations related to the timing of elective noncardiac surgery after percutaneous coronary interventions is provided in Table 43.2.[51] This important, still controversial, and evolving area is discussed further in Chapter 44.

Anticoagulants: Vitamin K Antagonists and Novel Oral Anticoagulants

VKAs are prescribed for stroke prevention in patients with atrial fibrillation (AF), for prevention of thrombotic or thromboembolic complications in patients with prosthetic valves, and for patients who require deep venous thrombosis prophylaxis and treatment. NOACs such as oral thrombin inhibitors and factor Xa inhibitors are prescribed for prevention of stroke in the management of AF but are not currently recommended for long-term anticoagulation of prosthetic valves because of an increased risk of thrombosis when compared with warfarin.[52–54] The risk of bleeding with any surgical procedure must be weighed against the benefit of remaining on anticoagulants. For example, an office-based procedure for minor dermatologic surgery may not require reversal of the anticoagulant.

Although prothrombin complex concentrates (PCCs) have been used to provide acute reversal in patients taking VKAs who require surgery, the current evidence base is less definitive about reversal of NOACs with PCCs.[55–59] Acute perioperative reversal of these agents may also require dialysis for dabigatran and titrated factor VII administration.[53,54] Specific parenteral antidotes for these agents are in clinical development and may offer the possibility of acute neutralization in urgent operative settings.[60–62] In elective surgical procedures that require adequate coagulation, discontinuation of NOACs for at least 48 hours is recommended, depending on factors such as the drug half-life, route of elimination, renal function, and hepatic function (see Chapter 35).[63] A current limitation of these agents is that conventional anticoagulation tests (eg, activated partial thromboplastin time, prothrombin time) do not adequately monitor the effects of NOACs. Certain tertiary care centers, however, develop nomograms for each agent in order to report specific serum levels of each drug.

TABLE 43.2 Percutaneous Coronary Intervention and Recommendations for Timing of Noncardiac Surgery

Percutaneous Coronary Intervention	*Recommended Delay of Elective Noncardiac Surgery (Days)*
Angioplasty	14
Bare metal stent	30
Drug-eluting stent	365

Management of Perioperative Anemia

Anemia is an important topic of discussion, especially because it may contribute to myocardial ischemia (see Chapter 34). Hemoglobin is a potent oxygen carrier, and ischemia may be triggered by both lack of oxygen delivery to poststenotic myocardium and demand for increased cardiac output to supply oxygen to other vascular beds. A common misconception among practitioners is that red blood cell (RBC) transfusions, assuming an appropriate increase in red cell mass, result in an immediate increase in the oxygen-carrying capacity of the blood and improve oxygen delivery to otherwise ischemic tissues. The exact amount of time during which the transfused RBCs replete intracellular 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP) is unclear, but this phenomenon certainly contributes to the necessary risk/benefit analysis of perioperative blood transfusion. Previous retrospective evidence suggested that the age of packed RBCs transfused may contribute to morbidity and mortality,[64] but this was later refuted by multicenter prospective data.[64,65]

Irrespective of the age of stored RBCs, blood transfusions increase morbidity and mortality as well as increase health care costs, and the hemoglobin transfusion thresholds needed to appropriately balance risk and benefit remain a moving target.[66] Carson and coworkers studied 2000 patients undergoing hip surgery who had either CAD or known risk factors for CAD and hemoglobin levels lower than 10 g/dL; they were treated with either a liberal transfusion strategy (threshold for treatment: hemoglobin <10 g/dL) or a conservative transfusion strategy (hemoglobin <8 g/dL).[67] There were no differences between groups in the 60-day end points of death or inability to walk, but the study was not sufficiently powered to show a difference between these two groups. In 2012, the American Association of Blood Banks recommended a restricted transfusion strategy (hemoglobin <7–8 g/dL) in asymptomatic, hemodynamically stable patients without CAD; a relatively restricted transfusion strategy in hospitalized patients with cardiovascular disease; and consideration of transfusion for patients with symptoms or hemoglobin levels lower than 8 g/dL.[68] In postoperative patients, the recommended maintenance hemoglobin concentration is 8 g/dL or greater unless the patient is symptomatic (eg, angina pectoris, HF). There are no specific recommendations for hemodynamically stable patients with acute coronary syndrome because of the lack of high-quality evidence for either a liberal or a restrictive transfusion strategy in these patients. Expert consensus has recommended a symptom-guided approach to evaluating the hemoglobin level when determining whether to transfuse an anemic patient.[68] In the perioperative setting, recent guidelines from the American Society of Anesthesiologists have recommended a restrictive transfusion strategy with strong consideration given to multimodal techniques to augment red cell mass, preserve hemostasis, and limit blood loss.[69]

Pulmonary Vascular Disease and Right Ventricular Dysfunction

Patients with pulmonary hypertension undergoing noncardiac surgery are at increased perioperative risk.[70] Perioperative events including hypoxia, hypercarbia, systemic hypotension, and positive-pressure ventilation may worsen pulmonary vascular resistance and RV systolic function.[71,72] In addition to the urgency of the surgery and the surgical risk category, perioperative risk factors for MACE in patients with pulmonary hypertension include the functional class, degree of RV dysfunction, and absence of specialized care.[73,74] Patients with significant pulmonary hypertension should undergo a thorough preoperative evaluation including determination of functional capacity, hemodynamics, and echocardiography to assess risk, severity, and RV function. In selected cases, right-sided heart catheterization may be indicated to complete the assessment.[75] Optimization of pulmonary hypertension and RV function is necessary to minimize cardiovascular risk throughout the perioperative period.[76]

Summary

Risk stratification of the cardiac patient undergoing noncardiac surgery is of paramount importance for the overall clinical outcome.[77] Perioperative risk calculators have been designed to help the perioperative team appropriately quantify the risk associated with a designated noncardiac procedure for a specific patient, although they have their limitations. These validated calculators are available online to make this determination of perioperative risk for MACE.

The 2014 ACC/AHA clinical practice guideline, *Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery*, addresses many management dilemmas in an evidence-based fashion with expert consensus where necessary. In addition, a multidisciplinary approach is advocated to develop perioperative consensus for the individual patient to minimize risk. Finally, establishing the patient's understanding of the risk and desire to proceed with surgery is at the heart of the overall assessment and development of a comprehensive perioperative care plan.

The Patient With Coronary Stents Undergoing Noncardiac Surgery

EMILIO B. LOBATO, MD | ANTHONY A. BAVRY, MD, MPH

KEY POINTS

1. Percutaneous coronary intervention (PCI) with stent placement is frequently performed, and a substantial number of patients who undergo PCI require subsequent noncardiac surgery.
2. The two types of stents currently available for clinical use are bare metal stents (BMSs) and drug-eluting stents (DESs).
3. The two main stent-related complications are restenosis and thrombosis.
4. The risk of restenosis peaks within the first year after PCI and more commonly occurs in patients with BMSs.
5. The risk of stent thrombosis is highest within the first 30 days regardless of stent type. It decreases subsequently but remains higher with DESs compared to BMSs, at least for the first year. Newer generations of DESs appear to be less thrombogenic than first-generation DESs.
6. Prolonged treatment with dual antiplatelet therapy (DAPT) is necessary to prevent stent thrombosis, yet the optimal duration with particular types of stents is unknown.
7. Several clinical, procedural, and angiographic risk factors for stent thrombosis are recognized. The most important is premature discontinuation of DAPT; yet many cases of stent thrombosis occur in the presence of platelet inhibitors.
8. The standard combination for long-term DAPT consists of acetylsalicylic acid (ASA) and clopidogrel; however, there is significant variability in patient response to each drug. The more potent drugs, prasugrel and ticagrelor, exhibit more predictable antiplatelet effects but are associated with a higher risk of bleeding.
9. The use of platelet function tests to individualize antiplatelet therapy has not proven superior in medical patients, but it has shown effectiveness prior to cardiac surgical procedures and may hold promise for noncardiac surgical procedures.
10. The incidence of perioperative stent thrombosis is low, but it is associated with major morbidity and mortality.
11. The two most important decisions for patients undergoing noncardiac surgery are timing of the procedure and management of antiplatelet therapy.
12. Most recommendations are not very well defined and are based on low-quality evidence and expert opinion. Management should balance each patient's specific thrombotic risk against a particular surgical procedure's specific hemorrhagic risk.
13. Elective surgery should be delayed 6 to 12 weeks after BMS placement and at least 6 months (and, preferably, 12 months) after DES placement, with ASA continued for most procedures. If surgery cannot be postponed, decisions on antiplatelet therapy should be based on the patient's individual thrombotic/hemorrhagic risk.
14. Selected patients may benefit from bridging therapy with intravenous platelet inhibitors, but such an approach is not without risks and is associated with increased hospitalization and cost.
15. The frequency and complexity of performing noncardiac surgical procedures in patients with coronary stents requires an interdisciplinary structured approach with input from the different specialties involved in the care of these patients.

Percutaneous coronary intervention (PCI) is one of the most common procedures worldwide, with approximately 600,000 PCIs performed annually in the United States alone.[1] The term includes balloon angioplasty, as well as coronary stent placement, with the overwhelming majority of individuals undergoing the latter because of its superior results in preserving vessel patency.

Despite the obvious advantages over balloon angioplasty, the long-term care of patients with coronary stents is haunted by the risk of restenosis and stent thrombosis.[2,3] Refinements in stent technology, implantation technique, and antiplatelet therapy have increased stent safety profiles[4]; however, long-term management still involves significant challenges in aiming to achieve an optimal balance of maintaining vascular integrity while minimizing thrombotic and bleeding risks (see Chapters 1, 3, and 20).

The reported incidence of noncardiac surgery (NCS) after PCI ranges from 4% to 11% at 12 months and from 7% to 34% by 2 years.[5,6] One of the greatest causes for clinical concern is how to best manage these patients, because the presence of coronary artery stents is a recognized risk for perioperative cardiac morbidity and mortality.[7–9]

The issue is further complicated by a frequent lack of consensus among perioperative providers, either due to unawareness or personal preferences, as a result of which patients may remain uninformed of potential risks.[10,11] Because of the magnitude of the problem, professional societies have provided guidelines for perioperative

physicians to assist in their evaluation and management, but these are mostly grounded on low-quality evidence and expert opinion.[12–14] Furthermore, they frequently disagree and/or are vague and ambiguous.[15] Additionally, rapid improvements in stent technology and new pharmacologic agents find their way into clinical use before long-term outcome from clinical trials are published, adding to the confusion about the best way to manage these patients in the perioperative period.

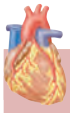
As part of a multidisciplinary team, anesthesiologists are in a unique position to provide important critical input, as they are frequently sought by perioperative providers for their expertise. It is therefore necessary to have a thorough understanding and familiarity with the basic concepts of coronary stenting, pharmacologic long-term management, and perioperative risks associated with this patient population.

Optimal Stenting Technique

Most stents are implanted following predilation of an atheromatous lesion with a high pressure balloon, but in some instances direct stenting may be considered (eg, absence of calcification, proximal lesions, or during ST-segment elevation myocardial infarction [STEMI]).[16] Regardless of technique, the single most important goal is to achieve full expansion of the arterial lumen, thus minimizing the risk of stent restenosis and thrombosis. Successful expansion should leave a minimal diameter stenosis of less than 10% and adequate blood flow without the presence of a thrombus, associated dissection, distal embolization, or occlusion of a side branch[17] (Box 44.1).

Failure to achieve maximum vessel dilatation may be caused by inadequate balloon expansion related to poor technique, location of the lesion, features of the atheroma, or stent design.[18] Suboptimal stent deployment is associated with a higher risk of periprocedural myocardial infarction and increased incidence of late cardiac events such as non–ST-segment elevation myocardial infarction (NSTEMI) and target vessel revascularization.[19–21]

Evaluation of stent expansion is commonly performed with angiography. Other techniques such as intravascular ultrasound, optical coherence tomography, and measurement of fractional flow reserve are also useful to predict optimal stenting results but are not employed routinely because most operators rely primarily on angiographic appearance[22–25] (see Chapter 3).



BOX 44.1 PERCUTANEOUS CORONARY INTERVENTION CRITERIA FOR SUCCESSFUL STENT DEPLOYMENT

Vessel diameter stenosis <10%
Adequate flow (TIMI 3)
Absence of thrombus, dissection, embolization, or vessel occlusion

TIMI 3, Thrombolysis in Myocardial Infarction Study Group grade 3 flow.

Types of Stents

The basic concept of a stent is that of a solid scaffold that prevents vessel closure due to elastic recoil or vessel contracture. In general, stents can be categorized according to material composition, durability, thickness of struts, and the presence of eluting drugs for local delivery[26–30] (Table 44.1).

Bare Metal Stents

Current bare metal stents (BMSs) are made of stainless steel, cobalt chromium, or platinum chromium. Stainless steel BMSs were the first devices used for coronary stenting.[31] They successfully reduced the incidence of abrupt vessel closure and restenosis compared with balloon angioplasty, thereby decreasing the rate of target lesion revascularization.[32–34] One advantage of BMSs is that on average, endothelial stent coverage is completed in approximately 12 weeks, which decreases the risk of stent thrombosis.[35] Nevertheless, despite refinements in stent design, significant restenosis within the stented segment develops in approximately 20% to 30% of lesions.[36–38]

Current accepted indications for placing a BMS include patients who are likely to be noncompliant with long-term dual antiplatelet therapy (DAPT); patients at a higher risk of bleeding, including individuals taking oral anticoagulants; and patients who are scheduled for NCS requiring cessation of antiplatelet therapy within 1 year after PCI.[17]

Drug-Eluting Stents

Drug-eluting stents (DESs) consist of a metallic stent platform coated with a polymer carrier vehicle that stores an antiproliferative agent.

TABLE 44.1 Types of Stents

Bare Metal Stents

Name	*Manufacturer*	*Stent Generation*	*Stent Platform*
Veri-FLEX	Boston Scientific	First	Stainless steel
Vision	Abbott Vascular	Second	Cobalt chromium
Integrity	Medtronic	Second	Cobalt chromium
REBEL	Boston Scientific	Third	Platinum chromium

Drug-Eluting Stents

Name	*Manufacturer*	*Stent Generation*	*Stent Platform*	*Polymer*	*Anti-Restenotic Drug*	*Elution Kinetics*
Cypher[a]	Cordis/J&J	First	Stainless steel	PEVA/PBMA	Sirolimus	80% at 4 weeks
Taxus[a]	Boston Scientific	First	Stainless steel	SIBBS	Paclitaxel	10% at 4 weeks
Xience	Abbott Vascular	Second	Cobalt chromium	PBMA/PVDF-HFP	Everolimus	80% at 4 weeks
Promus	Boston Scientific	Second	Cobalt chromium	PBMA/PVDF-HFP	Everolimus	80% at 4 weeks
Endeavor	Medtronic	Second	Cobalt chromium	PPChol	Zotarolimus	95% at 2 weeks
Resolute	Medtronic	3nd	Cobalt chromium	Biolynx	Zotarolimus	85% at 8 weeks
Promus Element	Boston Scientific	Third	Platinum chromium	PBMA/PVDF-HFP	Everolimus	80% at 4 weeks
Taxus Ion	Boston Scientific	Third	Platinum chromium	SIBBS	Paclitaxel	10% at 2 weeks
Nobori[b]	Terumo (Japan)	BP-DES	Stainless steel	PLA (biodegradable)	Biolimus	80% at 4 weeks
Biomatrix[b]	Biosensors (Singapore)	BP-DES	Stainless steel	PLA (biodegradable)	Biolimus	80% at 4 weeks

[a]No longer used (Cypher was discontinued in 2011).
[b]Not approved for use in the United States.
PBMA, Poly n-butyl methacrylate; *PEVA,* polyethylene vinyl acetate; *PLA,* polylactic acid; *PPChol,* phosphorylcholine; *PVDF-HFP,* poly vinylidene fluoride–hexafluoropropylene; *SIBBS,* styrene-b-isobutylene-b-styrene.

The carrier releases the drug in a gradual and controlled fashion (elution), allowing local diffusion into the vascular tissue, thus preventing excessive cell growth (neointimal hyperplasia) and encroachment into the lumen in response to device implantation.[39] DESs have been shown to outperform BMSs with respect to the rates of restenosis and target lesion revascularization, particularly within the first year after implantation.[40–44] Thereafter, it appears that the restenosis rate is similar between DESs and BMSs.[45–47]

Stent Platform

Stent design plays an important role in drug distribution into the vessel wall.[48] The configuration of the stent's struts directly determines the pattern and degree of drug delivery.[49,50] Also, the symmetric expansion of stents is essential to optimize drug diffusion. A large number of stent platform designs have been developed, but all of them can be categorized into those with closed or open cell configurations[51] (Fig. 44.1).

A closed cell stent achieves a more even expansion, and the constant cell spacing leads to more uniform drug distribution.[52] An open cell system has better conformability because of greater variation in the surface coverage between the inner and outer curvatures but at the expense of less uniform distribution.[52,53] Improvement in stent flexibility and decreased strut thickness have been shown to lessen arterial injury and decrease neointimal response[54–56] (Fig. 44.2). The optimal stent design for drug delivery should have a large stent surface area and a small cell gap, while maintaining conformability, radial support, and flexibility to reach complex coronary lesions.

Polymer Matrix

The function of a polymer matrix is that of a reservoir containing the antiproliferative drug during stent deployment, followed by gradual release of the agent into the local vessel wall.[57] The elution kinetics over a period of weeks or months following implantation are dictated by the type, composition, and design of the stent coating material.[58] Polymers can be broadly described as organic versus inorganic, bioabsorbable versus durable, and synthetic versus natural. Differences in polymer composition directly influence the length and extent of the inflammatory reaction on the vessel wall and, thus, the timing for re-endothelialization of the stent surface.[59–61]

Older DESs (so-called first-generation DESs) are composed of stainless steel platforms and durable polymers. These have been shown to produce long-term inflammatory reactions, resulting in delayed vascular healing and endothelial stent coverage.[62,63] Newer DESs (second and third generations) consist of cobalt or platinum chromium scaffolds and are coated with polymers that cause less local inflammation and less interference with re-endothelialization[64–66] (Box 44.2).

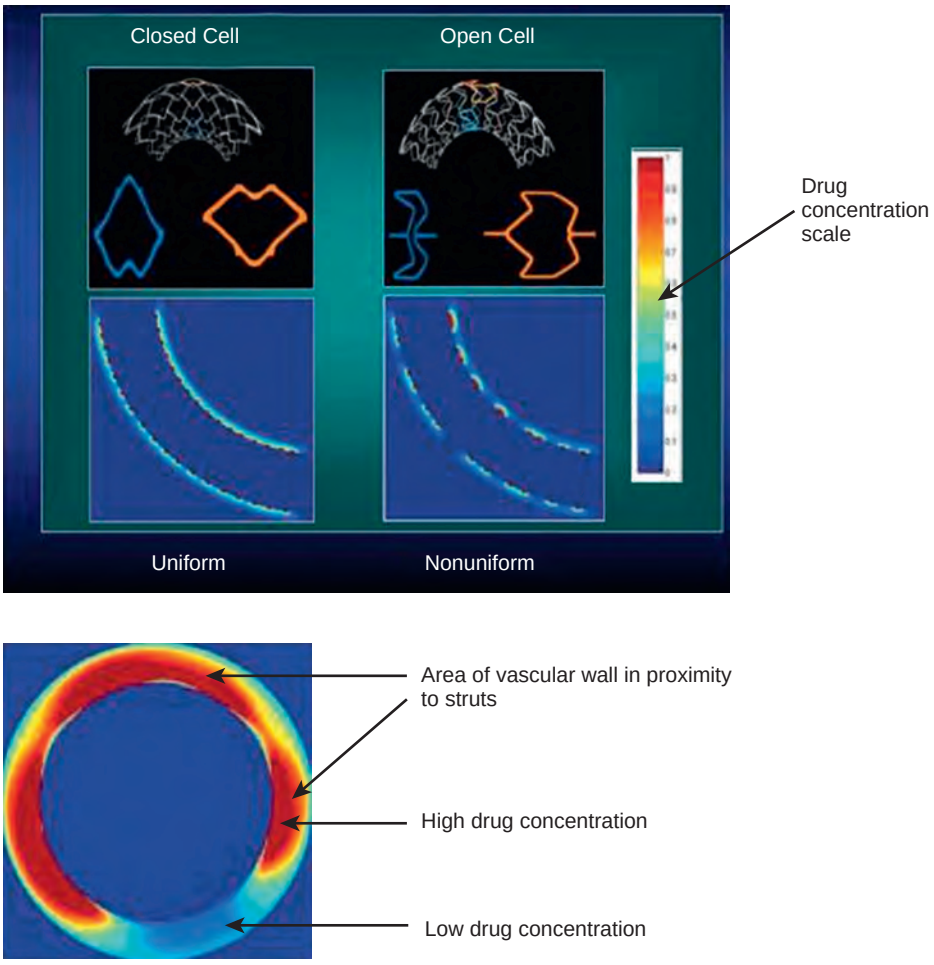


Fig. 44.1 *Upper panel,* Closed cell versus open cell configuration in a drug-eluting stent. Closed cell configuration *(left)* provides more scaffold support and more uniform drug distribution into the adjacent vascular wall than an open cell system *(right)* but at the expense of decreased flexibility. Drug concentration is shown by the color intensity in the column from highest *(red-brown)* to lowest *(blue). Lower panel,* Cross-section of a vessel after deployment of a drug-eluting stent showing nonuniform strut spacing resulting in uneven drug distribution. *(Reproduced with permission from Htay T, Liu MW. Drug-eluting stent: a review and update.* Vasc Health Risk Manag. *2005;1:263–276. Copyright Dove Medical Press.)*

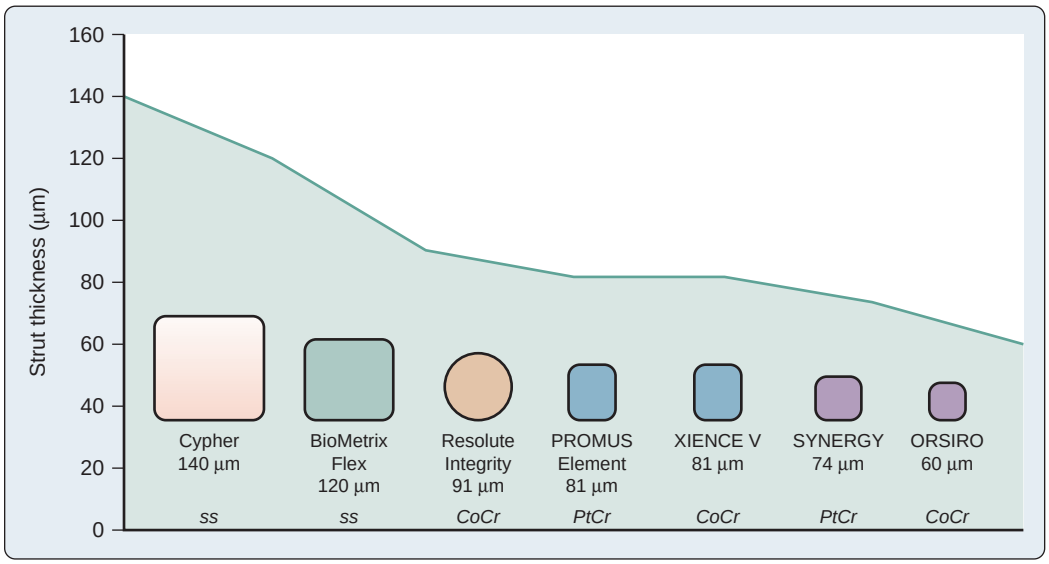

Fig. 44.2 Evolution of strut thickness in drug-eluting stent platforms. Thinner struts are made mainly from cobalt chromium *(CoCr)* or platinum chromium *(PtCr)* alloys, which have a higher mechanical strength than stainless steel. *(Modified with permission from Foin N, Lee RD, Torii R, et al. Impact of stent strut design in metallic stents and biodegradable scaffolds.* Int J Cardiol. *2014;177:800–808. Copyright Elsevier.)*

BOX 44.2 ADVANTAGES OF SECOND- AND THIRD-GENERATION DRUG-ELUTING STENTS

Improved flexibility
Thinner struts
Enhanced polymer biocompatibility
Better elution kinetics

Antiproliferative Agents

During DES design and manufacturing, multiple agents with the ability to prevent cell replication are tested; however, only five antirestenotic drugs are currently used in the clinical setting.

1. Sirolimus (also known as rapamycin) is a fermentation product of *Streptomyces hygroscopicus*. It functions as an antifungal macrolide with potent cytostatic properties. Sirolimus is a highly lipophilic molecule that readily diffuses across the membranes of vascular smooth muscle cells. In the cytoplasm, it binds to a specific intracellular protein. The resulting complex inhibits a regulatory enzyme called target of rapamycin (TOR), blocking cell progression from the G1 to S phase, thereby limiting smooth muscle cell replication and proliferation.[67,68]
2. Everolimus is a semisynthetic sirolimus derivative. It is slightly more lipophilic and more rapidly absorbed in the arterial wall.[69]
3. Zotarolimus is an equipotent analogue of sirolimus but with a shorter circulating half-life. It is also highly lipophilic.[70]
4. Biolimus is a lipophilic lactone, semisynthetic analogue of sirolimus. It is used primarily as the eluting agent in certain biodegradable polymer stents.[71]
5. Paclitaxel is an antineoplastic agent isolated from the bark of the Pacific yew tree *Taxus Brevifolia*, originally used to treat breast and ovarian cancer. It is also a lipophilic molecule that readily defuses across cell membranes. Paclitaxel acts by stabilizing cellular microtubules prior to cell division, thus preventing their disassembly, which is essential for the progression of the G2 to M phase in the mitotic cell cycle.[72] The end result is inhibition of smooth cell replication and migration.

First Generation Drug-Eluting Stents

Although widely used since first introduced in 2003,[52] first-generation DESs are rarely used today and have been largely replaced by more refined stents. First-generation DESs are comprised of a metallic stent platform, typically stainless steel, coated with a nonbiodegradable polymer that elutes either sirolimus (Cypher, no longer manufactured) or paclitaxel (Taxus).[73,74] Several trials demonstrated the superiority of DESs over BMSs in decreasing the rates of restenosis and target lesion revascularization, with the Taxus stent seemingly associated with a slight increase in stent thrombosis over the Cypher stent.[75,76] The majority of the existing body of literature regarding perioperative risk and management of surgical patients is based on first-generation DESs rather than the newer, safer, stents.

Second- and Third-Generation Drug-Eluting Stents

Second- and third-generation DESs offer numerous improvements that increase their safety profile over their first-generation counterparts.[77–80] They have decreased strut thickness, improved flexibility, enhanced polymer biocompatibility and drug elusion profiles, and superior re-endothelialization kinetics.[81] These devices are now the predominant coronary stents implanted worldwide.

Taxus Ion

This stent uses paclitaxel but with a unique polymer designed to maximize early release so most of the drug is eluted by 12 weeks. In addition, the system uses a platinum chromium strut system providing thinner struts, which are associated with lower levels of vessel wall inflammation.[82]

Zotarolimus Drug-Eluting Stents

Currently two of these stents are available. The Endeavor stent has a stronger cobalt chromium platform with improved flexibility. It also uses a phosphoryl choline polymer coating designed to maximize biocompatibility and minimize inflammation associated with previous polymers.[83] This shortens the drug elution time, so that 95% of the drug is eluted within 2 weeks, thereby allowing normal arterial repair to occur faster.

The Endeavor Resolute represents a refinement over the Endeavor stent. The main difference is the presence of a trilayered polymer made

up of three main components: (1) a hydrophilic polymer for biocompatibility, (2) a hydrophobic polymer for drug-elution control, and (3) a polyvinyl polymer that releases an initial surge of the drug immediately after implantation.[84] The net effect is suppression of the initial inflammatory response followed by 85% of the drug being eluded over the next 8 weeks.

Everolimus Drug-Eluting Stents

Two versions of the Everolimus DES exist. The Xience stent uses a cobalt chromium platform with a polymer (*N*-butyl-methacrylate) that allows 80% of the drug to be eluted within 4 weeks.[85] The Promus DES uses an identical polymer profile and drug elusion but offers improved drug delivery due to a mobile platinum-chromium scaffold.[86]

DESs are indicated for most coronary lesions, whereas BMSs are currently reserved for selective situations. In general, patients more likely to benefit from a DES are those with a high risk of restenosis that may lead to poor outcome. These include patients with left main coronary artery disease, ostial lesions, small vessels, previous in-stent restenosis, bifurcation lesions, long or multiple lesions or those in saphenous vein grafts, and patients with acute coronary syndromes (ACSs), diabetes, or chronic kidney disease.[86–90]

Differences Between Drug-Eluting Stents

All DESs are superior to BMSs by reducing the incidence of restenosis and target lesion revascularization at 12 months.[91] First-generation DESs are inferior to newer DESs regarding target lesion revascularization and late thrombosis.[91–93] With respect to second- and third-generation DESs, very little difference in outcomes are apparent between zotarolimus and everolimus DESs, although a slight decrease in stent thrombosis may be associated with the cobalt chromium everolimus stents.[94–96]

Biodegradable Coronary Stents

Although the newer generation stents have a lower incidence of stent thrombosis when compared to first-generation DESs, the stent platform and polymer matrix are permanent. A potential method to decrease stent thrombosis even further would be to shorten the length of exposure to either the polymer or the scaffold with the use of bioabsorbable stents, where either the polymer or the scaffold can degrade over time.[97–99] The main rationale for using a bioabsorbable polymer is based on the expectation of decreased chronic inflammation and improved vascular healing. The principle behind a bioabsorbable stent platform is grounded on the fact that restenosis is uncommonly seen after 12 months following a procedure[37,38]; thus, the clinical need for stent scaffolding is likely to be very limited.

Although these stents currently are not approved for clinical use in the United States, stents with bioabsorbable polymers have been extensively studied elsewhere.[100–103] Two recent meta-analyses compared bioabsorbable polymer stents against durable polymer DESs and BMSs.[104,105] The analyses demonstrated that such stents are superior to first-generation DESs and perhaps BMSs, and they are comparable to some of the second-generation DESs. Presently they are considered a reasonable alternative to second- and third-generation DESs.

Vascular and Biologic Response to Stent Placement

Most clinical decisions surrounding the perioperative evaluation and management of patients with coronary stents are based on the body's natural responses to the presence of a foreign body in the coronary lumen; therefore, it is important to review the associated pathophysiology as well as the therapeutic interventions aimed to counteract such reactions.

Balloon dilatation of an atheromatous lesion with concomitant stretching of the vascular wall initiates three sequentially distinct responses[106]:

1. Immediate vessel recoil
2. Negative arterial remodeling
3. Neointimal hyperplasia

Elastic recoil represents the immediate shrinkage of the vessel following PCI due to the elastic properties of the arterial wall, which usually occurs within 24 hours after the procedure. This is followed by negative remodeling, which is the process of local contraction of the arterial wall and narrowing of the lumen of the injured vascular segment. The cause of negative remodeling is not well established but may be related to the healing process as well as interactions between the vascular endothelium and laminar flow.[107] Neointimal hyperplasia constitutes a delayed healing response. This is represented by proliferation and migration of smooth muscle cells from the media and perhaps circulating endothelial progenitor cells from the bone marrow into the intima.[108,109]

Placement of an intracoronary stent eliminates the first two processes, leaving only that of neointimal hyperplasia playing a role in normal healing, as well as the exaggerated response responsible for restenosis. In addition, unlike plain balloon angioplasty, the permanent presence of a foreign body serves as a constant stimulus for thrombus formation due to activation of platelet function and coagulation mechanisms, which persist until complete endothelial stent coverage occurs.[110–113]

The cellular cascade initiated by stent deployment can be divided into three phases[114] (Fig. 44.3):

1. Early phase: Endothelial injury, platelet activation and inflammation with leukocyte recruitment, release of cytokines and growth factors. This response is followed by re-endothelialization and generation of neo-endothelium. In the presence of antiplatelet therapy, endothelial destruction stimulates the formation of a thin layer of thrombus consisting mainly of platelets covering the vascular and stent surfaces; in the absence of cytotoxic agents, complete coverage of neointima by endothelial cells is present after several weeks.[115]
2. Granulation phase: Replacement of the fibrin clot in injured areas by macrophages that are responsible for digesting cell debris and secretion of several growth factors, thus stimulating endothelial cell proliferation and smooth muscle cell migration.[116]
3. Tissue remodeling phase: Modification of muscle cells activated by growth factors and cytokines released by damaged endothelial cells and platelets as well as compressive vascular forces generated by the stent and low shear stress along the struts.[117,118] Smooth muscle cells undergo complex changes leading to migration and proliferation from the media toward the intima. This process is accomplished by a transformational change from a contractile to a synthetic phenotype, which enables smooth muscle cells to deposit an extracellular matrix.[119] This protein-rich matrix plays an important role as it interacts with cells and influences further cell adhesion, migration, and proliferation. Some individuals exhibit an exaggerated response, which seems to correlate with the extent and severity of vascular injury. In these circumstances, excessive neointimal growth will further encroach into the vessel lumen, leading to in-stent restenosis. The presence of antiproliferative agents blunts this response, thereby maintaining lumen patency. The trade-off is delayed endothelial stent coverage, which increases the risk of stent thrombosis (Fig. 44.4)

In-Stent Restenosis

This process involves a gradual renarrowing of the stented segment, or immediately proximal or distal to it, that is caused by excessive neointimal growth. Restenosis occurs as a result of peak neointimal thickening mostly between 4 and 12 months following stent placement.[120–122]

Clinical intervention is considered when the reduction in vessel diameter is 50% or greater in the presence of associated symptoms or signs of ischemia, or if there is a 70% or greater reduction in lumen diameter regardless of the presence of symptomatology.[123] *Target*

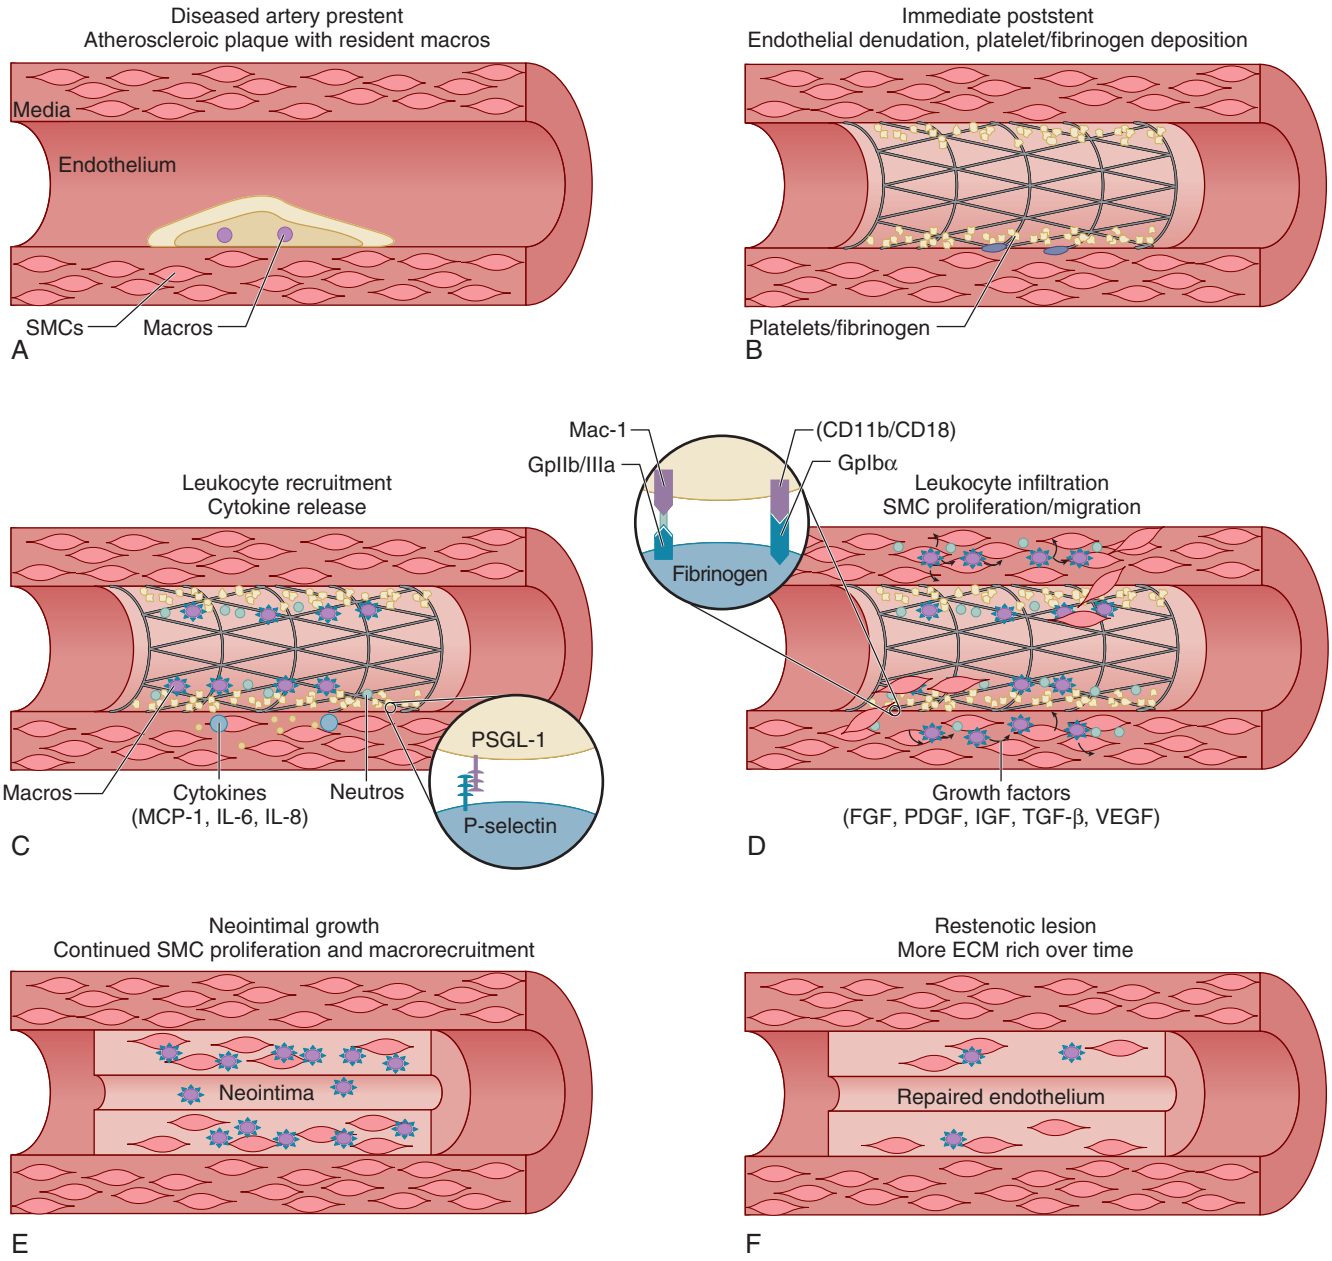

Fig. 44.3 (A) Mature atherosclerotic plaque before intervention. (B) Immediate result of stent placement with endothelial denudation and platelet and fibrinogen deposition. (C) and (D) Leukocyte recruitment, infiltration, and smooth muscle cell *(SMC)* proliferation and migration in the days after injury. (E) Neointimal thickening in the weeks after injury, with continued SMC proliferation and monocyte recruitment. (F) Long-term (weeks to months) change from a predominantly cellular to a less cellular plaque, rich on extracellular matrix. *(Reproduced with permission from Bhatia V, Bhatia R, Dhindsa M. Drug-eluting stents: new era and new concerns.* Postgrad Med J. *2004;80:13–18. Copyright BMJ Publishing Group Ltd.)*

vessel revascularization refers to any reintervention along the side of the stented vessel, whereas the term *target lesion revascularization* is defined by reintervention within the lesion itself. Types of restenotic lesions are shown in Fig. 44.5.[124]

The incidence of restenosis within the first year after PCI in patients with BMSs is approximately 20% to 30%.[125] Thereafter, myocardial ischemia, if present, occurs mostly from progression of native vessel disease.[126] DESs consistently reduce the incidence of in-stent restenosis and the rate of target lesion revascularization by about 75% with the benefits seen across all subgroups of patients.[127–130]

Types of Lesions

Management of discrete concentric lesions, with little or no calcification and without branch involvement, is associated with a high success rate. More challenging lesions conferring a higher risk for restenosis are those that are diffuse, more than 20 mm long, excessively tortuous, angulated, ostial, and involving vein grafts.[131] Additional predictors include small vessel size (<2.5 mm), multiple stents, stent strut thickness, stent underexpansion, and clinical comorbidities such as diabetes mellitus (particularly insulin dependent), metabolic syndrome, and hypertension[132,133] (Box 44.3).

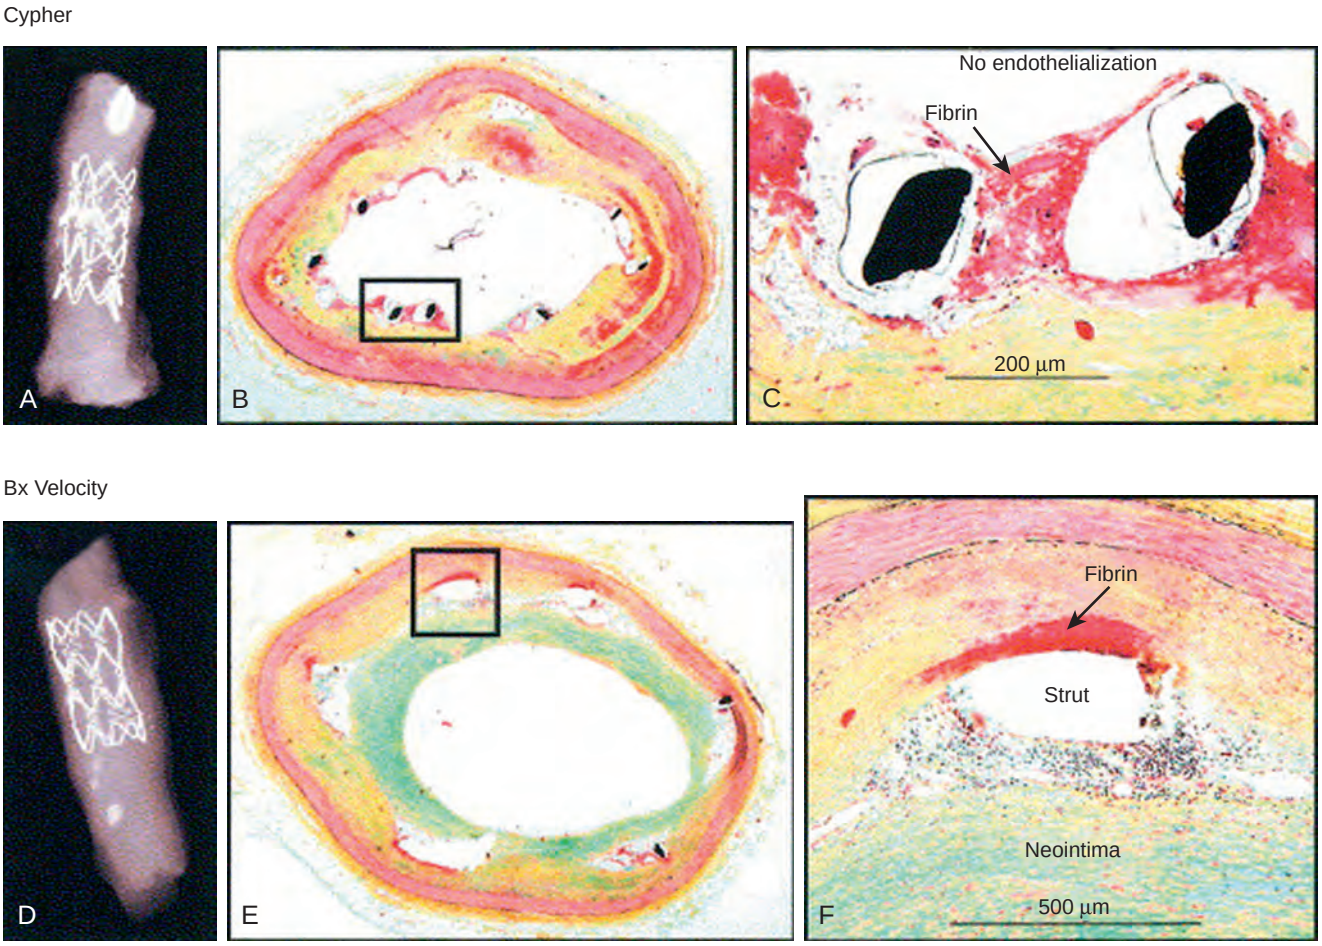

Fig. 44.4 A 65-year-old man who died from head trauma. The patient had received a proximal sirolimus drug-eluting stent (DES; Cypher) and a distal bare metal stent (BMS; Bx Velocity) in his left anterior descending coronary artery (LAD) 15 months before his death. (A) Radiograph of the stented LAD segments. (B) Histologic section of the DES showing minimal neointimal coverage of the struts. (C) High-powered magnification showing fibrin around the strut, rare endothelial cells, and no luminal thrombus. (D) Radiograph of the stented LAD segments. (E) Abundant neointimal tissue within the BMS *(green)* consisting of smooth muscle cells, extracellular matrix, and overlying endothelium. (F) Magnified section showing minimal fibrin underneath the strut, which is surrounded by lymphocytes; the luminal surface of the stent is covered by smooth muscle cells in a proteoglycan-collagen–rich matrix. All sections shown are stained with Movat pentachrome. *(Reproduced with permission from Joner M, Finn AV, Farb A, et al. Pathology of drug-eluting stents in humans: delayed healing and late thrombotic risk.* J Am Coll Cardiol. *2006;48:193–202. Copyright Elsevier.)*

Although less frequent with DESs, restenosis still occurs depending on periprocedural challenges and the complexity of the initial lesions.[134,135] Thus, unlike with BMSs, it seems that most predictors of restenosis with DESs relate more to lesion characteristics and technical aspects of stent deployment rather than to the clinical status of the patient.[136]

Clinical Presentation

Stent restenosis is primarily suspected by recurrent symptoms of myocardial ischemia. The most common syndrome is that of stable or progressive angina, but up to 10% of patients present with acute myocardial infarction.[137] The diagnosis of in-stent restenosis is confirmed by coronary angiography.

Treatment

In patients who are symptomatic and/or fulfill anatomic criteria, repeat PCI is frequently required. Most experts recommend balloon dilatation of the lesion and insertion of a DES because of the favorable profile against restenosis. Placement of a DES for the treatment of restenosis will require prolonged DAPT to minimize the risk of stent thrombosis. Patients for whom repeat PCI is not likely to be successful should be considered candidates for surgical myocardial revascularization. In those patients, placement of arterial grafts is preferable because of a higher long-term patency rate compared to saphenous vein grafts (see Chapter 20).

Stent Thrombosis

Definition

Thrombosis of a coronary stent is one of the most serious complications of PCI and is associated with major morbidity and mortality.[138] It is defined as an abrupt occlusion at the site of the stent resulting from a platelet-rich thrombus, which can occur anytime from the moment of stent placement to years after PCI.[139–141]

Clinicians in the past have used various definitions of stent thrombosis, which made interpretation of events very difficult. Since 2006, the Academic Research Consortium has proposed criteria for the diagnosis of stent thrombosis and timing of events in relation with the

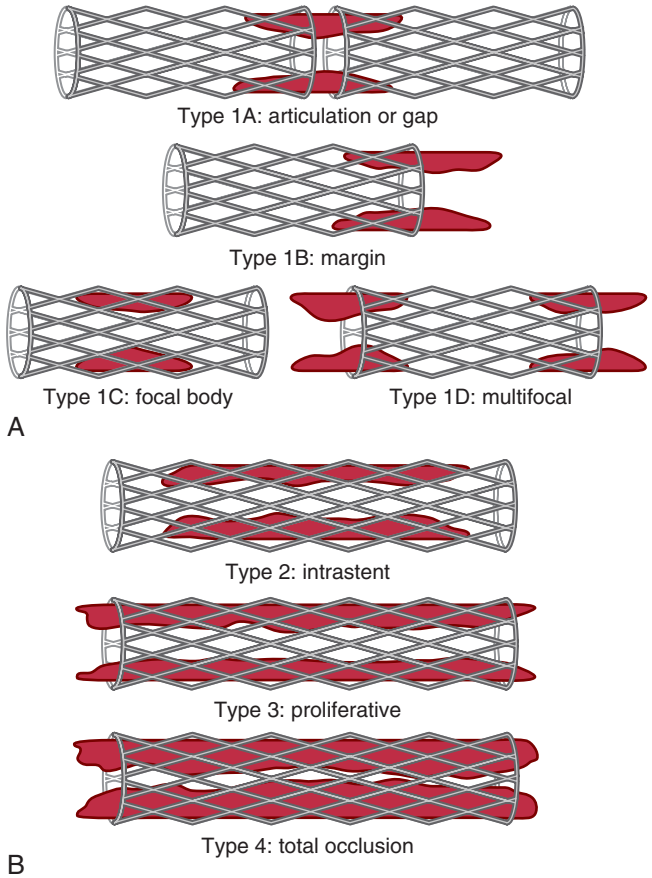

Fig. 44.5 Different angiographic patterns of in-stent restenosis. (A) Type 1: focal lesions (and subtypes) 10 mm or shorter. (B) Type 2: diffuse lesions 10 mm or greater; type 3: proliferative lesions 10 mm or greater, extending beyond the stent margins up to 5 mm; type 4: total occlusion. *(Modified with permission from Merhan R, Dangas G, Abizaid AS, et al. Angiographic patterns of in-stent restenosis: classification and implications for long term outcome.* Circulation. *1999;100:1872–1878. Copyright Wolters Kluwer Health.)*

BOX 44.3 RISK FACTORS FOR STENT RESTENOSIS

Lesion Characteristics
- Long

BOX 44.4 MECHANISMS OF STENT THROMBOSIS

Slow blood flow around stent
Exposure of platelets to nonendothelial surface
Absence or low response to platelet inhibition
Local hypersensitivity or inflammation of the vascular wall
Presence of neoatherosclerotic plaques

- Persistent slow coronary flow, which may occur with wall dissection or hypoperfusion
- Exposure of blood elements to prothrombotic constituents in the vasculature (eg, tissue factor, collagen) or to the stent itself before re-endothelial stent coverage
- Failure to suppress platelet aggregation during the period of high thrombotic risk, such as premature cessation of antiplatelet therapy or drug resistance

In some patients (particularly with DESs) who develop very late stent thrombosis (VLST), other factors such as hypersensitivity reactions, excessive fibrin deposits, and ruptured neoatherosclerotic plaques within the stent struts play an important role.[143]

Timing

Most cases of stent thrombosis occur within 30 days after placement irrespective of stent type, ranging from 0.5% in low-risk patients to 2.5 % in high-risk subjects.[144–146] Episodes of stent thrombosis during this period are commonly related to periprocedural complications or abrupt interruption of DAPT, such as major bleeding or emergency high-risk surgery.

Stent thrombosis with BMSs occurs much less often after 4 to 6 weeks.[147] This observation is consistent with angioscopic studies that have shown complete re-endothelialization by 3 to 6 months.[148] VLST is even more uncommon with BMSs, and it occurs most often after a repeat procedure performed in the stented segment.[47]

Similar to BMS, most episodes of stent thrombosis associated with DESs occur in the first year, with the majority of these occurring within the first 30 days after PCI.[149,150] The cumulative incidence of stent thrombosis with DES at 1 year is approximately 0.5% to 1%.[151] Events thereafter continue at a rate between 0.4% and 0.6% per year with higher rates occurring with first-generation DESs.[152,153]

TABLE 44.4 Risk Factors for Stent Thrombosis

Stent Type	*Procedure*	*Lesions*	*Clinical*
First-generation drug-eluting stent (DES) > second- and third-generation DES ≈ bare metal stent	Stent underexpansion or malposition Vessel dissection Incomplete strut coverage Prestent or poststent vessel stenosis Stent deployed on necrotic plaques	Ostial, long, bifurcations, multiple stents Small vessel diameter (<2.5 mm) Overlapping stents Saphenous grafts Prior brachytherapy	Premature discontinuation of dual antiplatelet therapy Prior stent thrombosis Percutaneous coronary intervention for acute coronary syndrome Documented high on-treatment platelet reactivity Diabetes mellitus Chronic kidney disease Heart failure with low left ventricular ejection fraction Cancer Systemic inflammatory conditions Cigarette smoking Cocaine use

Risk Factors for Stent Thrombosis

The complex interaction between the presence of a stent, blood elements, and vascular wall is a strong stimulus for thrombus formation. Thus, it is not surprising that multiple factors have been shown to predispose patients for LST and VLST[154–156] (Table 44.4).

Stent Type

The rates of LST and VLST are highest with first-generation DESs, whereas the risk is similar between BMSs and second and third generations of DESs.[157,158] Besides the slower rate of drug elution (eg, Taxus), thicker struts and localized hypersensitivity to the durable polymer are factors that increase the propensity of first-generation DESs toward LST and VLST, when compared to BMSs and newer DESs, due to delayed endothelial coverage. Biodegradable stents have a similar safety profile to that of BMSs, but they seem to be slightly inferior to cobalt chromium everolimus stents.

Procedure-Related Factors

Features that have been correlated with higher rates for stent thrombosis include incomplete stent apposition, which leads to static blood flow between the struts and the vascular wall; persistent vessel dissection; and incomplete strut coverage.[19,20,159] These factors highlight the importance of achieving optimal results via appropriate stent selection, as well as the right technique, determined by the clinical circumstance, location, and characteristics of the lesion.

Lesion-Related Factors

Lesion characteristics may present a risk for stent thrombosis, for example, plaques with a necrotic filling lipid core during ACS, in which struts have demonstrated reduced neointimal coverage.[160] Other factors (so-called off-label indications) include complex anatomy such as multiple lesions, small vessel size, lesions larger than 3 cm, ostial and bifurcation lesions, total occlusions, saphenous vein graft stenosis, previous stent thrombosis, and prior brachytherapy.[161–163] Patients with one or more of these conditions represent approximately 50% of the total number of PCIs performed.[164]

Treatment-Related Factors

Undoubtedly the single most important predictor of early and late thrombosis is premature discontinuation of DAPT (one or both drugs), presumably during the period when vascular healing is incomplete.[165] This change is commonly related to the need to perform surgery or invasive procedures, poor patient compliance, side effects from treatment (eg, bleeding), or economic hardship. Although the duration of such a period is still a matter of controversy, it is longer with DESs when compared to BMSs.[166–168] With any stent, the highest risk period is the first 30 days after implantation, which correlates with the highest intensity of the inflammatory/thrombotic response within the vascular wall.[169]

Between 1 and 6 months the risk for stent thrombosis decreases but still remains high, particularly in patients with other risk factors and those with first-generation DESs.[170,171] After 6 months, no difference was found in one study in the rates of stent thrombosis between DES patients who underwent temporary discontinuation of antiplatelet therapy under the direction of a physician and patients who did not undergo this therapy.[172] The risk of stent thrombosis, however, was significantly higher for those who discontinued DAPT abruptly because of either noncompliance or bleeding. With current generation stents it appears that temporary discontinuation of the adenosine receptor blocker after 6 months may be relatively safe in selected patients, as long as acetylsalicylic acid (ASA) is continued.[168,173] The timing of LST or VLST during discontinuation of DAPT ranges from a few days to several months, depending on the agent discontinued and additional risk factors contributing to a prothrombotic state (eg, surgery).[174]

Medical Comorbidities

Patients shown to be at increased risk for stent thrombosis include those with diabetes mellitus[175] (particularly those with insulin deficiency),[176] chronic kidney disease,[177] heart failure with systolic dysfunction,[146] malignancy,[146] low response to platelet inhibitors,[178] cigarette smoking,[179] and cocaine use.[180] The cause is multifactorial; mechanisms include increased platelet turnover, vascular inflammation, decreased endothelial nitric oxide production, overexpression of platelet receptors, deficient antithrombotic pathways, bypass of pathways blocked by antiplatelet agents, impaired fibrinolysis, and vascular constriction.

Management

Management of patients with stent thrombosis requires the immediate recanalization of the occluded artery by aspiration of the mural thrombus and restenting the vessel.[181] With emergency surgical intervention reserved for those in whom successful PCI may be unlikely, many practitioners will perform intravascular ultrasound–guided stent sizing and confirm complete stent apposition. Patients with stent thrombosis while taking clopidogrel are at increased risk for recurrent events. Often this drug is exchanged for a different agent such as prasugrel or ticagrelor.

Outcome

The consequences of stent thrombosis can be devastating, thus highlighting the importance of timely intervention. Reported acute mortality of patients with coronary stent thrombosis presenting as STEMI is higher than 50%,[182,183] and for survivors it is 20% to 25% at 6 months.[184] Furthermore, the incidence of recurrent stent thrombosis is approximately 10% to 12%.[185,186] Compared to treatment of patients with native lesions, treatment of patients with stent thrombosis seems to be associated with less procedural long-term success.[187,188]

Antiplatelet Therapy

Platelet Physiology

Platelets play a key role in normal hemostasis as well as thrombus formation. In an inactive state, platelets appear discoid in shape and do not adhere to the vascular endothelial wall or to each other. Once

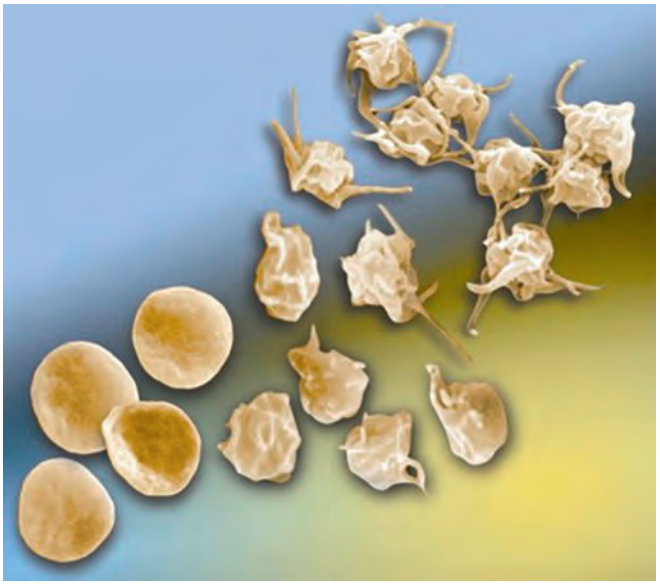

Fig. 44.6 Platelet shape change and aggregation. Scanned electron micrograph of resting *(lower left)*, partially activated *(center)*, and fully activated platelets *(upper right)*, showing the accompanying shape changes. Cytoplasmic projections are rich in activated fibrinogen (glycoprotein IIb/IIIa) receptors. *(Reproduced with permission from Michelson AD. Methods for the measurement of platelet function.* Am J Cardiol. *2009;103(suppl 2):20A–26A. Copyright Elsevier.)*

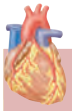
an endothelial injury occurs, platelets initially attach themselves to collagen or von Willebrand factor via glycoprotein membrane receptors (GpIb).[189] This initial phase (adhesion) is followed by subsequent activation. The activated platelet undergoes conformational changes, developing cytoplasmic projections (Fig. 44.6) rich in fibrinogen receptors (GpIIb/IIIa integrins).[189] In addition, procoagulants stored in alpha granules (thromboxane A2 [TXA2], adenosine) and dense granules (thrombin, CD4L ligand, CD6P) are released that serve to amplify the response via a positive feedback loop.[189–191] Platelet activation is followed by the phase of platelet aggregation in which activated GpIIb/IIIa receptors bind circulating fibrinogen, which acts as a bridge between neighboring platelets, binding them together.[191] Thrombin, generated from the action of tissue factor and released from platelet granules, cleaves fibrinogen into a mesh of fibrin that serves to stabilize the thrombus[192] (see Chapter 35).

Numerous pathways and platelet membrane receptors play important roles in the activation phase, thus providing pharmacologic targets for antiplatelet therapy[193,194] (Fig. 44.7). Currently, those available for platelet inhibition in patients with coronary stents include (1) activation of cyclooxygenase 1 (COX1) responsible for the production of TXA2; (2) adenosine-induced activation of membrane purinergic receptors P2X1, P2Y1, and P2Y12; (3) activation of protease-activated receptors by thrombin; and (4) active expression of membrane GpIIb/IIIa receptors (Box 44.5). Agents targeting other platelet receptors or pathways have been synthesized, but they have been found ineffective (eg, dipyridamole) or are at an early stage of development (eg, picotamide, terutroban).[193]

COX1-induced TXA2 production follows traumatic injury to the vessel wall during stent deployment whereby the eicosanoid arachidonic acid (AA) is synthesized from membrane phospholipids. COX1 acts on AA, inducing the production of prostaglandin H2, which then is transformed into TXA2.[193,194] The effects of TXA2 include changes in platelet shape, release of granular contents, and intense vasoconstriction.

Among other soluble agents, adenosine is released from neighboring red cells. In turn, adenosine attaches to its own purinergic receptors in the platelet membranes known as P2Y1, P2Y12, and P2X1.[195]



BOX 44.5 MECHANISM OF ACTION OF ANTIPLATELET AGENTS USED WITH CORONARY STENTS

ASA/aspirin: irreversible inhibition of cyclooxygenase 1
Clopidogrel and prasugrel: irreversible binding of P2Y12 receptors via active metabolite
Ticagrelor and cangrelor: reversible binding of P2Y12 receptors
Abciximab, tirofiban, eptifibatide: reversible binding of GpIIb/IIIa receptors

ASA, Acetylsalicylic acid.

Stimulation of the P2X1 receptor initiates platelet change, but alone it is not sufficient to amplify platelet activation and initiate platelet aggregation. This process depends mostly on activation of the P2Y12 receptor, which is primarily responsible for further procoagulant release (including TXA2) and expression of GpIIb/IIIa receptors.[194,195] The P2X1 receptor is involved in platelet shape change and activation from exposure to collagen under high-shear conditions.[195] A unique feature of purinergic receptors is their ability to block the intracellular production of vasodilator-stimulated phosphoprotein (VASP) via inhibition of adenylyl cyclase.[196] This is currently utilized as a laboratory test to check the effectiveness of adenosine antagonists.

Thrombin, the most potent platelet activator, binds to specific membrane proteins called *protease-activated receptors* (PARs).[197] Although four types have been described, only two, PAR-1 and PAR-4, are expressed on the platelet surface.[198] PAR-1 is the main receptor for thrombin and is activated at very low concentrations (100-fold lower than those required to activate PAR-4).[198,199] Stimulation of these receptors further increases granular content release and changes in platelet shape. In addition, the platelet membrane serves as a template for further thrombin production via the prothrombinase-tenase complex, which serves to amplify the coagulation cascade.[200] Currently, several platelet inhibitors are used in the management of coronary stents (Table 44.5).

Oral Antiplatelet Agents

Aspirin

Aspirin (ASA) exerts its effects through irreversible inhibition of platelet COX1 and COX2 with a 170-fold greater affinity for COX1.[201] Such enzymes, expressed in most cells, regulate the production of TXA2 in platelets, by the action of thromboxane synthetase. COX2 is present in the vascular endothelium, white cells, and immature platelets.[202] Endothelium-derived COX2 is associated with the synthesis of prostacyclin, which causes platelet inhibition and vasodilation; importantly, COX2 contained in monocytes and immature platelets can activate thromboxane synthetase during inflammatory response and conditions of high platelet turnover.[202]

ASA specifically and irreversibly inhibits platelet COX1 through acetylation of the amino acid serine in position 529, thereby blocking AA access to the COX1 catalytic site.[203] By inactivating COX1, ASA blocks the production of TXA2 through this pathway, rendering platelets incapable of functioning normally. At higher doses, aspirin also inhibits COX2-dependent prostacyclin synthesis in the endothelial cell. Other effects of ASA include enhanced fibrinolysis, as well as antioxidant, antiinflammatory, and antiatherosclerotic effects on endothelial cells and leukocytes.[204]

In normal subjects, a single dose of 30 mg of ASA is enough to produce complete and irreversible inactivation of COX1, with a ceiling effect observed on platelet activity with doses beyond 300 mg.[205] The current recommended dose to exert a fully antithrombotic effect is between 75 and 150 mg a day.

Plain ASA is rapidly absorbed through the gastric and enteric mucosa; peak plasma levels are seen within 30 or 40 minutes with a
